III. Electrochemical properties of ruthenium and rhodium complexes 365

Abstract. The redox properties of mononuclear and polynuclear rhodium and ruthenium complexes are examined. Attention is concentrated on the possible locations of the electronic changes in the redox transitions. The relation between the electrochemical parameters of the complexes and electronic spectroscopic data is traced. Extensive reference data are presented on the oxidation and reduction potentials of mononuclear and polynuclear rhodium and ruthenium complexes. The bibliography includes 133 references.

I. Introduction

Transition metal dinuclear and polynuclear complexes in which the central ions are linked to one another by different bridging ligands (inorganic ligands of the type of CN, SCN, OCN, etc. and organic ligands of the type of polyazabiphenyls and polyazaterphenyls) have been investigated very vigorously during the last decade. This applies particularly to ruthenium(II) compounds, which have proved extremely useful in many applied investigations. Such complexes are employed widely as photoluminescent substances, mediators of photochemical processes,[1, 2] and materials for non-linear optics.[3, 4]

In essence, the polynuclear complexes can be regarded as mononuclear complexes which contain organometallic ligands. For example, in the compound $L_nM^1CN \rightarrow M^2L_n$ one of the ligands is L_nM^1CN. Such ligands are of undoubted interest, since they contain transition metal atoms and tend to undergo redox transitions. In our view, the polynuclear complexes can serve as convenient models for the study of intramolecular electron transfer (charge transfer) processes from the metal (in the above example this is M^2) to the ligand (L_nM^1CN) (MLCT) or from the ligand to the metal (LMCT) both under the conditions of photochemical excitation and in electrochemical or chemical oxidation-reduction reactions.[5, 6]

Complexes of rhodium and ruthenium, the organometallic compounds of which have been investigated most widely, are considered in the present review. The theoretical ideas concerning the structure of transition metal complexes are discussed briefly in the first part within the framework of the molecular orbital method. The redox and spectroscopic properties of mononuclear complexes of ruthenium and rhodium are considered next, since such data are essential for the subsequent analysis of the electronic structures of the polynuclear bridged metal complexes to which the next section is devoted. In conclusion, tables giving compilations of the experimental oxidation and reduction potentials of mononuclear and polynuclear ruthenium and rhodium complexes are presented with an indication of specific experimental conditions (electrode material, solvent, supporting electrolyte, reference electrode) and also of the most probable locations of the electronic changes in the involved molecules of the complexes occurring in redox transitions (in those cases where such assignment to particular locations is possible). We suggest that such data will be useful to a wide range of chemists as regards comparison of the reactivities of these compounds in homogeneous reactions of different nature and not only in electronic processes.

II. Theoretical ideas on the structures of transition metal complexes

1. The redox levels of the octahedral complexes

The highly symmetrical transition metal complexes with six identical monodentate ligands L, for example $[Co(NH_3)_6]^{3+}$ or $Cr(CO)_6$, have the structure of a regular octahedron. If the metal–ligand bond is formed exclusively by the lone pair of the ligand and the π orbitals are not involved in the bonding, then the perturbation of the nine atomic orbitals (*d*, *s*, *p*) of the metal by the six group orbitals of the L_6 ensemble, having the O_h symmetry, results in the formation of the following energy levels of the complex ML_6 in the octahedral field: six bonding levels (σ), six antibonding levels (σ^*), and three degenerate non-bonding levels (t_{2g}) corresponding to the d_{xy}, d_{yz}, and d_{xz} orbitals of the metal, which are relatively little perturbed as regards energy and form (Fig. 1).[7] In the 18-electron complexes, all the bonding σ orbitals and t_{2g} orbitals are fully occupied. Consequently, in the simplest case, where the ligand is exclusively the donor of the lone pair of electrons and the molecular orbitals of the ligand (for example, π-type orbitals) not involved in bonding have low energies, the redox levels responsible for the oxidation potential (E^{Ox}, Fig. 1*c*) are the t_{2g} levels, which are the highest occupied molecular orbitals (HOMO) of the complex. Since the t_{2g} orbitals are largely located on the metal, it is usual to say that in the oxidation of ML_6 the electronic changes are 'localised on the metal atom'.

The position of the t_{2g} levels depends not only on the nature of the metal and its oxidation state but also on the donor strength of the ligands: if the ligands are strong donors (Fig. 1*a*) then the t_{2g} levels are raised, whilst in the case where they are weak donors (Fig. 1*b*) they are lowered, which is reflected in the oxidation potentials of the complexes.

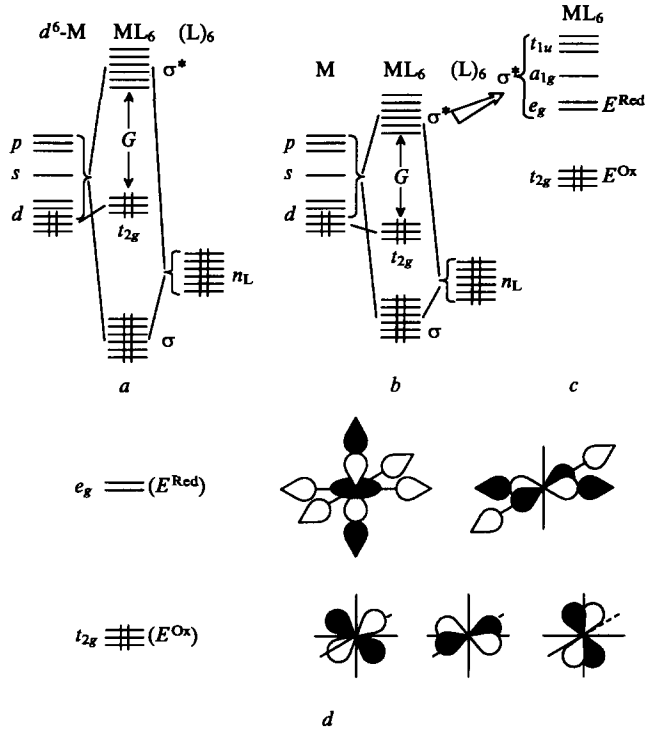

Figure 1. Energy levels of the octahedral complexes: (*a*) strong *n*-donor ligands; (*b*) weak *n*-donor ligands; (*c*) redox levels (t_{2g} and e_g) of the octahedral complex;[7] (*d*) the form of the frontier orbitals of the complex ML_6.

The six antibonding levels of the σ* type are divided into three blocks (Fig. 1*c*): the three degenerate t_{1u} orbitals have the highest energy, the a_{1g} orbital has a lower energy, and the two degenerate e_g levels have the lowest energy. The last levels are the redox levels responsible for the reduction of the complex (E^{Red}, Fig. 1*c*).

The form of the e_g orbitals is such that it is impossible to state *a priori* where the electronic changes during reduction are located: 'on the metal' or 'on the ligand', since, in contrast to the t_{2g} orbitals, the contributions of the ligand orbitals to the e_g levels can be significant. Therefore a special discussion of this problem is necessary in each specific case. The position of the e_g levels depends on the electron-donating capacity of the ligands. If the ligands are strong donors (Fig. 1*a*), then the splitting of the levels into the σ and σ* blocks is much more pronounced than in the case of weak donor ligands (Fig. 1*b*). As a result, the energy gap *G* between the highest occupied (t_{2g}) and lowest unoccupied (e_g) levels in the case of weak donor ligands is smaller than for the ligands with a greater electron-donating capacity. The chemical consequences of the change in the donor strength of the ligands are well known. Thus the octahedral complexes ML_6 with weak donor ligands are thermodynamically less stable and they pass more readily to paramagnetic moderate-spin or high-spin states, absorb light at longer wavelengths, etc. From the standpoint of redox chemistry, the transition from strong to weak ligands is expressed by a decrease in the electrochemical gap *G*,[8-10] defined as the difference between the redox potentials E^{Ox} and E^{Red} of the given compound.

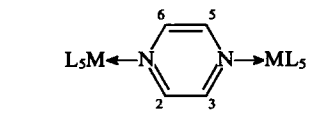
$$ML_6^{\cdot+} \underset{E^{Ox}}{\overset{-\bar{e}}{\rightleftarrows}} ML_6 \underset{E^{Red}}{\overset{+\bar{e}}{\rightleftarrows}} ML_6^{\cdot-},$$

$$G = E^{Ox} - E^{Red}.$$

The quantity *G* is related to the constant for the equilibrium between the 17-electron radical-cation and the 19-electron radical-anion derived from the ML_6 molecule.

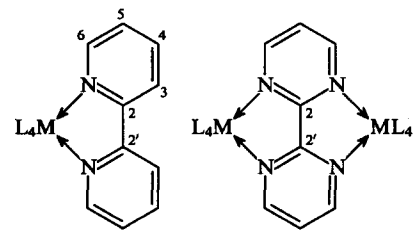
$$ML_6^{\cdot+} + ML_6^{\cdot-} \overset{K}{\rightleftarrows} 2ML_6;$$

$$\ln K = -(F/RT)G.$$



With decrease in *G*, *K* also diminishes, i.e. the equilibrium shifts to the left. This means that the 17-electron radical-cation (RC) and the 19-electron radical-anion (RA) are no longer quite so strongly destabilised relative to the 18-electron neutral complex ML_6 as in the case of compounds with large values of *G*. A complex with a narrow electrochemical gap, particularly in the case where it is uncharged and contains no strongly polar groups, i.e. has a moderate 'absolute electronegativity',[11] should be characterised by a tendency to enter into radical reactions. Similar considerations have been used in the classification of organomercury compounds in terms of their electrochemical potentials.[8]

Since the e_g levels of strong [donor?] ligands lie above those for the weak ligands, their complexes are reduced with a greater difficulty (i.e. the potentials E^{Red} have high negative values) and the 19-electron radical-anions formed, with an unpaired electron and a σ* orbital of the e_g type, are less stable.



There exists a whole range of experimental evidence concerning the instability of 19-electron radical-anions in the case of strong donor ligands. For example, since CO is a strong *n*-donor, on bombardment with electrons in an argon matrix at −196 °C $Cr(CO)_6$ affords the 17-electron radical-anion $Cr(CO)_5^{\cdot-}$ as the main product,[12] while $Co(NH_3)_6^{3+}$ (NH_3 is a weaker donor than CO) combines with an electron to form the high-spin 19-electron $Co(NH_3)_6^{2+}$ cation, which does not decompose.[13]

2. Bidentate chelating and bridge-forming nitrogen-containing heterocycles

Pyrazine (pz) **1** is a bridge-forming ligand, 2,2′-bipyridyl (bpy) **2** is a chelating ligand, and 2,2′-bipyrimidyl (bpm) **3** is both a bridge-forming and a chelating ligand.

1

2 **3**

These and similar ligands form stable complexes with many transition metals: their structures can be readily modified by introducing various substituents altering the σ-donor and π-acceptor properties of the molecules. An appreciable proportion of the present review is devoted to the description of complexes with precisely these or similar ligands.

In the pyrazine molecule, the two lone pairs of the nitrogen atoms, directed to the opposite sides, interact with one another in such a way that they become non-equivalent. This is manifested by the fact that the ionisation potential of one lone pair is higher by 1.72 eV than that of the other.[14] Ideas concerning the interaction of electron pairs 'through space' and 'through the bond' are usually employed to account for this effect.[15-18] Direct interaction through space leads to the formation of symmetrised n_+ and n_- levels, the energies of which differ little owing to the

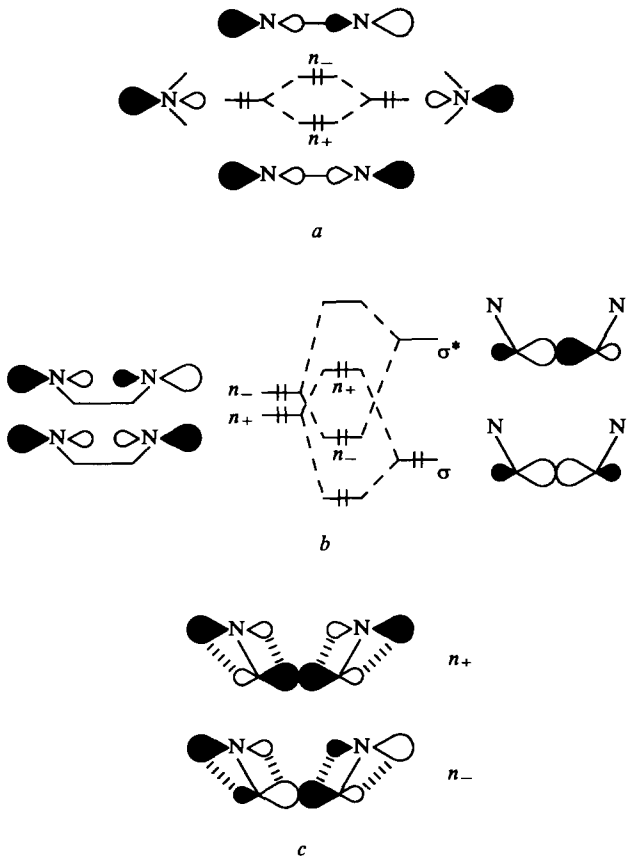


Figure 2. Interaction of the orbitals of the lone pairs of the nitrogen atoms in the pyrazine molecule: (*a*) through space; (*b*) through the C(2)–C(3) bond; (*c*) the form of the n_- and n_+ orbitals.

weak overlap as a consequence of the relatively large distance between the nitrogen atoms (Fig. 2*a*). We suggest that, as usual, combination in phase (n_+) has a lower energy than combination in antiphase (n_-). However, calculations and experiment have shown that the splitting between the levels n_+ and n_- is much greater than expected and moreover the n_+ level lies not below but above the n_- level by 1.72 eV.[7] Such an 'unnatural' order in the disposition of the levels can be explained by the fact that the lone pairs of the nitrogen atoms interact not only through space but also through C–C σ-bonds. Fig. 2*b* illustrates the interaction of the n_+ and n_- orbitals with the σ and σ* orbitals of the C(2)–C(3) bond in the pyrazine molecule. Compared with the weak 1,4-interaction between the nitrogen centres, the above 1,2-interactions of ($n_+ \pm \sigma$) and ($n_- \pm \sigma$) are strong. This leads to a greater splitting of the n_+ and n_- levels and to a change in their sequence. A similar interaction takes place with participation of the C(5)–C(6) bonds.

The molecular orbitals of complex **1** are constructed by a linear combination of the n_- and n_+ orbitals of pyrazine with the frontier orbitals of the two ML_5 fragments obtained by removing one ligand from the octahedral complex ML_6. The frontier orbital of the ML_5 fragment has the form shown in Fig. 3*a*.[7] On combining the bonding (M_+) and antibonding (M_-) combinations of the two frontier orbitals with the M_+ and M_- orbitals of the pyrazine lone pairs respectively, we obtain the pattern in the splitting of the levels shown in Fig. 3*b*. Since the M_+ and n_+ orbitals have more similar energies than the M_- and n_- orbitals, the M_+/n_+ splitting is greater than the M_-/n_- splitting. This renders the two M–N bonds in complex **1** equivalent, although in the pyrazine molecule the energies of the two electron pairs differ by 1.72 eV (see above).

Fig. 4 presents orbital diagrams for the chelate complex **2**: $L_4M(bpy)$. The ML_4 fragment has two almost degenerate frontier orbitals,[7] which are designated by the symbols M_+ and M_-

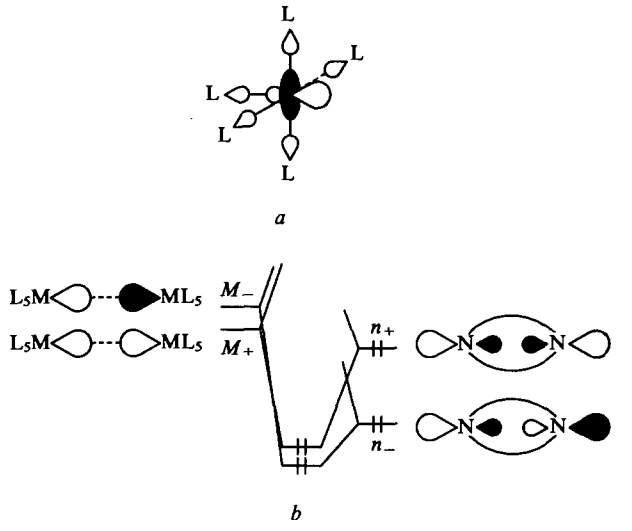

Figure 3. The form of the frontier orbital of the ML_5 fragment (*a*) and the orbital diagram for the interaction of the combination of two frontier orbitals in phase (M_+) and out of phase (M_-) with the n_+ and n_- orbitals of the lone pairs of pyrazine (*b*).

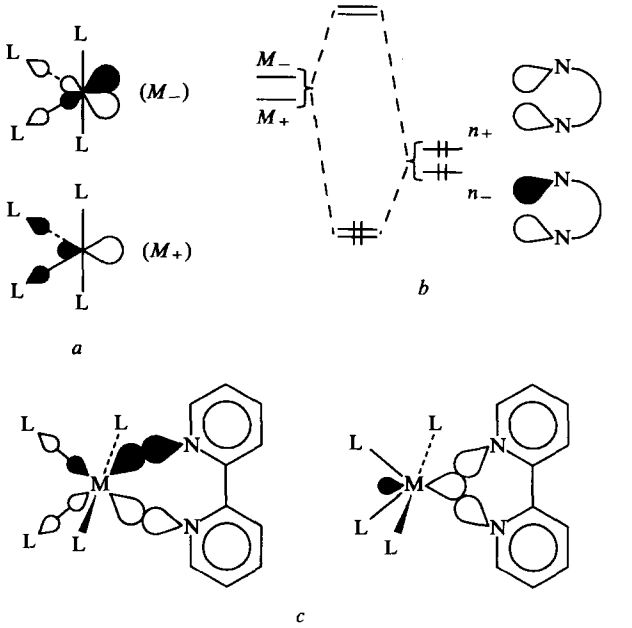
(Fig. 4*a*). In the 2,2′-bipyridyl molecule, the nitrogen *n* orbitals interact with one another through space and through the C(2)–C(2′) bonds similarly to the interaction of the orbitals in pyrazine. This interaction differs quantitatively from that in pyrazine, since the nitrogen lone pairs in the bipyridyl molecule are directed at an angle of 60° to one another and to the C(2)–C(2′)–L bond line. However, the qualitative pattern in the splitting of the levels of the lone pairs in he 2,2′-bipyridyl and pyrazine molecules is the same. The interaction of the M_+ and M_- orbitals with the n_+ and n_- orbitals (Fig. 4*b*) leads to strong chelate bonding (Fig. 4*c*).



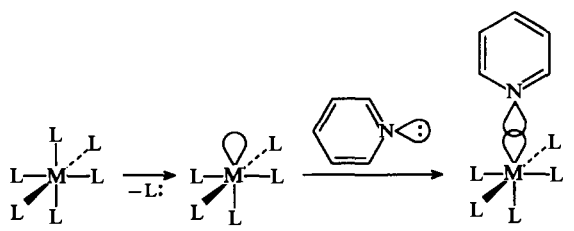


Figure 4. The form of the frontier orbitals of the ML_4 fragment (*a*), the diagram for the interaction of the frontier orbitals with the n_+ and n_- orbitals of the lone pairs in the 2,2′-bipyridyl molecule (*b*), and the form of the bonding molecular orbitals in the $L_4M(bpy)$ molecule (*c*).

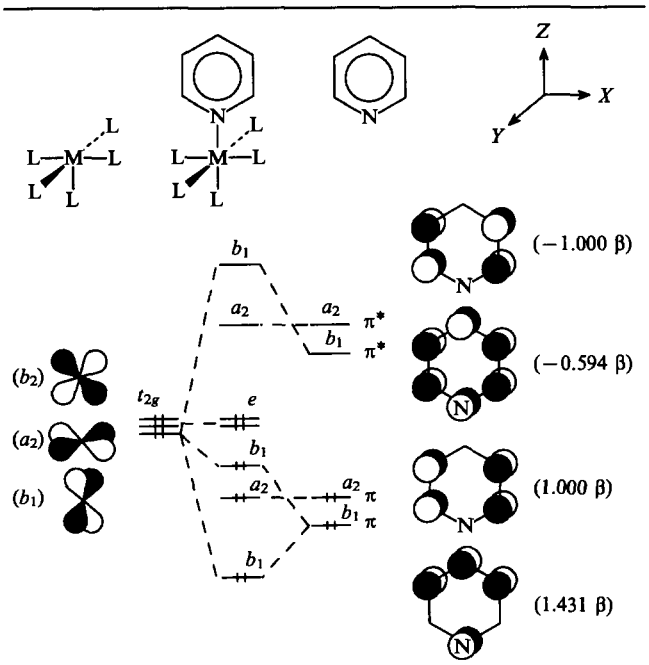
3. The π-bonds in the octahedron

On passing from simple Lewis ligands of the type of NH_3, aliphatic amines, and phosphines to ligands containing p or π orbitals (these comprise CO, CN^-, SCN^-, Cl^-, and many organic ligands, including nitrogen-containing heterocycles) the positions of the redox levels can change greatly. We shall consider, for example the situation where one, two, or three of the simple ligands L in the octahedral complex ML_6 are replaced by pyridine molecules.

The pyridine nitrogen atom has a lone pair located in the plane of the ring. This pair participates in the formation of the usual coordinate bond in the complex L_5MPy (Py = pyridine). Pyridine (photochemical ionisation potential IP = 9.7 eV[18]) is a stronger lone pair donor than NH_3 (IP = 10.9 eV) but weaker than $N(CH_3)_3$ (IP = 8.5 eV), i.e. in the series of nitrogen-containing bases it is a moderately strong donor. However, in contrast to NH_3 and NR_3, there is a π-system in the pyridine molecule which can interact with the t_{2g} levels of the complex.

Fig. 5 illustrates the form of the two highest occupied and the two lowest unoccupied π orbitals of pyridine. Evidently in the coordinated pyridine molecule there is a possibility of interaction of the occupied d_{yz} level of the metal with the π LUMO and the π-bonding pyridine orbital, lying a little below the HOMO, because all three orbitals have the same symmetry b_1. This results in the stabilisation of both the π-bonding and d_{yz} levels, which increases the stability of the complex compared with the complex in which there is no π bonding.



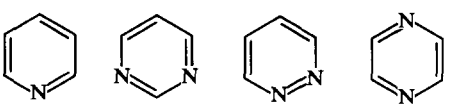


Figure 5. The π levels of the octahedral complex $L_5M(Py)$. The energies of the two highest occupied and the two lowest unoccupied π levels of the pyridine molecule, calculated by the Hückel method, are indicated in brackets.

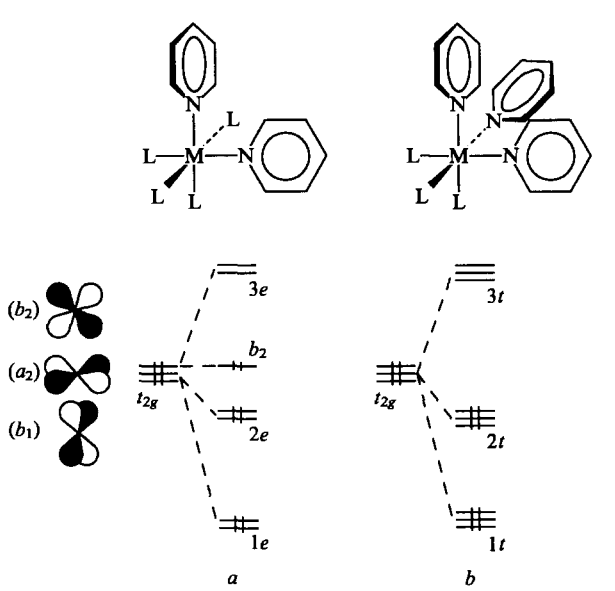
The diagram in Fig. 5 corresponds to the case where the perturbation exerted by the π* molecular orbital of the ligand (reducing the energy of the t_{2g} level) is greater than the perturbation by the π molecular orbital (which increases the energy of the level). This type of splitting is more pronounced the lower the energy of the $\pi(b_1)$ orbital and the smaller the difference between the energies of the $\pi^*(b_1)$ and t_{2g} orbitals. In the series of free ligands pyridine, pyrimidine, pyridazine, and pyrazine, the ionisation potentials for the n and $\pi(b_1)$ levels, determined experimentally by photoelectron spectroscopy in the gas phase,[19] as well as the half-wave potentials $E_{1/2}$ for reduction in dimethylformamide (DMF), characterising the position of the $\pi^*(b_1)$ level,[20] vary as follows:

		Pyridine	Pyrimidine	Pyridazine	Pyrazine
					
IP/eV	n:	9.7	9.7	9.3	9.3
	$\pi(b_1)$:	10.5	10.5	11.3	13.3
$-E^{Red}_{1/2}$/ V (n.c.e.):		2.20	1.82	1.66	1.51

Evidently, on passing from pyridine to pyrimidine, the stabilising π-acceptor effect of the ligand should change little, but for pyridazine and pyrazine the effect intensifies, since the energy of the destabilising $\pi(b_1)$ orbital and of the stabilising $\pi^*(b_1)$ orbital diminishes. Compared with pyridine and pyrimidine, pyridazine and pyrazine also have higher n levels, which is indicated by the corresponding ionisation potentials, i.e. they are stronger Lewis bases. Consequently the stability of the pyridazine and pyrazine complexes increases as a result of the intensification of not only the π-acceptor but also of the σ-donor properties.

The π-bonding of two or three azine molecules, located at the vertices of the same face of the octahedron entails a decrease in two or three t_{2g} levels of the metal (Fig. 6). This means that, if the



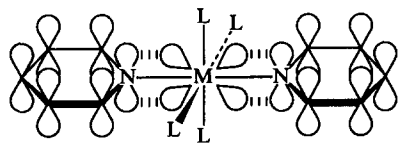


Figure 6. The π-bonding in the coordination of two (*a*) and three (*b*) pyridine molecules in orthogonal planes.

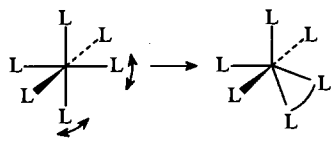
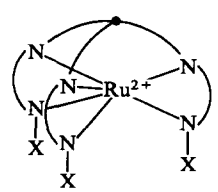
redox levels in the oxidation of the complexes are t_{2g} orbitals, then the oxidation potential of the complex $ML_3(azine)_3$ should increase relative to the oxidation potential of ML_6 (the oxidation should be hindered). A further increase in the number of ligands to six in the complex $M(azine)_6$ does not introduce significant changes into the perturbation pattern, since the π-systems of the two *trans*-ligands interact with only one of the t_{2g} orbitals, for example:



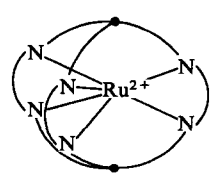
The positions of the $2t$ levels apparently change little (Fig. 6*b*).

If the ligand has fairly low acceptor π* orbitals but exhibits a π- or *p*-donor function, then the energy of the corresponding (in terms of symmetry) t_{2g} level increases, which destabilises the complex and diminishes its oxidation potential. Such ligands include, for example, Cl^- and other halide ions, ethers, or organic ligands of the Lewis *n*-type, which have electron-donating π-subsystems, in particular 4-mercaptopyridine.[21]

4. Geometrical distortions in the octahedron

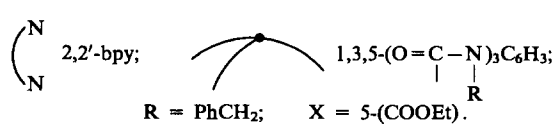


On coordination to bidentate ligands L–L, the structure of the regular octahedron is geometrically distorted when the length of the bridge is inadequate or the bridge is insufficiently flexible. These distortions are illustrated below schematically by arrows:



Analysis of the influence of the change in the bond angles between the L–M–L *cis*- and *trans*-bonds (see, for example Albright et al.[7] and the literature quoted therein) shows that the degenerate t_{2g} and e_g levels are lowered in the distorted octahedron. It was stated above that π-acceptor or π-donor ligands also create energy differences between the levels of the t_{2g} set. Since π overlap is a function of angular changes, the distortions in the octahedron also alter the degree of π bonding in the octahedron.

Geometrical distortions play an important role in 16-electron octahedral complexes ML_6. In order that such molecules should be in a low spin state, it is necessary that one of the t_{2g} levels should lie appreciably above the other two. This is achieved as a result of the combination of π bonding (if it is possible) with the geometrical distortions in the octahedron.



Particularly pronounced geometrical changes in the octahedron are observed in the case of the so called 'capped' ligands as well as ligands of the 'bicapped' type. The origin of these terms is clear from the three-dimensional formulae of compounds **4** and **5**, investigated by Barigelletti et al.,[22] presented below.

4
'capped'

5
'bicapped'

In this case, the six nitrogen atoms are arranged around the central metal ion, forming a trigonal prism. The six *n* orbitals of nitrogen, directed towards the centre of symmetry (D_{3h}), form six symmetrised group orbitals, the conventional representations of which are given in Fig. 7.

Fig. 7 shows that there is no fundamental difference between the octahedral and prismatic complexes: in both cases, the occupied t_{2g} levels (a_{1g} + e_{2g}) play the role of the HOMO, while the unoccupied e_g levels play the role of the LUMO.

Distortions can also arise owing to the rigidity of the bridging bidentate ligand. Thus the pyridine rings in 2,2'-bipyridyl cannot be located in the same plane owing to the repulsion of the hydrogen atoms in the 3- and 3'-positions, i.e. the molecule is twisted relative to the C(2)–C(2') axis; this alters the symmetry of the complex and the strength of bonding with the central metal ion.

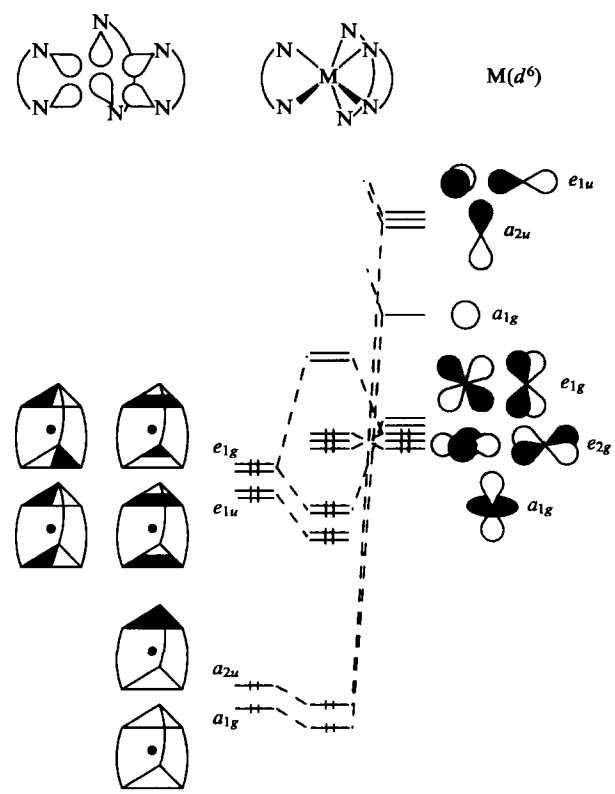


Figure 7. Molecular σ orbitals of the 'capped' and 'bicapped' complexes **4** and **5**.

5. Electrochemistry and photochemistry

In the general case, the electronic transitions in the spectra of transition metal complexes ML_6 can be divided into three types:[23]

(1) transitions between levels located predominantly on the metal, for example, the familiar d–d transition;

(2) transitions between levels predominantly located on ligands (for example, the π–π* transitions in aromatic ligands);

(3) transitions in which an electron is transferred from the metal to the ligand (MLCT) or, conversely, from the ligand to the metal (LMCT).

The possible electronic transitions for the symmetrical octahedral complex ML_6, in which the ligands L have π-systems, are illustrated schematically in Fig. 8. We may note that in the 17-electron complexes there is a possibility, apart from the transitions shown in Fig. 8, also of the $\pi L \rightarrow M(t_{2g})$ and $\sigma L \rightarrow M(t_{2g})$ transitions, while in the 19-electron complexes $M(e_g) \rightarrow \pi^* L$ transitions are possible. Among the transitions shown in Fig. 8, three (*c*, *d*, and *f*) correspond to the charge-transfer (CT) bands. In the spectra of 18-electron d^6 complexes with azine ligands, the

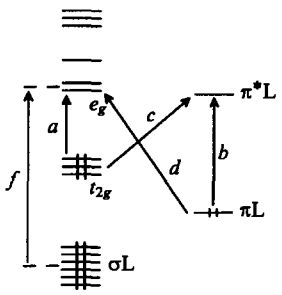

Figure 8. Schematic illustration of the main electronic transitions in the spectra of the complex of ML_6 with π-ligands. Transitions: (*a*) *d*–*d*; (*b*) πL→π*L; (*c*) $M(t_{2g})$→π*L(MLCT); (*d*) πL→$M(e_g)$ (LMCT); (*f*) σL→$M(e_g)$.

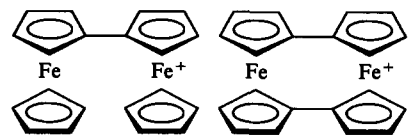
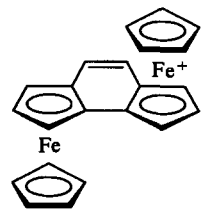
longest-wavelength band corresponds as a rule to the MLCT transition[1] $M(t_{2g})$→π*L, since the π and π* orbitals of these ligands are fairly low. This band usually has a low intensity, rarely exceeding 10^4 litre mol^{-1} s^{-1}, and in terms of this feature it can be distinguished from the more intense π→π* band. Thus the frontier orbitals of the azine complexes are $M(t_{2g})$ (HOMO) and π*L (LUMO).



For this reason, one can assume that in the general case the electronic changes occurring on electrochemical oxidation of such complexes should be localised 'on the metal', while in the electrochemical reduction they should be localised 'on the azine ligand'. Naturally, one is dealing with the so called 'primary electronic changes'. Electron transfer may be followed by intramolecular electron transfer (IET), as a result of which the electron in the radical-cation or radical-anion formed may be located in a region completely different from that to which it was initially transferred.

Dinuclear compounds of the type M^1–μ-L–M^2, where μ-L is a bridging ligand, for example, pyrazine, 4,4′-bipyridyl, cyanide, etc. while M^1 and M^2 are two different or identical organometallic residues, are of great interest. As a rule, complexes in which M^1 and M^2 are in oxidation states differing by unity are the most important. If the two metallic centres can interact with one another via a bridge, then there is a possibility of an IET process, which in the given instance is referred to as an intervalence [mixed valence ? Ed.] transition:

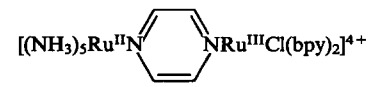


$$(M^1)^+ - \mu\text{-L} - M^2 \longrightarrow M^1 - \mu\text{-L} - (M^2)^+ .$$

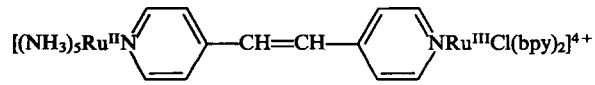
Robin and Day[24] proposed that mixed-valence complexes be divided into three classes in terms of the degree of delocalisation of the valence electrons. Compounds in which there is no interaction of any kind between centres with different oxidation states, i.e. the valences are fixed, are referred to as class I and the properties of these complexes are simply the sum of the properties of the two different centres. The fully delocalised systems, in which the two centres with different oxidation states are indistinguishable by methods with characteristic times greater than the time required for electron transfer, are referred to as class III. Compounds of class II occupy an intermediate position between classes I and III. In this case, there is a weak interaction between M^1 and M^2.

The intervalence transitions are usually investigated by spectroscopic methods. The biferrocenyl cations **6** and **8** and a number of others were particularly thoroughly investigated (see Richardson[6] and the references quoted therein). The electronic spectrum of the cation **6** in acetonitrile contains absorption bands at 545, 840, and, which is particularly important, at 1800 nm (ε = 750) in the near infrared. The 1800 nm band is not observed in the spectra of either Fc–Fc or Fc^+–Fc^+. On this basis, it was attributed to an intervalence or IET transition occurring as a consequence of optical excitation. The Mössbauer spectrum shows clearly that the cation **6** contains iron(II) and iron(III) and that a thermal electron exchange takes place at a rate of about 10^7 s^{-1}. Thus the ion **6** belongs to class II in terms of the classification of Robin and Day.

6 **7**

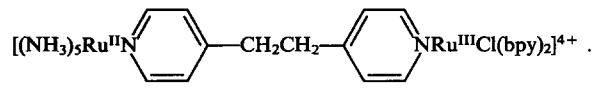


8



Electrochemical measurements have also shown that the cation **6** contains divalent and trivalent iron. Oxidation (E^{Ox} = 0.64 V in CH_3CN) and reduction (E^{Red} = 0.31 V) involve iron(II) and iron(III) respectively.[25]

Thus in the mixed-valence complexes the redox centres in the anodic and cathodic processes are different metal ions. However, in dinuclear bridged complexes of the type L_nM–μ-L–ML_n with two identical metals in the same oxidation state and with the same ligand environment, the electronic changes on reduction may be localised on the bridging or terminal ligand.



The band in the near infrared corresponds to charge transfer between two metallic centres (MMCT). It has been observed for many bridged bimetallic ruthenium complexes, for example, for the pyrazine and dipyridylethylene complexes presented below (the extinction coefficients are given in brackets):[26]

960 nm (530)

680 nm (< 300)

MMCT (band absent)

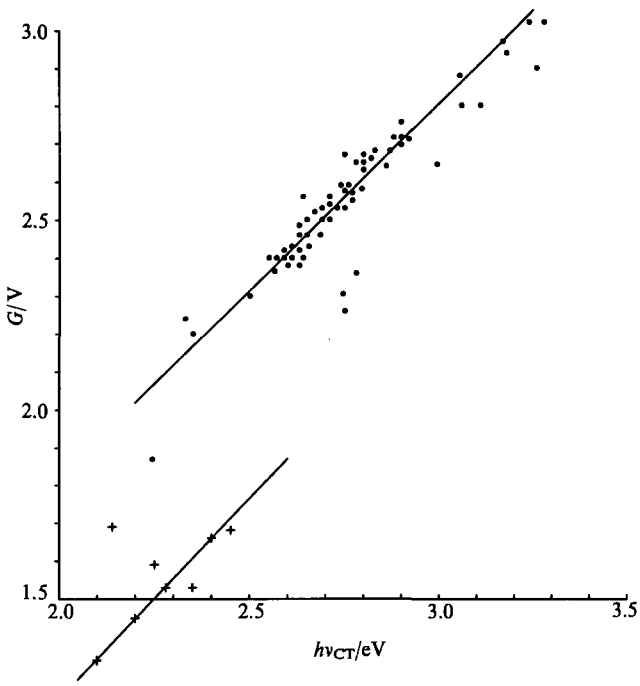
However, on passing to the dipyridylethane bridge, the MMCT band vanishes as a consequence of the absence of conjugation between the pyridine rings.

It is natural to expect that there should be a linear correlation between the energy of the long-wavelength charge-transfer band and the electrode potentials of the complexes, because the same frontier orbitals are involved both in photo-excitation and in electrode processes. The correlation equation is

$$G = ah\nu_{CT} + b, \qquad (1)$$

where G is the 'electrochemical gap' (in volts), defined as the difference between the oxidation (E^{Ox}) and reduction (E^{Red}) potentials of the given complex ($G = E^{Ox} - E^{Red}$), $h\nu_{CT}$ is the energy of the charge-transfer band or the 'spectral gap' (in eV), and a and b are constants. From general considerations, it is to be expected that a should be close to unity.

There have been a number of studies in which measurements were made of three parameters simultaneously ($h\nu_{CT}$, E^{Ox}, and E^{Red}) in fairly wide series of ruthenium complexes.[27–37]



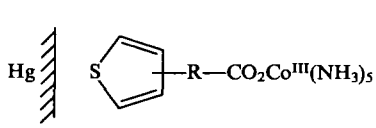


Figure 9. Relation between G and $h\nu_{CT}$ for ruthenium(II) complexes based on data in Refs 27–33.

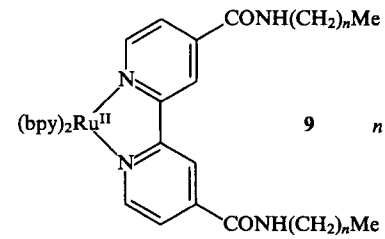
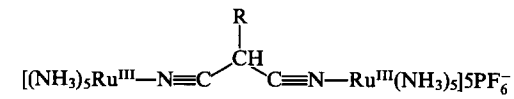
Fig. 9 presents the relation between the spectral and electrochemical gaps for ruthenium(II) complexes constructed on the basis of the results of these studies. Evidently there is a linear relation between G and $h\nu_{CT}$ with a slope close to unity. A number of points deviate from the overall straight line, the deviation of the points in the lower left-hand corner of the diagram, designated by crosses, being most pronounced. They form their own straight line with a slope which is also close to unity. The reason for this is apparently that the majority of the 70 points plotted on the graph correspond to compounds with bidentate ligands of the type of α,α′-bipyridyl, 2,2′-bipyrimidyl, and similar compounds. On the other hand, the crosses correspond to compounds with six monodentate ligands, for example, $Ru(NH_3)_5L$, $(Py)Ru(NH_3)_4L$, $(3\text{-ClPy})Ru(NH_3)_4L$ (where L = 4-cyano-*N*-methylpyridinium), etc.[28] The shift of the points is caused by the change in the constant b in Eqn. (1). This constant probably depends largely on solvation. Indeed, it has been shown that MLCT depends exceptionally strongly on the solvent [nitromethane, acetonitrile, propylene carbonate, acetone, DMF, and dimethyl sulfoxide (DMSO) have been investigated] and this solvatochromism cannot be accounted for simply in terms of the dielectric properties of the solvents. There is evidence that the charge transfer depends on the specific interaction of the solvent with a coordinated NH_3 molecule.



When the redox properties of the complexes are considered, it is essential to take into account primarily also the possibility of the specific interaction with the electrode material. For example, the pentamminecobalt(III) complex containing a carboxylate ion with a thienyl substituent as the sixth ligand is reduced at a mercury cathode not at the metal atom but initially at the thienyl group with subsequent electron transfer to the metal via the IET process described above.[38] This is associated with the strong specific interaction of the sulfur atom with mercury, which is responsible for the following orientation on the electrode:



III. Electrochemical properties of ruthenium and rhodium complexes

1. Mononuclear ruthenium complexes

There has been a particular growth of interest in the chemistry of ruthenium complexes in recent years because ruthenium compounds have been finding increasing application in various fields. For example, since complexes containing ruthenium in different oxidation states are more stable than the analogous iron complexes, they can serve as a convenient model for the study of various redox reactions in biological systems where a ruthenium atom replaces an iron atom. In this connection, studies have been made[39] on the redox properties of tetra(*o*-aminophenyl)porphyrins containing ruthenium(II) combined with various axial ligands. Certain ruthenium compounds are of interest as nonlinear optical materials. Thus ruthenocene and its derivatives exhibit a second-order nonlinear optical effect.[3] Similar properties have been observed in recent years also in other ruthenium complexes, in particular those containing bipyridyl (compound **9**) and bridging (compound **10**) ligands.[4, 40]

9 $n = 1, 5, 11, 15, 17$

10

R = H, Bu^t

Considerable attention has been devoted to the study of polypyridylruthenium(II) complexes (Tables 1 and 2). More than 200 bidentate (LL) polypyridyl ligands used in the chemistry of ruthenium(II) have been examined in a review,[2] which also presents the oxidation-reduction potentials of a large number of the homoleptic complexes $Ru(LL)_3^{2+}$ synthesised. It is important to note that the different one-electron transitions observed on cyclic voltammograms for the ruthenium(II) complexes can be readily related in many instances to specific donor or acceptor orbitals.

Polypyridylruthenium(II) complexes are oxidised with participation of the t_{2g} orbitals d_{xy}, d_{xz}, and d_{yz}, which are located on the metal atom. This results in the formation of low-spin ruthenium(III) complexes with the $4d^5$ configuration, which are resistant to ligand substitution. This has been confirmed with the aid of orbital diagrams.[41]

$$[Ru^{II}(LL)_3]^{2+} \rightleftharpoons [Ru^{III}(LL)_3]^{3+} + \bar{e}\,.$$

It has been established that the Ru(II)/Ru(III) redox transitions in complexes with polypyridyl ligands lie within a narrow range of potentials [about 1.53 V relative to the saturated calomel electrode (s.c.e.)]. The replacement of one or several polypyridyl ligands can significantly alter these potentials. Thus the substitution of one bpy in $Ru(bpy)_3^{2+}$ by two chloride ions affords $Ru(bpy)_2Cl_2$ and lowers the oxidation potential to 0.63 V, while the introduction of two CO molecules instead of bpy increases the oxidation potential of $[Ru(bpy)_2(CO)_2]^{2+}$ to 2.18 V.

Table 1. Data on the electrochemical oxidation of mononuclear ruthenium complexes.

$[Ru(2,3\text{-dpp})(bpy)_2]^{2+}$	1.31	$Ru^{II/III}$	Pt, MeCN, Et_4NClO_4, s.c.e.	103

Note. [a] The abbreviations of the ligand names are given in the text of the corresponding sections. Those not mentioned in the text are as follows: dpk = 2,2'-bipyridyl ketone; R_2dsc = dialkyl-substituted diselenocarbamate; (o-NH_2)TPP = tetra-o-aminophenylporphyrin; tpy = 2,2',6',2''-terpyridine; PBzImH = 2-(2-pyridyl)benzimidazole; OBzImH = 2-(o-hydroxyphenyl)benzimidazole; PImH = 2-(2-pyridyl)imidazole; $Fc^{+/0}$ = ferrocene-ferrocenium cation redox couple.

[b] ECLS denotes the most probable sites where the electronic changes are localised in the redox transitions. An empty column means that the assignment is difficult. The symbol L indicates that the reduction involves one of the ligands.

[c] In all tables, the conditions in the electrochemical measurements are listed in the following order: material of the working electrode, solvent, supporting electrolyte, reference electrode.

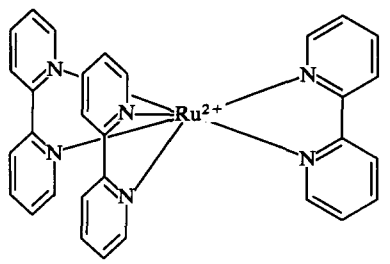
Polypyridylruthenium(II) complexes can be reduced with participation of orbitals located both on the metal atom and on the ligand. If the ligand field is strong and (or) the ligands are readily reducible, then the reduction proceeds with participation of the π^* orbital of the ligand. A similar picture is usually observed for polypyridylruthenium(II) complexes.[1, 2, 35, 41, 42, 44] The reduced form retains the low-spin $4d^6$ configuration and the reduction process is reversible:

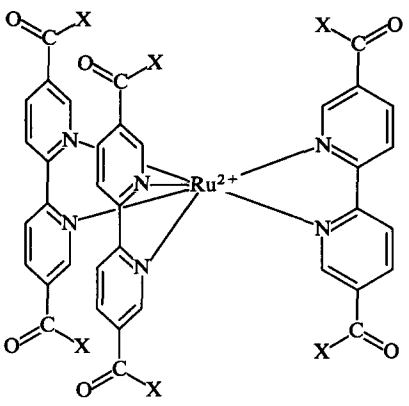
$$[Ru^{II}(LL)_3]^{2+} + \bar{e} \rightleftharpoons [Ru^{II}(LL)_2(LL^-)]^+ .$$

Thus the additional electron is localised on a specific ligand. It is of interest that the complex $[Ru(bpy)_3]^{2+}$ may be reduced with consumption of $6\bar{e}$, affording $[Ru^{II}(bpy)_3]^{4-}$. If the complex is heteroleptic, then the ligands are reduced consecutively in a sequence determined by the energies of their π^* orbitals.



If the ligand field is weak, and (or) the ligands are difficult to reduce, then the e_g orbital, with an octahedral symmetry and largely located on the metal ion, may assume the role of the LUMO. In this case, the reduction product is an unstable low-spin d^7 system, in which one ligand is rapidly split off, which makes the reduction process irreversible:

$$[Ru^{II}(LL)_3]^{2+} + \bar{e} \rightleftharpoons [Ru^{I}(LL)_3]^+ \longrightarrow [Ru^{I}(LL)_2]^+ + LL.$$

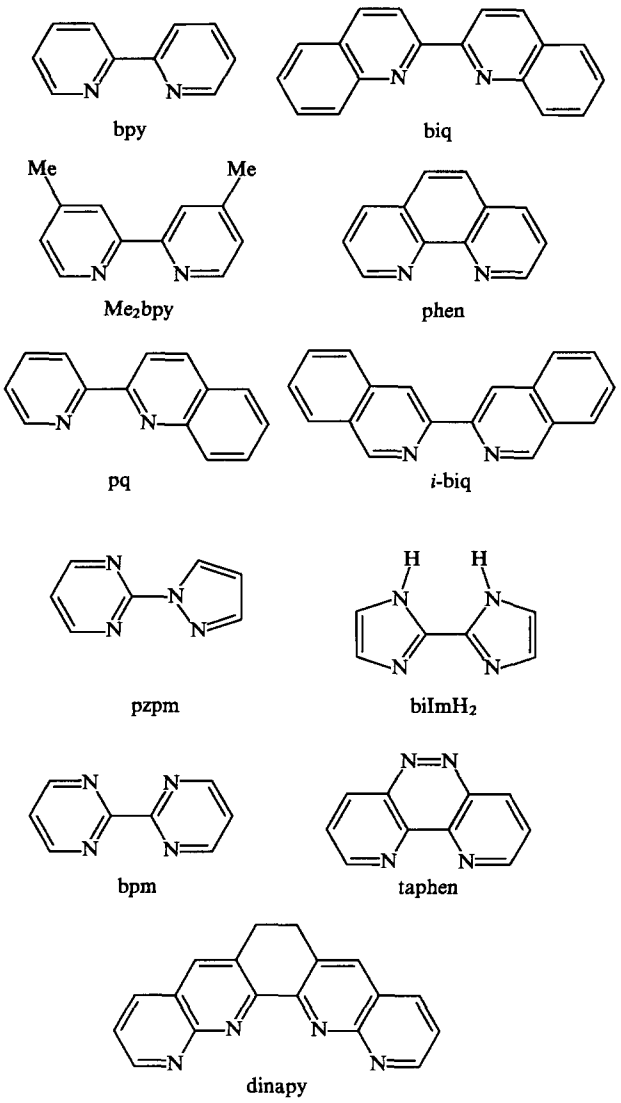


However, such processes are uncharacteristic of polypyridylruthenium complexes.

The electrochemical behaviour of the 'capped' (compound **4**) and 'bicapped' (compound **5**) see above) polypyridylruthenium(II) complexes and the comparison with their initial $Ru(bpy)_3^{2+}$ **11** and $Ru[5,5'\text{-}(EtO_2C)_2bpy]_3^{2+}$ **12**, a characteristic feature of which

is the distortion of the octahedral coordination sphere of the metal, are of interest.[22]

11

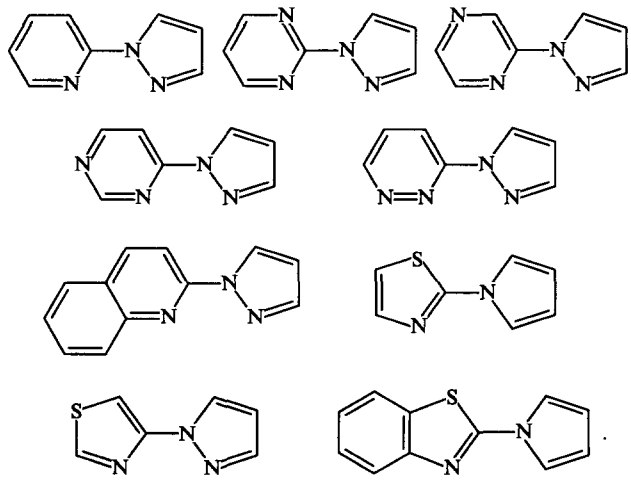


12

X = OC_2H_5

Complexes **4** and **5** are oxidised with one one-electron wave corresponding to oxidation 'at the metal atom' and are reduced with three one-electron waves corresponding to the reduction of the three bidentate ligands. The observed redox processes are reversible with the exception of the oxidation of compound **5**, as a result of which the process is kinetically controlled (i.e. the electron transfer is slow) even though stable species are formed. The low rate of electron transfer in the oxidation of compound **5** has been explained by steric hindrance, which precludes the approach of the metal atom to the electrode surface. Complexes **4**, **5**, and **12** are oxidised at identical potentials, which are more positive than for complex **11**. The equality of the oxidation potentials of compound **5** and **12** is surprising. In this case, one should apparently take into account the difference between the solvation energies of the oxidised and reduced forms and also the strain in the metal–ligand bonds due to the presence of the cage structure.

Electrochemical and spectroscopic data for the trisheteroleptic complexes $[Ru(LL)(LL)'(LL)'']^{2+}$ are very rarely encountered in the literature. The electrochemical behaviour of a series of nine recently synthesised complexes of the type $[Ru(bpy)(biq)(LL)]^{2+}$ (LL = Me_2bpy, phen, pq, *i*-biq, pzpm, $biImH_2$, bpm, taphen, and dinapy) has been investigated.[42] These complexes are especially interesting because the redox processes in them proceed with participation of orbitals located on four different centres: M, LL, LL', and LL''. The electrochemical behaviour of $[Ru(bpy)(biq)(LL)]^{2+}$ is qualitatively similar to that of other polypyridylruthenium(II) complexes:[2, 41, 43] a single metal oxidation wave and a series of three waves corresponding to the reduction of the ligands are observed on the cyclic voltammogram. In order to assign the reduction waves to a particular ligand, a comparison was made with the known reduction potentials of homoleptic[2, 29, 33, 41, 44–49] and bisheteroleptic[2, 29, 33, 44–47, 49–51] complexes. For LL = Me_2bpy and phen, the first reduction wave was attributed to biq, the second to bpy, and the third to the LL ligands. For LL = pq, the order in which the ligands are reduced is as follows: biq is reduced initially, is followed by pq, and finally bpy is reduced. In the case of LL = *i*-biq, the interpretation of the first two waves (biq and bpy)



is not open to doubt, while the third wave may correspond both to the second stage of the reduction of biq and to the reduction of *i*-biq. For LL = pzpm, data on homoleptic complexes were not obtained. However, examination of the correlations between the spectroscopic and electrochemical quantities leaves no doubt that the biq ligand is the first to be reduced. Clear-cut data have not been obtained for LL = $biImH_2$, but it is clear from the first reduction potential (−1.66 V relative to the s.c.e.) of $[Ru(bpy)_2(biImH_2)]^{2+}$ that $biImH_2$ is reduced with more difficulty than bpy.[50] The first reduction potential of $[Ru(bpy)(biq)(biImH_2)]^{2+}$ was therefore attributed to the biq ligand. For LL = bpm, the sequence of the reduction waves is probably as follows: biq, bpm, bpy. The taphen ligand is very unusual, its π^* orbital being located mainly on the peripheral nitrogen atoms and having a low energy.[52] The most probable sequence in the reduction of the ligands of $[Ru(bpy)(biq)(taphen)]^{2+}$ is as follows: taphen is reduced initially and is followed by biq and bpy. Judging from the homoleptic complexes,[44, 53] dinapy is reduced more readily than biq, so that the order of the reduction of the ligands in $[Ru(dinapy)(biq)(bpy)]^{2+}$ should be as follows: dinapy, biq, bpy.

It has been shown[42, 54, 55] that in the polypyridylruthenium(II) complexes reduction involves in the first place the π^* orbital, with which the appearance in the spectra of the band due to charge transfer from the metal to the ligand (MLCT) is also associated. One can therefore expect a linear correlation[2, 29, 30, 33, 42, 45, 56, 57] between the energy of the absorption (or emission) maximum and the electrochemical gap $G = [E_{1/2}Ru(LL)_3^{III/II} - E_{1/2}Ru(LL)_3^{II/I}]$, which is a measure of the difference between the energies of

the HOMO and the LUMO of the ruthenium(II) complexes. Such correlation has indeed been observed for a series of polypyridyl complexes investigated (Fig. 9), with the exception of $[Ru(taphen)_3]^{2+}$.[42, 45] For this complex, both the long-wavelength absorption band and the emission band correspond to excited states with a higher energy than might have been expected on the basis of the reduction potential. This can be accounted for by the participation of the ligand biq in the spectral transitions, whereas the π^* orbital of the ligand taphen, localised mainly on the peripheral nitrogen atoms, participates in the redox transition. It is not clear why emission takes place from a high (with participation of biq) charge-transfer state and not from a low state (with participation of taphen).[42, 52] It may be that ligand–ligand interactions occur in the complexes investigated, which may be due both to electronic perturbations, transmitted mainly by the metal, and steric interactions of ligands such as biq.

The majority of studies devoted to the polypyridyl-ruthenium(II) complexes constitute in essence attempts to select the necessary properties of the ground and excited states of the complexes by replacing one or several bpy ligands by other nitrogen-containing chelating ligands, mainly by six-membered aromatic nitrogen-containing heterocycles (azines). Electrochemical studies on complexes containing five-membered aromatic heterocycles (azoles) have been recently initiated.[32] It has been shown[32] that such ligands modify to a greater extent the properties of ruthenium complexes, since the π-excess azoles differ radically from the π-deficient azines. The study of various heteroleptic complexes $[Ru(bpy)_2(LL')]^{2+}$ and homoleptic complexes $[Ru(LL')_3]^{2+}$ showed that the reduction involves the ligand and is almost always reversible.[32] In this case, the symbol LL′ designates bidentate ligands containing five- and six-membered heterocycles having the following structures:

For the series of complexes $[Ru(bpy)_{3-x}(LL')_x]^{2+}$, the dependence of E^{Ox} on x is linear for a wide range of LL′. The slope of the straight line can be used to estimate the relative contributions of the π-donor and π-acceptor properties of the ligands LL′.[32, 58]

In the study of the redox transitions of $[Ru(NH_3)_5L]^{III/II}$ (L = py-X; X = Me, Cl, $CONH_2$, CF_3, COMe, CHO, COOH, H),[59] it was noted that complexes with unsaturated π-ligands have appreciably more positive reduction potentials than the hexammine or aquo-complexes. The electron-accepting substituents X in $[Ru(NH_3)_5(py\text{-}X)]^{2+}$ increase the formal potentials E_f, i.e. the π-acceptor properties of the ligands facilitate the reduction of the oxidised complex. If yet another ammonia molecule in the complex is replaced by the ligand L′, with strong π-acceptor and weak σ-donor properties, the ruthenium(II) complex is stabilised relative to the ruthenium(III) complex, which means that the redox transition in $[Ru(NH_3)_4LL']^{III/II}$ is facilitated.[60] This is confirmed by the results of a study[61] in which measurements were made of the reduction potentials of a series of *trans*-$[Ru(NH_3)_4LL']^{3+}$ [L,L′ = pyridine, 4-picoline (4-pic), isonicotanimide (isn), 4-acetylpyridine (4-acpy), pyrazine (pz), or pyrazinium (pzH^+)] with a fixed ligand L. In terms of their ability to facilitate the reduction of the ruthenium complex, the ligands investigated can be arranged in the sequence pz > 4-acpy > isn > py > 4-pic. Comparison of the redox potentials of *cis*- and *trans*-$[Ru(NH_3)_4(isn)L]^{2+}$ showed that the *cis*-isomers are reduced more readily than their *trans*-analogues. Taking into account the fact that only one of the *d* orbitals of the metal participates in the bonding to both heterocyclic ligands, one may conclude that the heterocyclic ligands in *trans*-$[Ru(NH_3)_4(isn)L]^{2+}$ are coplanar.

The ruthenium and rhodium complexes are interesting because they can serve as convenient models for the study of the influence of the metal atom coordination on the properties of the ligands. For example, by comparing the rate of the alkaline hydrolysis of the CN group in the pentammine complexes $[M(NH_3)_5(RCN)]^{n+}$ (M = Ru, Rh; R = Me, Ph; n = 2, 3), it is possible to estimate the electronic influence of the central atom on the organic ligand.[62] The ruthenium(II) and rhodium(III) complexes are isoelectronic ($4d^6$) and differ only in the charge, while the ruthenium(III) and rhodium(III) complexes have the same charge but differ in the number of *d* electrons of the metal [Ru(III)—$4d^5$]. It was found that complexes containing ruthenium(III) are hydrolysed much more readily than their $4d^6$ rhodium(III) and ruthenium(II) analogues. This is due to the ability of ruthenium(III) to function as a π-acceptor (by virtue of the t_{2g} vacancy in the *d* orbitals) and to stabilise the negative charge arising when the nitrile carbon atom is attacked by the OH group. The ruthenium(II) complex hardly undergoes alkaline hydrolysis, since it is an electron donor in relation to the π-acceptor unsaturated organic ligands.

The capacity of ruthenium(III) for reverse π-bonding has been confirmed also by electrochemical studies on pentammine-ruthenium(II) complexes containing quinone diimine ligands.[63] Thus the abstraction of one electron alters radically the influence of the metal atom on the ligands. The determination of the potentials and of the nature of the redox transitions can therefore be extremely useful for the elucidation of the change in the electronic properties of the central metal atom and the ligands bound to it.

The olefin complexes of ruthenium(II) have been investigated.[64–66] $[Ru(CO)_2L(\eta^4\text{-cot})]^{2+}$ (where L = CO or PPh_3 and cot = cyclooctatetraene) is oxidised at a platinum electrode in a single irreversible one-electron stage.[64] Complexes of the type $[Ru(NH_3)_5(olefin)]^{2+}$, where styrene, *p*-vinylbenzoic acid, cyclohexa-1,3-diene, and a number of others were used as the olefins, have been investigated by cyclic voltammetry.[65] The introduction of substituents into the aromatic rings of the ligands does not affect the electrochemical oxidation potential, while the pentammine environment is more likely to compensate for the charge on the ruthenium centre than a polycarboxylate environment.

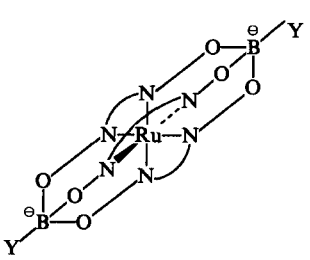
The electrochemistry of the mixed-ligand ruthenium(II) and ruthenium(III) complexes containing various β-diketonate ligands has been studied.[67] The *d*-π molecular orbitals, formed from the t_{2g} orbitals d_{xy}, d_{xz}, and d_{yz} of ruthenium, assume the role of the HOMO and the LUMO of the tris(β-diketonato)ruthenium complexes. Linear correlations have been found[67] between the ligand composition and the $E_{1/2}$ for the oxidation and reduction of the complexes. For example, the reduction potentials of the mixed-ligand complexes can be estimated from these linear relations when the $E_{1/2}$ for the reversible redox transitions in the corresponding homoleptic complexes are known:

$$E^{III/II}(L''_nL'_{3-n}) = (n/3)E^{III/II}(L''_3) + (1-n/3)E^{III/II}(L'_3)\ .$$

The ligand η^5-C_5Ph_5 is known to stabilise paramagnetic complexes, which makes it possible to investigate[68] by cyclic voltammetry the ruthenium(II) complexes containing this ligand, in particular $[RuBr(CO)_2(\eta^5\text{-}C_5Ph_5)]$, $[RuBr(CO)L(\eta^5\text{-}C_5Ph_5)]$ [where L = PPh_3, PEt_3, $P(OMe)_3$], $[Ru(CO)LL'(\eta^5\text{-}C_5Ph_5)]^+$

[where L = PEt_3 or $P(OMe)_3$; L′ = CO, C_2H_4, PEt_3, MeHC=CHMe, $P(OMe)_3$], [$RuMe(CO)_2(\eta^5\text{-}C_5Ph_5)$], and [$RuR(CO)(PEt_3)(\eta^5\text{-}C_5Ph_5)$] (where R = Me, Et, COMe, CH=CHMe). It is seen from the analysis of the oxidation potentials that:

(1) the C_5Ph_5 ligands stabilise the cations $[Ru^{III}Br(CO)L(\eta^5\text{-}C_5Ph_5)]^+$ [L = PPh_3, PEt_3, $P(OMe)_3$] and $[Ru^{III}R(CO)(PEt_3).(\eta^5\text{-}C_5Ph_5)]^+$ (R = Me, Et, COMe);



(2) the substitution of CO by L lowers the equilibrium potentials E^0;

(3) bromides are oxidised with greater difficulty than complexes containing σ-bound organic groups;

(4) the π-donor properties of the ligand have little influence on E^0.

The oxidation of sandwich complexes having the composition $(\eta^5\text{-}C_9H_7)Ru(\eta^5\text{-}L)$ (L = C_5H_5, C_5Me_5, C_9H_7) has been investigated.[69] The reversible transfer of one electron leads to the formation of 17-electron radical-cations, the stability of which depends on the properties of the η-ligand and the nucleophilicity of the medium.

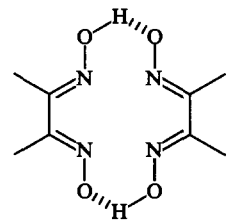
The influence of the steric and electronic effects on the stability of boron-containing ruthenium(II) and ruthenium(III) complexes has been investigated.[70] The cathodic (I_{pc}) and anodic (I_{pa}) currents have been determined by cyclic voltammetry for the quasi-equilibrium couple Ru(II/III); their ratio I_{pc}/I_{pa} served as a criterion of the stability of the ruthenium(III) complex. The increase in I_{pc}/I_{pa} for a series of substituents Y, i.e. $n\text{-}C_{10}H_{21}O > n\text{-}C_5H_{11}O > Bu^nO > Pr^nO > EtO > MeO \simeq Pr^iO$, permits the conclusion that the stability of the ruthenium(III) complex increases with increase in the length of the chain of the alkoxy-groups. However, it is believed that this effect is not related to the electronic or steric effects of the alkoxy-substituents, whereas the decrease in I_{pc}/I_{pa} on passing from $Ru(chd)_3(BOPr^n)_2$ to $Ru(chd)_3(BOPr^i)_2$ indicates a decrease in the stability of the high-valence complex with increase in the bulk of the alkoxy-groups.

Here O—N N—O is

(1) a 1,2-cyclohexanone dioxime residue (chd) with Y = Ph, Bu^n, Me, F or OR (R = Me, Et, Pr^n, Bu^n, $n-C_5H_{11}$, $n-C_{10}H_{21}$),

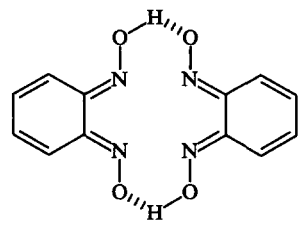
(2) a diphenyl-glyoxime residue (dpg) with Y = Bu^n or OMe, or

(3) a dimethyl-glyoxime residue (dmg) with Y = Bu^n or OMe.



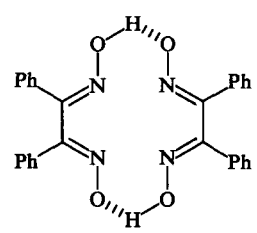
The study of the high-valence ruthenium(IV) complexes is of special interest, since they may prove to be promising catalysts (see, for example, Refs 71–73). The ruthenium(IV) complexes are relatively rare, and only a few of them have been reliably characterised (see Refs 74–76 and the literature quoted therein).

Ruthenium(II) complexes containing macrocyclic ligands which are difficult to oxidise can be readily oxidised at platinum, gold, or carbon glass electrodes with formation of hexacoordinate complexes formally corresponding to ruthenium(III) and ruthenium(IV), for example:[76]



$$Ru(dmgH)_2(PPh_3)_2 \rightleftharpoons [Ru(dmgH)_2(PPh_3)_2]^+ + \bar{e},$$

$$[Ru(dmgH)_2(PPh_3)_2]^+ \rightleftharpoons [Ru(dmgH)_2(PPh_3)_2]^{2+} + \bar{e}.$$



The ruthenium(III) complexes are relatively stable at room temperature, while the formation of the formally tetravalent ruthenium(IV) complexes frequently requires cooling to −78 °C.

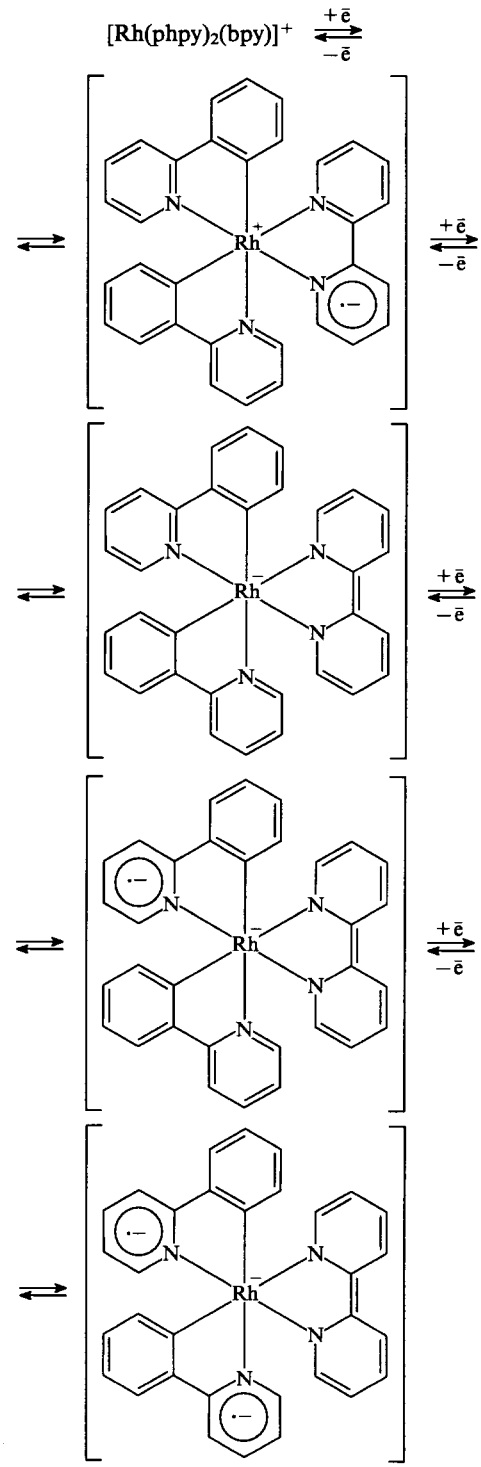
It has been shown[76] that the stability of the ruthenium(IV) complexes increases significantly on replacement of nitrogen- or oxygen-containing donors (*N*-methylimidazole, DMSO, pyridine, etc.) by phosphine ligands. However, the formation of a high-valence ruthenium(IV) complex on oxidation of the complex $[Ru(bpy)_2(biBzIm)]^{2+}$ (where $biBzImH_2$ = 2,2′-bibenzimidazole) can be observed by cyclic voltammetry at a carbon glass (CG) electrode at a potential scanning rate $> 5\ V\ s^{-1}$.[77] In contrast to the complex $[Ru(bpy)_3]^{2+}$, for which the second anodic wave corresponds to the oxidation of the ligand,[78] it was shown in this case[77] that the oxidation takes place at the ruthenium atom and that a low-spin d^5 [ruthenium(III)] complex is indeed formed.

The replacement of the nitrogen-containing macrocyclic system by other ligands, for example, 8-hydroxyquinoline, lowers the stability of the ruthenium(IV) complexes. The ability of nitrogen-containing macrocycles to stabilise metals in high oxidation states is known. For example, the complex $[Hg^{III}(N_4)]^{3+}$ (where N_4 = 1, 4, 8, 11-tetraazacyclotetradecane) with a lifetime of about 5 s at −78 °C has been obtained by electrochemical oxidation.[79, 80] Ruthenium(IV) complexes not containing macrocyclic ligands could not be isolated, although electrochemical evidence for their formation has been obtained.[81, 82] It is noteworthy that a true ruthenium(IV) complex is obtained only

if the ligand is not oxidised. In certain cases, the ligand may be oxidised after the electron transfer from the metal atom, i.e. there is a possibility of an intramolecular reaction involving electron transfer from the ligand to the metal, which means that the ruthenium(IV) complex cannot be claimed to be the final product of the electron transfer. The involvement of ligands such as dimethylglyoxime and its derivatives in such processes is unlikely, so that complexes containing them are extremely convenient for the synthesis of ruthenium(IV) compounds. There exists another point of view, according to which ruthenium(IV) complexes may be regarded as ruthenium(III) radicals.[77] The oxidation of the complex $Ru(dtc)_3$ (where dtc = dithiocarbamate) leads to the formation of heptacoordinate ruthenium(IV) complexes of the type $[Ru(dtc)_3Solv]^{2+}$ (Solv = solvent molecule)[83] or dimeric ruthenium(III) complexes. Similarly the oxidation of ruthenocene affords $[Ru^{IV}Cp_2Solv]^{2+}$.[84] The heptacoordinate ruthenium(IV) complexes are more stable than the hexacoordinate complexes.[76]

In conclusion one should note that, in order to be able to compare the electronic properties of different compounds on the basis of electrochemical parameters (current, potential), one has to be sure that the diffusion coefficient is constant for the given series of compounds. Measurements have been made[85] of the diffusion coefficients of a large series of ruthenium(II) complexes in solution in acetonitrile using a rotating disc electrode and it was shown that the diffusion coefficient remains almost constant, while the rate of electron transfer increases with decrease in the redox potential.



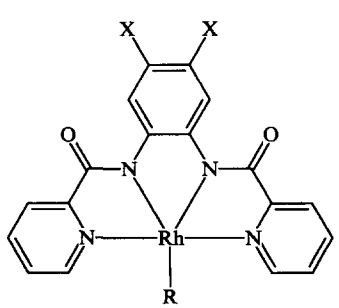
2. Electrochemical properties of mononuclear rhodium complexes

Comparison of the electrochemical properties of complexes containing metal atoms in the d^6 and d^8 configurations, for example, ruthenium(II) (d^6) and rhodium(I) (d^8) compounds, is of definite interest from the theoretical point of view. The energy difference between HOMO and LUMO is much smaller if the central metal atom has the d^8 configuration and not the d^6 one. This is apparently due to the fact that in the former case the unoccupied orbital is a ligand orbital, whilst the HOMO is localised on the metal atom.[86] For metal complexes with the d^6 configuration, both the HOMO and the LUMO are localised on the metal. This is confirmed, for example, by data on the electrochemical oxidation and reduction of dienerhodium(I) complexes containing cycloocta-1,5-diene (cod) or norbornadiene (nbd) ligands with 2,2′-bipyrimidine (bpym) (Tables 3 and 4).[86]

Extensive studies have been made on rhodium(III) complexes containing bipyrimidine and a number of other ligands capable of forming ortho-metallated derivatives, for example $[Rh(phpy)_2(phen)]^+$, $[Ru(thpy)_2(phen)]^+$, $[Rh(phpy)_2(biq)]^+$, $[Rh(phpy)_2(bpy)]^+$, and $[Rh(thpy)_2(bpy)]^+$, where phen = 1,10-phenanthroline, biq = 2,2′-biquinoline, and $phpy^-$ and $thpy^-$ denote the *ortho*-C-deprotonated forms of 2-phenylpyridine and 2-(2-thienyl)pyridine.[87–90] The *ortho*-metallated complexes constitute a new potential class of mediators for photochemical and chemiluminescence reactions. Four reversible waves are observed in the reduction of $[Rh(phpy)_2(bpy)]^+$ at a platinum disc electrode and a mercury dropping electrode in DMF at a low temperature (−54 °C).[87, 89] On the basis of the behaviour of the homoleptic complexes $Ru(bpy)_3^{2+}$,[33, 43] $Ir(bpy)_3^{3+}$, and $Ir(phpy)_3$,[89] as well as the dimer $[Ru(phpy)_2Cl]_2$,[91] one may conclude that the appearance of such a large number of reduction waves should be associated not only with ligand orbital association processes but also with the acceptor orbitals localised on the pyridine rings of the individual ligands. The first wave has been attributed to the reduction of the ligand bpy, while the group of three closely spaced waves is associated with the reduction of the two $phpy^-$ ligands and the second stage of the reduction of bpy (Scheme 1).

Three reversible waves are observed in the electrochemical reduction of $[Rh(phpy)_2phen]^+$ and $[Rh(phpy)_2(biq)]^+$. Thus each heteroleptic complex has virtually the same set of reduction waves regardless of whether the ligands are linked to a

Scheme 1



rhodium(III) atom or to, for example, an iridium(III) atom and the process proceeds consecutively with respect to each of the pyridine rings present in the molecule;[87] the difference between the wave [half-wave?] potentials is 0.2–0.3 V. The oxidation of rhodium(III) complexes listed above, with *ortho*-metallated nitrogen-containing ligands, takes place at the metal atom.

The correlations between the electrochemical parameters and electronic spectroscopic data for rhodium complexes have been examined.[87, 92–94] Cyclic voltammetric data[87] have shown that N,N-coordinated ligands are reduced more readily than the N,C-coordinated ones (for example, $phpy^-$). This shows that the π^* LUMO is to a large extent associated with the N,N-coordinated ligands. However, it follows from the absorption spectra[87] that the MLCT band with minimum energy corresponds to the electron transfer from the metal to the N,C-coordinated ligands and not to

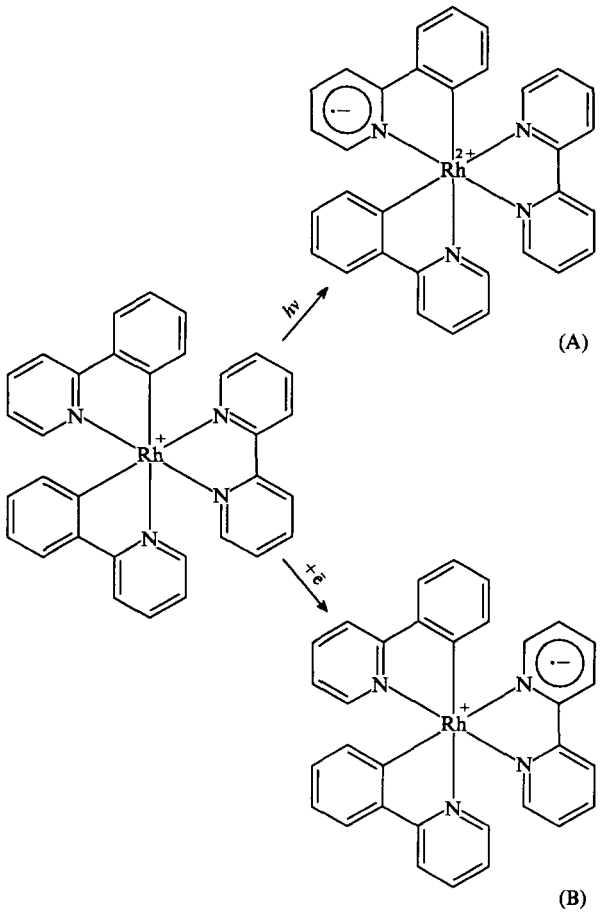


Table 3. Data on the electrochemical oxidation of mononuclear rhodium complexes.

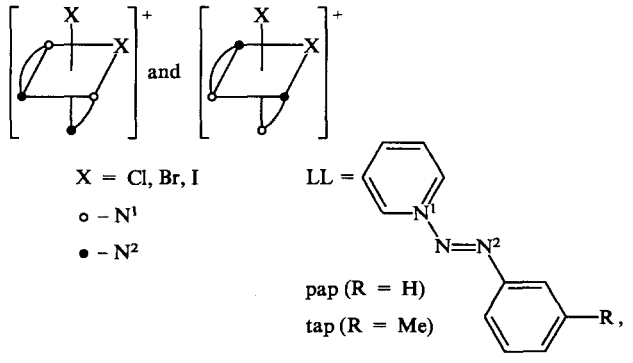
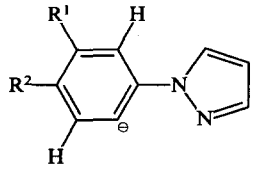
the more readily reducible N,N-coordinated ligands. The reasons why the energies of the Rh→N,C and Rh→N,N transitions do not reflect the energies of the corresponding π^* orbitals are probably as follows. First, the octahedral t_{2g} d orbitals of the metal are split in different ways owing to the different electron-donating capacities of the N,N- and N,C-ligands and the d orbitals of the metal participating in the Rh→N,C transitions have a higher energy than the d orbitals involved in the Rh→N,N transitions. Secondly, owing to the different nature of the Rh–N,C and Rh–N,N bonds, the interaction between the outer electron shells in the excited state (A) and in the radical (B) may differ greatly, so that on photoexcitation the radical cation (A) is more stable while on electrochemical reduction radical (B) is more stable (see over).

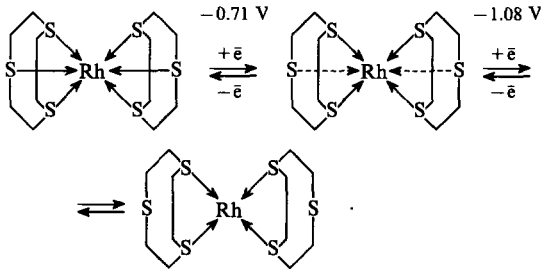


X = H, Cl;
R = Me, Et, Pr.



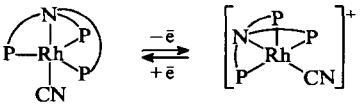
The dianionic amide chelating ligands containing a pyridine fragment are capable of stabilising transition metals in high oxidation states, which makes it possible to obtain fairly stable rhodium(IV) complexes. The electrochemical oxidation of such complexes has been investigated,[95] but the attempts to find a correlation between λ_{max} in the electronic absorption spectra of these compounds and their oxidation potentials were also unsuccessful. Thus the simplified picture of the 'localisation of the electronic changes' associated with the spectroscopic and electrochemical transitions ('on the metal' or 'on the ligand'), widely used for transition metal compounds, does not always yield a satisfactory description, particularly in the case of systems containing *ortho*-metallated ligands, where the metal–ligand bonds are significantly covalent.

The redox properties of 2-arylazopyridinerhodium(III) complexes $[RhX_2(LL)_2]ClO_4$, having the structure



have been investigated by cyclic voltammetry at a platinum electrode.[96] The studies were carried out over a wide range of potentials: from 2.0 to −1.5 V. Three cathodic waves were observed, but the reduction products were unstable and were not isolated in a pure form. The EPR spectra of the electrolysis products at a reduced temperature (−13 °C) showed that the unpaired electron in the reduction products $[RhCl_2(LL)_2]$ and $[RhCl_2(LL)_2]^-$ is located on orbitals with a predominant ligand character, i.e. reduction takes place 'at the azo-group'.

The electrochemical behaviour of mixed-ligand rhodium(II) complexes containing neutral pyridine (bpy) and quinoline (biq) as well as anionic 1-phenylpyrazole ligands substituted in the benzene ring has been studied.[97] The results are in many respects similar to those observed for other cyclo-metallated rhodium(III) complexes:[88, 92] the reduction proceeds in the first place at the bpy ligand, while the oxidation is irreversible and belongs to processes 'localised on the metal'.



ppz⁻ ($R^1 = R^2 = H$)
(3-Clppz)⁻ ($R^1 = Cl$, $R^2 = H$)
(4-NO_2ppz)⁻ ($R^1 = H$, $R^2 = NO_2$)

Cyclic voltammetry at a platinum electrode of the homoleptic hexathia-coordinate complex $[Rh(LLL)_2](PF_6)_3$ (LLL = 1,4,7-trithiacyclononane) indicates the occurrence of two chemically reversible reduction processes, corresponding to the redox transitions Rh(III/II) and Rh(II/I). The cathodic reactions can be represented schematically as follows:[98]

The 19-electron complexes $[Rh(LLL)_2]^{2+}$ are less stable than the corresponding complexes $[Pd(LLL)_2]^{3+}$, which also have a central atom with the d^7 configuration. This is associated with the smaller formal charge on the rhodium atom. In the rhodium(I) complex, the metal has so many electrons that it is coordinated to only four and not six sulfur atoms. The cation $(Rh(LL)_2]^+$ is a very powerful reductant.

The redox properties of 18-electron pentacoordinate trigonal-bipyramidal rhodium(I) complexes containing σ-cyanide and σ-acetylide ligands, [(LLLL)Rh(CN)] and [(LLLL)Rh(C ≡ CPh)] [where LLLL = $N(CH_2CH_2PPh_2)_3$ or $P(CH_2CH_2PPh_2)_3$], were subjected to a comparative analysis.[93] It was found that there is little difference in the electrochemical behaviour of these complexes. π- and σ-bonding with the transition metal atom is characteristic of the cyanide and acetylide ligands. As a result of the one-electron oxidation of the above complexes, a stable paramagnetic rhodium(II) complex having the structure of a square pyramid is formed, for example:

Further oxidation of the rhodium(II) complex leads to the unstable rhodium(III) species, which rapidly decompose with formation of dicyanide complexes:

$$2[(LLLL)Rh(CN)]^{2+} \longrightarrow [(LLLL)Rh(CN)_2]^+ + [(LLLL)Rh]^{3+}.$$

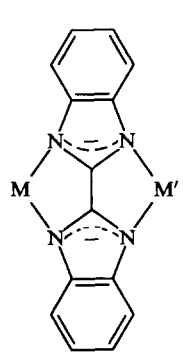
Without knowing the structures of the intermediates, it is difficult to explain the pathway leading to the formation of the final dicyanide complex. The initial dimerisation with formation of a bridged tetracation $[(LLLL)Rh(\mu\text{-}CN)_2Rh(LLLL)]^{4+}$ and its subsequent decomposition appear most likely. Dicationic rhodium(III) acetylide complexes are more stable than the cyanide complexes. As expected, the acetylide ligands proved to be better donors, although not very much better, than the cyanide ions.

Terminal rhodium(II) and rhodium(III) complexes of acetylene have been obtained[94] by electrolysis at a controlled oxidation potential of the neutral rhodium(I) complexes [(LLLL)Rh(C≡CR)], where R = Ph, COOEt, or CHO. Comparison of the stretching vibration frequencies of the C≡C bond in a series of complexes $[(LLLL)Rh(C{\equiv}CR)]^{n+}$ (n = 0–2) or of the redox potentials in a series of complexes [(LLLL)RhX] (X = Cl, H, C ≡ CR, CN or CO) indicates a fairly considerable interaction between the d–π-orbital of the metal and the π* orbital of the acetylide. Such interaction is reflected in the properties of the carbon–metal bond in the rhodium(I) and rhodium(II) complexes. On passing from ligands without π-acceptor properties (H, Cl) to strong π-acceptors, the potential E_0 of the Rh(I)/Rh(II) redox couple increases in the sequence Cl > H > C≡CR > CN > CO. The σ-acetylide compounds lie halfway between the hydride and cyanide complexes, E^0 depending on the electronic properties of the substituent at the C≡C bond.

The study of the electrochemical properties of the porphyrins[99] made it possible to deduce a series of empirical rules whereby it is possible to determine the direction of the redox process. According to one of them, the electronic changes involve the ligand environment if in the electrochemical reduction process the difference between $E_{1/2}$ for the metalloporphyrin and $E_{1/2}$ for the free porphyrin is negative. This conclusion is based on the hypothesis that the metal exerts a positive inductive effect and therefore shifts the σ-electron density closer to the ligand. A similar approach has been used in an electrochemical study of tetra(3,5-di-*tert*-butyl-4-hydroxyphenyl)dodecachlorophthalocyanine complexes

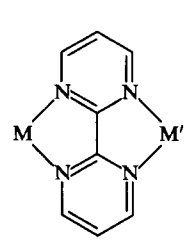
of various metals, including rhodium and ruthenium.[100] The oxidation and reduction processes can be described by means of the following scheme:

$$PcMX_n \begin{cases} \xrightleftharpoons{+\bar{e}} (PcMX_n)^- \xrightleftharpoons{+\bar{e}} (PcMX_n)^{2-} \\ \xrightleftharpoons{-\bar{e}} (PcMX_n)^+ \xrightleftharpoons{-\bar{e}} (PcMX_n)^{2+} \end{cases}$$



Pc = phthalocyanine, X = axial ligand.

It was shown that the magnesium, zinc, copper, and nickel complexes are oxidised and reduced with participation of the ligand, while the rhodium, ruthenium, osmium, cobalt, palladium, and platinum complexes are oxidised 'at the ligand' and their reduction takes place with participation of the metal ion.



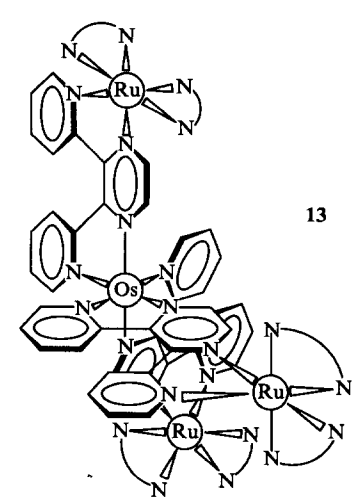
3. Polynuclear ruthenium and rhodium complexes

The redox chemistry of polymetallic complexes containing different bridging ligands is of special interest. Many natural products contain such fragments. By varying the structure of the bridging ligand, it is possible to alter the degree of metal–metal interaction and also the rate of the inner-sphere electron transfer. Complexes of metals in the same valence state as well as mixed-valence bimetallic complexes are known. Despite the fact that the study of the electrochemical properties of homonuclear and heteronuclear polymetallic complexes with organic ligands was begun comparatively recently, numerous interesting data, significantly expanding our ideas concerning their structure and properties, have already been obtained. The key component in such systems is the bridging ligand, since many properties of the complexes depend on the size, form, and electronic nature of the bridge; in certain cases, the bridge participates directly in electrochemical and photochemical processes.

Investigations of a series of 2,2′-bibenzimidazolyl (biBzIm) bridged homobinuclear and heterobinuclear complexes $[(bpy)_2M(biBzIm)M'(bpy)_2]^{n+}$ (n = 2–4; M = Ru, Os; M′ = Ru) and their fragments (mononuclear complexes) $[M(bpy)_2(biBzImH_2)]^{2+}$, $[M(bpy)_2(biBzIm)]$, and $[M'(bpy)_3]^{2+}$ have been performed.[101] The 2,2′-bibenzimidazolyl bridging ligand is structurally similar to the 2,2′-bipyrimidyl (bpm) ligand.

M(biBzIm)M′

M(bpm)M′

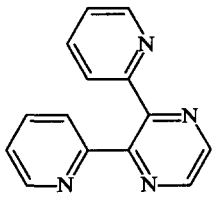


The distance between the metallic centres in these two complexes is in fact the same but the charges on the ligands are different; biBzIm has a charge of 2–, while bpm is neutral. All the dinuclear bisimidazolyl complexes investigated (with the exception of the ruthenium-nickel complex) give rise to two one-electron reversible waves on oxidation, whilst the complex containing ruthenium and nickel gives rise to one wave corresponding to the Ru(II)/Ru(III) transition. The potentials of the two oxidation waves of the heterobinuclear [Ru, Os] and [Ru, Co] complexes were compared with the potentials of the corresponding mononuclear complexes $[M(bpy)_3]^{2+}$, which made it possible to attribute the first electrode process (at the lower potential) to the Os(II)/Os(III) and Co(II)/Co(III) transitions and the second to the Ru(II)/Ru(III) transition. Comparison of the oxidation potentials of the dinuclear and mononuclear complexes $[M(bpy)_2(biBzImH_2)]^{2+}$ shows that the first oxidation potentials of the dinuclear complexes $[(bpy)_2M(biBzIm)M'(bpy)_2]^{n+}$ are lower by 0.3 V than the potentials of the corresponding mononuclear complexes. Hence it was concluded[101] that biBzIm exhibits electron-donating properties in the dinuclear complexes. On the other hand, the first oxidation potential of the dinuclear complex $[(bpy)_2Ru(bpm)Ru(bpy)_2]^{4+}$ is higher by 0.4 V than that of the corresponding mononuclear complex, which indicates the electron-accepting character of the bmp bridge. The potential of the Ru(II)/Ru(III) redox transition in the dinuclear complexes depends only on the charge of the second metal ion. This made it possible to conclude that the electron delocalisation via the biBzIm bridge is relatively slight and that electrostatic interactions have become an important potential-determining factor. Knowing the difference between the potentials of the different redox couples, it is possible to calculate the comproportionation constant (K_{com}).

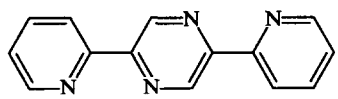
$$[M^{II}-biBzIm-M^{II}]^{2+} + [M^{III}-biBzIm-M^{III}]^{4+} \rightleftharpoons 2[M^{II}-biBzIm-M^{III}]^{3+}$$

For example, $K_{com} = 8.2 \times 10^4$ for M = $Ru(bpy)_2$.[101]

2,3-Di(2-pyridyl)pyrazine (dpp) is an interesting nitrogen-containing bridging ligand. The complex $[Ru(dpp)_3]^{2+}$ is of great practical importance,[102] since it is capable of forming polymetallic chains, which makes it possible to obtain a new class of polynuclear complexes capable of accumulating solar energy. The strength of the electronic interaction between the metal atoms in the ground state of the bimetallic and polymetallic complexes depends on the distance between the metal atoms and on the degree of conjugation in the π-system of the bridging ligand. The transmission of the influence along the bridge can be estimated by comparing the potentials E^{Ox} of complexes of the type $[(LL)_2Ru^{II}(\mu\text{-}L)]^{2+}$ (LL = bpy or phen and μ-L = dpp, dpq, or bpm is the bridging ligand) with the first oxidation potentials of the corresponding complexes $[(LL_2Ru^{II})_2(\mu\text{-}L)]^{4+}$. The small difference between the oxidation potentials of the monometallic and bimetallic complexes (eg. ΔE = 10 mV) indicates an insignificant change in the energy of the t_{2g} orbitals and hence a weak interaction between the two metallic centres in the bimetallic complex. If the interaction had been stronger, the bimetallic complex would have been oxidised at more positive potentials and ΔE could have reached several hundreds of millivolts.



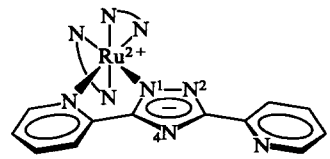
The redox properties of the heterometallic complex $Os[(\mu\text{-}2,3\text{-}dpp)Ru(bpy)_2]_3^{8+}$ **13**,[103] its homometallic analogue $Ru[(\mu\text{-}2,3\text{-}dpp)Ru(bpy)_2]_3^{8+}$ **14**,[102] and also the mononuclear



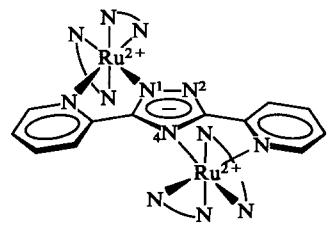
13

complexes $[Ru(2,3\text{-dpp})(bpy)_2]^{2+}$ **15**[104, 105] and $[Os(2,3\text{-dpp})_3]^{2+}$ **16**[105] have been investigated by cyclic voltammetry. A single one-electron reversible wave, attributed to the oxidation of the metal, was observed in the electrochemical oxidation of the mononuclear complexes. When the homotetrametallic complex **14** is oxidised, it gives rise to a three-electron wave corresponding to the oxidation of the peripheral ruthenium atoms. Oxidation at the central ruthenium atom is not observed, since the atom is bound to three strong π-acceptor dpp bridging ligands. In the oxidation of compound **13**, a one-electron reversible wave followed by a three-electron quasi-reversible wave is observed. The first anodic process was attributed to the oxidation of the osmium atom and the second to the oxidation of the three ruthenium atoms. In the reduction of compounds **13**, **14**, and **16**, three one-electron waves, associated with the reduction of the three dpp ligands (since they are reduced much more readily than bpy), were observed. It has been noted[102, 103] that the bridging ligands are as a rule reduced more readily to an extent of approximately 0.4 V than the structurally similar terminal ligands. The several indistinct waves observed at potentials more negative than −1.35 V probably correspond to further reduction of dpp and the one-electron reduction of the bpy ligands. The sequence in the reduction of the ligands in complex **15** is similar: dpp followed by bpy. On the basis of the reversibility of all three reduction waves for the tetrametallic complexes, one may postulate that these systems can serve as multielectron oxidising agents in the ground state.

A study[106] of the mononuclear and dinuclear ruthenium(II) complexes $[Ru(L)(CO)_2Cl_2]$ and $(\mu\text{-}L)[Ru(CO)_2Cl_2]_2$, containing the 2,3- and 2,5-isomers of di(2-pyridyl)pyrazine (dpp) as the bridging ligands, showed that the interaction between the metallic centres depends not only on the structure of the bridge but also on the nature of the ligands bound to the metal.



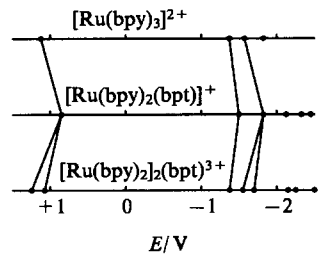
2,3-dpp



2,5-dpp

Monometallic and bimetallic complexes were oxidised with a single irreversible wave at a potential of about 2.0 V. Since the oxidation waves were observed only for the complexes and not for the free ligands, they apparently correspond to the oxidation of the metal ion. The high positive oxidation potentials agree well with the electron-accepting character of the CO ligands. The oxidation potentials of the monometallic and bimetallic complexes are similar, whence one may conclude that the bond between the two metallic centres is very weak. This can be accounted for by the strong mesomeric effect of the CO ligands. The first reduction wave for all the compounds of the given series is reversible and corresponds to the reduction of the aromatic ligand (dpp). Its potential diminishes in the sequence free ligand, mononuclear complex, dinuclear complex. This is associated with the fact that the electron density on the ligands diminishes on coordination to the electron-deficient ruthenium atom. A satisfactory linear correlation has been observed between the reduction potentials and the energies of the MLCT bands in the electronic spectra (see Section II.5).

The electrochemical behaviour at the carbon glass electrode of the polypyridine bisheteroleptic complexes has been investigated:[1, 107, 108] the mononuclear complex $[Ru(bpy)_2(bpt)]^+$ **17** and the dinuclear $[Ru(bpy)_2]_2(bpt)^+$ **18** [bpt = anion of 3,5-bis(2-pyridyl)-1,2,4-triazole].



17

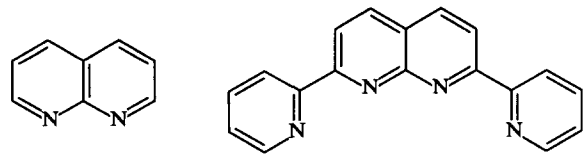
18

The anion bpt^- is particularly interesting, because, in contrast to the majority of other polypyridine bridging ligands, it carries a negative charge and exhibits a high σ-donor and low π-acceptor capacity. The redox potentials were measured using differential pulse polarography. The mononuclear complex **17** gives rise to one oxidation wave[107] and five reduction waves.[1, 108] The dinuclear complex **18** is oxidised in two stages,[107] while on reduction it gives rise to six waves, the first of which is a two-electron wave.[108] The protonated bpt^- anion (Hbpt) is not reduced at potentials up to −2.8 V. Scheme 2 illustrates the changes in E^{Red} and E^{Ox} on passing from $[Ru(bpy)_3]^{2+}$ to $[Ru(bpy)_2(bpt)]^+$ and then to the dinuclear complex.

Scheme 2

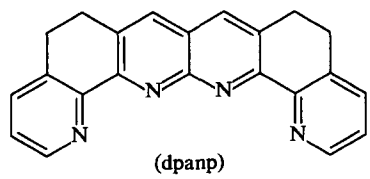
In particular, it follows from the analysis of Scheme 2 that, by virtue of the non-equivalence of the disposition of the two $[Ru(bpy)_2]^{2+}$ fragments relative to the bridge, two well-separated oxidation waves are obtained for the dinuclear complex, the difference between the potentials of which is 0.32 V. This permits the calculation of the comproportionation constant by using the equation $RT\ln K_{com} = F(\Delta E)$.

$$[M^{III}, M^{III}] + [M^{II}, M^{II}] \overset{K_{com}}{\rightleftharpoons} 2[M^{II}, M^{III}] .$$



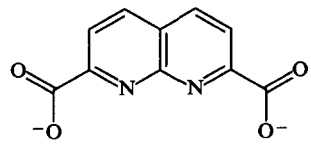
The value $K_{com} = 2.4 \times 10^5$ obtained indicates a fairly strong interaction between the metallic centres.

The first and second reduction potentials of $[Ru(bpy)_2bpt]^+$ are satisfactorily correlated with the corresponding reduction potentials of $[Ru(bpy)_3]^{2+}$ and hence can be attributed to the reduction of the coordinated bpy ligands.



The splitting of the waves on passing from the mononuclear to the dinuclear compound in the reduction process is much smaller than the splitting observed in the oxidation process, so that the two centres involved in the reduction (ligands) are further apart than the two centres involved in the oxidation.

Detailed analysis of the electrochemical data obtained led to the conclusion[107] that the bridging bpt^- ligand hardly participates in the formation of the π LUMO of the complex.



There exists a series of dinuclear copper, nickel, rhodium, and ruthenium complexes in which 1,8-naphthyridine (np) and its derivatives participate as the bridging ligands.[109, 110]

(np) (dpnp)

(dpanp)

$(dcnp)^{2-}$

These complexes are remarkable, because the small distance between the two metal nuclei leads to synergistic effects,[111, 112] especially in the homogenous catalysis.[113, 114] The oxidation of the rhodium complexes proceeds with participation of the orbitals localised on the metallic centres, while the reduction involves the ligand. It is of interest to note that the 2Ru(III)/Ru(III), Ru(II) transition in the complex $[Ru_2(OAc)_3(dcnp)]$ takes place very readily (0.33 V), while the Ru(III), Ru(II)/2Ru(II) transition is fairly difficult to achieve (−1.11 V), which indicates a greater stability of the system of the $[Ru^{III}, Ru^{II}]$ type. The stability of the $[Ru^{III}, Ru^{II}]$ complex can be estimated with the aid of the comproportionation constant

$$[Ru^{II}, Ru^{II}] + [Ru^{III}, Ru^{III}] \overset{K_{com}}{\rightleftharpoons} 2[Ru^{II}, Ru^{III}],$$

$$\ln K_{com} = \frac{F}{RT}(E_2^0 - E_1^0),$$

where E_2^0 and E_1^0 are the potentials of the 2Ru(III)/Ru(III), Ru(II) and Ru(III), Ru(II)/2Ru(II) redox transitions.

$K_{com} = 2.5 \times 10^{24}$ for the $[Ru_2(OAc)_3(dcnp)]$ complex,[110] which is one of the most stable mixed-valence complexes. For the analogous complex containing chloride instead of acetate ligands, $K_{com} = 3.5 \times 10^{23}$.[115] For comparison, we may point out that, for example, in the case of bimetallic ruthenium complexes, containing the bidentate bridging ligands 2,3-dpp and 2,3-di(2-pyridyl)quinoxaline (2,3-dpq), the comproportionation constant is of the order of 10^3. This value is the most typical for systems of this kind.[116]

It also follows from the electrochemical data[110] that the interaction between the metal atoms in the isovalent $[Ru^{II}, Ru^{II}]$ complex containing the dpp and dpq ligands is weak. The data presented indicate the important role of the aromatic bridging ligands in the redistribution of electrons between the two metallic centres.

The irreversible reduction wave of the complex $[Ru_2(OAc)_3(dcnp)]^-$ [formally corresponding to the 2Ru(II)/Ru(II)Ru(I) transition] is observed at very high cathodic potentials and has been attributed[110] to electron transfer to an orbital localised on the $(dcnp)^{2-}$ ligand.

The dependence of the distribution of electron density between the metal and the ligands on the introduction of a second substituent into the molecule has been investigated in relation to dienerhodium complexes containing bipyrimidine ligands.[86] Comparison of the spectroscopic and electrochemical properties of the mononuclear and dinuclear complexes $[Rh(nbd)(bpym)]^+$, $[Rh(cod)(bpym)]^+$, $[Rh(nbd)]_2(bpym)^{2+}$, and $[Rh(cod)]_2(bpym)^{2+}$ (where nbd = norbornadiene and cod = cycloocta-1,5-diene) showed[86] that in all cases the lowest excited state corresponds to the MLCT transition (Rh→bpym), while reduction involves in the first place the bpym ligand. The energy levels participating in the MLCT transition and also those associated with one-electron oxidation and reduction are very similar for the mononuclear and dinuclear complexes.

However, luminescence is observed for the mononuclear complexes but not for the dinuclear one. The reason for this is apparently the interaction of the two metallic centres. We may note that the potentials of the first and second reduction waves for $[Rh(cod)]_2(bpym)^{2+}$ are approximately equal to the reduction potential of the mononuclear complex (Tables 4 and 6), which shows that the introduction of the second Rh atom does not induce an appreciable change in the π^* level (b_1) of the bridging bipyrimidyl ligand. The dinuclear complexes are oxidised ($E_{1/2}$ = 1.0 V) with somewhat more difficulty than the mononuclear ones, which agrees fully with the electrostatic requirements. The potential of the second oxidation wave of the dinuclear rhodium complex is more positive by 0.42 V than that of the first wave. For the polynuclear ruthenium(II) complexes, the quantity $\Delta E_{1/2} = E^2_{1/2} - E^1_{1/2}$ can be regarded as a quantitative measure of the interaction between the two metallic centres.[117] Using a similar test, one may conclude that the interaction of the two rhodium(I) atoms in the $[Rh(cod)]_2(bpym)^{2+}$ ion is very significant.

In order to investigate the nature of the bonding in the cyanide-bridged rhodium and ruthenium complexes having the general formula $M^1-CN\rightarrow(M_2)^+$ [where M^1 and(or) M^2 = $(\eta^5\text{-}C_5H_5)Rh(\eta^3\text{-}C_3H_5)$ or $(\eta^6\text{-}Ph)Ru(\eta^3\text{-}C_3H_5)$], a study was made of their oxidation and reduction reactions and also of the corresponding characteristics of their mononuclear fragments.[118] All the complexes are reduced in the first place at the 'cationic' fragment (M^{2+}). This results in the formation of the cyanide M^1CN, which is reduced in the second stage:

$$M^1-CN\rightarrow(M^2)^+ \xrightarrow{+\bar{e}} M^1CN \xrightarrow{+2\bar{e}} \text{products} + CN^-.$$

The fact that the first electron transfer is followed by the chemical stage involving the cleavage of the bridge has been confirmed by the irreversible nature of the reduction process and also by the very great similarity between the potential of the second stage in the reduction of the bridged complex and the potential E^{Red} of the mononuclear cyanide complex forming part of its composition. The mechanism of the oxidation of complexes of this type is much more complex. The number of electrons involved in the oxidation depends greatly on the structure of the complex. The irreversibility of all the oxidation waves shows that the radical-cation formed initially undergoes rapid consecutive reactions. Detailed analysis of the electrochemical parameters showed that the centres at which the electronic changes are localised in the oxidation of the complexes can be different, but the bridge is not cleaved in the oxidation of any of the complexes investigated.[118] This demonstrates a fairly high strength of the $N\rightarrow M^+$ bond and the delocalisation of the charge on the cationic fragment over the entire $M^1-C\equiv N\rightarrow(M^2)^+$ chain. The oxidation at the 'cationic' metal atom observed for the complexes $RhCNRu^+$ and RhCNRh, which at first sight appears unlikely, can be accounted for by the charge redistribution. Comparison of the spectroscopic and electrochemical data has shown[118] that linear correlations between the electrochemical potentials and the frequency of the CN group stretching vibrations occur for a series of compounds in which the electronic changes are localised at the same centre.

The electrochemical behaviour of the mixed-valence cyanide-bridged complexes $[(NH_3)_5RuCNRu(bpy)_2CN]^{3+}$ and $[(NH_3)_5RuCNRu(bpy)_2CNRu(NH_3)_5]^{6+}$, which can be designated by [3.2] and [3.2.3] in conformity with the oxidation state of the ruthenium atoms, has been investigated[34] by polarographic and cyclic voltammetric methods and by electrolysis at a controlled potential. The oxidation potentials of the complexes [3.2] and

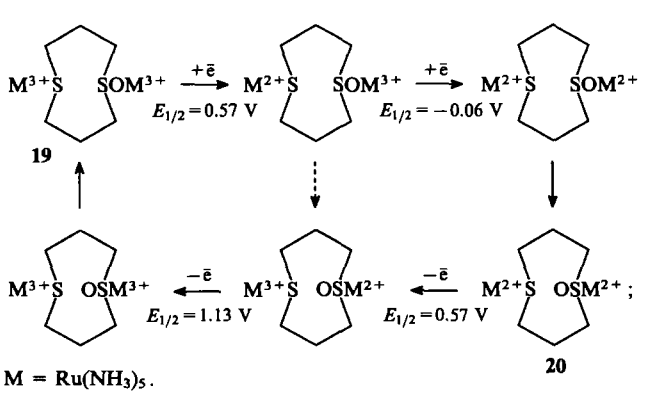
[3.2.3] are similar to the corresponding potentials for $[Ru(bpy)_2(CN)]^{2+}$, while the reduction potentials are virtually identical with the cathodic potentials of the pentammineruthenium(III) complexes. The compound [3.2] undergoes one-electron reversible reduction, while in the reduction of the compound [3.2.3] two consecutive one-electron reversible transitions are observed. These have similar standard potentials and lead to the formation of the complexes [3.2.2] and [2.2.2]. The comproportionation constant, determined electrochemically for the equilibrium

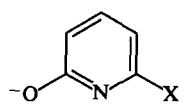
$$[3.2.3]+[2.2.2] \overset{K_{com}}{\rightleftharpoons} 2[3.2.2],$$



is 24, whence it follows that the amount of the complex [3.2.2] in the half-electrolysed [3.2.3] solution is about 70%.

Dinuclear complexes containing complex nitrile bridges as well as their constituent mononuclear fragments have also been investigated by cyclic voltammetry.[119]

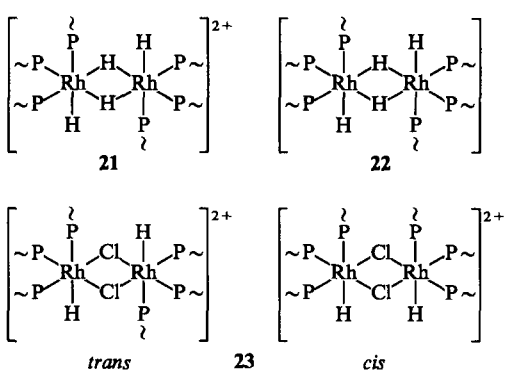
Two reversible one-electron oxidation waves, corresponding to the Ru(II)/ Ru(III) transitions, were observed for the dinuclear complex in which the bridging group is $(CN)_2C=C(CF_3)_2$. When the two rhodium atoms are linked by phthalodinitrile, a single two-electron oxidation wave is observed. The waves observed on reduction of dinuclear complexes of this type are quasi-reversible and correspond to the transfer of one electron to the nitrile ligand. The electron transfer in the dinuclear complex may be accompanied by isomerisation. The redox properties of (1,5-dithiacyclooctane 1-oxide)bis(pentammine)ruthenium(II) **19** may serve as one of the striking examples of such a process.[120] The electrochemical behaviour of the dinuclear system is presented in Scheme 3.



Scheme 3

M = $Ru(NH_3)_5$.

Evidently there are two types of mixed-valence complexes, one of which may be obtained only by the reduction of the stable form **19**, while the other can be obtained only by the oxidation of the stable form **20**.

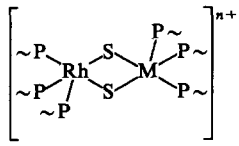


The electrochemical oxidation and reduction of the dinuclear rhodium, manganese, and cobalt complexes containing the methylene bridge has been studied.[121] The oxidation of the dirhodium complexes $Rh_2(hp)_4$, $Rh_2(chp)_4$, and $Rh_2(mhp)_4$ containing substituted *o*-hydroxypyridyl anions as the ligands has been investigated[122] by cyclic and a.c. voltammetry.

hp (X = H)
chp (X = Cl)
mhp (X = Me)

The oxidation potentials of the dirhodium fragment in such complexes depend not only on the nature of the substituent in the pyridine rings of the ligands but also on the solvent. They shift to the more cathodic with increase in the electron-donating strength of the solvent. A correlation has been found[124] between the oxidation potentials of these three complexes and the Taft resonance parameters of the substituents in the pyridine ring. The products of the one-electron oxidation of complexes containing the $[Rh_2]^{4+}$ fragments have been characterised spectroelectrochemically.

It is of interest to compare the electrochemical properties of complexes containing different inorganic bridging ligands. The electrochemical reduction of the dinuclear rhodium complexes $[(triphos)RhH(\mu\text{-}X)_2RhH(triphos)]^{n+}$ [X = H, Cl; *n* = 2, 0; triphos = $MeC(CH_2PPh_2)_3$], containing two hydride or chloride bridges, has been investigated.[123]



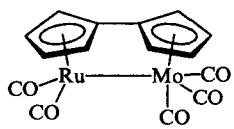
Complex **21** is reduced at the platinum electrode in two reversible one-electron stages:

$$[(triphos)RhH(\mu\text{-}H)_2RhH(triphos)]^{2+} \overset{+\bar{e}}{\underset{-\bar{e}}{\rightleftharpoons}}$$
$$\rightleftharpoons [(triphos)RhH(\mu\text{-}H)_2RhH(triphos)]^{+} \overset{+\bar{e}}{\underset{-\bar{e}}{\rightleftharpoons}}$$
$$\rightleftharpoons [(triphos)RhH(\mu\text{-}H)_2RhH(triphos)] .$$

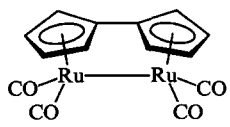
The complete electrochemical reversibility of these redox transitions shows that a significant structural reorganisation does not take place within the limits of the skeleton of the complex. As was to be expected, the oxidation potentials of complex **22** are identical with the potentials of the reduction wave of complex **21**. The presence of chloride bridges in the molecule alters sharply its redox properties and reversible electron transfer becomes impossible. The cyclic voltammogram for complex **23** shows a two-electron reduction peak, while the presence of several small anodic peaks, revealed by reverse scanning, indicates the occurrence of rapid fragmentation reactions accompanying the electron transfer.

Homobinuclear and heterobinuclear complexes having the general formula $[(triphos)Rh(\mu\text{-}S)_2M(triphos)]^{n+}$ (M = Rh, Co, n = 2; M = Pt or Fe, n = 1), and containing sulphide bridges have been investigated.[124]

Two consecutive cathodic processes were observed in all cases, the species formed in each stage being relatively stable:



$$[Rh^{III}, M^{III}] \underset{-\bar{e}}{\overset{+\bar{e}}{\rightleftharpoons}} [Rh^{III}, M^{II}] \underset{-\bar{e}}{\overset{+\bar{e}}{\rightleftharpoons}} [Rh^{II}, M^{II}] .$$

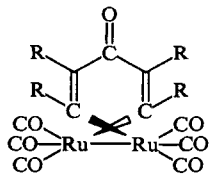


The difference between the potentials of the redox transitions in the two stages makes it possible to calculate[124] the compro-portionation constant:

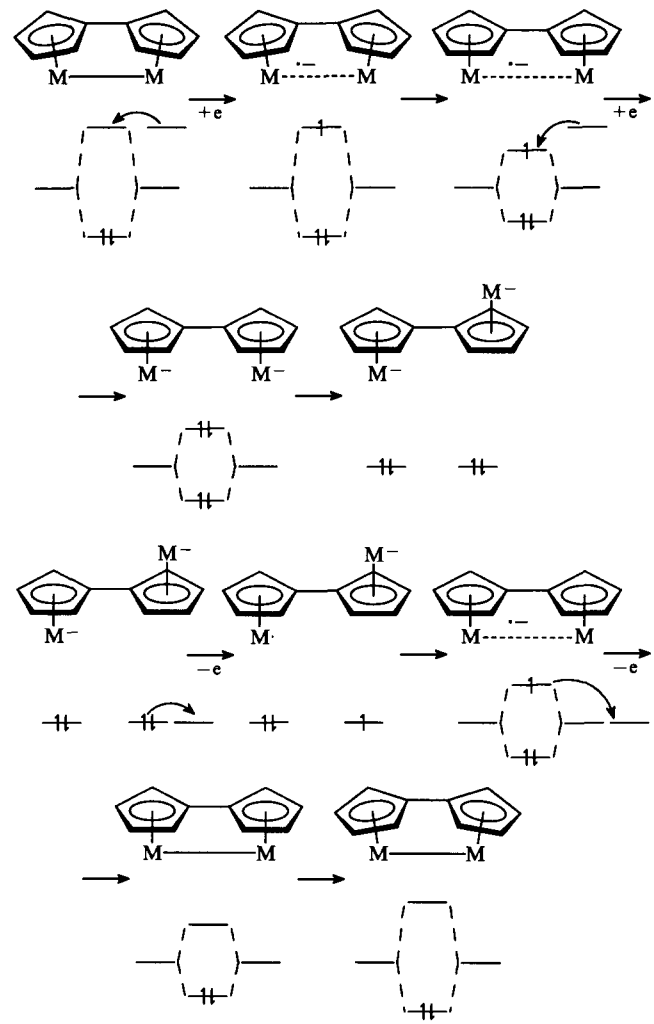
$$[Rh^{III}, M^{III}] + [Rh^{II}, M^{II}] \overset{K_{com}}{\rightleftharpoons} 2[Rh^{III}, M^{II}] .$$

It is equal to 2×10^9 for the dirhodium complex, while in the case where M = Co we have $K_{com} = 3 \times 10^{15}$. The coordination polyhedron of each metal atom does not change and there is only some increase in the distance between the metal atoms in the consecutive reduction stages.[124]

Yet another type of dinuclear complex exists which contains simultaneously both a bridging ligand and a direct metal–metal bond. The bimetallic fulvalene complexes of ruthenium and molybdenum belong to this class.[125]

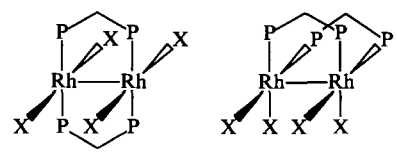


These complexes are oxidised in one two-electron irreversible stage. The irreversibility of the wave can be explained by the reaction of the dication formed with the solvent. The oxidation potentials of these and similar complexes with other metals are between 1.0 and 1.1 V (relative to the normal hydrogen electrode) regardless of the nature of the metals in the complexes. This led to the conclusion that an electron is removed from the orbital localised on the ligand. The reduction of the complexes depends greatly on the nature of the metal. Cyclic voltammetric and coulometric data support the *ece*-mechanism of the reduction process, (i.e. the alternation of stages: electrochemical, chemical, electrochemical — see diagram at the top of the next column).



Presumably the first electron, transferred to the antibonding orbital of the M–M bond, lowers its order; this entails the initial formation of a radical-anion, the steric structure of the species changes, and the latter is reduced more readily than the initial complex.

The electrochemical behaviour of 'flyover-bridged' ruthenium complexes having the structure



R = Alk, Ph.

has been investigated.[126] Both the anodic and cathodic processes take place with participation of one electron. The presence of

ligands having a higher ratio of the σ-donor and π-acceptor properties than CO renders the reduction process thermo-dynamically harder and favours oxidation.

Dirhodium complexes containing the $[Rh_2]^{4+}$ fragments are used widely as catalysts.[111, 112] The electrochemical properties of the complexes $Rh_2Cl_2(OOCMe)_2(dppm)_2$ and $Rh_2Cl_4(dppm)_2$ (dppm = diphenylphosphinomethane) have been investigated. The existence of structures of two types is possible for such complexes:

X = Cl, MeCOO.

Both complexes are oxidised and reduced irreversibly and their potentials E^{Red} and E^{Ox} differ very significantly. The difficulty of obtaining the $[Rh_2^{5+}]$ species, indicated by the oxidation potentials of these compounds (1.47 and 1.44 V respectively), is apparently due to the fact that the diphenylphosphinomethane and chloride ligands stabilise fairly effectively the $[Rh_2^{4+}]$ fragment. The complex $Rh_2Cl_2(dppm)_2(Ph_2PC_6H_4)_2$ is oxidised much more readily (0.86 V relative to Ag/AgCl) than the first two.

The relative ease of the $Rh_2^{4+} \rightarrow Rh_2^{5+}$ oxidative transition for the third complex suggests that $[Rh_2Cl_2(dppm)_2(Ph_2PC_6H_4)_2]^+$ can be readily obtained chemically, which was in fact subsequently achieved using NO^+ as the oxidising agent.[127]

V.	Conclusion	403

Abstract. The review is devoted to the analysis of experimental data on the selectivity of the interaction of nucleic acids with antisense oligonucleotides and their derivatives, which lead to the prospect of achieving a highly selective influence on many biochemical and molecular-genetic processes in living organisms. Theoretical estimates of the level of specificity of the interaction of nucleic acids and the thermodynamic parameters of the formation of perfectly and imperfectly matched complementary complexes are examined in the review. Attention is concentrated on the complementation accuracy of the interaction of DNA and RNA with oligonucleotides and their derivatives in various model systems both *in vitro* and *in vivo*. Data on the specificity of the inhibition of translation with the aid of antisense oligonucleotides in model systems *in vitro* are analysed. The question of the influence of the steric structure of the nucleic acid molecule on the accuracy and efficiency of the interaction with antisense oligonucleotides and their derivatives is discussed. The bibliography includes 247 references.

I. Introduction

The selective interaction between nucleic acids is of cardinal importance in ensuring the occurrence of key life processes. It is sufficient to recall that the specific interaction of complementary nucleic acid sequences constitutes the basis of the double helix DNA structure established by Watson and Crick. The principle of complementarity in fact determines the selective interaction of nucleic acids with antisense RNA, oligonucleotides, and their derivatives. (Such compounds are referred to as antisense on the basis of their ability to form a complementary complex with the selected nucleic acid sequence — the NA target, which is a sense sequence.) All this leads to the prospect of being able to exert a site-specific ('addressed') influence on many key biochemical and molecular-genetic processes occurring with participation of nucleic acids both *in vitro* and in the living cell *in vivo*.[1,2] By virtue of the numerous interesting possibilities of this approach, including specific influence on intracellular processes, as well as the advances in the field of oligonucleotide synthesis, the method of site-specific action, based on the use of antisense oligonucleotides, has attracted increasing attention in recent years.[3–5]

One of the versions of this approach, first formulated at the end of the 1960s, has been called complementarily addressed (site-specific in modern parlance) modification.[6–8] It is based on two processes: in the first, a reactive derivative of the oligonucleotide, complementary to a specific section of the NA target, forms with this section a specific complementary complex and thus directs (addresses) the action of the reactive part of the molecule; in the second, there is a direct chemical reaction (alkylation, photomodification, cleavage) with a nucleic acid base near this section. This approach is regarded nowadays as the most universal method whereby nucleic acids can be highly selectively influenced in order to suppress the development of viral infections and the tumour process induced by mutations in protooncogenes, which are responsible for the malignant degeneracy of the cell.[5,9]

For the wide scale employment of this approach both in research and for therapeutic purposes, it is important that the interaction of the oligonucleotide or its reactive derivative with the NA target should occur with a high selectivity. According to statistics,[1] the sequence of a random 17-unit oligonucleotide is repeated in the human genome only once and one may therefore expect an extremely effective interaction of the NA target with oligonucleotides of this length. However, a fairly extensive set of experimental data, showing that the specificity of the interaction of nucleic acids (the formation of a perfectly matched complementary complex) is low has now accumulated. There is a high probability of the formation of imperfectly matched (containing noncanonical base pairs or loops) or partial (only part of the antisense oligonucleotide is in the complex) complexes with different sections of the NA target. Furthermore, the efficiency of complex formation with an antisense oligonucleotide is influenced enormously by the steric structure and by the accessibility of the selected section for the binding of the NA target. The same problem arises also when oligonucleotides or their derivatives are used for site-specific mutagenesis or as hybridisation probes.

The experimental data on the selectivity of the interaction of nucleic acids which have accumulated hitherto are analysed in the present review. They are examined in order of increase in the complexity of the model system investigated: from perfectly and

imperfectly matched complementary complexes formed by oligonucleotides to the interaction of antisense oligonucleotides with high-molecular-mass nucleic acids in systems *in vitro*. To facilitate the assimilation of such data, the first Section of the review quotes theoretical estimates of the level of selectivity of the interaction of nucleic acids and the second quotes the thermodynamic parameters of the formation of perfectly and imperfectly matched complementary complexes. The section devoted to the interaction of reactive derivatives of oligonucleotides with NA targets is based largely on the results of studies carried out at the Novosibirsk Institute of Bioorganic Chemistry of the Siberian Division of the Russian Academy of Sciences. It should be noted that the present review analyses only those studies concerning the interaction of high-molecular-mass NA targets with oligonucleotides in which the level of accuracy of the interaction of the nucleic acids was estimated or if sufficient experimental data were available to make such an estimate.

II. Theoretical estimates of the specificity of the interaction of nucleic acids

One of the sources of errors in the application of site-specific influences to nucleic acids is the possibility of the formation of imperfectly matched complexes. Theoretical estimates of the level of modification of nucleic acids in imperfectly matched complexes have been carried out.[10-12]

The influence of temperature and the concentration of the reagent (reactive oligonucleotide) on the specificity of the interaction of the oligonucleotide probe and the NA target has been analysed.[10] In order to estimate the contribution of the imperfectly matched complexes, it was suggested that the discrimination parameter (∇), characterising the ratio of the degrees of binding of the reagent in the regular and imperfectly matched complexes, be used to estimate the contribution of imperfectly matched complexes. The final expression for ∇ is as follows:

$$\nabla = \{\alpha - \lg[X]\}\frac{n-n'}{n'},$$

where [X] is the concentration of the reagent and n and n' are the lengths of the perfectly and imperfectly matched duplexes. Hence it follows that the value of ∇, i.e. the discrimination between perfectly and imperfectly matched duplexes, is determined by the length of these duplexes and depends logarithmically on the probe concentration, diminishing significantly with its increase. According to estimates made for oligonucleotide concentrations of 10^{-8} and 10^{-2} M, the parameter ∇ attains the maximum value at a reaction temperature equal to the melting point (T_m) of the perfectly matched duplex.

The ratio r' of the sum of the equilibrium nonspecific binding constants $\sum K_n^i = K_n$ for different types of imperfectly matched complexes [noncanonical pairs ('mismatch'), dangling ends, and 'extra' or projecting bases ('bulge') in the target and the oligonucleotide] to the formation constant of the perfectly matched duplex K_s ($r' = K_n/K_s$) has been estimated[11] with the aid of a statistical approach. The results enabled the authors to reach the following conclusions. The main contribution to K_n comes from complexes with dangling ends. In order to diminish the fraction of such complexes, it is necessary to employ reagents containing G · C pairs at the ends, because the difference between the stabilities of the perfectly and imperfectly matched duplexes, associated with the absence of the terminal G · C pair from the imperfectly matched complex, is 5–6 times greater than that due to the absence of the terminal A · T pair. The fraction of binding into imperfectly matched complexes can be significantly reduced if long oligonucleotides are employed or the condition $K_s x_0 \ll 1$, where x_0 is the oligonucleotide concentration, is maintained. It is noteworthy that all the calculations in the above study[11] were performed subject to certain assumptions. Thus the authors assumed that the terminal noncanonical pairs are fully fused and do not contribute to the stability of the duplex. The numerical changes in the free energy of the duplex associated with the formation of noncanonical pairs, calculated from the data of Aboul-ela et al.,[13] were averages and did not take into account the immediate environment. The degree of destabilisation of the duplex induced by the extra base was determined from experimental data of the same study for the extra cytosine and was assumed to be the same for all the bases. However, the assumptions made by the authors should not alter fundamentally the conclusions reached.

The kinetic aspects of the specificity of the interaction of the addressed reagent and the matrix have been examined[12] and it was shown that the nonspecificity of the interaction of the oligonucleotide reagent and the matrix may be of two types. Firstly, there is the nonspecificity associated with the reaction outside the complex, previously considered in a number of studies.[14-16] Secondly, the nonspecificity is induced by the formation of imperfectly matched complexes. The results of the analysis of the possible level of the nonspecific modification of both types for the 302-membered DNA fragment by reagents of different lengths (6–14 units) showed that the contribution of the nonspecific modification of the second type increases with decrease in the length of the nucleotide part of the reagent. It is noteworthy that the nonspecificity of the modifications of both types depends on the reagent concentration: the specificity of the modification of the NA target falls with increase in the reagent concentration.

III. Thermodynamic parameters of the formation of perfectly and imperfectly matched duplexes and the characteristic features of their steric structure

1. Perfectly matched duplexes

According to modern ideas, the characteristic features of the behaviour of double-helix nucleotide structures in solution are determined by the interactions between the heterocyclic bases, the influence of the solvent, the ionic strength, and the electrostatic interactions of the phosphate groups. In the complementary complex, the change in the state of each nucleotide unit cannot take place independently of the neighbouring units, which is responsible for the cooperative nature of the formation and dissociation of the double helix structures. Thermodynamic data for the DNA duplexes have been examined in detail in a number of reviews.[17-19] Natural RNA produce the right-handed *A* form of the double helix, which differs from the *B* form of DNA by the pitch of the helix in eleven bases (one more than in the *B* form of DNA). The most important differences between DNA and RNA involve the conformation of the nucleotide: in RNA the sugar residue has the C(3′)-*endo*-conformation, whilst in DNA it has the C(2′)-*endo*-conformation. The differences between the sugar conformations lead to the appearance of differences in the distances between the phosphates of the polynucleotide chain: 5.9 Å in the RNA duplexes and 7 Å in the DNA duplexes.[20] The relative stability of the *B* form of the DNA duplexes depends on the sequence of chains forming the duplex or, in other words, the stability of the base pair is determined by its immediate neighbours.[13,21-24] The overall stability and the conditions governing the fusion of any DNA duplex can be predicted on the basis of its primary structure, provided that the parameters ΔG_0, ΔH_0, and ΔS_0 are known for each pair of nearest neighbours[24] (Table 1). The free energy of formation of the perfectly matched duplex (ΔG_0) is determined by the sum of the free energies of formation of the pairs of nearest neighbours (ΔG_x) and can be readily estimated from the data in Table 1 by the formula

$$\Delta G_0 = -(\Delta G_{in} + \Delta G_{sym}) + \sum_x \Delta G_x,$$

Table 1. Thermodynamic parameters of the formation of pairs of nearest neighbours in DNA duplexes[24] (1 M NaCl, 25 °C, pH 7.0).

Pair	$-\Delta H_0$ / kcal mol^{-1}	$-\Delta S_0$ / cal mol^{-1} K^{-1}	$-\Delta G_0$ / kcal mol^{-1}

CG/GC	11.9	27.8	3.6
GC/CG	11.1	26.7	3.1

where ΔG_{in} is the change in the ΔG_0 of formation of the duplex as a result of initiation and ΔG_{sym} is a quantity which explains the difference between the entropies of the duplex formed by a self-complementary sequence and the duplex formed by two complementary sequences; ΔG_{in} = 5 kcal mol^{-1} for the complex originating from the G · C pair and 6 kcal mol^{-1} for the complex originating from the A · U pair; ΔG_{sym} = 0.4 kcal mol^{-1} for the duplex formed by a self-complementary sequence and is zero for the complex formed by two complementary sequences. ΔH_0 and ΔS_0 for the formation of the perfectly matched duplex are determined similarly. The thermodynamic parameters of the formation of a long DNA duplex can be readily determined from the three-dimensional diagram presented in a review.[19]

Table 2 lists the thermodynamic parameters of the formation of the G · C or A · U pairs in RNA duplexes obtained by the method of nearest neighbours.[25-28] The thermodynamic parameters of the formation of each duplex are determined in the same way as for the DNA duplexes.[24]

The most characteristic feature of the secondary structure of RNA is the formation of hairpins. The groups at the ends of the hairpin usually comprise 4–6 bases and stabilise the entire hairpin. The quantity $\Delta\Delta G_0$ depends to a large extent on the sequence of bases in the loop and on the base pair closing the loop, varying from −3 to 1.5 kcal mol^{-1}.[29-33] Under these conditions, all the bases even in the short groups (3–5 nucleotides) are stacked together with the ribose ring and each ribose residue has the N conformation, which enables the nucleotide to stretch to the maximum length.[20,30] In the general case, the loops formed by deoxyribooligonucleotides stabilise the entire hairpin to a somewhat lesser extent, but the dependence of the stabilising effects on the base sequence in the loop is retained.[32,33]

The only form in which the double helix RNA exists is the *A* conformation. Depending on the conditions in their formation and the sequence, DNA duplexes can exist in the form of the *A* and *B* conformations or the left-handed *Z* conformation. According to a number of data,[18,19,34-37] the *A* form of the helix is more characteristic of the RNA–DNA duplex, although under certain conditions and depending on the sequence, other conformations can also occur. A comparative analysis of the thermodynamics and kinetics of the formation of hybrid duplexes has been carried out.[18,35,37-41] On the basis of the analysis of the fusion curves and NMR spectroscopic data, the following stability series has been established for RNA–DNA duplexes: $dA_5 \cdot dT_5 > rA_5 \cdot dT_5 > rA_5 \cdot rU_5 > dA_5 \cdot rU_5$ (T_m = 27.5, 22.9, 19.1, and 0 °C respectively).[35] It is noteworthy that very few data are available on the stabilities of the RNA–DNA duplexes and they are contradictory. For the majority of the duplexes investigated, it has been found that the hybrid duplexes are less stable than the corresponding RNA or DNA duplexes.[42] Evidently the stability of the hybrid duplexes, like that of deoxyribo- and ribo-analogues, is determined by their primary structure.

Table 2. Thermodynamic parameters of the formation of pairs of nearest neighbours in RNA duplexes[28] (1 M NaCl, 25 °C, pH 7.0).

2. Imperfectly matched nucleic acid duplexes

Interest in imperfectly matched nucleic acid duplexes arose initially apparently in the course of the study of the mechanisms of the transmission of kinetic information. In replication, transcription, or reverse transcription, the accuracy of the transmission of genetic information is ensured by the complementary interactions of nucleic acids, but this entails also the inclusion of error bases.[43,44] On the other hand, complexes of this type are formed in codon–anticodon interactions on formation of the steric structure of RNA (G · A and G · U pairs). The formation of imperfectly matched duplexes is widely used in the technique of site-specific mutagenesis.

a. Duplexes with dangling bases at the ends

Terminal unpaired bases, adjoining a long double helix (core), are a characteristic element of the secondary structure of RNA and are involved in many biological processes. The addition of an unpaired base at the 3′- and 5′-end of the RNA duplex stabilises the core duplex as a result of the stacking interaction of the dangling base with the last complementary pair of the duplex. The paired base at the 3′-end of the RNA duplex stabilises the duplex to a greater extent under these conditions than the 'dangling' 5′-end; the difference between the melting points of such duplexes is 8 °C at an oligonucleotide concentration of 10^{-4} M. The addition of a 3′-terminal unpaired base is comparable to the addition of the A · U pair. The stabilising effect of the noncomplementary bases at the ends of the RNA duplex diminishes in the sequence[45,46] 3′-A > 3′-U > 5′-A ≃ 5′-U. Similar results were obtained in the study of the influence of unpaired bases at the ends on the stability of the core duplexes[28,47] GGCC/GGCC, CCGG/CCGG, and CGCG/CGCG. The stabilising effect of unpaired terminal bases increased in the sequence 3′-C < 3′-U < 3′-G ≃ 3′-A and the increase in the free energy of the duplex as a result of the stabilising effect of the unpaired bases at the ends was then 10%–20%, 30%–70%, and 60%–95% of the increase in ΔG_0 due to the formation of the corresponding complementary pair. On average, the 5′- and 3′-noncomplementary bases contribute −0.2 and −(0.4–1.8) kcal mol^{-1} to the ΔG_0 of formation of an RNA duplex.[48,49]

The influence of the unpaired terminal base on the stability of the core DNA duplex is the opposite of the influence of the dangling base on the RNA duplex: the DNA duplexes are stabilised to a greater extent by the unpaired base at the 5′-end.[50,52] A study of the structure and thermodynamic features of the behaviour of the core duplexes containing unpaired thymidine residues at the 5′- and 3′-ends showed that the addition of a dangling 5′- or 3′-thymidine to the core duplex increases the T_m of the duplex. The 5′-terminal thymidine exerts a greater stabilising effect: T_m = 8.3–9.3 °C and 5.0–3.0 °C for the unpaired 5′- and 3′-thymidine residues respectively. Analysis of the circular dichroism (CD) spectra of the core duplexes and their derivatives with unpaired thymidine residues at the 3′- or 5′-ends

showed that the entire duplex, including the dangling end, is in the *B* conformation whilst the unpaired base is in a stack with the core duplex.[52]

b. Duplexes with extra (bulging) bases

The inner loop, consisting of a single base, or the extra (bulging) base are frequently encountered elements of the secondary structure of DNA and RNA. The special interest in projecting bases is associated with the fact that in DNA such a base is a 'hot' spot for mutations, whilst in RNA an extra adenosine frequently appears at the protein binding sites. The main question concerning this element of the secondary structure is whether the extra base belongs to the double helix or whether it forms an inner loop and is displaced from the stack.

The extra adenine in the duplex **1** is involved in a stacking interaction with neighbouring cytidine and guanine residues and does not form an inner loop. The conformation of the complementary pairs on either side of the projecting base is not altered, but the phosphodiester linkage opposite the extra adenine is somewhat lengthened, which leads to the loosening of the structure of the duplex and to a slight change in the torsional angles of the phosphodiester linkage. The melting point of the duplex with bulging adenine is lower by 19 °C than T_m for the perfectly matched duplex, but the fusion of such a duplex takes place cooperatively, including the bulging adenine.[53,54]

$^{5'}$CGC^{A}GAATTCGCG$^{3'}$ / $_{3'}$GCG–CTTAAGCGC$_{5'}$ **1**

$^{5'}$CAAA^{C}AAAG$^{3'}$ / $_{3'}$GTTT–TTTC$_{5'}$ **2**

The activation energy for the formation of the duplex **1** ($E_{act\text{-}A}$) is appreciably higher than the activation energy for the formation of the perfectly matched complex.[55] Whereas the rate-limiting stage in the formation of the perfectly matched duplexes is the formation of the nucleation core,[35] in the duplex with projecting adenine complex formation is inhibited at a defective section of the structure,[55] which leads to an appreciable increase in the activation energy and a broadening of the temperature range in which duplex **1** fuses.

The NMR spectra of nonexchanging protons and the nuclear Overhauser effect (NOE) spectra of the imino-protons of the bases, located on either side of the extra cytidine in duplex **2**, led to the conclusion that such cytidine is outside the helix and that the conformation of the A · T pair adjoining it is greatly modified. Duplex **2** is highly destabilised compared with the perfectly matched complex (T_m for duplex **2** is lower by 15 °C than T_m for the perfectly matched complex and $\Delta\Delta G$ = 2.9 kcal mol^{-1}). The decrease in the stability of the duplex has an enthalpy origin and is a consequence of the breakdown of the stacking interactions in this duplex.[56] At a low temperature (about 0 °C), the projecting cytidine is outside the duplex and, on raising the temperature (>40 °C), the fraction of conformations in which the extra cytidine forms part of the helix increases.[57]

The extra adenine and guanine adjoining the G · C pair (duplexes **A** and **G**) participate in the stacking interactions with the adjoining bases and are clearly part of the double helix (Scheme 1).

Scheme 1

$^{5'}$GATGGGCAG$^{3'}$ / $_{3'}$CTACCCGTC$_{5'}$ **N**

$^{5'}$GAT–GGGCAG$^{3'}$ / $_{3'}$CTA$_{C}$CCCGTC$_{5'}$ **C**

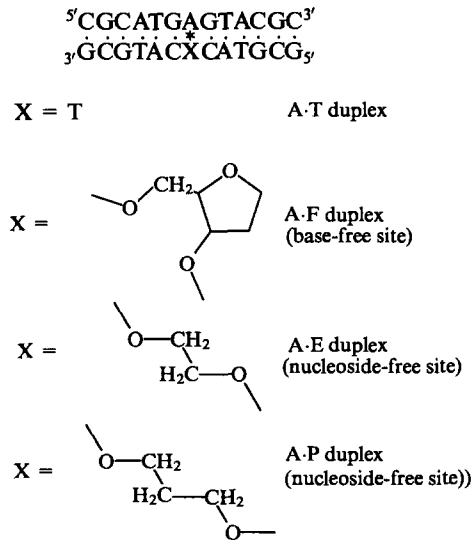
^{5}GAT–GGGCAG$^{3'}$ / $_{3'}$CTA$_{A}$CCCGTC$_{5'}$ **A**

$^{5'}$GAT–GGGCAG$^{3'}$ / $_{3'}$CTA$_{G}$CCCGTC$_{5'}$ **G**

The destabilising effect of these bases is strictly localised and does not extend over the entire duplex. The bulging cytidine is in the $C_{(4)}$ backbone of duplex **C** and is, as it were, delocalised over the $C_{(4)}$ sequence. This decreases the destabilising effect of the extra cytidine on the double helix; T_m for duplex **C** is higher by 5.7 °C than for duplex **A** or **G**.[58,59] Comparison of the structures of ribo- and deoxyribo-duplexes containing bulging uridine or thymidine (duplexes **3** and **4**) showed that the bulging thymidine in **4** is built into the double helix without causing any appreciable distortions in the *B* form of DNA, while the extra uridine in duplex **3**, having the same composition, is outside the helix. The regular structure of the *A* form of RNA is also unaffected under these conditions.[60,61]

$^{5'}$r(CUGG^{U}GCGC)$^{3'}$ / $_{3'}$(GACC–CGCG)r$_{5'}$ **3**

$^{5'}$d(CTGG^{T}GCGC)$^{3'}$ / $_{3'}$(GACC–CGCG)d$_{5'}$ **4**



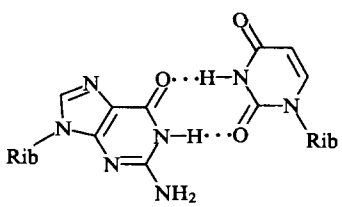
There are comparatively few experimental data concerning the influence of the projecting base on the structure and stability of RNA duplexes. The study of the thermodynamic behaviour of 14 synthetic ribooligonucleotides, assuming in solution the hairpin shape with four bases in the loop and one projecting base in the stem, showed that the introduction of the extra base into the double helix region destabilises the duplex. The magnitude of the effect is determined by the type of base: the greatest destabilising effect is shown by the extra adenine and guanine ($\Delta\Delta G_A^{37\,°C}$ = 3.3 kcal mol^{-1} and $\Delta\Delta G_G^{37\,°C}$ = 3.5 kcal mol^{-1}) and the smallest is exerted by the extra uridine ($\Delta\Delta G_U^{37\,°C}$ = 2.7 kcal mol^{-1}).[31]

c. Duplexes with point breaks

Point breaks as well as nonpurine and nonpyrimidine sites are frequently encountered in the DNA structure. However, comparatively few data have accumulated at the present time concerning the influence of such damage to DNA on the structure and stability of the DNA duplexes. Similar data on RNA duplexes are altogether lacking. Four 12-unit duplexes of identical composition with a point break have been investigated by NMR and NOE spectroscopy. It was found that they all have a helix in the *B* form and differ slightly in stability from the perfectly matched duplex. Fusion of the duplex with a point break takes place cooperatively. Apparently the point break does not alter appreciably either the stability or the structure of these DNA duplexes.[62] Somewhat different results for the influence of point breaks on the stability of a DNA duplex have been obtained in another study.[63] The introduction of a point break into the ring structure diminishes T_m for such a duplex by 27 °C (1 M NaCl).

The introduction of a base-free site into the structure of the duplex lowers the melting point of the duplex by 10–12 °C compared with the perfectly matched duplex. The destabilisation of the duplex by a 'hole' is comparable to the effect of the introduction into the duplex of a T · T pair (T_m = 66, 53–56, and 56 °C for the perfectly matched 13-unit duplex, the duplex with a nonpyrimidine site in the 7-position, and the duplex with a T · T pair in the 7-position respectively.[64] The influence of the base-free site and the nucleoside-free site on the structure of the DNA duplex has been investigated in greatest detail[65] in relation to the duplex having the composition shown in the next column.

The changes in all the thermodynamic parameters induced by the damage to the duplex resulting from the formation of a 'hole' are very great (ΔT_m = 13.9, 12.9, and 14.4 °C for the duplexes A · F, A · E, and A · P respectively) and greatly exceed the values predicted for such duplexes by the nearest neighbours method. The results show that these changes in the stability of the duplex are associated with the absence of a base and not the absence of a sugar residue. The cooperative nature of the helix–coil transition hardly changes on passing from the duplex A · T to the duplexes A · F and A · E. This suggests[57,65] that the sugar phosphate skeleton of the DNA molecule is in fact responsible for the cooperative nature of the helix–coil transition on fusion.



The data presented permit the conclusion that, although the introduction of a point break lowers the stability of the DNA duplex, it does not affect its structure, whereas nonpurine and nonpyrimidine sites lead to appreciable changes in the structure of the duplex as a result of the disturbance of the stacking interactions in the double helix.

d. Duplexes containing noncanonical base pairs

Noncanonical or irregular base pairs are very often encountered in the molecules of both RNA and DNA. All noncanonical pairs can either form an inner loop made up of two bases, or can participate in the stacking interactions of the double helix, or can form a noncanonical ('wobble') pair. In analysing any noncanonical pair, it is essential to answer the following questions: (1) what structural changes are introduced by the given irregular pair into the conformation of the duplex; (2) what thermodynamic and kinetic parameters of the formation of the duplex are altered under the influence of the given noncanonical pair; (3) in what way are hydrogen bonds formed in the given noncanonical pair. All these questions have been examined in detail in a review.[18] This section presents data concerning only the influence of noncanonical pairs on the stability of RNA and DNA duplexes.

The G · U or G · T pair. The G · U pair is one of the most thoroughly investigated, most frequently encountered, and most stable of the irregular pairs. The formation of hydrogen bonds in the G · U pair, put forward by Watson and Crick, is illustrated in the scheme below:

G · U

X-Ray diffraction analysis of an 8-unit duplex with two central G · T pairs as well as NMR spectroscopy of poly(dGT) [the appearance in the spectra of two signals in the region of 11 p.p.m. (resonance of the >N–H...O = C< hydrogen bond) and two signals in the region of 8 ± 0.5 p.p.m. (-resonance of the free NH_2 group)] yielded rigorous experimental evidence showing that the bases in the G · T and G · U pairs in long DNA or RNA duplexes are paired and built into the double helix.[22, 23, 54, 66–69]

The G · T pairs exert extremely little influence on the overall structure of the duplex and hardly disturb the stacking interactions in it. On formation of such a pair, small changes occur only in the torsional angle of the *N*-glycoside component of uridine, which is the main reason for the destabilisation of duplexes with G · U pairs compared with perfectly matched duplexes.[66, 70] Comparison of three 8-unit duplexes,[71] containing two G · T, two G · C, or two A · T pairs in the 3- and 4-positions, showed that both G · T pairs participate in the formation of the double helix, but the rotation of the helix at the G · T pair is by 44.3° (instead of 31.5° for the classical pair), while at the G · C pair, which follows G · T, the rotation is by only 22°.

The melting point of the 8-unit duplex with two G · T pairs in the centre is lower by 20 °C than T_m for the perfectly matched duplex (52 and 72 °C respectively), while $\Delta\Delta G_0 = 2-3$ kcal mol^{-1}.[66, 71] Similar results have been obtained in the X-ray diffraction analysis of an 8-unit duplex containing two I · T pairs in the centre.[72] It was found that a thermodynamically more favourable situation arises if the two G · T pairs follow one another and are not separated by classical pairs. The degree of destabilisation of the duplex ($\Delta\Delta G_0$) is in this case 1 kcal mol^{-1} per G · T pair.[71]

The rate of exchange of the protons of the G · T pairs[22, 23] in the 3- and 10-positions in a 12-unit duplex at 35 °C exceeds (approximately by an order of magnitude) the rate of exchange of the protons of the G · C pairs in the same positions in the duplex, which indicates a looser structure of the G · T pair, more accessible to the solvent, compared with the G · C pair. Data confirming the formation of the looser structure in duplexes with G · T pairs have also been obtained in other studies.[67, 68]

Comparison of the thermodynamic parameters of the formation of 16 duplexes containing an inner G · U or A · U pair revealed that the G · U pair stabilises the duplex (compared with the loop at this site) and that its contribution to ΔG_0 of formation of the duplex depends on the immediate environment.[73] If the G · U pair adjoins an A · U pair, then the increase in the free energy of the duplex is $-(0.5-0.7)$ kcal mol^{-1}, but, when it adjoins a G · C pair, then $\Delta G_0(G \cdot U) \simeq \Delta G_0(A \cdot U) = -(1.3-1.9)$ kcal mol^{-1}. On average, the inner G · U pair is less stable to the extent of 0.7 kcal mol^{-1} than the A · U pair.[48, 70, 73] The greater stability of the G · U pair with a G · C pair on its side, compared with the G · U pair adjoining an A · U pair, can be explained by more effective stacking interactions of the G · U and G · C pairs compared with the G · U and A · U pairs. Comparison of the ribo-duplexes containing a central G · U, G · C, or A · U pair showed that the T_m of the duplex with a G · U pair is approximately equal to the T_m of the duplex shortened by one unit. The G · U pair itself is a site of instability in the double helix.[74]

The G · A pair. This 'wobble' pair is of special interest, because it is the usual element forming the steric structure of RNA.[75] At neutral pH, one can postulate four different versions of the formation of hydrogen bonds in the G · A pair (Fig. 1).[75, 76] It is noteworthy that the conformation *a* has been predicted and detected in the RNA double helix,[75] while the conformation *b* has been confirmed experimentally in a study of model DNA duplexes.[77, 78] Until recently, there was no experimental confirmation of the existence of the conformations *c* and *d* for the G · A pair. In the conformations *a* and *b*, there is a characteristic propeller-like disposition of the bases relative to one another (the angle of rotation is 24.8°), which facilitates the formation of hydrogen bonds between guanine and adenine.[77, 79] The G · A pair fits satisfactorily into the double helix of the *B* form, causing virtually no disturbance to the stacking interactions in the duplex, while the changes in the torsional angles of the bases are within the limits characteristic of canonical base pairs.[77, 80, 81] The destabilising effect of the G · A pair is manifested by a decrease in the T_m of the duplex by 10 °C per G · A pair compared with the perfectly matched duplex. The perturbations introduced by the G · A pairs are local in character and are not propagated along the helix.[13, 77]

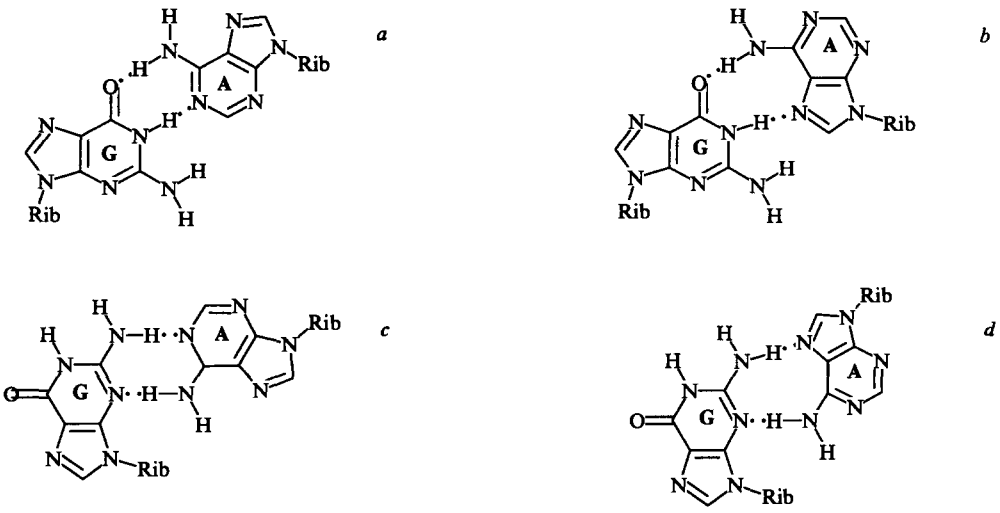


Figure 1. Four versions of the formation of hydrogen bonds in the G · A pair.

Comparative study of 13 dodecamers, differing in the number of G · A pairs, their positions, and their environments, revealed the influence of the nearest neighbours on the stability of the imperfectly matched duplex with such noncanonical pairs. It was found that the most stable sequences, containing two adjoining G · A pairs, have thermodynamic parameters of formation approximately equal to the parameters of formation of the perfectly matched duplex. However, the same sequences with a single G · A pair are appreciably destabilised compared with the perfectly matched duplex.[82,83]

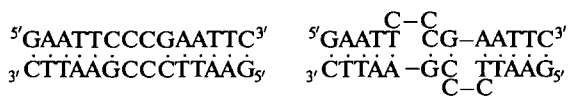
In a comparatively recent study of a 10-unit duplex formed by the oligonucleotide d(ATGAGCGAATA), containing four G · A pairs and a noncomplementary adenine unit at the 3'-end, direct evidence was obtained for the existence of the conformation *d* of the G · A pair. This duplex produced the *B* form of the double helix and was distinguished by an anomalously high stability, approximately equal to the stability of the perfectly matched complex, which was explained by the very effective stacking interactions between the bases of the opposite chains (G_3 with G_7 and A_4 with A_8).[84] The study of the contribution of the hydrogen bonds formed within the G · A pairs to the stability of the RNA duplexes (not less than -1.4 kcal mol^{-1} per pair) makes it possible to explain this anomalously high stability of the imperfectly matched duplex with G · A pairs.[83]

The A · A pair. The A · A pair does not form stable hydrogen bonds. The incorporation of the d(A · A) pair in the double helix takes place as a result of the stacking of adenine units with neighbouring bases and is accompanied by the distortion of the planar structure of the heterocyclic base, in order to decrease the overlap of the exocyclic amino-groups of the adenine units, and by appreciable rearrangements of the sugar phosphate skeleton of the duplex.[85]

The G · G pair. Indirect evidence for the existence of this pair has been obtained in a number of studies,[86-88] but the existence of this wobble pair in a duplex was first demonstrated by Cognet et al.[89] According to two-dimensional NMR data, the bases of this pair participate effectively in the stacking interactions of the double helix and the double helix itself has the classical *B* form. The imino-protons of the bases participate in the formation of the hydrogen bond of the G · G pair; one of the guanine units assumes the normal *anti*-conformation, whilst the other assumes the *syn*-conformation or one close to it. Such a pair has a symmetrical structure and does not introduce perturbations into the regular structure of the *B* form of DNA. There are no data on the thermodynamic stability of duplexes with G · G pairs.

Purine–purine pairs cause a marked destabilisation of the double helix. Comparison of the thermal stabilities of oligomer-polymer duplexes having the structures $dG_ndG_{12}A_mC_x$ and $dG_ndG_{10}G_mC_x$ (n = 100, m = 0–6, x = 5–41) with different numbers of d(A · G) and d(G · G) pairs showed that the destabilisation of the duplex is proportional to the number of noncanonical pairs.[87] The presence of a cluster of noncanonical G · A or G · G pairs does not, however, affect the cooperative nature of the fusion of the duplex, which constitutes additional confirmation that the irregular purine–purine pairs are built into the regular double helix. Long DNA duplexes, containing one noncanonical pair, are resistant to the action of S1 nuclease. The increase in the length of the section with noncanonical pairs from 2 to 6 bases increases the sensitivity of the duplex to S1 nuclease: the duplex is cleaved by S1 nuclease under identical conditions to the extent of 4% and 30% for duplexes with one and six G · G pairs respectively.[87]

The influence of nearest neighbours on the destabilising effect of the purine–purine noncanonical pair has been investigated.[70,74,82] According to NMR spectroscopic data, 5-unit duplexes are not formed if the G · A or G · G pairs are flanked by A · U pairs, whereas duplexes in which the G · A or G · G pairs are flanked by G · C pairs are fairly stable (T_m = 26 °C). Data confirming the marked dependence of the stability of the duplex with purine–purine pairs on its base sequence have also been published.[82,84,87,90]



The A · C pair. According to literature data,[77,91] the A · C pair is stabilised by one hydrogen bond between the N(6) protons of the amino-group of adenine and the N(3) or O(2) protons of cytidine, but the possibility of the formation of an A · C pair, stabilised by two hydrogen bonds in the case of adenine in the tautomeric form, is not ruled out. The rate of exchange of the imino-protons in the G · C and A · T pairs adjoining a noncanonical A · C pair in a duplex with two A · C pairs increases compared with the perfectly matched duplex by factors of 3 and 2 respectively. Consequently the destabilising influence of the A · C pair is not localised and is propagated along the double helix.[91] The incorporation of an A · C pair in a DNA duplex is accompanied by small changes in the sugar phosphate skeleton of the duplex, ensuring the occurrence of stacking interactions between the A · C pair and the adjoining bases.[92] The introduction of an A · C pair into the centre of a 17-unit duplex lowers its melting point compared with the perfectly matched duplex by 10 °C. The stability of the duplexes containing noncanonical pairs diminishes in the sequence[93] G · C > A · T > G · U > A · C. Comparative analysis of data on the hybridisation of 11-, 14-, and 17-unit oligonucleotides with the DNA of the phage φX 174 and with the

DNA of a mutant phage in which a point exchange of G · A has taken place at the oligonucleotide binding site demonstrated that all three probes are bound much more weakly with the mutant DNA. The introduction of one A · C pair into the duplex lowers the dissociation temperature of these probes by 12 °C, which corresponds to the 'loss' of approximately three G · C pairs.[94]

The U · U pair. The existence of the U · U pair has not been demonstrated experimentally. The five-membered self-complementary oligonucleotide AGUCU exists preferentially in the single-stranded form. The U · U pair in the centre of the duplex leads to its complete destabilisation, while the duplex with the G · C pair at the same site has[74] a melting point of 25 °C.

The T · T pair. According to NMR data, the T · T pair is not stabilised by a hydrogen bond,[13] but it can be built into the double helix under these conditions with minimum disturbances to the structure of the duplex and leads to a decrease in its T_m compared with the perfectly matched 12-unit duplex by 11 °C. This pair forms a locally unstable section in which the dissociation of the duplex is initiated on raising the temperature simultaneously with a process occurring from the end of the duplex.[51,95] The T · T pair destabilises the duplex to the greatest extent[13,85] if it is incorporated in the ATA/TTT sequence, exerting the least effect in the CTG/GTC sequence.

The C · C pair. There is at present no experimental evidence in the literature for the formation of hydrogen bonds between the bases of the C · C pair. The absence of hydrogen bonds stabilising the C · C pair as well as the poor overlap (stacking) of the unpaired cytosine with the adjoining bases of the duplex lead to the bulging of the C · C pair with formation of an inner loop.[70,74] It has been shown[96] that duplex **5** exists not in the form of a hairpin with an inner loop comprising four cytidine units but has the structure **6** with bulging cytidine units. Such rearrangement of the duplex is accompanied by a change in the sugar phosphate skeleton only in the looped out nucleotide, whereas the entire remainder of the duplex has the *B* form of DNA.

5 **6**

The appearance of the C · C pair in the duplex causes an appreciable increase in the enthalpy of formation of the duplex: $\Delta H_0 = -77$ kcal mol^{-1} for $[(Ap)_3A(pU)_4]_2$ and $\Delta H_0 = -43$ kcal mol^{-1} for $[(Ap)_4C(pU)_4]_2$, and reduces its melting point by 10–17 °C, which corresponds to the loss of two A · U pairs.[97]

In the study of the crystal structure of the dodecameric RNA duplex containing three noncanonical pairs in the centre, it was observed that four noncomplementary bases do not form an inner loop, giving rise to a fairly regular helix incorporating the G · U and U · C pairs.[98] These results are the first experimental evidence for the existence of the U · C pair in the crystal. This pair forms one hydrogen bond and is stabilised by hydrogen bonds with water molecules, forming bridges between the nitrogen atom of the heterocyclic base and the oxygen atom attached to phosphorus. The authors mention particularly the influence of the hydrogen bonds between the OH groups of ribose, the oxygen atoms at the phosphorus, and the water molecules on the stabilisation of the duplex structure.[98]

3. Comparative analysis of the influence of noncanonical base pairs on the stability of DNA and RNA duplexes

It is quite evident that the less the stability of an imperfectly matched complex, formed fortuitously by an oligonucleotide and the NA target, differs from the stability of the perfectly matched duplex, the higher the level of their nonspecific interaction. Comparison of the destabilising influence of various structural anomalies (noncanonical pairs, projecting bases, dangling ends) in order to discover those which destabilise the duplex to the least extent is therefore extremely urgently required. An extensive set of experimental data, including also the thermodynamic parameters of the formation of imperfectly matched complexes with structural anomalies, has now accumulated, but these data are somewhat heterogeneous and do not permit unambiguous conclusions about the degree of the destabilising influence of each separate noncanonical base pair or some other structural anomaly in the duplex.[13,18] It is noteworthy that the destabilising influence of each structural anomaly depends also on the environment in which it is located i.e. on the nearest neighbours.[13,84,89] Thus the core component of the duplex usually remained unchanged in studies where the relative stabilities of different noncanonical pairs were estimated. This was the reason for the considerable discrepancies between the estimates of the stability of noncanonical base pairs obtained by different workers:[13,23,99]

T · G > G · G = G · A > G · T > A · G = C · T >
T · C = A · A = T · T > C · A > C · C > A · C;[13]
G · T = T · G > A · G > T · T = C · T > G · A = G · G >
T · C > A · A > A · C > C · A > C · C;[99]
G · T > G · A > A · A = T · T = C · A > C · T.[23]

Noncanonical base pairs are arranged in order of decreasing stability.

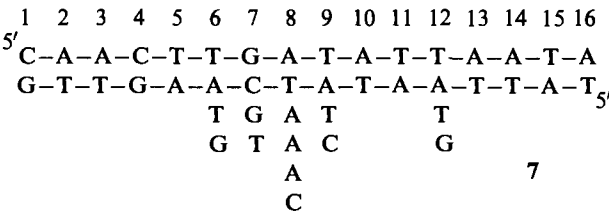
Considerable discrepancies are observed not only in the estimates of the relative stabilities of various noncanonical base pairs but also in the absolute differences between the thermodynamic parameters for perfectly and imperfectly matched complexes incorporating the same noncanonical pair. Thus, the destabilising influence of the A · C pair with a constant environment can be determined from the results of different studies:[13,100] $\Delta\Delta G_0$(A · C) = 2.7 kcal mol^{-1} (Ref. 100) and 3.5 kcal mol^{-1} (Ref. 13). However, such a difference between the destabilising effect of the given noncanonical base pair cannot be accounted for by the differences either between the experimental conditions or between the lengths of the duplexes investigated.

The destabilising effect of different noncanonical bases on the stability of core duplexes has been studied in greatest detail in several investigations.[13,56,99,100] Corresponding parameters for the destabilisation of the duplex owing to the formation of noncanonical pairs as a function of nearest neighbours have been determined experimentally.[13] These data are presented in Table 3.

The influence of all possible noncanonical pairs on the thermodynamics of the formation of a 17-unit DNA duplex (with mismatches located within the centre of the duplex) has been investigated.[99] On the basis of the analysis of the ΔH_0 and ΔS_0 for a noncanonical base pair, i.e. the parameters which describe the stacking interactions of the given pair with the adjoining bases, the authors classified different mismatches in terms of their involvement in the formation of the duplex: (1) Wobble pairs or irregular pairs stabilised by hydrogen bonds. These are characterised by a strong stacking interaction with the adjoining bases. Such pairs do not disturb either the overall stacking of the duplex or the conformations of the sugar phosphate residue; the entropy of formation of the wobble pair is approximately equal to the entropy of the Watson–Crick pair, while the enthalpy of formation is somewhat lower. The T · G, G · G, C · A, A · A, and A · G pairs belong to the class of wobble pairs. (2) Open pairs, i.e. pairs which do not form hydrogen bonds but are involved in the stacking interaction with

Table 3. Destabilisation of the double helix by the formation of noncanonical base pairs.[13]

Base pairs	ΔG_0 kcal mol^{-1}	ΔH_0 kcal mol^{-1}	ΔS_0 cal mol^{-1} K^{-1}
A–T–A / T–G–T	0	−8.1	−27
A–G–A / T–G–T	0.2	−6.0	−20
A–G–A / T–A–T	0.3	−5.1	−18
A–G–A / T–T–T	0.7	0.8	1
A–A–A / T–G–T	1.2	7.6	22
A–C–A / T–T–T	1.2	−5.7	−23
A–T–A / T–C–T	1.5	−2.5	−13
A–A–A / T–A–T	1.5	10.6	31
A–T–A / T–T–T	1.5	−7.1	29
A–C–A / T–A–T	1.9	7.2	38
A–C–A / T–C–T	2.0	−7.8	−33



the bases of the chain. Such pairs introduce the greatest perturbation and destabilise the duplex. (3) Weak pairs linked by only one hydrogen bond; the stacking interaction is unlikely in this instance. The enthalpy of formation of a weak pair is approximately equal to half the enthalpy of formation of a wobble pair.

It is noteworthy that the melting points of the duplexes differing only in the orientation of the irregular pair are not the same although the environment of these pairs and hence the interplanar contacts do not change. Data obtained recently indicate the extremely anomalous influence of adjacent inverted G · A pairs on the stability of DNA duplexes.[82,84] The replacement of two canonical pairs in the decameric duplex by two isolated G · A pairs lowers the association constant by a factor of $10^3-4\times10^5$. Four inverted G · A pairs arranged in pairs destabilise the duplex by a factor of 4.5, but, in the presence of the same number of G · C pairs in this duplex as in the perfectly matched complex, an anomalously stable duplex is produced (the association constant increases by a factor of 5–40). Similar data have been obtained[90] also for ribo-duplexes containing a G · A pair.

The influence of the location of the noncanonical pairs on the stability of duplex **7**, which is a fragment of the DNA of the bacteriophage φX 174 and is the binding site of the gene A protein, has been investigated.[100] Duplexes containing noncanonical pairs fuse at a lower temperature than the perfectly matched duplex **7**. The destabilisation of the duplex is greater when the irregular pair substitutes a G · C not a A · T pair and also if the noncanonical pair is located closer to the centre of the duplex (cf. the duplexes 8-AA and 12TG in Scheme 2).

Three probable structures were analysed for all the duplexes in Scheme 2: (1) the formation of inner loops. This process should be accompanied by the loss of the stacking interaction of two base pairs, an appreciable increase in ΔH_0, and a change in the free energy of the duplex ($\Delta\Delta G_0$) in the range 5.5–7.0 kcal mol^{-1}. (2) The formation of a structure with bulging bases. This should be accompanied by the elimination from the stacking interaction of one base pair and should involve $\Delta\Delta G_0$ = 7.0 kcal mol^{-1}. (3) The formation of a noncanonical base pair. This process is characterised by the retention or slight alteration of the values of ΔH_0 and low values of $\Delta\Delta G_0$. According to the thermodynamic parameters presented above, these duplexes, illustrated in the scheme, form noncanonical pairs and not any other structures.

Scheme 2

Duplex	T_m °C	$-\Delta G_0$ kcal mol^{-1}	$\Delta\Delta G_0$ kcal mol^{-1}
7	52.0	15.8	–
6-TG	45.1	13.2	2.6
7-GT	42.9	12.7	3.1
8-AA	42.1	12.6	3.2
8-AC	40.6	12.1	3.7
9-TC	43.0	13.1	2.7
12-TG	46.9	14.0	1.8

The influence of the terminal noncanonical pair on the stability of the duplex has been studied only for oligoribo-nucleotide duplexes.[49,101] The free energy increment following the addition of the terminal noncanonical pair to the core duplex was on average −0.5 to −2.3 kcal mol^{-1} depending on the form of the noncanonical pair and the last base of the core duplex: $\Delta\Delta G_0$(G · U) ≃ $\Delta\Delta G_0$(A · U) ≃ −1.3 kcal mol^{-1}; the addition of a pyrimidine–pyrimidine or purine–pyrimidine pair (but not G · U) increased the stability of the duplex by −0.5 kcal mol^{-1}, while the addition of a purine–purine pair had an effect comparable to that of the addition of a dangling end (the contribution to ΔG_0 by this pair is −0.2 kcal mol^{-1}). It has been shown[102] that the stabilising influence of the terminal mismatch increases in the sequence A · C ≃ A · A < A · G ≃ A · U (data obtained for the CCGG/GGCC core duplex).

Comparative analysis of the data presented in a number of studies[13,49,56,99,101] permits the claim that the addition of the weakest noncanonical pair U · C at the end of the duplex does not alter its stability, while the appearance of an isolated G · U pair in the central part of the duplex causes its appreciable destabilisation.

The study of Gillam et al.[42] is the only one in which the stabilities of imperfectly matched heteroduplexes were compared. The melting points of the mismatched duplexes were determined from the temperature dependence of the degree of binding of the oligonucleotides to d(pT)$_9$ immobilised on a resin. The following noncanonical pairs were analysed: T · dC; T · rC; T · dG; T · rG; T · T; T · U. Ribooligonucleotides form less stable duplexes with immobilised d(pT)$_9$ than do deoxyribooligonucleotides. Only duplexes containing the T · rG pair are an exception. The destabilising effect of this pair is much smaller than that of the dT · dG pair. The stability of the duplex with the T · rG pair corresponds to that of the duplex shortened by one A · U pair. Furthermore, the influence of the position of the irregular pair in the duplex on its stability was demonstrated in the same study. The terminal irregular pair induces a minimal destabilisation of the double helix (ΔT_m = 4 °C for dT$_9$ · dA$_8$ and dT$_9$ · dA$_8$G) compared with the irregular pair at the centre of the duplex (ΔT_m = 15 °C for dT$_9$ · dA$_8$ and dT$_9$ · dA$_5$GA$_3$).

In considering the problem of the reparation of the noncanonical pairs,[88,90] the authors conclude that the stable pairs (G · T and T · G), introducing minimal perturbations into the DNA structure, are repaired most effectively. The degree of reparation is 93% for the G · T pair and 55% for the T · G pair, whereas other mismatches are recognised by the cell repair system to a much lesser extent. The degree of reparation is less than 5% for the A · G and C · T pairs and 42% for the G · A pair.

The experimental data considered in this Section indicate unambiguously that the greatest contribution to the decrease in the complementary accuracy of the interaction of nucleic acids should come from imperfectly matched complexes with structural

anomalies at the ends of the duplex, which agrees with theoretical estimates of Perelroyzen and Vologodskii.[11] However, one should not forget at the same time the possibility of the formation of imperfectly matched complexes with an increased stability, e.g. such as the duplexes with inverted noncanonical G · A pairs.

IV. Accuracy of the interaction of RNA and DNA molecules with oligonucleotides and their derivatives

A number of approaches have been developed in recent years for the investigation of the structure and functions of nucleic acids based on the use of antisense oligonucleotides and their derivatives.[1] The antisense oligonucleotides, which are complementary to different sequences in the composition of single-stranded and double-stranded nucleic acids, have the ability to form specific complexes with these nucleic acids (duplexes and triplexes), which prevents the interaction of the nucleic acids with ribosomes and DNA or RNA polymerases both *in vitro* and *in vivo*.[2,9]

There exist several main requirements on which these approaches are based. Firstly, oligonucleotide derivatives must permeate the cell and must be sufficiently stable under *in vivo* conditions. Secondly, oligonucleotides or their derivatives must form a complex with the selected nucleic acid sequence. Thirdly, the formation of the complex must inhibit the functions of the given nucleic acid. Fourthly, the antisense oligonucleotides must not interact with other sequences in the cell apart from the one chosen.[9] It is quite evident that the last two principles are closely interrelated—a specific interaction with the selected sequence is impossible without the formation of a highly stable complementary complex.

The thermodynamic parameters of the formation of perfectly matched DNA and RNA duplexes as well as the defects in the double helix having a destabilising effect on the duplex were examined in the previous Sections. All these data were obtained in the study of model oligomeric duplexes. The next section will deal with studies on the interaction of oligonucleotides or their derivatives with the NA target, in which the accuracy of the interaction of the oligonucleotide with the selected nucleic acid was estimated.

1. Model systems

a. Oligonucleotides with the usual phosphodiester linkage

The specificity and effectiveness of complex formation by a series of synthetic oligonucleotides with a length corresponding to 8–14 units (ON) with the M13mp3 phage DNA have been investigated.[103] Two oligonucleotides out of the eleven investigated [one a 12-unit oligonucleotide (ON-12) and the other a 14-unit oligonucleotide (ON-14)], complementary to the 3366-3377 and 2216-2230 sections of the phage DNA respectively, were bound at 4 °C to the DNA target at more than one site (the ON-12 and ON-14 concentrations were 2 μM). The binding of these oligonucleotides to the DNA target with formation of imperfectly matched complexes was confirmed by the elongation of ON-12 and ON-14 as primers under the influence of DNA polymerase at 20 °C. It is noteworthy that under the same conditions two 10-unit oligonucleotides, forming with the M13mp3 DNA duplexes with a length equivalent to 10 base pairs and containing a central G · T pair, were not built up by DNA polymerase, while a 13-unit oligonucleotide containing an analogous noncanonical pair was built up by the enzyme until the phage DNA was replicated.

The influence of noncomplementary pairs in the matrix · primer duplex on the effectiveness of the chain elongation reaction with the aid of the Taq DNA polymerase and the AMV reverse transcriptase has been investigated in a series of studies.[104–108] The presence of a single mismatch within the matrix · primer duplex did not produce an appreciable effect on the yield of the product of the amplification of the HIV-1 gag-region, whereas the presence of a noncanonical base pair at the 3′-end affected the yield of the PCR-product. The 3′-terminal T · C, T · G, T · T, G · G, and A · C pairs were amplified with the same effectiveness as the perfectly matched duplex, whereas the A · G, G · A, and C · C pairs at the 3′-end of the duplex decreased the overall yield of the PCR product by a factor of 100 and the A · A pair decreased it by a factor of 20. The influence of the G · A and A · G mismatches on the yield of the product was the same. The minimum effect on the yield of the PCR-product was exerted by mismatches generated by T with G and by C with T. The presence of two irregular pairs in the vicinity of the 3′-end of the primer · matrix duplex (the last four bases of the duplex), one of the mismatches being 3′-terminal (apart from the irregularly paired thymidine), leads to the virtually complete cessation of the elongation reaction.[104] It is noteworthy that the data on the thermodynamic stability of such imperfectly matched duplexes do not explain the results obtained by the authors. Similar data have been obtained[105] for the elongation of an imperfectly matched primer · matrix duplex with the aid of the AMV reverse transcriptase. The decrease in the overall concentration of dNTP from 800 to 50 μM[104] or from 200 to 2 μM[106] led to the elongation mainly of only the perfectly matched duplex (the G · G and C · T mismatches respectively). With increase in the temperature of the annealing of the primer · matrix duplex from 44 to 55 °C, only the perfectly matched duplex was elongated, while no elongation was observed in the duplexes with the 3′-terminal A · A and T · T mismatches.[107] The elongation of only the perfectly matched duplex could be achieved also using shorter primers: 10 out of the 12 possible noncanonical pairs at the 3′-end of the duplex completely stopped the elongation if short (10-unit) primers were employed.[108]

Analysis of a series of oligonucleotides, complementary to the Shine–Dalgarno sequence in the *E. coli* 16S rRNA, forming with the latter perfectly (AGAGGAGGU, ON/r) and imperfectly matched complexes (GGAAGGAGC, ON/i-1; GGAGAAGC, ON/i-2; AUUUCUUCUAUG, ON/i-3) showed that the effectiveness of the inhibition of the binding of Qβ RNA to the 70S ribosomes of *E. coli* depends on the stability of the 16S rRNA · oligonucleotide duplex: ON/r: ΔG = 16.9 kcal mol^{-1}, binding inhibited by 87.2%: ON/i-1: ΔG = −11.1 kcal mol^{-1}, binding inhibited by 56.6%; ON/i-2: ΔG = −7.9 kcal mol^{-1}, binding inhibited by 42.6%; ON/i-3: ΔG = −1.1 kcal mol^{-1}, no inhibition observed.[109] The oligonucleotide 'probing' of the 16S rRNA molecule forming part of the composition of the 30S ribosomal subparticles in *E. coli* by 8–15 unit oligonucleotides demonstrated that, at an oligonucleotide concentration of 1 μM, there is a possibility of the formation of an imperfectly matched complex with exposed RNA sections, containing five classical Watson–Crick pairs at the 3′-end of the duplex.[110]

The site-specific cleavage of mRNA of prothymosin-α, isolated from the cytoplasm of lymphocytes stimulated by the staphylococcal enterotoxin, in the presence of a 12-unit oligonucleotide (GCAGGGCGTCTC) and RNase H takes place within both perfectly and imperfectly matched duplexes. The imperfectly matched ON-12 binding site was identified from the size of the hydrolysis product and was found to contain three irregular pairs (structure **8**).[111]

The mRNA of γ-interferon was cleaved in the same investigation in the presence of a 24-unit oligonucleotide ON-24 (at a concentration of 1 μM). Although, apart from forming a complex with the 603–625 sequence of the mRNA of γ-interferon, ON-24 can form an imperfectly matched duplex with a length equivalent to seven base pairs with the TGCCTGC sequence of mRNA, the products of the cleavage of RNA at this site were not detected. Evidently the difference between the

stabilities of the perfect and imperfect ON-24 · mRNA of γ-interferon duplexes proved insufficient for discrimination between these sites by RNase H.

The accuracy of the formation of the duplex is particularly important in site-specific mutagenesis. 8–12-Unit oligonucleotides containing the base to be replaced in the centre proved to be most convenient for the introduction of point mutations into the DNA molecule.[112] The stability of the imperfectly matched duplex containing one noncanonical pair proved to be the decisive parameter on which depended the yields of the mutant DNA. The yield of the mutant DNA increased from 0.05 to 20% on reducing the hybridisation temperature from 33 to 0 °C for the 8-unit oligonucleotide with the G · T pair in the centre. The use of a 10-unit oligonucleotide with a similar irregular pair[113] increased the yield of the mutant DNA to 38% at 10 °C. When the base to be replaced was shifted from the 3'-end to the centre of the oligonucleotide, the yield of the mutant DNA rose from 8 to 20% respectively. Although duplexes with an irregular pair at the end are in fact more stable, the oligonucleotides forming such duplexes are probably poor primers for DNA polymerase.[113]

When oligonucleotides complementary to the mutation site were used, it was shown that the effectiveness of the correction of the DNA sequence with the aid of DNA polymerase is linked directly to the stability of the oligonucleotide (primer) · DNA duplex. With increase in the length of the primer from 11 to 17 bases, the yield of the 'corrected' phage φX 174 DNA (the mutant strain am3 was corrected) increased from 0.02 to 13.9%. Furthermore, the two oligonucleotides placed one immediately behind the other (in a tandem fashion) (simulation of point dissociation) were more effective in the synthesis of the 'corrected' DNA than short oligonucleotides [yield of φX 174 phage DNA (%): 1.2 for ON-11 + ON-6 and 0.02 and 0 for ON-11 and ON-6 respectively; 14.0 for ON-14 + ON-6 and 1.9 for ON-14; 32.5 for ON-17 + ON-6 and 13.9 for ON-17].[114]

The pentadecadeoxyribonucleotide, fully complementary to the RNA segment (synthesised on the *E. coli* tryptophan operon) responsible for the regulation of attenuation, was used[115] to investigate the role of the secondary structure of RNA in the termination of transcription. The essential feature of the approach employed in the above study[115] is that the oligomer is bound in a complex with a selected section of the synthesised transcript, preventing thereby the formation of the corresponding 'terminator' secondary structure in this segment of RNA and behaving therefore as an antiterminator. It was shown that, in the presence of a 500-fold excess of the oligomer (2 μM, 37 °C) relative to the matrix, the yield of the transcript exceeded by a factor of approximately four the yield of the product in the control experiment (without the oligonucleotide). On the other hand, the yield of the transcript synthesised in the presence of the same oligomer (and under the same conditions) on the *Ser. marcescens* tryptophan operon exceeded the yield of the product in the control experiment by a factor of only 1.2. In the latter case, the oligomer might have formed a duplex containing two noncanonical pairs with the corresponding section of the transcript, in contrast to the perfectly matched complex formed by the oligomer with the selected section of RNA synthesised on the *E. coli* tryptophan operon.

A general approach to the formation of oligonucleotide probes for mRNA with an unknown primary structure has been proposed[116] (if it is assumed that the aminoacid sequence of the corresponding protein is at least partly known). This approach is based on the use as the primer or the probe of an oligonucleotide complementary to the section of mRNA coding for tetrapeptides consisting of the aminoacids Phe, Tyr, His, Asn, Asp, Cys, Gln, Lys, Glu, Trp, and Met. Taking into account the degeneracy of the code, such an oligonucleotide will form with mRNA a duplex containing either G · C or G · U pairs. Furthermore, T · G or T · A pairs may be encountered. The probe, constructed in accordance with this principle for gastrin mRNA (containing two G · U pairs) was hybridised with the mRNA, but its efficiency as a primer was lower by a factor of 2 than the efficiency of the oligonucleotide fully complementary to the given section. Furthermore, in the case of oligonucleotides with two G · U pairs, the primer underwent both hybridisation and elongation only on denaturation of the mRNA.

The exact selection of hybridisation conditions makes it possible to distinguish the RNA or DNA sequences containing at least one replacement at the probe binding site.[117,118] Thus the presence of one G · T pair (instead of G · C) at the centre of the binding site for a 14-unit oligonucleotide (ON-14-B) decreased the degree of its hybridisation with the rabbit β-globin mRNA to 8% compared with the degree of hybridisation of the oligonucleotide fully complementary to the same section (ON-14-A) {1 M NaCl, 37 °C, [ON-14-A] = [ON-14-B] = 0.15×10^{-9} M}. The dissociation temperatures of the complexes[117] mRNA · ON-14-A and mRNA · ON-14-B differed by 5 °C.

The hybridisation of 23-unit oligonucleotides with the initial and mutant DNA depended on the type of irregular pair at the oligonucleotide binding site. The oligonucleotide ON-23, complementary to the adenovirus Ad-2 DNA, was hybridised also with the DNA of the Cyt-15 mutant strain. The duplex ON-23 · Cyt-15 DNA contained the T · T pair. On the other hand, the oligonucleotide ON-23M, complementary to the Cyt-15 DNA, gave rise to a very weak signal due to hybridisation with the Ad-2 DNA. In the latter case the duplex contained the A · A pair, which can be explained by the greater destabilising effect of this pair on the double helix than the effect of the T · T pair.[118]

The differences between the stabilities of the perfectly matched duplex and the duplex containing one irregular pair were used to diagnose sickle cell anaemia. The 19-unit oligonucleotides ON-19-A, complementary to the normal globin mRNA (mRNA-A), and ON-19-S, complementary to a mutant mRNA (mRNA-S), gave rise to cross-hybridisation at 45 °C (level of hybridisation 10%–15%); the complex mRNA-A · ON-19-S contained one A · A pair, while the complex mRNA-S · ON-19-A contained one T · T pair. An increase in the hybridisation temperature to 55 °C led[119] to a rigorously specific interaction of the above oligonucleotides with the corresponding mRNA. The accuracy of the interaction of short probes with lengths equivalent to 7, 9, or 12 oligonucleotide units proved low and led to intense cross-hybridisation. Thus the 9-unit and 12-unit probes, complementary to the gene for the phage T4 lysozyme, were hybridised to the extent of 15%–18% with the DNA of the lysozyme-free G223 phage and 10% with the total RNA of *E. coli*.[120] At a hybridisation temperature lower by 15–20 °C than the melting point of the perfectly matched complex, the 12–15-unit oligonucleotides were effectively hybridised with the DNA of the *lac* operon (of not only the wild strain but also of a series of mutant strains) with formation of duplexes containing noncanonical pairs of the type C · A, G · A, T · T, etc. The degree of cross-hybridisation depended under these conditions on the type of the irregular pair: the degree of hybridisation for oligonucleotides forming a complex with the G · A pair was lower than for those forming a complex with the C · A pair. An increase in the hybridisation temperature from 30 to 37 °C made it possible to avoid the cross-hybridisation of these probes.[121]

b. Nonionic analogues of oligonucleotides

Nonionic analogues of oligonucleotides (phosphotriesters, methylphosphonates) have been proposed as antisense oligonucleotides for the inhibition of the expression of genes *in vivo*. Unchanged oligonucleotides readily permeate into the cell via passive diffusion. The use of nonionic analogues of oligonucleotides as inhibitors of the translation of mRNA or the expression of genes has been examined in detail in a number of reviews.[1–3,122]

In the study of the binding of ethyl phosphotriesters of oligonucleotides complementary to the anticodon loop (dTpTpCpA, ON-I) and the CCA-end (dGpGpT, ON-II) of yeast and *E. coli* $tRNA^{Phe}$, it was observed that the constants for

the binding of these derivatives to $tRNA^{Phe}$ are higher than for the unmodified oligonucleotide. At 0 °C (1 M NaCl, 10 mM, Mg^{2+}), the binding constant (K_x) was 3600 litre mol^{-1} for ON-I and 2400 litre mol^{-1} for the diester analogue.[123] As expected, at 0 °C ON-II at a concentration of 270 μM inhibited the aminoacylation of all five tRNA investigated (specific to Phe, Lys, Tyr, Pro, and Leu) to approximately the same extent (60% – 80%). At a concentration of 364 μM, ON-I inhibited the aminoacylation of $tRNA^{Phe}$ as a result of the formation of a perfectly matched duplex with the tetranucleotide sequence in the anticodon loop of $tRNA^{Phe}$. Together with this finding, the inhibition of the aminoacylation reactions of other tRNA was also observed[124] in the presence of ON-I: by 35% for $tRNA^{Leu}$, by 12% for $tRNA^{Lys}$, and by 0.7% for $tRNA^{Pro}$. When the methyl phosphate derivatives (the modified phosphate is designated by an asterisk) of the oligonucleotides dAp*Ap*Ap*A (M-ON-1) and dGp*Gp*U (M-ON-2), complementary to the sequence in the anticodon loop of $tRNA^{Lys}$ and the CCA-end of tRNA respectively, were used as the aminoacylation reaction inhibitors, the nonspecific inhibition of the aminoacylation of $tRNA^{Phe}$ by 9% and of $tRNA^{Leu}$ by 12% was observed in the presence of M-ON-1 (0 °C). In the presence of a similar oligonucleotide derivative dAp*Ap*Gp*A (M-ON-3), forming with the anticodon loop of $tRNA^{Lys}$ a duplex with one G · U pair, the level of inhibition of the aminoacylation reaction of $tRNA^{Lys}$ was 35% (whereas for M-ON-1 it was 88%), while the degrees of aminoacylation of $tRNA^{Phe}$ and $tRNA^{Lu}$ did not change.[125]

The experimental data on the thermodynamics of the duplexes formed by phosphodiester and methylphosphonate oligonucleotides are represented in the most complete form in the communications of Quartin and Wetmur[126] and Miller et al.[127] The change in the free energy of the duplex as a consequence of the introduction of one methylphosphonate linkage instead of the diester linkage is $\Delta\Delta G_0 = -0.75$ kcal mol^{-1} (1 M NaCl, 25 °C) regardless of the type of base in the oligonucleotide. These duplexes are additionally stabilised as a result of the decrease in the overall charge per pair of nearest neighbours containing the methylphosphonate linkage.[126]

The increase in the stability of the duplexes formed by methyl phosphate derivatives of oligonucleotides influences the complementation accuracy of the interaction of such derivatives with nucleic acids and their fragments. The photomodification of a 35-membered oligonucleotide by dodecameric methylphosphonates carrying 4'-aminoalkyl-4,5',8-trimethylpsoralen at the 5'-end has been investigated.[128] It was shown that the degree of photomodification of the ON target depends greatly on the accuracy of the formation of the duplex with the reagent (Table 4). Noncanonical pairs adjoining the reactive component of the derivative reduced sharply the degree of photomodification of the target. These results agree well with data obtained in a study[129] where it was shown that the biological and biochemical activity of oligonucleoside methylphosphonates falls sharply when defects appear in the duplex.

Table 4. The influence of the accuracy of the formation of the duplex on the degree of photomodification of a 35-unit oligonucleotide by the psoralen derivative of a methylphosphonate dodecamer.[128]

Duplex	Degree of photomodification (%)
Perfectly matched	85
Central T·pair	53
3'-Terminal T · C pair	58
5 G · T pairs at one pair intervals	33
3 T · C pairs at one pair intervals	19
4 T · C pairs at one pair intervals	0

c. Phosphorothioate analogues of oligonucleotides

The phosphorothioate analogues of oligonucleotides, containing a sulfur instead of an oxygen atom at the phosphorus atom, also belong to oligonucleotide derivatives with a modified phosphodiester linkage. The replacement of an oxygen atom by a sulfur atom increases the resistance of such derivatives to the action of intracellular nucleases.[130] The thermodynamic parameters of the formation of duplexes between the usual DNA or RNA and the phosphorothioate derivatives of oligonucleotides have been published.[1,131–134] Unfortunately, there are no data concerning the accuracy of the interaction of the phosphorothioate derivatives of oligonucleotides with model NA targets.

d. Derivatives of oligonucleotides containing α-anomeric units

During the last few years, methods have been developed for the synthesis of oligonucleotides resistant to the action of nucleases and consisting of the α-anomers of nucleotides (see the relevant reviews[135–137]). α-Oligonucleotides form a double helix with a complementary chain consisting of natural β-anomers of α-anomers of nucleotides. Both chains of the α · β duplex have a parallel orientation and the duplex itself belongs, according to NMR data, to the *B* conformation of DNA and has a right-handed twist to the extent of 70 ± 10%.[138] The melting point of duplexes[140] of the type α · β{α[(Tp)$_7$T] · β[d(pA)$_8$]} (30 °C) is higher than the T_m of the corresponding β · β duplex (24 °C),[139] which indicates the greater stability of the α · β duplexes compared with the β · β duplexes. On the other hand, the melting point of the heterooligomeric duplexes of the type α[d(TCTAAAC)] · · β[d(AGATTTG)] hardly differs from that of the corresponding β · β duplex (33 and 36 °C respectively).[141] Detailed thermodynamic studies of the duplexes β[d(CCTTCC)] · β[d(GGAAGG)], α[d(CCTTCC)] · β[d(GGAAGG)], and β[d(CCTTCC) · ·α[d(GGAAGG)] permitted the conclusion that the stability of the α · β duplexes depends on the nature of the bases in the α-chain (purine or pyrimidine) at least for homopurine or homopyrimidine sequences.[142] Comparison of the β · β duplexes mentioned above (T_m = 19 °C) with the α · β duplexes (T_m = 28 °C) showed that the α · β duplexes are more stable in 1 M NaCl than the β · β duplexes, provided that the α-chain consists of pyrimidine bases.[136] The duplexes of the α-oligonucleotides [α(T$_p$)$_7$T] with natural RNA [poly(rA)] are more stable than the analogous duplexes with poly(dA) (T_m = 29 and 17 °C respectively), while the β-dT$_8$ · poly(rA) duplex is less stable than dT$_8$ · poly(dA) (T_m = 14 and 17 °C respectively).[143] Data on the accuracy of the interaction of α-oligonucleotides with natural DNA or RNA targets are lacking in the literature.

e. Derivatives of oligonucleotides bound covalently to duplex-stabilising groups

The oligonucleotides bound covalently via an oligomethylene bridge to a dye molecule form duplexes with an increased stability (ΔT_m = 20 – 30 °C) as a result of the intercalation of the dye in the mRNA · antisense oligonucleotide double helix.[131,144,145] The synthesis and the mechanism of the action of such oligonucleotide derivatives have been considered in detail in a number of reviews.[5,146,147] The stability of the duplex poly(rA) · dT$_{6-8}$ increases appreciably (ΔT_m = 20 – 30 °C) if the oligothymidylate is bound covalently via one of the ends to 9-aminoacridine.[139,144,148] Another dye — *N*-(2-hydroxyethyl)-phenazinium — has been used[149,150] to increase the stability of the DNA duplexes. The oligonucleotide carrying a phenazinium residue at the 5'-end activated the replication of the M13mp7 bacteriophage DNA to the extent of 65%, while the free oligonucleotide showed no inactivation activity.[150] Unfortunately, the accuracy of the interaction with the NA target was not specially estimated in the studies devoted to such oligonucleotide derivatives. All the investigations were performed either on homopolymer matrices or on short DNA fragments.

2. Inhibition of the translation of mRNA

In recent years, antisense oligonucleotides and their derivatives have been used rigorously as specific inhibitors of the expression of genes.[1,5,151,152] The approach is based on the hypothesis[158-161] that, after the formation of a duplex with an antisense oligonucleotide, mRNA either loses the ability to be translated by the ribosome[153-157] or is cleaved by RNase H.

Standard cell-free protein-synthesising systems [the lysate of rabbit reticulocytes, the extract from wheat germ (WGE), and the oocytes of *Xenopus laevis*] are used to study the inhibiting activity of oligonucleotides or their derivatives on the translation of mRNA. The activity of RNase H is particularly high in the wheat germ extract.[159,162,163] Tests showed that the low activity of RNase H in a freshly prepared lysate of rabbit reticuloycytes is sufficient to hydrolyse exogenic mRNA with an antisense nucleotide.[160] In *Xenopus laevis* oocytes, RNase H activity is observed in the nucleus and in the cytoplasm.[159,164]

The most readily available mRNA of rabbit[157,159,165-169] or mouse[160] globins were used as the matrix. In addition, viral RNA sometimes served as a matrix: from the Rous sarcoma (RSV),[170,171] the Sendai virus,[172] the encephalomyocarditis virus,[173] and the tobacco mosaic virus.[174] Since the level of specificity of the inhibition of the translation was estimated in some investigations, the results of the latter will be considered in greater detail.

It has been shown[170] that the translation of 35S RNA from the Rous sarcoma virus (RSV) was effectively translated in WGE in the presence of the 13-unit oligonucleotide d(AATGGTAAATGG), complementary to the 3'- and 5'-terminal sequences of this RNA. Simultaneously with the suppression of the translation of the RSV RNA (approximately to the extent of 88%), the inhibition of the translation of AMV (avian myeloblastosis), the rabbit globin mRNA, and the BMV (broom mosaic virus) RNA to the extent of 57, 25, and 30% respectively has been observed (the data are quoted for a RNA : ON-13 ratio of 1 : 20 at 25 °C). The degree of inhibition of the translation of all the types of RNA increased with increase in the ON-13 concentration, but at low ON-13 concentrations (RNA : ON-13 = 1 : 2) mainly the translation of the oncovirus RNA (RSV and AMV RNA) was inhibited — to the extent of 27% and 10% respectively. Analysis of the sequence showed that ON-13 could form an imperfectly matched complex with AMV RNA with a length equivalent to 13 base pairs and containing three noncanonical pairs — two in the centre and one at the 3'-end. The degree of homology of the above oligomer with BMV RNA and globin RNA was not determined.

The inhibition of the translation of the mRNA in WGE as a result of the formation of an imperfectly matched complex with an antisense oligonucleotide has been observed.[164] All three oligonucleotides investigated, specific to β-globin mRNA, had incomplete complementation sites on the α-globin mRNA. Thus ON-17 could form with α-globin mRNA an imperfectly matched duplex comprising ten base pairs, three of which were noncanonical, ON-12 could form an imperfectly matched duplex consisting of seven base pairs with a central A · C pair, and finally ON-8 could form a duplex containing seven base pairs with a terminal irregular pair. The inhibition of the translation of the α-globin mRNA was observed only in the presence of ON-8 (the degrees of inhibition of β- and α-globin mRNA were 65% and 15% respectively). Apparently, in the case of ON-17 and ON-12 the difference between the stabilities of the perfectly and imperfectly matched duplexes, formed by these oligonucleotides with the β- and α-globin mRNA, was sufficiently high to prevent altogether the formation of an imperfectly matched complex at 25 °C and a concentration of the oligonucleotides of 10 μM or the complex was not recognised by RNase H.

The formation of an imperfectly matched complex between the α-globin mRNA and a 30-unit oligonucleotide complementary to the 270-300 fragment of the β-globin mRNA was detected from the cleavage of α-globin mRNA in the presence of saturation concentrations of the 30-unit oligomer in the *Xenopus laevis* oocytes.[159] The degree of homology between the α-globin mRNA and ON-30 was 60%. The non-specific inhibition of the translation of globin mRNA by oligonucleotides complementary to the 5'-nontranslatable sequence has been observed.[160] This finding was accounted for by the high level of homology between the nontranslatable sequences in the α- and β-globin mRNA. As a result of the high degree of homology (about 50%) between the 5'-terminal sequences of all the mRNA of the Sendai virus, the 20-unit oligonucleotide, complementary to the 1-20 fragment of the nucleocapsidyprotein (NP) mRNA reduced the yields of the products of the translation of all the mRNA of this virus due to the formation of a partial complex with a length equivalent to ten base pairs and a 10-unit sequence, which is virtually common to all the mRNA of the Sendai virus.[172]

The nonspecific inhibition of the translation of the BMV RNA in the lysate of rabbit reticulocytes (RRL) by a 15-unit oligonucleotide complementary to the vesicular stomatitis virus (VSV) was explained by the inhibition of the translating capacity of ribosomes as a result of the binding of the above ON-15 to 18S rRNA. The level of the nonspecific inhibition of the translation of the BMV RNA depended on the ON-15 concentration and showed a distinct tendency towards saturation. The maximum attained degree of inhibition of the translation was 88% and 43% in the presence of 40 μM ON-15 and 41% and 2% in the presence of 10 μM ON-15 for VSV and BMV RNA respectively.[175] Although, according to the authors claim there is no homology between the BMV RNA, 18S rRNA, and the above ON-15, the inhibition of the translation of the BMV RNA as a result of the formation of an imperfectly matched complex with the oligonucleotide appears more likely than nonspecific inhibition of the translating activity of ribosomes.

It has been shown[173] that the translation of the encephalomyocarditis viral RNA in the RRL is inhibited approximately to the extent of 60% with the aid of 25 μM 13-unit oligonucleotide, which forms a perfectly matched complex with the 751-763 section. The replacement of the central G · C pair of this duplex by the G · A pair (one base of ON-13 is altered) leads to a fourfold decrease in the degree of inhibition of the translation (down to 14%) at the same ON-13 concentration.

Interesting data on the complementation accuracy of the interaction of antisense oligonucleotides or their methylphosphonate analogues with a NA target have been obtained in a series of studies by Miller and coworkers[165-167,176,177] of the inhibition of the translation of rabbit globin mRNA *in vitro*. Phosphodiester oligonucleotides with a length equivalent to 8-10 units inhibited the translation of the globin mRNA in the RRL and WGE (0-200 μM solution of the (oligonucleotide, 0.3 μg of mRNA). The above oligomers were fully complementary to the sequences located in the 5'-nontranslatable region and the region of the AUG codon in either α- or β-globin mRNA. All the oligonucleotides synthesised formed a duplex with the selected mRNA sequences, which was demonstrated by building up these oligonucleotides (as primers) using a reverse transcriptase. However, despite the fact that these oligonucleotides were effective translation inhibitors, the complementation accuracy of their interaction with mRNA was low. For example, the ON-12 oligonucleotide inhibited the translation of the α-globin mRNA (it was complementary to its 28-39 section) by 97% in the RRL and by 100% in the WGE at a concentration of 100 μM. However, the ON-12 inhibited simultaneously the translation of the β-globin mRNA by 96 and 100% in the RRL and WGE respectively. At a ON-12 concentration of 5 μM, the degree of inhibition of the translation of α- and β-globin mRNA was 15 and 14% in the RRL and 75 and 14% in the WGE respectively. Similar results were obtained for all seven nucleotides investigated.[165]

Short 4-12 unit oligonucleoside methylphosphonates (M-ON), exactly complementary to the same sections of the globin mRNA as the phosphodiester oligonucleotides used by

Blake et al.,[165] have been investigated.[166,176] The prehybridisation of M-ON with mRNA increased the degree of inhibition of the translation of the mRNA in the RRL by 20%–30%. It is surprising that at 37 °C the M-ON-4 (Cp*Cp*Ap*T) (complementary to the 37–40 and 54–57 sections in α- and β-globin mRNA respectively) at a concentration of 100 μM did not inhibit the translation of mRNA, while at a concentration of 200 μM the degree of inhibition of the translation of α- and β-globin mRNA was 28% and 42% respectively. As in the study of Murakami et al.,[167] the M-ON complementary to the α-globin mRNA inhibit the translation of both mRNA to approximately the same extent, particularly at high M-ON concentrations (200 μM) and when the stage involving the transhybridisation of the mRNA with the M-ON is carried out.

Direct comparison of the inhibiting activities of the ON and M-ON permits the conclusion that the M-ON are not more effective and specific translation inhibitors than the phosphodiester oligonucleotides. The low specificity of the ON and M-ON with lengths equivalent to 4–12 units as well as their low effectiveness in inhibiting translation can be explained by several causes. Firstly, the 5'-nontranslatable region in the rabbit α- and β-globin mRNA exhibits a high degree of homology. Therefore, apart from the binding site selected on one mRNA, each nucleotide can form also imperfectly matched complexes with the other mRNA. However, the authors, in discussing the possibility of the formation of such complexes, seek only those sections of the mRNA which can form with the M-ON or ON a continuous duplex with a length equivalent to not less than four base pairs (the so called partial duplex[47]) and fully reject the possibility of the formation of longer duplexes containing noncanonical pairs or, in other words, imperfectly matched complexes.[165,166] Secondly, the influence of the secondary structure of mRNA on complex formation is not considered.[175]

A low specificity of the action of short M-ON (9-unit oligonucleotides) has also been observed in the inhibition of the translation of the mRNA of the N, NS, and GVSV proteins in the RRL at 30 °C. On concentrating M-ON-9 (complementary to the N protein mRNA, section 14–22), the inhibition of the synthesis of the N protein by 77% was accompanied by the inhibition of the syntheses of the NS and M proteins by 38% and 43% respectively.[178] The low specificity of the inhibition of the translation observed at high concentrations (100–150 μM) of M-ON-9, was explained by the formation of partial complexes between M-ON-9 and other VSV mRNA. Furthermore, despite the absence of experimental evidence, the authors suggest[178] that the secondary structure of the mRNA exerts a strong influence on the specificity and effectiveness of the inhibition of the translation.

The site-specific inhibition of the translation takes place also when the M-ON forms with the mRNA a duplex containing noncanonical pairs. Three octamers (M-ON-8_{1-3}), complementary to the AUG region of the codon for the ras p21 BALB protein mRNA, inhibited translation of the mRNA in conformity with the stability of the duplexes formed. Thus M-ON-8_1[177] inhibited the synthesis of the protein by 97%; M-ON-8_2, forming with the mRNA a duplex containing one irregular pair in the centre, caused 31% inhibition; whereas M-ON-8_3, forming with the mRNA a duplex with two noncanonical pairs in the centre, inhibited the translation to the extent of 9%.

At a certain temperature and certain concentrations of the antisense oligonucleotides, the degree of inhibition of the translation of mRNA depends on the length of the oligonucleotide employed, i.e. on the stability of the duplex. The 12-unit oligonucleotide complementary to the initiator region of trypanosomal mRNA is less effective in inhibiting translation[179] (degree of inhibition 20%–25%) than ON-22 and ON-34 (translation inhibited to the extent of 65%–70% and 95%–100% respectively) at 25 °C and a concentration of 15 μM. The decisive importance of the stability of the mRNA · ON duplex in inhibiting the translation of the given mRNA in the RRL and WGE can be additionally illustrated by data from other studies.[180,181] Thus the 12-unit oligonucleotide complementary to the 2-13 sequence of the *T. brucei* mRNA inhibits the translation of the mRNA but not that of *T. vivax* (another species of African trypanosomes) at 22 °C. It was found that ON-12 forms with the *T. vivax* mRNA a duplex (its dissociation temperature is 22 °C) containing two irregular pairs — G · A and T · T.

It has been demonstrated[145,182] that the 18-unit oligonucleotide carrying at the 3'-end a 9-aminoacridine residue inhibits the expression of pKH113 by 55% (at an ON-18 concentration of 30 μM). A slight inhibition of the expression of pBR322 (by 10%) is observed simultaneously, evidently owing to the formation of an imperfectly matched complex with a length equivalent to 11 units and containing two noncanonical base pairs at the 5'-end of the duplex (G · T and C · T) in the 3234 region of the pBR322 nucleotide residue.

In all the studies examined in this section, short (4-13)-unit oligonucleotides at high concentrations (40–200 μM) were used to inhibit the translation of mRNA *in vitro*. The low specificity of the inhibition of the translation was apparently associated with the fact that the difference between the stabilities of the imperfectly and perfectly matched complexes at high concentrations of the oligonucleotides virtually disappeared and both types of duplexes functioned as inhibitors of the initiation of translation (binding to ribosomes) or served as substrates of the RNase H.

The specificity of the inhibition of the translation of mRNA *in vitro* increases sharply when long antisense oligonucleotides are employed. Thus the translation of the mRNA of trypanosomes was inhibited specifically (degree of inhibition 95%–100%) by 22- and 34-unit oligonucleotides at a concentration of 25 μM in the WGE. The BMV RNA, the degree of translation of which in the presence of the same oligonucleotides remained unchanged, was employed as a control.[179] The translation of the tobacco mosaic virus (TMV) RNA was inhibited specifically (to the extent of 90%–95%) by two 26-unit oligonucleotides (at a concentration of 10 μM) in the RRL at 30 °C. Under the same conditions, the level of translation of the BMV RNA remained unaltered.[174] Specific inhibition of the translation of the rabbit β-globin mRNA in the presence of the α-globin RNA was achieved using 20–25- and 48-unit oligonucleotides at a concentration of 5.3 μM (2.6 μM for ON-48) at 37 °C in the RRL. The level of inhibition was[169] 55%–88% for ON-20(25) and 80%–98% for ON-48.

The use of antisense oligonucleotides with lengths equivalent to 21–49 units, complementary either to the translation initiation region or the part of the mRNA molecule coding for the enzyme dehydrofolate reductase–thymidylate synthetase of *Plasmodium falciparum*, led to the inhibition of the translation of mRNA in the RRL system by not more than 60% at a concentration of the 49-unit oligonucleotide of 190 μM. The main reason for the low inhibiting capacity of such long oligonucleotides relative to their length and concentration employed is apparently the inaccessibility of sections of the mRNA for the formation of such a long duplex.[156] Unfortunately, there are at present insufficient data to discuss the specificity of the inhibition of translation of the mRNA of the rabbit globins with the aid of 17-unit phosphorothioate oligonucleotide derivatives (S-ON) or α-oligomers having the same length in the RRL, WGE, and *Xenopus laevis* oocytes.[157,168]

3. Accuracy of the interaction of the oligonucleotides and their derivatives with the NA target *in vivo*

Antisense oligonucleotides and their derivatives can be regarded as possible future therapeutic antitumour, antiviral, and antibacterial agents. This explains the enormous interest in the study of the action of antisense oligonucleotides *in vivo*. The mechanism of the permeation of oligonucleotide derivatives into the cell and their utilisation have been examined in detail in a number of studies.[159,183–187]

a. *Xenopus laevis* oocytes

The *Xenopus laevis* oocytes are some of the simplest *in vivo* systems.[188] Exogenic mRNA and DNA, introduced into the *Xenopus* oocytes by microinjections, are expressed in the given system; under these conditions, the nuclear cytoplasmic transcripts are equally accessible for the interaction with (19–20)-unit oligonucleotides and antisense RNA.[189,190] As in the *in vitro* translation system, one of the mechanisms of the action of the oligonucleotides *in vivo* involves[189] oligonucleotide-specific cleavage of the exogenic mRNA by the endogenic RNase H. Unfortunately, there are no literature data concerning the influence of the accuracy of the interaction of antisense oligonucleotides on the degree of inhibition of the translation or transcription of exogenic mRNA or DNA in the *Xenopus laevis* oocytes. Oligonucleotides with a length corresponding to 18–23 nucleotide residues[191] inhibit by 85%–98% the translation of the mRNA of interleukins IL-2 and IL-3 in the *Xenopus laevis* oocytes at a concentration less than 1 μM; on the other hand, the inhibition of the synthesis of β-tubulin in the same system requires a concentration of the 27-unit oligonucleotide of 20 μM.[192]

b. The accuracy of the antiviral activity of oligonucleotides

The majority of studies of the functioning of antisense oligonucleotides *in vivo* have been carried out on cultivated cell strains infected with viruses. This is evidently associated with the fact that sequences of viral RNA or DNA and the characteristic features of the development of the viral infection of the cell are known for many viruses and also with the relative simplicity of the determination of the effect of an antisense oligonucleotide on the viral gene. Studies on the antiviral effect of antisense oligonucleotides have been carried out on the viruses of the Rous sarcoma (RSV),[193] vesicular stomatitis (VSV),[178,194] herpes (HSV),[129] human immunodeficiency (HIV),[195–200] and influenza.[201–203] However, the mechanism of the antiviral action of antisense oligonucleotides has not been demonstrated in any of the above studies. Furthermore, direct evidence has not been obtained for the formation of a duplex between the oligonucleotide and the viral RNA or DNA *in vivo*. Nevertheless, numerous experimental data have accumulated which it would be of interest to examine from the standpoint of the specificity of the interaction of oligonucleotides or their derivatives with the NA target.

Thus the virtually quantitative inhibition of the multiplication of the Rous sarcoma virus in a culture of fibroblasts from chick embryos took place[193] on treatment with a 13-unit protected oligonucleotide complementary to the 3′- and 5′-terminal sequences of the RVS RNA at an ON-13 concentration in the medium of 2 μM. Some data on the dependence of the degree of inhibition of the viral infection on the accuracy of the interaction of the oligonucleotide with the NA target have been obtained[129] in a study of the inhibition of the replication of the HVS DNA by the octanucleoside methylphosphonate d(TpCp*Cp*Tp*Cp*Cp*Tp*G) (M-ON-8). This octanucleoside methylphosphonate is complementary to the acceptor site for the splicing of the HSV-1 mRNA 4 and 5. A virtually quantitative inhibition of the multiplication of the virus (the extent of 90%–95%) occurred on treatment with 75 μM M-ON-8, added to the medium simultaneously with the virus or before the latter. When M-ON-8 was added to the medium (at a concentration of 150 μM) 1 h after infection, the degree of inhibition of the development of the virus did not exceed 40%. Simultaneously with the inhibition of the HSV, the synthesis of a number of low-molecular-mass proteins of the host cell by M-ON-8 to the extent of 10%–30% occurred. Furthermore,[139] M-ON-8 was able to form a complex with a length equivalent to 6 base pairs in the acceptor site for the splicing of the IE mRNA 4 and 5 of the HSV-2 genome and hence to inhibit the multiplication of the HSV-2 virus (by 70% at an M-ON-8 concentration of 5 μM) just as effectively as that of the HSV-1 virus. Moreover, M-ON-8 could form a partial duplex with a length equivalent to 7 base pairs with the mRNA of the L protein of the VSV and with the 72–80 sequence of the rabbit β-globin mRNA. In conformity with the above findings, M-ON-8 (150 μM) inhibited the synthesis of the VSV L protein by 85% during multiplication in the mouse L cells and the translation of the β-globin mRNA by 75%–78% in the RRL *in vitro*.[166]

The increase in the length of the antisense oligonucleotide with increase in concentration made it possible to achieve rigorously selective inhibition of the multiplication of the virus. It has been shown[194,204] that a 15-unit oligonucleotide (at a concentration in the medium of 200–400 mM), bound covalently by the 3′-end to poly-L-lysine, inhibits specifically (by 85%–98%) the multiplication of the VSV, without inhibiting at the same time either the synthesis of the host protein or the encephalomyocarditis virus. The function of poly-L-lysine (molecular mass 14000) is to stimulate the permeation of the antisense oligonucleotide into the cell.

In contrast to model systems, antisense oligonucleotides can inhibit *in vivo* the development of the virus at any ripening stage. For example, for the human immunodeficiency virus (HIV), the target acted upon by antisense oligonucleotides may be the 5′-end of the viral RNA and the regions of all the initiator codons, the sections of the viral RNA involved in the splicing process (the donor and acceptor splicing sites), and the polyA backbone. Furthermore, with the aid of oligonucleotides it is possible to affect the activity of the viral reverse transcriptase, the region of the viral genome responsible for transactivation (the TAR region), and many other stages in the ripening of the virus. It has been shown[196,205] that the greatest inhibition of the multiplication of the HIV virus in the Molt-3 cells is observed in the interaction of ON-20 with the splice acceptor site (5349-5368) of the tat III gene. The repeating sequences, the nontranslatable 5′-regions of the mRNA of viral proteins, and the polyA backbone at the 3′-end of viral RNA are next as regards sensitivity to antisense nucleotides. It has been shown that the effectiveness of the inhibition of the virus depends on the length of the antisense oligonucleotide. Thus ON-12, ON-15, and ON-20, complementary to the 5349-5368 sequence, inhibit the development of synsytium by 64%, 64%, and 73% at concentrations in the medium of 26.0, 19.7, and 15.4 μM respectively.

Oligonucleotides forming complexes with viral RNA containing noncomplementary bases at the 3′-end of the oligonucleotide are effective inhibitors of viral revertase [reverse transcriptase]. Thus ON-26 and ON-14, which form with viral RNA duplexes having three and two noncomplementary bases at the 3′-end of the oligonucleotide, inhibit the enzyme activity of the HIV revertase by 80% and 75% respectively. The inhibition[205] of the synthesis of the viral proteins p15 and p24 in the presence of the same nucleotide takes place to the extent of 4%–8% only.

Tests of the antiviral activity of 15- and 20-unit oligonucleotides containing a modified linkage (phosphorothioates, butylphosphoramidates, phosphoromorpholidates, phosphoropiperazidates) led to the observation that not only antisense oligonucleotides but also ON-20 with a random sequence and homooligomers with the same length exhibit an anti-HIV activity.[196,199,200,206,207] According to the authors, there is a possibility here of several mechanisms of action of such oligonucleotides. Firstly, since the homooligomers are better substrates for the HIV revertase than the heterooligomers, they can function as competing inhibitors of the viral revertase. Secondly, the homooligonucleotides can form imperfectly matched long duplexes, which are sufficiently stable to be cleaved by RNase H. Thirdly, one cannot fully rule out a completely different inhibition mechanism. It is noteworthy that, whereas the homooligomers and oligonucleotides with a random sequence inhibit effectively the development of HIV when added to the medium simultaneously with the virus or even before the latter, the antisense oligonucleotides inhibit HIV satisfactorily also in chronically infected cells.[197,199,200] This difference can apparently be explained by the fact that any oligonucleotide and virus added to the medium simultaneously or with a small time interval (early

infection) have more possibilities for interaction (the oligonucleotide may prevent the permeation of the virus into the cell, may intensify the action of RNase H). It has been shown[197] that, in the early stages of the infection with the HIV virus, the concentrations of phosphorothioate derivatives of oligonucleotides [an antisense oligonucleotide (S-ON-I), an oligonucleotide forming an imperfectly matched duplex with eight mismatches (S-ON-II), and S-dA_{20}] necessary to inhibit the development of syncytia are approximately the same. In a chronic infection, the attainment of the same level of inhibition requires an increase in the S-ON-I, S-ON-II, and S-dA_{20} concentrations by factors of 3, 8, and 11 respectively. Similar results were obtained in other investigations.[196,206] In order to achieve 50% inhibition of the HIV virus in chronically infected cells, it was necessary to use concentrations of the antisense ON-20, the ON-20 with a random sequence, and $(dA)_{20}$ of 12, 46, and 60 μg ml^{-1}. Two random ON-20 oligonucleotides (manifesting an anti-HIV activity and serving as a control for antisense ON-20), complementary to the 5349-5368 and 280-299 HIV RNA sequences, were subjected to computer analysis.[206] It was found that the ON-20 with a random sequence, complementary to the 5349-5368 fragment, can form a perfectly matched duplex, having a length equivalent to six base pairs, with the 917–928 section or a duplex, having a length equivalent to 12 base pairs and containing two noncanonical pairs, with the same sequence. The ON-20 oligonucleotide, which is random as regards the 280–299 sequence, can form in the 8421-8437 region either a six-unit duplex or a duplex having a length equivalent to 17 base pairs with four irregular pairs. Furthermore, sequences such as T_4, T_5, A_4, and A_5 are encountered in the HIV genome 49, 13, 149, and 50 times respectively. Thus the antiviral activity of the "random" oligonucleotides and homooligomers may be associated with their ability to form imperfectly matched complexes with HIV RNA having a length equivalent to four base pairs and more and a stability which is sufficient for the manifestation of the activity of RNase H.

Oligonucleotides with a modified phosphodiester linkage exhibit a stronger antiviral activity than those with the usual phosphodiester linkage despite the virtually identical stabilities of the duplexes; O-ON-20 (T_m of the duplex 55 °C, determined at an oligonucleotide concentration of 5 μM) inhibits syncytia by 68% at a concentration in the medium of 100 μg ml^{-1}. The inhibition effected by MO-ON-20 (T_m of the duplex 51.5 °C, 5 μM), S-ON-20 (T_m of the duplex 49 °C, 5 μM), and *N*-butylphosphoramidate-ON-20 (T_m of the duplex 45 °C, 5 μM) is to the extent of 90%, 90%, and 100% respectively at concentrations in the medium of 25 μg ml^{-1} in each case.[197,199,206,207]

The study of the anti-HIV activity of antisense oligonucleotides with a modified phosphodiester linkage (phosphorothioates and nucleoside methylphosphonates) yielded a considerable amount of experimental data indicating a different inhibition mechanism, which rules out the formation of a complementary complex or, in other words, a sequence-independent inhibition of the development of the virus. Thus the methylphosphonate derivative of the 8-unit oligonucleotide d(CpCAATTCT) (the underlined nucleotides have been modified), complementary to the splice acceptor site of the HIV-1 tat-3 gene, inhibited specifically the development of synsytium and the activity of the viral revertase at a concentration of 100 μM. The synthesis of the viral RNA was inhibited both by the 8-unit nucleotide and by the oligonucleotide complementary to it (sense sequence).[198]

In the study of the antiviral activity of phosphorothioate derivatives of hetero- and homo-oligomers, it was observed that the 14-unit phosphorothioate analogues (25 μM) have the same inhibiting activity (93%–95%) as the analogous derivatives of oligonucleotides having the same sequence as the HIV RNA (78%–100%). In addition it has been observed that the decisive factor is the length of the phosphorothioate derivative:[195,199,208,209] the inhibiting effect of oligocytidine phosphorothioates increases in the sequence $d(p_SC) < d(p_SC)_{14} < d(p_SC)_{28}$. It has been suggested that such derivatives are inhibitors of the DNA polymerase activity of the reverse HIV transcriptase. It is also possible that the production of interferon is stimulated under the influence of phosphorothioate analogues of oligonucleotides.[195] The complete inhibition of the reproduction of HIV-1 in H9 cells has been achieved[209] with the aid of the phosphorothioate derivative of a 27-unit oligonucleotide (25 μM) complementary to the regular HIV-1 gene rev. The mechanism of such effective action of the above derivatives has not been ultimately elucidated. Phosphorothioate analogues of 2′-*O*-methylribooligonucleotides with a length equivalent to 10–30 units also exhibited an antiviral activity, while the 2′-*O*-methylated oligoribonucleotides and their deoxy-analogues did not inhibit HIV in MT-4 cells.[210]

c. Inhibition of the expression of genes *in vivo*

The expression of the c-myc gene constitutes a good model for the study of the inhibition of gene expression under the influence of antisense oligonucleotides,[211–214] since the lifetime of the c-myc mRNA and proteins is 20–30 min. In the study of the expression of the c-myc gene, T-lymphocytes of human peripheral blood, stimulated by phytohaemagglutinin (PTH), are usually employed. Antisense oligonucleotides are added to the medium up to a concentration of 30 μM 4 h before the stimulation of the T-lymphocytes by PTH. It has been shown[211] that a 15-unit oligonucleotide complementary to the first five codons for c-myc mRNA inhibits the mitogen-stimulated proliferation of cells to the extent of 80%, while an oligonucleotide with a random or coding sequence does not have an inhibiting effect on the cell proliferation. A similar pentadecamer induced in another study[212] a decrease in the level of synthesis of c-myc protein by 50%–80%. The inhibition of the expression of the c-myc gene is associated with the decrease in cell growth and the induction of myeloid differentiation. Treatment of HL cells with antisense 15-unit oligonucleotides (4 μM, 37 °C), which form complexes containing from 2 to 12 irregular base pairs (T_m = 56 °C and 41 °C for the perfectly matched duplex and the duplex with two G · T pairs respectively) did not alter the time required for the doubling of the number of cells. In the presence of the fully complementary nucleotide, the cell doubling time increased by a factor greater than 2.

The rigorously specific inhibition of the expression of the c-myc gene by the antisense 15-unit oligonucleotide complementary to the first five codons of the c-myc RNA apparently occurs[213] because, according to the calculated secondary structure of the c-myc mRNA, the ON-15 binding site is in the region of the loop, i.e. is open to interaction with ON-15. The specific inhibition of the expression of the c-myc gene, associated with the decrease in the level of both the c-myc protein and the c-myc mRNA, was achieved with the aid of a 17-unit antisense nucleotide bound covalently to poly-L-lysine.[214] At the concentrations employed (less than 1 μM), neither the random oligonucleotide nor one forming an imperfectly matched complex with six mismatches exerted an appreciably inhibiting effect on the expression of the c-myc gene.

Apart from the studies listed above, there is an enormous number of others devoted to the action of antisense oligonucleotides on different mRNA and genes in which the level of specificity of the interaction could not be determined simply. The inhibiting effect of the oligonucleotide was followed either from the enzyme activity of, for example, chloramphenicol : acetyl transferase[215] or from the inclusion of ^3H TTP in Balb/c3T3 cells after incubation with an oligonucleotide complementary to PCNA mRNA.[216]

4. Interaction of reactive derivatives of oligonucleotides with NA targets

The mechanism of the inhibiting activity of antisense oligonucleotides on different biochemical and molecular-genetic processes *in vitro* and *in vivo* includes as one of the main stages the formation of a complementary complex between the oligonucleotide and the NA-target. As shown in previous Sections, the stability of the ON-NA target duplex is one of the decisive parameters for the effective inhibition of both the translation of mRNA and the expression of genes.

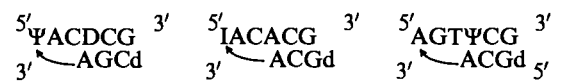
In order to create more effective inhibitors, derivatives of oligonucleotides capable of forming duplexes with an enhanced stability have been devised. Thus the introduction into the oligonucleotide of intercalators such as acridine, *N*-(2-hydroxyethyl)-phenazinium, and ethidium bromide leads to an appreciable stabilisation of the duplex, but the complex formation itself remains an equilibrium process. Furthermore, it is well known that the translating ribosome possesses unwinding activity, i.e. the ability to melt fairly stable duplexes.[153,154] On the other hand, it has been shown in a number of studies that, in order to inhibit the translation of mRNA, RNase H is necessary apart from the complex formation with the antisense oligonucleotide. However, not all the heteroduplexes are cleaved by the RNase. For example, the derivatives of oligodeoxyribooligonucleotides with a modified phosphodiester linkage (phosphorothioates) are very stable in the cell and form stable complexes with RNA, which are not substrates of RNase H.

Derivatives of antisense oligonucleotides which would not only form a stable duplex with the NA target but would also damage the nucleic acid molecule as a result of a site-specific interaction, or, in other words, contain the reactive unit, are therefore very promising. There is then a possibility of several types of reactive groups bound covalently to the antisense oligonucleotide:

(1) alkylating groups which lead to the formation of a covalent bond between the oligonucleotide and the NA target;

(2) groups capable of being photoactivated, the activity of which is induced by UV radiation, resulting also in the formation of a covalent bond between the 'addressed' reagent and the nucleic acid;

(3) cleaving groups, that is groups such as Fe · EDTA, Cu · 1, 10-phenanthroline, and Fe(Co, Mn) · porphyrins, as a result of the activity of which the sugar phosphate skeleton of the nucleic acid is cleaved.



The methods of synthesis of oligonucleotides, the properties important for their use, and the results of the specific action of these derivatives on NA targets have been examined in a number of reviews.[5,9,217–222]

The majority of studies on the site-specific modification or site-specific damage of the NA target have been carried out on model matrices: synthetic oligonucleotides, homopolymers, short DNA fragments (up to 400 bases), tRNA, and 16S rRNA, oligonucleotides of different lengths being used. The advantages of the reactive groups used were demonstrated, the effectiveness of the reaction was estimated, and modification conditions were selected in these studies. In some investigations, the positional specificity of the modification was determined.[216–220] The specificity of the modification (complementation accuracy) was studied only in a few investigations, which will be examined in the present section.

Certain data on the accuracy of the interaction of the reagent and the NA target may be found in a series of communications (see the relevant reviews[2,5,9,219,221,229]) on the site-specific modification of nucleic acids by oligonucleotide derivatives containing the *N*-2-chloroethyl-*N*-methylaminophenyl group bound either to the 3′-end of the oligonucleotide via a benzylidene linkage or to the 5′-end via phosphoramide linkage.

The first experiments on the site-specific modification of natural nucleic acids (23S + 16S rRNA of *E. coli*) by derivatives of tetra-, penta-, and hexaadenylates carrying the 2′,3′-*O*-[4-*N*-(2-chloroethyl)-*N*-methylamino]benzylidene group (=CHRCl) at the 3′-end of $(Ap)_{n-1}A=CHRCl$ ($n = 4-6$)[229–231] demonstrated the highly effective modification of 16S + 23S rRNA. At a concentration of the reagents less than or equal to the concentration of the NA target, between 70 and 98% of the reagent present in the reaction medium was consumed on the alkylation of the RNA. This process was not distinguished by chemical selectivity—all the bases, except uridine, were modified.[230] The degree of modification of 16S + 23S rRNA was[230] 5 mol of $(Ap)_4A=CHRCl$ per mole of RNA at 20 °C and about 30 mol at 5 °C. According to the analysis of the sequence, in 16S and 23S rRNA there are no U_5 and longer fragments capable of ensuring the formation of a sufficiently long duplex with the reagent and only three U_4 and 24 U_3 sequences. Reagents of the type $(Ap)_{n-1}A=CHRCl$ ($n = 4-6$) apparently formed either partial duplexes with the U_3 and U_4 sequences or imperfectly matched complexes incorporating the U_3 and U_4 backbones. The values of $R_{x(app)}$ for the binding of the reagents $(Ap)_{n-1}A=CHRCl$ ($n = 4-6$) to RNA, found by Karpova,[229] proved to be similar and corresponded to $(3-7)\times10^5$, 7×10^5, and $(3-7)\times10^5$ litre mol^{-1} for reagents with $n = 6$, 5, and 4 respectively. Comparison of the values of $K_{x(app)}$ with those of K_x estimated by the method of Uhlenbeck et al.[97] showed that $K_{x(app)}$ is approximately equal to K_x for the duplex $A_4 \cdot U_4$.

The selectivity of the site-specific modification of nucleic acids was first estimated in the determination of the points where yeast $tRNA_I^{Val}$ was modified by the reagent d(pCpG)rA=CHRCl.[232,233] It was shown that three bases in $tRNA_I^{Val}$ with the same disposition relative to its CpG sequence, are alkylated. The modification occurred in the following duplexes:

where the arrow indicates the tRNA sequence. The adenine residue in these duplexes either forms an irregular pair or does not participate in complex formation.[234]

Subsequently, a similar analysis of the accuracy of the interaction of the addressed reagent and the NA target was carried out for the $ClRCH_2NH$ reagents. It was shown[235] that the reagent $ClRCH_2NH$-p(dAACCA) alkylates selectively the G_{24} $tRNA^{Phe}$ base of *E. coli*. Judging from the position of the modification point, G_{24} is alkylated in the imperfectly matched complex

where the arrow indicates the *p*-NA-CH_2-RCl group, whereas the section of the $tRNA^{Phe}$ molecule to which the reagent was addressed is involved in the formation of the secondary structure.

The reagent $ClRCH_2NH$-p(dATTTTCA), fully complementary to the sequence in the anticodon loop of $tRNA^{Phe}$, modifies three guanine residues:[236] G_{10}, G_{24}, and $G_{28/29}$. Whereas the alkylation of $G_{28/29}$ most probably takes place when it is part of the composition of a perfectly matched duplex with the selected sequence, G_{10} and G_{24}, which have similar secondary and tertiary structures, are apparently modified when they are part of the composition of an imperfectly matched complex with the corresponding sequence in the D-loop.

The ratios of the rates of the addressed and unaddressed (outside the complex) modifications (f) for $G_{24}+G_{10}$ and $G_{28/29}$ are 58 and 460 respectively, i.e. the level of the nonspecific modification is 2% for G_{10} and G_{24} and less than 0.3% for $G_{28/29}$. The results of the analysis of the modification points of tRNA indicate an enormous influence of the steric structure on the selectivity of the site-specific modification.

Interesting results have been obtained in studies[150,237] on the site-specific modification of the 302 unit DNA fragment by $-NHCH_2RCl-$ and $>CHRCl$ derivatives of 6-14-unit oligonucleotides. It was shown that, by virtue of the formation of an inner hairpin, the 144–149 section is entirely inaccessible for the binding of the reagent $ClRCH_2NH$-pd(TTCCC)rA, whereas the open 261–266 section is modified by this reagent. The modification of this fragment when the latter forms part of an imperfectly matched duplex with an oligo-G-sequence near its 5'-end has also been observed. In addition, the alkylation of G_{179}, which is apparently close to the reagent binding section (261–274), has been noted.[16,149,237-237]

The problem of the selectivity of the site-specific modification has been investigated in greatest detail in a series of studies[240-244] in relation to the modification of the 16S rRNA of *E. coli*, the length of which is equivalent to 1542 nucleotides, by oligonucleotide derivatives carrying the $>CHRCl$ group at the 3'-end. In such a long target, having a fairly complex steric structure, one may encounter, together with sequences fully complementary to the oligonucleotide address, also incompletely complementary fragments. Such fragments may be detected with the aid of a special program for the analysis of nucleic acid sequences — context analysis.[245] For example, according to the data of such analysis, the reagent complementary to the 771–781 region may form imperfectly matched complexes, containing at least five canonical base pairs, also with 12 sections of 16S rRNA. Estimation of the interaction energy showed[240] that at least three out of the twelve imperfectly matched duplexes of the reagent with the target have a stability which does not differ greatly from that of the fully complementary duplex, namely the duplexes with the sequences 442–452, 663–683, and 883–893. It has been demonstrated experimentally that this reagent does indeed modify 16S rRNA along eight sections and that four of these are modified to approximately the same extent (771–781, 442–452, 663–673, and 883–893). This apparently means that the reagent does not interact via all the bases with the fully complementary section, since the complementation section is involved in the formation of the secondary structure. A similar influence of the steric structure on the effectiveness of the site-specific modification has been demonstrated also in the alkylation of 16S rRNA by other reagents[240-242] and in the site-specific modification[235,236] of $tRNA^{Phe}$.

The influence of temperature and the reagent concentration on the selectivity of the modification has been investigated.[243] At 20 °C, the increase in the reagent concentration from 1.3×10^{-1} to 2.5×10^{-6} M entailed the increase in the overall limiting degree of modification of 16S rRNA from 0.05 to 0.62, whereas the modified fraction in the perfectly matched complex fell from 0.38 to 0.22. On raising the modification temperature from 20° to 40 °C at a reagent concentration of 4×10^{-5} M, the overall degree of modification fell from 2.57 to 0.64, but the modified fraction in the perfectly matched complex increased under these conditions from 0.24 to 0.35. Thus, despite the complexity of the model investigated, its modification is likewise determined by the stability of the duplexes formed by the reagent with the NA target. The additional stabilisation of the 16S rRNA · reagent duplex with the aid of an auxiliary effector oligonucleotide [complementary to the section of 16S rRNA immediately adjoining the reagent binding section, carrying at its 5'-end the *N*-(2-hydroxyethyl)-phenazinium residue and stabilising the duplex as a result of the cooperative interaction with the reagent[246]] led to an increase by a factor greater than 2 in the modified fraction of the RNA in the perfectly matched complex but did not affect under these conditions the modification of the imperfectly matched duplexes.[244]

Unfortunately there are virtually no data on the selectivity of the inhibition with the aid of reactive oligonucleotide derivatives of any biochemical processes occurring with participation of nucleic acids. In this connection, one may mention only two studies where the inhibition of the translation of mRNA with the aid of reactive oligonucleotide derivatives was investigated. It has been shown[247] that preliminary incubation of the total mRNA of the cells of the MOPC 21 mouse plasmocytoma with the $ClRCH_2NH$ derivative of an 11-unit oligonucleotide complementary to the sequence of the light chain of immunoglobulin G (coding for the variable section of the protein) leads to the quantitative inhibition of the synthesis of not only the light but also the heavy chain of Ig-G in the RRL.

Similar results have been obtained in a study[221] in which psoralen derivatives of 12-unit oligonucleotides were used to inhibit the synthesis of mouse α- or β-globins in the RRL. The reagent, fully complementary to the α- or β-globin mRNA, inhibited the synthesis of both globins to approximately the same extent. However, the authors of the above studies do not discuss the results from the standpoint of the specificity of the interaction of derivatives of antisense oligonucleotides with mRNA.

V. Conclusion

The data presented in the review show that the problem of increasing the complementary accuracy of the interaction of RNA and DNA with antisense oligonucleotides and their derivatives is a principal one in the study of effect of site-specific interaction on nucleic acids both *in vitro* and *in vivo*. The experimental data available at present on the thermodynamics of perfectly matched duplexes and duplexes with structural anomalies, obtained in the study of the interaction of model oligonucleotides, permit the hope that, by virtue of the destabilising effect of one or several mismatches, extra bases, or loops, a fairly selective interaction may be achieved between the NA target on the oligonucleotide complementary to the selected section.

In the case of site-specific modification, the problem of increasing the complementation accuracy reduces in essence to the exclusion from the reaction sphere of imperfectly matched complexes between the NA target and the 'addressed' reagent. As can be seen from the data discussed, in certain cases highly selective interaction may be achieved in systems *in vitro* either by carrying out the modification at a temperature close to the melting point of the perfectly matched complex or by using fairly low concentrations of the 'addressed' reagent ($10^{-8}-10^{-9}$ M). However, it is then necessary to take into account the fact that, simultaneously with the increase in the selectivity of the modification, the degree of alkylation of the nucleic acid along the selected section will diminish. Furthermore, in systems *in vitro* an increase in the selectivity of the site-specific modification can be achieved by employing effector oligonucleotides stabilising the duplex, which are complementary to the sequence of the NA target adjoining the binding site of the 'addressed' reagent and carrying the *N*-(2-hydroxyethyl)phenazinium residues at one or both ends. Although impressive advances have in fact now been achieved in the application of this approach to increase the selectivity and effectiveness of the site-specific modification of synthetic oligonucleotides and fragments of single-stranded DNA with a weak secondary structure, there are so far insufficient data to postulate that this approach will prove just as productive when applied to high-molecular-mass nucleic acids having a complex steric structure.

Evidently, in inhibition with the aid of antisense oligonucleotides and their derivatives of processes such as translation, transcription, and others, occurring in systems *in vitro* let alone *in vivo*, the accuracy of the effect is determined not only by the differences between the stabilities of the perfectly

and imperfectly matched complexes but also by the steric structure of the NA target, the interaction of the antisense oligonucleotides with other biopolymers involved in the process investigated, and also the mechanism of the inhibition of the given process with the aid of the antisense oligonucleotide. For example, translation is inhibited because mRNA is either cleaved by RNase H or loses the capacity to be translated by the ribosome after the formation of a duplex with the antisense oligonucleotide. Therefore one can hardly assume that the approaches developed for model systems where synthetic oligonucleotides or fragments of single-stranded DNA are used as matrices can be sufficiently effective in increasing the specificity of the inhibition of the above processes.

In our view, the methodology of the approaches used to increase the specificity of the influence on the genetic apparatus requires profound physicochemical and biochemical studies in model systems involving different stages of the processes which ensure the storage, replication, and utilisation of hereditary information (replication, transcription, reparation, translation, etc.) in cells and viruses. The possibility of establishing the primary structure of virtually any nucleic acid allows the creation of specific oligonucleotide and polynucleotide addresses to a great variety of sections of the generic apparatus in living organisms, and the development on this basis of new approaches designed to increase the selectivity of the specific influence, which take into account fully both the characteristics of the steric structure of the given nucleic acid and the imperfect direct repetitions of selected complementation sections, as well as data on the thermodynamics of perfectly and imperfectly matched duplexes.

Thus the problem of the complementation accuracy of the interaction of antisense oligonucleotides and their derivatives with nucleic acids is at present one of the most acute problems in the study of site-specific influences on nucleic acids.

Studies of heterogeneous catalytic systems and of their models by scanning tunnelling microscopy

Sh K Shaikhutdinov, D I Kochubei

Contents

I. Introduction	409
II. Principles of the scanning tunnelling microscopy method	410
III. Studies of surfaces by scanning tunnelling microscopy	410

Abstract. Studies of carbon materials, oxides, metals, clusters, and model catalysts, of potential interest in the field of heterogeneous catalysis, are reviewed. The principles of the method and its possible applications are discussed. 127 references.

I. Introduction

Progress in heterogeneous catalysis is largely dependent on improvements in our understanding, at the molecular level, of surface structures and of surface processes. Various methods of studying surfaces are used for this purpose. Workers in this field have tried for many years to see atoms by observations in an optical microscope. This visualisation of the surface structure at the atomic level was made possible by the development, in 1981, of scanning tunnelling microscopy (STM).[1]

The principle of the STM effect is based on recording the tunnelling current between the sample and a needle scanning the sample surface (Figure 1). We know that in the case of a one-dimensional potential barrier[2] the tunnelling current is exponentially dependent on the width and height of the barrier (the distance between the tip of the needle and the surface, i.e. the tunnelling length, and the work function of the sample and needle materials respectively). This exponential dependence accounts for the high resolving power of the STM method (~ 1 Å in the plane of the surface and 0.1 Å at right angles to it). Furthermore, studies by STM offer the additional advantage that the measurements are non-destructive, are aimed at the surface layer itself, and can be made in liquids and in gases as well as in a vacuum. The main weaknesses of the method, which limit the range of applications of STM, include the stringent elimination of all mechanical vibrations, the small size (up to 10 μm^2) of the scanning region, and (perhaps most importantly) the fact that the measurements are confined to electrically conducting samples. The latter limitation provided a stimulus for the development of a whole family of new microscopes based on the STM concept: these include the atomic force microscope, which can be used with non-conducting as well as with conducting materials, the magnetic force microscope, the thermal microscope, and others.[3]

Recent studies of scanning tunnelling microscopy and of similar methods of surface analysis have shown that the analytical possibilities of these techniques are increasingly wide-ranging.[4, 5]

In spite of many suggestions of potential applications of STM in studies of catalytic systems, the first reports of studies of actual catalysts have only recently appeared. Evidently, difficulties have been encountered firstly because heterogeneous catalysts usually consist of a multiphased system on a highly dispersed (and often non-conducting) carrier, and secondly because at present surface structures are studied by STM without an element analysis. Therefore research must be confined to model systems consisting of metal single crystals, small particles on a conducting substrate, metal oxides, and carbonaceous materials. The present review is aimed at materials of these types.

STM began to be used here later than in some other countries, and this partly accounts for our lag in this field. We hope that this review will stimulate the interest of Russian physical chemists and encourage them to study by STM the atomic structure of reactions on surfaces more widely.

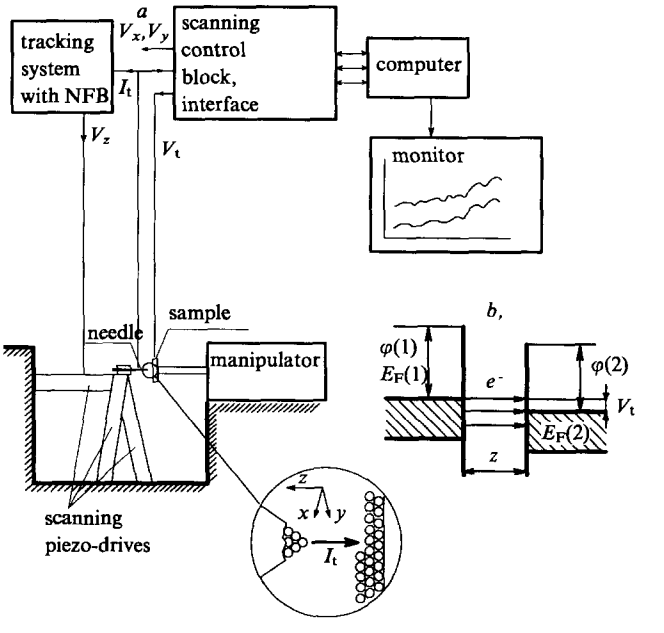

Figure 1. Block diagram of the STM (*a*) and schematic representation of the tunnelling process between the metallic needle and the sample (*b*). E_F is the Fermi energy, φ is the work function of the sample, V_t is the tunnelling voltage, I_t is the tunnelling current, z is the tunnelling distance, $V_{x,y}$ is the voltage applied to the scanning piezo-drives, V_z is the voltage applied to the z piezo-drives of the feedback system.

II. Principles of the scanning tunnelling microscopy method

Various types of STM have already been developed, including designs in which tunnelling microscopy is combined with other analytical methods of surface analysis.[6-8] A block diagram of an STM and of its component parts is shown † in Figure 1. Elements common to all types of STM include a vibration isolation system, which limits the amplitude of external perturbations of the tunnelling length to 0.05 Å; a system which allows the needle to be brought gradually closer to the surface until a tunnel current is obtained; an electronic system with negative feedback (NFB), which maintains the required tunnel current; a scanning needle with a tip having the smallest possible radius of curvature (ideally, terminating in a single atom), which mainly determines the spatial resolution of the apparatus; a frame scanning apparatus, based on piezoelectric ceramics (piezo-drives); a computer system for controlling the scan and for collecting and processing the required data.

In the topographic regime the negative feedback loop keeps the tunnel current constant throughout the scan. Under these conditions the vertical displacement Δz of the piezo-drive relative to the scanning plane reflects the geometry of the surface, and the STM picture is a $\Delta z(x, y)$ representation. In the fast scanning (constant height) regime the negative feedback loop does not follow the outline of the surface, and under these conditions the changes in the tunnel current ΔI are recorded, and the structure of the surface is obtained as a $\Delta I(x, y)$ representation. The latter regime can be used with relatively smooth surfaces, as in layer structures or single crystals, on which collisions between the needle and the surface are less likely.

An absolute calibration of the three-dimensional STM representation is usually obtained with samples of highly oriented pyrolytic graphite or samples containing monoatomic steps.

Obviously, the one-dimensional tunnelling model is a simplified first approximation which offers a qualitative interpretation of the STM picture. Attempts to develop a theory of three-dimensional tunnelling have met serious computational difficulties.

The tunnel current under conditions of weak binding between the electronic states on the surface of the needle and the sample is given by the expression[9]

$$I \approx \int_{-\infty}^{\infty} \rho_s(E+eV)\rho_t(E)|M(E)|^2[f(E)-f(E+eV)]\mathrm{d}E, \quad (1)$$

where E is the energy of a given electronic state, M is a matrix element of the electronic transition, $f(E)$ is the Fermi function, $\rho(E)$ is the state density function in the sample (s) and in the needle (t), and V is the tunnelling voltage.

At low voltages, and on the assumption that the point of the needle can be described by a hemisphere with its centre at the point $\mathbf{r}$ and that the wave function which describes the electronic structure of the surface has the form of an s-type atomic function, formula (1) can be simplified to[10,11]

$$I \sim V\rho_s(\mathbf{r}, E_F)\rho_t(E_F), \quad (2)$$

where $\rho_s(\mathbf{r}, E_F)$ and $\rho_t(E_F)$ are the densities of states at the Fermi level in the sample and in the needle respectively.

It is clear from Eqn (2) that in the topographic regime (I = const) the z-displacement of the STM needle, for which $\rho_t(x, y)$ is constant during the scan, takes place over a contour of constant local density of electronic states on the sample surface.

The results obtained by STM reflect not so much the geometric topography of the surface as its electronic structure, which is itself determined by the arrangement of the atoms. For example, the true position of the carbon atoms on the STM picture of the graphite surface is unquestionable. However, the image of a single atom adsorbed on an ideally smooth surface scanned by an atomically sharp needle can have different heights, depending on the tunnelling voltage, and it can even appear as a hollow.[12,13] This is due to the dependence of the electronic state density on the applied tunnelling voltage [see Eqn (1)]. This phenomenon complicates the interpretation of the observed STM picture, but it also allows the surface states to be probed. For small needle potentials, expressions of the following general form have been obtained for the differential conductivity:[14,15,18]

$$\frac{\mathrm{d}I}{\mathrm{d}V} \sim \rho_s(\mathbf{r}, V)T(V),$$

where $T(V)$ is the transparency of the barrier for a tunnelling voltage V.

By establishing the dependence of the tunnel current on the voltage we can measure the density of electronic states above and below the Fermi level, and in particular we can obtain direct information on the position of the energy gap in semiconductors. Experimentally this is done by suppressing the negative feedback during the time needed to measure the current–voltage characteristic. If this procedure is applied at all the scanning points on the surface the method is called scanning tunnelling spectroscopy (STS). It has yielded spectroscopic representations $[I(x, y, V)]$ of Si(111)–(7×7)[16,17] and GaAs(110)–(1×2) structures,[18] from which the atoms on the surface could be identified.

Thus more detailed information on the structure of the surface can be obtained by recording the STM image for different values of the tunnel voltage.

The parameters which mainly determine the tunnelling by electrons are the height and shape of the tunnel barrier. From the simplified formula for the tunnelling current

$$I \propto V\exp(-az\sqrt{\varphi}),$$

where a is a constant, it follows that the average barrier height φ can be determined by measuring the changes in barrier current (ΔI) produced by changes in the tunnelling distance z,

$$\varphi \approx \left(\frac{\Delta \ln I}{\Delta z}\right)^2.$$

The work function of the material of the sample is obtained in this way.[2] These measurements are usually made by the phase detection method: this gives the STM representation as a $\varphi(x, y)$ dependence, which often offers a contrast better than that of a $\Delta z(x, y)$ topogram of the surface. It should be noted that the measured absolute values of the work function are often much lower than the known values, even when the experiment is carried out in a high vacuum. Usually this is attributed to adsorbates on the surface of the sample or of the needle.[19] Another possible explanation is that at short distances between the needle and the sample the height of the barrier decreases until a point contact is produced.[20-22]

Thus in order to analyse the processes taking place in STM and the experimental results obtained by this method we require additional information, including new theoretical models of the electronic structure of the surface.

III. Studies of surfaces by scanning tunnelling microscopy

1. Carbon materials

Highly oriented pyrolytic graphite (HOPG) is one of the materials most extensively studied by scanning tunnelling microscopy. It offers a number of advantages for the development of the STM technique, including a flat hexagonal layer structure extending over thousands of angstroms, and it is chemically inert. Nevertheless the STM pictures show some unusual features even for this relatively simple material.

Thus, samples of HOPG have shown an anomalously high atomic corrugation (the Δz_{max} value for an atomically flat surface

†The present writers have constructed an STM on the basis of an SO-03 Auger spectrometer.

with periodic packing), making neighbouring atoms non-equivalent in the STM picture and producing a trigonal rather than hexagonal symmetry in the resulting map.[23, 24]

One possible explanation of the anomalous corrugation, reaching ~1 Å, is that the tunnelling current is proportional to the local density of electronic states. According to theoretical calculations[11, 14, 25] the contours of constant density of states at the Fermi level show corrugations with an amplitude of ~0.8 Å, whereas in the total charge density contours the corrugations are only 0.2 Å high.

However, giant corrugations up to 8 Å in amplitude are often observed: these cannot be explained in terms of changes in the local charge density. One explanation proposed for this phenomenon assumes that at small tunnelling distances the interaction between the point and the sample produces elastic shifts of the surface atoms of graphite, and thus enhances the observed amplitude of the corrugations.[26] An alternative explanation relies on the shift of impurities and adsorbates (rather than of the graphite atoms themselves) on the surface of the sample or of the needle. Thus, it has been shown by electron microscopy[27] that when graphite is scanned in air microscopic carbon whiskers are formed on the tip of the needle: their deformation under the action of interatomic forces centred on the sample is assumed to result in giant corrugations.

The apparently trigonal symmetry of the basal plane of HOPG is usually attributed to the asymmetry of the local charge density distribution between neighbouring atoms. The local electron density on the surface is lower on the carbon atoms located above the atoms of the second layer, and therefore their image is suppressed in the STM picture.[28]

Another special feature of HOPG is the presence of surface superstructures, detected as a regular variation of the amplitude of the atomic corrugation of the graphite.[29–32] The lattice periodicity of the superstructures can reach hundreds of angstroms. Evidently, these superstructures can be classified into two groups.[33] The first includes superstructures whose period and amplitude depend on the angular mismatch between neighbouring graphite layers. In this case the STM picture reflects a real property of the surface: the difference in azimuthal orientation between the first two layers of graphite atoms. In the second group we find superstructures with constant period and amplitude, which show a sharp transition to the normal graphite structure. In this case the STM picture does not reflect the real structure of the surface: it is due to the presence on the tip of the needle of a crystalline graphite layer plane-parallel to the surface. The second class of superstructures is the more common, suggesting ready contamination of the point.

Effects arising from the formation of structures differing from the normal graphite structure can complicate the study of molecules adsorbed on HOPG, especially when the adsorbate is accommodated with a periodic packing.

The symmetry type of the STM picture of HOPG is determined by the electronic structure of the neighbouring carbon atoms, which is strongly influenced (as was pointed out above) by their interaction with the atoms of the underlying layer. This effect has been allowed for[34–39] in studies of graphite intercalation compounds (GIC) whose Fermi surface was controlled[40] by introducing electron donors or acceptors.

Thus, the STM pictures[34] of a GIC of the donor type (MC_8, M = K, Rb, Cs) show a 2×2 structure over a wide range of tunnel voltage and current (Figures 2*a* and 2*b*), determined by the distribution in space of a layer of donors under a layer of graphite.[37, 38] In the $CuCl_2$–HOPG system, which contains a GIC of the acceptor type,[35] the STM picture depended on the sign of the tunnelling voltage. When the electrons are tunnelling from the needle into the sample (at the electron localisation sites shown in Figure 2*d*) the STM picture has a clearly developed hexagonal symmetry. This indicates equivalence of the carbon atoms in the elementary cell of the basal plane, corresponding to a large decrease in the interaction between planes. When the polarity is inverted the STM picture is determined by the layer of acceptors and by their distribution under the upper graphite layer. However, a similar dependence of the STM image on the sign of the applied voltage is not found in compounds of graphite with electron donors. This means that in GIC of the donor type both occupied and unoccupied states are present near the Fermi level, and can contribute to the tunnelling. In the case of intercalation by a donor the charge transfer is relatively large, and if the packing of the donor layer matches that of the graphite the modulation of the electron density in the surface layer by the intercalated metal is more marked than in compounds of the acceptor type, in which the charge transfer is small and the packing is unmatched.[35]

A study of the $KHgC_4$ and $KHgC_8$ systems detected[39] a matched 2×2 superstructure in addition to the hexagonal graphite structure. This work led to the conclusion[34, 39] that the 2×2 structure is the result of a periodic arrangement of the potassium ions beneath a graphite layer. Furthermore a new orthorhombic superlattice was detected for the $KHgC_8$ complex, with parameters $a = b = 8.9$ Å and $\angle\gamma = 89°$, whose orientation is independent of the orientation of the graphite lattice. This structure is believed to be related to the waves of charge density observed in layer systems based on metal chalcogenides.

It can be seen that tunnelling microscopy offers valuable new information in studies of intercalation compounds.

Important new topics in the study of carbon materials include defect structures on the surface, the processes induced by bombarding the surface with various particles, and the amorphisation of graphite.[41–44] In particular, treating pyrolytic graphite with a methane plasma in a high-frequency discharge produces a strong modification of the surface:[44] the bombardment by the plasma ions yields amorphous formations ~50 Å in diameter which increase in number (but not in size) as the exposure time is increased. Obviously, regions of amorphous carbon are formed on defects induced by the plasma ions. In samples which had not been bombarded reproducible patterns could not be obtained because the operation of the STM was destabilised by the formation of an electrically insulating layer on the surface.

Recently reported[45–49] studies of other carbon materials have greater practical interest than the studies of HOPG. Thus, graphite structures obtained by the pyrolysis of various hydrocarbons have been examined,[45, 46] as well as carbon fibres.[47, 49] As could have been expected, pyrolytic graphites have a planar structure, but unlike the HOPG they contain large structurally

inhomogeneous regions determined by the method of preparing the graphite. The structure of the carbon fibre also depends on the method of synthesis, and on the temperature of heat treatment. For example, high-temperature graphitisation of the fibre results in ordering of the structure at the atomic level, as is clearly shown by the STM pictures.[47]

Scanning tunnelling microscopy has been used successfully in studies of the processes involved in the etching of the basal plane of graphite during the gasification of HOPG in air.[50, 51] This work has made clear the unique possibilities of the method in studies of reaction kinetics at the molecular level.

Heating a clean, freshly cleaved HOPG surface at 773 – 873 K in air produces a uniform distribution of circular etch pits one monolayer deep over the surface. The concentration of these pits varies between 0.1 and 13 μm^{-2} in different samples. Their diameter (but not their number) increases linearly with the time of heat treatment. The rate constant for the removal of carbon on one active centre calculated[50] from kinetic data is 0.5 s^{-1}. A typical activational temperature dependence of the growth rate of the diameter for the monolayer etch pits has been observed[51] between 773 and 973 K. The activation energy determined from these data is 127 kJ mol^{-1}, which is close to the value[51] obtained gravimetrically (147 kJ mol^{-1}). Successive heating and cooling cycles increase the size of the old pits as well as producing new pits. Therefore the etching is controlled by the presence of vacancies or impurities on the surface. Increasing the heat treatment temperature above 973 K produces a large number of concentric pits one monolayer deep, and at 1173 K the STM picture consists of conical craters.

Many different types of tracks, channels, and craters are seen on samples which have been stored in air for long periods or exposed to chemically active (or even inert) materials before being heat treated. Since in these cases the STM pictures are independent of the nature of the impurity on the HOPG surface it has been suggested[50] that the carbon gasification centres may be formed by the mechanical interaction of the impurity particles and the graphite particles.

2. Metals

Attempts to achieve a resolution sufficient to observe atoms on a clean metal surface have long been unsuccessful, though some workers have observed monatomic steps and reconstructions of the surface of single crystals induced by gases.[52–54] The lack of resolution on an atomic scale on metallic surfaces has been interpreted as a manifestation of the high level of delocalisation of the electron density in metals. The first report of atomic resolution on a close-packed surface of monocrystalline gold was published[55] in 1987. The anomalously high amplitude (up to 0.5 Å) of the atomic corrugations was stressed. By analogy with graphite this phenomenon was ascribed to the presence of local surface states near the Fermi level. In the following year another group of workers[56] proposed a different explanation of the atomic resolution which they had observed on an Al(111) monocrystal. A reasonably reproducible method of modifying the point of the STM to give an enhanced resolution was proposed: it was based on the experimental observation that the point is elongated by ~25 Å when a pulse of increased tunnelling voltage is applied to it over a gold or aluminium sample. It was suggested that this pulse induces the transfer of a small cluster of material from the substrate to the tip of the needle, thus increasing the contrast of the image. The same workers attribute the anomalously high corrugations to elastic deformations of the resulting cluster by the interatomic forces which it experiences from both sides (the needle and the sample).

Different theoretical interpretations of the anomalous amplitude of the atomic corrugations on metal surfaces have already been proposed. According to one of these the resolution of a tungsten needle[57] can be ascribed to the elimination of all impurities from the needle, giving ideally clean tungsten, whose d_{z^2} atomic function has a smaller radius of curvature than the generally adopted s wave function model of the electronic structure of the point. An alternative theory[58] postulates that for small tunnelling gaps (in which the atomic corrugations of metals surfaces are observed) large changes in the electronic structure of the surface can take place, and the tunnelling current can no longer be assumed to flow between unperturbed electronic states In this case localised electronic states induced by the point above the Fermi level appear on the surface. It was shown that their energy distribution and the effective height and width of the tunnelling barrier are very different in the regions above the atoms and above the vacancies. As a result the contrast of the STM representation of the metal surface increases until atomic resolution is achieved. The amplitude of the atomic corrugation calculated by this model (~0.3 Å) is close to the experimentally observed value (0.1 – 0.5 Å).

The achievement of resolution on an atomic scale on metals stimulated new studies of metal surfaces, including processes leading to their reconstruction. The positions of the atoms on a reconstructed metal were first established for the (111) gold surface.[59, 60] We know that gold is the only metal with a face-centred cubic (f.c.c.) packing in which reconstruction of the (111) face into a hexagonal close-packed (h.c.p.) structure is observed. Woll et al.[59] and Barth et al.[60] were able to visualise $(23 \times \sqrt{3})$ elementary cells forming a structure of parallel lines (Figure 3*a*). A more detailed study[60] also revealed superstructures identified as 120° breaks in the lines approximately 250 Å apart, producing a zigzag pattern in the STM (Figure 3*b*). Surface steps and bulk defects do not impede the passage of the lines, though they affect the details of the picture. It is interesting to note that these lines are always closed. These results suggest a model of the reconstruction consisting in a transition from f.c.c. to h.c.p. packing in the upper atomic layer.

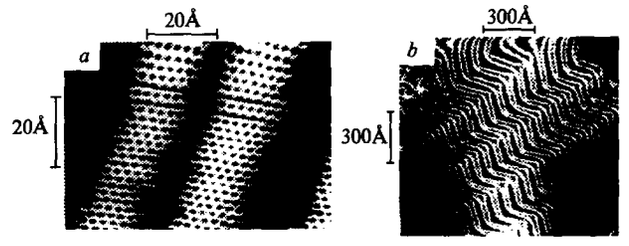

Figure 3. STM image[60] with atomic resolution of the reconstructed Au(111) surface.
(*a*) structure of parallel lines, the frame defines the elementary $23 \times \sqrt{3}$ cell, difference in height between the black and the white areas 0.2 Å; (*b*) structure of the zig-zag lines.

Scanning tunnelling microscopy results have also shown[61] that carefully prepared, clean (110) faces of platinum and gold undergo a thermodynamically stable (1×2) reconstruction by the 'absent rows' model rather than through impurity effects (Figure 4). The (1×2) reconstruction remains stable even near a screw dislocation. Increasing the concentration of impurity (mainly calcium) decreases the relative proportion of regions with a (1×2) structure and increases the proportion of (1×7) and (1×5) structures. Ultimately, at high impurity concentrations, we obtain a (1×3) structure consisting of (111) micro-facets.

An analysis of sequential STM representations of an Au(110)-(1×2) structure, obtained in a period of several hours in an ultra-high vacuum,[62] revealed a substantial motion of the surface atoms. The structural changes were found to be related to defects on the steps (i.e. to kinks) on the (100) microfacets, confirming the earlier hypothesis of an important contribution to mass transfer from these defects.

A study of the fine structure of the steps on an Ag(111) face showed that at room temperature this structure includes an irregularity of subatomic dimensions, indicating a motion of the atoms along the steps between successive frames of the scan.

Lowering the temperature to 27 K in order to lower the mobility of the atoms removes the kinks from the steps.

In situ studies by STM of the Ag(111) surface gave visual evidence[64] that an increase in temperature converts an initially regular (though stepped) surface into a disordered system as a result of the surface diffusion of atoms, with an effective transition temperature of ~350 K. The list of metals which have been studied by STM is continually growing. In particular, studies of chromium monocrystals have been reported.[65, 66]

Studies of the interaction of gases with the structure of the surface are of special interest. These are conveniently classified into two groups. The first includes the visualisation of adsorbed molecules and the identification of their adsorption sites, the second deals with surface reconstruction processes induced by gases.

The adsorption sites of the molecules can be determined only when the STM offers atomic resolution. One of the earliest studies of the adsorption of oxygen[67] was carried out on an Al(111) monocrystal surface. Even at low coverages (up to 5% of a monolayer) islets of adsorbed oxygen uniformly distributed over the surface can be distinguished, but they appear as depressions 10–20 Å in diameter rather than as prominences. This confirms that the STM image describes the local distribution of electron density. After being annealed at 800 K the sample shows some characteristic surface formations: a mound surrounded by a ring of six depressions, with three aluminium atoms round each depression. These structural features were interpreted as oxide nuclei.

The STM image of molecules adsorbed on a substrate is the result of changes in the local electron density not only at the site of the adsorbate but also on the neighbouring atoms of the substrate, as was demonstrated[68] for carbon atoms adsorbed on Al(111). As can be seen from Figure 5, the carbon atom adsorbed on a hexagonal metal lattice has a trigonal symmetry. The images of the six aluminium atoms nearest to this carbon atom differ markedly from those of the more remote atoms. Three of them are bound to the carbon and appear as pits, whereas the other three seem to project above the surface. The authors conclude from these results that the apparent changes in the vertical position of the aluminium atoms are more probably due to a redistribution of the electron density than to genuine structural changes.

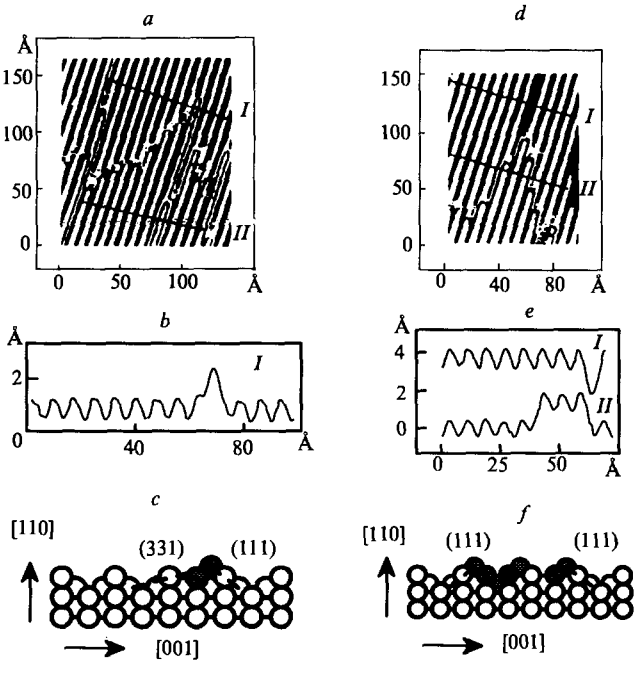

Figure 4. STM images[61] of the reconstructed Au(110) surface.

The scanning tunnelling microscopy method has also been used[69] in studies of the adsorption of oxygen on a Ni(100) single crystal. At 400 K and 15% coverage square pits with a side of ~4 Å were found in the STM pictures, and ascribed to oxygen atoms. These pits are located over cavities of the square nickel lattice. Unlike the oxygen atoms adsorbed on Al(111) the oxygen atom on Ni(100) do not tend to form islets and appear to be uniformly distributed over the surface. However, a more detailed study revealed some ordering of the adatoms on the surface. Statistical evidence of interaction between the adatoms up to the third nearest neighbour was obtained. Gradually increasing the coverage of the surface produces first a $p(2 \times 2)$ and then a $c(2 \times 2)$ packing of the adsorbed layer.

Studying the distribution of the adsorbed molecules over the surface gives information on their interaction. Thus, the formation of sulfur clusters on the Re(0001) face has been observed[70, 71] in this way. At low surface coverages (up to 25% of a monolayer) the sulfur atoms are located over the c.p.h. cavities of the Re lattice, forming $p(2 \times 2)$ or (less often) $c(\sqrt{3} \times 5)$ structures. At higher surface loadings the more close-packed $(\sqrt{3} \times \sqrt{3})R30°$ structure is replaced by clusters of three, four, or six atoms, but not by dimers, indicating the presence of three-centre interaction. The authors suggest[70, 71] that this interaction takes place through the substrate, because the distance between the sulfur atoms in the clusters is much greater than the interatomic distance in the S_2 and S_8 molecules. This assumption is also confirmed by the absence of a similar effect when the S/Mo(001) system is studied in the air.[72]

Scanning tunnelling microscopy has been successfully applied in a study of the structure of surfaces during the adsorption of

aromatic compounds. Ordered (3×3) circular formations, occasionally with a resolved fine structure ascribed to benzene rings, have been observed[73] in the coadsorption of benzene and CO (up to saturation) on a Rh(111) surface. In a study of the adsorption of naphthalene on Pt(111) it was found[74] that the adsorbed molecules can be accommodated in three positions differing by a 120° rotation of the molecule in the plane. At low coverages the naphthalene molecules are distributed uniformly, and they can rotate round their axis and move over the surface, as was demonstrated by comparing successively recorded STM pictures. The mobility of the adsorbate is greatly suppressed at higher coverages.

With large molecules the site of attachment to the substrate is difficult to determine, because several such sites may be involved, but under these conditions the visualisation of the molecule by STM can be improved until the structure of the molecule is resolved. Thus, the electron density distribution in copper phthalocyanine adsorbed on a Cu(100) substrate has been established in this way.[75] It was pointed out that this was made possible only by a correct choice of the metal support, since the phthalocyanine molecule can move along the surface (like silver phthalocyanine on a polycrystalline silver foil[76]).

The adsorption of molecules is often accompanied by reconstruction of the surface, but different types of reconstruction can be encountered, depending on the nature of the adsorbate and of the metal, on the type of face, on the temperature and on the coverage.[77]

The O/Cu system has been studied most intensively by scanning tunnelling microscopy.[78–83] On the STM pictures of the clean Cu(110) surface the monatomic steps were found to have the shape of a fringe.[78] This was interpreted as evidence of a substantial amount of diffusion of the copper atoms over the surface. Quantitative estimates of the diffusion coefficient obtained from successive STM pictures showed that a monolayer of copper adatoms (removed from the steps) can be formed in less than 20 s at room temperature. When adsorbed oxygen is present on the surface the wandering copper adatoms are captured by the oxygen atoms and the surface is reconstructed, giving a (2×1) structure formed from O–Cu–O chains extending above the base plane and oriented in the [001] direction. At higher coverages the chains combine into islets elongated in the same direction, denoting a greater probability of capture of the wandering adatom at the end of the chain than on its side. The larger islets are less mobile, but individual chains can be captured by them to produce even larger islets. By visualising the dynamics of this process[79] at about 1 frame s^{-1} it can be shown that copper atoms are transferred from the steps to the terraces on the surface. This leads to the so-called additional rows model, which differs from the missing rows model by stipulating mass transfer in the opposite sense. At even greater exposures the (2×1) structure is converted into a $c(6 \times 2)$ structure. In this case the formation of islets of the new structure beings on the steps.

Unlike the Cu(110) face, the Cu(100) gives a $(2\sqrt{2} \times \sqrt{2})R45°$ structure under the influence of oxygen. Under these conditions successive STM pictures show[80] that the nucleation and growth of islets takes place on the terraces, and that the steps are almost unaffected. The islets grow preferentially in the [010] and [001] directions. This is taken[80] as direct evidence that the reconstruction of the (100) face takes place by the missing rows model with formation of O–Cu–O chains in the [001] direction, which then coalesce in the [010] direction to give islets.

Two previously unknown structures containing 29 and 44 (1×1) cells respectively have been discovered[84] in the O/Cu(111) system. They were ascribed to the mixing of the hexagonal lattice of the $Cu_2O(111)$ face with the (1×1) copper lattice.

Surface reconstruction under the influence of alkali metals is well known, but only one study of this effect has so far been reported:[85] the mechanism of the reconstruction of the Cu(110) face induced by potassium. It was shown that at low coverages the potassium atoms are uniformly distributed as single atoms or as chains of 2 or 3 atoms in the [110] direction, and that these species (unlike oxygen) are not captured by surface steps. It is suggested that copper atoms under the potassium atom are squeezed out and migrate along the surface, ultimately landing on steps. Increasing the coverage to 15% of a monolayer results in growth of the chains, with formation of (1×4) and (1×3) structures. At still higher coverages the reconstruction ceases and the well known (1×2) structure is observed.

STM studies of the morphology of Pt(111) samples after the ion bombardment and annealing[86, 87] have made an important contribution to our understanding of the role of defects in surface processes. Irrespectively of the nature of the ion (He^+, or Ar^+) trigonal craters are formed on the metal surface at low doses and for annealing temperatures below 700 K. Increasing the annealing temperature results in the formation of monolayer pits and islets, whether the anneal is carried out during the bombardment or after it. This shows that an increase in temperature produces a substantial mass transfer between the layers. The islets formed under these conditions have a trigonal symmetry, indicating thermodynamic equilibrium. It is assumed[86, 87] that these processes are common to all metals with an f.c.c. lattice [at least, on the (111) face].

Real polycrystalline systems have not been studied in depth so far. They were used as samples during the initial stages of the development of tunnelling microscopy. Thus, Gimzewski et al.[88] compared the topographies of silver films evaporated on substrates at different temperatures with the aim of establishing the effect of surface roughness on the enhancement in hyper Raman scattering. Some studies of the epitaxy of metallic layers on metals should also be noted.[89]

The above STM studies of metals were carried out on monocrystalline samples under vacuum conditions, in conjunction with data obtained by electron-spectroscopy and structural methods of analysis such as low-energy electron diffraction, Auger spectroscopy, X-ray spectroscopy, UV electron spectroscopy, etc. Of course, under these conditions the information content of the scanning tunnelling microscopy method is substantially enhanced. Comparing different methods allows us to use scanning tunnelling microscopy in cases where alternative methods are unsatisfactory, for example owing to the small size of the metallic particles, to their very low concentration, or to their amorphous structure.

3. Clusters and small particles

The development of tunnel microscopy has stimulated considerable interest from workers engaged in the study of clusters. Applying STM to cluster studies usually involves the following steps: depositing the substance of interest on a flat, electrically conducting substrate in concentrations low enough to allow the atomic structure of the substrate to be observed; a quantitative element analysis of the composition of the surface; visualising the particles in the STM. In spite of the apparent simplicity of this approach only a few studies of clusters by scanning tunnelling microscopy have been reported. Difficulties are met even at the stage of choosing a substrate. A clean surface and ultra-high vacuum conditions are needed when monocrystals of metals or of semiconductors (of the silicon type) are chosen. In this respect pyrolytic graphite is more convenient, but (as was said above) there may be problems in interpreting the STM representation because of the possible formation of anomalous superstructures on the graphite substrate. Difficulties are also met in ensuring uniform deposition of the clusters because of the possibility of very rapid diffusion on the inert pyrographite surface, and also of uneven evaporation of the solvent when the clusters are deposited from a solution. Lastly, treating HOPG with acetone produces a regular structure with a period of ~4 Å (which eventually disappears), and treatment with a solution of $[Et_4N]_3[Re_7C(CO)_{21}]$ in acetone produces a hexagonal structure with a period of 10 Å in addition to amorphous aggregated formations.[90]

A more uniform distribution of the particles is obtained by molecular beam deposition in a stream of inert gas or by thermal evaporation in a vacuum, with condensation of the atoms on a substrate. Ligand-free particles of different size can be obtained by varying the deposition conditions. Clusters with a ligand coat and molecular complexes are usually deposited from solutions on a graphite or gold substrate. Often the deposition of the particles and the element analysis of the surface are carried out in a vacuum, and the STM study in the air (sometimes including a repeated check for changes in composition of the surface during the vacuum treatment). However, some ambiguity in the interpretation of the results cannot be avoided in these experiments.

The potential advantages of STM in studies of small particles were first demonstrated by the observation of isolated particles of silver, gold, and aluminium on a graphite substrate.[91, 92] In spite of the high mobility of the adatoms relatively stable single atoms of the metal could be detected near the larger particles. Dimers and linear trimers were also seen in the STM pictures. It should be noted that atoms were never observed over the cavities in the graphite lattice: from this result, and from an analysis of the interatomic distances, the authors suggested the presence of a strong interaction between the metal and the carbon substrate, which is suppressed by increasing the size of the particle.

This conclusion was tested by statistical studies[93] of the position of the metal atoms, and by determining the length of the metal–metal bonds in the platinum dimers and trimers. It was found that the position of the metal atoms was stable in time. An analysis of the position of the single metal atoms with respect to the graphite lattice showed that no preferential binding site could be identified, though the metal atom had the highest probability of lying above a carbon atom not directly bound to the lower layer. The average Pt–Pt distance in the dimers was 2.45 ± 0.26 Å, i.e. close to the lattice parameter of the graphite. However, the relatively wide distribution of the Pt–Pt bond lengths made it impossible to establish unambiguously whether this agreement was fortuitous or whether it was the result of platinum–carbon interactions. The trimers were mostly linear, or arranged as equilateral triangles. The average bond length of the trimers was 2.66 ± 0.32 Å, suggesting a predominant effect from the metal–metal bonds.

Humbert et al.[94] studied clusters of gold and palladium deposited by the atomic beam method in a Knudsen cell on a single crystal of natural graphite at 623 K. Under these deposition conditions the particles grow as a result of the diffusion of adatoms over the surface. According to transmission electron microscopy results the particles were condensed mainly along the graphite steps. The STM images revealed both large (~100 Å) and small particles (~15 Å), with a ratio of height to diameter of ~0.1, indicating a strong compression of the particles.

The preferential formation of flat structures is confirmed by a statistical analysis of more than 200 particles of platinum on graphite at different coverages. When the coverage is increased from 10% to 50% of a monolayer the particle diameter increases from 47 to 80 Å, whereas the average height (3.8 Å) stays practically constant. Unfortunately, these results were obtained by working in the air, which gave an oxygen content of the surface 3–4 times higher than in the initial sample immediately after evaporation of the metal. Therefore it is not clear whether the results apply to particles of platinum or of its oxide.[95]

In order to establish the effect of exposure to air on the observed form of the clusters Humbert et al.[96] compared the STM pictures obtained by depositing palladium particles in a vacuum and in air. The clusters were deposited by the atomic beam method on to a graphite substrate heated to 573 K, previously irradiated in a low-energy (50 eV) ion beam with a dose of less than 10^{12} ions cm^{-2} in order to increase the concentration of adsorbed particles on the surface. According to those workers the shape of the larger particles (> 100 Å) was unaffected by deposition in air. On the other hand an unexplained corrugation of atomic dimensions was seen on the surface of the smaller particles (15 Å) in air.

Clusters of gold deposited by a molecular beam on an atomically flat gold substrate were used to examine possible explanations of the compression of the particles observed in the STM, including artefacts associated with the production of the STM image.[97] The authors concluded that the compression occurs only in particles of size smaller than a critical size determined by the nature of the substance. The compression is due to plastic deformation, which lowers the surface energy at the contact with the substrate.

More recent papers have described STM studies of large Au_{55} clusters stabilised by ligands[98, 99] and of Pd_{561} clusters,[99] deposited from solutions on HOPG or gold substrates. The difficulty of working with these materials is stressed: the surface mobility is high, especially on graphite, and the cluster can be entrained by the point until it is transferred to the needle of the microscope. Therefore the results so far are only tentative. Similar investigations of the visualisation of heteropoly acids (hydrogen tungstophosphate)[90, 100] and BiI_3 clusters[101] have been reported.

A new class of carbon compounds (the fullerenes) has recently come to the fore in the study of clusters. Their properties have been studied by various physical methods, including scanning tunnelling microscopy.[102, 103] After mild evaporation of C_{60} and C_{70} clusters on to a gold substrate regular close-packed spherical structures spaced at a distance of ~11 Å between centres were observed on the surface. Furthermore after deposition on the Au(110) face [but not on the (111) face] C_{60} showed intramolecular structure both in air and in an electrochemical cell containing a solution of $HClO_4$.[104] A model of the electron tunnelling which allows for superexchange interactions was developed from the STM images obtained in this work.

The present writers believe that studies of clusters and of small particles by scanning tunnelling microscopy will develop mainly in the following directions: the achievement of intramolecular resolution (for example, at low temperatures); studies of the dynamics of the cluster behaviour in adsorption processes and during changes in temperature; studies of electronic structure. All these directions need new theoretical models to be developed in order to interpret the STM representations of the clusters.

4. Model catalysts

Alumina or silica are often used in industrial catalysts as carriers with a highly developed surface. Unfortunately these carriers are electrically insulating, and therefore the catalysts cannot be studied by scanning tunnelling microscopy. Substrates of carbon materials or of 3*d* metal oxides have been used for STM studies of model catalysts. Studies of transition-metal oxides are also of independent interest because these materials are themselves catalysts for many processes. Titanium oxide has been studied most intensively by scanning tunnelling microscopy.

The TiO_2 surface partially reduced in hydrogen has been studied in air as a function of the conditions of surface treatment (polishing and etching),[105] and the effect of the potential applied to the sample in an electrochemical cell on the STM picture has also been examined.[106] It was found that stable images of *n*-TiO_2 are obtained only when negative potentials are applied to the sample, suggesting a system of energy bands typical of semiconductors. The band structure of the oxide was established by tunnelling microscopy (TS) on *n*-TiO_2(001) samples[107, 108] and reduced TiO_2(110) samples.[109] The measurements were made in air. The edges of the energy gap were determined from the tunnelling spectra.[107] A hysteresis observed[108] in the tunnelling spectra was ascribed to surface states induced within the energy gap by the electric field.

From the tunnelling spectroscopy results the width of the energy gap was found[109] to be only 1.7 eV [(+0.25)–(–1.35) eV relative to the Fermi level], i.e. much smaller than the bulk value (~3.0 eV). (The possibility of this effect being due to the presence

of a large number of states near the band edges cannot be excluded, since the measurements were made in air.) Of course, a stable STM picture cannot be obtained when the applied tunnelling voltage brings the Fermi level of the metal of the needle within the forbidden band of the oxide. However, the adsorption of phenol, for example, on the titanium oxide surface produces a surface state within the energy gap ~0.45 eV below the Fermi level. Scanning for this potential difference produced STM images of the phenol, which appeared to be adsorbed parallel to the plane of the oxide. These workers adopted the approach used in scanning tunnelling spectroscopy: they scanned the sample at a predetermined tunnelling voltage.

Rohrer et al.[110] obtained atomic resolution on a sample of reduced $TiO_2(110)$ by careful surface preparation and by operating the STM in an ultra-high vacuum. The STM image showed some clearly developed lines alternating (with a period of 8.5 Å in the [111] direction) with a less well developed corrugation having a period of 3.4 Å along the lines. This picture was interpreted as an ordered packing of two-dimensional defects (crystal lattice shifts).

As in the case of titanium oxide, atomic resolution could not be obtained in an STM study[111] of ZnO(0001) monocrystals. Attention was paid mainly to the effect of surface geometry on the electronic structure of the surface. The STM pictures of the ZnO crystal contained a large number of steps in the [1010] and [1120] directions. The tunnelling spectroscopy results suggest that these steps lead to the formation of surface states in the forbidden energy gap which are probably responsible for the chemical reactivity of the surface.

The scanning tunnelling microscopy method can be used to study strong metal–substrate interactions. According to one of the models the effect is caused by the decoration of the metallic particle by the carrier, with formation of new active centres on the metal–oxide interface. One approach to the study of these interactions is to use oxide samples deposited on a metallic substrate (i.e. a reversed-phase model of the catalyst), because the electrical conductivity of the oxides is low and the effects of surface charge are substantial.

Thus, STM has been used[112] to study islets of MnO_x deposited on a Ni(111) substrate during the adsorption of CO. Measurements of the perimeter of the particles as a function of the mean coverage revealed a correlation with data for the thermal desorption of CO. These results confirm the earlier conclusion that the increased rate of hydrogenation of CO is associated with the CO adsorption centres at the metal–oxide interface.

Islets 20 Å in diameter, in the form of rings, were observed[113] on Rh(111) at submonolayer coverages of TiO_x. The ring shape was obtained only when negative tunnelling voltages were applied to the sample, and therefore its origin must be electronic. These observations were explained in terms of partial reduction of the TiO_2 at the perimeter of the particle.

Unlike TiO_2 zirconium oxide (ZrO_2) is not easily reducible as a substrate. ZrO_2/Pd(100) systems have been studied by scanning tunnelling microscopy. The results[114] suggest the presence of different types of region in this system. The first is assigned to metallic palladium, the second to semiconducting zirconium oxide. The third region is seen only on samples prepared by thermal oxidation in air at 673 K of $Zr(OC_2H_5)_4$ sublimed on a Pd(100) substrate. According to EXAFS spectroscopy results this region may be associated with palladium oxide. It has been suggested that in an oxidising atmosphere the zirconium oxide is uniformly distributed over the whole surface of the substrate. After treatment in hydrogen at 773 K for one hour the oxide islets develop a bulk structure with a sharp metal–oxide boundary. It is suggested that this boundary prevents the decoration of the metal particles by the reduced oxide when zirconium oxide is used as the carrier.

One method of visually resolving the phases in the STM picture relies on the large difference in work function between the metal and the substrate. This conclusion was reached in one of the first studies of model catalysts: ultra-dispersed particles of gold and platinum on carbon substrates, and of titanium oxide.[115] The same approach was used in the Pt/Ga_2O_3 system.[116] The metal particles were identified with a greater contrast by superposing the $\varphi(x, y)$ distribution map on the topogram of the same area of the surface. By comparing the maps thus obtained before and after an anneal of the sample at 1100 K large differences in the structure of the sample were detected. Before the anneal the platinum islets were circular and of similar size, but after being annealed the surface developed a patchwork appearance with the islets concentrated mainly along the grain boundaries of the Ga_2O_3: this may account for the decrease in the free platinum surface (according to Auger spectroscopy results) and in the catalytic activity towards the oxidation of CO (according to mass spectrometry results).

It is well known that catalytic activity is largely determined by the method of preparation of the catalyst: its previous history, and its treatment and conditioning. Therefore studies of all these stages are of interest. In this respect the studies of the effect of various pretreatments on the morphology of platinum particles on a graphite surface are particularly meaningful.[117,118] The particles were obtained by various methods, including the reduction in hydrogen of tetrachloroplatinic(II) acid H_2PtCl_4 or of tetra-ammineplatinum nitrate for 2 h at 723 K. A graphite surface (clean, or treated with nitric acid for 50 h at room temperature) was used as substrate. Detailed studies by STM were carried out at each stage. Thus, the modification of graphite by HNO_3 produced a more uniform distribution of the precursor, and the platinum salt gave smaller associations than the H_2PtCl_4. The size and the distribution of the reduced particles were less dependent on the nature of the precursor, but their microstructure and morphology were strongly influenced by the previous history of the sample. Thus, in the reduction from tetra-ammineplatinum on a substrate treated with HNO_3 the reconstruction of the platinum surface into a structure close to $(111)(\sqrt{3} \times \sqrt{3})$ induced by atmospheric oxygen was visualised for the first time for small particles.

The dynamics of the changes in the morphology of the particles on a graphite surface during the reduction of platinum from H_2PtCl_4 were studied under conditions analogous to those used in the preparation of the platinum catalyst.[118] It was shown that for short reduction times (0.5 h, 723 K) rod-shaped particles are formed, both large (1000–2000 Å long and 100–500 Å high) and small (280 Å long and 30 Å high). This large scatter suggests a partial reduction of the precursor. After being reduced for 2 h the particles break down into crystallites, ellipsoid in shape, and ultimately (after 60 h) they produce particles with a nominal diameter of ~170 Å and ~20 Å high, showing a well faceted surface. On the other hand the platinum particles evaporated in a vacuum and treated with hydrogen at 623 K for 0.5 h are spherical, with a diameter of 25–100 Å and an atomically disordered surface structure.

The study of the shape of the particles reduced from H_2PtCl_4 for different times showed that the crystallite shape is determined mainly by the reduction conditions and is less dependent on the precursor, on the type of graphite substrate, and on the method of deposition. It was found that a small proportion of the crystallites is spherical (with a ratio of length to width not greater than 1.2), and that the proportion of these increases with the reduction time though not above 40%. This is surprising, since crystallites of platinum in thermodynamic equilibrium (a metal with an f.c.c. structure) should be spherical. Studies of the degree of sphericity of the particles could be of interest in relation to the thermodynamics of small supported particles.

Molybdenum disulfide occupies a special place among model catalysts, because it has a layer structure similar to that of graphite, built of S–Mo–S packets. The atomically flat surface of MoS_2 makes this a convenient substrate for visualising deposited molecules; furthermore molecules can, in principle, be intercalated between the layers, and this should help to explain

the nature of superconductivity in structures of reduced dimensionality (see Heckl et al.[119]). The strong localisation of the electron density makes atomic resolution possible, confirming the hexagonal packing of the upper layer.[120] However, the element which appears in the STM image has not yet been identified.[121–123]

Monolayer particles of MoS_2 deposited on a pyrolitic graphite substrate have been studied in this way.[123] It was found that if the layer of sulfide is surrounded by water molecules its surface undergoes a (2×1) reconstruction. When the sample is dried an STM picture identical to that of the surface of the bulk crystal is observed. By combining the results obtained from STM and EXAFS measurements the authors constructed a model in which the molybdenum had distorted octahedral surroundings in solvated samples. The aim of those studies was to determine the mechanism of the action of hydrodesulfurisation catalysts.

Only a few studies of industrial catalysts by scanning tunnelling microscopy have been reported so far.[124–127] The first dealt with the surface topography of an iron–zirconium alloy (the precursor of an ammonia synthesis catalyst).[124]

Besenbacher et al.[125] observed a very dispersed structure in a passivated ammonia synthesis catalyst containing iron. In addition to pores and cracks they found parallel ridged structures corresponding to the crystallographic orientation of magnetite grains. They suggested that these lines appear in the STM as a result of the FeO/Fe epitaxy accompanying the passivation of the catalyst, and that they correspond to the [110] direction of the iron lattice.

Studies of the platinum–rhodium gauze catalyst used in HCN synthesis showed that the surface roughness of this catalyst varies with the conditions of the reaction.[126] However, the increase in the surface area of the catalyst during the activation calculated from STM data (as compared with the initial surface) was not more than two-fold, which is an order of magnitude less than the values obtained by other methods. Therefore the authors concluded that the main contribution to the increase in area is provided by the formation of crystallites more than 1 μm in diameter, and not by changes in morphology on a submicrometre scale.

Ex situ studies of the morphological changes in a supported Ag/SiC catalyst (for the conversion of ethylene glycol into glyoxal) were made possible by the formation of a conducting layer of silver over the whole surface of the carrier.[127] According to the scanning tunnelling microscopy results the silver particles are sintered into larger flat formations under the conditions of the reaction. Additions of small quantities of diethyl phosphite to improve the selectivity of the reaction produce a marked change in the topography of the catalyst, giving a surface of the fractal type, probably as a result of chemical erosion.

Thus tunnelling microscopy is often the only suitable method of studying catalytic systems. The amount of information which it yields on model catalysts depends on the specific properties of the system of interest.

* * *

The results discussed above show that scanning tunnelling microscopy is a powerful instrumental method of studying the surface of electrically conducting systems. Further improvements in the method for *in situ* temperature and adsorption studies and the application of the scanning tunnelling spectroscopy method in conjunction with fast scanning regimes should offer new prospects of studying the kinetics of surface processes at the atomic-molecular level.

Abstract. In the early 1970s Osawa (and also Bochvar and Gal'pern) theoretically discussed the possibility of the existence of polyhedral carbon clusters, and predicted some of their properties. In 1985 it was established by spectral methods that carbon clusters containing an even number of atoms (mainly C_{60} and C_{70}) are formed under certain conditions when graphite is evaporated under the influence of laser radiation. These discoveries stimulated extensive studies of the synthesis of polyhedral carbon clusters of various molecular masses, and descriptions of their molecular and electronic structure and of their chemical properties. The most important results achieved in these areas of research are reviewed. The bibliography contains 194 references.

I. Introduction

A remarkable discovery in the chemistry of one of the best known of all the elements (carbon) was reported during the late 1980s. A group of workers, including Kroto (UK, Sussex University) and Heath, O'Brien, Curl, and Smalley (USA, Rice University),[1] studied the mass spectra or graphite vapour obtained by laser irradiation of a solid sample and observed peaks corresponding to masses 720 and 840. They suggested that these peaks correspond to the individual molecules C_{60} and C_{70}, and that the C_{60} molecule is a truncated icosahedron with an I_h symmetry while C_{70} is a more extended structure with an ellipsoidal (D_{5h}) symmetry type (Figures 1 and 2). This paper was followed by a report[2] of the observation of a peak with $m/e = 859 = (720 + 139)$ in the mass spectrum of the vapour of graphite doped with La atoms, from which it was concluded that the internal cavity of the spheroidal C_{60} molecule can incorporate a lanthanum atom with formation of the endohedral La @ C_{60} complex. Both these hypotheses were subsequently confirmed quite unambiguously.

Polyhedral carbon clusters were called fullerenes [and their prototype, C_{60}, buckminsterfullerene (BF)] from the name of the distinguished American architect Richard Buckminster Fuller (1895–1983).† The publication of these results stimulated wide-ranging studies of the spectroscopic and other physical properties of the structure of fullerene[3] clusters.

The next step forward was taken in 1990 by Krätschmer, Lamb, Fostiropoulos, and Huffman,[4] who developed a method of preparing gramme quantities of carbon clusters by burning graphite electrodes in an electric arc in a helium atmosphere at an optimised (subatmospheric) pressure. In a study of the preparative conditions of carbon clusters in specific assemblies it was shown that the deposited soot contains a mixture of these clusters, which can be separated by extraction. As reported,[5–7] the content of carbon clusters can vary between 3% and 44%. The most selective method of separating the carbon clusters is by successive extraction with different solvents.[5] The clusters isolated in this way included molecules containing up to 200 carbon atoms. The ratio of the main components (C_{60}/C_{70}) is usually $(80 \pm 5)/(20 \pm 5)$. Approximately 1% of the graphite black consists of the heavier clusters. Other workers[6,7] detected even heavier carbon clusters in graphite black, as well as the oxide $C_{60}O$.

The most laborious part of the process is the separation of the components, since as a result of the very small structural differences between the components the properties of the various polyhedral carbon clusters such as solubility and adsorbability are also very similar. Separation can be achieved only by column or liquid chromatography methods, which are time-consuming as well as requiring large amounts of solvents.[8,9] These methods can separate some of the higher fullerenes as well as C_{60} and C_{70}.[10] However, some important technical improvements have now been introduced into the processes: these offer a faster separation, a better yield of pure products, and a more modest consumption of solvents.[11–14].

The detection of polyhedral carbon clusters in the soot deposits formed by burning benzene and other hydrocarbons[15] was unexpected. The ratio of the main components varies according to the combustion conditions, and the proportion of C_{70} can be as high as 85%. However, it has not yet been established whether this method is of preparative value.

† The C_{60} cluster, of icosahedral I_h symmetry, has the shape of a truncated icosahedron, similar to a football. Therefore this cluster has also been called carbo-*s*-icosahedron, footballene, or soccer ball.

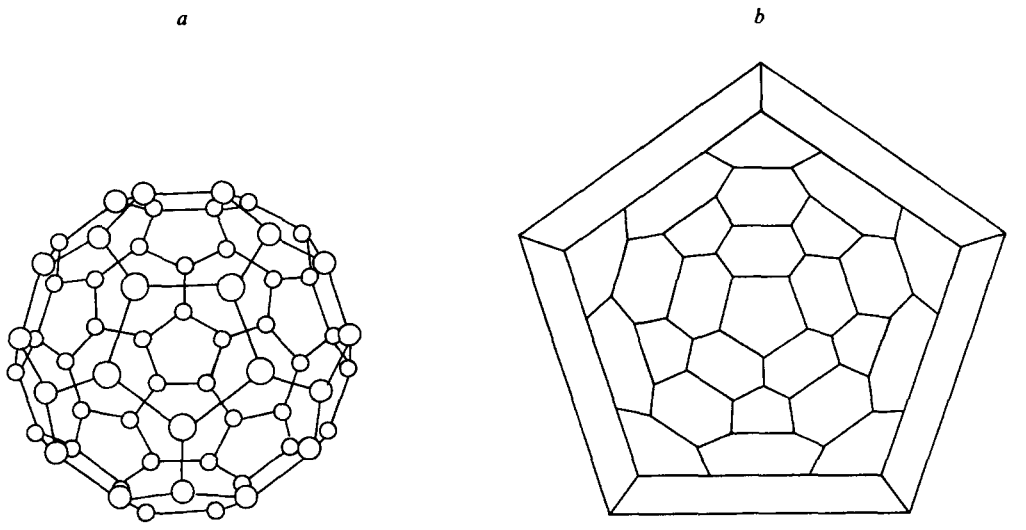

Figure 1. I_h-C_{60} carbon cluster (*a*) and its molecular diagram (*b*).

These methods of preparative synthesis of carbon clusters made a substantial number of fullerenes available to researchers and made possible the detailed study of their physical and chemical properties. Various derivatives of the fullerenes were also produced. Papers describing the synthesis of crystalline samples of C_{60} and of doped systems of the A_nC_{60} type attracted special attention. The salts of BF with alkali metals (n = 3) have superconducting properties at T_c = 18 K (A = K) and at T_c = 28 K (A = Rb).[16,17] Some reports of the preparation of superconducting doped fullerenes with higher values of T_c have not been confirmed. The highest adequately reproducible critical temperature T_c so far reported for the fullerene series is 33 K (for the caesium–rubidium salt Cs_2RbC_{60}).[18]

The main aim of the present review is to assess the current state of research on the molecular and electronic structure and on the chemical properties of the fullerenes (with the use of information available up to the second half of 1992). Because of the wide scope and of the rapidly increasing number of publications on this topic the review cannot claim to be exhaustive. Several reviews of the fullerenes have already appeared,[19,20] but it is difficult to disagree with the statement[21] that any such review should be treated as out of date even on the day of its publication unless transmitted by electronic mail. However, the conceptual and the analytical parts of recent publications should be of more lasting value.

II. Topological and metric characteristics of polyhedral carbon clusters

Various convex polyhedra are used to model the structure of carbon clusters. The topological characteristics of the clusters, defined by systems of two-centre carbon–carbon bonds, are described in terms of these polyhedra. However, it follows from the theory of valency that not all polyhedra are equally suitable for describing the carbon skeleton. The most successful for this purpose[22] are the polyhedra with faces consisting of five-, six-, seven-, or possibly eight-membered rings.‡

We shall call F the number of faces of the polyhedron, V the number of vertices, and E the number of edges. A simple relationship, known as Euler's theorem, exists between these quantities: $V+F-E = 2$. According to the theory of valency each carbon atom in the polyhedral cluster should have either three or two neighbours. It follows that in the topological method of modelling these structures the choice of polyhedra can be confined to figures in which all the vertices have an order of three. These polyhedra can be represented as planar uniform molecular diagrams of order three. By placing new vertices on some of their edges we obtain molecular diagrams which describe the topology of carbon clusters containing atoms with a coordination number of two.[23] Polyhedra with a greater number of vertices are difficult to represent clearly as three-dimensional figures. Therefore planar images (Schlegel diagrams) are used to describe the higher fullerenes. Two diagrams of this type are shown in Figures 1 and 2 for the clusters C_{60} (truncated icosahedron) and C_{70}. We shall denote as n_i the number of faces having i angles. In this case the following equality applies to polyhedra of this class:

$$3n_3 + 2n_4 + n_5 = 12 + n_7 + 2n_8 + 4n_{10} + \ldots$$

It follows directly from this formula that if the faces of a convex polyhedron in which all the vertices are of order three consist exclusively of five- and six-membered rings we must have n_5 = 12. In other words any polyhedron of this type [(5,6)-polyhedron] has not less than 20 vertices, and contains 12 five-membered rings.§ Furthermore the following formulae, which apply to the system, can be useful for discussing the topology of the clusters:

$$2E = 3V, \quad 2E = \sum jn_j, \quad n_6 = \tfrac{1}{2}V - 10 - 2n_7$$

(for polyhedra with faces consisting of five-, six-, and seven-membered rings respectively).

(5,6)-Polyhedra in which none of the pentagonal faces are contiguous are of special interest from the chemical point of view. The truncated icosahedron has the smallest number of vertices among the polyhedra of this class (V = 60).

The other criteria used in the selection of polyhedra and useful for describing the carbon skeletons are based on an analysis of their metric characteristics, consistent with the topology of the polyhedron. These characteristics include the length of the edge and the angles between the edges and between the faces. The values of these parameters, calculated for polyhedra with an ideal geometry, are used to determine the size of the corresponding carbo-polyhedra and to infer the degree of strain of their σ-frame, defined in terms of the distortions of the bond angles from their ideal values.[25–31] Table 1 shows the geometric characteristics of three polyhedra: the dodecahedron, the *s*-octahedron, and the *s*-icosahedron.

‡ We know that in some polyhedra all of the faces are regular polygons. If all these polygons are equal the resulting polyhedron is called Platonic or regular. If some of the faces are different, though formed by regular polygons, the polyhedron is called Archimedean or semiregular.[24]

§ The dodecahedron is the simplest member of the family of (5,6)-polyhedra, with n_6 = 0 six-membered rings.

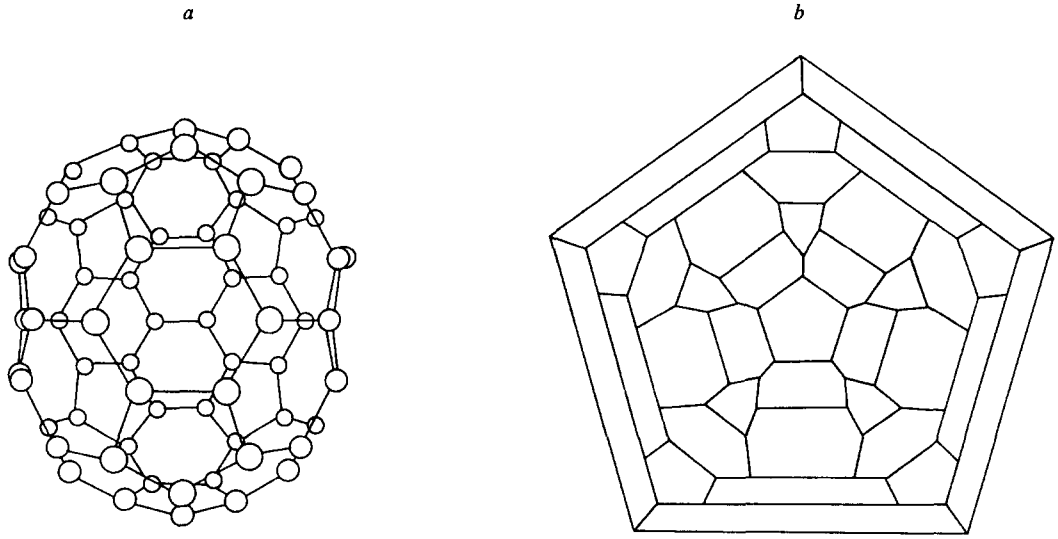

Figure 2. D_{5h}-C_{70} carbon cluster (*a*) and its molecular diagram (*b*).

We shall now examine in more detail some of the methods of constructing polyhedra to be used in the molecular modelling of the structure of carbon clusters.

The triangulation method.
Methods of designing carbon clusters of icosahedral symmetry have been discussed in several papers.[27,29,32,33] These clusters are conveniently generated by the triangulation of a sphere circumscribed about the icosahedron. The first stage is the triangulation of each face of the regular icosahedron, which divides it into small equilateral triangles. This procedure is described in terms of two integers b and c, with $b \geqslant c \geqslant 0$, and leads to a triangulation of the sphere containing V vertices: $V = 20(b^2+bc+c^2)$. Among these vertices 12 have a degree of five, and the remainder have a degree of six. If $b = c$, or $bc = 0$, the deltahedron¶ corresponding to this sphere has the I_h symmetry group. In other cases the polyhedra have the I symmetry group. Furthermore by joining the centres of adjacent faces we convert the deltahedron into a dual polyhedron: a (5,6)-polyhedron of icosahedral symmetry. In this way we can model the structures of giant fullerenes of icosahedral form. The method can also be used to model the structure of clusters of tetrahedral and even lower symmetry groups.[33] Figure 3 shows the self-repeating fragments of some of the icosahedral clusters with a large number of vertices.

The method based on the triangulation of a sphere is widely used in geodesy and in architecture. The general principles governing the application of this approach to the construction of geodesic domes were formulated by R Buckminster Fuller. The structure of the C_{60} cluster can be interpreted as the combination of two hemispheres covered with a network of five- and six-membered rings.

The leapfrog method.
The method of constructing carbo-polyhedra now known as the leapfrog method was proposed by Fowler.[34] Its application involves starting, for example, from a (5,6)-polyhedron with a relatively small number of vertices. A new vertex is then inserted at the centre of each face of the polyhedron, and connected (by new edges) to the nearest existing vertices. The next stage produces a dual polyhedron. This procedure yields a polyhedron with a number of vertices three times greater than in the original polyhedron. The essential features of the leapfrog method are illustrated in Figure 4.

¶ The term deltahedron denotes a polyhedron in which all the faces are triangular.

The petal method.
This method of constructing polyhedra was proposed for the modelling of structures having an axis of symmetry of fairly high order (5, 6, or 7). It relies on the construction of a self-repeating fragment consisting of several condensed rings. The fragments (or petals) are then interconnected to form new faces (Figure 5). The petal method has also been used in the design of chiral and of polar carbo-polyhedra.[28,29,35]

The spiral method.
This method relies on representing the structure of a polyhedron as a planar diagram in which the vertices lie on concentric circles. In this case the structure of the polyhedron can be coded as a sequence of numbers denoting the size of the rings met along a spiral path which begins at the central ring and then passes in turn through the faces of the neighbouring rings.[36] A path of this type for the C_{60} cluster is illustrated in Figure 6. To progress from the topological description of the carbon clusters to a more detailed analysis of their structure and to a prediction of their physicochemical properties we must apply physicochemical methods such as those of quantum chemistry and of molecular mechanics.

III. Quantum chemistry of the fullerenes

The quantum-chemical models of carbon clusters of the polyhedral type described in papers published up to 1985 were based on classical convex polyhedra (the dodecahedron and the truncated icosahedron).[25,37,42] The π-electron model, known to be a convenient method of describing planar conjugated hydrocarbons and their hetero analogues,[43] has been applied to the C_{20} (carbo-dodecahedron) and C_{60} (carbo-*s*-icosahedron) carbon clusters. Strictly speaking a π electron system cannot exist in a polyhedral molecule, which is non-planar and has an approximately spherical surface. However, the bonds in a carbo-polyhedron can be described by the following procedure, which is used in classical (planar) conjugated systems: each carbon atom contributes three hybrid orbitals and three electrons to the formation of three two-electron (localised) σ-bonds with neighbouring atoms. The fourth electron is placed in a hybrid ρ-orbital orthogonal to the three σ-orbitals oriented along the bonds to the neighbouring atoms.[25,29,31] Bochvar et al.[25,38,39] discussed the structure of the ρ-electron system by using the Hückel approximation in conjunction with the concepts adopted in that theory to describe the classical π-electron systems.

Table 1. Some geometric characteristics of polyhedra.[30]

Characteristic	Dodecahedron	*s*-Octahedron	*s*-Icosahedron
Number of vertices	20	24	60
Number of faces	12 pentagons	6 quadrangles + 8 hexagons	12 pentagons + 20 hexagons
Diameter of inscribed sphere (for a CC bond length of 1.40)	3.118	3.429	6.348
Angle between edges and radius vector/°	110.90	108.26	101.65

Some relevant aspects of the Hückel theory should be stressed in order to make clear the significance of the results obtained in the many calculations of carbo-polyhedra in the ρ approximation published in the last 5–7 years. We should note first of all that the Hückel method is essentially topological. In its simplest variant it merely takes account of the nature of nearest neighbours (i.e. of the presence of chemical bonds) and ignores the metric characteristics of the molecule. Two empirical parameters are used in the Hückel method: the Coulombic (α) and the resonance integral (β). These quantities are used to describe the Hamiltonian for the π-electron system and to calculate the one-electron energy levels ε_i as the linear functions

$$\varepsilon_i = \alpha + x_i\beta,$$

where x_i are the characteristic numbers of the molecular diagram which describes the σ skeleton of the carbo-polyhedron. Energy levels with $x_i > 0$ are called bonding, and those with $x_i < 0$ are called antibonding. The energy level $\varepsilon_i = \alpha$ is called nonbonding. A similar terminology is used for the molecular orbitals (MO).

The fundamental concept of the Hückel theory is the formation of closed electron shells. This property is found in systems in which all the bonding MO are doubly occupied in the ground state, and the nonbonding and antibonding energy levels are vacant. If the molecule in the ground state possesses unoccupied as well as doubly occupied bonding orbitals the system is said to have a pseudo-closed shell. The presence of a closed electron shell denotes a kinetically stable system. The stability usually increases with the width of the energy gap $\Delta\varepsilon$ which separates the antibonding from the bonding energy levels. The systems which contain unoccupied bonding energy levels can have an increased tendency towards the formation of anions. The presence of occupied antibonding energy levels stabilises the oxidised forms. The case of an occupied nonbonding level usually requires a more detailed analysis.

Various form of resonance energy are used, in addition to the delocalisation energy, to calculate the stabilisation of the ρ-electron systems of carbo-polyhedra: these include the topological resonance energy,[29,44,45] the resonance energy of Hess and Schaad,[46] calculated by the fused rings method,[47] and some other similar characteristics. All these quantities are commonly used to determine the degree of aromaticity of classical conjugated hydrocarbons. However, these calculations have also been used[27–29,48,49] to establish the relative stability of unsaturated polyhedral carbon clusters.

Since 1985, when the original paper by Kroto et al.[1] was published, the fullerene problem has stimulated increasing theoretical interest. Many studies by quantum-chemical methods in various approximations of the electronic structure of footballene (I_h-C_{60}) were published, as well as studies of its isomers, anions, cations, and of polyhedral carbon clusters with different numbers of atoms, including the higher fullerenes. Calculations were made in the restricted and the expanded Hückel,[26–34,36–39,42,48–64] MNDO,[64–71] and AMI methods,[72–74] in the nonempirical MO LCAO SCF method in different basis sets,[71,73,75–77] in the CNDO[30,39,78] and INDO methods,[79] and in the Pariser–Parr–Pople method allowing for configuration interaction,[80–82] the X_α method,[83,84] and the methods of molecular mechanics with estimates of the vibration frequencies.[83–89] We shall examine in some detail some of these papers, highlighting those which appear to have played a dominant role in our understanding of the special features of the chemical structure of polyhedral carbon clusters.[29,36,66,69]

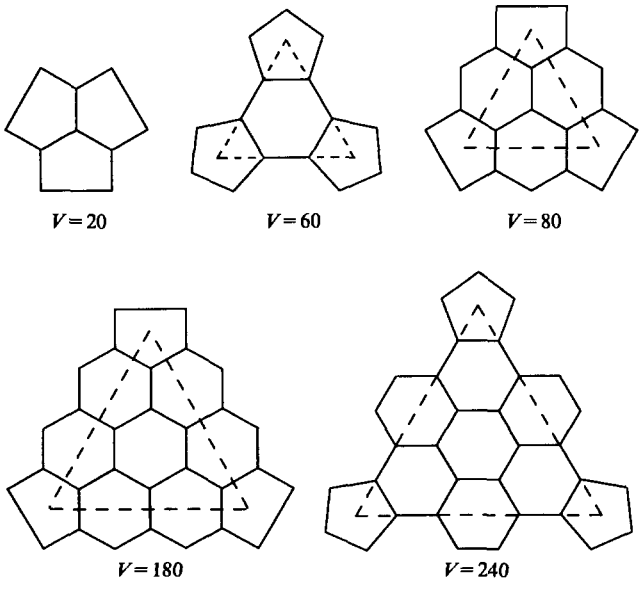

Figure 3. Self-repeating fragments of some icosahedral clusters.

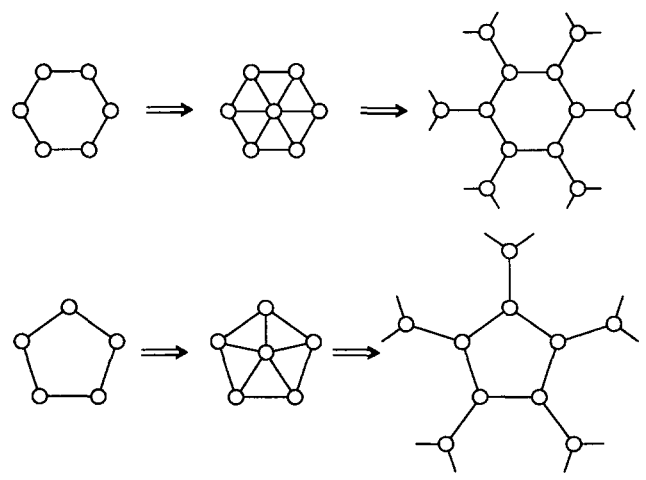

Figure 4. Scheme illustrating the construction of the higher fullerenes by the addition of one corner at the centre of each face of the initial (5,6) polyhedron.

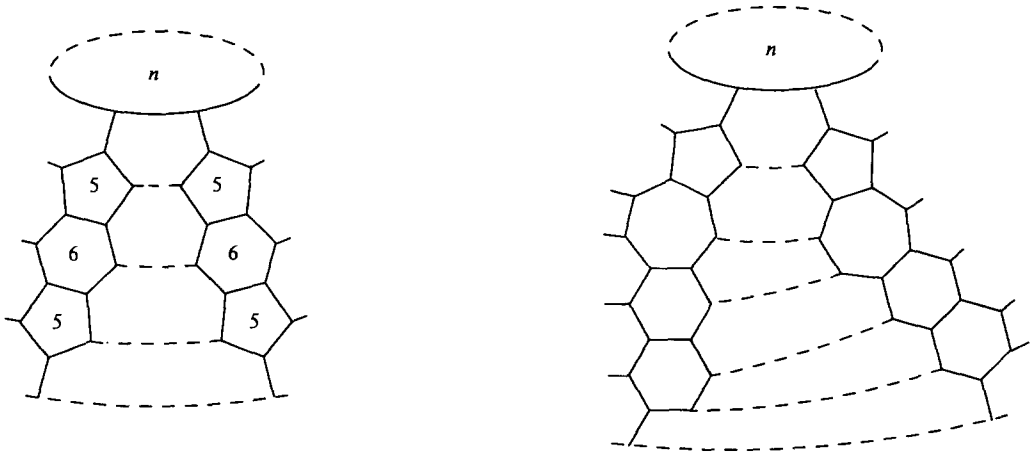

Figure 5. Examples of the basic fragments used in the design of carbon clusters with 5th- and 6th-order symmetry axes.

Schmalz and coworkers[29] developed a simple method of designing polyhedral structures with the D_{nd} and D_{nh} symmetry groups and used it to model the electronic structure of more than 30 carbon clusters of that type in the topological approximation. An analysis of their results[29] led to the formulation of several rules governing the stabilisation of polyhedral structures. The following are the most important:

1. Stable carbon clusters are polyhedra in which each carbon atom has a coordination number of 3.
2. The carbo-polymers containing only five- and six-membered rings are the most stable.
3. The most symmetric carbon clusters are the most stable.
4. Five-membered rings in the polyhedra should be isolated.
5. The shape of the carbo-polymers should be approximately spherical.

Some corollaries of these rules should be noted. For example, it follows from the first rule that the number of vertices in the cluster should be even (odd clusters of larger size have not been reported), and from the second rule we conclude that any polyhedron in this class should contain exactly 12 pentagons. No limit is placed on the number of hexagons. Footballene (I_h-C_{60}) is the smallest cluster which satisfies the fourth rule.

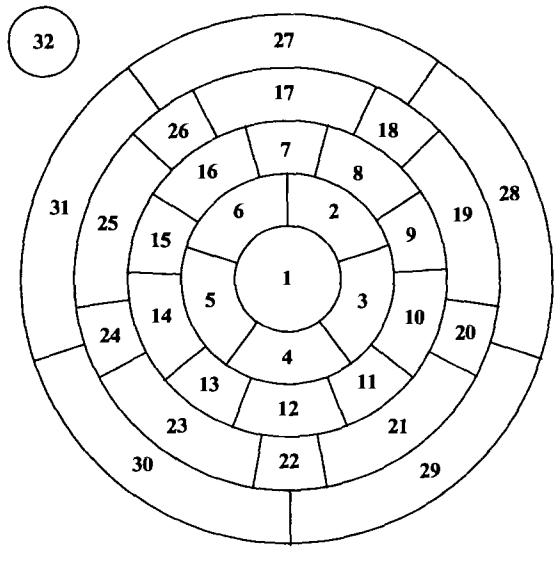

Figure 6. Structures of the I_h-C_{60} cluster coded with a system of concentric rings. Faces numbered clockwise in a spiral path. The code for the I_h-C_{60} cluster is 566 666 565 656 565 665 656 565 656 666 65. The first number of this code is the number of sides of the ith face. The last number corresponds to the infinite face of the molecular diagram [D E Manolopoulos, J C May, S E Down *Chem. Phys. Lett.* **181** 105 (1991)].

The number of isomers of the polyhedral C_n structures should increase rapidly with the number of atoms, even if only the (5,6)-polyhedra are considered. The C_{20} carbododecahedron has no isomers in this class of polymers, but (for example) in the polymer with $n = 78$ we find 21 822 isomers. Therefore the listing of all possible polyhedral structures with a given number of atoms is not an easy problem. The problem becomes even more complex when *a priori* estimates of the energetic and of the spectral characteristics of these structures are required. Hückel's topological approximation is often used as a rapid method of analysis, and the most probable structures are identified as a result of these calculations and studied in more detail. Papers in which Hückel's method is used account for a substantial proportion of the theoretical publications on the electronic structure of carbon clusters. Therefore it is natural to ask to what extent the Hückel approximation is suitable for solving problems in the structural chemistry of the fullerenes.

Let us consider, in this context, the results of some studies which are not only of intrinsic interest but also confirm the usefulness of the Hückel method for analysing the properties of carbon clusters. We note first of all that in the case of the most widely studied cluster (C_{60}) all the higher-level methods of calculation give a scheme of one-electron energies similar to that given by the Hückel method.[20]

Newton and Stanton[66] reported calculations on footballene and on some other carbon clusters by the MNDO method. In the case of C_{60} the authors[66] analysed the structure of the frontier orbitals and established that the HOMO are functions consisting (to within 97%) of the radial p-orbitals of the carbon atoms.

Bakowies and Thiel[69] studied approximately 30 carbon clusters of very different structure: clusters of icosahedral and of tetrahedral symmetry, and spherical or barrel-shaped clusters with groups of D_{nd} and D_{nh} symmetry. The choice of the systems was largely dictated by the results of MNDO calculations with full optimisation of the geometry. The structures examined included a giant C_{540} cluster of icosahedral symmetry. Schmalz et al.[29] determined the geometric characteristics and the heats of formation of the clusters. They found that the heats of formation of some of these carbon superclusters are directly proportional to the energy of delocalisation calculated by the Hückel approximation, which includes corrections for the resonance integrals (associated with the deviation of the cluster structure from a spherical form).

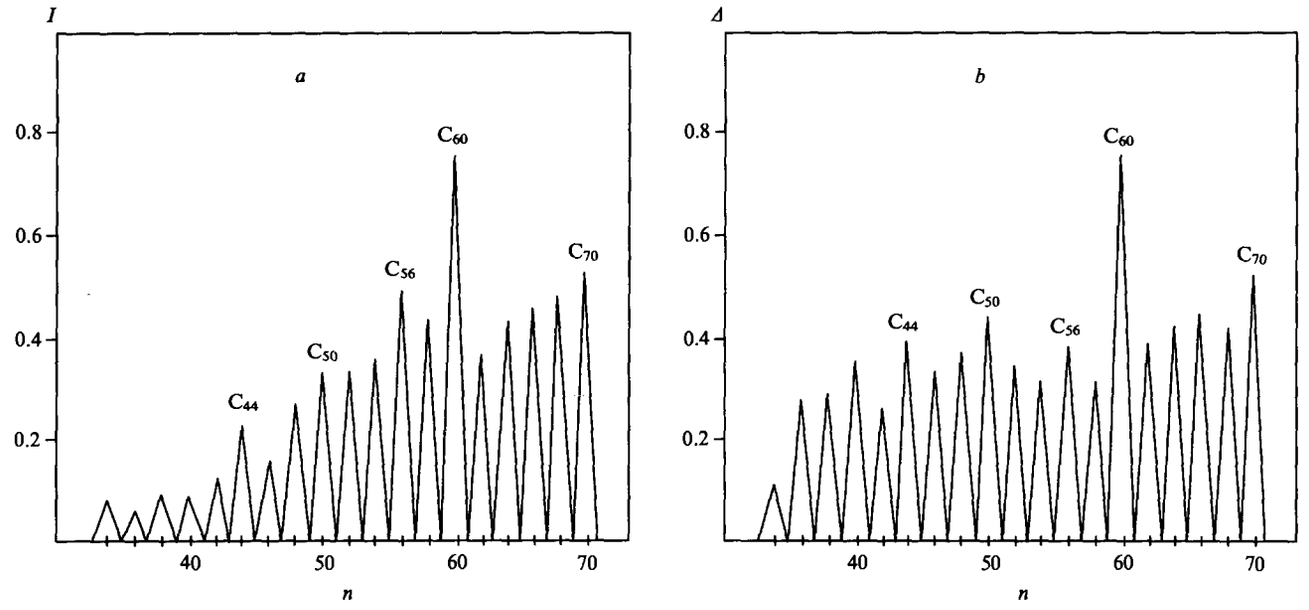

Figure 7. Relative intensities in the mass spectra of the C_n carbon clusters for $34 \leqslant n \leqslant 70$ (*a*). Energy gaps separating the filled from the empty energy levels (in the ground state) of the C_n clusters (*b*). The width Δ of these energy gaps was calculated in the topological approximation by the Hückel method and expressed in units of the resonance integral β.

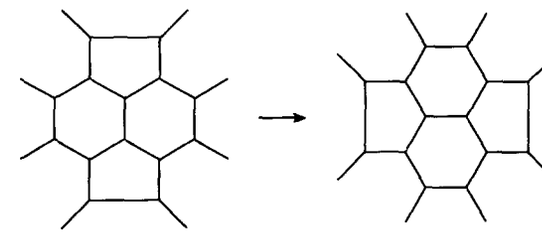

An interesting paper by Manolopoulos et al.[36] reports a correlation between the intensities of the mass spectra of the ions obtained from C_n^+ carbon clusters, where $34 \leqslant n \leqslant 70$, produced by laser evaporation of graphite, and the values of the energy gap $\Delta\varepsilon$ in the ρ-electron spectra calculated by the simple Hückel method for the corresponding fullerenes (Figure 7). Among all the possible isomers of the C_n clusters they chose those with the largest energy gap $\Delta\varepsilon$.

It is clear from this brief analysis that in systems of the polyhedral type with an almost spherical form it is convenient to use the Hückel approximation, since this method gives valuable information on the electronic properties of the systems. Let us examine in greater detail some of the characteristics of the geometry and of the electronic structure of the C_{60} and C_{70} clusters and of carbo-polyhedra with a greater number of atoms, and also of endohedral complexes.

1. C_{60} clusters

Many isomers can be constructed from 60 carbon atoms: one of these is the I_h-C_{60} cluster. Its geometric characteristics were established by electron diffraction[92] and X-ray structural analysis† (the structure of the osmium derivatives has been reported[93]), and calculated by various quantum-chemical methods.[49,54,66,68,72,73,75,76] Bonds of two types are found in the I_h-C_{60} cluster: r_1, specific to the five-membered rings, and r_2, common to the pentagonal and the hexagonal faces. All the methods of calculation indicate an alternation of the two bond lengths (r_1 and r_2), in keeping with the experimental results ($r_1 = 1.401$, $r_2 = 1.456$ Å).[92,93] The C_{60} isomers can be constructed in different ways. For example, from the dodecahedral C_{20} structure a new structure (C_{60}) consisting of three-membered and ten-membered rings can be obtained by truncating the vertices. A series of C_{60} isomers was generated by the petal method.[29] Isomers of the fullerene type can be obtained from I_h-C_{60} as a result of Stone–Wales regrouping in the pyracyclene fragments.[63] However, this operation leads to the appearance in the new isomer structures of adjacent five-membered rings (pentalene fragments), which destabilise the carbon cluster.

† H B Burgi, E Blanc, D Schwarzenbach, S Liu, Y Lu, M M Kappes, J A Ibers *Angew. Chem.* **104** 667 (1992).

It follows from the results of extensive theoretical studies that the icosahedral BF structure is the most stable of the polyhedral C_{60} isomers. The stability of the I_h-C_{60} footballene is usually attributed to the presence of 12 equivalent (partially overlapping) corannulene structural fragments, each containing a five-membered ring surrounded by five hexagons, which ensure that the pentagons are mutually isolated. Qualitative considerations indicating instability of structures containing adjacent five-membered rings are confirmed by calculations[71] by the semiempirical MNDO method and by the nonempirical MO LCAO SCF method in the two-exponential 3-21G basis, applied to C_{60} isomers containing two, three, and four pairs of adjacent five-membered rings. It was established that the most stable isomer of this type has a C_{2v} symmetry and an energy 2 eV higher than the energy of the I_h-C_{60} isomer. Each pair of adjacent five-membered rings makes approximately the same contribution (1.0 ± 0.2 eV) to the destabilisation energy of the I_h-C_{60} structure.

The effect of the pentalene fragments on the stability of the C_{60} isomers was discussed by Stanton[70] in relation to the photodissociation reactions of the C_{60} cluster, and also of some other carbon clusters studied by O'Brien et al.[94] MNDO calculations of the equilibrium geometry, of the heats of formation, and of the ionisation potentials of several carbon clusters (C_{62}, C_{60}, C_{58}, C_{56}, C_{54}, C_{52}, and C_{50}) have also been reported.[70] Estimates of the heats of isomerisation of these polyhedral clusters by the Stone–Wales mechanism have been obtained, as well as estimates of the heats of elimination of the C_2, C_4, and C_6 fragments from footballene (C_{60}) and from the C_{62} cluster. These calculations also confirm the conclusion that the presence of pentalene fragments destabilises the carbon clusters. It was found that the elimination of C_2 from the C_{62} cluster is strongly endothermic ($\Delta H = 99$ kcal mol^{-1}), but the heat of this

reaction is much smaller than that of the reaction $C_{60} \rightarrow C_{58} + C_2$ (ΔH = 273 kcal mol^{-1}). We also note that the same workers[70] described the structure of one of the most stable polyhedral isomers of C_{30}.

These results indicate that the structure of footballene is more stable than that of its polyhedral isomers. However, under certain conditions other isomers can also exist as metastable high-energy species. It has been shown[95] that a series of C_{60} isomers is present in the flame produced by the combustion of benzene.

2. Aromaticity of the C_{60} fullerene

The Japanese workers Yoshida and Osawa[37] have proposed a definition of a new class of conjugated molecules, which they called superaromatics. They assigned to this class of compounds molecules of polyhedral form which contain electrons in molecular orbital delocalised on the surface of a three-dimensional structure having an almost spherical symmetry.‡ They suggested as an illustration the hypothetical C_{60} molecule with the structure of a truncated icosahedron. This C_{60} molecule possesses a system of mobile electrons which contributes additional stabilisation to the polyhedron, as in the benzene molecule. Independently of the work of Yoshida and Osawa[37] polyhedral analogues of the classical aromatic systems (containing only carbon) were discussed by Bochvar and Gal'pern.[25,38] They produced[25] the first quantitative estimates of the resonance energy (or delocalisation energy) for this unusual type of conjugated molecule. It was concluded[25] that the C_{60} cluster has a greater resonance energy than the benzene molecule, and that in keeping with the quantum-mechanical criterion of aromaticity the C_{60} molecule should be assigned to a new class of aromatic systems.

We should stress the fact that the term 'aromaticity' has long been used in organic chemistry. It is associated with the presence of a large group of physicochemical properties (listed, for example, by Vol'pin[90]). However, the use of the term aromaticity has always been ambiguous to some extent, depending on whether the main stress of the argument lay on the chemical properties or on the molecular and the electronic structure (compare, for example, the definitions of this term given in Refs 90 and 91).

An analysis of the chemical properties of footballene shows that this molecule cannot be classified as an aromatic compound. Indeed, most of the known derivatives of footballene were prepared by addition reactions at multiple bonds (see Section VI).

However, according to the physical criteria the C_{60} molecule can be assigned to the group of aromatic systems [for example, the C–C bond lengths in C_{60}, though different for the (6, 6) and the (6, 5) bonds, are close to the bond lengths in graphite; furthermore the C_{60} system absorbs light at relatively long wavelengths, has a closed electron shell, and its resonance energy is relatively high].

The resonance energy is often used as a measure of the stability of the system relative to some standard structures. Comparative estimates of the resonance energy of C_{60} have been calculated[29] by different methods: Hückel's method, the methods of Hess and Schaad and of Randic, the conjugated rings method, and some others. The results are consistent with the aromaticity of BF in the sense of the quantum-chemical criteria, though according to most of these criteria the aromaticity of BF is lower than that of benzene.

Thus the aromaticity concept developed for the classical conjugated molecules cannot be applied to molecules of the fullerene type. The term 'pseudoaromaticity' gives a more accurate description of the formation of a single delocalised π-electron system, with a definite energy gain. The most important physical properties of BF are listed below.[18]

Structural data

Cubic crystal structure:
- $Fm\bar{3}m$ (T > 260 K)
- $Pa\bar{3}$ (T < 260 K)

Diameter of carbon cage: 7.1 Å

Bond lengths:
- C=C 1.391 Å,
- C–C 1.455 Å

Nonvalence distance between C_{60} molecules in the crystal: 3.1 Å

Bulk modulus: 18 GPa

Density: 1.65 g cm^{-3}

Spectral characteristics

Electron affinity: 2.6–2.8 eV

Ionisation potential: 7.6 eV

Energy gap: 1.9 eV

^{13}C NMR chemical shift: 142.68 p.p.m.

Vibration frequencies:
- IR: 528, 577, 1183, 1429 cm^{-1}
- Raman: 1250, 1422, 1467, 1573 cm^{-1}

Refractive index: 2.2 (630 nm)

3. The C_{70} cluster

The structure of the C_{70} cluster was determined by electron diffraction[96] and X-ray structural analysis of the iridium derivatives,[97] and calculated by various quantum chemical methods (see, for example, Ref. 77). It was established[96] that the C_{70} cluster has a fullerene structure with an ellipsoidal shape, described by the D_{5h} symmetry group. The C–C bond length varies between 1.37 and 1.47 Å. The shortest bonds are those connecting the vertices of two different pentagons; the longest are found within the five-membered rings. The 'height' of the molecule is 7.8 Å. As reported,[96] the equatorial part of C_{70} has a diameter of 6.94 Å and is narrowed by 0.05 Å. The lengths of the C–C bonds found by the XSA method for the iridium derivative of C_{70}[97] agree on the whole with the values obtained[96] by electron diffraction.

Formally the D_{5h}-C_{70} cluster can be obtained from two halves of the C_{60} cluster by inserting five pairs of carbon atoms in the equatorial plane.

The D_{5h}-C_{70} cluster, like the I_h-C_{60}, contains only isolated five-membered rings. In the spheroidal I_h-C_{60} molecule the carbon atoms are equivalent: they can be readily divided into pairs contributing to the formation of bonds between adjacent five-membered rings, which are equivalent in pairs. The I_h-C_{60} structure can also be described in terms of pyracyclene fragments or fragments of the corannulene type, which are structurally equivalent in pairs. However, the ellipsoidal D_{5h}-C_{70} structure cannot be described in terms of the fragments of a single type defined above. In the D_{5h}-C_{70} molecule corannulene and pyrene structural units can be distinguished in addition to the pyracyclene fragments.

The nonequivalence of the carbon atoms in the C_{70} molecule results in different values of the chemical shifts in the ^{13}C NMR spectra. Five types of atoms are present in the C_{70} molecule, with a corresponding number of signals. The following interpretation of the chemical shifts in the D_{5h}-C_{70} cluster has been proposed:[98] the signal at 130.8 p.p.m. is assigned to the carbon atoms of the ten pyrene fragments, the signals which appear in the range of 147.8–150.8 p.p.m. are assigned to the three different carbon atoms of the pyracyclene fragments, and the signal at 144.4 p.p.m. is assigned to the corannulene carbon atoms.

This interpretation of the chemical shifts in the D_{5h}-C_{70} cluster was used in subsequent work to model the structure of higher fullerenes in terms of their NMR spectra.[10]

‡ An English translation of part of the relevant paper,[37] kindly supplied by Professor Osawa, was used in the preparation of this review.

4. C_n clusters with $n > 70$

As was pointed out above, the number of isomers of the C_n clusters increases rapidly as n increases, even if the analysis is confined to fullerenes containing five- and six-membered rings. However, the number of isomers is greatly decreased if only the clusters which obey the isolated pentagons rule are considered. For C_{78} the number of isomers containing only isolated pentagons is five; for C_{84} it is 24, and for C_{90} it is 46.[55] However, the number of these isomers also increases fairly rapidly as n is increased. Therefore qualitative methods of predicting the structure and the properties of polyhedral clusters containing more than 70 atoms are of interest. One of these methods is based on the Hückel approximation. It was used by Fowler et al.[57,60] to formulate a group of rules analogous to the classical $(4n+2)$ Hückel rule, which must be satisfied by a closed electron shell. The most generally applicable of these rules can be formulated as follows.[60]

Rule 1. The isomers of the C_n clusters with $n = 60+6k$, $(k \geqslant 1)$ include at least one molecule with a closed electron shell for each integral value of k.

Rule 2. The isomers of the C_n clusters having a fifth-order axis of symmetry with $n = 70+30k$ or $n = 84+36k$ include at least one molecule with a closed electron shell for each integral value of $k \geqslant 0$.

Rule 3. The cluster C_{3m} obtained from the cluster C_m by a 'leapfrog' operation has a closed electron shell.

In the presence of a closed electron shell the difference between the HOMO and the LUMO energy ($\Delta\varepsilon$) is often used as a measure of the relative stability of carbon clusters. As was said above, this quantity is sufficiently well correlated with the intensities of the mass spectra of the $C_{34}-C_{70}$ carbon clusters obtained by the laser evaporation of graphite. However, the estimates of the stability of the higher fullerenes based on the width of the energy gap $\Delta\varepsilon$ are not always reliable. Thus, three structures (of D_{6h}, T_d, and D_2 symmetry) have been proposed[60] for the C_{84} cluster. A fourth isomer, of D_{7d} symmetry, was later added to this list.[99] The main parameters of the electronic structure of these four isomers, calculated by Hückel's method, are shown in Table 2.

It can be seen that the energy characteristics of the D_{7d}-C_{84} structure are close to the corresponding values for footballene (C_{60}). Furthermore the energy gap $\Delta\varepsilon$ for D_{7d}-C_{84} differs from the value for footballene by only $0.011\,|\beta|$, and therefore the structure of D_{7d}-C_{84} should be the preferred structure. However, calculations[71] by the MNDO and the nonempirical variant of the MO LCAO SCF method in the 3-21G basis showed that this is not the case. It was established[71] that the three structures of the C_{84} cluster with D_{6h}, T_d, and D_{7d} symmetry actually correspond to local minima on the potential energy surface, and that the D_{6h}-C_{84} structure is more stable than T_d-C_{84} [by 23.4 kcal mol^{-1} (MNDO) or by 18.2 kcal mol^{-1} (*ab initio*)]. Furthermore the energy of the D_{7d}-C_{84} structure is higher by several tens of kcal mol^{-1} than the energy of the T_d-C_{84} structure.

Table 2. Energy characteristics of the C_{84} isomers calculated by the Hückel method.[99]

Cluster	Symmetry	HOMO (β)	LUMO (β)	$\Delta\varepsilon$ ($\lvert\beta\rvert$)[a]	E_d (β)[b]
C_{84}	T_d	0.572	−0.124	0.696	0.559
	D_{6h}	0.529	0	0.529	0.558
	D_2	0.497	−0.117	0.614	0.558
	D_{7d}	0.607	−0.139	0.746	0.556
C_{60}	I_h	0.618	−0.139	0.757	0.553

[a] $\Delta\varepsilon$ is the width of the forbidden band
[b] E_d is the delocalisation energy per electron

This example shows that topological methods can give erroneous results in the comparison of the energy characteristics of the higher fullerenes. However, were it not for the topological approximation there would have been no progress in the search for possible structures, in the detection of isomers, in the interpretation of the NMR spectra, and in some other aspects of the structural chemistry of the fullerenes. A paper by Fowler et al.[100] in which the topological isomers of C_{84} of the fullerene type are characterised is noteworthy in this respect.

The structures of the higher fullerenes with a number of carbon atoms $\leqslant 84$ have also been discussed.[57-59,67] Table 3 shows reported data on the structure of the C_n carbon clusters with $60 \leqslant n \leqslant 78$, which satisfy the isolated pentagon rule and have a closed electron shell. The table also gives the characteristics of the ^{13}C NMR spectra and the heats of formation of the isomers, calculated by the molecular mechanics method.

Table 3. C_n fullerenes with closed and with pseudo-closed electron shells for $60 \leqslant n \leqslant 78$, ^{13}C NMR spectra, and calculated heats of formation.

Structure	Line intensity	ΔH_f°/kcal mol^{-1}
I_h-C_{60}	1(60c)	573.0
D_{5h}-C_{70}	3(10c), 2(20c)	–
D_{6h}-C_{72}	2(24c), 2(12c)	–
D_{3h}-C_{74}	1(2c), 4(4c), 4(12c)	–
D_2-C_{76}	19(4c)	–
C_{2v}-C_{78}	18(4c), 3(2c)	695.7
D_{3h}-C_{78}	13(6c)	697.8
C_{2v}-C_{78}	17(4c), 5(2c)	694.3
D_{3h}-C_{78}	5(12c), 3(6c)	702.3
D_{3h}-C_{78}	5(12c), 3(6c)	697.8

Note. Data for two symmetries (C_{2v} and D_{3h}) are given for the C_{78} fullerene

Fullerenes with a large number of atoms (giant fullerenes), including the extended carbon structures of the fullerene type, have been studied extensively.[59,101-106] Methods of modelling their structure have stimulated most interest. Thus, Kroto[101] proposed using spherical models for the giant fullerenes. The suggested structures are very attractive at first sight. Furthermore quantum-chemical calculations[69] for large clusters suggest that even a giant fullerene of icosahedral symmetry as large as C_{540} may be stable. Nevertheless the formation of hollow giant fullerenes of the spheroidal type seems unlikely, because these molecules must include a large proportion of empty space. It is difficult to believe that in the synthesis of the giant clusters C_n by the evaporation of graphite or by the combustion of benzene the inner cavity of the cluster is not filled by other smaller species formed from carbon atoms, or by other (impurity) atoms. Therefore the possibility that giant fullerenes have a more complex structure cannot be excluded. For example, these clusters may have a structure of the onion bulb type. Some of the giant fullerenes could be cylindrical, or they could have more complex cellular structures. Carbon clusters of these types (capsulenes, barrelenes, tubulenes, kegs, torenes, etc.) have been widely discussed.[31,64,102-108]

Cylindrical structures can be described as homologous series. Thus, Gal'pern et al.[64] have examined the molecular and the electronic structure of barrelenes of general formula C_m ($m = 36+12n$). In the limit, cylindrical carbon clusters can be treated as infinite macromolecules, and their corresponding endohedral complexes (containing linear chains of atoms within the carbon cylinder §) can be treated as molecular conductors.[106]

§ The possible formation of isolated homoatomic chain macromolecules consisting of atoms of the first or of the second period has long been a topic of discussions among specialists.[109] The formation of lead conductors within carbon microtubes up to 2 nm in diameter has recently been reported [P M Ajayan, S Iijima *Nature (London)* **361** 333 (1993)].

The properties of the carbon cylinders depend on the radius and on the character of the end groups. Carbon clusters with a closed electron shell should have the form of cylinders closed at the ends (capsulenes, barrelenes). Open carbon cylinders can have no independent existence, because they include many radical centres at their ends. However, by saturating the free valencies of these radicals we can create cylindrical macromolecules having favourable properties as electronic conductors. Mathematical models of these systems, including their toroidal analogues, were first discussed by Heilbronner[110] in 1954 from the standpoint of a study of the electronic structure of homologous series of polynuclear aromatic hydrocarbons. More recently renewed interest has been shown in the search for new classes of quasi-one-dimensional conductors.[111,112]

The production of filiform carbon crystals, probably composed of microtubulenes, has been reported.[103]

In principle the possible formation of carbon structures with carbon atoms distributed over surfaces of various types should also not be excluded. For example, Lenosky et al.[104] have considered the case of surfaces with a negative curvature.

5. Endohedral fullerene complexes

Let us now turn to inclusion compounds of the $M_n @ C_m$ type. The first results of quantum-chemical calculations on these systems were reported by Bochvar et al.,[38,39] who applied the CNDO/2 method with partial optimisation of the geometry to the system $M^+ @ C_{24}$, with M = Li, Na. In these calculations the C_{24} cluster was assumed to be a truncated octahedron. According to the results the introduction of a Li cation at the centre of the carbo-*s*-octahedron stabilises the C_{24} system, whereas Na^+ has a destabilising effect. This is because in the case of Li the whole of the positive charge is transferred to the carbon skeleton whereas with Na 30% of the charge remains on the metal atom. A high energy barrier has to be overcome in order to extract the M^+ cation through the centre of the hexagonal face. This effect ensures the kinetic stability of $M^+ @ C_{24}$.

Relatively few calculations on endohedral clusters have been published. Special interest was stimulated by detailed calculations on Li^+C_{60} by Bakowies and Thiel,[69] who considered the case of Li^+ present both within and outside the C_{60} cluster. It was found that the formation of the endohedral $Li^+ @ C_{60}$ cluster requires a large consumption of energy (ΔH = 30 kcal mol^{-1}), whereas the formation of an exohedral cluster, with the Li^+ located outside the carbon cage over a pentagonal or hexagonal ring, results in a substantial gain in energy.

The charge on the Li atom is positive varying between 0.5 and 0.8 a.u. The position of the Li cation at the centre of the cage does not correspond to the absolute minimum: the cation can move almost freely within the polyhedron to a point 1.4 Å from the centre. However, as in the case of $M^+ @ C_{24}$, the emergence of the M^+ cation from the carbon cage requires overcoming a high potential barrier (> 75 kcal mol^{-1}), which ensures the kinetic stability of this type of endohedral complex.

Nonempirical calculations of the clusters $X @ C_{60}$ (X = O, F, K, Ca, Mg, Cr, Ba, La, Eu, U) have been reported. Chand et al.[113] used the Hartree–Fock method in conjunction with a relativistic potential for the core electrons. It was assumed that the impurity atom is located at the centre of the carbon cage. Calculations in the approximation of an energy functional dependent on the local electron density[114] were carried out with the exchange-correlation potential proposed by Barth and Hedin.[115] By analysing the Mulliken populations it was established that a charge of $\sim 2.85e$ is retained on the carbon skeleton. The highest occupied energy level corresponds to the MO localised on the carbon atoms.

From the calculations[113] on the $M @ C_n$ inclusion compounds it can be seen that the role of the atom (or ion) within the carbon cage is principally to donate electrons to the ρ-electron shell of the carbon core. The extent of electron transfer and the stability of the system depend on the relative values of the redox properties of the additive atom and of the carbon cluster. Thus the La atom donates two 6*s* electrons to the delocalised system of the carbon cage, occupying two vacant orbitals of the C_{60} clusters, and the third valence electron remains localised on the 5*d*-AO. We may conclude from the results of the calculation[113] that the $La @ C_{60}$ complex should have chemical properties similar to those of fullerene in a triplet excited state. The electronic structure of the endohedral $M @ C_n$ complexes has been discussed also by other workers.[116–119]

The acceptor capacity of the C_n clusters can be evaluated qualitatively at the level of the Hückel approximation. Thus it was shown[56] that the C_n^{2-} dianions with n = 74, 82, and 88 are the most stable of these species. It is stressed that these dianions are convenient structures for the formation of endohedral complexes with metals which donate two electrons to the ρ system of the surrounding cage. In particular, the stability of the C_{3v}-C_{82}^{2-} cluster is specially noted. This conclusion agrees with experimental data indicating the existence of a long-lived $La @ C_{82}$ cluster and defining the charge distribution pattern in the system.[56]

6. Unstable fullerenes

Most of the theoretical papers in which polyhedral carbon clusters are discussed are mainly concerned with structures which satisfy variously defined stability criteria and in particular with clusters having a closed electron shell. The presence of an open electron shell in a polyhedral C_n cluster denotes a fairly high reactivity. Such a cluster is kinetically unstable, and difficult to isolate. However, knowing the geometry of the ground state and the electronic structure of the C_n cluster with an open electron shell it is often possible to make a qualitative estimate of the stable derivatives of such a cluster. Therefore the unstable structures also are of interest, and it is reasonable to treat them as intermediates whose stabilisation under prescribed conditions can lead to the creation of new types of materials.

Let us examine some examples. The simplest member of the fullerene family is the carbododecahedron C_{20}. The earliest calculations on the cluster C_{20}, made first in the Hückel ρ approximation[25] and then by the expanded Hückel method,[38] showed that this fullerene has an open electron shell and that its ground state should be triplet. Recent nonempirical calculations by Parasuk and Almlöf[120] confirmed this conclusion from which it follows that the C_{20} cluster should be a chemically active species. One of the methods of preparing stable, less reactive systems relies on passing from the C_{20} cluster to its carborane derivative $C_{18}B_2$.[25,121]

The D_{6h}-C_{36+12n} family of clusters of the barrelene type has been discussed.[64,122] It was established that these clusters have an open electron shell. However, it appeared that the highest partially occupied doubly degenerate level is a bonding level and that two electrons are not sufficient to fill it. Therefore it was concluded that the D_{6h}-C_{36+12n} clusters can readily form dianions.[64] They can be stabilised in the solid phase by the addition of alkali metal atoms.

Another interesting method of stabilising polyhedral clusters was proposed by Guo et al.[117] It was shown that the most stable C_{28} isomer has a tetrahedral (T_d) type of symmetry (Figure 8). At each corner of the tetrahedron we find a group of three condensed pentagonal rings: the carbon atoms shared by the three rings lie exactly at the corners of the tetrahedron. The electronic ground state of the C_{28} cluster has the $^5A_2$ configuration. One of the four unpaired electrons is located on a molecular orbital of a_1 symmetry, whereas the other three are on orbitals of t_2 symmetry. The tetrahedral C_{28} cluster can be formally treated as a super-atom with a valency of four, able to form compounds analogous to those of the quadrivalent carbon atom in the sp^3 hybridisation state.

Furthermore, calculations[117] by the nonempirical SCF method showed that the $C_{28}H_4$ molecule (of T_d symmetry) should be extremely stable. This molecule could be appropriately called supermethane. However, there is an alternative method of

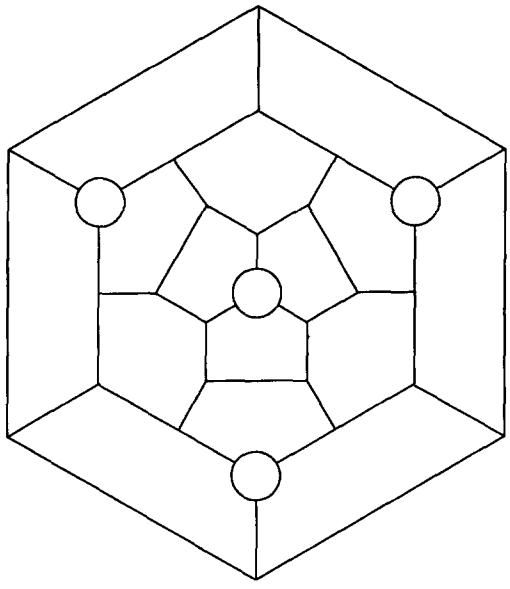

Figure 8. Molecular diagram for the C_{28} cluster of tetrahedral symmetry. The corners denoted by open circles correspond to carbon atoms lying on third-order axes of symmetry.

stabilising C_{28}: by introducing into the inner cavity of the polyhedron a quadrivalent atom such as Ti or U to form endohedral M @ C_{28} compounds. Mass spectral data for samples obtained by laser evaporation of a recently prepared composite (graphite – UO_2) were also reported.[117] These suggest the existence of U @ C_{28} clusters.

We should also point out that by analogy with the carbon atom in the sp^3 hybridisation crystal lattices of the diamond type can be constructed from the C_{28} super-atom, as well as some other lattices. The C_{28} super-atom can find applications in the design of superaliphatic hydrocarbons $[(C_{28}H_2)_m(C_{28}H_3)_n]$.

7. Polyhedral clusters of atoms of other elements

The synthesis of polyhedral clusters of carbon atoms strongly stimulated the search for analogous structures composed of atoms of elements of group IV of the Periodic Table, or of mixed clusters of atoms of elements from groups III and V, For example, Nagase and Kobayachi[123] have discussed the stability of the O_h-Si_{24} cluster, of the icosahedral Si_{60} cluster, and of the endohedral M @ Si_{60} complexes, where M = Ne, F^-, or Na^+. The calculations were carried out by the Hartree–Fock–Roothaan method. A two-exponential basis was used for Si_{60}, and an effective nonempirical potential for the cores of the Si atoms. The structure of the Si_{60} cluster was optimised by postulating the retention of the I_h symmetry group. It was established that bonds of two types are present in the Si_{60} cluster: bonds shared by two hexagons have a length of 2.189 Å, and those shared by a pentagon and a hexagon have a length of 2.266 Å. The highest occupied energy level (−6.5 eV) has a five-fold degeneracy, and the lowest unoccupied level (−2.5 eV) is triply degenerate. The structure of the Si_{60} cluster was found to be stable with respect to certain distortions which lower the symmetry. It was shown that the Na^+ @ Si_{60} complex is much more stable than F^- @ Si_{60}, unlike the X @ C_{60} complexes (X = Na^+, F^-), to which the inverse order of stability applies. The structure of the Si_{24} cluster was calculated on the assumption that the O_h symmetry group is retained. It was pointed out that the total potential energy surface does not contain a local minimum corresponding to this structure.

It should be noted that problems relating to the structure of clusters of silicon atoms have been widely discussed in the literature.[124, 125] The results of mass-spectral analyses suggest that silicon (unlike carbon) tends to form clusters with an odd number of atoms.[124] The greater length of the Si – Si (as compared with the C–C) bond may assist the formation of three-dimensional structures on whose surface partially conjugated Si_m chains are accommodated. This model was constructed for the Si_{45} cluster[125] by the molecular mechanics method. Evidently the structure of the Si_{45} cluster[124] is a reflection of the greater tendency of Si atoms to form single bonds.

We know that the elements of the third period do not form aromatic compounds.[126] Therefore the problem of synthesising the silicon analogue of footballene is of great interest to theoreticians as well as to experimentalists.

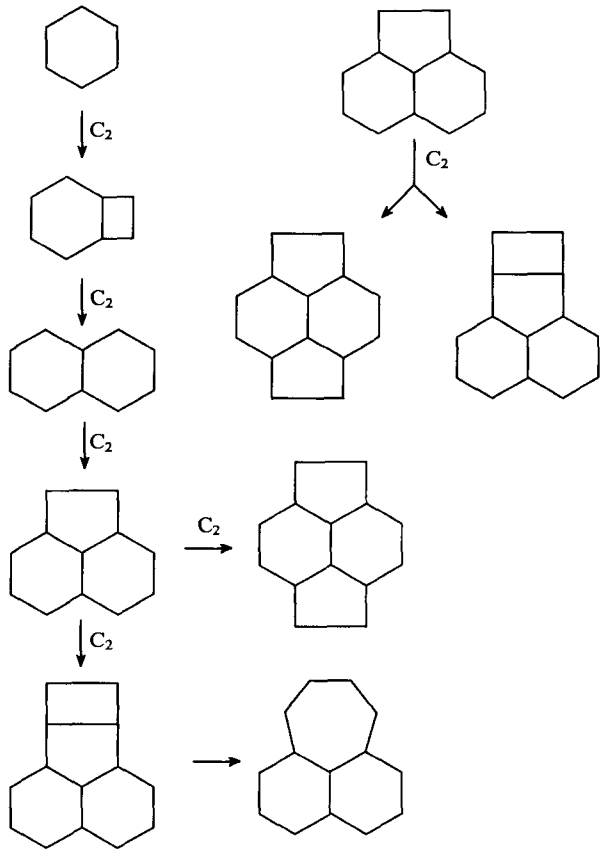
The ability of boron atoms to form polyhedral structures of composition C_nB_m is beyond doubt.[121] Similarly, the replacement of some carbon atom in a polyhedral cluster by nitrogen is not incompatible with the general principles of valency theory. However, it is reasonable to ask whether the homonuclear N_n or B_n clusters can exist.

In the former case the clusters could play the role of Lewis superbases, in the latter they could be superacids. The possibility of combining boron and nitrogen atoms within the same molecule has already been established in nature for a small molecule: borazole, a very stable compound of aromatic character.

The study of the possible existence of N_n clusters has a long history, and is directly related to the stability of hexa-azabenzene (the cyclic molecule N_6), which has been discussed extensively (see for example, the work of Gal'pern et al.,[127] and Stankevich et al.[128] and the references quoted in those papers).

It was concluded[127, 128] that the repulsion between the neighbouring unshared electron pairs could be responsible for instability of the cyclic N_6 molecule. In principle this destabilising factor should also be found in polyhedral systems. Chen Cheng et al.[129] reported the results of calculations by the MINDO/3, MNDO, and AMI methods for a dodecahedral N_{20} cluster. The equilibrium geometry was identified, and the heat of formation of the cluster was calculated as well as the heats of the reactions $10N_2 \rightleftharpoons N_{20} \rightleftharpoons 20N$. All three methods lead to the conclusion that a local energy minimum exists for the N_{20} cluster. The following values (in Å) were obtained for the N–N bond lengths: 1.484 (AMI), 1.426 (MNDO) and 1.347 (MINDO/3). The N_{20} cluster was found to be more stable than a system of 20 nitrogen atoms but less stable than a system of 10 nitrogen molecules (AMI, MNDO).

The stability and the electronic structure of polyhedral clusters of the mixed type $(C_nB_mN_k)$ were discussed by Xia et al.,[130] who calculated by the MNDO method the electronic structure of the 60-atom systems C_{60}, B_2C_{58}, N_2C_{58}, BNC_{58}, $C_{12}B_{24}N_{24}$, and $B_{30}N_{30}$, and obtained their heats of formation. It was established that all the mixed systems have a stability close to that of C_{60}. According to these workers[130] it should be easier to synthesise the $B_{30}N_{30}$ than the C_{60} cluster, but no attempt appears to have been made so far to prepare that cluster.¶



IV. Mechanism of formation of the fullerenes and of endohedral complexes

The mechanism of formation of the fullerenes is not known in detail. There are only some general considerations on the growth of the carbon cluster by the successive addition of C_2 particles, which are thought to be predominant in graphite vapour.[131] Experimental morphological observations (the spiral growth of cylindrical tubes in tubulenes[97]) cannot be extended to the closed molecules of the higher fullerenes.

The main structural difference between the fullerenes and graphite is the presence of pentagons in the former. The first pentagon (surrounded by hexagons) leads to the formation of

¶ Reports of the synthesis of M_8C_{12} systems, where M = Ti, Zr, V, have recently appeared [B C Guo, K P Kerns, A W Gastleman *Science* **256** 515 (1992)]. Dodecahedral structures, with each M atom associated with three C atoms, were assigned to these molecules.

corannulene (a nonplanar structure), and the formation of a heptagon can lead to the same result.[132] The formation of even a single nonhexagonal ring is a prerequisite for the eventual conversion of the structure into a closed figure. The formal scheme described in the next section explains the formation of nonhexagons during the initial stages of the process.

The presence of pentagons is the critical stage in the *de novo* formation of endohedral metal complexes. It should be noted first of all that endohedral complexes have been described only for group III metals (lanthanum, yttrium, and scandium). These metals are characterised by the formation of π-cyclopentadienyl (cp) complexes with η^5 coordination, and π-arene complexes with η^6 coordination are practically unknown in this case. According to the hypothesis formulated by one of us[132] this difference is critical in the formation of endohedral metal fullerenes with the participation of intermediates of the $(\eta^5\text{-}C_5H_5)_nM$ type (n = 1, 2) with a closed fullerene shell. Thus η^5 coordination with several cp ligands is also characteristic of other metals (for example, uranium), and in these transition metals, as in nickel and iron, η^5 coordination is preferred over η^6.

If the $(\eta^5\text{-}C_5H_5)_nM$ intermediates are important in the synthesis of endohedral complexes it may be preferable to introduce into the graphite electrode the already prepared cp_2M-X complex instead of the metal salt (or, indeed, the oxide) in view of the high affinity of the group III metals for oxygen, which may produce an undesirable competition for the metal. The prepared cp–M fragment is stable in an inert gas atmosphere, and it can arrange itself in hexagons during high-temperature dehydrogenation, which favours the formation of endohedral complexes of the fullerenes with other metals possibly in high yields. The *de novo* synthesis of endohedral fullerene complexes thus described, i.e. the synthesis at the instant of the formation of the fullerene spheroid itself, was complemented by another approach different in principle. It was shown mass-spectrometrically[133–137] that when an inert gas is bombarded with a beam of accelerated C_n^+ cation radicals endohedral $X@C_n$ complexes are formed with the inert gases (helium or neon) in an ionised form. A special technique was developed to reduce the $He@C_{60}$ reversibly in the gas phase and to detect it.[137] These studies were recently reviewed by Schwarz.[138]

V. Classification of the forms of carbon with a regular structure

Known forms of carbon with a regular structure are most rationally classified as molecular or covalent crystals. Molecular crystals are composed of individual molecules (carbon clusters) of finite size: the fullerenes. Covalent crystals are characterised by polymeric structures.

The structures of covalent crystals are conveniently described in terms of infinite graphs. In this method of description diamond corresponds to a uniform graph of order 4. By constructing such a graph in three dimensions we can easily represent the diamond structure, which corresponds to the closest packing of carbon atoms.

Graphite is described by a disconnected graph consisting of an infinite number of two-dimensional lattices. Each of these lattices can be realised as a hexagonal grid on a plane. The third allotropic form of carbon (carbyne[139]) is described in terms of an infinite number of simple, rectilinear paths.

The real structures of diamond, graphite, and carbyne suggest a three-dimensional, a quasi-two-dimensional, and a quasi-one-dimensional character for these allotropic modifications of carbon, accurately reflected by the theory of hybridisation.

In addition to the above, there are many other methods of regularly filling a three-dimensional space with carbon atoms. Some of these are described in the monograph by Wells,[24] who used infinite graphs with coordinates. The construction of nets of trigonal carbon atoms has also been described:[140,141] it was shown that in addition to diamond, graphite, and carbyne, which display (in the ideal case) the sp^3, sp^2, and sp hybridisation of the atomic orbitals, crystalline modifications of carbon with an intermediate hybridisation are possible, and also mixed forms of carbon containing tetragonal, corner, and trigonal atoms.

A mechanism allowing the regrouping of several nets of this type into planar graphite layers has been proposed.[142] In the crystals the graphite layers are at a distance of 3.35 Å from each other. This defines the 'thickness' of the graphite layer, i.e. its extent in a direction perpendicular to the plane. Since this is infinitely small in comparison with the size of the graphite plane the three-dimensional structure of the graphite layer can be characterised by the effective dimensionality $2+\varepsilon$ where $0 < \varepsilon \ll 1$. Similarly the van der Waals interaction defines the thickness of the carbyne filament. The three-dimensional structure of the carbyne molecule can be described as $1+\delta$, where $0 < \delta \ll 1$. Obviously, on this scale the effective dimensionality of diamond is described by the number 3, corresponding to that of three-dimensional space.

Let us now consider a fragment of a hexagonal net on a plane, in the shape of an infinite band. This fragment can be rolled into a hexagonal net (tubulene), drawn over the lateral surface of a cylinder, and in this way chiral tubulenes of different size can be produced.

The tubulene form of carbon is intermediate between diamond and the fullerenes. The growth of carbon tubes of different diameter has been observed experimentally by Iijima.[103]

If the network on a plane consists of 5- and 6-membered rings it can be treated as the result of defect formation in an ideal hexagonal system. Toroidal structures (the torenes) can be formed from fragments of this net in the form of an infinite band. A combination of tubulenes can give tubular systems with bifurcations, and also structures whose atoms are located on a surface having a negative curvature.[104]

We should also note that the structures of all the forms listed above can be interpreted as the result of 'grafts' between chain carbon molecules.

Some workers suggest[20] that the mechanism of formation of the fullerenes from carbon vapour includes a process of the grafting type as one of its initial stages.

The classification of the regular carbon structures proposed by one of us[35] is shown in Figure 9.

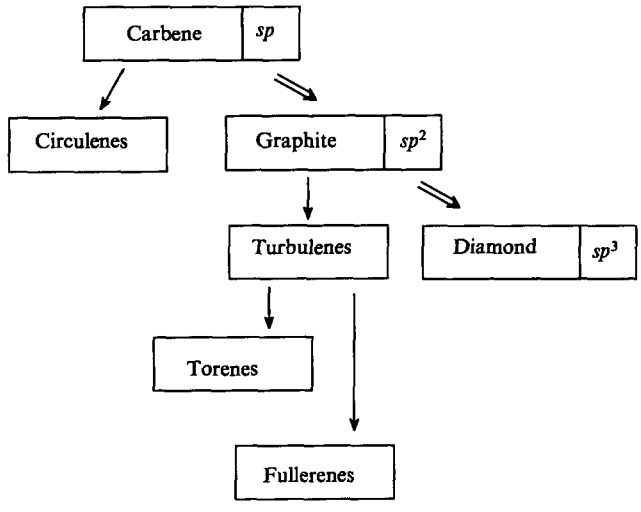


Figure 9. Classification of the regular carbon structures.[35]

VI. Chemical properties of carbon clusters

The unique structural features of the fullerenes, causing unsaturation of all the bonds in the absence of substituents, make only two types of primary reaction possible in this system: the withdrawal of electrons and the addition of electrons or of groups. The replacement of already present groups and their removal are secondary reactions of the derivatives. It follows from the above that the fullerenes are electrophilic and good electron acceptors. They readily undergo addition of nucleophiles, and also of free-radical and of carbenoid species. Nearly all the reactions studied in fullerenes took place on C_{60} or its mixtures with C_{70}. Nothing is known about the chemical properties of the higher fullerenes.

1. Reactivity of C_{60}

a. Addition of hydrogen and halogens

The addition of several hydrogen molecules takes place under the conditions of the Birch reaction in the presence of an alkali metal in ammonia or in an amine, giving $C_{60}H_{36}$ as the main product, from which (as reported[143]) the $C_{60}H_{60}$ fullerene can be obtained. Dihydrofullerene $C_{60}H_2$ was obtained by selective hydrozirconylation of C_{60} followed by hydrolysis.[144]

$$C_{60} + cp_2Zr(H)Cl \longrightarrow C_{60}H(Zr\,cp_2Cl) \xrightarrow{H_2O} C_{60}H_2$$

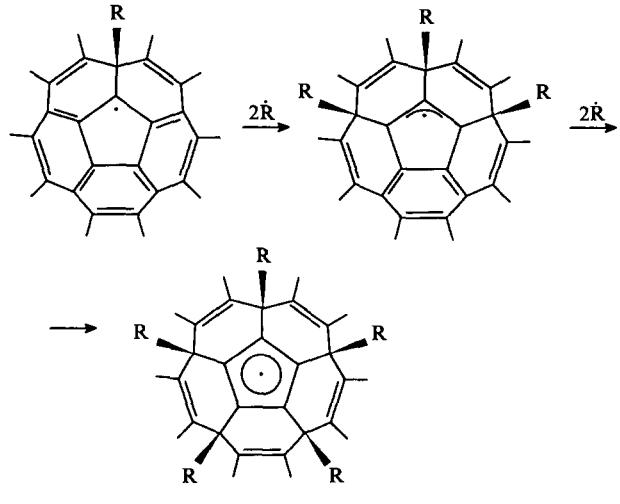
8% ($\delta_H = 5.07$ p.p.m.)

A theoretical evaluation of all the possible isomers of $C_{60}H_2$ has been reported:[145] many of the isomers are found to be stable.

Buckminsterfullerene adds on some fluorine atoms in the presence of XeF_2, and complete fluorination is observed when solid C_{60} is treated with gaseous fluorine.[146,147] The fullerene $C_{60}F_{60}$ is a colourless crystalline substance soluble in THF and in acetone. Its ^{19}F NMR spectrum contains only one singlet line. The chlorination and bromination reactions are reversible, and iodine undergoes almost no addition. Chlorination and bromination yield a mixture of products containing (on average) 22 chlorine atoms and 28 bromine atoms respectively. Some bromofullerenes have been isolated in a pure form. The halogen atoms in the halogenofullerenes are easily replaced by nucleophilic OH or NH_2 groups.[148-150]

b. Electrochemical reduction

The electrochemistry of the fullerenes has been studied by a few groups of workers. By examining a continuously increasing range of electrolytes and solvents it was shown that 6 electrons can be added sequentially and reversibly to C_{60}.[151] It is interesting to note that no difference was observed between the first ionisation potentials of C_{60} and C_{70}.[152] The C_{60}^{n-} anions are anion radicals for odd values of n, but for even n the spin pairing problem prevents the observation of the ESR spectrum under certain conditions. Some work on the electrochemistry of BF derivatives has been published recently.[153]



c. Reduction by metals

The transfer of electrons from alkali metals to fullerenes has been studied in reasonable detail both in solutions and in films. The stimulus for this work was the discovery of superconductivity in the M_3C_{60} phase.[17] The highest critical temperature observed for the caesium–rubidium salt Cs_2RbC_{60} was 33 K. We note that the superconducting salts are ion radicals and have a face-centred cubic lattice.[154] Changing from Cs_2RbC_{60} to Cs_3C_{60} produces a different type of lattice, and the superconductivity disappears.

Other metals and their salts can also transfer electrons to the fullerenes. However, these compounds have not been adequately studied. It was recently shown that the C_{60} anion radical is formed during the homogeneous reduction of C_{60} by samarium(II) iodide in THF.[155]

d. Addition of free radicals

Krusic et al.[156] observed the very easy addition to C_{60} of free radicals with their centre over the carbon, oxygen, or sulphur atoms. By using ESR they established the structure of some of the most stable radical products of repeated additions. An analysis of the hyperfine splitting lines showed that the most stable radicals are those of the allyl and cyclopentadienyl type, with three or five benzyl radicals added at the (6, 6) bonds.[157] The benzyl radical used in this work was labelled with the ^{13}C isotope at the methylene group.

We have studied the addition to C_{60} and C_{70} of free radicals in which the spin density was concentrated on an atom which had a magnetic moment (phosphorus, boron, tin, etc.).[158-160] This approach is useful because it allows the hyperfine splitting in the ESR spectra to be observed without introducing an isotopic label. The addition of the phosphoryl radical, conveniently generated by the photolysis and thermolysis of the mercury salt $Hg[P(O)(OR)_2]_2$, was studied in most detail. The spin density in

the phosphoranylfullerenyl radical was almost fully localised on three carbon atoms of the short-range surroundings. We studied the kinetics of the reversible dimerisation of this radical.

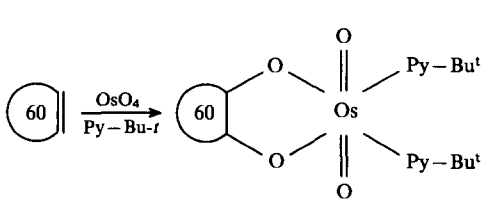
$$2C_{60}^{\cdot}-P(O)(OR)_2 \rightleftharpoons [C_{60}-P(O)(OR)_2]_2$$

e. Ion-radical salts

In addition to the salts with alkali metals mentioned above other ion-radical salts have also been described.† The electrolysis of C_{60} in a mixture of THF and CH_2Cl_2 in the presence of tetraphenylphosphinium chloride gave the paramagnetic salt $Ph_4P^+ \ldots C_{60}^- \ldots (Ph_2PCl)_2$.[161] The interaction of C_{60} with the electron-donor complex of low-valency chromium **1** in toluene solution gave the salt **2** as a result of electron transfer from **1** to the fullerene.

$$C_{60} + \underset{\mathbf{1}}{(TPP)Cr(II)} \underset{THF}{\overset{PhMe}{\rightleftharpoons}} \underset{\mathbf{2}}{C_{60}^-(TPP)Cr(III)^{\cdot+}}$$

The addition of THF causes dissociation of salt **2**. The reaction of BF in toluene solution with a 20-fold excess of tetrakis-(dimethylamino)ethylene produces the salt $C_{60}(TDAE)_{0.86}$. This ion-radical salt undergoes a ferromagnetic transition at 16.1 K, which is the highest reported temperature for an organic ferromagnetic.[163]



f. Oxidation and reactions with Lewis acids

Buckminsterfullerene C_{60} forms a cation radical under the influence of Lewis acids (for example, SbF_5).[164] However, in order to obtain stable derivatives from these cation radicals it is convenient to use $AlCl_3$, which yields the polyarylated fullerenes $C_{60}H_nAr_n$ ($n \simeq 12$).[165]

$$C_{60} \xrightarrow[AlCl_3]{ArH\ (exc.)} C_{60}H_nAr_n$$

Oxidation with oxygen. Buckminsterfullerene reacts with oxygen only when irradiated:[166] the triplet state of C_{60} is formed first, and energy transfer from this state produces singlet oxygen which reacts directly with the fullerene. Under these conditions some of the carbon–carbon bonds are broken and carbonyl groups are formed, with evolution of CO and CO_2. One direction of the reaction produces the oxides $C_{60}O$ and $C_{70}O$, which are usually found in mixtures of fullerenes.[167]

Oxidation with OsO_4. The oxidation of olefins by osmium tetroxide with opening of the double bond and formation of 1,2-diol ethers is well known. This reaction has been observed with C_{60}.

The conditions needed to produce the pure mono-derivative have been identified, and an X-ray diffraction analysis of the compound has been reported.[87, 168–170] The first experimental data on the geometry of the BF were obtained for this compound.

†A complex with the (+)-DIOP ligand (the first optically active organometallic derivative in the fullerene series) was obtained in a similar way [V V Bashilov et al. *Izv. Ross. Akad. Nauk, Ser. Khim.* 428 (1993)].

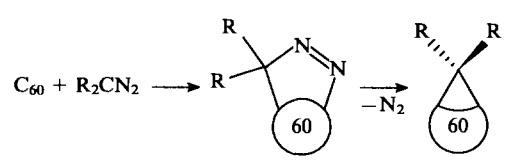
g. Fullerenes as ligands

The presence of a continuous 'electron cloud' in a fullerene polyhedron allows us, in principle, to select different numbers of electrons as participants in the bonding to give metal complexes. The formation of the following types of complex can be postulated:

η^1 — a simple complex with a σ bonding at one vertex (an even number of groups can be found in a non-free-radical product),
η^2 — a π-olefin complex at an edge or the geometrically equivalent double σ bonding at neighbouring vertices,
η^3 — a π-allyl complex,
η^4 — a π complex of the trimethylenemethane or 1,3-diene type,
η^5 — a π-cyclopentadienyl complex,
η^6 — a π-arene complex.

The stable complexes so far identified all belong to the first two types. Other types do not appear to have been prepared as yet. The last two types are of special interest because double π complexes of metals with nonadjacent hexagonal faces of C_{60} should be chiral and therefore could occur in an optically active form.[171]

Reactions with low-valency complexes of the transition metals. The analogy between fullerenes and the electron-acceptor olefins is clearly seen in the formation of π complexes with some transition metals. The reaction of C_{60} with ethylene-bis-(triphenylphosphine)platinum results in the addition of between 1 and 6 L_2Pt fragments: the first and the second of these complexes have been characterised by X-ray structural analysis.[172–174] In the $(\eta^1\text{-}C_{60}).(PtL_2)_6$ complex the six L_2Pt groups are disposed octahedrally, forming a molecule with the T_h symmetry. The reaction of C_{60} with tetrakis-(triphenylphosphene)palladium gives the complex $(\eta^2\text{-}C_{60})Pd(PPh_3)_2$,



$$C_{60} + (Ph_3P)_4Pd \longrightarrow (\eta^2\text{-}C_{60})Pd(PPh_3)_2 ,$$

whose structure[175] is very similar to that of its platinum analogue: the only difference is that the coordinated C–C bond is less stretched and has approximately the same length as the corresponding bond in the initial fullerene.‡ The reaction of C_{60} with the zero-valent $Pd_2(dba)_3$ complex yields insoluble oligomeric products of composition $C_{60}Pd_x$.[176]

$$C_{60} + Pd_2(dba)_3 \longrightarrow C_{60}Pd_x + dba .$$

In the olefin complexes with Ir(I) the olefin can be removed by buckminsterfullerene, whereas the CO, PPh_3 and $P(OMe)_3$ molecules remove the fullerene from the complex.[177–179]

Reactions with diazo compounds. Fulleroids. A new type of product was obtained by Wudl[180–182] from the reaction between buckminsterfullerene and diaryldiazo compounds. The first stage was probably [3 + 2]-cyclo-addition with formation of pyrazolene. However, after one hour a mixture of products of composition $C_{60}[CR_2]_n$ (where n = 1–6, R = Ar) was precipitated from a toluene solution.

3

‡The electrochemical synthesis of the salt $[(Ph_3P)_2N]^+C_{60}^-$ has recently been reported [H Moriyama, H Kobayashi, A Kobayashi, T Watanabe *J. Am. Chem. Soc.* **115** 1185 (1993)]. Single crystals of this salt have been studied by the X-ray structural method.

A remarkable feature of the fullerene structure is the breaking of one C–C bond in the reaction with carbenes, forming a bridge consisting of a tetrahedral carbon atom with two aryl substituents. The structures **3** formed in this way were called fulleroids. This is still the only way so far reported of preparing fullerenes with an odd number of carbon atoms: all the other fullerenes known at present have an even number of carbon atoms.

All the 6 homologous fullerenes with $n = 1-6$ (R = Ph) have been isolated and characterised spectroscopically (and also by X-ray structural analysis in the case of the first homologue). The methanoannulene structure for the compound **3** is suggested by the large distance between the carbon atoms of the pair (1.84 Å) and also by comparing the NMR spectra of this compound with those of the Vogel model compounds.[183]

The addition of the Ar_2C species to the final product takes place at a (6, 6) bond, but it was established that two additional isomers can be formed and then be converted into the main isomer. Surprisingly, in a recent study[184] of the reaction of C_{60} with unsubstituted diazomethane the addition of CH_2 was found to take place on a (6, 5) junction. Thus the regioselectivity of the formation of the fulleroid depends on the nature of the substituents on the carbene carbon (Figure 10).

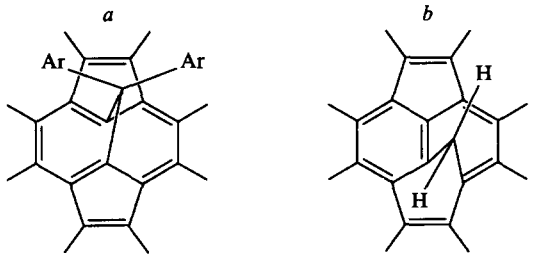


Figure 10. Fragments of the surface of $C_{60}CR_2$ fulleroids. *a* with the carbene added across the (6,6) bond, *b* with the carbene added across the (6,5) bond.

A recent publication[185] suggests that the thermolysis of azides in the presence of C_{60} produces azafulleroids; in one of these, the azide $Me_3SiCH_2CH_2OCH_2N_3$ with the ^{15}N isotopic label, it was shown that the nitrene group breaks a (5, 6) carbon bond.

We should stress the difference in structure between the adducts of C_{60} with a true (carbon) carbene or nitrene and with a platinum (or palladium) carbenoid (see above). Obviously, for carbon and nitrogen the most favourable process is the breaking of the strained cyclopropane fragment, giving two σ bonds, whereas with a transition metal the η^2 coordination is preferred.

2. Reactivity of C_{70}

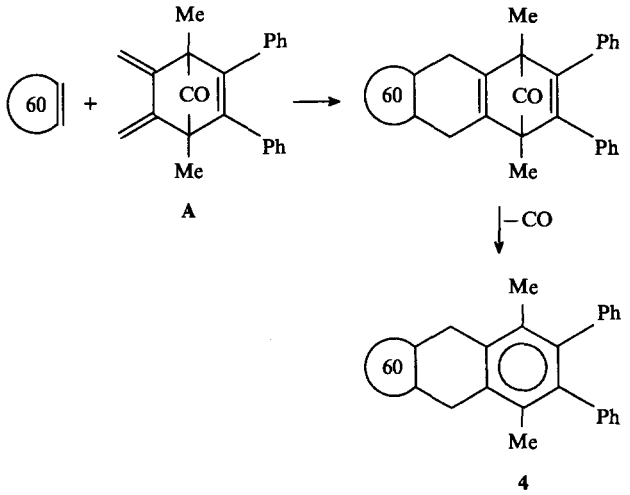
Studies with C_{60}/C_{70} mixtures failed to detect a significant difference in reactivity between the two. Therefore, since pure C_{70} is more difficult to prepare than pure C_{60} its chemical properties have been less widely studied.

Balch et al.[179] have described the synthesis and the structure of the complex of iridium(I) with C_{70}.

$$Ir(CO)(PPh_3)_2Cl + C_{70} \longrightarrow (\eta^2\text{-}C_{70})Ir(CO)(PPh_3)Cl$$

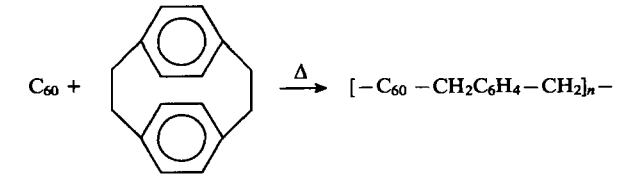
Precise information on the geometry of fullerene-70 itself was inferred from the structure of this complex. Iridium is added across a (6, 6) edge at the 'sharp' end of the egg-shaped molecule. As reported,[179] the freedom of this end of the molecule from departures from a spheroidal shape favours bond formation. The iridium complex of C_{70} could not be obtained from the η^5-indenyl derivative of iridium.[178]

The reaction of C_{70} with the $^{\bullet}P(O)(OR)_2$ phosphoranyl radicals has been studied by ESR.[160] The primary products were found to be three different phosphoranylfullerenyl radicals corresponding to addition at nonequivalent corners of a nongraphite type (i.e. not at the junction of three hexagons).



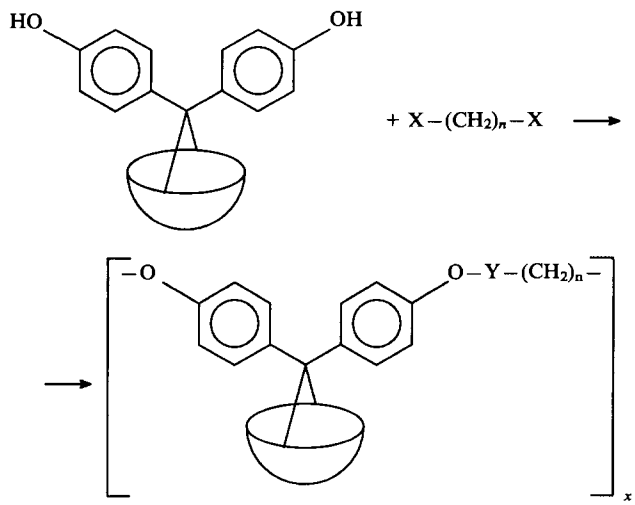
3. Other chemical properties

Inclusion compounds in which hydrophobic fullerenes act as guests for the inclusion of appropriate hosts within molecules or lattices are of special interest. It should be possible to separate the different fullerenes by this method. However, so far only one detailed publication has appeared,[185] describing the structure of the inclusion compound of C_{60} and hydroquinone with a stoichiometry of 1 : 3. The formation of a complex of γ-cyclodextrine with C_{60} has also been reported.[187] However, the formation of the inclusion compound was inferred only from the evidence of the absorption spectrum of a dilute aqueous solution.



For many reactions of the fullerenes no corroborated data are available, but tentative advance reports can be found in papers on related topics. Thus, we know that fullerenes react with anthracene, cyclopentadiene, phosphines, and amines but only the adduct of C_{60} with morpholine has been described in sufficient detail.[188] A light yellow substance whose analysis indicated the addition of 6 equivalents of the amine was precipitated from a solution of C_{60} in morpholine. The ^1H NMR spectra of this compound suggest the presence of a dynamic process, interpreted as the motion of H atoms over the surface of the spheroid.

Reliable descriptions of two cases of cycloaddition at a double bond of fullerenes in purely carbon systems are available.



The reaction with dehydrobenzene takes place as a [2+2] cycloaddition, leading to adducts of the biphenylene type.[189] To identify the product of the Diels–Alder [4+2] reaction a special diene was used (structure A), whose adduct with fullerene undergoes partial aromatisation thus preventing the retro-decomposition.[190] The stable end product **4** was characterised by X-ray structural analysis.

The prospects of including fullerenes in polymeric systems have been examined. Thus polydiazo compounds can be converted into polyfullerenes of the 'pendant chain' type.[182] By exploiting the tendency of benzyl radicals to combine with fullerenes a polymer in which the C_{60} spheroids are connected in a chain by xylylene radicals was synthesised: pyrolysis of this material gives [2,2]-paracyclophane.[191]

Clearly, multiple grafting of the chains with formation of net polymers is possible. Polymers of the polyester and polyurethane types have been obtained[192] from a fulleroid containing two *p*-hydroxyphenyl groups and derivatives of dibasic carboxylic acids.

X = –COCl, *n* = 8, Y = –CO–
X = –NCO, *n* = 6, Y = –CO–NH–

Very useful information is given by a quantitative study[193] of the solubility of C_{60}. The best solvent is carbon disulfide, in which the solubility of C_{60} greatly exceeds the solubility in any other solvent. The solvents can be arranged in the following series of decreasing ability to dissolve the fullerenes: carbon disulfide ≫ toluene > benzene > mesitylene ≫ carbon tetrachloride > methylene chloride ≫ tetradecane > dodecane > decane > cyclohexane > dioxan ≈ hexane > isooctane ≈ octane ≫ pentane.

We also have a report[194] of the preparation of mixed polyhedral carbon–lanthanide clusters (C_nLn_m) in a solution of the iron–carbon eutectic.

No information on the biological activity of the compounds of the fullerene series has been published so far. Nevertheless their ability to generate singlet oxygen under UV irradiation justifies the expectation of oxidation catalysis *in vivo*, which implies biological activity.

VII. Conclusions

This review has dealt only with the most interesting and promising directions in the chemistry of the fullerenes. Evidently, during the next few years these areas will be actively developed, and will stimulate increasing interest in both experimentalists and theoreticians.§ These directions include, in particular:

— the development of new cheaper and more convenient methods and schemes for the preparation and separation of the pure C_{60} and C_{70} fullerenes;

— the synthesis of fullerenes containing a greater number of carbon atoms;

— the development of methods of synthesis of heterofullerenes consisting of polyhedra of noncarbon atoms (boron, nitrogen, transition metals, etc.), and the synthesis of new endohedral complexes;

— the development of reliable theoretical methods of predicting the physicochemical properties of carbon clusters and of their hetero-analogues and endohedral complexes;

— the computer modelling of the mechanism of formation of fullerenes, tubulenes, torenes, and other carbon clusters;

— the creation of methods of selective functionalisation (i.e. the preparation or individual fullerene derivatives);

— the preparation of optically active fullerene derivatives and their study by chiro-optical methods;

— the creation of a fund of information on the biological activity of the fullerenes and of their derivatives, and the assessment of the ecological safety of the fullerene derivatives.

§This expectation is supported by the appearance of a new international and interdisciplinary journal: *Fullerene Science and Technology*. The first issue of this journal was produced in February 1993 by Marcel Dekker.

VI.	Conclusion	445

Abstract. The problems arising in the choice of additives that will improve the temporal and thermal stability of the non-crystalline state of materials are discussed. Transition metal oxides and amorphous metal alloys form suitable subjects for studying the effect of crystal-chemical and energy factors on the stabilisation of amorphous substances. Data on the stabilisation of the amorphous matrix by introducing alloying additives which form solid solutions with isovalent and heterovalent substitution in the cationic sublattice, chemical compounds, and alloys, are reviewed. Criteria for selecting inhibitors that will stabilise the amorphous state of a material are formulated. The bibliography comprises 63 references.

I. Introduction

In the technology of the production of many inorganic materials, e.g. oxides and metal alloys, use is often made of metastable and amorphous modifications of substances. The use of amorphous oxides in the preparation of complex coordination compounds makes it easier for solid state reactions to occur. Such oxides are used in energy-saving technologies that allow homogeneous materials to be produced under optimum conditions. Amorphous metal alloys possess special magnetic properties and resistance to corrosion; this makes them interesting topics for research. One of the problems in studying the amorphous state of a material is to find the factors affecting its time-dependent and thermal stability. This review is only concerned with an analysis of certain general structural and energy characteristics of the non-crystalline state of a solid which can be used to formulate criteria for searching for inhibitors that will hinder the transition of the amorphous to the crystalline state. As the non-crystalline state of matter is as widespread as the crystalline state, we may expect that general physicochemical principles will also be satisfied for amorphous materials.[1]

When analysing publications on the physicochemical properties of amorphous compounds we encounter the problem of comparing the properties of materials with the same or similar compositions but which have sometimes been produced under extremal conditions. For example, in the production of amorphous metal strips the rate of quenching reaches 10^8–10^{10} deg s^{-1}. This makes comparison (and recommendations) difficult because the thermodynamic functions of a substance are dependent on the method of preparation if the material is not in an equilibrium state. In a practical respect the temperatures of relaxation (T_{rel}) and crystallisation (T_{cr}) of amorphous materials, at which irreversible changes in the structure takes place, are very important, as is also, in a number of cases, the loss of valuable technological qualities. These temperatures sometimes vary by some tens of degrees for similar specimens produced in different laboratories. One must therefore concentrate on criteria for the correctness of the measurements of thermodynamic properties. Such measurements are valid if the internal state of the system remains unchanged during the measurement of the property. In this respect the certification of amorphous compounds produced by chemical methods is simpler and more reliable because such methods are milder and more easily reproduced and monitored.

Chemical methods for obtaining complex coordination compounds frequently involve the use of coprecipitation of metal hydroxides followed by dehydration which produces an intermediate state that is amorphous to X-rays. The crystallisation of such amorphous oxides sometimes has an 'explosive' character and is accompanied by a chemical reaction between the oxides giving a 100% yield of the substance being prepared. Oxides play an important role in chemical thermodynamics and can be used as models for the study of physicochemical aspects of the metastable state of matter.

Measurements of the heat capacity (C_p) and crystallisation temperature of amorphous compounds are fully valid if the time over which the property is measured is shorter than the relaxation time of the system. In most instances the thermodynamic properties of amorphous materials are measured with the use of differential thermal analysis (DTA) and/or differential scanning calorimetry (DSC) with a rate of heating less than 10 deg min^{-1}, which is much higher than the rate of relaxation of the system at temperatures a long way from the relaxation and crystallisation temperatures. This guarantees reproducibility of the properties of the specimens because the conditions under which heat is absorbed and evolved are reversible. The thermodynamic properties of metastable and amorphous modifications of solids can serve as characteristics of their stability and reactivity.

Most transition metal oxides and metal alloys belong to the category of coordination compounds. Structural studies on amorphous materials of different provenance indicate that the metal atoms have coordination polyhedra (CP), the various modes of linking of which provide short-range order in these materials in the absence of translational symmetry. A knowledge of the distinctive features and types of CPs is essential for an understanding of the reaction mechanisms in crystalline and non-crystalline states of solids and the use of the CP as a structural fragment which is common to both states enables them to be discussed from a common standpoint.

Examples indicating the polyhedral structure of amorphous oxides are given below. In films of amorphous oxides (e.g. Fe_2O_3, Al_2O_3, Nb_2O_5, and WO_3) obtained by pyrolysis of organometallic compounds in an O_2 atmosphere the first coordination number (CN) of the metal is smaller than in known crystal structures. The parameters of the structure of amorphous phases are determined by analysing the radial distribution function (RDF).[2] For example, an analysis of the RDF of an amorphous Fe_2O_3 film showed that the Fe–O distance (1.95 Å) is smaller than the corresponding distance in crystalline α-Fe_2O_3 (2.01 Å). The iron atoms in amorphous Fe_2O_3 are located in both octahedral and tetrahedral holes in a disordered packing of oxygen atoms. The presence of such holes is characteristic of the metastable modification γ-Fe_2O_3. The short-range order in the amorphous α-Fe_2O_3 is similar to that in γ-Fe_2O_3. The first coordination peak in the RDF at an Fe–O distance of 1.95 Å and the fact that $5 < CN < 6$ indicates that amorphous Fe_2O_3 can be described with the use of the most likely structural elements (MLSE).[3] A similar approach was developed elsewhere.[4]

The quantitative relationships between the types of polyhedra may vary depending on the method by which the amorphous materials have been obtained. For example, the model for the structure of an amorphous film of Al_2O_3 is a linear group of three polyhedra, two of which are AlO_6 octahedra with a shared edge and the third is an AlO_4 tetrahedron which shares a corner with one of the octahedra. For a film obtained by pyrolysis of aluminium isopropoxide at 670 K with 50 vol.% O_2 in the gas phase on an NaCl base, the mean CN(Al) is 5.3. If the O_2 concentration is raised to 75 vol.% the MLSE is a group of three AlO_4 tetrahedra, two of which have a shared face and the third is linked to them by a corner.[5]

The model of MLSE for an amorphous film of Nb_2O_5 is a linear group of three polyhedra: two tetragonal pyramids and one tetrahedron linked by corners, with a mean CN(Nb) of 4.5. The model of MLSE for amorphous WO_3 is a group of tetragonal pyramids and octahedra with a mean CN(W) of 5.5. In crystalline WO_3 the octahedron is the main coordination polyhedron. Thus the models of the atomic groupings can be regarded as subcells of the structure of amorphous oxides which are joined together to form a chain without any long-range order and are space-filling. This enables models for amorphous oxides to be obtained.[6]

A similar situation is observed in studies of amorphous alloys. The amorphous state of metal alloys is characterised by atomic short-range order and it is thermodynamically metastable.[7] Fragments of the crystal structure of metal alloys are retained in the amorphous state and the chief 'amorphising' elements are boron, carbon, and phosphorus. The stability of amorphous alloys against diffusion decomposition is associated with the presence in the alloy of fragments with rigid metal–non-metal covalent bonds. These fragments may have a composition corresponding to a stable or metastable crystalline state and a similar nearest coordination sphere.[8] To describe the Fe–B system (alloys with the approximate composition $Fe_{0.8}B_{0.2}$ form the subject of experimental studies particularly frequently) a trigonal prism model with an Fe_3C type CP has been used.[9] The tendency to amorphisation is related to the variation in the type of linking of these prisms. Clearly, the more stable such fragments the more difficult it is for disintegration of the amorphous alloy to occur on its crystallisation.

The view that transition metal oxides can be regarded as inorganic polymers with M–O covalent bonds and that the structure of the polymers can be modelled by a three-dimensional chain composed of deformed oxygen polyhedra[10] is valid. Most transition metal oxides are semiconductors or insulators. According to Ioffe "all the main properties of a semiconductor, including its band structure, are determined by the short-range order — the chemical bonds within one unit cell of the crystal".[11]

These preliminary remarks are, of necessity, fragmentary in nature but they indicate that the structures of the first coordination spheres of amorphous and crystalline structures have similar features and it is only in the more distant coordination spheres that differences are observed. It may therefore be expected that when explaining the reasons responsible for the features of the crystallisation of amorphous compounds, irrespective of their nature, the energy and crystal-chemical properties of the coordination polyhedra will be of predominant importance.

For most amorphous oxides and metal alloys, which are investigated by thermal methods, simultaneous structural studies are not carried out. The crystallisation of amorphous compounds may be accompanied by a change in the CN in the nearest neighbours. The enthalpies of the change in CN of some cations with oxygen nearest neighbours are known[12] and they are less than 5% of the enthalpies of atomisation of the oxides. Hence, to a first approximation, the effect of a change in the coordination of the metal cation when amorphous oxides and their solid solutions crystallise can be neglected (such data are not yet available for some cations). Furthermore, the ratio of the different polyhedra in the MLSE may vary depending on the method used to obtain the amorphous compound. Therefore it will henceforth be assumed that the coordination numbers of the cations are the same in the primary matrix and in the alloying constituent.

II. Crystallisation of oxides that are amorphous to X-rays

The general criteria for searching for inhibitors that will stabilise the amorphous state of a solid can be recognised by experimental studies of the crystallisation of simple amorphous (to X-rays) oxides, solid solutions, and chemical compounds with different polyhedral structures. The principal method for obtaining amorphous oxides is the careful decomposition of the hydroxide at low temperatures. Suitable model subjects are the oxides Fe_2O_3, Cr_2O_3, Al_2O_3, and ZrO_2, solid solutions based on them, and chemical compounds formed by them; these are widely used in electronic engineering. The phase transformations occurring on dehydration of the hydroxides and subsequent crystallisation of the amorphous oxides are normally studied by DTA, DSC, X-ray phase analysis, and Raman spectroscopy. By using these methods the sequence of chemical and physical changes can be reconstructed.

The preparation and crystallisation of amorphous Fe_2O_3, forming α-Fe_2O_3, had already been described by Mendeleev[13]

Table 1. *Temperatures of commencement of crystallisation and enthalpies of crystallisation of oxides from the amorphous state.*

Oxide	T_{cr} / K	$-\Delta H_{cr}$ / kJ mol^{-1}	$-\Delta H_{fus}$ / kJ mol^{-1}	$-\Delta H_{cr}/\Delta H_{fus}$	Ref.

who remarked on the spontaneous heating of dehydrated $Fe_2O_3 \cdot 1.5H_2O$.

Hydroxides of iron, chromium, and zirconium have been obtained by precipitation from solutions of the nitrates with ammonia solution[14-16] The DSC thermograms of hydroxides previously dried (100–120 °C) show endothermic effects due to the removal of water. After this the materials were oxides amorphous to X-rays. At higher temperatures exothermic effects due to crystallisation were observed, and these effects are sometimes 'explosive' in character.

The changes occurring in the hydroxides on heating have been assessed from X-ray phase analysis and Raman spectroscopic data. In the Raman spectra the bands due to M–O–H and H–O–H stretches disappear as the temperature is increased. The temperatures and enthalpies of crystallisation of the amorphous oxides are given in Table 1. T_{cr} and ΔH_{cr} from different publications show marked differences, i.e. undoubtedly the method of preparing the amorphous compounds affects their properties. As short-range order exists in the amorphous phase the value of ΔH_{cr} for the amorphous material cannot be larger in absolute magnitude than ΔH_{fus} for the crystalline material.

Publications on the determination of ΔH_{cr} for Fe_2O_3 have been analysed critically.[14] It was shown, in particular, that the value of ΔH_{cr} for Fe_2O_3 found by quantitative differential thermal analysis (−134 kJ mol^{-1} [17]) is obviously too high. This method is inaccurate and therefore the values of ΔH_{cr} for Fe_2O_3 and the other oxides (TiO_2, Al_2O_3, Cr_2O_3) must be regarded as estimates.

The enthalpies of fusion of crystalline M_2O_3 (M = Al, Cr, Ti, Sc) are 100–125 kJ mol^{-1} but the entropies of fusion are ~46 J mol^{-1} K^{-1}.[18] Since hematite α-Fe_2O_3 dissociates to magnetite and O_2 at 1 700 K (which is much lower than the melting points of the other M_2O_3, *viz.* 2 100–2 700 K), it is unlikely that the enthalpy of crystallisation of Fe_2O_3 would be of the same order of magnitude (100–125 kJ mol^{-1}) or even exceed the enthalpies of fusion of the thermodynamically stable oxides. The ratios $\alpha = \Delta H_{cr}/\Delta H_{fus}$, indicating the high energy capacity of the amorphous oxides, are also given in Table 1.

III. Crystallisation of solid solutions of oxides

The effect of adding 5–10 mol% of oxides on T_{cr} and ΔH_{cr} of amorphous Fe_2O_3 and ZrO_2 has been investigated.[15, 19-23] The main aim of this research was to find oxides which might stabilise the amorphous state of the primary matrix in the model specimens. Small amounts of additives can be introduced into a matrix of the main component and may form a solid solution, if this is permitted by the size factor, or form a chemical compound with the main component.

1. Formation of solid solutions with isovalent substitution

Studies of the effect of M_2O_3 additives (M = Al, Ga, Cr, Sc, In, La, Tm, Yb) on the variation in T_{cr} of amorphous Fe_2O_3 led to the following conclusions. In the same type of processes of solid-solution formation there is a correlation between increasing crystallisation temperature and an increase in the bond energy ε(M–O) as compared to ε(Fe–O). The higher ε(M–O) the higher the temperature of commencement of reorganisation of fragments of the structure of amorphous oxides that are formed by dehydration of coprecipitated hydroxides with subsequent crystallisation of the solid solutions based on hematite. Such solutions are formed by introducing the oxides of aluminium, chromium, gallium, indium, and scandium but the introduction of lanthanum, thulium, and ytterbium oxides, whose cations are larger, leads to crystallisation of a two-phase mixture of the orthoferrite-perovskites $MFeO_3$ with Fe_2O_3. T_{cr} and $-\Delta H_{cr}$, obtained by the DSC method, for the amorphous oxides $M_xFe_{2-x}O_3$ are given, together with their rhombohedral lattice parameters, in Table 2; crystal-chemical and energy characteristics of M^{3+} cations, and the bond energies ε(M–O) in the oxides, calculated by a method proposed previously,[24] are given in Table 3.

The increase in T_{cr} on the introduction of lanthanum, terbium [thulium? (Ed. of translation)], and ytterbium oxides is determined mainly by the high M–O bond energies. On crystallisation in an iron oxide matrix a chemical reaction takes place to form islets of a new phase: the orthoferrite $MFeO_3$. The new phase, which is distributed uniformly throughout the whole volume of the oxides crystallising, inhibits the formation of hematite and consequently the upper temperature boundary of the exothermic effect is not recorded and the large lanthanide ions do not enter into the hematite structure.

The change in the CN of the metal on insertion into the hematite structure (CN = 6, octahedron) also has an effect on the temperature range for crystallisation. The insertion of Ga^{3+} and Cr^{3+} ions, with radii similar to that of Fe^{3+}, leads to differing thermograms. The crystallisation range of the Ga–Fe solid solution is more extended than the Cr–Fe crystallisation range, reflecting the diffusion difficulties associated with the change in

Table 3. Crystal-chemical and energy characteristics of M^{3+} ions and bond energies ε(M–O) in the oxides M_2O_3.

Property	In^{3+}	Ga^{3+}	Fe^{3+}	Cr^{3+}	Sc^{3+}	Al^{3+}	Yb^{3+}	Tm^{3+}	La^{3+}
ε(M–O)[a]/ kJ g^{-1} electron^{-1}	179	195	199	222	–	255	–	–	–

$r(M^{3+})$[a]/ Å	0.80	0.62	0.65	0.62	0.75	0.53	0.87	0.88	1.03
ΔT_{cr}/ K	−9	−7	–	40	46	60	70	112	176
$\Delta\varepsilon$/ J g^{-1} electron^{-1}	−20	−2	–	23	84	56	39	58	83
Crystallisation products	Solid solution based on hematite α-Fe_2O_3 + $MFeO_3$								

Note. ΔT_{cr} is the change in the crystallisation temperature of Fe_2O_3 per 5 mol% of additive and $\Delta\varepsilon = \varepsilon(M-O) - \varepsilon(Fe-O)$; the scale of $\Delta\varepsilon$ shows the enthalpy of formation of the paired-electron bonds per 1 g-mol of electrons.

[a] CN = 6.

[b] In the individual oxide.

the CN of one of the gallium ions in the thermodynamically stable modification β-Ga_2O_3. This modification may be produced in the crystallisation of the coprecipitated hydroxides. In β-Ga_2O_3 one of the cations is tetrahedrally, and the other octahedrally, coordinated by O^{2-} ions. The structure of Cr_2O_3 is however similar to that of Fe_2O_3 and there is therefore no change in the CN of chromium on formation of a $Cr_2O_3-Fe_2O_3$ solid solution.

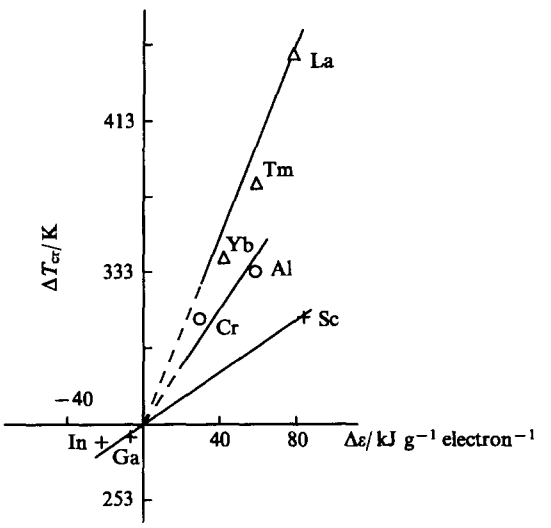

Figure 1. The change in the temperature of commencement of crystallisation of amorphous oxides $\Delta T_{cr} = T_{cr}[(M_xFe_{1-x})_2O_3] - T_{cr}(Fe_2O_3)$ plotted as a function of the bond energy difference Δε.

The function $\Delta T_{cr}(\Delta\varepsilon)$ is shown in Fig. 1 for three groups of additive cations: Al and Cr; In, Ga, and Sc; and La, Tm, and Yb. For the cations in the first group a CN of 6, which is characteristic of them in the pure oxides and in a thermodynamically stable state, is retained in the solid solution. The CN of the cations in the second group changes on formation of the solid solution. On insertion of the additive cations in the third group crystallisation of the two-phase mixture α-Fe_2O_3 + $MFeO_3$ takes place. For all three groups of additive cations the dominant factor affecting the stabilisation of the amorphous state of iron oxide is the metal–oxygen bond energy.

2. Formation of solid solutions with heterovalent substitution

The effect of heterovalent additives on the stability of the amorphous oxide has been investigated in the case of ZrO_2. Crystallisation of amorphous ZrO_2 on heating in a calorimeter leads to the formation of the metastable cubic modification, in contrast to the crystallisation of amorphous Fe_2O_3 in which the stable phase α-Fe_2O_3 is formed. The high-temperature cubic modification of ZrO_2, which is formed by crystallisation from the melt, is stabilised at low temperatures by the introduction of lanthanide oxide additives. The introduction of 5 mol% $MO_{1.5}$ leads to stabilisation of the cubic modification of ZrO_2 which persists down to 1 070 K and on subsequent cooling to 300 K. T_{cr} and ΔH_{cr} for the cubic solid solutions are shown in Table 4 and Fig. 2. ε(M–O) and the radius of the lanthanide ion (CN = 8) clearly have the main influence on T_{cr}. In Fig. 2 two coordinate fields, situated above and below the abscissa axis, can be distinguished. The ions occuring in the first field are those of yttrium, scandium, terbium, praseodymium, and neodymium, the insertion of which increases the temperature stability of the amorphous ZrO_2 matrix. The M–O bond energies in these oxides are greater than or almost the same as ε(Zr–O), which is equal to 268 kJ g^{-1} electron^{-1} in the cubic modification. In the second field the europium and ytterbium ions, which have ε(M–O) < ε(Zr–O), occur. The introduction of oxides with a lower chemical potential for oxygen favours an increase in the crystallisation temperature of the solid solution, i.e. these oxides are inhibitors of crystallisation of the amorphous state.

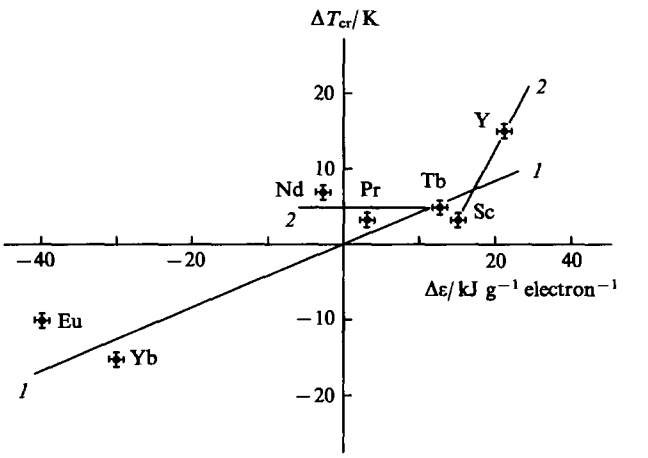

Figure 2. The change in the crystallisation temperature of solid solutions $\Delta T_{cr} = T_{cr}(Zr_{0.95}M_{0.05}O_{1.975}) - T_{cr}(ZrO_2)$ plotted as a function of the bond energy difference $\Delta\varepsilon = \varepsilon(M-O) - \varepsilon(Zr-O)$.

Table 4. Crystal-chemical and energy characteristics of the oxides $Zr_{1-x}M_xO_{2-x/2}$.

Oxide	ε(M – O) / kJ g^{-1} electron^{-1}	$r_{M^{3+}}$ / Å	$\Delta r_{M^{3+}}$ / %	T_{cr} / K	$-\Delta H_{cr}$ / kJ mol^{-1}
ZrO_2	268	0.84	–	666–715	21.0±0.46
$Zr_{0.95}Y_{0.05}O_{1.975}$	290	1.02	21	680–715	18.0±0.86
$Zr_{0.95}Sc_{0.05}O_{1.975}$	283	0.87	3.6	669–771	17.5±0.53
$Zr_{0.95}Pr_{0.05}O_{1.975}$	271	1.13	34	669–775	15.0±0.78
$Zr_{0.95}Nb_{0.05}O_{1.975}$	266	1.11	27	672–775	14.5±1.6
$Zr_{0.95}Eu_{0.05}O_{1.975}$	229	1.07	23	655–754	17.5±1.0
$Zr_{0.95}Tb_{0.05}O_{1.975}$	281	1.04	24	671–781	18.0±0.6
$Zr_{0.95}Yb_{0.05}O_{1.975}$	238	0.99	18	651–741	17.5±0.6

The large praseodymium and neodymium ions produce a slight increase in T_{cr} of amorphous ZrO_2 although their ε(M–O) values are close to ε(Zr–O). Y_2O_3, which has a high ε(Y–O) bond energy and also a large Y^{3+} cation, is an effective stabiliser of the amorphous state. In this instance the crystal-chemical and energy factors act in the same sense. The introduction of the large europium and ytterbium ions, which form oxides with lower M–O bond energies, does not have a stabilising influence. The straight line *1* in Fig. 2, which is drawn through all the points including the coordinate origin, confirms the dominant influence of the energy factor on T_{cr} but allowance for the crystal-chemical size factor adds a correction to the prediction. The broken line *2* also objectively reflects the influence of the additive on T_{cr} of the solid solution. It has been found[20] that introducing an M_2O_3 additive into the solid solution displaces ΔH_{cr} in a positive direction from −21 to −18 to −15 kJ mol^{-1}. The less negative values of ΔH_{cr} are due to the positive enthalpy of mixing (ΔH_{mix}) when heterovalent solid solutions are formed. An analysis of ΔH_{cr} with the aim of eliminating ΔH_{mix} showed that small ΔH_{mix} values are not at variance with the formation of solid solutions in the $Y_2O_3-ZrO_2$ system.

Table 5. Temperatures and enthalpies of crystallisation of the solid solutions $Zr_{1-x}Fe_xO_{2-x/2}$ and $Zr_{1-x}Mg_xO_{2-x}$.

Solid solution	T_{cr}/K	$-\Delta H_{cr}$/kJ mol^{-1}
$Zr_{0.75}Fe_{0.25}O_{1.875}$	851–943	12.0±1.5
$Zr_{0.5}Fe_{0.5}O_{1.75}$	921–1007	7.7±1.5
$Zr_{0.95}Mg_{0.05}O_{1.95}$	717–777	16.5±1.1
$Zr_{0.5}Mg_{0.5}O_{1.5}$	835–886	9.1±0.3

An unexpected result was obtained[21] regarding the effect of introducing Fe_2O_3 into ZrO_2 on T_{cr} for the solid solution $Zr_{1-x}Fe_xO_{2-x/2}$ (x = 0.25 and 0.50) (Table 5). The formation of the solid solution leads to an increase in T_{cr} compared to T_{cr} for the two amorphous oxides although $\varepsilon(Fe-O) < \varepsilon(Zr-O)$. This result is attributed to the polyhedral structure of the solid solution. Results obtained by the method of hyperfine structure of the X-ray absorption spectrum show[25] that in the cubic solid solution with x = 0.3 the ZrO_8 polyhedra are linked by their edges, the FeO_4 tetrahedra are linked by their edges to the ZrO_8 polyhedra and by two corners to other FeO_4 tetrahedra. The increase in T_{cr} is due to the formation of FeO_4 tetrahedra which are energetically less stable than FeO_6 octahedra which might appear on formation of the hematite structure. In order to form FeO_4 polyhedra a potential barrier must be overcome because the $FeO_6 \rightarrow FeO_4$ transition is accompanied by the absorption of heat (22.2 kJ mol^{-1}).[12] The small positive values of ΔH_{mix} which have been calculated[21] are not at variance with the formation of solid solutions in the $Fe_2O_3-ZrO_2$ system.

The introduction of the additive MgO has a similar effect on the increase in T_{cr} for ZrO_2.[23] In this instance the crystallisation is 'explosive' in character and T_{cr} increases compared to the value for zirconium dioxide by 200 K for every 5 mol% of MgO. MgO_8 polyhedra are formed in the cubic solid solution, the enthalpy change in the process MgO_6(octahedron)$\rightarrow MgO_8$(cube) being 71 kJ mol^{-1}.[24] To overcome the potential barrier on formation of the cubic environment of O^{2-} ions around the magnesium ion the amorphous oxides must be heated to $T > T_{cr}$ for ZrO_2, i.e. the reason for the stabilisation of the amorphous ZrO_2 is the same as when Fe_2O_3 is introduced although $\varepsilon(Mg-O) < \varepsilon(Zr-O)$.

Thus when the enthalpy of the change in the CN of the additive cations on their insertion into the solid solution has high positive values, a considerable increase in T_{cr} of the primary matrix is possible.

In research on the preparation of the adsorbents $xAl_2O_3 \cdot yZrO_2$, $xAl_2O_3 \cdot yY_2O_3$, etc.[26–28] the crystallisation temperature of coprecipitated hydroxides was shown to increase on formation of solid solutions. This phenomenon was called a protective effect from crystallisation of the components. The introduction of Al_2O_3 into a ZrO_2 matrix by heating the coprecipitated hydroxides $Al(OH)_3/Zr(OH)_4$ increases T_{cr} for tetragonal ZrO_2 by 400 K compared with the value for amorphous ZrO_2 (445 °C).[29] The energetics nature of this effect was not considered in these papers[26–29] although its interpretation may, in our opinion, be similar to that discussed above for the introduction of Fe_2O_3 and MgO into ZrO_2. The formation of Al_2O_3/ZrO_2 substitutional solid solutions will be accompanied by a change in the CN of aluminium on its insertion into zirconium positions with high CNs (7 or 8). This type of coordination is not typical of aluminium and in order to form AlO_7 or AlO_8 fragments a high potential barrier must be overcome. Magnus's crystal-chemical rules, which determine the possible CNs of cations from the ratio of the cation and anion radii, lead to the same conclusion. The enthalpy of the change in the coordination in the transition $AlO_6 \rightarrow AlO_n$ (n = 7 or 8) is not known but it probably has a high positive value. This inhibits the crystallisation of the oxides. The final products of the coprecipitation of the hydroxides $Al(OH)_3/Zr(OH)_4$ may be mixtures of polymorphs of ZrO_2 depending on the ratio of the aluminium and zirconium concentrations, the conditions used to precipitate the hydroxides, and whether the solid solutions are heated or maintained isothermally at high temperatures.[28, 30]

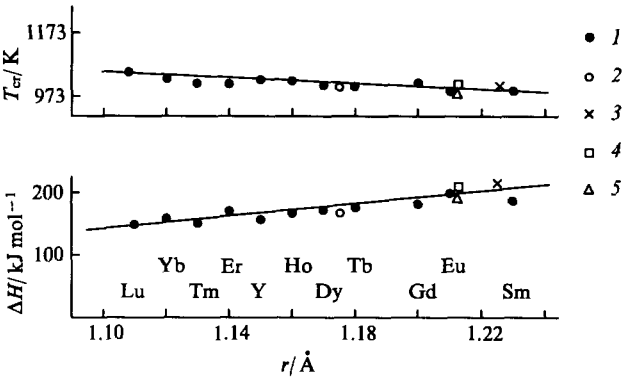

Figure 3. Variation of T_{cr} and ΔH_{cr} with the ionic radius of the lanthanide: *1*) lanthanide ions; *2*) $LuEu_2Fe_5O_{12}$, *3*) $Nd_{0.94}Gd_{2.06}Fe_5O_{12}$, *4*) $Lu_{0.48}Sm_{2.52}Fe_5O_{12}$, *5*) $La_{0.24}Gd_{2.76}Fe_5O_{12}$.

The effect of stabilisation of amorphous films based on ZrO_2 with Y_2O_3 introduced, which were obtained by electron-beam vaporisation, has been noted.[31] Crystalline films of ZrO_2 are obtained at as low a temperature as 420–470 K but the introduction of 10–20 mol% Y_2O_3 enables the amorphous state to be preserved up to 520–550 K. The crystallisation temperatures of the amorphous films are much lower than those of the amorphous compounds obtained from coprecipitated hydroxides but the introduction of Y_2O_3 into the film leads to stabilisation of the amorphous state.

IV. Crystallisation of chemical compounds from coprecipitated hydroxides that are amorphous to X-rays

The formation of chemical compounds with a more complex crystal structure than those of simple oxides or their solid solutions also increases the time-dependent and thermal stability of the amorphous state. Systematic studies have been carried out on the process of crystallisation of the ferrogarnets $E_3Fe_5O_{12}$, orthoferrites with the perovskite structure type $EFeO_3$ (E = a lanthanide ion), and compounds with the magnetoplumbite structure $MFe_{12}O_{19}$ (M = Pb, Sr, Ba).[32–37]

1. Formation of $E_3Fe_5O_{12}$

The distinctive features of the process of crystallisation of ferrogarnets from the amorphous (to X-rays) state of the oxides by DSC are associated with a change in the mechanism of the solid-state reaction. In the garnet structure there are three non-equivalent positions for the cations in an oxygen environment: $3E^{3+}$ are in EO_8 dodecahedra, $3Fe^{3+}$ in FeO_4 tetrahedra, and $2Fe^{3+}$ in FeO_6 octahedra. For the formation of the complex garnet crystal structure temperatures higher than T_{cr} for amorphous Fe_2O_3 are required (Fig. 3).

Lanthanide ferrites with the garnet structure are formed only for E = Sm ... Lu; larger lanthanide ions will not enter the garnet structure owing to steric hindrance. However, lanthanum, praseodymium, and neodymium ions can be inserted into the garnet structure if lanthanide ions with a smaller radius are introduced at the same time. The dependence of T_{cr} and ΔH_{cr} on the radius of the lanthanide is shown in Fig. 3. In general, ΔH_{cr} decreases and T_{cr} increases along the series Sm ... Lu. The formation of garnets with the large ions Sm ... Dy, and also the solid solutions $Lu_{0.48}Sm_{2.52}Fe_5O_{12}$, $La_{0.24}Gd_{2.76}Fe_5O_{12}$, $LuEu_2Fe_5O_{12}$, and $Nd_{0.94}Gd_{2.06}Fe_5O_{12}$ in which the mean radii of the lanthanide ions do not exceed the ionic radius of Sm^{3+}, is

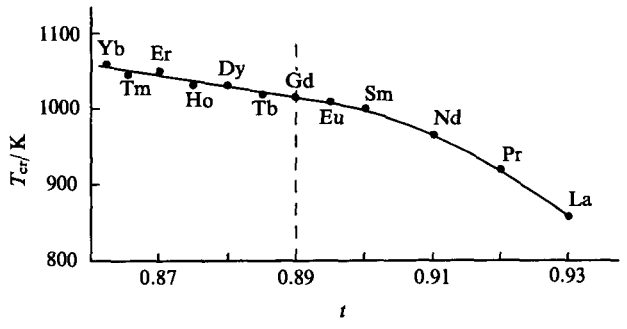

Figure 4. Dependence of T_{cr} for lanthanide orthoferrites on the stability factor t:

$$t = \frac{r_{Ln^{3+}} + r_{O^{2-}}}{\sqrt{2}(r_{Fe^{3+}} + r_{O^{2-}})}$$

accompanied by a single sharp exothermic effect within a narrow temperature range. The ferrogarnets of Ho ... Lu are formed by a more complex mechanism with an increasingly distinct separation into two crystallisation stages and a higher temperature range for the reaction. The decrease in ΔH_{cr} with increasing atomic number of the lanthanide is due to an increase in the degree of distortion of the EO_8 dodecahedra along the series Eu ... Lu. When the components are in a stoichiometric ratio crystallisation gives single-phase green garnets which have Raman spectra consistent with the published spectra. $Lu_3Fe_5O_{12}$ could not be prepared; all attempts gave a mixture of the garnet and the perovskite $LuFeO_3$ or the oxides.

The crystal-chemical factor is clearly dominant in the crystallisation of these coordination compounds which form three sublattices. On going from the state in the oxides ($6O^{2-} + 2\square$, where $\square$ represents a vacancy) there is a monotonic decrease in the enthalpy of the change in the CN of the lanthanide ions as the atomic number of the lanthanide increases, *viz.* $E(Gd^{3+}) = 33$, $E(Y^{3+}) = 71$, $E(La^{3+}) = -31$ kJ ($4O^{2-} + 3O^{2-} \rightarrow LaO_8$).[38] These individual values fit the straight line $E(E^{3+}) = f[r(E^{3+})]$, where r is the ionic radius of the lanthanide. The presence of the hydrates $E(OH)_3$ and $Y(OH)_3$ in the coprecipitated hydroxides increases T_{cr} for amorphous Fe_2O_3 from 260 to 720–770 °C, i.e. it promotes stabilisation of the amorphous state of the dehydrated oxides.

2. Formation of the orthoferrite-perovskites $EFeO_3$

Crystallisation of the coprecipitated hydroxides $E(OH)_3$/ $Fe(OH)_3$ to form lanthanide orthoferrites is observed in the range 850–1170 K. On formation of the orthoferrites of La ... Sm the DSC thermograms show a single exothermic peak due to crystallisation extending over a 70 K range. In the formation of $EuFeO_3$ the peak begins to split, the crystallisation of $GdFeO_3$ spans a range of 100 K, and at the end of the lanthanide series the crystallisation of thulium and ytterbium orthoferrites takes place in two stages extending over a range of 150 K. As for the ferrogarnets, the decrease in the ionic radius of the lanthanide at the end of the series is accompanied by a decrease in ΔH_{cr} of the orthoferrite and an increase in the thermal stability of the amorphous state. The dependence of T_{cr} on the stability factor is shown in Fig. 4. For perovskites with tervalent cations the lower limit of the t factor is 0.89. In the vicinity of $t = 0.89$ there is a change in the slope of the curve showing the dependence of T_{cr} (and ΔH_{cr}) on t and the peaks due to crystallisation start to split. The inhibiting effect of the E_2O_3 is shown by a 300–600 K increase in T_{cr}, or 6–13 K for each 1 mol% of the E_2O_3 additive if it is assumed that ΔT_{cr} is proportional to the amount of E_2O_3. These values of ΔT_{cr} are comparable with those observed when 5 mol% of ytterbium, thulium, or lutetium are introduced into Fe_2O_3 (15–30 K per mol% of the additive).

3. Formation of the hexaferrites $MFe_{12}O_{19}$

To prepare the hexaferrites $MFe_{12}O_{19}$ (M = Pb, Sr, Ba) with the magnetoplumbite structure the methods of obtaining coprecipitated hydroxides described previously[39–41] were used. The crystallisation of strontium and barium hexaferrites takes place in a single stage at 730 and 650 °C respectively. The complex coordination structure of the hexaferrites contains four types of CP in each formula unit: an MO_{12} cubo-octahedron, an FeO_5 trigonal bipyramid, two FeO_4 tetrahedra, and nine FeO_6 octahedra. This is a more complex structure than that of the perovskites or garnets. The formation of FeO_5 and FeO_4 polyhedra is energetically less favourable than the formation of FeO_6 octahedra and consequently the formation of the structure may be particularly inhibited when the crystal-chemical factor is added to the energy factor [$\varepsilon(Sr-O) > \varepsilon(Fe-O)$ and $\varepsilon(Ba-O) > \varepsilon(Fe-O)$].

A characteristic feature of the exothermic effect due to crystallisation of coprecipitated lead and iron hydroxides is that it is spread out over the range 390–670 °C on formation of $PbFe_{12}O_{19}$. Furthermore the products of the crystallisation reaction also contain α-Fe_2O_3; this is not inconsistent with the known metastability of $PbFe_{12}O_{19}$, whose enthalpy of formation from the oxides is estimated to be 37 kJ mol^{-1}.[42] In an attempt to synthesise $SrFe_{12}O_{19}$ a qualitatively similar thermogram was obtained by heating coprecipitated strontium and iron hydroxides; crystallisation of $SrFe_{12}O_{19}$ takes place at 567–777 °C. The higher temperature is due to the higher value of $\varepsilon(Sr-O)$. The formation of a mixture of the hexaferrite and hematite is also observed in this case.

The thermogram of coprecipitated barium and iron hydroxides shows a pronounced effect due to the 'explosive' formation of single-phase $BaFe_{12}O_{19}$ within the narrower temperature range 723–818 °C. The bond energies $\varepsilon(Sr-O) = 249$ and $\varepsilon(Ba-O) = 244$ kJ g^{-1} electron^{-1} agree with experimental error (± 10 kJ mol^{-1}) and overall the inhibiting effect of the large cations on the temperature of formation of the hexaferrites increases in the order Pb–Sr–Ba as $\varepsilon(M-O)$ increases. The increase in T_{cr} over the value for iron oxide is 130–460 K when 7.7 mol% of additive is introduced into the cationic sublattice, i.e. 16–60 K per mol% of the additive. This is the same order of magnitude as the increase in T_{cr} for the solid solutions based on hematite and containing 5–10 mol% of additive cations (see above). The increases in the crystallisation temperature (in K) occurring on formation of solid solutions of the oxides and chemical compounds with alloying additives introduced (calculated per 1 mol% of additive in the cationic sublattice) are given below:

Solid solution	$E_3Fe_5O_{12}$	$EFeO_3$	$MFe_{12}O_{19}$
14–30	17–20	6–13	14–60

We may conclude that the crystal-chemical (size) factor is predominant in inhibiting the crystallisation of the amorphous phase. However a definite answer to this problem is not possible in all instances. The bond energies must also be taken into account, especially if the effects of the bond energy and the size factor compensate each other to some extent.

V. Crystallisation of amorphous metal alloys

The chief 'amorphising' elements in transition metal (TM) alloys are boron, carbon, and phosphorus. One of the major problems in studying alloys (AAs) is to find the factors governing their thermal stability. We shall consider two factors which affect the stability of AAs: the nature of the metal and of the amorphising element. Both factors are, as a rule, connected with aspects of the metal–non-metal interaction and with thermodynamic stimuli of crystallisation of the AA.

Table 6. Bond energies $\varepsilon(M-X)$ and ΔH_f for compounds used to estimate the increase in thermal stability of AAs.

An irreversible transition of an AA to the crystalline state is often of a diffusion character. As in the case of oxides, stability against diffusion decomposition can be attributed to the presence in the alloy of fragments with rigid metal–non-metal covalent bonds.[43] These fragments may have a composition corresponding to a stable or metastable composition of the crystalline compound or alloy and a similar nearest coordination sphere to that in the crystal. The tendency to amorphisation is dependent on the variation in the type of linking of the coordination polyhedra in the alloy. Clearly, the higher the chemical bond energy in such fragments the more difficult it is for diffusion decomposition of the AA to occur on its crystallisation.

The question of a correlation of the structure of AAs and the bond energies $\varepsilon(M-X)$ (X = B, C, P) with the thermodynamic stability of the alloys has been raised in a general form repeatedly. However, there has rarely been any estimation of $\varepsilon(M-X)$ in a quantitative form suitable for solving practical problems, particularly those associated with estimating the enthalpies of formation (ΔH_f) of the alloys. This is because, until recently, there were no reliable thermochemical data on ΔH_f for many borides, carbides, and phosphides. The regeneration of interest in fundamental investigations of the structural and thermodynamic properties of these compounds has promoted a substantial development of a simple model for calculating the bond energies $\varepsilon(M-X)$ and hence ΔH_f.

The calculation of $\varepsilon(M-X)$ was carried out using a simplified model which takes into account the structural, thermochemical, and electrophysical properties of the compounds. The basis of the calculation has been published[44–48] for the compounds MB_n, MC_n, MN_n, MC_nO_m, and MN_nO_m, where M is a transition metal.

In these calculations the enthalpy of atomisation (ΔH_a) of the compounds to the monoatomic gas state is represented by the sum of the bond dissociation energies. In the general case for metal-like compounds of the MX type we can write

$$\Delta H_a = E_{free} + E(M-X) + E(M-M) + E(X-X)$$

$$= \Delta H_aM + \Delta H_aX - \Delta H_fMX.$$

The terms in this equation allow for the partial contributions of the free electrons of the conduction band (E_{free}), the band of covalent metal–non-metal bonds [$E(M-X)$] and metal–metal bonds [$E(M-M)$], and also non-metal–non-metal bonds [$E(X-X)$] if they are formed, e.g. as in the higher borides. For some compounds the individual contributions cannot be taken into account (for example in lower borides of the MB type where the boron atoms can be regarded as isolated). Calculations of the bond energies $\varepsilon(M-X)$ and the enthalpies of formation of transition metal borides, carbides, and phosphides (Table 6) have been carried out.[48, 49] The method of calculation is fairly simple and does not involve quantum-chemical calculations.

The data in Table 6 show that in general within the Groups of the Periodic Table the bond energies $\varepsilon(M-B)$ increase as the atomic number of the metal increases. The same trend applies to other binary compounds (oxides, halides, nitrides, etc.). Within the Periods $\varepsilon(M-X)$ decreases as the atomic number of the element increases and is approximately constant for the elements in the iron triad. $\varepsilon(M-X)$ is approximately constant for the compounds within one system; this makes it possible to estimate ΔH_f for compounds recorded on the M–X equilibrium diagrams that are unstable or have not been studied, or to estimate the compositions of alloys from the mean values of $\varepsilon(M-X)$. The approximate constancy of $\varepsilon(M-X)$ is consistent with the known principle of transferability of the characteristics of a chemical bond in compounds.

The absolute deviations of the mean values of $\varepsilon(M-X)$ from the bond energies in the individual compounds do not exceed ± 10 kJ g^{-1} electron^{-1}, which is within the error of the thermodynamic quantities.

Alloying of the binary alloys with a third component (a transition metal or X) has an appreciable effect on the time-dependent and thermal stability of an AA. It is questionable whether the bond energies calculated using thermodynamic data for the crystalline state are adequate for the bond energies in an AA. A statistical analysis of ΔH_{cr} for 40 amorphous alloys with different chemical compositions showed that the mean value of ΔH_{fus} for substances forming AAs is 16.3 kJ g-atom^{-1} but ΔH_{cr} for the amorphous alloys is −7.5 kJ g-atom^{-1}. Thus for the transition liquid→amorphous material there is a margin of internal excess enthalpy per 1 g-atom of the AA of −8.8 kJ g-atom^{-1}.[50] The value 7.5 kJ g-atom^{-1} is close to the values of the enthalpies of phase transitions and represents the difference in the enthalpies of the amorphous and crystalline materials. This value is close to a theoretical estimate based on the assumption of a non-equilibrium electronic state for the interacting atoms.[51] Such estimates agree with the conclusion[1] that the main condition for obtaining a non-crystalline state of a solid is an excess binding enthalpy equal to $0.5\Delta H_{fus}$.

The short-range order in the AA corresponds to the arrangement of the atoms in the crystal structures of some actual

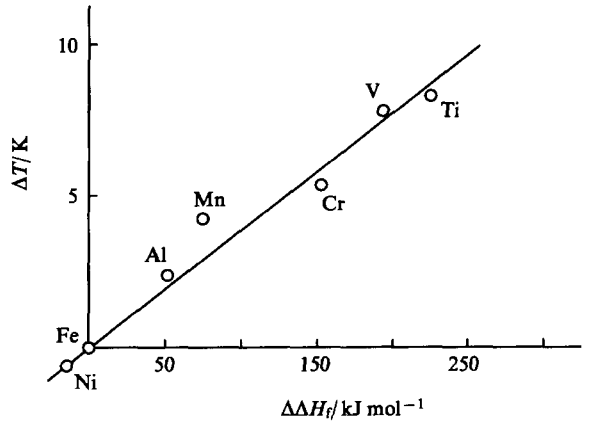

Figure 5. The change in the crystallisation temperature of the amorphous alloys $Fe_{80}M_5B_{15}$ for alloying with 1 atom % M plotted against the difference $\Delta\Delta H_f = \Delta H_f(M_3B) - \Delta H_f(Fe_3B)$ (3 atom % alloying in the case of Al).[52]

compounds that are present in the equilibrium diagrams (e.g. Co_3B or Ni_3B, where each boron atom is coordinated by nine metal atoms). The preservation in the AA of the coordination polyhedra that occur in the crystalline state makes it unnecessary to use the concept of variable valency to account for the energetics of the crystallisation of the AA.[51] The transition from the amorphous to the crystalline state can be treated as a form of polymorphic transformation. The amount 7.5 kJ g-atom^{-1} is only 1%–2% of the values of the enthalpies of atomisation of crystalline borides, carbides, and other compounds and the use of M–X bond energies calculated for compounds in the crystalline state for the amorphous alloys as well is therefore justified. It has been shown[50] that the ratio (α) of the experimental values of ΔH_{cr} for an AA and $\Sigma x_i \Delta H_i$ for the components of the alloy, where x_i is the mole fraction and ΔH_i the enthalpy of fusion of the ith component, is 0.3–0.5. This range of values corresponds to the excess enthalpy remaining in AAs obtained by various methods (spinning, condensation from the gas phase, cathode sputtering, etc.). It is easily seen that α for AAs is similar to α for oxides (see Table 1);† this indicates that the excess enthalpy in non-crystalline materials is approximately constant, irrespective of their chemical nature and method of preparation.

Let us consider two extreme cases in the variation of α. When $\alpha \rightarrow 1$ crystallisation of the amorphous material is accompanied by evolution of heat. The heat effect is similar in absolute magnitude to ΔH_{fus} of the crystal. The amorphous material retains the structure of the melt near to the equilibrium melting point. When $\alpha \rightarrow 0$ the quenched melt or other non-crystalline materials are similar in structure to the equilibrium crystal and there is no appreciable thermal effect on the thermogram. Such a material will have a similar diffraction pattern to the equilibrium crystal. In certain instances crystallisation of the AA gives strips containing a microcrystalline phase together with the amorphous phase.

For the methods used to obtain non-crystalline materials the degree of crystallinity could be described by the quantity $\beta = 1-\alpha$, so that $0.5 < \beta < 0.7$.

The introduction of 3d transition metals into an AA of the Fe_3B type increases the T_{cr} of the alloy if the 3d metal is in a Period to the left of iron. For $Fe_{80}M_5B_{15}$ (M = Ti ... Ni) T_{cr} increases, per 1 mol% M alloying content, in the order Mn–Cr–V–Ti but the introduction of nickel reduces T_{cr}.[52] Elsewhere[53] similar behaviour was observed for the series Ni–Co–Fe–Cr–V although different T_{cr} values are obtained by different authors owing to the use of different conditions for obtaining the AA and different rates of heating in the calorimeter. There is a linear relationship between the change in the crystallisation temperature of amorphous $Fe_{80}M_5B_{15}$ alloys when they are alloyed with metals and the difference in the enthalpies of formation of the alloys $\Delta\Delta H_f = \Delta H_f(M_3B) - \Delta H_f(Fe_3B)$ (Fig. 5).[48] $\Delta H_f(M_3B)$ was calculated on the basis of the bond energies ε(M–B) (see Table 6). There is obviously a connection between the decrease in the activity of boron on formation of borides with high ΔH_f values and the increase in the thermal stability of the AA. The thermal stability is associated with the formation of boron positions in the AA that have a lower energy and so inhibit crystallisation.[52] It can therefore be predicted that the T_{cr} of alloys of this type can be increased considerably by alloying with lanthanide, Sc, and Y borides.

It is clear from Table 6 that $\varepsilon(M-P) \simeq \varepsilon(M-C)$ and $\varepsilon(M-B)$ is ~10% higher. The similarity of the M–X bond energies in these compounds and the compatibility of the fragments facilitates alloying of amorphous alloys based on the Fe–B system with boron, carbon, and phosphorus. The formation of the more exothermic iron phosphides, for example, as compared to the borides, leads to a reduction in the thermodynamic activity of iron in the alloy. Analysis of experimental data on T_{cr} for AAs in M–X (M = Fe, Co, Ni) systems showed that T_{cr} is 610–680 K for the phosphides, 600–700 K for borides, and only 450 K for Fe_3C.[54] These values accurately reflect the main trends: Fe_3C, which is endothermic, has the lowest value of T_{cr} while the exothermic phosphides and borides have high thermal stability. Therefore the reason for the variation in T_{cr} of an amorphous material irrespective of its nature is the formation of more stable fragments of compounds that strengthen the matrix of the amorphous compound.

The validity of the conceptual approach based on a quantitative consideration of the energy non-equivalence of coexisting bonds is confirmed by recently published data on the effect of alloying the primary matrix with transition metal additives on the relaxation temperature. An analysis has been carried out[55] of publications[56–58] in which the effect of replacing iron in alloys with compositions close to Fe_4B or Fe_5B was determined. To a first approximation the compositions of the alloyed materials can be described as 95 mol% Fe_4B + 5 mol% M_4B (M = Co, V). The enthalpies of formation of the alloys were calculated[55] from the equation

$$\Delta H_f = 0{\cdot}95\Delta H_f(Fe_4B) + 0.05\Delta H_f(M_4B),$$

on the assumption that the enthalpy of mixing is zero. The reduction in the relaxation temperature when cobalt is introduced into the alloy $Fe_{0.81}B_{0.19}$ and the increase when vanadium is introduced are due to the fact that $\Delta H_f(Co_4B) < \Delta H_f(Fe_4B)$ but $\Delta H_f(V_4B) > \Delta H_f(Fe_4B)$. The enthalpies of formation of Co_4B, Fe_4B, and V_4B are −21, −25, and −213 kJ (mol M_4B)$^{-1}$ respectively. The introduction of vanadium, which forms a boride whose ΔH_f is more negative than $\Delta H_f(Fe_4B)$, favours a reduction in the activity of boron in the Fe–B system, hinders the diffusion mobility of fragments of the amorphous structure, and

Table 7. Transition temperatures of amorphous alloys and the calculated enthalpies of formation of the alloys.

Alloy	T_{rel}/K, T_{cr}/K	ΔT_{rel}/K, ΔT_{cr}/K	$-\Delta H_f(M_xB)$ / kJ mol^{-1}
$Fe_{0.81}B_{0.19}(Fe_{4.26}B)$	603	–	25
$Fe_{0.76}Co_{0.04}B_{0.20}(M_4B)$	595	−8	24.8
$Fe_{0.75}V_{0.04}B_{0.21}(M_{3.76}B)$	663	60	34.4
$Fe_{0.74}Co_{0.10}B_{0.16}$	688	–	24.7
$Fe_{0.74}Co_{0.05}Cr_{0.05}B_{0.16}$	733	45	34.2
$Fe_{0.74}Cr_{0.10}B_{0.16}$	763	75	43.5

Note. The values given for the first three alloys are T_{rel} from the data of Barricco et al.[56] (x = 4); those for the other alloys are T_{cr} from other data[57, 58] (x = 5). The possible error in ΔT_{rel} for the second alloy is ±50% owing the small scale of the figure in the paper.[56]

† We recall that the values of α from the data of Natarajan et al.[17] are estimated

Table 8. Changes in T_{cr} for the alloys $Fe_{79-x}B_{16}Si_5M_x$ (x = 4).

Element	T_{cr}/K	ΔT/K	ΔT/K per 1 mol%
V	806	30	7.5
Cr	790	14	3.5
Nb	816	40	10
Mo	814	38	9.5
Ni	773	−3	−0.8
Fe	776	–	–

increases the potential barrier to relaxation. The introduction of cobalt, on the other hand, reduces the relaxation temperature of the alloy (Table 7).

In the case of alloys with compositions close to M_5B studies have been made of the effect of T_{cr} of replacing the cobalt in $Fe_{0.74}Co_{0.10}B_{0.16}$ by chromium.[57, 58] Replacing 50%–100% of the cobalt by chromium leads to an increase in T_{cr} by 45–75 K. The introduction of chromium, vanadium, molybdenum, niobium, and nickel into the AA with the more complex composition $Fe_{79-x}B_{16}Si_5M_x$, which contains two amorphising elements (boron and silicon), gives similar results (Table 8).[59]

Barrue et al.[59] arranged the alloying elements in order of decreasing atomic radius: Nb > Mo > V > Cr, noting that there is a correlation between the size of the substituent atom and T_{cr} of the alloy. However, the size of the atom is larger for 4*d* elements than for their 3*d* analogues. Comparison of the pairs V–Cr and Nb–Mo indicates a semi-quantitative correlation: the increase in T_{cr} on introducing vanadium and niobium is more marked than on introducing chromium and molybdenum; this is consistent with the greater thermodynamic stability of borides of Group V elements compared with those of Group VI elements.

The change in T_{rel} and T_{cr} for AAs with the still more complex compositions $Fe_{39}Ni_{36}Cr_5P_{14}B_6$, $Fe_{76}Co_4B_{20}$, and $Fe_{75}V_4B_{21}$, as compared with the typical matrix $Fe_{81}B_{19}$ (Fe_4B), has been studied by DSC.[56] The introduction of chromium, phosphorus, and vanadium into $Fe_{81}B_{19}$ leads to the formation of chromium and vanadium borides and phosphides that are thermodynamically more stable than Fe_4B. An important feature of the method used[56] was an X-ray diffraction examination of both sides of the amorphous strip from the quenched melt; this confirmed the absence of crystallisation throughout the whole thickness. A study has been made of the effect of high-melting metals on the thermal stability of amorphous bands of Ni–M–B alloys (M = Zr, Nb, Mo; 13–14 mol% B, 5–14 mol% M).[60] The alloys containing zirconium retain an amorphous state at higher temperatures than those containing niobium and molybdenum and the crystallisation temperatures of the AAs increase linearly with increasing zirconium and molybdenum concentrations. This effect is consistent with the greater stability of zirconium borides as compared with molybdenum and niobium borides.

A comprehensive study of the dependence of T_{cr} on features of the electronic structure of the AAs $Fe_{75}B_{20}M_5$, where M = Ni, Co, Cr, V, Mo, W, and Nb, has been carried out.[53] Calorimetric studies showed that T_{cr} increases for this set of metals: 415, 467, 502, 566, 597, 611, and 613 °C, and this is consistent with the increase in the thermodynamic stability of M_4B fragments in sets of 3*d* and 4*d* metals. The similarity of T_{cr} for the niobium and vanadium [tungsten? Ed.] alloys is also consistent with the known diagonal similarity between elements in the Periodic Table.[61] The increase in T_{cr} for the alloys formed by metals in the same Group, e.g. the Group VI metals Cr–Mo–W, is consistent with the general tendency for the borides to have increasing ΔH_f values and hence for there to be increasing stability of the structural fragments. K_α emission spectra have been studied for the series under discussion (with the use of an electron microbeam as the excitation source). The shift of the K_α band of the compound, as compared with the K_α band of boron, from 1 to 1.35 eV as we pass along the series Ni ... Nb is due to an increase in the degree of overlap of the *d* electrons of the transition metal atoms with the 2*p* electrons of boron. This implies an increase in the M–B bond strength along this series, as is confirmed by thermodynamic calculations.

The introduction of 5 mol% of such elements as chromium, vanadium, molybdenum, niobium, tungsten, and tantalum into the alloy $Fe_{80}B_{20}$ increases T_{cr};[62] however the interpretation of the observed linear relationship $T_{cr} = f(Z/U)$, where Z is the atomic number of the element and U is the $M \rightarrow M^+$ ionisation potential, raises doubts as to the appropriateness of using such an argument for the function because there is no evidence that the M atoms are singly ionised in the borides.

There are wide discrepancies in the published values of the crystallisation temperatures for the replacement of the iron in FeB_n alloys by other transition metals. This is due to differences in the conditions of preparation of the AAs; the preparation is carried out under extremal conditions and is evidently not sufficiently reliably monitored (rate of quenching, thickness of the AA strip, possible deviations from the prescribed composition of the mixture due to evaporation of the components with different vapour pressures, methods of measuring T_{cr}, etc.). The use of high-sensitivity DSC enables observations to be made up to the crystallisation temperature of the alloy on changes in the solid state due to relaxation of the quenched alloy, the Curie temperature of the α-Fe phase which separates out, the crystallisation temperature of α-Fe, and, only after this, on T_{cr} for the alloy.[63] Consequently in working on this review we did not undertake the task of covering all the published literature in this field but have selected for investigation only the most representative topics which had been dealt with properly and contain reliable primary information. The increasing number of publications on the experimental thermodynamics of AAs means that it is necessary to look for criteria for choosing model AAs which might serve as key compounds in the chemical thermodynamics of non-crystalline materials. The use of such 'benchmarks' in research will contribute to a more reasoned comparison of the properties of the alloys.

VI. Conclusion

This review deals with the results of experimental studies of the conditions of crystallisation of amorphous materials in the presence of alloying additives that reduce the diffusion mobility or increase the thermodynamic stability of fragments of the amorphous matrix. Additives that are effective stabilisers of the amorphous state of coordination compounds (oxides) are oxides in which the metal–oxygen bonds are stronger than those in the primary matrix and the cations are larger than those in the primary matrix. A change in the CN of the additive cation on insertion into the amorphous matrix has an inhibiting effect when the enthalpy of the change in coordination during crystallisation of the amorphous phase has a high positive value. An increase in the crystallisation temperature of the solid solution is due to a potential barrier being overcome on formation of the less stable coordination polyhedron of the additive cation which is 'finely adjusted' to the polyhedron of the cation in the matrix. As a simplification it is assumed that the enthalpies of the change in the coordination of the cations in the primary matrix and in the additive are identical in the amorphous and crystalline states.

The crystal-chemical factor is dominant for the introduction of additives capable of forming compounds with a complex polyhedral structure and with the same crystal structure. The variation in the bond energies $\varepsilon(M-O)$ in a series of lanthanide oxides is not monotonic owing to the 'bivalence' of europium and ytterbium in the metallic state and the necessity, in contrast to the other lanthanides, to promote a third electron when the oxide E_2O_3 is formed. However, the crystallisation temperatures of the amorphous phases do increase monotonically with increasing atomic number of the lanthanide. The insertion of a new phase of compounds with a complex structure inhibits crystallisation and amorphous compounds must be heated to a higher

temperature even in those instances where the concentration of the additive is small but its insertion into the matrix of the primary material is impossible for crystal-chemical reasons.

The effects of introducing a third component into amorphous binary metal alloys on the thermal stabilisation are interpreted from the same conceptual standpoints. The main thermodynamic reason for an increase in the crystallisation temperature of the amorphous material irrespective of its chemical nature is the formation of fragments of more stable compounds which strengthen the amorphous matrix and inhibit diffusion processes.

The energy content of amorphous materials is 20% – 50% of the enthalpy of fusion of crystalline phases. The increase in the crystallisation temperature on the introduction of alloying components into amorphous oxides and metal alloys is 5 – 60 K per mol% of the component.

Abstract. Data on the carbene reactions of diazoesters with carbon – hydrogen, heteroatom – hydrogen, carbon – carbon, carbon – heteroatom, and heteroatom – heteroatom σ-bonds in organic molecules, demonstrating the synthetic possibilities of such reactions as an effective and universal method of the alkoxycarbonylmethylenation of organic compounds, are considered systematically. The bibliography includes 179 references.

I. Introduction

The reactions involving the carbene decomposition of the esters of diazoacetic and other carboxylic diazoacids (diazoesters) are widely used in organic synthesis for the preparation of the esters of cyclopropanecarboxylic and cyclopropenecarboxylic acids from unsaturated compounds.[1-8] The reactions of diazoesters with saturated compounds, leading in the general case to the insertion of the $CRCO_2R^1$ fragment in the X – Y σ-bonds as a result of the dissociation of these bonds and formation of new C – X and C – Y bonds, are much less well known. This reaction can be achieved either as a concerted process via a three-centre transition state with retention of the configuration of the asymmetric atom (pathway *a*) or as the opposite stepwise process involving racemisation, of the type of abstraction – recombination with participation of radical species (pathway *b*), dipolar intermediates (pathway *c*), or ylide structures (pathway *d*) (Scheme 1).

Clearly the operation of a particular pathway is mainly determined by the structure of the substrate and also by the mode of generation of the carbene. The synthetic importance of reactions of this type is due to the possibility of the introduction of functional groups at carbon atoms of saturated compounds. However, until recently, their use in organic synthesis was restricted because of the lack of convenient methods for the generation of alkoxycarbonylcarbenes (ACC) capable of entering into selective reactions with σ-bonds. The photolytic and thermal dediazotisation of diazoesters leads to the formation of extremely active carbenes, which react nonselectively with an acceptor to form a large number of products. Catalytic dediazotisation on treatment with traditional catalysts based on copper compounds leads to more selective carbenes but ensures the necessary preparative selectivity of the reactions of diazoesters with saturated compounds only in individual instances.

Scheme 1

Only the latest advances in the catalysis of the carbene decomposition of diazoesters and in first place the use of rhodium(II) compounds as catalysts of this process[9] led to the possibility of the wide scale employment of the insertion reactions for the alkoxycarbonylmethylenation of a wide variety of saturated compounds. Since the discovery of rhodium catalysis, extensive experimental data have accumulated, which, however, have not been treated systematically, although individual examples of reactions of this type have been included in virtually all the reviews devoted to the chemistry of diazoesters.[2-8,10]

In the present review, an attempt is made for the first time to consider systematically the literature data on the reactions of diazoesters with saturated compounds. The review is not exhaustive and its aim is to provide only a general idea about the synthetic possibilities of reactions of this type. For convenience, the entire data have been grouped in terms of the types of bonds involved in the reaction: carbon – hydrogen, heteroatom – hydrogen, carbon – carbon, carbon – heteroatom, and heteroatom – heteroatom. Within the groups, the classification is based on the type of compounds incorporating these bonds and the kind of heteroatom.

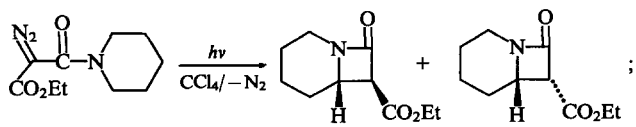
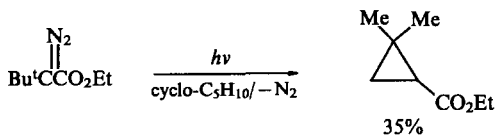
II. Carbon–hydrogen bonds

1. Aliphatic C–H bonds

Reactions involving the insertion of ACC in the C–H bonds of alkanes, alkenes, and alkynes are known. They can be represented by the following equation in a general form:

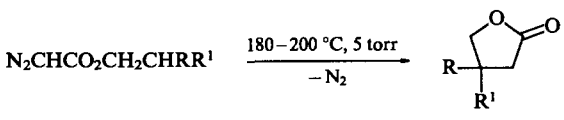


The reaction with alkanes is of limited synthetic applicability because the low selectivity of the highly reactive ACC in relation to primary, secondary, and tertiary C–H bonds and the ease of the dimerisation of carbenes usually lead to mixtures of products, although their overall yields reach 90% when rhodium(II) carboxylates are used as catalysts.[11] The rules governing the catalytic action of the above catalysts as a function of the structure of the substrate, diazoester, and the counterion and the catalyst concentration have been examined.[12,13] The formation of the products of insertion in the C–H bonds of alkanes in high yields (~90%) has been noted in the dediazotisation of diazoesters with an unsaturated alcoholic component, for example, prenyl diazoacetate in hexane in the presence of $CuCl_2$.



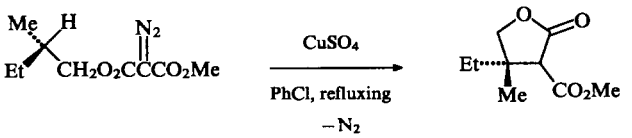
The intermolecular C–H insertion reaction has found a practical application in the modification of ethylenepropylene rubber, which is achieved by treating the latter with ethyl diazoacetate (EDA) at 210 °C (degree of functionalisation 5%–10%).[14]

The intramolecular C–H insertion reactions are of much greater synthetic importance. These reactions proceed with preparative yields even under the conditions of the photolysis or pyrolysis of diazoesters (Scheme 2).[15–17]



Scheme 2

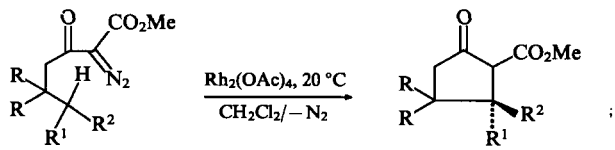
overall yield 80%; 1 : 2 ratio



35%

20%

Preparative yields can be achieved also using copper compounds as catalysts of the dediazotisation of the diazoesters (Scheme 3).[18]

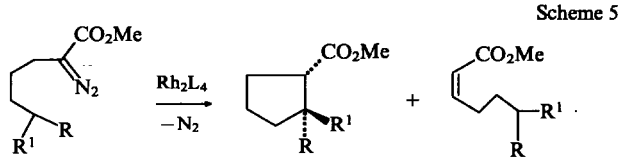


Scheme 3

48%

The use of rhodium(II) carboxylates makes it possible to carry out the reactions under milder conditions, which promotes an increase in the yields of products and the process selectivity (Scheme 4).[19,20]

Scheme 4



55%–77%

R = Me, Pr^i, C_8H_{17}, $H_2C{=}CH$, $Me_2C{=}CHCH_2$,
$R^1 = R^2$ = H, Me.

The reactivity of the C–H bonds in this reaction diminishes in the sequence C_{tert}–H > C_{sec}–H > C_n–H and all the bonds are more reactive than the C–H bonds of the benzyl and allyl types.[21,22]

When the molecule contains long unbranched hydrocarbon chains, the bond subjected to attack by the carbene centre is exclusively a C–H bond at the ε-carbon atom with formation of cyclopentane derivatives.[23] The insertion reaction is then complicated by the competing processes involving the elimination of a β-hydrogen atom with formation of acrylic acid derivatives, the relative contributions of these pathways depending on the ligand at the rhodium atom (Scheme 5).

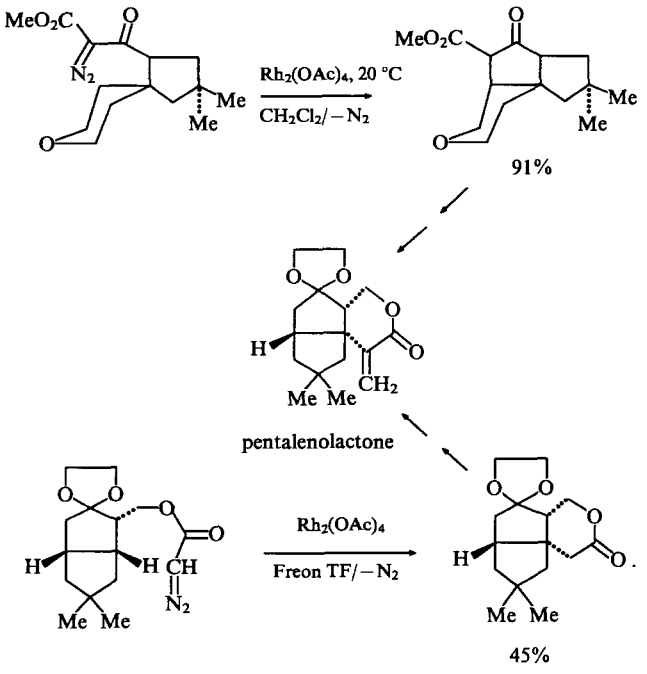
$OCOCF_3$	93	52:48	99	26:74

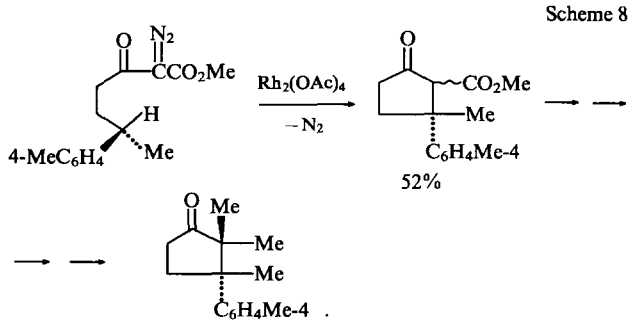
The steric factor can exert an even greater influence on the course of the process than the electronic factor, as a result of which the carbene may cyclise with participation of not the tertiary but the secondary carbon atom (Scheme 6).[24,25]

Scheme 6



34%, *trans*

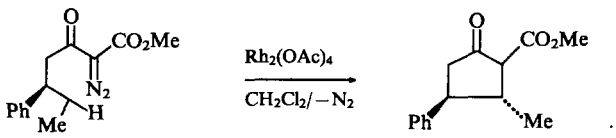
These examples demonstrate in addition the ability of rhodium compounds, in contrast to the copper catalysts, to effect the C–H insertion reactions even in the presence of a double bond.



The marked sensitivity of the intramolecular insertion reactions to steric factors must be taken into account in choosing a strategy for the synthesis of the target products. Thus the two schemes proposed by Taber and Schuchardt[26] and Cane and Thomas[27] for the synthesis of pentalenolactone are based on the preferential attack by the carbene on the sterically most accessible bonds, although in the second case this leads to the formation of a six-membered and not a five-membered ring (Scheme 7).

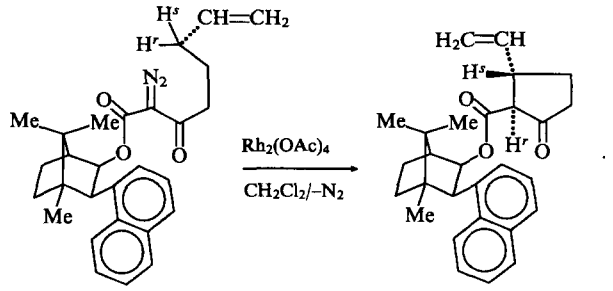
Scheme 7

The intramolecular insertion reaction with participation of rhodium complexes of carbenes, generated by the dediazotisation of β-oxodiazoacetates, is distinguished by a high degree of stereoselectivity and proceeds with retention of the configuration of the attacked carbon atom, which enabled, for example, Taber et al.,[22] to use this reaction for the synthesis of α-cuparenone (Scheme 8).



Scheme 8

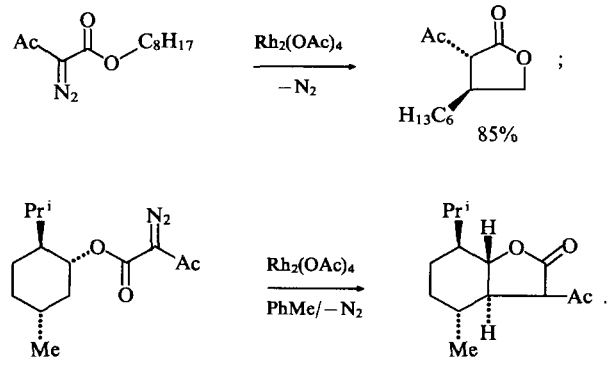
α-cuparenone



The same group of workers established that the substituents in α-acetyldiazoacetates increase the *trans*-selectivity of the intramolecular C–H insertion (Scheme 9)[28] and the enantioselectivity of the cyclisation to form the rhodium complex of a carbene from the chiral oxodiazoester precursor **3** (Scheme 10).[29] The bulky α-naphthyl substituent in the above diazoester effectively shields one of the sides of the acyl substituent and favours the insertion of the carbene centre in the C–H^r bond. The hydrolysis and decarboxylation of the esters thus obtained permit the enantioselective synthesis of cyclopentanones with an enantioselective excess (e.e.) up to 98%.

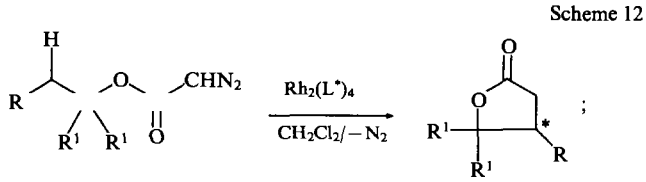
Scheme 9

66%, *trans*



Scheme 10

3 e.e. 98%



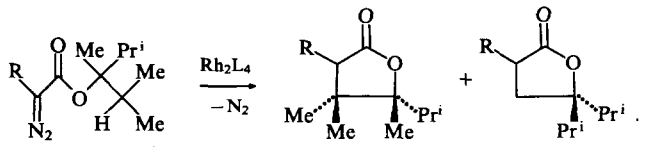
The C–H insertion reactions involving the alcoholic part of α-diazoacetates on treatment with rhodium(II) acetate and acetamide proceeds with a selectivity which is just as high. Thus it is possible to obtain γ-lactones with high regio- and diastereoselectivities and a virtually complete conversion of the diazoester (Scheme 11).[30]

Scheme 11

Data have been published recently on the asymmetric synthesis of lactones with a high enantioselectivity (enantiomeric excess up to 85%) via intramolecular C–H insertion reactions of carbenes generated from certain alkoxyethyl diazoacetates on treatment with chiral rhodium(II) carboxamides, in particular tetrakis(5-methoxycarbonylpyrrolidin-2-one)dirhodium(II) [Rh_2(MEPY)$_4$].[31] The configuration of the resulting lactone is then determined by that of the catalyst ligand and the substituent R (Scheme 12).

Scheme 12

R = MeO, EtO, $PhCH_2O$, Ph; 42%–56%



R^1 = H, Me; L* = (*R*)- or (*S*)-MEPY. e.e. 77%–85%

By 'grafting' this catalyst to the polyethylene, it is possible to achieve the enantioselective synthesis of lactones in a heterogeneous version, which simplifies significantly processes involving the recovery of the expensive rhodium catalysts.[32]

Unfortunately, the effectiveness of this catalyst is inferior to that of the homogeneous catalyst and is reduced sharply after its repeated use.

It is noteworthy that the intramolecular C–H insertion reactions with participation of the alcoholic components of diazoesters are extremely sensitive to the structure of the diazoester and the catalyst counterion. Thus, under the influence of rhodium(II) perfluorobutyrate, alkyl diazoacetates (ADA) and alkyl α-acyldiazoacetates cyclise with the preferential formation of the products of insertion in the C–H bonds formed by the primary carbon atom, the process selectivity being somewhat higher in the case of ADA (Table 1). On the other hand, under the influence of rhodium(II) acetate, the insertion takes place mainly, and in the presence of rhodium(II) acetamide, exclusively in tertiary C–H bonds.[30]

Table 1. The regioselectivity of the intramolecular C–H insertion reactions with participation of the alcoholic component of diazoacetates.

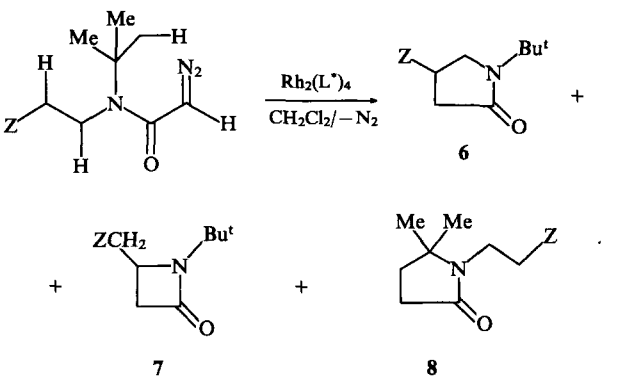
OAc	81	53:47	97	90:10
acam	96	>99:1	89	>99:1

Note. pfb = perfluorobutyrate and acam = acetamide.

The influence of the ligand on the selectivity of the rhodium(II)-catalysed C–H insertion processes has been demonstrated in relation to the intramolecular reactions of diazoamides. Thus in the case of substituted *N*-(*tert*-butyl)-*N*-ethyldiazoamides, the attack by the carbene centre can be directed to all the C–H bonds of the ethyl and *tert*-butyl fragments. However, depending on the counterion, it is possible to achieve the required specific cyclisation of the carbene with an appreciable enantioselectivity (Table 2).[33]

The dediazotisation of diazoamides containing an aromatic fragment proceeds either via insertion in the C–H bond at the δ-carbon atom or with participation of the multiple bonds of the aromatic substituent, depending on the ligand (Scheme 13).[34]



Scheme 13

The substituents at the carbon atom of the diazo-group also affect significantly the regioselectivity of the dediazotisation of aromatic aryl-substituted diazoamides. Diazoamides with electron-accepting substituents, for example, Ac, CO_2R, or SO_2Ph, are dediazotised on treatment with $Rh_2(OAc)_4$ usually with the preferential formation of the products of insertion in aliphatic C–H bonds (Scheme 14), although the cyclisation of certain α-acyldiazoamides is accompanied by the formation of products of insertion in aromatic C–H bonds (Scheme 15).[35]

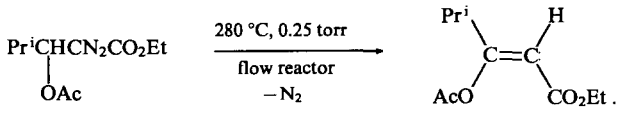
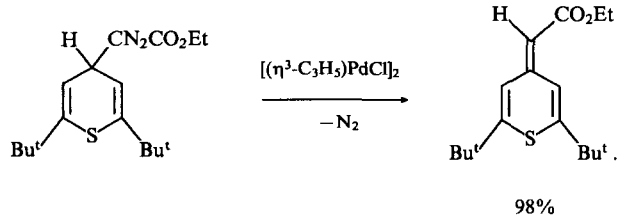
61% 26%

Scheme 15



R = CO_2Me 88% R = Ac 61%

An interesting instance of intramolecular reactions of diazoesters with participation of C–H bonds is the [1,2]-hydride shift of the hydrogen atom to a neighbouring carbene centre with formation of acrylic acid derivatives.



In the absence of active carbene acceptors, this rearrangement is the main pathway in the dediazotisation of diazoacetic acid esters on heating (Scheme 16)[36] and on treatment with catalysts based on transition metals (Schemes 17 and 18)[37,38] and Lewis acids (Scheme 19).[39]

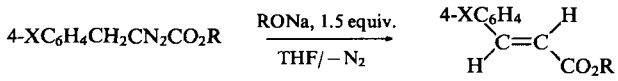
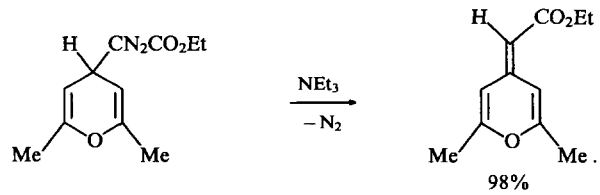
[a] Another product is methylbicyclo[1.1.0]butanecarboxylate (yield 51%).



Scheme 19

DCC = dicyclohexylcarbodiimide;
X = H, NO_2, MeO; R = Me, Et.



The yields of the acrylic acid derivatives thus obtained reach 98%, the (Z)-isomer predominating. Furthermore, in the case of the H-shift of the hydrogen atom in the methylene fragment, the reaction leads to the (Z)-isomer only. Similar reactions of diazoesters can be initiated also by bases.[39,40] However, in this case the reaction leads to the (E)-isomer (Scheme 20).

Scheme 20

X = H, NO_2, MeO; R = Me, Et

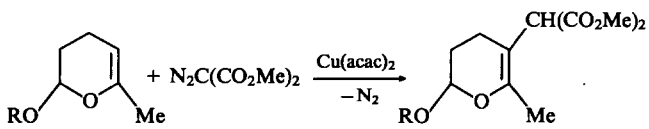
98%

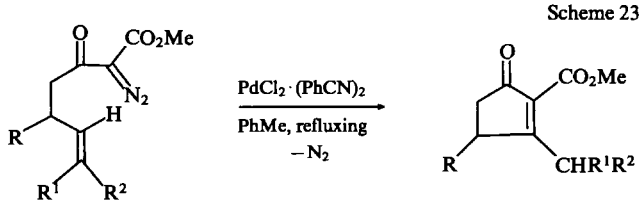
The migration of a hydrogen atom in the rhodium(II)-catalysed dediazotisation of certain diazoesters with an active methylene group proceeds to an appreciable extent even in the presence of methanol (Scheme 21),[37] which is an active carbene acceptor under these conditions (Section III).



Scheme 21

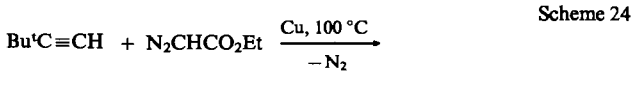
80% (1:1)

A few examples of reactions involving the insertion of carbenes in the vinyl C–H bonds of alkenes are known. Thus, although the ACC generated by the photolysis or pyrolysis of alkyl diazoacetates afford predominantly cyclopropane adducts on reaction with olefins, the products of insertion in the vinyl C–H bonds are also formed in a small amount (3%–5%).[41] On the other hand, the catalytic dediazotisation of alkyl diazoacetates makes it possible to obtain the corresponding C–H insertion products with a high selectivity. In particular, the formation of vinyl insertion products has been observed in the reaction of dimethyl diazomalonate (MDM) with vinyl ethers in the presence of copper catalysts (Scheme 22).[42]



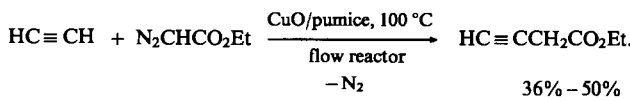
Scheme 22

76%–80%



The intramolecular reaction of 2-diazo-3-oxohept-6-enoates on treatment with palladium(II), leading to methyl 3-alkylcyclopent-2-enecarboxylates in 34%–73% yields (Scheme 23), belongs formally to this type of reactions.[43]

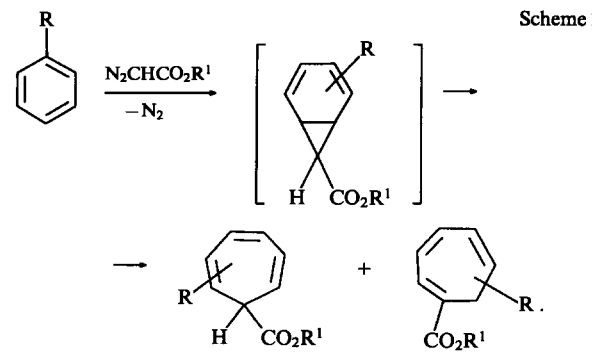
Scheme 23



The reaction with ethyl diazoacetate under these conditions leads to the cyclopropane adduct only.[44] Instances of the insertion of ACC in a C–H bond at an *sp*-hybridised carbon atom in alkynes are also known. As in the case of alkenes, here the direct insertion of carbenes in these bonds with formation of the esters of alk-3-ynoic acids is scarcely possible, because the photolysis of alkyl diazoacetates in the presence of terminal alkynes leads only to products of C–H insertion in alkyl substituents together with cyclopropenes. The formal products of insertion in an acetylenic C–H bond in terminal acetylenes, observed[45] in the catalytic dediazotisation of alkyl diazoacetates, are most probably formed from the 1-pyrazoles produced initially (Scheme 24).[46]

Scheme 24

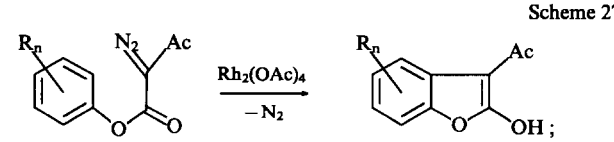
The only example of a preparative reaction of this type is the copyrolysis of acetylene with ethyl diazoacetate over a copper catalyst in a flow reactor, which leads to a butynoic acid ester in a yield up to 50% (Scheme 25).[47]



Scheme 25

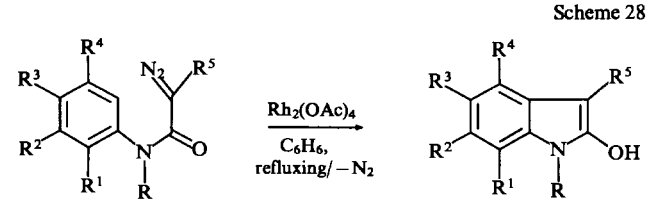
2. C–H bonds in aromatic compounds of the benzenoid series

The carbenes generated by the dediazotisation of diazoesters add to the multiple bonds of aromatic compounds in the absence of more active acceptors (Scheme 26). However, bicyclo[4.1.0]-heptadienes are usually not identified in the reaction products because they readily isomerise to 1-*H*-cyclohepta-2,4,6-triene-carboxylates and the thermodynamically more stable 7-*H*-cyclo-hepta-1,3,5-trienecarboxylates.



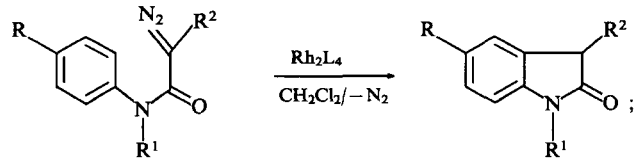
Scheme 26

Much attention has been devoted in recent years to the study of the intramolecular cyclisation reactions of ACC containing aromatic substituents. However, these reactions result in the formation not of cycloheptatriene derivatives but of the products of the formal insertion of the carbene in aromatic C–H bonds. Although it has still not been ultimately established whether this entails the concerted insertion of the carbene in a C–H bond or the isomerisation of the cyclopropane adduct formed initially, this reaction constitutes a convenient method of synthesis of polycyclic systems.



For example, the dediazotisation of phenyl α-acetyldiazo-acetates (Scheme 27)[48] or *N*-phenyldiazoamides (Schemes 28 and 29),[35,49,50] initiated by rhodium(II), is accompanied by the intramolecular cyclisation of the corresponding metal carbene complexes with formation of substituted enols of benzo[*b*]-furanone or oxindoles respectively in satisfactory yields.

Scheme 27



R = H, 2-Me, 2-Br, 3,4-OCH_2O; 92%–98%.

Scheme 28

R = Alk, CH_2Ph, R^5 = H, Ac;

L = OAc, $OCOCF_3$, pfb, acam;

R = R^2 = H, R^1 = Me (86%),
R = MeO, R^1 = Bu, R^2 = SO_2Ph (98%).

At the same time, the cyclisation of *N*-(2-arylethyl)diazoamides on treatment with rhodium(II) compounds proceeds via two other competing pathways: with participation of the multiple bonds of the aromatic ring to form δ-lactams **9** containing a cycloheptatriene fragment and also with participation of α-C–H bonds of the alkyl chain to form γ-lactams **10** (Scheme 30).[51] The selectivity of this reaction depends decisively on the catalyst counterion. Thus the use of $Rh_2(OAc)_4$ leads to a mixture of the products indicated. The δ-lactams are formed exclusively in the presence of rhodium(II) perfluorobutyrate, while the γ-lactams are formed in the presence of rhodium(II) caprylamide.

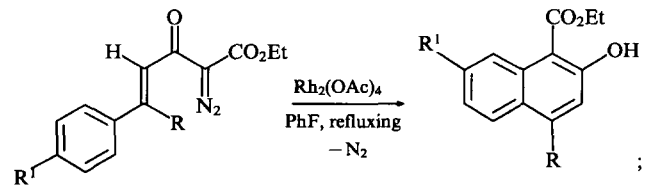
R = H, MeO, NO_2

L = OAc, 85% (68:32);
pfb, 80% (95:5);
caprylamide, 65% (3:97).

Another example of the influence of the nature of the dediazotisation catalyst on the chemoselectivity of the intramolecular cyclisation reactions of aromatic diazoesters is the cyclisation of α-(indolylacetyl)diazoacetates. In the presence of $Pd(OAc)_2$, the reaction proceeds with participation of the heterocyclic fragment (Scheme 31, pathway *a*), while on treatment with $Rh_2(OAc)_4$ it involves the benzene ring (pathway *b*).[52]

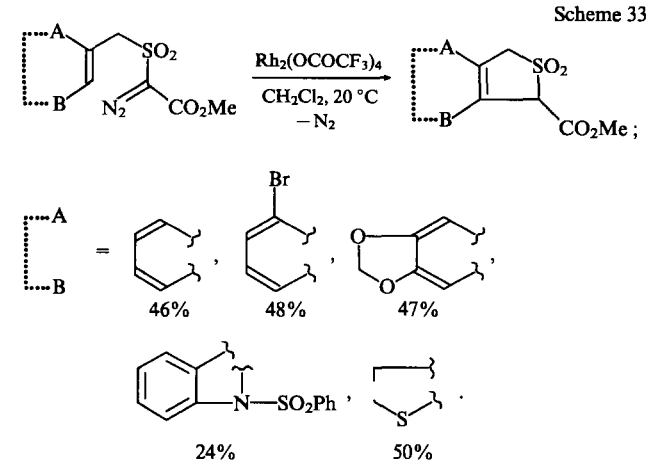
Scheme 31



R = H, Ts, CH_2Ph;
R^1, R^2 = H, Alk; R^3 = Me, Et.

This course of the process is apparently determined by the different mechanisms of the catalytic action of palladium and rhodium compounds in the carbene reactions with participation of diazoesters, although in the case of palladium compounds the authors postulate the involvement not of carbene but of carbonium ion intermediates.

The intramolecular C–H insertion in the aromatic ring is preferable in certain cases even in the presence of a multiple bond in the molecule, as has been observed in the case of ethyl α-(arylvinylcarbonyl)diazoacetates, in which the double bond is deactivated by conjugation with the carbonyl group.[53] The reaction affords derivatives of β-naphthols in high yields (Scheme 32).

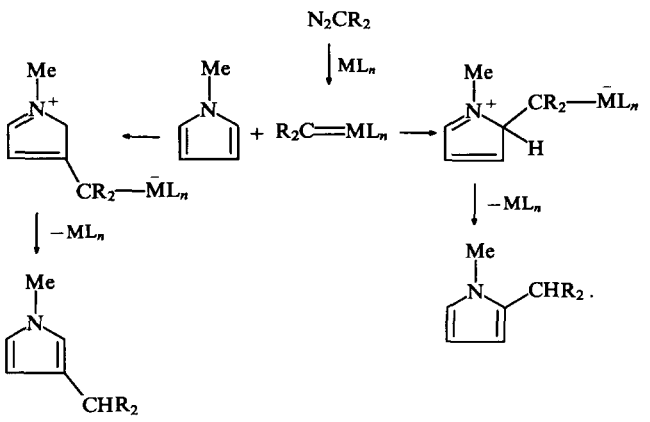


Scheme 32

R = Ph, R^1 = H (90%);
R = C_6H_4Me-4, R^1 = Me (76%);
R = C_6H_4Cl-4, R^1 = Cl (97%).

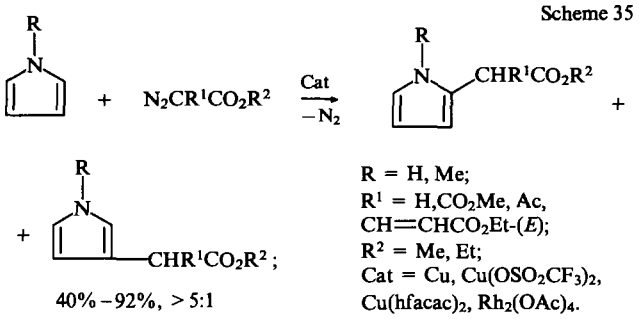
On treatment with rhodium(II) compounds, intramolecular cyclisation takes place also in the case of α-[aryl (or heteroaryl)-methanesulfonyl] diazoacetates, which leads to the corresponding benzo[*c*]thiophene 1,1-dioxides in moderate yields (24%–48%) (Scheme 33).[54]

Scheme 33



3. C–H bonds in heteroaromatic compounds

The nature of the multiple bonds in heteroaromatic compounds, which occupy an intermediate position between aromatic bonds of the benzenoid type and conjugated bonds of diene systems, as well as the presence of a nucleophilic heteroatom are responsible for the wide variety of reactions of compounds of this class with carbenes or their transition metal complexes. However, selective reactions of diazoesters with heteroaromatic compounds, accompanied by the formation of products of insertion in C–H bonds, are known.

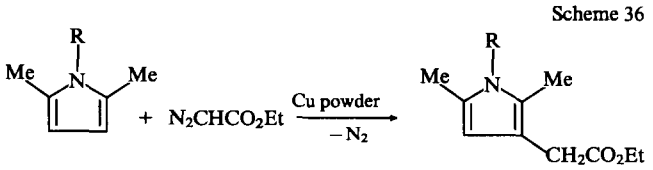


The commonest C–H insertion reactions occur in the pyrrole series, which can be explained by the greater aromatic character of the pyrrole ring.[55] As a result, the insertion products are formed as electrophilic substitution by the metal-carbene in the heteroaromatic ring via a metastable σ-complex (Scheme 34).

Scheme 34

The reactions of diazoesters with pyrrole itself and *N*-alkylpyrroles lead only to the products of formal insertion in the C–H bonds of the pyrrole ring, among which products of insertion in the α-C–H bonds predominate; the formation of N–H insertion products was not observed at all under these conditions (Scheme 35).[56–58]

Scheme 35

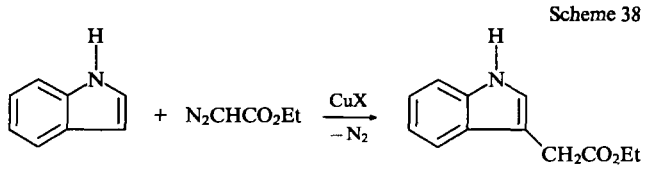


The regioselectivity of this reaction depends on the catalyst, the diazo-compound and the substituent at the nitrogen atom. The highest yields (up to 92%) and the highest reaction selectivity (>90%) in relation to the product of insertion in α-C–H bonds have been achieved in reactions involving dimethyl diazomalonate and homogeneous catalysts based on copper(II) compounds or $Rh_2(OAc)_4$. The reactions of ethyl diazoacetate and other diazoesters with pyrroles proceed in general with lower yields of the insertion products and a lower selectivity; rhodium compounds rapidly lose their activity in the dediazotisation of ethyl diazoacetate under these conditions and afford complex mixtures of products with traces of C–H insertion products.

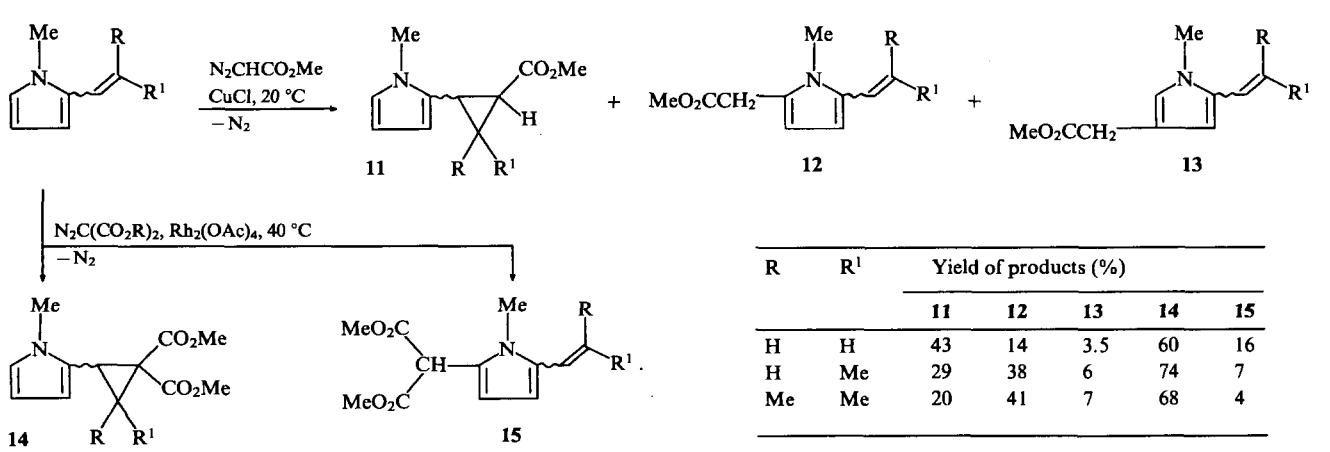
The influence of *N*-alkyl substituents reduces to an increase in the fraction of the β-isomer with increase in the steric effect of this substituent in the series H < Me < Pr^i < Bu^t with the exclusive formation of the β-isomer in the case of the *tert*-butyl group.

Substituents in other positions in the pyrrole ring do not influence the regioselectivity of the reaction regardless of their nature, with the exception of the case where they occupy the 2- and 5-positions in the ring. The reaction of ethyl diazoacetates with such pyrroles leads to the product of insertion in the β-C–H bonds (Scheme 36).[59]

Scheme 36



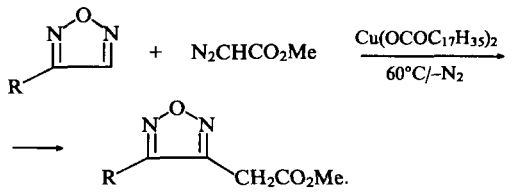
59%



The possibility of competition between the reactions involving the attack by the carbene on the pyrrole ring and the alkenyl group arises in reactions with participation of 2-alkenyl-1-methylpyrroles, as a result of which cyclopropane adducts involving the exocyclic double bond are formed together with the C–H insertion products (Scheme 37).[60] The relative contributions of these reaction pathways are determined by the structure of the diazoesters and to a lesser extent of the substituent at the double bond. In reactions with participation of dimethyl diazomalonate, the alkylation of the pyrrole ring in the α-position predominates in all cases, while in the reaction involving methyl diazoacetate this process becomes the main one only in the presence of substituents at the double bond.

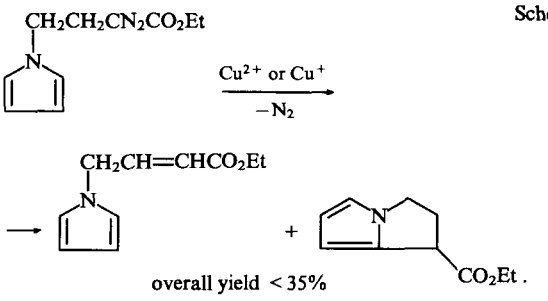
Certain other heteroaromatic nitrogen-containing compounds also behave similarly to pyrroles in reactions with diazoesters. Thus the esters of the corresponding heteroarylacetic acids are the main products of the reactions of ethyl diazoacetate with indoles[61] (Scheme 38) and furazans[62] (Scheme 39). The β-isomer predominates in the products of the reaction with indole under these conditions.

Scheme 38



Scheme 37

R	R^1	Yield of products (%)				
		11	**12**	**13**	**14**	**15**
H	H	43	14	3.5	60	16
H	Me	29	38	6	74	7
Me	Me	20	41	7	68	4

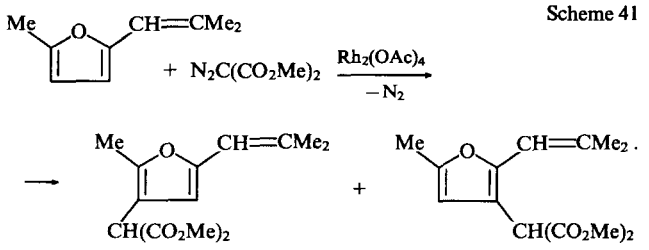


Scheme 39

9%–12% R = H, Ph, 2-thienyl.

Several examples of the intramolecular C–H insertion with participation of the pyrrole ring are known. Thus the carbenes generated by the dediazotisation of α-(2-pyrrolylethyl)diazoacetate (Scheme 40)[63] or α-(3-indolesulphonyl)diazoacetate[64] are converted into the corresponding polyheterocycles albeit with low yields (see Scheme 33).

Scheme 40

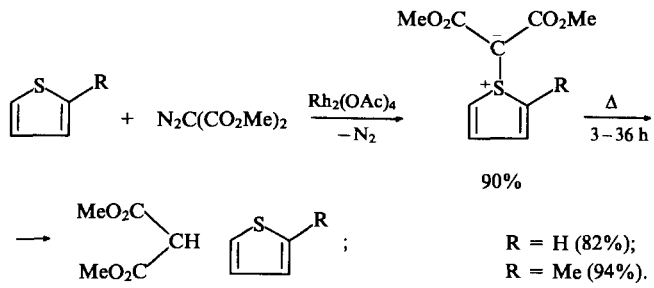


overall yield < 35%

On the other hand, the complexes of carbenes formed from 2-diazo-4-(4-indolyl)-3-oxobutanoates cyclise with participation of the indole ring in yields up to 76% (Scheme 31, pathway *a*).

In the series of thiophene and furan derivatives, only isolated instances of C–H insertion reactions are known. The reason for this is the low aromaticity of thiophene and furan compared with pyrrole and the presence of lone pairs at the O and S atoms, as a result of which the main primary reaction products are the corresponding S and O ylides. The subsequent reactions of these ylides lead in certain cases to C–H insertion products.

Thus the C–H insertion products, namely 3-furylmalonates, are formed in the reaction of 5-methyl-2-(2-methylprop-1-enyl)-furan with dimethyl diazomalonate (Scheme 41).[65]



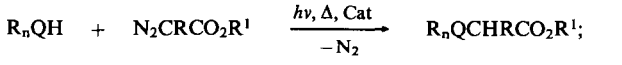
Scheme 41

80% (1:1)

Several examples of the formation of C–H insertion products in the reactions of dimethyl diazomalonate with thiophene are known. Thus the reaction of diazomalonates with thiophenes, catalysed by $Rh_2(OAc)_4$ at 20 °C, leads to the corresponding stable ylides in yields up to 90%. The thermal rearrangement of the ylides affords acceptable yields of 2-thienylmalonates, which are convenient synthons for the preparation of semisynthetic antibiotics of the β-lactam type, for example, cephalothin (Scheme 42).[66,67]

Scheme 42

90%



R = H (82%); R = Me (94%).

Other examples of the C–H insertion in reactions with thiophenes are examined in Section V devoted to reactions involving C–S bonds.

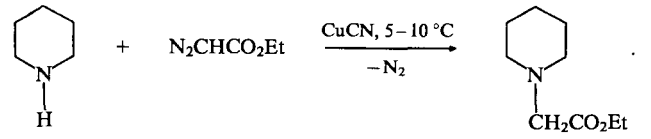
III. Heteroatom–hydrogen bonds

On irradiation, heating, or under the influence of catalysts, diazoesters react with compounds containing a heteroatom–hydrogen bond with formation of products of the insertion of the corresponding carbenes — esters of acetic acid derivatives.

Reactions involving insertion in the N–H, O–H, S–H, Si–H, Ge–H, and P–H bonds, which as a rule proceed selectively and with high yields of the insertion products, are now known.

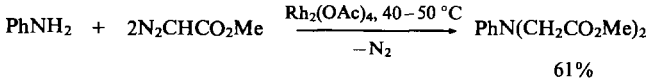
Q = N, O, S, Si, Ge.

1. N–H bonds



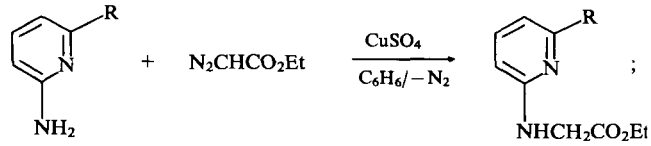
Regardless of the method of dediazotisation, both aliphatic (Schemes 43 and 44)[68] and aromatic primary and secondary amines (Schemes 45 and 46)[69,70] react with alkyl diazoacetates, affording high yields of *N*-alkylated glycine esters.

Scheme 43



Cat = CuCN (72%), CuCl (33%).

Scheme 44

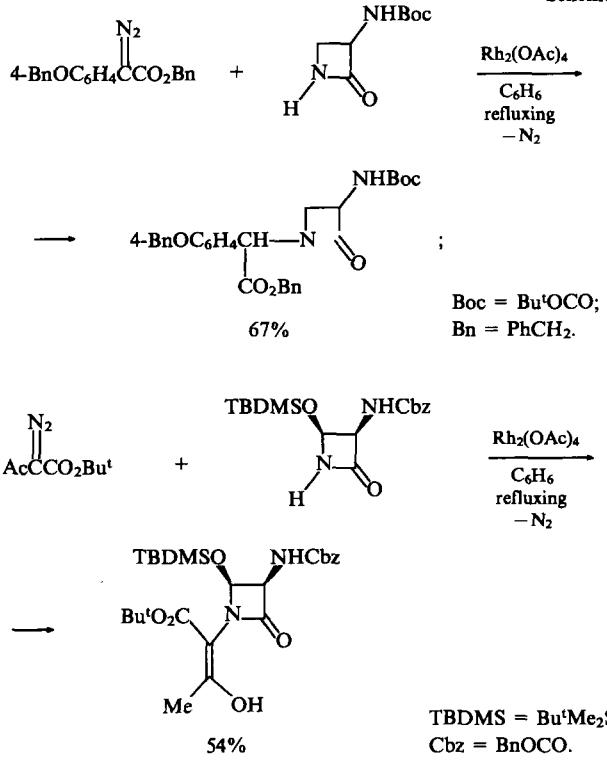


72%

Scheme 45

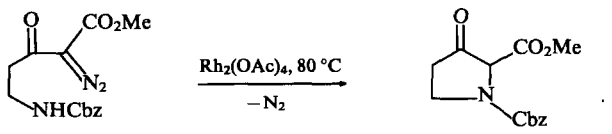
61%

Scheme 46



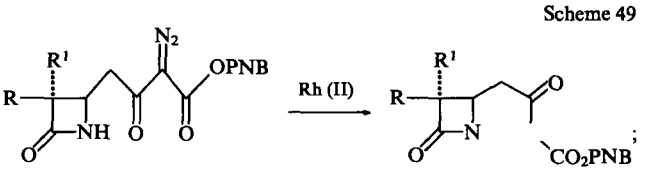
R = H, Me.

The intermolecular N–H insertion proceeds so readily that the catalytic dediazotisation of 2-alkylaminoethyl diazoacetates, even in the presence of olefins, leads not to cyclopropane adducts but exclusively to oligomers, which are formed as a result of the insertion of the carbene centre in the N–H bond of another molecule.[71]



The use of rhodium(II) acetate as the catalyst makes it possible to achieve the intermolecular N–H insertion reactions with labile products such as azetidinones. In the case of 3-aminoazetidinones, this reaction is exclusively selective, involving only the ring nitrogen atom, and leads to *N*-alkylated azetidinones — synthons for the preparation of β-lactam antibiotics (Scheme 47).[72,73]

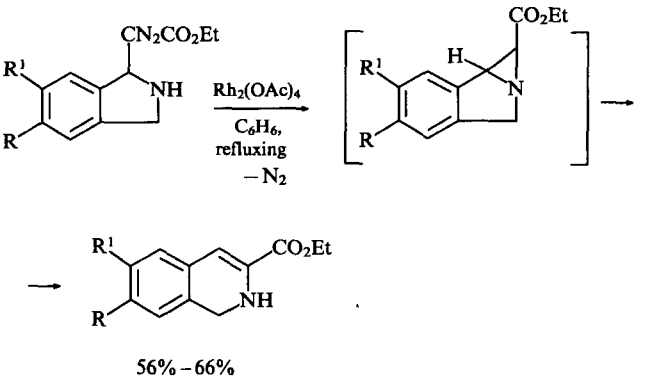
Scheme 47



Examples of the intramolecular N–H insertion of carbenes, generated from diazoesters under the conditions of their dediazotisation by rhodium(II) compounds, are also known. However, these reactions take place effectively only in the case of compounds containing a N–H bond at a carbon atom in the δ-position. Thus the cyclisation of methyl 5-amino-2-diazo-3-oxopentanoate leads to methyl 3-oxopyrrolidine-2-carboxylate in 90% yield (Scheme 48).[74]

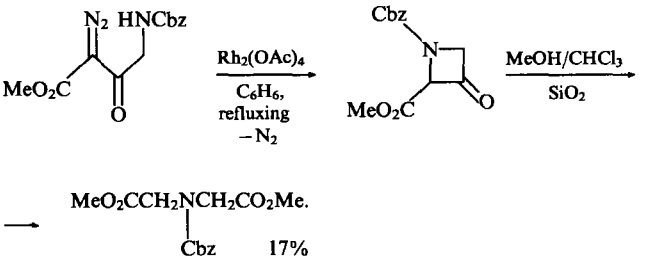
Scheme 48

The $Rh_2(OAc)_4$-catalysed intramolecular N–H insertion reaction with participation of the corresponding metal-carbene complexes derived from α-acyldiazoacetates containing an azetidinone fragment is used widely for the synthesis of β-lactam antibiotics (Scheme 49)[75] (for the references to studies up to 1985, see Maas[7]).



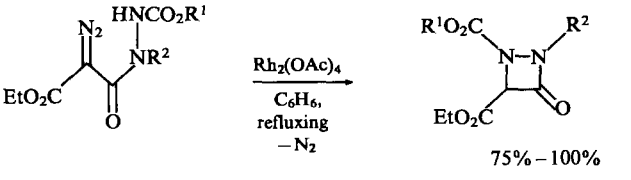
Scheme 49

PNB = $C_6H_4NO_2$-4. 50% – 100%



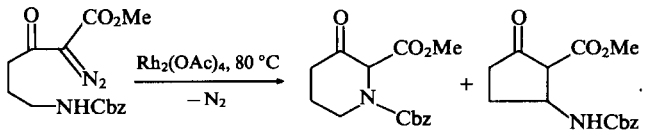
The number of examples of intramolecular cyclisation involving a more or less remote amino-group is extremely small. In particular, the cyclisation of β-aminodiazoesters has been described recently. The unstable aziridines formed initially in this case readily isomerise under the reaction conditions with the opening of the three-membered ring to give dihydroisoquinoline-carboxylates (Scheme 50).[76]

Scheme 50



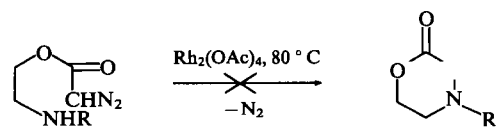
Intramolecular N–H insertion reactions with participation of a γ-amino-group are also known. For example, the $Rh_2(OAc)_4$-catalysed dediazotisation of the *N*-protected methyl 4-amino-2-diazo-3-oxobutanoate leads, admittedly with a low yield, to 3-oxoazetidine-2-carboxylate, which readily isomerises during isolation to a glycine derivative (Scheme 51).[74]

Scheme 51



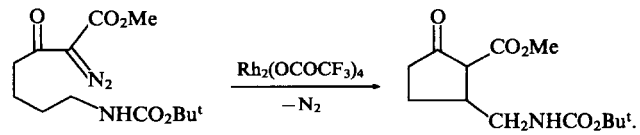
The monocarbazides of diazomalonates cyclise significantly more readily under these conditions, forming 1,2-diazetidinones in high yields (Scheme 52).[77]

Scheme 52



The intramolecular N–H insertion reaction involving diazoesters with an ε-amino-group is frequently complicated by the formation of side products of insertion in a C–H bond in the γ-position (Scheme 53)[74] or it does not occur at all, as happens in the reactions of 2-aminoethyl esters of diazoacetic acid (Scheme 54).[71]

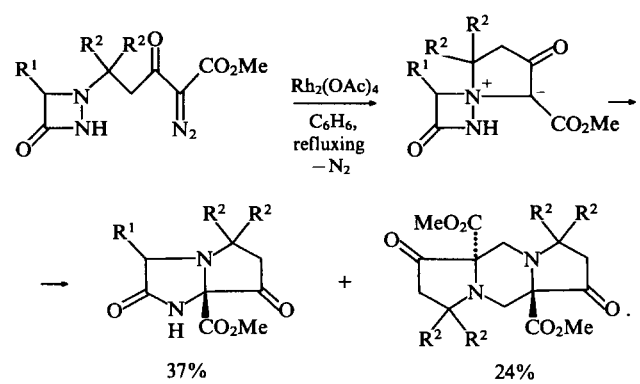
Scheme 53



70% 10%

Scheme 54

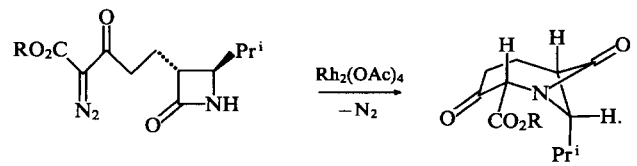
The available information about the possibility of the N–H insertion with participation of more remote amino-groups is contradictory. Thus the cyclisation of methyl 7-*tert*-butoxycarbonylamino-2-diazo-3-oxoheptanoate leads exclusively to the products of insertion in a C–H bond at the ε-carbon atom (Scheme 55).[78]



Scheme 55

73%

On the other hand, in the absence of C–H bonds at the ε-atom, as happens, for example, in methyl 2-diazo-5-(3-oxo-2*H*-1,2-diazetidinyl)-3-oxopentanoate, the products of insertion in a ring C–N bond of the diazetidine are formed, apparently via the intermediate formation of ylides (Scheme 56).[79]



Scheme 56

37% 24%

However, the intramolecular insertion of the carbene centre in a N–H bond separated by a chain of five carbon atoms has been recently observed (Scheme 57).[80]

Scheme 57

50%

2. O–H bonds

The reactions of alkyl diazoacetates with hydroxyl-containing compounds, leading to the formation of the products of the insertion of the corresponding carbenes in the O–H bonds, are fairly varied. Thus certain organic acids, for example, trifluoromethanesulfonic acid, are capable of reacting with ethyl diazoacetate in liquid SO_2 even at −78 °C with formation of the corresponding sulfonate of glycolic acid in 73% yield (Scheme 58).[81]

Scheme 58

$$CF_3SO_2OH + N_2CHCO_2Et \xrightarrow[-78\,°C/-N_2]{\text{liquefied } SO_2} CF_3SO_2OCH_2CO_2Et.$$

However, other hydroxylated compounds (water, alcohols, carboxylic acids) afford the O–H insertion products only in the photolytic, pyrolytic, or catalytic dediazotisation of alkyl diazoacetates[68,82] or their α-metallated derivatives (Scheme 59).[83]

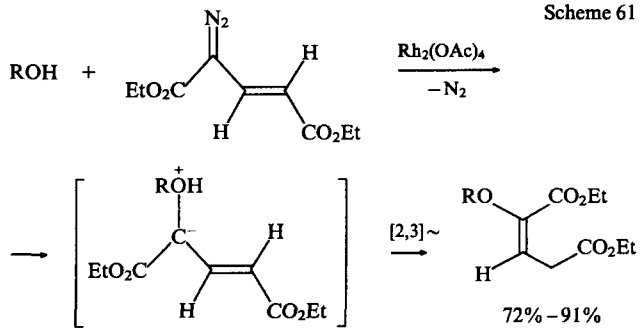
Scheme 59

$$ROH + N_2CR^1CO_2R^2 \xrightarrow[-N_2]{h\nu,\ \Delta,\ Cat} ROCHR^1CO_2R^2;$$

R = H, Alk, Ac; R^1 = H, HgMe; R^2 = Alk.

This reaction acquired preparative importance only after the discovery of catalysts based on rhodium compounds, which ensure preparative yields (in excess of 80%) of the products in the case of various diazoesters and a wide range of hydroxylated compounds.[7]

The high efficiency of these catalysts makes it possible to carry out reactions also with diazoacetic acid esters having a complex structure (Scheme 60).[84]

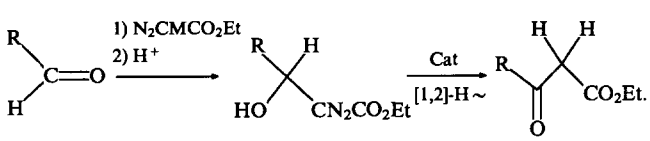


Scheme 60

$$H_2O + N_2CHCO_2CH_2C{\equiv}CH \xrightarrow[CH_2Cl_2/-N_2]{Rh_2(OAc)_4,\ 20\,°C}$$

$$\longrightarrow \underset{15\%}{HOCH_2CO_2CH_2C{\equiv}CH} + \underset{20\%}{O(CH_2CO_2CH_2C{\equiv}CH)_2}.$$

In the case of carbenes containing an allyl fragment, for example, the metal-carbene complex formed on dediazotisation of ethyl α-(2-ethoxycarbonylvinyl)diazoacetate on treatment with $Rh_2(OAc)_4$, the insertion reaction is accompanied by a [2,3]-sigmatropic rearrangement (Scheme 61).[85]

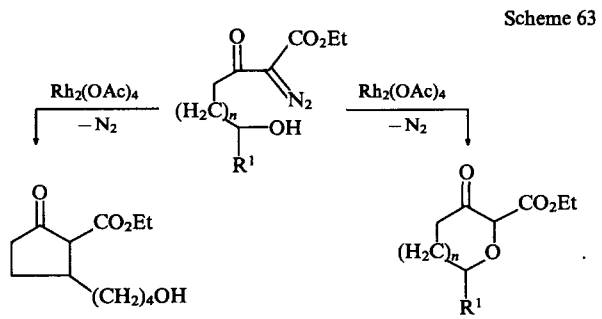


Scheme 61

R = Me, Et, Pr^i, Bu^t.

Instances of intramolecular reactions of diazoesters with participation of O–H bonds are known. However, these have a number of characteristic features compared with the analogous N–H insertion reactions. Thus the dediazotisation of α-diazo-β-hydroxyacetates, catalysed by rhodium(II) carboxylates, leads not to three-membered heterocycles (oxirans in the given instance), of the kind observed in the reactions involving β-amino-α-diazoacetates (Scheme 50), but to acyl acetates as a result of a [1,2]-H shift (Scheme 62).[36,86–89]

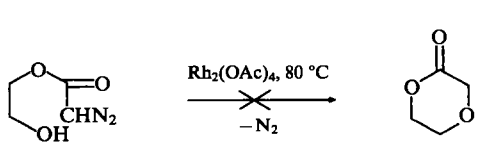
Scheme 62



M – metal; Cat = Rh_2L_4; SnX_2;
R = H, Alk, Ph, $H_2C=CH$, *trans*-PhCH=CH.

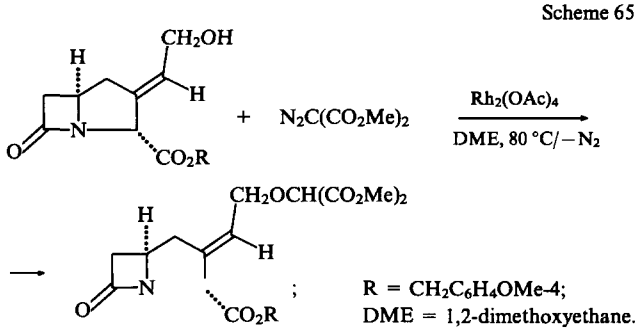
71%–100%

Furthermore, similar cyclisations involving hydroxylated diazoesters lead readily to six-, seven-, and eight-membered cyclic esters in satisfactory yields,[90,91] whereas heterocycles containing more than six atoms cannot be obtained as a rule with the aid of similar N–H insertion reactions. However, the attempts to obtain oxygen-containing heterocycles with more than eight atoms by this procedure have led to the formation of cyclopentanones — the products of the competing C–H insertion (Scheme 63).[90]



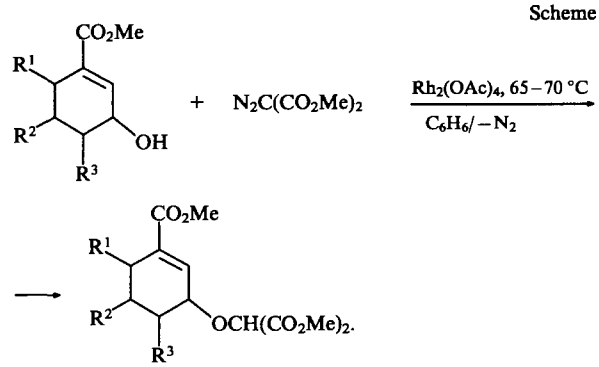
Scheme 63

n = 5, R^1 = H. n = 1–3, 24%–78%.



The attempt to obtain 1,4-dioxanone by the cyclisation of 2-hydroxyethyl diazoacetate was also unsuccessful. The dediazotisation of this diazoacetate led to the formation of oligomers, apparently as a result of intermolecular O–H insertion (Scheme 64).[92]

Scheme 64



Special mention should be made of the reactions of carbenes, generated from diazoesters, with allyl and propargyl alcohols, because in this case the ACC are capable both of being inserted in the O–H bonds and of adding to the multiple bond with formation of cyclopropane or cyclopropene adducts.[93,94] However, instances are known where the interaction with allyl alcohol in accordance with the O–H insertion mechanism proceeds with a high selectivity and high yields of the corresponding esters (Schemes 65 and 66).[95–98]

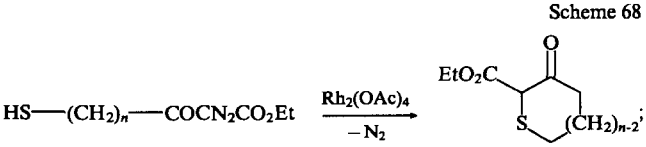
H	–O–		82	98

3. S–H, Si–H, Ge–H, and P–H bonds

Isolated examples of the reactions of diazoesters with the S–H bond, leading to the formation of esters of thioglycolic acid, have been described in the literature. In the reactions with thiols, both CuCl[67] and $Rh_2(OAc)_4$ are used as the catalysts of the dediazotisation of alkyl diazoacetates (Scheme 67).[99]



Scheme 67

Cat = CuCl, $Rh_2(OAc)_4$.

However, rhodium(II) compounds are usually employed for theintramolecular reactions of mercaptodiazoesters (Scheme 68).[73,77]

Scheme 68

n = 3 (73%), n = 4 (35%).

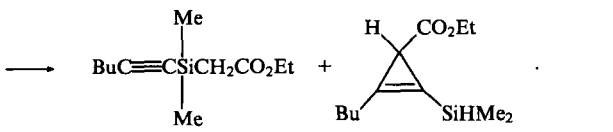
The reactions of diazoesters with mono-, di-, and trisubstituted hydrosilanes, leading to esters of acetic acids, are of preparative importance. The reactions proceed with high yields both under the conditions of the thermal decomposition of alkyl diazoacetates (Scheme 69) and on treatment with catalysts — copper compounds and $Rh_2(OAc)_4$ (Scheme 70).[100-102]

Scheme 69

$$PhMe_nSiH_{3-n} + N_2CHCO_2Et \xrightarrow[-N_2]{130-140\ ^\circ C} PhMe_nSiH_{2-n}CH_2CO_2Et;$$

n = 0 (59%), 1 (92%), 2 (94%).

Scheme 70



$$RR^1R^2SiH + N_2CHCO_2R^3 \xrightarrow[-N_2]{Cat} RR^1R^2SiCH_2CO_2R^3;$$

Cat = Cu, 94 °C (< 90%);
$Rh_2(OAc)_4/CH_2Cl_2$ (90%-94%).

Under these conditions, the addition to the triple bond in hydroxyacetylenes competes to only a slight extent with the Si–H insertion reactions (Scheme 71).[103]

Scheme 71

$$BuC{\equiv}CSiMe_2H + N_2CHCO_2Et \xrightarrow[-N_2]{150\ ^\circ C\ (or\ CuCl,\ 80\ ^\circ C)}$$

50%–60% 5%–15%

There are data indicating the possibility of the insertion of carbenes, generated by the dediazotisation of α-triethylgermyldiazoacetates, in the Ge–H bond of triethylgermane and in the Sn–H bond of trineopentylstannane (Scheme 72).[104] In the case of stannanes, this reaction proceeds in the absence of catalysts (Scheme 73).

Scheme 72

$$Et_3GeCN_2CO_2Et + Et_3GeH \xrightarrow[C_6H_6/-N_2]{Cu,\ 100\ ^\circ C} (Et_3Ge)_2CHCO_2Et.$$

66%

Scheme 73

$$(neo\text{-}C_5H_{11})_3SnCN_2CO_2Et + (neo\text{-}C_5H_{11})_3SnH \xrightarrow[C_6H_6/-N_2]{100\ ^\circ C}$$

$$\longrightarrow [(neo\text{-}C_5H_{11})_3Sn]_2CHCO_2Et.$$

It has been established recently that products of P–H insertion may be formed in 16%–39% yields under the conditions of the benzophenone-sensitised photolysis of certain diazoesters in the presence of dimethyl phosphorothioite (Scheme 74).[105,106]

This reaction proceeds more selectively under the conditions of catalytic dediazotisation of diazoesters by $Cu(acac)_2$; the yields of the corresponding P–H insertion products reach 83%.[107]

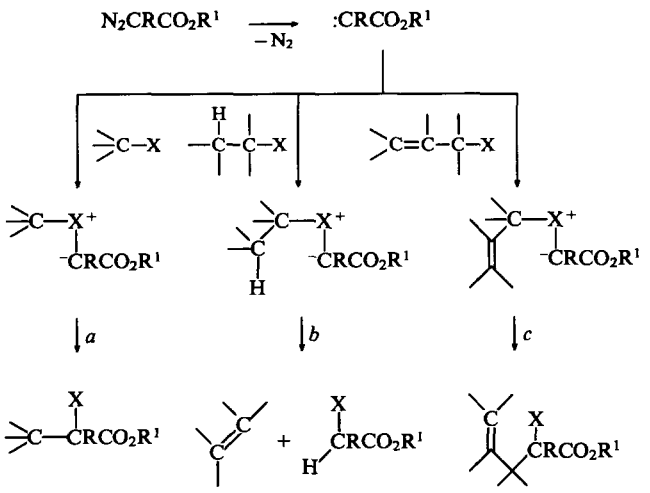
Scheme 74

$$N_2CRCO_2R^1 + (R^2O)_2\overset{\overset{S}{\|}}{P}H \xrightarrow[-N_2]{h\nu\ (Cat)} (R^2O)_2\overset{\overset{S}{\|}}{P}CHRCO_2R^1;$$

R = H, Ph, Ac, CO_2Me; R^1 and R^2 = Me, Et.

IV. Carbon–carbon bonds

The dediazotisation of certain α-diazocarboxylates may be accompanied not only by a [1,2]-H-shift (Section II, 1) but also by the [1,2]-shift of the carbon atom to the carbene centre generated with formation of the products of the formal insertion of the carbene in the C–C bond. Rearrangements of this type usually occur in the catalytic and photolytic decomposition of diazoacetates containing a cyclic substituent in the α-position. The dediazotisation of such diazoesters leads to ring expansion by one carbon atom and may serve as a convenient method for the formation of higher homologues of alicyclic compounds. The data concerning the [1,2]-carbon shift in a series of α-cyclyldiazoacetates are in Table 3.



The [1,2]-carbon shift reactions are frequently accompanied by other reactions, for example, the [1,2]-hydride shift (Table 4, example 1). Combination of the [1,2]-H and [1,2]-C shifts in the transition metal-catalysed dediazotisation of certain α-diazo-β-hydroxycarboxylates without a hydrogen atom in the α-position leads to a mixture of α-acyl-α-alkylacetates (Table 4). In the case of cyclic α-diazo-β-hydroxycarboxylates (Table 4, examples 1–5), the analogous reactions are accompanied by the unexpected migration of the less substituted carbon atom and lead to the formation of 2-oxocyclocarboxylates.

High and in certain cases quantitative yields of target products as well as the availability of the initial α-diazo-β-hydroxycarboxylates, obtained by the reaction of carbonyl compounds with alkyl diazoacetates, make this reaction a convenient preparative method for the formation of higher homologues of carbonyl compounds.

V. Carbon–heteroatom bonds

Under the conditions of their dediazotisation, diazoesters react with various compounds containing carbon–heteroatom bonds. A common feature of this large group of reactions is the mechanism of the primary step, which consists in the attack by the carbene on the lone pair of the heteroatom with formation of an ylide. The subsequent reactions of these ylides, determined by the structure of the substrate, are fairly varied. The [1,2]-shift of the carbene fragment from the heteroatom to a neighbouring carbon atom occurs most frequently (the Stevens rearrangement) with formation of the product of the formal insertion of the carbene in the C–X (Scheme 75, pathway *a*), which is sometimes complicated by the elimination of a hydrogen atom attached to the β-carbon atom with transfer of the HX fragment from the substrate to the carbene (pathway *b*). In the case of allyl derivatives, the [2,3]-sigmatropic rearrangement of the ylide takes place effectively and leads to the insertion product (pathway *c*).

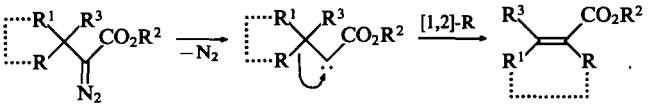
Scheme 75

All these processes, which lead to significant changes in the carbon skeleton of the initial molecule, take place selectively in many instances and constitute an effective pathway to the introduction of functional groups into acyclic heteroatomic compounds and the synthesis of carbofunctional heterocycles. Numerous studies devoted to the mechanistic aspects of the insertion reactions of this type have been described in detail in a number of reviews.[3,7,118–120] We shall deal with the synthetic possibilities of these reactions.

It has now been established that diazoesters are able to interact with C–Hal, C–N, C–O, and C–S bonds; individual examples of reactions involving C–Se are known; in conformity with the logic adopted for the presentation of data, they are considered in the Section devoted to the C–S insertion (Section V.4).

1. Carbon–halogen bonds

The interaction with monohaloalkanes leads to esters of monochloroacetic and ω-haloalkanoic acids as a result of β-elimination and C–H insertion respectively and usually proceeds nonselectively, as a result of which the reaction has no preparative value. The reaction of ethyl diazoacetate with bromotrinitromethane, which leads to the product of C–Br insertion in 67% yield, is an exception (Scheme 76).[121]



Scheme 76

$$(O_2N)_3CBr + N_2CHCO_2Et \xrightarrow[-N_2]{\text{ether, 20 °C}} (O_2N)_3CCHBrCO_2Et.$$

The reactions of diazoesters with allyl halides, which contain two reaction centres in the molecule (the double bond and the C–Hal bond), have been investigated quite vigorously. It was established that carbenes in the singlet state are equally involved in the addition to the double bond with formation of cyclopropane adducts and in the reaction with the C–Hal bond with formation of ylides, undergoing the [2,3]-rearrangement to the C–Hal insertion products; on the other hand, triplet carbenes add preferentially to the multiple bond.[3] This finding enabled Ando[119] to propose allyl halides as test reagents for the spin state of carbenes generated by the dediazotisation of alkyl diazoacetates.

The reaction of alkyl diazoacetates with allyl halides has acquired preparative importance after the appearance of catalysts based on rhodium(II) carboxylates, which make it possible to increase significantly the selectivity of the processes involving the insertion of carbenes in the C–Hal bond. The use of $Rh_2(OAc)_4$ for the dediazotisation of ethyl diazoacetate in the reaction with allyl iodide makes is possible to obtain the ester of 2-iodobut-3-enoic acid in a virtually quantitative yield (Scheme 77).[122]

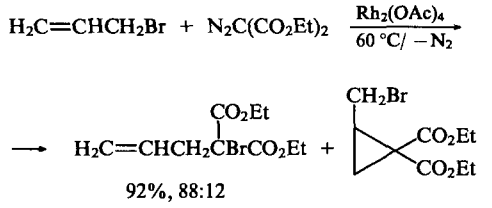
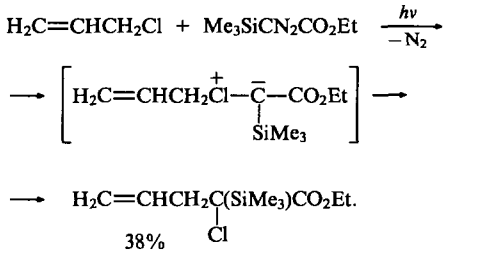
		C	~100 (1:0)	87
		A	55 (cm[b])	117

Scheme 77



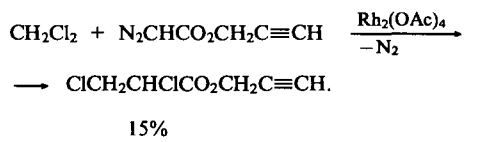
Cat	Hal	Yield (%)	
		18	19
$Rh_2(OAc)_4$	I	98%	–
$Rh_2(OAc)_4$	Cl	<2%	95%
$Rh_2(OAc)_4$	Br	30%	46%
Cu bronze	Br	50%	6%



However, in the case of allyl bromide and chloride, the cyclopropane formation reaction is the main one; the decrease in the fraction of the C–Hal insertion products under these conditions in favour of cyclopropane adducts takes place in parallel with the decrease in nucleophilicity in the sequence I > Br > Cl, which confirms the ylide mechanism of the reaction. Thus allyl chloride affords the ester of 2-chloromethylcyclopropanecarboxylic acid in a yield exceeding 95% in the reaction with ethyl diazoacetate in the presence of $Rh_2(OAc)_4$. Nevertheless, when the same catalyst is used in the reaction with allyl bromide, the process proceeds nonselectively and leads to the formation of almost equal amounts of cyclopropane adducts and α-bromobutenoates, the use of copper bronze permitting some increase in the process selectivity as regards the insertion product.

Metal–carbene complexes generated from dimethyl diazomalonate on treatment with rhodium catalysts[122] and carbenes formed on photolysis of ethyl α-trimethylsilyldiazoacetate[123] show an even greater tendency to form ylides with allyl halides. In the first case (Scheme 78), the product of insertion in the C–Br bond of allyl bromide predominates even when $Rh_2(OAc)_4$ is used, whilst in the second (Scheme 79) the corresponding cyclopropane adduct is not formed at all.

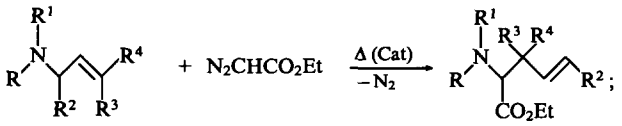
Scheme 78



Scheme 79

The photolytic decomposition reactions of diazoesters in the presence of polyhaloalkanes, which were investigated vigorously in the 1950s,[3] have not found preparative applications because of their low selectivity. The synthetic possibilities of catalytic processes have been scarcely studied, although examples of such processes, described recently, yielded promising results. Thus, the ability of propargyl diazoacetate to afford the product of insertion in the C–Cl bond of methylene chloride in the presence of $Rh_2(OAc)_4$ has been established recently (Scheme 80).[84]

Scheme 80



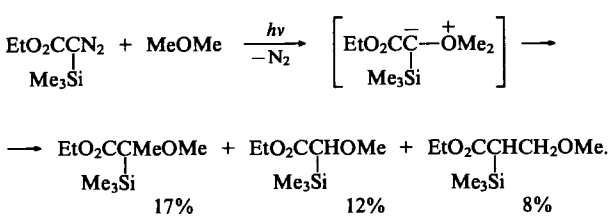
The analogous reaction does not take place with methyl diazoacetate.

2. C–N bonds

The number of examples of preparative syntheses based on the reactions of alkyl diazoacetates with amines, leading to products of the insertion of alkoxycarbonylcarbenes in the C–N bond, is limited. The interaction of ethyl diazoacetate with tertiary allyl amines on heating to 144–175 °C or on treatment with catalysts based on rhodium(II), copper(II), cobalt(II), and nickel(II), or zirconium(IV) compounds at 60 °C leads, as a result of the [2,3]-rearrangement, to esters of unsaturated *N,N*-dialkylamino-acids in high yields (Scheme 81).[124]

Scheme 81

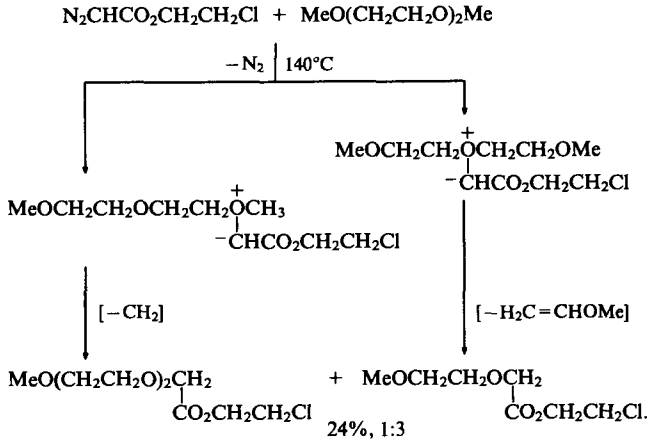
30%–99%



R, R^1 = alkyl or R + R^1 = $(CH_2)_n$ (n = 5–6) or $CH_2OCH_2CH_2$; R^2 = alkyl; R^3, R^4 = alkyl or $R^3 + R^4$ = α,ω-alkenyl.

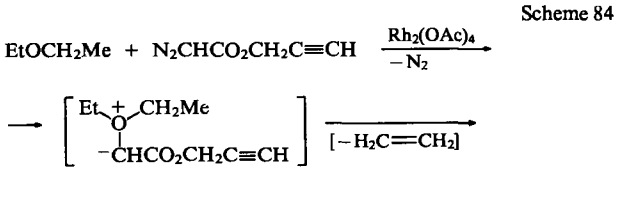
The reaction is extremely sensitive to the catalyst concentration. The highest yields have been achieved for a catalyst : amine molar ratio of 1 : 800; with increase in catalyst concentration, there is an appreciable increase in the contribution of the competing addition of the carbene to the double bond.[125]

3. C–O bonds



The reactions of diazoesters with acyclic ethers, initiated by irradiation (Scheme 82),[123] heating (Scheme 83),[126] or treatment with $Rh_2(OAc)_4$ (Scheme 84),[124] usually proceed nonselectively, leading to esters of alkoxyacetic acids as a result of the β-elimination reaction of the O ylides formed initially. The formation of C–O insertion products is observed in exceptional instances.

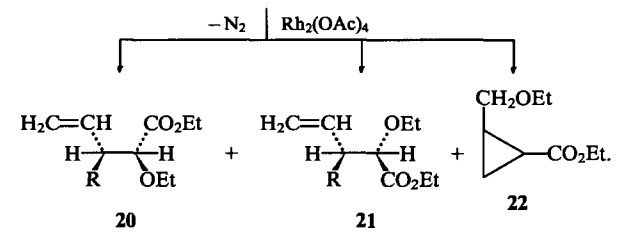
Scheme 82



17% 12% 8%

Scheme 83

24%, 1:3

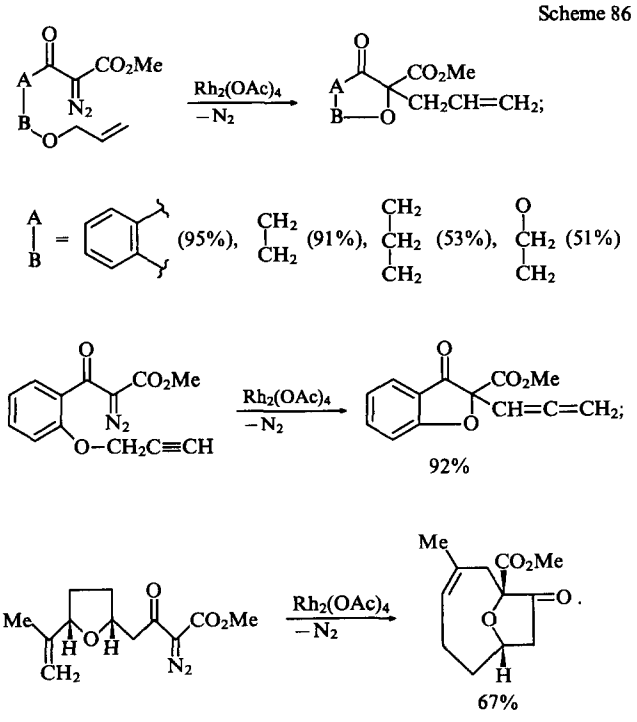


Scheme 84

30%

Although the reaction of ethyl diazoacetate with allyl ethyl ether in the presence of $Rh_2(OAc)_4$ does lead to C–O insertion products as a result of the [2,3]-rearrangement of the ylide, it too is complicated by the competing formation of cyclopropane adducts, the fraction of which may reach 30% (Scheme 85).[127]

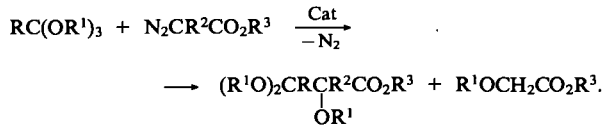
Scheme 85



R	Configuration of double bond	Overall yield (%)	Product ratio		
			20	21	22/(20+21)
Ph	E	95	83	17	27
Ph	Z	95	6	94	26
Me	E	86	79	21	8
Me_3Si	E	68	97	3	6

The [2,3]-rearrangement itself then proceeds with a high degree of diastereoselectivity.

The $Rh_2(OAc)_4$-initiated intramolecular cyclisation of α-acyldiazoesters containing an allyloxy- or propargyloxy-fragment takes place with a high selectivity (Scheme 86).[128]



Scheme 86

These reactions lead to five- and six-membered oxacyclanones as a result of C–O insertion and the [2,3]-rearrangement.

The formation of products of the formal C–O insertion has been noted also in the reactions of ethyl diazoacetate with acetals and orthoesters. On treatment with BF_3 etherate, the reactions of diazoesters with orthoesters lead under these conditions exclusively to C–O insertion products. The metal-catalysed processes are less selective and are accompanied by β-elimination (Scheme 87).[129]

Scheme 87

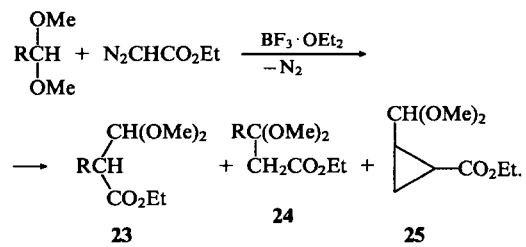
$Rh_2(OAc)_4$, 60 °C	3%–20%	11%–27%
$Cu(OTf)_2$, 20 °C	38%–46%	6%–20%

R = H, Me, Et; R^1 = Me, Et;
R^2 = H, CO_2Me; R^3 = Me, Et.

In the presence of $Rh_2(OAc)_4$, ethyl diazoacetate reacts with acrolein dimethyl acetal to form the product of the [2,3]-rearrangement of the O ylide together with the cyclopropane adducts (Scheme 88).[130]

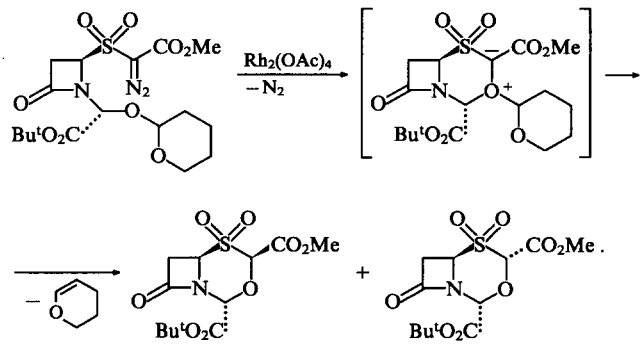


Scheme 88

76 : 24, overall yield 47%.

However, when this reaction is initiated by BF_3 etherate, the main and sometimes the only products are those of the formal C–C insertion — the diacetals of derivatives of formylacetic acid (together with small amounts of cyclopropane adducts) (Scheme 89).[131]

Scheme 89



23 **24** **25**

R	T/°C	Overall yield (%)	Product ratio

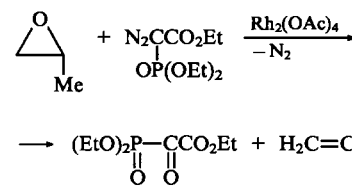
The β-elimination reaction of an endocyclic O ylide has been used recently for the preparative synthesis of antibiotics of the 3-oxacepham series (Scheme 90).[132]

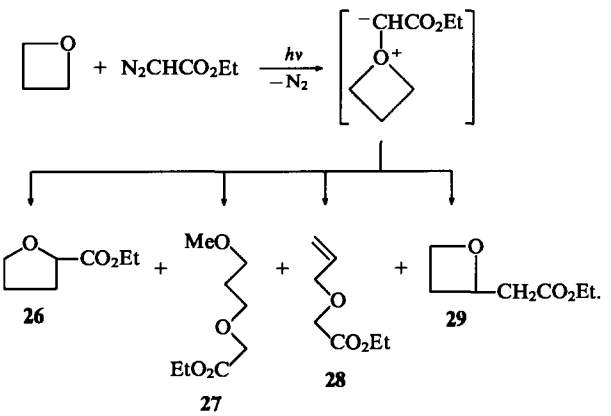
Scheme 90

The reaction of diazoesters with cyclic oxa-compounds has a number of characteristic features, the decisive factor being the ring size. Dimethyl diazomalonate and methyl α-trimethylsilyldiazoacetate induce the deoxygenation of oxirans in the presence of $Rh_2(OAc)_4$, which proceeds with retention of the configuration of the initial oxirans in the olefins formed and with high yields of the latter (Scheme 91).[133]



Scheme 91

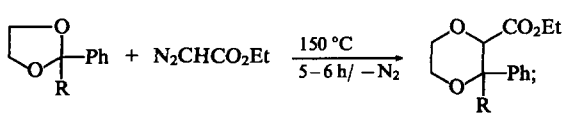
R^2 = CO_2Me, $SiMe_3$.



The analogous reaction of α-phosphoryldiazoacetate with methyloxiran has been used to synthesise oxophosphonates (Scheme 92).[134]

Scheme 92

On photolysis of ethyl diazoacetate in oxetan, the ylide formed is converted into the ester of tetrahydrofuran-2-carboxylic acid as the main product as a result of the Stevens rearrangement (Scheme 93).[135] However, in methanol the main process becomes the solvolysis of the ylide, which leads to ring opening and the formation of the ester of alkoxyacetic acid.



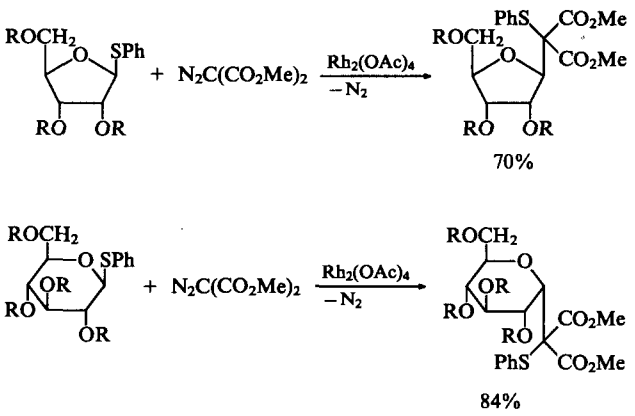
Scheme 93

Solvent	Overall yield (%)	Product ratio			
		26	27	28	29
Oxetan	54	70.3	–	12.2	17.5
MeOH	54	23.6	51.9	6.3	18.2

The interaction of ethyl diazoacetate with 1,3-dioxolans leads to 1,4-dioxanecarboxylates—the products of the formal C–O insertion of ethoxycarbonylcarbene—apparently as a result of the Stevens rearrangement of the corresponding O ylides (Scheme 94).[134]

Scheme 94

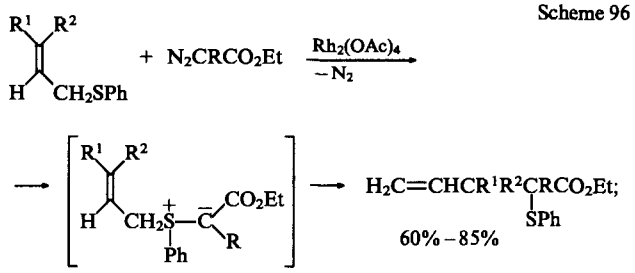
R = H (48.5%); Me (6.5%).



The low yields of the products formed (less than 50%) are due to the fairly severe reaction conditions (150 °C), but there are no literature data concerning the possibility of using milder conditions, for example, dediazotisation in the presence of $Rh_2(OAc)_4$.

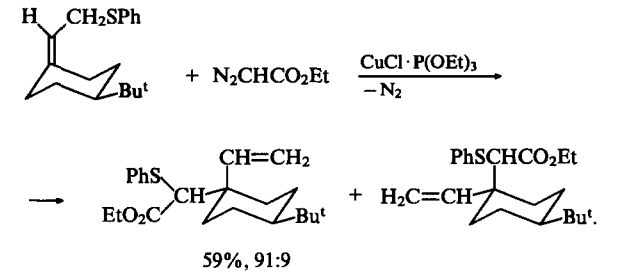
4. C–S and C–Se bonds

The greater nucleophilicity of the sulphur atom compared with nitrogen or oxygen atoms is responsible for the high reactivity of sulphur-containing compounds and hence for the greater variety of the synthetic possibilities of their reactions with carbenes. This explains the special interest in the study of the reactions of diazoesters with compounds containing C–S bonds, which has been reflected in the large number of studies described in the literature. Furthermore, in the reactions of diazoesters with sulphur-containing compounds, it has been possible to isolate stable S ylides and to investigate the reactions of the latter, obtaining thereby direct evidence for their involvement in the formation of the final products.



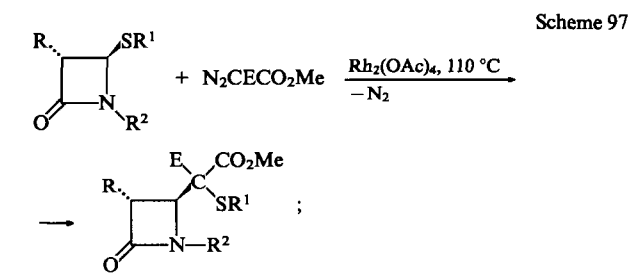
Diazoesters react with virtually any acyclic sulfides to form the C–S insertion products as a result of the [1,2]-shift of the carbene fragment in the S ylide formed initially (Scheme 95).[137]

Scheme 95



Allyl sulfides react under these conditions with a [2,3]-rearrangement (Scheme 96).[138,139]

Scheme 96

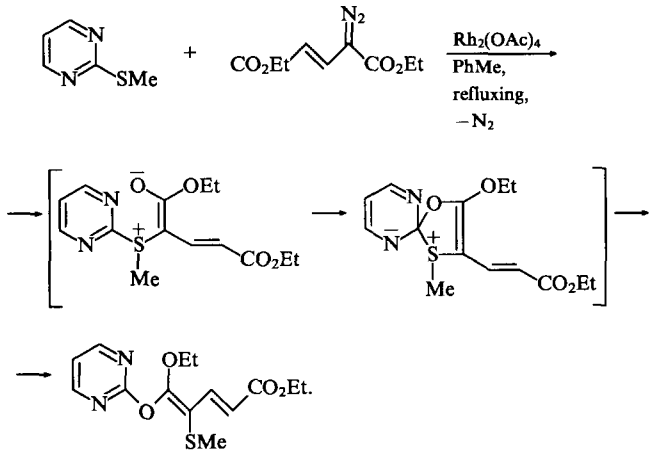


R = CO_2Et, $P(O)(OEt)_2$.

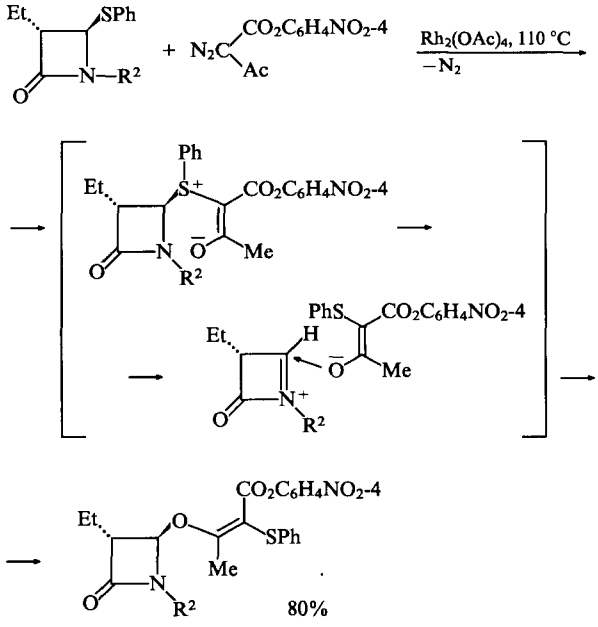
59%, 91:9

The attack on the sulfur atom in the carbenes generated from diazoesters takes place preferentially even in the presence in the substrate molecule of other heteroatoms, for example, oxygen or nitrogen (Scheme 97).[140]

Scheme 97



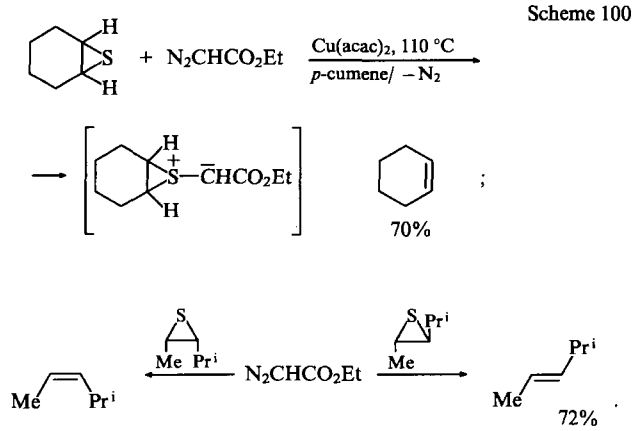
R, R^1 – Alk, Ph, CH_2Ph;
R^2 = H, $CH_2CO_2R^3$, $SiMe_2Bu^t$;
E = CO_2R^4, $P(O)(OEt)_2$.



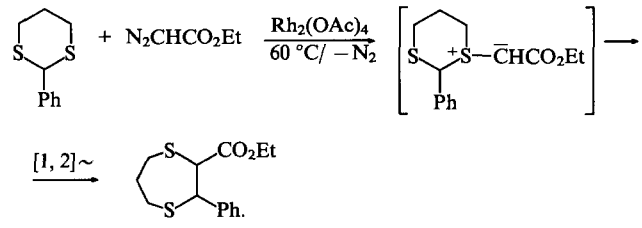
Furthermore, the interaction of such polyheteroatomic molecules with certain diazoesters, for example with ethyl α-(2-ethoxycarbonylvinyl)diazoacetate (Scheme 98)[141] or with 4-nitrophenyl α-acetyldiazoacetate (Scheme 99),[142] gives rise to

the possibility of the additional stabilisation of the cationic and ionic centres in the resulting S ylide which promotes its [1,4]-rearrangement with formation of an *O*-alkylated product.

Scheme 98

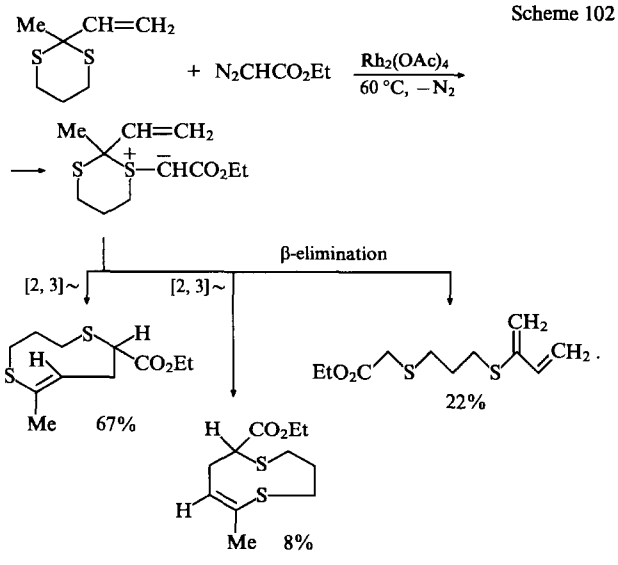


Scheme 99



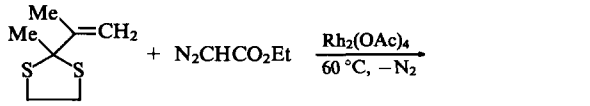
The carbene decomposition of alkyl diazoacetate in the presence of cyclic thioethers also leads to the formation of S ylides, the subsequent reactions of which are usually accompanied by a change in ring size. For example, as in the reactions with oxirans, the interaction of ethyl diazoacetate with thiirans is accompanied by selective desthiylation with formation of olefins retaining the initial configuration of the three-membered heterocycle (Scheme 100).[143]

Scheme 100

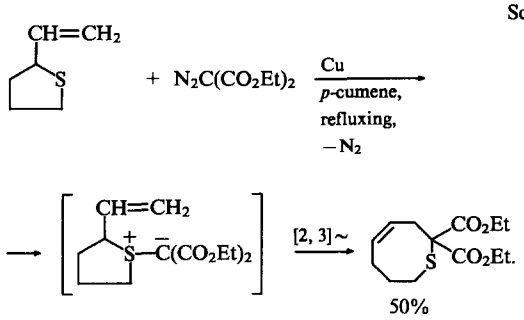


On the other hand, the $Rh_2(OAc)_4$-catalysed interaction of ethyl diazoacetate with 2-phenyl-1,3-dithiane is accompanied by the insertion of the ethoxycarbonylmethylene fragment into the six-membered ring as a result of the Stevens rearrangement of the S ylide formed initially and leads to the corresponding 1,4-dithiepan (Scheme 101).[129]

Scheme 101

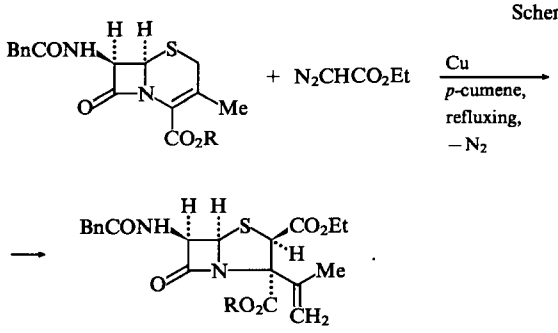


The interaction of alkyl diazoacetates with thiacyclanes containing an unsaturated fragment involves either the substrate ring expansion or ring contraction depending on whether the double bond is in the side chain or in the ring. Thus the $Rh_2(OAc)_4$-catalysed interaction of diazoesters with 2-vinyl-1,3-dithiane (Scheme 102),[129] 2-isopropenyl-2-methyl-1,3-dithiolan (Scheme 103),[129] and 2-vinyltetrahydrothiophene (Scheme 104)[144] leads, as a result of the [2,3]-sigmatropic rearrangement of the S ylides, to nine- and eight-membered thiacyclanes together with the acyclic β-elimination products.

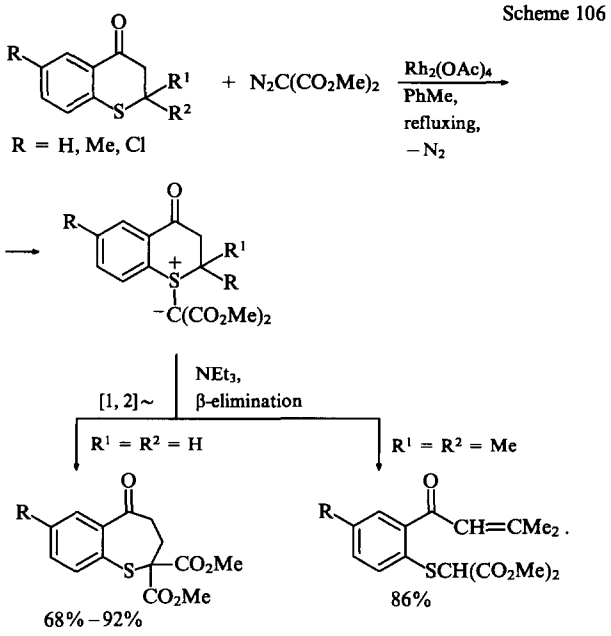


Scheme 102

Scheme 103

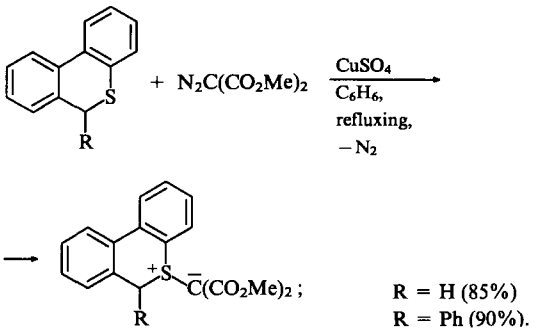


Scheme 104



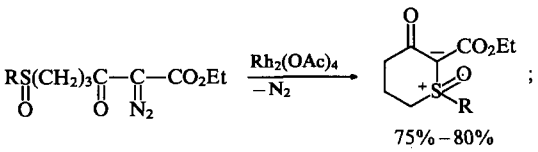
On the other hand, the reaction of ethyl diazoacetate with the esters of cephalosporanic acid, containing a double bond in the heterocycle, is accompanied by ring contraction with formation of the esters of 3-isopropenylpenicillanic acid (Scheme 105).[145]

Scheme 105



In contrast to alkyl diazoacetates, diazomalonates and diazomalononitriles react with thiacyclanes to form fairly stable S ylides, which can be isolated in a pure form as the main or even the only reaction products, which makes it possible to investigate their subsequent reactions. For example, the $Rh_2(OAc)_4$-catalysed decomposition of dimethyl diazomalonate in the presence of thiachromones leads to stable S ylides, the decomposition of which takes place only on treatment with triethylamine and leads to homothiachromones or thiobenzophenone as a result of the [1,2]-shift and β-elimination respectively (Scheme 106).[146]

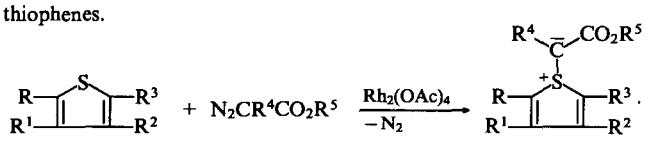
Scheme 106



The S ylides formed are sometimes so stable that they do not rearrange even on fusion at temperatures above 100 °C (Schemes 107–109).[147–149]

Scheme 107

Scheme 108



Scheme 109

As already mentioned above, stable ylides are also formed in yields up to 98% in $Rh_2(OAc)_4$-catalysed reactions of diazomalonates with thiophenes at 20 °C (Table 5).

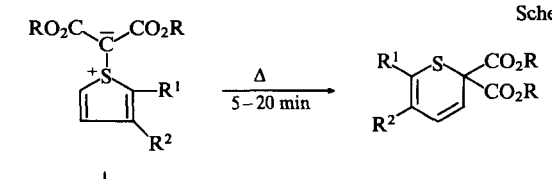


Table 5. The formation of ylides in the reactions of diazoesters with thiophenes.

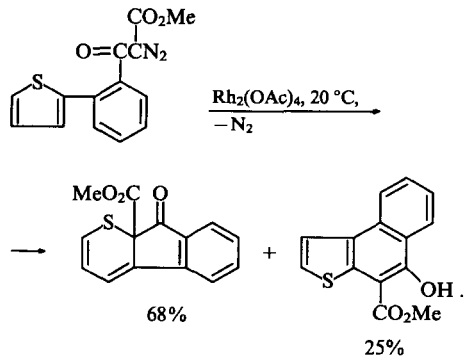
$CH=CMe_2$	H	H	H	CO_2Me	Me	40	153

The thermal rearrangement of such ylides leads to acceptable yields of C–S insertion products (2*H*-thiopyrans), which are subsequently converted into the thermodynamically more stable (2-thienyl)malonates (Section II. 2).[154,155] The final composition of the products of the thermal isomerisation of S ylides is determined by the nature of the substituents, temperature, and duration of heating (Scheme 110). Thus brief heating (for less than 20 min) of thiophenium bis(*tert*-butoxycarbonyl)methylides leads to the corresponding 2*H*-thiopyrans in yields up to 98%. After more prolonged heating of the ylides, 2-substituted thiophenes are formed.

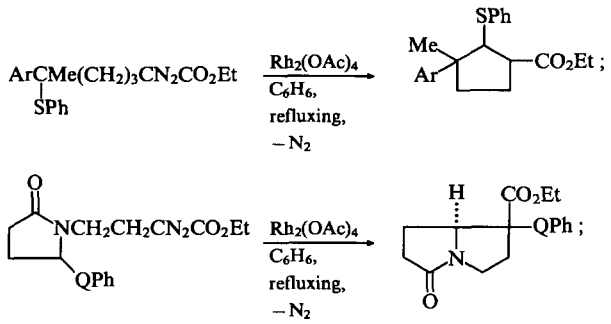
Scheme 110



R	R^1	R^2	Yield (%)
Me	H	H	82
Me	Me	H	94

R	R^1	R^2	Yield (%)
Me	H	H	30
Me	Br	H	89
Bu^t	H	H	84
Bu^t	Me	H	98
Bu^t	I	H	60
Bu^t	$PhOCH_2$	H	97
Bu^t	Br	H	75
Bu^t	H	Br	22

The ease with which ylides rearrange to 2*H*-thiopyrans depends on the nature of the substituents. Thus the 2-phenoxymethyl-substituted ylide is converted into the corresponding 2*H*-thiopyran during crystallisation from methylcyclohexane, while the 3-bromo-substituted ylide is converted *in situ*.

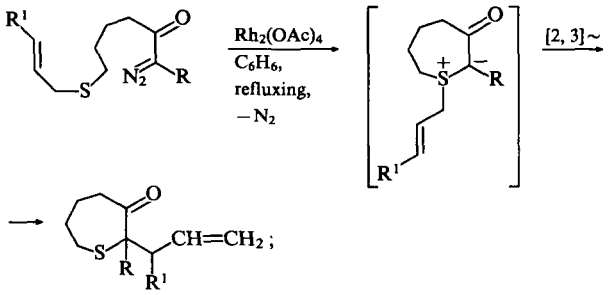


The formation of 2*H*-thiopyrans together with 2-substitution products has been observed also in the isomerisation of cyclic S ylides formed during the rhodium(II)-catalysed dediazotisation of the thienyl-substituted α-acyldiazoester (Scheme 111).[156]

Scheme 111

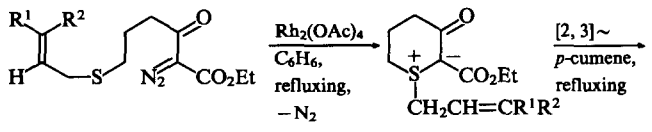
Similar intramolecular reactions of sulphur- and selenium-containing diazoesters constitute an effective synthetic method for the preparation of cyclic and condensed systems. For example, the metal-carbene complexes generated by the dediazotisation of 6-phenylthiodiazoalkanoates in the presence of $Rh_2(OAc)_4$ readily cyclise to five-membered rings (Scheme 112).[157,158]

Scheme 112



Q = S (55%), Se (36%).

Unfortunately, cyclic compounds containing six and more atoms in the ring cannot be obtained in this way because of the active competition by the C–H insertion reaction.[150]

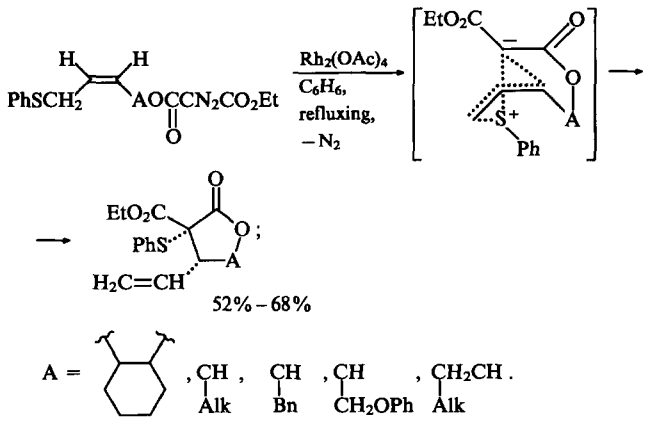


The formation of heterocycles containing more than five atoms in the ring is observed in the intramolecular reactions of the carbenes generated from diazoesters containing an allyl fragment. Thus the $Rh_2(OAc)_4$-catalysed dediazotisation of 7-allylthio-2-diazo-3-oxoheptanoates and 6-allylthio-2-diazo-3-oxohexanoates results in the formation of 3-thiepanones and 3-thianones in high yields (Schemes 113 and 114);[149] the C–H insertion products were not detected under these conditions.

Scheme 113

R = CO_2Et, R^1 = Ph (29%).

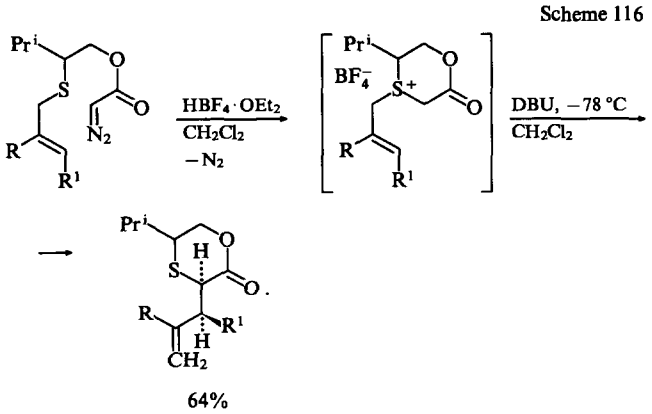
Scheme 114



55–85%

R^1	R^2	Yield (%)
Me	Me	66
H	H	59
Ph	H	78
Me	H	71

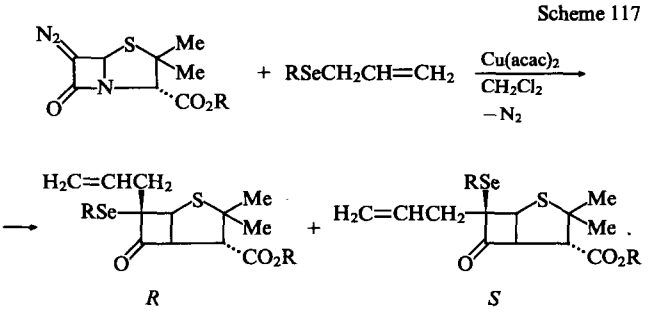
The presence of the allyl fragment in the alcoholic component of the monoethyl diazomalonate molecule also makes it possible to synthesise vinyl-substituted five- and six-membered cyclic lactones as a result of the stereoselective [2,3]-rearrangement of the S ylide arising on cyclisation of the carbenes stabilised on rhodium(II) (Scheme 115).[149,160]



Scheme 115

52%–68%

The diastereoselectivity of this reaction can be increased significantly by using $HBF_4 \cdot Et_2O$ as the agent promoting the heterocyclisation of diazaesters and subsequently treating the resulting thiooxonium salt with 1,8-diazobicyclo[5.4.0]-undec-7-ene (DBU). Thiooxanones were obtained in this way from allylthioalkyl diazoacetates in satisfactory yields and with a high diastereoselectivity (in excess of 93%) (Scheme 116).[161]



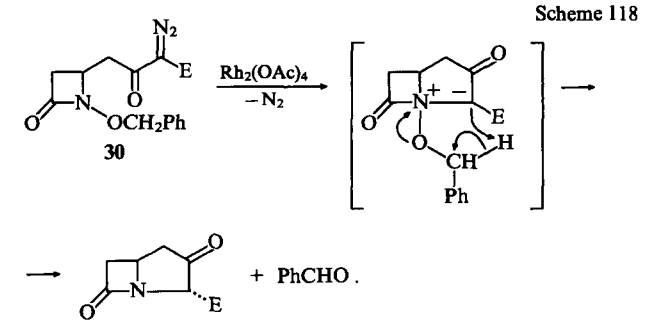
Scheme 116

64%

There are only isolated examples of reactions involving insertion in the C–Se bond. Thus the reaction of a cyclic diazoamide with allyl phenyl selenide in the presence of $Cu(acac)_2$ leads to a mixture of equal amounts of the corresponding isomeric C–Se insertion products with an overall yield of 64% (Scheme 117).[162]

Scheme 117

The analogous reaction of this diazoamide with allyl sulfides proceeds more selectively with the (*R*)-isomer predominating. Its fraction can reach 87%.

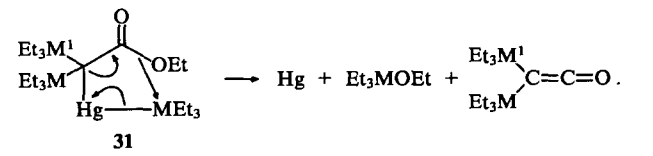


VI. Heteroatom–heteroatom bonds

The reactions of diazoesters involving the insertion of the carbene fragment in a heteroatom–heteroatom bond are presented in Table 6.

These reactions also take place with the intermediate formation of ylides. In the carbene reactions of diazoesters with organosilicon compounds (examples 5–7, Table 6), β-elimination and C–H insertion processes take place in the ylides formed apart from the [1,2]-shift, which lowers the preparative value of these reactions.

The reactions of ylides do not always lead to the products of the insertion of the carbene in the bond being attacked. Thus the intramolecular attack by the carbene centre on the N–O bond in the diazolactam **30** (E = CO_2Me) leads to an N ylide, the rearrangement of which is accompanied by the dissociation of the N–O bond and the formation of a N–C bond (Scheme 118).[178]



Scheme 118

30

It is suggested that the formation of organoelement ketenes as a result of the interaction of α-metallated diazoesters with bis(triethylsilyl)- or bis(triethylgermyl)-mercury (examples **20**–**22**) takes place owing to the decomposition of the unstable product **31** of the insertion of the carbene in the Hg–Si or Hg–Ge bond formed initially (Scheme 119).

Scheme 119

31

It is noteworthy that the formation of the formal insertion products is not always associated with the reactions of diazoesters via the carbene pathway. For example, although the interaction of ethyl diazoacetate with *tert*-butyl hypochlorite does lead to the product of the insertion of the carbene fragment $CHCO_2Et$ in the O–Cl bond (examples **1** and **2**, Table 6), the attempts to achieve

[a] Formed as a result of the solvolysis of the O–Cl insertion product.
[b] The yield is not indicated.

the capture of the carbene by the olefin under these conditions were unsuccessful. The formation of the O–Cl insertion products was observed also in the reaction of ethyl diazoacetate with ethers in the presence of SO_2Cl_2 (examples **3** and **4**, Table 6). Yet another example of reactions of this type is the $BF_3 \cdot Et_2O$-catalysed interaction of the cyclic diazoamide **32** with diphenyldiselenium, which leads to 6,6-di(phenylselenyl)penicillanate in a satisfactory yield (Scheme 120).[178]

Scheme 120

32

* * *

The data presented in this review clearly demonstrate, in relation to insertion reactions, the considerable potential possibilities of the use of the chemistry of diazoesters in organic synthesis. Quite recently, the principal application of diazoesters was still the reaction involving the conversion of olefins into cyclopropane derivatives. At the present time, progress in the field of homogeneous catalysis has made it possible to include in practical preparative organic synthesis also reactions which seemed to be exotic in earlier studies, such as the insertion of alkoxycarbonylcarbenes in a carbon–carbon or carbon–heteroatom bond. Study of the literature shows that the development of this branch of the chemistry of diazoesters has proceeded in two directions, which are of key importance for the expansion of the applications of these reagents in organic synthesis.

The first of these is associated with the increase in the selectivity of the reactions with participation of diazoesters. It involves mainly studies on the enantioselective and stereoselective synthesis of cyclic compounds by the catalytic dediazotisation of diazoesters. The aim of the second aspect was to expand the applications of insertion reactions with participation of diazoesters in organic synthesis. It has developed, in its turn, both in connection with the search for new reactions of diazoesters and their involvement in reactions with compounds of new classes such as the synthesis of new diazoesters for the construction of specified structures, in particular natural products.

The successful development of these two types of studies will depend, in our view, on the progress in the development of synthetic methods for the introduction of the functional diazo-group into the molecules of organic acid esters and also on the search for new effective and selective catalysts of the dediazotisation of diazoesters and the advances in the elucidation of the mechanisms of catalytic reactions undertaken to allow the regulation of such reactions.

Fine organic synthesis with the aid of heteropolycompounds

I V Kozhevnikov

Contents

I. Introduction	473
II. Acid catalysis	473
III. Liquid-phase oxidation reactions	482
IV. Conclusion	487

Abstract. The use of heteropolycompounds (heteropolyacids and their salts) as acid and oxidation catalysts of fine organic synthesis reactions is examined. The use of heteropolycompounds in the synthesis of antioxidants, medicinal preparations, vitamins and other products produced on a small scale is discussed. Examples of the practical application of catalysis by heteropolycompounds are presented. The bibliography includes 177 references.

I. Introduction

Catalysis by heteropolycompounds (HPC) is one of the important aspects of the modern science of catalysis.[1–9] Studies in this field have been already prosecuted vigorously for 20 years. They permitted significant progress in the understanding of the mechanism of the catalytic effect of HPC at the molecular level and have led to the creation of a series of new industrial processes.

HPC have unique physicochemical properties. Catalysts based on them have a definite and well established structure. HPC catalyse effectively both acid-dependent and oxidation reactions and are frequently superior in their activity and/or selectively to known analogues.[2–4, 6] Their likely usefulness is indicated, in particular by the development and application in Japan of a series of new large-scale organic synthetic processes in which HPC are employed as catalysts (Table 1).[7] These processes include the oxidation of methacrolein to methacrylic acid, the hydration of olefins to alcohols, and polymerisation of tetrahydrofuran with ring opening (a stage in the synthesis of polyurethanes).

The use of HPC as catalysts of fine organic synthetic processes is very promising. By virtue of the high price of the products, the gain in selectivity as a result of the introduction of a more effective catalyst frequently covers severalfold the cost of the catalysts. Numerous studies have been carried out recently on the application of HPC as antioxidants, medicinal preparations, vitamins, biologically active substances, etc. There exist numerous patents for the application of HPC in fine organic synthesis. Some developments have already been applied in practice. The discussion of these new data is in fact the principal aim of the present review. The review is addressed primarily to synthetic chemists in order to draw their attention to the considerable possibilities which have arisen as a result of the application of HPC in synthetic practice. Attention is concentrated on acid-dependent and oxidation reactions of organic molecules in the liquid phase in homogeneous and heterogeneous systems. Certain new data concerning the preparation and properties of HPC-based catalysts are also considered. More complete information about the synthesis and the physicochemical and catalytic properties of HPC may be found in monographs and reviews.[1–14] The catalytic properties of HPC have been examined in greatest detail in a recently published review.[2]

II. Acid catalysis

HPC are representatives of the large class of polynuclear complexes which combines a multiplicity of compounds differing in chemical composition and structure.[13] Despite their wide variety, until recently only the most stable and well investigated HPC have been used almost exclusively in catalysis. They contain the heteropolyanions $XM_{12}O_{40}^{x-8}$, where X is the central atom (Si^{4+}, P^{5+}, etc.), x is its oxidation state, and M is the metal ion (Mo^{6+}, W^{6+}, V^{5+}, etc.). The cations may be protons, metal ions, etc. These HPC have the well known Keggin structure (Fig. 1),[15] which includes the XO_4 tetrahedron surrounded by 12 MO_6 octahedra with common vertices and edges. Subsequently, for specially stipulated cases, HPC will be understood as compounds having this structure.

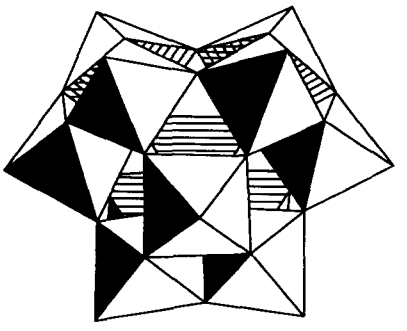

Figure 1. The structure of the heteropolyanion $XM_{12}O_{40}^{x-8}$ (α-isomer).[15]

Mainly the heteropolyacids $H_{8-x}[XM_{12}O_{40}]$ (HPA) are used in acid catalysis. Their high effectiveness as acid catalysts is due to a number of causes. In the first place, they are strong Brønsted acids, stronger than many of the usual acids employed as catalysts.[4] Heteropolyacids are readily soluble in water and

Table 1. Industrial heteropolyacid-catalysed processes.[7]

Reaction	Catalyst	Scale of industrial production/tonnes	Year of introduction
$CH_2=C(CH_3)CHO \xrightarrow{O_2} CH_2=C(CH_3)COOH$	Mo–V–P–HPA	95000	1982
$CH_2=C(CH_3)_2 \xrightarrow{H_2O} (CH_3)_3COH$	$H_3PMo_{12}O_{40}$	56000	1984
$CH_3CH=CHCH_3 \xrightarrow{H_2O} CH_3CH(OH)CH_2CH_3$	$H_3PMo_{12}O_{40}$	40000	1985
 $\xrightarrow{H_2O}$ $HO\text{-}[(CH_2)_4\text{-}O]_n\text{-}H$	$H_3PW_{12}O_{40}$	–	1987

oxygen-containing solvents and their thermal stability is high in the solid state. Because of this, they are used as both homogeneous and heterogeneous catalysts. Being 'soft' bases, heteropoly-anions (HPAN) are capable of effecting the specific coordination of the molecules of organic reagents, which may activate the latter in particular chemical reactions.[6, 7] The inertness of heteropoly-anions in relation to many side reactions, characteristic of organic reagents, which readily occur in the presence of the usual inorganic acids (sulfonation, chlorination, etc.), is important for homogeneous catalysis.[4] Because of the lability of their crystal structures and the high mobility of protons, solid heteropolyacids are capable of effecting not only the usual catalysis involving the active centres on their surface but they can also participate in bulk-phase catalytic action, like concentrated solutions of acids ('pseudoliquid phase').[6]

Data concerning the acid properties of heteropolyacids and their applications in acid catalysis have been examined in a number of reviews.[2, 4, 6]

1. Preparation of the catalysts

Heteropolyacids such as $H_3PW_{12}O_{40}$, $H_4SiW_{12}O_{40}$, and $H_3PMo_{12}O_{40}$ are used industrially in Russia and abroad in the form of hydrates. They are readily available. They are usually obtained by acidifying an aqueous solution containing the sodium salt of the heteroelement and sodium tungstate or molybdate and are isolated by extraction with ether.[10, 13, 14] Certain heteropoly-acids, in particular $H_3PMo_{12}O_{40}$ and mixtures of heteropolyacids having the composition $H_3PO_4 \cdot nMoO_3$ ($n = 6-9$), can be obtained by the direct reaction of the corresponding acids and oxides in solution without extraction with ether.[14, 16–18]

New possibilities in the synthesis of heteropolyacids have been provided by electrodialysis. This method makes it possible to obtain many heteropolyacids in quantitative yields from sodium salts.[19–25] An effective electromembrane method of synthesis of $H_3PW_{12}O_{40}$ by the reaction of Na_2WO_4 with H_3PO_4 in aqueous solution followed by the removal of Na^+ with the acid of a selective cation-exchange membrane has been developed and applied in industry.[22–24] The method is illustrated schematically in Fig. 2.

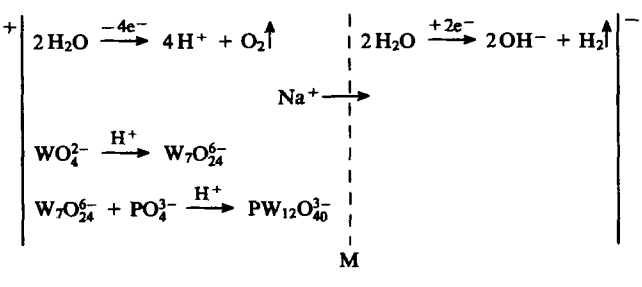

Figure 2. Schematic illustration of the synthesis of $H_3PW_{12}O_{40}$ with the aid of electrodialysis. M = cation-exchange membrane.

The $PW_{12}O_{40}^{3-}$ anion is formed in the anodic compartment of the electrodialyser from WO_4^{2-} and PO_4^{3-} taken in virtually stoichiometric proportions. The necessary acidification of the solution is achieved by electrolysing water. Heteropolyacids are synthesised in two stages.[21–24] In the first stage, in the absence of phosphate ions, WO_4^{2-} is converted into the isopolytungstate $W_7O_{24}^{6-}$. H_3PO_4 is then introduced and the electrochemical process is continued until completion. Under the influence of electric potential, Na^+ ions migrate from the anodic to the cathodic compartment through the cation-exchange membrane. This results in the concentration of aqueous $H_3PW_{12}O_{40}$ and NaOH solutions in the anodic and cathodic compartments respectively. The solution of the heteropolyacid is concentrated and the solid acid is crystallised out. Alkali is used to obtain Na_2WO_3 from WO_3 or H_2WO_4. Thus the process is waste-free. The yield of the heteropolyacid is close to 100% relative to tungsten. The Na^+ content in the final product does not exceed 0.01 wt.%. Other heteropolyacids, for example, $H_4SiW_{12}O_{40}$, $H_5PW_{11}TiO_{40}$, $H_5PW_{11}ZrO_{40}$, $H_6PW_{11}BiO_{40}$, $H_5PW_{11}CeO_{40}$, $H_6P_2W_{21}O_{17}$, and others, can be obtained similarly.[19, 21, 25]

As a rule, the tungsten acids are the best acid catalysts in the series of heteropolyacids. This is due to their greater acidity, resistance to hydrolysis, and thermal stability and also their lower oxidation potential compared with molybdic and vanadic acids.[4] However, cases are known also where Mo-HPA are used, for example, in industrial olefin-hydration processes.[7]

Massive heteropolyacids have a low specific surface ($1-5\ m^2\ g^{-1}$)[4, 26, 27] and are readily soluble in water and oxygen-containing organic solvents but are insoluble in hydrocarbons. The specific surface of insoluble salts, for example $Cs_{3-x}H_xPW_{12}O_{40}$,[28, 29] is $100-200\ m^2\ g^{-1}$. The porous structure of HPC has been examined.[30] Tungsten heteropoly-acids are stable up to ~400 °C.[31] The thermal stability of salts of heteropolyacids is higher than that of the acids themselves.

The strength and number of the acid centres of the hetero-polyacid can be regulated by selecting the outer-sphere cation, by replacing the central atom and the metal atom in the structure of the polyanion, and also by using carriers of different nature and by changing the concentration of the heteropolyacid on the latter.[4]

The disposition of heteropolyacids on inert carriers makes it possible to increase their surface area, but the strength of the acid centres is then somewhat reduced.[32] The deposited heteropoly-acids are usually obtained by impregnating or adsorbing the heteropolyacids from solutions on carriers. The adsorption of heteropolyacids from solutions in various solvents on silica gel, alumina, and activated charcoal has been investigated.[32, 33]

Silica gel is most often used as the carrier for the heteropolyacid in acid catalysis, whilst activated charcoal is more rarely employed; more basic carriers such as Al_2O_3 and MgO reduce the acidity of the heteropolyacid.[4, 34–36] When the heteropolyacid is deposited on SiO_2, its structure is retained.[34] According to X-ray diffraction data,[32, 34] a crystalline phase of the heteropolyacid appears on SiO_2 when the heteropolyacid content is >20%. Three forms of $H_4SiW_{12}O_{40}$ have been observed on the

Table 2. Dissociation constants of heteropolyacids in acetone at 25 °C.[4]

Acid	pK_1	pK_2	pK_3
$H_3PW_{12}O_{40}$	1.6	3.0	4.0
$H_4PW_{11}VO_{40}$	1.8	3.2	4.4

$H_4SiMo_{12}O_{40}$	2.1	3.9	5.9
H_2SO_4	6.6	+	+
HCl	4.3	+	+
HNO_3	9.4	+	+

SiO_2 surface by electron microscopy: isolated heteropolyacid molecules, 50 Å clusters, and 500 Å crystallites.[32] The ratios of these forms depend on the amount of deposited heteropolyacid.

Catalysts obtained by depositing the heteropolyacid on its insoluble isostructural salt, for example, $H_{3+n}PMo_{12-n}V_nO_{40}/K_3PMo_{12}O_{40}$ ($n = 0-3$) have attracted interest recently.[37, 38] Such systems have an increased thermal stability. They are apparently analogous to the insoluble acid salts of the type $Cs_{3-x}H_xPW_{12}O_{40}$.[28, 29]

Heteropolyacid-based catalysts are activated before use by thermal dehydration. For the complete removal of water from the heteropolyacid, it is sufficient to heat it *in vacuo* at 200–250 °C for 1–2 h.

2. Acid properties of heteropolyacids

Heteropolyacids are strong Brønsted acids,[1-9] whilst heteropolyanions are 'soft' weakly solvated bases.[39] In solutions, heteropolyacids are stronger than many usual inorganic acids such as H_2SO_4, HCl, HBr, HNO_3, etc. (Table 2). The strength of heteropolyacids with the Keggin structure depends only slightly on their composition. However, tungsten heteropolyacids are appreciably stronger than molybdenum heteropolyacids. The strongest and the most stable among the acids of the M_{12}-series is $H_3PW_{12}O_{40}$.[4] The dissociation constants of heteropolyacids in water,[40, 41] acetone, ethanol, and acetic acid[42, 43] and their Hammett acidity functions in water and water–acetic acid, water–dioxane, water–ethanol, and water–acetone mixtures[44, 45] have been measured. The activities of water in $H_3PW_{12}O_{40}$ solutions have been determined.[44]

Solid heteropolyacids exhibit purely Brønsted acidity[46, 47] and are stronger than traditional acid catalysts such as aluminosilicates, H_3PO_4/SiO_2, and HX and HY zeolites.[46] The acidity of massive and deposited heteropolyacids has been investigated by various methods. These include the indicator method,[48, 49] measurement of diffusion coefficients[50] and ionic conductivities,[49, 51] ion exchange,[52] thermal desorption of bases,[46] IR spectroscopy,[34, 46, 47, 53] broad band ^1H NMR[11, 31, 54, 55] and ^1H NMR (MAS),[56, 57] ESCA,[58] etc.

According to adsorption calorimetric data,[59] the protic centres of $H_3PW_{12}O_{40}$ are fairly homogeneous (Fig. 3) and their strength is close to that of H-mordenite.† After deposition on silica gel (20% HPA/SiO_2), the protic centres are weakened, their strength approaching that of the protic centres of the HX and HY zeolites, and the centres become less homogeneous.[59] The strength of the acid centres of the deposited $H_3PW_{12}O_{40}$ diminishes in the sequence of carriers $SiO_2 > Al_2O_3 >$ activated charcoal (Sibunit).[59] The cause of the reduced acidity of the heteropolyacids on charcoal is so far obscure.

The structure of the protic centres of heteropolyacid-based catalysts has been studied.[4]

Neutral salts of heteropolyacids are also used in acid catalysis because they are capable of forming protic centres on interaction with the reaction medium.[2, 4, 6] Two mechanism of the generation

† Centres on which the heat adsorption of ammonia exceeded 90 kJ mol^{-1} were classified as protic.[59]

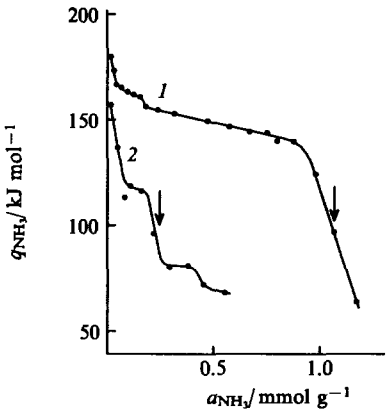

Figure 3. Differential heats of adsorption of NH_3 on $H_3PW_{12}O_{40}$ (*1*) and 20% $H_3PW_{12}O_{40}/SiO_2$ (*2*) at 150 °C. The position on the abscissa axis corresponding to the numbers of protic centres in the specimens are designated by arrows.[59]

of protic centres in heteropolyacid salts are distinguished[2, 6] — hydrolytic (for salts with the Al_3^+, Zn_2^+, etc. cations) and oxidation-reduction (for Cu^{2+}, Pd^{2+}):

$$Al^{3+} + H_2O \longrightarrow Al(OH)^{2+} + H^+ ,$$

$$Ag^+ + \frac{1}{2}H_2 \longrightarrow Ag^0 + H^+ .$$

The HPC containing simultaneously outer-sphere protons and transition metal cations are capable of acting as bifunctional catalysts. The hydroisomerisation of alkanes[2] on (Pt, Pd)/$H_3PW_{12}O_{40}$ may serve as an example.

The nature, strength, and number of acid centres can be regulated specifically by varying the chemical composition of the HPC, the type of carrier, the concentration of the HPC on the carrier, the conditions in the preliminary treatment of the catalyst, etc. The Keggin structure is retained over a wide range of acid properties of the HPC, which has been established reliably by spectroscopic methods (IR, ^{31}P, ^{17}O, ^{95}Mo, ^{183}W, ^{51}V, etc. MNR).[4, 11, 13] Because of these valuable properties, HPC are of great interest both for applied acid catalysis and as model systems for the study of fundamental problems of catalysis at the molecular level.

3. Mechanisms of acid catalysis by heteropolyacids

a. Homogeneous catalysis

The mechanism of the homogeneous acid catalysis by heteropolyacids is in principle similar to the mechanism of the catalysis by solutions of inorganic acids. In the simplest case, it can be represented schematically as follows:

$$S + HA \rightleftharpoons SH^+ + A^- ,$$

$$SH^+ \xrightarrow[(A^-)]{} P + HA ,$$

where S is the substrate, HA the catalyst, and P the product. Being stronger, heteropolyacids are capable of protonating the substrate and activating it for subsequent chemical reactions more effectively than the usual inorganic acids. As a result of this, heteropolyacids are as a rule much more active than inorganic acids.

Organic reactions in the presence of heteropolyacids and inorganic acids usually obey the same rules. Many examples of the parallel variation of the catalytic activity of heteropolyacids and their dissociation constants (the Brønsted equation) are known.[2, 4] In concentrated solutions of heteropolyacids, the rate

constant is found to depend on the Hammett acidity function H_0.[45, 60] Thus the rate constants for the hydration of isobutene in aqueous solution in the presence of $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ at 25 °C obey the equation[60]

$$\lg k = -1.04H_0 - 3.46.$$

The same relation holds for H_2SO_4, HCl, HNO_3, and $HClO_4$. On this basis, it has been suggested[60] that the hydration of isobutene in the presence of heteropolyacids and inorganic acids proceeds via the generally accepted mechanism in which the rate-limiting stage is the conversion of the π-complex between the olefin and H^+ into a carbonium ion.

$$(CH_3)_2C{=}CH_2 \overset{H^+}{\rightleftharpoons} (CH_3)_2C^{\overset{H^+}{\cdot\cdot}}{=}CH_2 \longrightarrow (CH_3)_3C^+ \xrightarrow{H_2O} (CH_3)_3COH + H^+ .$$

At the same time, the mechanisms of the catalytic action of heteropolyacids and inorganic acids in solutions differ somewhat, which is associated with the greater degree of dissociation of heteropolyacids and the high charge on the heteropolyanions. This is manifested primarily by a strong salt effect, which is observed in ionising media, for example, in water.[45, 60] This is indicated by the variable order of the reaction with respect to the catalyst, exceeding unity. Thus the formal order of the isobutene hydration reaction with respect to the heteropolyacid in dilute solutions (0.02–0.1 M heteropolyacid) is 1.2–1.5, while in concentrated solutions (up to 0.5 M) it is 2.0–2.2.[60] In the presence of inorganic acids, the reaction is virtually first-order. The contribution of the salt effect to the rate constants for the reactions of a non-electrolyte with an ionic reagent can be estimated with the aid of the Sechenov equation. In the case of bimolecular reaction, we have

$$\lg k = \lg k_0 + (B - B^{\neq})[H^+],$$

where k is the second-order rate constant at the given concentration $[H^+]$, $k_0 = k$ at $[H^+] = 0$, and B and $B^{\neq}$ are the salting-out coefficients in the ground and transition states.[60] This equation holds satisfactorily in the hydration of isobutene in the presence of both heteropolyacids and inorganic acids. Hence it was concluded that the true order of the reaction with respect to the heteropolyacid unity, as in the case of inorganic acids, and that its increase with increase in the concentration of the heteropolyacid is due to the salt effect.[60] The values of k_0, B, $B^{\neq}$, and $B-B^{\neq}$ for the hydration of isobutene in the presence of

	$10^4 k^0$ / litre mol^{-1}	B / litre mol^{-1}	$B^{\neq}$ / litre mol^{-1}	$B-B^{\neq}$ / litre mol^{-1}
$H_3PW_{12}O_{40}$	20.0±3	−0.87	−3.0	2.1
$H_4SiW_{12}O_{40}$	17.0±4	−0.87	−3.0	2.1
HNO_3	3.8±0.4	−0.02	−0.2	0.2
H_2SO_4	5.0±1	+0.08	−0.2	0.3

different acids (at 25 °C) are given below:[60]

Evidently the constants k_0, extrapolated to $[H^+] = 0$, correspond approximately to the basicities of the acids, i.e. the rates of reaction per proton are similar regardless of the type of acid catalyst. Judging from the negative values of B and $B^{\neq}$, 'salting-in' i.e. a decrease in the level of the free energy of the ground and transition states due to the salt effect, almost always occurs. As was to be expected, the more polar transition state is 'salted-in' to a greater extent under these conditions. The fact that the salt effect $B-B^{\neq}$ is an order of magnitude higher for HPA than for inorganic acids is striking. This can be explained satisfactorily by the expected influence of ionic strength on the rate of the interaction of the polar molecule with an ion, because on complete dissociation of a 1–4 electrolyte ($H_4SiW_{12}O_{40}$) the ionic strength is ten times greater than on dissociation of a 1–1 electrolyte (HNO_3).

The kinetics of polar reactions involving ionic reagents are usually investigated in solutions with a fairly high constant ionic strength established by the addition of a neutral electrolyte in order to compensate for the salt effect. We may note that in the case of heteropolyacids the strong salt effect frequently renders this procedure relatively ineffective and this complicates the determination of the true order of the reaction with respect to HPA.

A number of workers have postulated the ability of 'soft' heteropolyanions to effect the specific coordination of organic molecules.[6, 7] Thus, a detailed study[2] of the hydration of isobutene in the presence of heteropolyacids made it possible to interpret the high order of the reaction with respect to the heteropolyacid on the hypothesis of a two-pathway mechanism:

Here (*a*) is the usual pathway which was already considered above and (*b*) is the pathway involving the formation of a complex between the heteropolyanion and the olefin, in which the latter is activated as a result of the coordination to the heteropolyanion. It has been suggested that the increase in the order of reaction with respect to the heteropolyacid may in fact be explained by the presence of pathway (*b*).

In reality both mechanisms of this industrially important reaction are probably in essence the same and the difference consists merely in the interpretation of the influence of the medium. In one case, this is done within the framework of the traditional approach involving allowance for the salt effect, where the medium is regarded as a continuum, whilst in the other this is done at the molecular level during the formation of weak complexes between the heteropolyanion and the substrate. In our view, further investigations in order to find evidence for the possibility of the formation of such complexes are of great interest.

b. Heterogeneous catalysis

In heterogeneous systems, heteropolyacids also exhibit a very high activity. As a rule, heteropolyacids are more active than traditional catalysts such as Al_2O_3, $Al_2O_3-SiO_2$, the HX and HY zeolites, etc., which is fully consistent with the relative strengths of the solid acids.[2, 4, 6] As already mentioned, heteropolyacids exhibit a purely Brønsted acidity, in contrast to oxide systems which have both Brønsted and Lewis acid centres.

Massive heteropolyacids possess very strong and fairly uniform protic centres, but their specific surface is low (1–5 $m^2\ g^{-1}$). Following deposition on an inert carrier, the accessible surface of the heteropolyacid increases, but the acid centres become weaker and less uniform.[59] For reactions occurring on moderately strong acid centres in the vapour or liquid phase, 20% HPA/SiO_2, where HPA = $H_3PW_{12}O_{40}$ or $H_4SiW_{12}O_{40}$, while SiO_2 is coarsely porous silica gel with a specific surface of 200–300 $m^2\ g^{-1}$, may serve as the optimum catalyst. Such a catalyst may be obtained by impregnating SiO_2 with an aqueous solution of the heteropolyacid with subsequent drying in air and activation by vacuum heat treatment at 200–250 °C. The heteropolyacid exists on the surface of this catalyst in the form of isolated molecules and 50 Å clusters; the Keggin structure of the heteropolyacid is retained under these conditions.[32]

Massive heteropolyacids behave in many respects like solutions, which provides a basis for the expectation of a similarity in

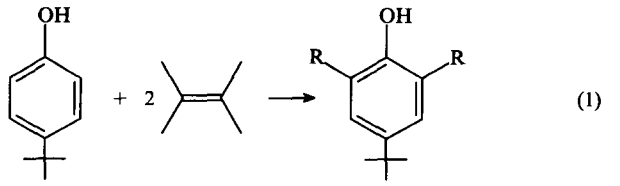
the mechanisms of the action of homogeneous and heterogeneous heteropolyacid-based catalysts. This is associated primarily with the fact that both in solution and in the solid state heteropolyacids have the same molecular (Keggin) structure. The high proton conductivity of the heteropolyacids and their ability to form solvates with polar organic molecules also play an important role.[2, 4, 6] These properties are manifested more strikingly in low-temperature reactions (< 300 °C), where the Keggin structure is retained.

The strength of solid heteropolyacid hydrates diminishes in the sequence[4]

$$H_3PW_{12}O_{40} > H_4SiW_{12}O_{40} \cong H_3PMo_{12}O_{40} > H_4SiMo_{12}O_{40},$$

which is identical with the series based on the strength of the heteropolyacids in solutions (Table 2). The catalytic activity of the heteropolyacids usually diminishes in the same sequence in both homogeneous and heterogeneous systems.[2, 4]

The hydrates of heteropolyacids exhibit a high proton conductivity.[2-4, 6] The migration of H^+ via the system of hydrogen bonds constituting the crystal structure of the heteropolyacid takes place with a low activation energy and virtually just as readily as in aqueous solutions, the electrical conductivity increasing with increase in the degree of hydration of the heteropolyacids. The anomalously high mobility of H^+ may be one of the reasons for the high catalytic activity of massive heteropolyacids, since it increases the effective concentration of H^+ in the surface region.

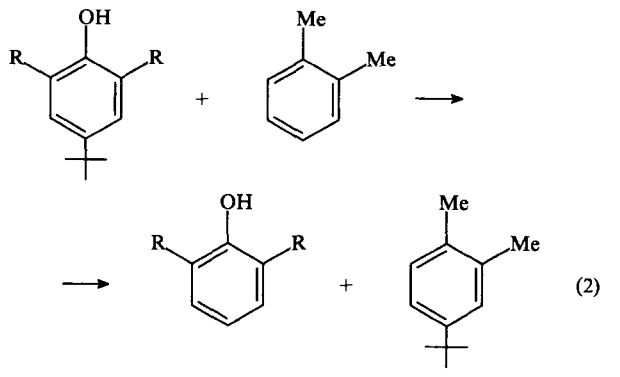


Solid heteropolyacids and their soluble salts have a high affinity for the molecules of polar substances such as alcohols, ketones, ethers, amines, etc. These substances are absorbed in large amounts in the bulk of the crystalline heteropolyacids with formation of solvates.[2-4, 6] The sorption of non-polar hydrocarbons (alkanes, olefins, arenes) is insignificant. They are adsorbed only on the surface of the heteropolyacids.

Because of the ease of sorption of polar molecules, their catalytic reactions can occur not only on the surface but also in the bulk of massive heteropolyacids. Solid heteropolyacids behave in relation to polar substances very similarly to concentrated solution, i.e. all the acid protons, and not only the surface protons, participate in the catalytic reaction. This phenomenon, unusual for heterogeneous acid catalysis, is designated by the term 'pseudoliquid phase'.[2, 6] In contrast to polar molecules, non-polar reagents are incapable of being absorbed in the bulk phase of heteropolyacids; they interact only with the surface of the catalyst. The 'pseudoliquid phase' apparently plays a significant role in reactions of polar substances at low temperatures, i.e. under conditions where the degree of sorption of the substrate in the bulk phase of the catalyst is high. In high-temperature processes, the contribution of the bulk phase reaction is probably not so significant. For a more detailed treatment, see other communications.[2, 4, 6]

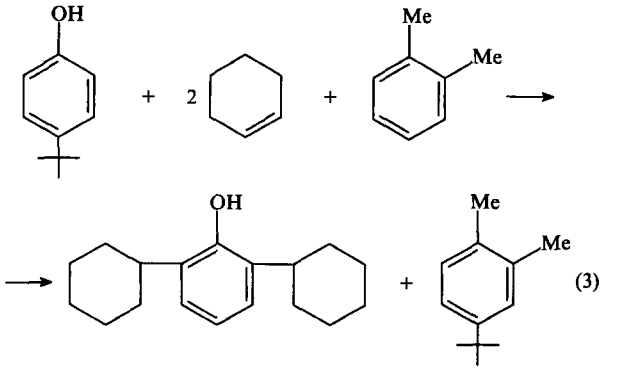
4. Alkylation, dealkylation, and transalkylation of phenols

These reactions are of practical importance and are used widely in industry to obtain antioxidants, thermo- and photo-stabilisers, biologically active substances, etc. A wide variety of acid–base catalysts are used to carry them out: inorganic acids, sulfonic acids, cation-exchange resins, aluminosilicates, and metal salts and oxides.[61-64]



Heteropolyacids exhibit a high catalytic activity in reactions involving the alkylation of benzene and alkylbenzenes by olefins.[34, 65-67] Phenol is also readily alkylated on heteropolyacids, but the reaction in non-selective.[68-71] *p*-(*tert*-Butyl)phenol (TBP) is alkylated more selectively. Its reaction with cyclohexene, hex-1-ene, styrene, and benzyl chloride in the presence of the massive acids $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ and the acids deposited on SiO_2 (1% relative to TBP) at 100–150 °C affords 2,6-dialkyl-4-*tert*-butylphenols in 63%–90% yield.[68, 69]

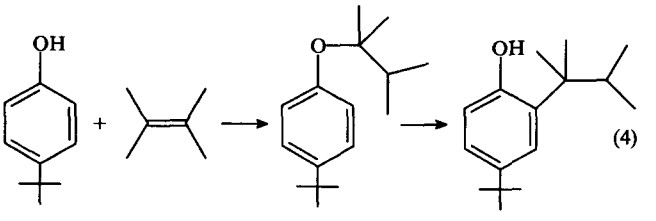
(1)



The most selective reaction is that with styrene: the yield reaches 90% for 100% conversion of TBP (100–110 °C, 1 h). In the case of α-methylstyrene, monoalkylation takes place preferentially and the yield of 4-*tert*-butyl-2-cumenylphenol is 70%.

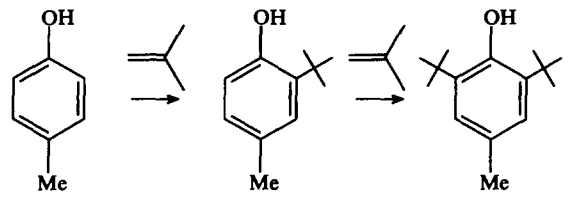
The alkylation of TBP by olefins in the presence of heteropolyacids in *o*-xylene, which is an acceptor of the *tert*-butyl group, makes it possible to obtain 2,6-dialkylphenols without the intermediate isolation of 2,6-dialkyl-4-*tert*-butylphenol. The *tert*-butyl group is eliminated quantitatively via the reaction

(2)



2,6-Dicyclohexylphenol was obtained in this way in 77% yield.[68, 69] The *tert*-butylxylene formed in this reaction can be used in the synthesis of pigments.

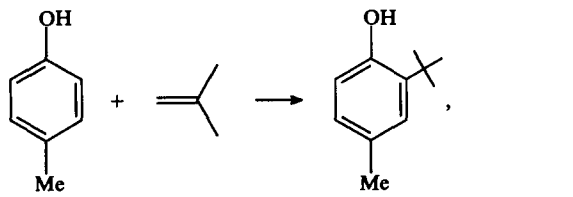
(3)



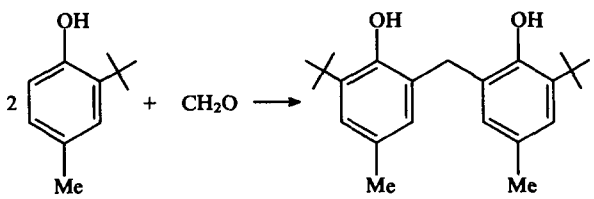
Heteropolyacids are insoluble in the reaction mass, are readily separated from the latter, and can be reused.

The alkylation of TBP apparently proceeds via a mechanism involving the formation of ethers as the primary products with their subsequent rearrangement to the *C*-alkylation products. This has been confirmed by the detection of ethers in the initial stage of the reaction.[68, 69]

(4)



The acid alkylation of *p*-cresol by isobutene is an important industrial reaction used in the synthesis of phenolic antioxidants.[62]

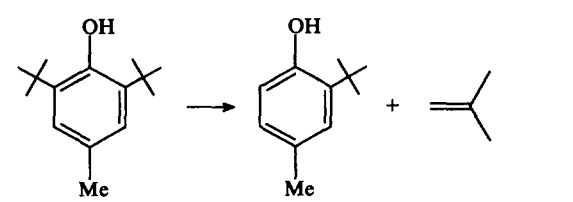


(5)

This reaction proceeds smoothly when the heteropolyacid is used as a heterogeneous catalyst. The activity of heteropolyacids in the *p*-cresol and TBP alkylation reactions (calculated per available proton) is greater by four orders of magnitude than the activity of sulfuric acid, which can be explained by the stronger acidity of the heteropolyacid.[68]

An industrial version of the alkylation of *p*-cresol by isobutene in the presence of $H_3PW_{12}O_{40}$ has been developed at the Institute of Catalysis of the Siberian Division of the Russian Academy of Sciences. This reaction is the first stage of the synthesis of the antioxidant Agidol-2 [2,2'-methylenebis(6-*tert*-butyl-4-methylphenol)], widely used to stabilise polymeric materials.[62]

(6)

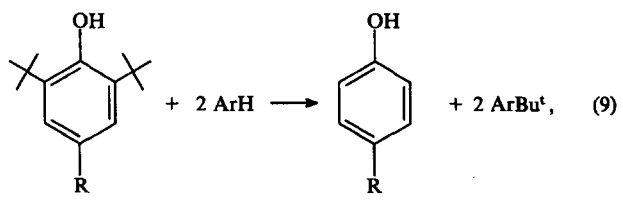


(7)

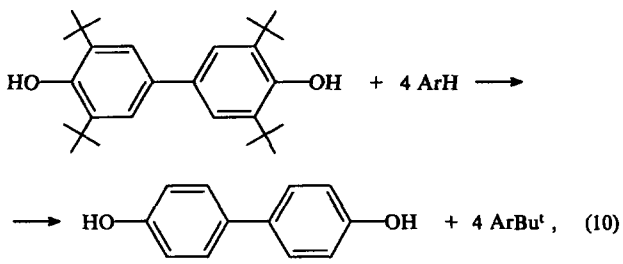
Agidol-2

The second stage [reaction (7)] is carried out by familiar method with HCl as the catalyst.[62] The use of a heteropolyacid instead of sulfuric acid made it possible to eliminate completely the formation of toxic cresol-sulfate waste water in the first stage of the process. The consumption of *p*-cresol was reduced, because its sulfonation and losses during neutralisation and washing were eliminated. The duration of the alkylation stage was shortened and charring was sharply reduced.

The dealkylation of derivatives of 2,6-di-*tert*-butylphenol to 2-*tert*-butylphenols is also widely used in the synthesis of phenolic antioxidants.



(8)



The acids $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ are effective homogeneous and heterogeneous catalysts of this reaction, in which the substituents can be not only the methyl group but also H, Et, and CH_2CH_2COOMe.[72–74] The heterogeneous process takes place at 130–150 °C in the presence of a catalyst (<1%) in the substrate melt.[72, 73] Molybdenum heteropolyacids are rapidly deactivated as a result of their reduction by the reaction medium. Heteropolyacids are tens of times more active than heterogeneous catalysts such as cation-exchange resins, aluminosilicates, aluminium sulfate, etc. The homogeneous process is even more effective. In solution in acetic acid, dealkylation takes place even at 80 °C. The catalytic activity of heteropolyacids is correlated with their strength and exceeds by a factor greater than 100 the activity of sulfuric acid.[74]

The transalkylation of 2,6-di-*tert*-butylphenols in the presence of heteropolyacids has been studied in detail.[70, 75–77] This important reaction is used widely in organic synthesis for the regioselective introduction of functional groups in phenols.[78, 79] Aromatic compounds (ArH) such as benzene, toluene, *o*-xylene, naphthalene, etc. are used as acceptors of the *tert*-butyl group, while the catalysts are H_2SO_4, $4\text{-}MeC_6H_4SO_3H$, $MeSO_3H$, CF_3SO_3H, zeolites, aluminosilicates, and the perfluorosulfonic acid cation exchanger Nafion-H.[78–81]

Massive and deposited tungsten heteropolyacids (0.5–7%) are universal catalysts of the complete *trans*-de-*tert*-butylation of phenols

(9)

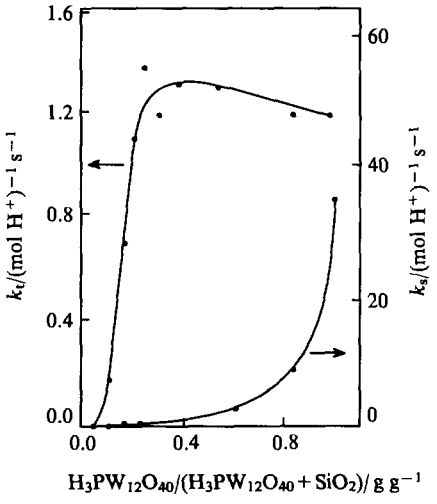
(10)

where R = H, Me, Et, $(CH_2)_2COMe$, $(CH_2)_2COOMe$, $(CH_2)_3OCOMe$, $(CH_2)_3Cl$, and $(CH_2)_3OCOC_{17}H_{35}$. These reactions take place at 100–140 °C with the molar ratio ArH : (2,6-di-*tert*-butylphenol) = 2 : 1 in 0.2–4 h with a yield of 92%–98%. The best *tert*-butyl group acceptors are toluene and *o*-xylene. The catalyst can be readily separated from the reaction mass and can be reused. Heteropolyacids are more active in the transalkylation reaction of phenols compared with other acid catalysts. Even Nafion-H, the strength of which is similar to that of superacids,[82] is appreciably inferior to heteropolyacids as regards activity in these reactions.[76, 81]

The de-*tert*-butylation reaction of 2,6-di-*tert*-butylphenols is first-order with respect to phenol and heteropolyacid. Its rate depends on the nature of ArH. This dependence is analogous to that observed in electrophilic substitution in aromatic compounds. The rate constant ratios k_{ArH}/k_{PhH} at 20 °C (2% $H_3PW_{12}O_{40}$) are given below:[77]

ArH	PhH	PhMe	PhBu^t	*o*-$Me_2C_6H_4$	*m*-$Me_2C_6H_4$
k_{ArH}/k_{PhH}	1.0	6.9	1.5	12	0.95

When catalysts on a carrier are used, the rate of reaction depends significantly on the amount of deposited heteropolyacids. Fig. 4 illustrates the dependence of the rate constants k_t and k_s for the de-*tert*-butylation of 2,6-di-*tert*-butyl-4-methylphenol on the amount of the acid $H_3PW_{12}O_{40}$ deposited on silica gel (k_t and k_s are the rate constants referred respectively to the total number of protons of the heteropolyacid in the catalyst and to the number of surface protic centres of the heteropolyacid). With increase in the amount of the deposited heteropolyacid, the strength of the protic



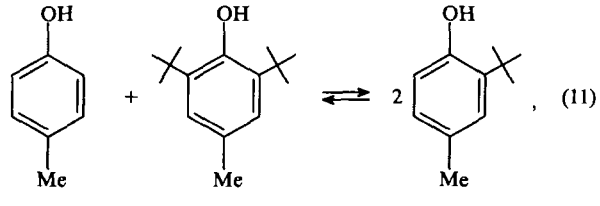


Figure 4. Dependence of the constants k_t and k_s on the ratio $H_3PW_{12}O_{40}/(H_3PW_{12}O_{40} + SiO_2)$.[77]

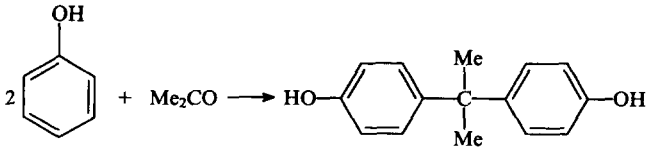
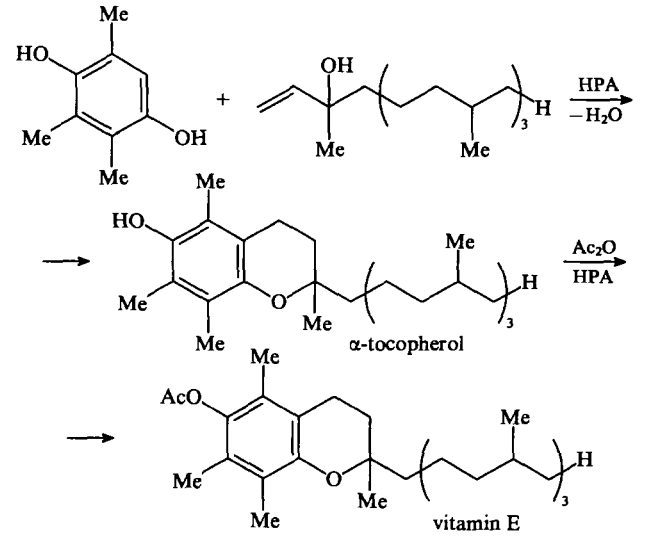
centres also increases and there is a simultaneous decrease in the surface area of the catalyst and hence a decrease in the number of accessible protic centres. Evidently k_t increases rapidly with increase in the concentration of the heteropolyacid on the carrier, reaches a maximum, and then slowly decreases. This type of dependence has been explained by the competitive influence of the increase in the strength of the acid centres, on the one hand, and the decrease in their number on the catalyst surface, on the other.[77] A similar dependence has been observed in the vapour phase dehydration of *tert*-butyl alcohol on $H_3PW_{12}O_{40}$ and $H_3PMo_{12}O_{40}$.[83] In contrast to k_t, the constant k_s increases monotonically with increase in the heteropolyacid concentration on the carrier, which indicates the existence of a correlation between the catalytic activity and the strength of the acid centres.[77]

Heteropolyacids are effective catalysts of the reaction



(11)

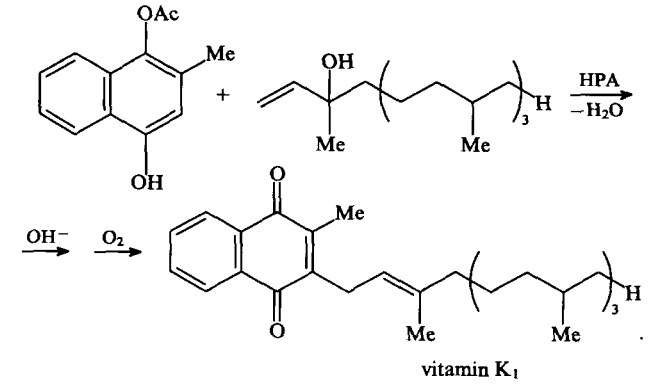
which, together with reaction (5) and (8), is used in industry for the synthesis of phenolic oxidants. In this case too, heteropolyacids are more active than sulfuric acid by four orders of magnitude per accessible proton.[76]



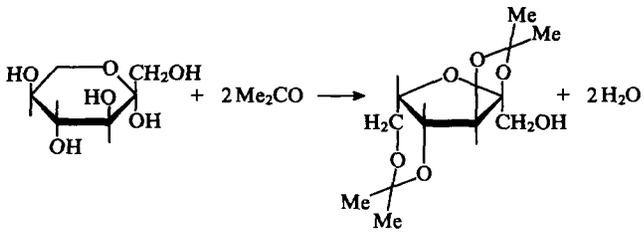
An industrial method of synthesis of 2-*tert*-butyl-4-methylphenol via reaction (11) using heteropolyacids instead of sulfuric acid has been developed at the Institute of Catalysis of the Siberian Division of the Russian Academy of Sciences. It has the same advantages as the alkylation of *p*-cresol via reaction (6) examined above.

5. Condensation reactions

Heteropolyacids have long been used as catalysts of condensation reactions.[4] They catalyse the condensation of acetone with formation of mesityl oxide and alkylbenzenes under both homogeneous[84, 85] and heterogeneous[86] conditions. Bisphenols are obtained by condensing phenols and ketones in the presence of a heteropolyacid:[87]

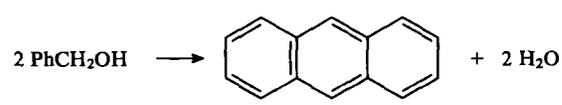


It has been established recently that heteropolyacids catalyse effectively the condensation stage in the synthesis of vitamins E, K_1, and C.[88-90] The acids $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ catalyse the condensation of isophytol with 2,3,5-trimethylhydroquinone (TMHQ) with formation of α-tocopherol and the conversion of the latter into the acetate (vitamin E):[88, 89]



The condensation reaction proceeds both in homogeneous (in acetic acid and butanol) and heterogeneous (in toluene and *o*-xylene) systems. Heteropolyacids are introduced in an amount of about 1% relative to TMHQ. The yield of the product reaches 91%–92% and the content of vitamin E in the latter is 95%. In industry, $ZnCl_2$ or sulfuric acid is used as the catalyst for the synthesis of α-tocopherol.[91] When $ZnCl_2$ is employed, a high-quality product (yield ~80%) is obtained with a vitamin E content in excess of 95%.[92] A significant disadvantage of this method is the high consumption of the catalyst (about 1 mol of $ZnCl_2$ per mole of TMHQ) and the formation of a large amount of waste. When sulfuric acid is used, the product contains 10–20% of impurities which are difficult to separate from vitamin E.[93] The use of heteropolyacids instead of $ZnCl_2$ increases the yield of vitamin E by 10% without reducing the quality of the product. Heteropolyacids can be readily separated from the reaction mass without neutralisation and can be reused.

Heteropolyacids are also effective in the related condensation reaction between isophytol and 1-acetoxy-4-hydroxy-2-methylnaphthalene, which is a key stage in the synthesis of vitamin K_1.[88, 89] In this reaction, heteropolyacids are approximately 50 times more active than $ZnCl_2$ and aluminosilicates.[94]



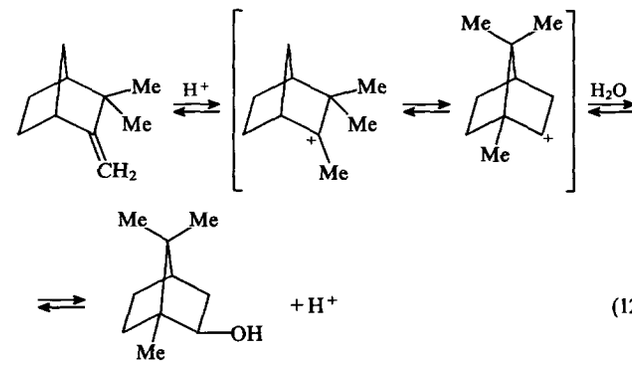
The reaction of L-sorbose with acetone — one of the stages in the synthesis of L-ascorbic acid (vitamin C) — takes place in acetone and the yield of diacetone-L-sorbase (DAS) in the presence of 0.1%–0.35% of $H_3PW_{12}O_{40}$ or $H_4SiW_{12}O_{40}$ as the catalyst is then 85%.[88, 90]

The water formed in the reaction is distilled away or eliminated by absorbing it with the NaA zeolite. The reaction of L-sorbose with acetone is carried out in industry in the presence of oleum (the yield of DAS is ~80%[91]). Oleum is added in a large amount (~5% relative to acetone), because it serves both as the catalyst and as the dehydrating agent. A disadvantage of this process is the large amount of sodium sulfate waste obtained when oleum is neutralised. Thus the use of heteropolyacids makes it possible to increase appreciably the yield of DAS and to diminish significantly the amount of waste on neutralisation of the catalyst.

Heteropolyacids catalyse the condensation of benzyl alcohol with formation of anthracene, but the yield of anthracene is lower than in the case where weaker solid acids, such as the HY zeolite and fluorinated alumina, are used.

In terms of the yield of product at 300 °C, the catalysts can be arranged in the following sequence (the yield expressed as a percentage is indicated in brackets): Al_2O_3 (14) < $H_4SiW_{12}O_{40}$ (25) < $H_3PW_{12}O_{40}$ (33) < F^-/Al_2O_3 (46) < HY (50). The reason for the lower activity of the heteropolyacids may be their small specific surface compared with HY and F^-/Al_2O_3 and also the absence of Lewis acid centres from the heteropolyacid if such centres are required for the given reaction.[95]

The polycondensation of benzyl alcohol is catalysed by $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$.[96] The chiral acid $H_6P_2Mo_{18}O_{62}$, having the Dawson structure, induces the asymmetric polycondensation of benzyl alcohol.[97] In the presence of the homogeneous *l*-brucine–$H_6P_2Mo_{18}O_{62}$ system, benzyl alcohol is converted into an optically active polybenzyl:



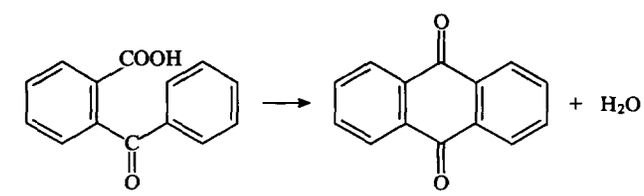
$$n\mathrm{PhCH_2OH} \longrightarrow \{\mathrm{C_6H_4CH_2}\}_n + (n-1)\mathrm{H_2O}\ .$$

When the non-chiral acid $H_6P_2Mo_{18}O_{62}$ is used, an optically inactive polybenzyl is produced.

6. Hydration reactions

The hydration of olefins in the presence of heteropolyacids has been thoroughly investigated in both liquid and vapour phases.[4] As already mentioned, the liquid-phase hydration of propene and butenes in the presence of heteropolyacids is used in industry to synthesise the corresponding alcohols.[7]

The acids $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ proved to be excellent catalysts of the homogeneous hydration of camphene to isoborneol — an intermediate in the synthesis of camphor (50 °C, [HPA] = 0.05 in a Me_2CO–H_2O mixture):[98]

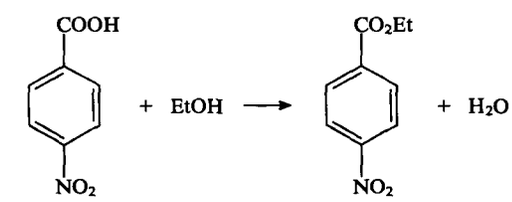


(12)

Isoborneol is virtually the only product of this reaction. The degree of conversion of camphene is 35%. The stronger acid $H_3PW_{12}O_{40}$ is somewhat more active than $H_4SiW_{12}O_{40}$. In the presence of sulfuric acid, reaction (12) proceeds much more slowly: under comparable conditions, the degree of conversion of camphene does not exceed 3%. This reaction may be of practical interest as a direct single-stage method of synthesis of isoborneol. The existing method of its synthesis consists of two stages and bornyl acetate is formed as an intermediate.

When cycloalkenes are hydrated in the presence of a catalyst consisting of a concentrated aqueous solution of an aromatic sulfonic acid and a tungsten heteropolyacid with the Keggin structure, cycloalkanols are formed with a selectivity >99%. The use of heteropolyacids makes it possible to increase the yield of the alcohols and to lower the corrosion activity of the reaction mixture.[99]

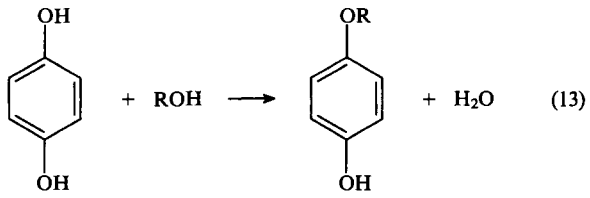
The hydration of phenylacetylene in the presence of a heteropolyacid at 60 °C has been investigated. Heteropolyacids are more active in this reaction than sulfuric or perchloric acid.[100]



The heteropolyacid $H_3PW_{12}O_{40}$ can be used instead of sulfuric acid as the catalyst of the dehydration of *o*-benzoylbenzoic acid to anthraquinone.[101]

7. Esterification (etherification) reactions

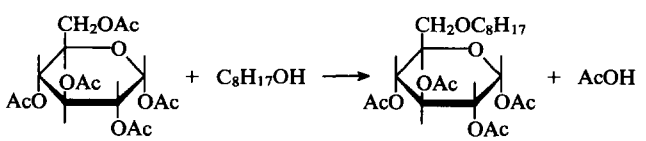
Heteropolyacids are effective catalysts of the synthesis of ethers and esters.[4] Their use in esterification reactions in the synthesis of medicinal preparations is promising.



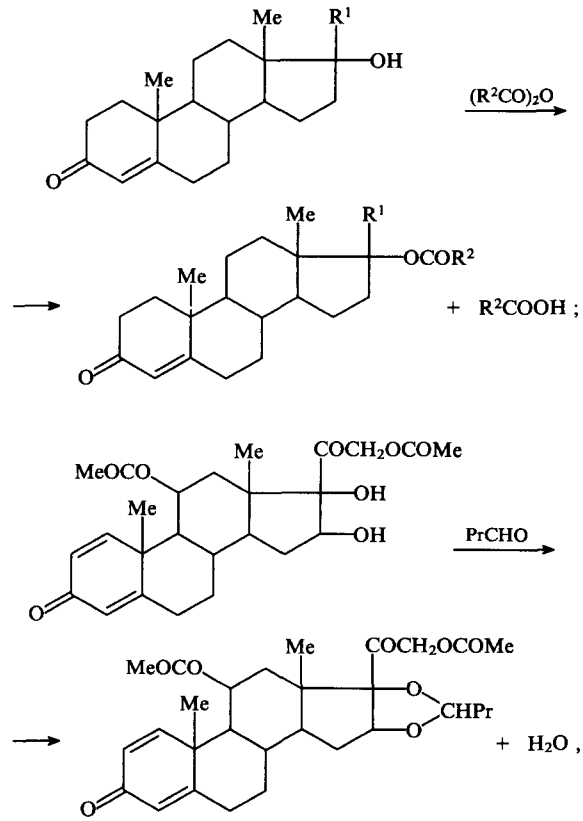
The ethyl ester of *p*-nitrobenzoic acid (PNBA) — an intermediate in the synthesis of the analgesic preparations anesthesin and novocain — was obtained in a yield >99% by esterifying PNBA with ethanol in the presence of $H_3PW_{12}O_{40}$ (3%–7%) at 75 °C.[102]

The water formed in the reaction is distilled away as the azeotrope with toluene. At the end of the reaction, the reaction mass divides into two separate phases. The upper layer contains ethyl *p*-nitrobenzoate mixed with toluene and the alcohol and the lower consists of a solution of the heteropolyacid in ethanol. As a result of this, the catalyst can be readily separated from the reaction product without neutralisation and can be reused. Activity is not lost under these conditions.

Sulfuric acid is used industrially as the catalyst for the synthesis of the ethyl ester of PNBA. This method is characterised by a low yield of the product (75%) and a large amount of waste formed as a result of the neutralisation of sulfuric acid.[103] Thus the application of heteropolyacids in this reaction makes it possible to increase significantly the yield of the product and to diminish the amount of waste. The catalytic activity of the heteropolyacids in the esterification of PNBA is close to that of the KU-2-8 cation-exchange resin[104]



Massive heteropolyacids and heteropolyacids deposited on SiO_2, Al_2O_3, or TiO_2 are used as catalysts of the synthesis of hydroquinone monoethers, which are employed in the manufacture of medicinal preparations and perfumes, stabilisers, polymerisation inhibitors, etc. For example, the use of 1-hexanol in reaction (13) makes it possible to obtain the corresponding monoether with a selectivity of 99% in the presence of $H_3PMo_{12}O_{40}$ (3%) for a hydroquinone conversion of 83% (105 °C, 5 h).[105]

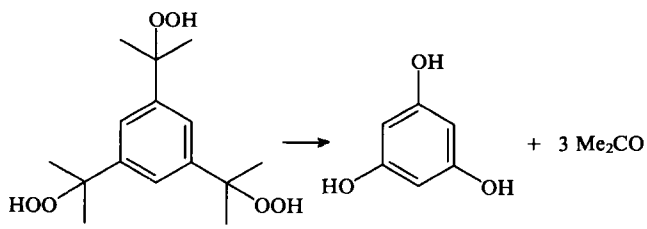


(13)

Dialkyl phthalates, which are used as plasticisers, have been obtained by esterifying phthalic anhydride with C_8-C_{10} alcohols at 100–120 °C in the presence of the homogeneous or heterogeneous $H_3PW_{12}O_{40}$ catalyst (1%–2%). In the latter case, the heteropolyacid deposited on activated charcoal was employed. The catalytic activity of the heteropolyacid is greatly superior to that of H_2SO_4 and toluene-*p*-sulfonic acid. The HPA/C catalyst is less active than the homogeneous catalyst, but has the advantage of being readily removed from the reaction mixture.[106]

The synthesis of glycosides using heteropolyacids as catalysts is of industrial importance.[7] There exist numerous patents concerning the use of this reaction. On interaction with alcohols in the presence of a heteropolyacid (85 °C, 4 h), monosaccharides are readily converted into glycosides in 47%–83% yield. Thus the reaction of pentaacetylglucose with 1-octanol in the presence of $H_3PMo_{12}O_{40}$ (3%) afforded octyl tetraacetylglucoside in 70% yield.[107] Glycosides have found applications as medicinal preparations.

The esterification of steroids and their conversion into acetals take place with quantitative yields in the presence of the catalysts $H_3PW_{12}O_{40}$ and 25% $H_3PW_{12}O_{40}/SiO_2$ (1.5%–9%) in MeCN, CH_2Cl_2, or C_6H_6 (40–82 °C, 0.5–4 h):



where R^1 = H or COMe and R_2 = Et or Pe.[108] These reactions represent stages in the synthesis of modified hormones.[109] In benzene, where the heteropolyacid is insoluble, such reactions proceed heterogeneously; the catalyst can be separated from the reaction mixture without neutralisation and can be reused. The activity of the heteropolyacid is close to that of $HClO_4$ and is much greater than that of 5-sulfosalicylic acid.

8. Other reactions

The acids $H_3PMo_{12}O_{40}$ and $H_4SiMo_{12}O_{40}$ catalyse the acylation of aromatic compounds (the Friedel–Crafts reaction).[110–112]

Heteropolyacids are highly active and selective homogeneous[36, 113] and heterogeneous[114, 115] catalysts for the decomposition of cumenyl hydroperoxide to phenyl and acetone. Phloroglucinol was obtained by means of a similar procedure involving the decomposition of 1,3,5-tris(hydroperoxy-isopropyl)benzene in the presence of a heteropolyacid at 50–100 °C with a selectivity of 97% and a hydroperoxide conversion of 89%.[116]

The hydrolysis of sucrose in the presence of $H_4SiW_{12}O_{40}$ has been investigated.[117]

III. Liquid-phase oxidation reactions

The liquid-phase oxidation of organic substances catalysed by heteropolyanions takes place in homogeneous or heterogeneous (two-phase) systems. In the latter case, phase transfer catalysts are frequently used. O_2, H_2O_2, alkyl hydroperoxides and, more rarely, other substances are used as oxidants. The oxidation-reduction properties of heteropolyacids, their synthesis, state in the solution, and applications as catalysts of liquid-phase oxidation have been examined in a number of reviews.[2, 3, 8, 13, 118-120]

1. Oxidation with oxygen

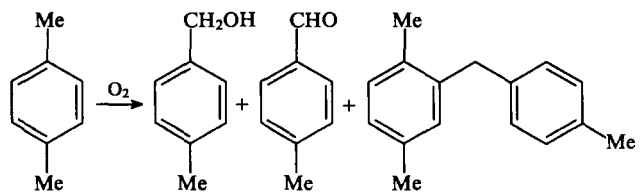
Mixed molybdovanadophosphoric heteropolyanions $PMo_{12-n}^{6+}V_n^{5+}O_{40}^{(3+n)-}$ (HPAN-n, n = 2–6) are used preferentially as catalysts in these reactions.[3, 8, 118-120] They have a fairly high oxidation potential [0.7 V relative to the normal hydrogen electrode (n.h.e.)] and are themselves capable of oxidising a large number of organic and inorganic substances. At the same time, the HPAN-n are reversibly acting oxidants, i.e. their reduced forms can be readily reoxidised to the initial HPAN-n with the aid of O_2.

$$\text{Red} + \text{HPA-}n + i\,H^+ \longrightarrow \text{Ox} + H_iHPA\text{-}n\,, \quad (14)$$

$$H_iHPA\text{-}n + i/4\,O_2 \longrightarrow \text{HPA-}n + i/2\,H_2O\,. \quad (15)$$

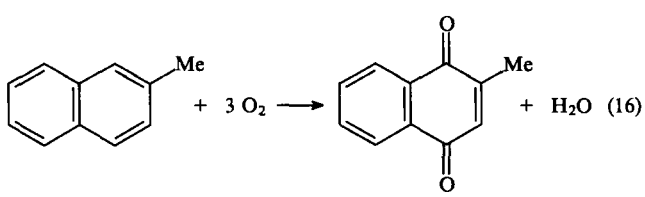
Here Red and Ox are respectively the i-electron reductant (substrate or the reduced form of the cocatalyst) and its oxidised form, $H_iHPA\text{-}n = H_i[H_{3+n}PMo_{12-n}^{6+}V_{n-i}^{5+}V_i^{4+}O_{40}]$ is a heteropolyblue, i.e. the reduced form of HPAN-n ($i \leqslant n$).[3, 8, 118-120] The reversibility of the oxidation-reduction reactions of HPAN-n in fact constitutes the basis of their use as catalysts of a large number of liquid-phase oxidation reactions. Certain other mixed heteropolyanions, having similar properties, for example, $H_3PMo_6W_6O_{40}$, are also used for this purpose.[121, 122]

The HPAN-n-catalysed oxidation reactions proceed via a multistage mechanism in conformity with Eqns. (14) and (15).[3] Reactions (14) and (15) can be carried out simultaneously in one reactor or separately. In the second case, direct contact between the organic substrate and O_2 is excluded. The catalysts may be the HPAN-n themselves (one-component systems) or their combinations with other compounds (two-component systems). Among the latter, the HPAN-n + Pd(II)/Pd(0) redox system is the most important. It is analogous to the catalytic system $CuCl_2$ + Pd(II)/Pd(0) used to oxidise ethylene to acetaldehyde (the Wacker process), but, in contrast to the latter, it can work in the absence of Cl^- ions, which increases the selectivity of the process and lowers the corrosion activity of the catalyst solution.[3] The use of the HPAN-n + Pd(II) system in liquid-phase oxidation reactions has been examined in a number of studies.[3, 8, 118-120] Other redox systems based on HPAN-n are also known. Their second component is Tl(III)/Tl(I),[123, 124] Pt(IV)/Pt(II),[125] Ru(IV)/Ru(III), Ir(IV)/Ir(III),[126] Br_2/Br^-,[127] and I_2/I^-.[128] In two-component systems, the substrate is usually oxidised by the cocatalyst and the HPAN-n ensures the regeneration of the cocatalyst via reactions (14) and (15).



The HPAN + Pd(II) and HPAN + Rh(I) systems are also used in carbonylation hydroformylation, and hydrogenation reactions.[129-133]

Homogeneous catalysts based on HPAN-n consist as a rule of complex equilibrium mixtures of polyanions of different composition with products of the degradative dissociation of the heteropolyanion. All these species can function as the active form of the catalyst. Thus, in oxidation of hydrogen sulfide by the Mo_{12}-molybdophosphate at pH 3, the active role is played by isopolyanions for example, $Mo_7O_{24}^{6-}$ or $Mo_8O_{26}^{4-}$ in equilibrium with the heteropolyanion.[134] In the oxidation of alkylbenzenes and phenols by oxygen in the presence of HPAN-n, the true oxidant is most likely to be the VO_2^+ ions formed as the result of the dissociation of HPAN-n.[135-137]



Free vanadium(IV) in the form of the VO^{2+} ion is hardly oxidised in acid aqueous solutions but is fairly readily oxidised when it is part of the compositions of HPAN-n [Eqn. (15)].[3] This reaction proceeds via a many-electron mechanism involving the consecutive transfer of three or four electrons in the complex of $H_iHPAN\text{-}n$ with O_2.[3] In contrast to the HPAN-n blues, the more readily oxidised blues derived from the tungsten heteropolyanions $PW_{12}O_{40}^{3-}$ and $SiW_{12}O_{40}^{4-}$ (E = 0–0.1 V) are oxidised by O_2 via a one-electron mechanism.[138]

a. Oxidation of arenes

Heteropolyanions in acetic acis solutions oxidise methylbenzenes with formation of a mixture of aromatic alcohols, aldehydes, and di- and poly-aryl methanes. In the presence of O_2, the reaction can proceed catalytically.[135] The true arene oxidants are probably the VO_2^+ ions which have emerged from the coordination sphere of HPAN-n. The rate of oxidation of arenes decreases in the sequence durene > mesitylene > p-xylene > toluene. The reaction apparently proceeds via the formation of aromatic radical-cations as intermediates.[135]

2-Methylnaphthalene (MN) is oxidised to 2-methyl-1,4-naphthoquinone by oxygen (3–8 atm) in the presence of 0.02–0.2 M HPAN-n as the catalyst. The reaction is carried out in a $AcOH-H_2O-H_2SO_4$ solution at 120–140 °C and its selectivity is 82% for a 2-methylnaphthalene conversion of 78%.[139] 2-Methyl-1,4-naphthoquinone is an intermediate in the synthesis of group K vitamins. It is obtained industrially by the stoichiometric oxidation of 2-methylnaphthalene by chromium trioxide in 40–50% yield.[91, 140] This reaction can be carried out catalytically with a higher yield with the aid of HPAN-n an O_2 as the oxidant:

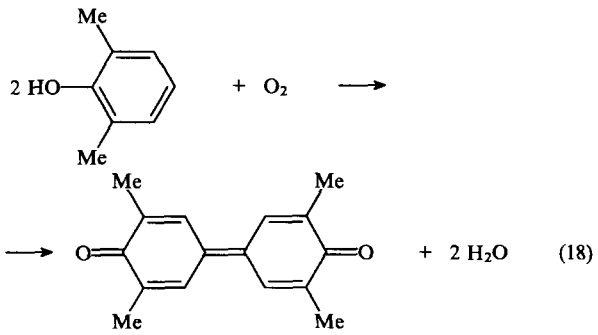
Heteropolyanions catalyse the oxidative ring bromination of arenes with HBr as the brominating agent and O_2 as the oxidant.[127]

$$ArH + HBr + \frac{1}{2}O_2 \longrightarrow ArBr + H_2O\,.$$

The arenes brominated include benzene, its derivatives, naphthalene, thiophene, etc. The reaction proceeds in an $AcOH-H_2O-H_2SO_4$ solution at 50–100 °C. The bromination of the ring in arenes is effected by Br_2, which is formed as a result of the bromination of bromide ions by HPAN-n. In the case of alkylbenzenes, the alkyl groups are also oxidised. An advantage of this method is the possibility of using Br^- in the reaction instead of Br_2.

The HPAN-n + HBr system brominates phenol selectively in the *para*-position.[141]

Many stoichiometric reactions involving the oxidation of organic substances by palladium(II) compounds can be carried out catalytically with O_2 as the oxidant and the HPAN-n + Pd(II) two-component system as the catalyst.[3, 8, 118-120] Thus the



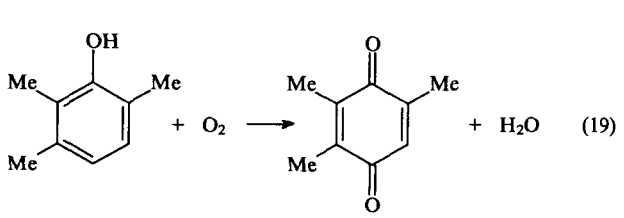
oxidative coupling of arenes in the presence of the HPAN-*n* + Pd(II) system makes it possible to obtain in a single stage biaryls — valuable intermediates in inorganic synthesis:

$$2\,ArH + \frac{1}{2}O_2 \longrightarrow Ar-Ar + H_2O, \quad (17)$$

where ArH = C_6H_6, PhAlk, PhCl, PhCOOH, $PhCF_3$, thiophene, etc.[142-144] The reaction proceeds under very mild conditions at 50–90 °C and an O_2 pressure of 1.5 atm. The selectivity in relation to biaryls is 70%–93%. It is noteworthy that in the absence of HPAN-*n*, reaction (17) requires a temperature of 150 °C and a pressure of 25 atm.[120] The mechanism of the oxidative coupling of arenes under the influence of palladium(II) has been examined in other reviews.[120, 145]

b. Oxidation of phenols

The compounds of many metals are capable of catalysing the oxidative coupling of phenols to diphenoquinones in solutions.[146] The coupling of 2,6-dialkylphenols (mainly 2,6-xylenol) under the influence of oxygen in the presence of copper complexes of amines is of practical importance:



(18)

Diphenoquinones are used to synthesise bisphenols, which are used widely as stabilisers of polymers, oils, etc.[62]

The activity of heteropolyanions in reaction (18) is greater than that of copper compounds. The oxidative coupling takes place in H_2O, AcOH–H_2O, or MeOH–H_2O at 25–50 °C and an O_2 pressure of 1–5 atm. The diphenoquinones are insoluble under these conditions and can be readily isolated from the reaction mixture by crystallisation. The catalyst can be used repeatedly without loss of its activity. 2,2',6,6'-Tetramethyl- and 2,2',6,6'-tetra-*tert*-butyl-diphenoquinones have been obtained by this method in 100% yield relative to the initial phenol.[147]

The oxidation of 2,3,6-trimethylphenol (TMP) is of interest for the synthesis of 2,3,5-trimethyl-1,4-benzoquinone (TMBQ), which is an intermediate in the synthesis of vitamin E.[148] The oxidation of TMP by oxygen in the presence of HPAN-*n* as the catalyst in solution in aqueous acetic acid makes it possible to obtain TMBQ with a selectivity of 86% for 100% conversion of TMP.[136, 137]

(19)

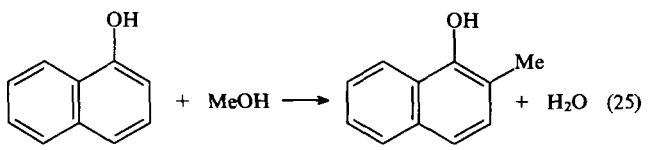
2,2',3,3',6,6'-Hexamethyl-4,4'-bisphenol (HMBP), the product of the oxidative coupling of TMP, is also formed under these conditions. The process selectivity depends on the water concentration in the reaction mixture: with increase in [H_2O], the yield of HMBP increases owing to the decrease in the yield of TMBQ. The bisphenol HMBP itself undergoes oxidative conversion into TMBQ via the intermediate formation of hexamethyldiphenoquinone (HMDQ).

Evidence has been obtained that the activity of the oxidant arises through the VO_2^+ ions formed as a result of the dissociation of HPAN-*n*. A mechanism has been proposed for reaction (19) involving the one-electron oxidation of TMP (ArOH) by VO_2^+ ions with formation of TMBQ and vanadium(IV) followed by the oxidation of vanadium(IV) to vanadium(V) by oxygen in the coordination sphere of HPAN-*n*.[137]

$$\text{HPAN-}n \rightleftharpoons V(V) + \text{HPAN-}(n-1), \quad (20)$$

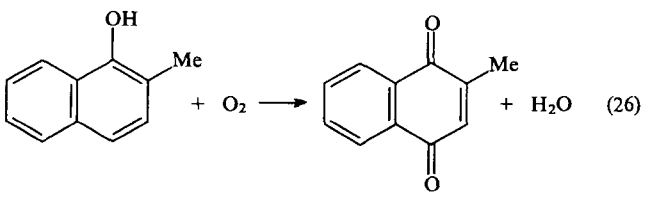
$$V(V) + ArOH \longrightarrow ArO^{\cdot} + V(IV) + H^+, \quad (21)$$

$$2\,ArO^{\cdot} \longrightarrow HMBD \xrightarrow{Ox} HMDQ \xrightarrow{Ox} TMBQ, \quad (22)$$



$$V(IV) + \text{HPAN-}n + H^+ \rightleftharpoons V(V) + H(\text{HPAN-}n), \quad (23)$$

$$4\,H(\text{HPAN-}n) + O_2 \longrightarrow 4\,\text{HPAN-}n + 2\,H_2O. \quad (24)$$



The stage involving the formation of the phenoxyl radical [reaction (21)] is probably rate-limiting.

The oxidation of sterically hindered phenols to benzoquinones by oxygen in the presence of manganese(II) complexes of heteropolytungstates has been investigated.[149]

A new two-stage method of synthesis of vitamin K_3 from 1-naphthol has been developed.[150] It involves the alkylation of 1-naphthol by methanol to 2-methyl-1-naphthol and the oxidation of the latter to 2-methyl-1,4-naphthoquinone.

(25)

(26)

The alkylation reaction (25) is carried out in the vapour phase in the presence of an iron–vanadium catalyst. The oxidation stage (26) is carried out in the liquid phase using HPAN-*n* as the catalyst. Reaction (25) proceeds with a selectivity in excess of 90% and reaction (26) with a selectivity of 83%. As a result of this, the ultimate selectivity greatly exceeds the selectivity in the industrial single-stage synthesis of vitamin K_3 by the stoichiometric oxidation of 2-methylnaphthalene by CrO_3.[91, 140]

2. Oxidation by hydrogen peroxide

The tungsten(VI) and molybdenum(VI) heteropolyanions catalyse various reactions involving the oxidation of organic substances by hydrogen peroxide in homogeneous or two-phase systems under the conditions of phase transfer catalysis. Such reactions include the epoxidation of olefins, the oxidation of alcohols, glycols, phenols, etc.[2] The active intermediates in these reactions are peroxoheteropolycomplexes. In many cases, it was possible to detect them spectroscopically[151, 152] and sometimes to isolate them.[153]

In the homogeneous oxidation of allyl alcohol by H_2O_2 in aqueous solution in the presence of $H_3PW_{12}O_{40}$ at pH 0.7–1.8, glycerol is formed in 64%–100% yield relative to the peroxide which has reacted (70–90 °C, 1–2 h). The primary product is probably an epoxide, which rapidly hydrolyses to glycerol in an acid medium. The peroxo-complexes of heteropolyacids containing up to four peroxo-groups linked to the $PW_{12}O_{40}^{3-}$

anion, have been detected in the reaction system by ^{31}P NMR. The heteropolyacid does not decompose during the reaction.[151]

The catalytic activity of heteropolyanions of different types in the homogeneous reaction involving the oxidation of cyclohexene by hydrogen peroxide in acetonitrile at 35 °C has been investigated. The heteropolyanions employed include $PW_{12}O_{40}^{3-}$ and the lacunary anion $PW_{11}O_{39}^{7-}$ and complexes with transition metal ions $PW_{11}O_{39}M^{x-}$, where M = Ni(II), Co(II), Cu(II), Fe(II), Cr(III), Ru(IV), Ti(IV), and V(V). The anion $PW_{11}O_{39}^{7-}$ shows the highest catalytic activity and selectivity in relation to epoxycyclohexane. The anion $PW_{12}O_{40}^{3-}$ is much less active. The cobalt (II), copper(II), and ruthenium(IV) complexes are inactive in the oxidation of cyclohexene but rapidly decompose H_2O_2. The nickel(II), titanium(IV), and vanadium(V) complexes are inert both in the oxidation of the substrate and in the decomposition of H_2O_2. The iron(II) and chromium(III) complexes are moderately active catalysts of the oxidation of cyclohexene, but the reaction proceeds nonselectively.[152]

Cyclopentene is oxidised by hydrogen peroxide to glutaraldehyde in the presence of the mixed heteropolyacids $H_3PMo_{12-n}W_nO_{40}$ (n = 1–9) in solution in tributyl phosphate (TBP) in 60% yield relative to the H_2O_2 employed (35 °C, 3 h). Water is removed from the H_2O_2–TBP system by vacuum distillation. Other heteropolyacids have been investigated in this reaction. The yield of glutaraldehyde (mol%) decreases in the sequence[154] $H_3PMo_{10}W_2O_{40}$ (16) > $H_3PMo_{12}O_{40}$ (47) > $H_4GeMo_{12}O_{40}$ (21) > $H_3PMo_{10}V_2O_{40}$ (6) > $H_3PW_{12}O_{40}$ (5) > $H_4SiMo_{12}O_{40}$ (1).

The two-phase system including immiscible aqueous and organic phases and a phase transfer catalyst is used widely in reactions involving oxidation by H_2O_2.[154–160] Convenient organic solvents are $1,2\text{-}Cl_2C_2H_4$, $CHCl_3$, CCl_4, C_6H_6, etc. The phase transfer catalysts employed are tetraalkylammonium (C_6–C_{18}) cetylpyridinium, etc. cations (Q^+). The catalytic system is usually prepared as follows. Active peroxo-complexes are formed initially in the aqueous phase from the tungsten(VI) or molybdenum(VI) starting compounds (for example, the heteropolyanions or $WO_4^{2+} + PO_4^{3-}$, etc.) and hydrogen peroxide. The initial heteropolyanions can then partly decompose on reaction with the excess H_2O_2.[161] Next the organic phase with the phase transfer catalyst dissolved in it is added. This results in the formation of Q^+ salts with peroxoheteropolyanions, which are soluble in the organic phase and are almost fully transferred to the latter. This is followed by the addition of the organic substrate, for example, an olefin, and the reaction begins. The oxidation takes place preferentially in the organic phase via the transfer of an oxygen atom from the peroxo-complex to the substrate. The peroxo-complexes are regenerated at the interface via the interaction of the heteropolyanion with the hydrogen peroxide in the aqueous phase. The mechanism of the catalytic epoxidation of the olefins by hydrogen peroxide in the two-phase system in the presence of $PW_{12}O_{40}^{3-}$ is illustrated schematically in Fig. 5.

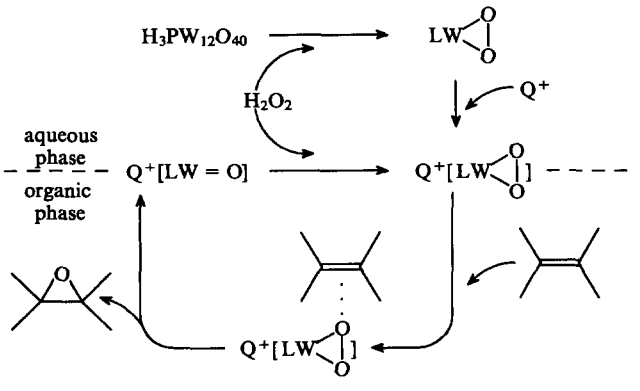


Figure 5. Epoxidation of olefins by hydrogen peroxide in a two-phase system.

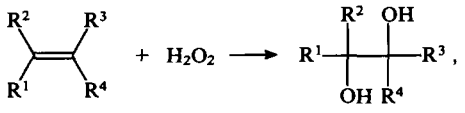

Tetrahexylammonium heteropoly-11-tungstates are active catalysts of the oxidation of cyclohexene by 30% aqueous H_2O_2 in the 1,2-dichloroethane–water two-phase system. The reaction proceeds in the organic phase and the main product is cyclohexanediol. The products of the oxidative cleavage of the ring—adipaldehyde and adipic acid—are also formed in 30%–45% yield. In contrast to the lacunary M_{11}-HPA, the saturated M_{12}-HPA proved to be virtually inactive.[156]

The tetrakis(diperoxotungsto)phosphate $Q_3^+[PW_4O_{24}]^{3-}$ [$Q^+ = N(C_6H_{13})_4^+$, $N(C_8H_{17})_3(CH_3)^+$, etc.] is an effective stoichiometric reagent for the epoxidation of olefins in aprotic solvents and is also an effective catalyst of this reaction with H_2O_2 in a two-phase system.[153, 158] This compound has been isolated and its structure has been characterised by X-ray diffraction[153] (Fig. 6).

The anion $PW_4O_{24}^{3-}$ has the C_2 symmetry and consists of a central PO_4 tetrahedron and four distorted $W(O_2)_2O_3$ pentagonal bipyramids linked to it via the oxygen atoms. The bipyramids are grouped into two pairs with common edges. Each tungsten atom is linked to two peroxide groups located in the equatorial plane of the pentagonal bipyramid. It is of interest to note that tungsten(VI) and molybdenum(VI) have the same coordination environment in their monomeric diperoxo-complexes, which are capable of the effective epoxidation of olefins.[159]

The epoxidation of oct-1-ene with 15% H_2O_2 in the presence of $PW_4O_{24}^{3-}$ in the 1,2-dichloroethane–water system affords epoxyoctane in 89% yield relative to the initial hydrogen peroxide for a H_2O_2 conversion of about 100% (70 °C, 1.5 h). The reaction is stereoselective: *cis*-hex-2-ene is converted solely into the *cis*-epoxide, while *trans*-hex-2-ene is converted into the *trans*-epoxide.[153]

The heteropolyanion in $Q_3^+[PW_4O_{24}]^{3-}$ catalyses the conversion in the two-phase system of water-insoluble olefins of different structure into water-soluble vicinal *trans*-glycols in 71%–88% yield (60–70 °C, 1–4 h, 2%–4% H_2O_2, pH 1.2–1.5)[158]

where R^1–R^4 = H, Me, Et, Bu, Ph, etc. The glycols formed are present almost entirely in the aqueous phase and can be readily isolated from the reaction mixture. The vicinal glycols are used for the preparation of cosmetics and perfumes, photographic materials, etc.

The epoxidation of oct-1-ene by hydrogen peroxide in the $CHCl_3$–H_2O system has been investigated under the conditions of phase transfer catalysis in the presence of the heteropolyanion $XM_{12}O_{40}^{n-}$ and $X_2M_{18}O_{62}^{n-}$ and the isopolyanions $M_xO_y^{z-}$ (M = Mo or W; X = P, Si, or B) as precursors of catalytically active peroxo-complexes. The state of the complexes in the system has been characterised by a number of spectroscopic methods.

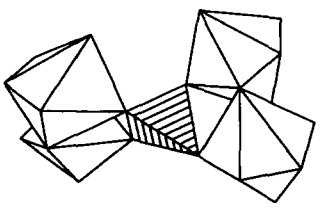

Figure 6. The structure of the peroxoheteropolyanion $PW_4O_{24}^{3-}$ (according to the data of Venturello et al.[153]).

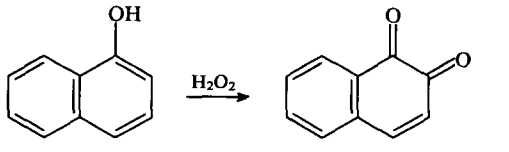
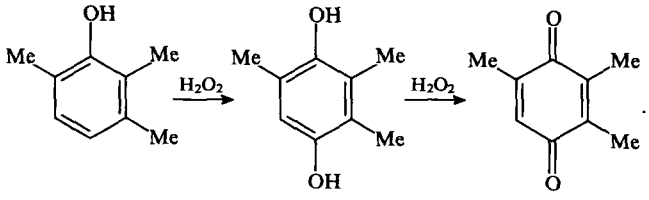


It was established that the anions $BW_{12}O_{40}^{5-}$, $SiW_{12}O_{40}^{4-}$, and $P_2W_{18}O_{62}^{6-}$ are altogether inactive and do not change during the reaction, while $PMo_{12}O_{40}^{3-}$ exhibits a low activity. On the other hand, $PW_{12}O_{40}^{3-}$ exhibits a high activity (the yield of the epoxide is 79% relative to oct-1-ene for a 95% selectivity) when the catalytic system is formed beforehand by the reaction of the heteropolyanion with H_2O_2 in aqueous solution in the absence of Q^+ and oct-1-ene. When all the reagents are mixed simultaneously, the activity of $PW_{12}O_{40}^{3-}$ is zero. A higher activity is shown by tunstic acid (yield 76%) and $H_2W_{12}O_{42}^{10-}$ (yield 67%), their activity being independent of the method used to carry out the reaction. Heteropolyanions having the Keggin structure decompose in the presence of an excess of H_2O_2 {$[H_2O_2]/[M]$ = 30–355 mol mol^{-1}} with formation of the peroxo-complexes $PM_4O_{24}^{3-}$ and $M_2O_{11}(H_2O)_2^{2-}$. It has been suggested that $PM_4O_{24}^{3-}$ is in fact the active species responsible for epoxidation when $PM_{12}O_{40}^{3-}$ is used under the conditions of phase transfer catalysis.[161]

The epoxidation of styrene–butadiene and isobutene–isoprene copolymers by hydrogen peroxide in the presence of $PW_4O_{24}^{3-}$ has been investigated.[162]

The cetylpyridinium salt of $PW_{12}O_{40}^{3-}$, which can be readily obtained by the reaction of $H_3PW_{12}O_{40}$ with three equivalents of cetylpyridinium chloride, catalyses a large number of reactions involving oxidation by hydrogen peroxide. They include the epoxidation of olefins, allyl alcohols, and α,β-unsaturated carboxylic acids, the oxidation of secondary alcohols to ketones, the oxidation of α,ω-diols to lactones, the oxidative cleavage of vicinal diols and olefins to give carboxylic acids, etc. These reactions proceed under mild conditions and with satisfactory yields.[157, 163, 164] Alkynes are also oxidised smoothly in this system to carboxylic acids.[165]



The oxidation of primary and secondary aliphatic and aromatic amines with 35% H_2O_2, catalysed by peroxo-heteropolytungstates, leads to the formation of oximes and nitro-compounds in a high yield in homogeneous or two-phase systems.[166]

α- and β-Naphthols ($\sim 10^{-3}$ M) are oxidised by H_2O_2 (2%–15%) to 1,2-naphthoquinone in 80%–98% yield at 20 °C in the 1,2-dichloroethane–water system in the presence of peroxoheterotungstates and trioctylbenzylammonium chloride (TOBAC).

When the naphthol concentration is increased, C–C coupling products are formed. The catalytic system is prepared by mixing PO_4^{3-}, WO_4^{2-}, and TOBAC in molar proportions of 8 : 4 : 3. It is suggested that the active form of the catalyst is the peroxo-complex $PW_4O_{24}^{3-}$. The reaction proceeds via the intermediate formation of semiquinone radicals, which have been detected by the EPR method.[167]

Heteropolyacids with the Keggin structure catalyse the oxidation of 2,3,5- and 2,3,6-trimethylphenol (TMP) to 2,3,5-trimethyl-1,4-benzoquinone (TMBQ) by hydrogen peroxide in solution in acetic acid with a selectivity of 65%–78% for a TMP conversion of 94%–100%.

The hydroxylation of the benzene ring catalysed by the heteropolyacid probably results in the initial formation of 2,3,5-trimethylhydroquinone, which is subsequently rapidly oxidised to TMBQ.[168] Apparently in this case the heteropolyacid behaves as a Brønsted acid catalyst. TMP is oxidised similarly by hydrogen peroxide in the presence of sulfuric acid.[169] In acetic acid in the presence of a strong inorganic acid, H_2O_2 is rapidly converted into peracetic acid, which is probably the true hydroxylating agent.[170]

The molybdovanadium isopolyacids $H_2V_{12-x}Mo_xO_{31}$ (x = 0–4) catalyse the oxidation of 1,2,4-trimethylbenzene to TMBQ by peracetic acid in solution in acetic acid (20 °C, 4 h) with a selectivity of 12%–31% for a trimethylbenzene conversion of 15%–22%.[171]

The oxidation of ethylbenzene by hydrogen peroxide in acetonitrile in the presence of $H_3PW_{12}O_{40}$, $H_3PMo_{12}O_{40}$, and their tetrabutylammonium salts has been investigated. The main reaction product is acetophenone (selectivity 100%, PhEt conversion 5%–17%).[172]

3. Oxidation by hydroperoxides

The epoxidation of hex-1-ene by isopropylphenyl hydroperoxide (IPPHP) in isopropyl alcohol in the presence of heteropolyacid salts at 110 °C proceeds with a selectivity of approximately 100% with respect to epoxyhexane for an IPPHP conversion >80%. The rate of reaction is described by the kinetic equation $w = k[\text{HPAN}]^p[\text{IPPHP}][C_6H_{12}]$, where p = 0.5–0.9 for [HPAN] = $(0.2–9)\times 10^{-5}$ M. The catalytic activity of heteropolyacid salts decreases in the sequence $Na_3PMo_{12}O_{40} \simeq AlPMo_{12}O_{40} > Na_4PMo_{11}VO_{40} > Na_4SiMo_{12}O_{40} \gg Na_3PW_{12}O_{40}$. The heteropolyacids themselves are ineffective in epoxidation because they catalyse the decomposition of IPPHP to phenol and acetone. It has been suggested that the reaction mechanism involves the decomposition of the heteropolyanion with formation of monomeric molybdenum(VI) complexes, which are the true epoxidation catalysts.[173]

Transition metal complexes of the lacunary heteropoly-11-tungstate (p-$Bu_4N)_4HPW_{11}O_{39}M$, where M = Mn(II), Co(II), Cu(II), Fe(II), etc., catalyse the oxidation of cyclohexanol and adamantane by butyl hydroperoxide (TBHP) in benzene. The selectivity in the formation of the oxidation products (cyclohexanone or 1-adamantanol, 2-adamantanol, and 2-adamantanone) reaches 90% relative to the TBHP which has reacted. Such complexes catalyse also the oxidation of olefins (cyclohexene, hex-1-ene, norbornene, and cyclooctene) by iodosobenzene and pentafluoroiodosobenzene in acetonitrile. The manganese(II) and cobalt(II) complexes exhibit the highest activity.[174, 175]

The compound $[(C_6H_{13})_4N]_5SiW_{11}O_{39}Ru(H_2O)$ catalyses the liquid-phase oxidation of alkanes and alkenes by oxidants such as TBHP, potassium persulfate, sodium periodate, and iodosobenzene.[176]

4. Other reactions

The stoichiometric oxidation sclareol (a labdanediol) by the $PW_{11}O_{39}Tl^{4-}$ anion containing thallium(III) has been investigated. The main reaction products are epoxy-derivatives of labdane.[177]

Table 3. Acid catalysis by heteropolyacids in liquid-phase fine organic synthetic reactions (catalysts: $H_3PW_{12}O_{40}$, $H_4SiW_{12}O_{40}$, $H_3PMo_{12}O_{40}$, HPA/SiO_2).

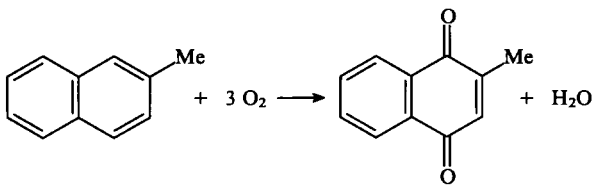
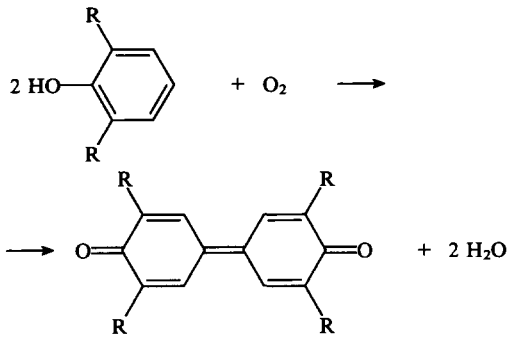
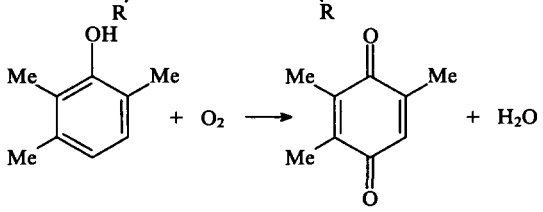
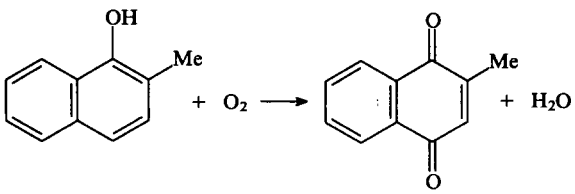
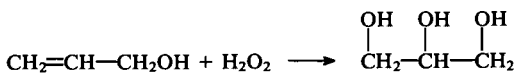
IV. Conclusion

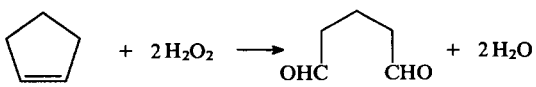


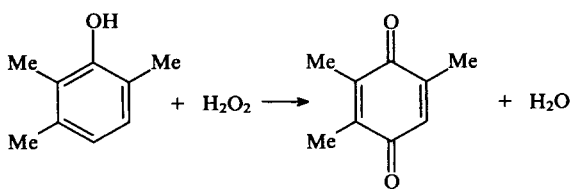












Considerable progress has been achieved during the last 20 years in the study of the catalysis by heteropolyacids. Their industrial use in organic synthetic processes has been initiated (Table 1). The employment of heteropolyacids in fine organic synthesis has given rise to considerable possibilities. The data obtained hitherto definitely indicate the likely usefulness of heteropolyacids as catalysts of fine organic synthetic reactions. Tables 3 and 4 give a compilation of the most important acid-dependent and oxidation reactions discussed in the present review. In many of them, heteropolyacids have significant advantages as regards their activity and/or selectivity compared with traditional catalysts. Some of these reactions are already being used in industry. Thus the heteropolyacid-catalysed alkylation and transalkylation of phenol derivatives is used in Russia for the synthesis of antioxidants. There are data[7] concerning the industrial application of hydropolyacids in the synthesis of glycosides in Japan. In the future the number of such processes will undoubtedly increase.

We may note the principal causes of the high effectiveness of heteropolyacid-based catalysts in organic synthesis compared with other catalytic systems. The advantages of heteropolyacids are manifested most strikingly in acid catalysis. The high effectiveness of heteropolyacids as acid catalysts is primarily due to their high Brønsted acidity, which exceeds the acidity of inorganic acids and traditional solid acid catalysts. This makes it possible to carry out the catalytic process at a lower catalyst concentration and/or a lower temperature, which tends to increase the process selectivity and permits an appreciable diminution of the amount of waste on neutralisation of the catalyst. Furthermore, by virtue of the inertness of their anions, heteropolyacids do not enter into side reactions with organic reagents, a feature typical for the usual inorganic acids (sulfonation, chlorination, nitrogenation, etc.). Heteropolyacids may be used as homogeneous or heterogeneous (massive and deposited) catalysts. In contrast to inorganic acids, heterogeneous heteropolyacid-based catalysts can be readily separated from the reaction products without neutralisation and can be reused. The heterogeneous systems are in many respects similar to concentrated solutions of heteropolyacids ('pseudoliquid phase') and exhibit a high catalytic activity in low-temperature reactions. In homogeneous systems the heteropolyacids are usually neutralised at the end of the reaction, as in the case of the inorganic acids. However, when heteropolyacids are used the amount of alkali consumed and hence the amount of waste is tens of times smaller. We may note that certain homogeneous systems divide into layers in the presence of heteropolyacids with formation of two immiscible phases, one of which contains the heteropolyacid and the other the reaction product. In such cases, the catalyst is also readily separated from the product and can be reused. Similar heterophase systems are used in the industrial polymerisation of tetrahydrofuran (Table 1)[2, 7] and in the esterification of *p*-nitrobenzoic acid with ethanol in the presence of $H_3PW_{12}O_{40}$, already noted above.[102]

The use of catalysts based on heteropolycompounds in liquid-phase oxidation reactions is also promising (Table 4). Heteropolycompounds can be employed as stoichiometric oxidants or catalysts together with oxidants such as O_2, H_2O_2, organic hydroperoxides, etc. The application of two-component catalysts incorporating transition metal complexes and a heteropolycompounds as cocatalysts appreciably expands the range of possible oxidation reactions.[3] The acid-base and oxidation-reduction properties of heteropolycompounds and the possibility of their specific regulation permit the employment of such compounds as bifunctional catalysts in processes involving coupled electron and proton transfer, which are fairly common in liquid-phase oxidation. An example of the bifunctional activity of HPC is provided by the vapour-phase oxidation of acrolein over $H_3PMo_{12}O_{40}$.[1, 2]

Much still remains to be done both in the field of fundamental research into the catalysis by HPC and in their practical employment. The unique physicochemical properties of HPC give rise to considerable potential possibilities for the investigation of the elementary steps in homogeneous and heterogeneous acid and oxidative catalysis. There is no doubt that the research into the mechanism of the catalytic activity of HPC will be continued and intensified at the molecular level with employment of HPC of different structural types. These systems are of special interest for the investigation of bifunctional catalysis and of the relation between homogeneous and heterogeneous catalysis. As regards practical application, the expansion of the research into the catalysis by HPC in fine organic synthesis, the development of new more effective methods of synthesis of HPC and catalysts based on them, methods for their isolation, regeneration, and utilisation, and the study of the corrosion activity of HPC solutions, their toxicity, etc. is of current interest.

Radiation-induced inactivation of proteolytic enzymes

M A Orlova

Contents

I. Introduction	493
II. Irradiation of proteases in the solid and immobilised states	494
III. The effect of ionising radiation on aqueous solutions of proteolytic enzymes	495
IV. Application of the method of radiation-induced inactivation of proteolytic enzymes	506

Abstract. Data on the mechanism of the inactivation of proteases under various conditions and the possible applications of these processes are surveyed. Serine, sulfhydryl, acid, and metal-containing proteases are considered. Attention is concentrated on the conformational changes in radiolytic processes: their dependence on the pH of the medium and the correlations with the change in the aminoacid composition of the enzymes. The bibliography includes 90 references.

I. Introduction

Ionising radiation occupies a special place in the series of influences on biological objects. This is associated, firstly, with the fact that there exists a natural radioactive background stimulating changes in the processes occurring on Earth. Secondly, the technological use of ionising radiation and nuclear processes has led to the possibility of the directed liberation of an enormous amount of energy and contamination of the ecosystem with the subsequent increase in the natural radioactive background and irradiation of the population with small doses; expressed quantitatively, this corresponds to an appreciable increase in the natural total annual irradiation dose received by the population, which up to 1986 was about 3×10^6 Gy person^{-1}.[1] It is evidently important to study such influences on the human organism as a whole and on its individual systems in order to discover the adaptive and protective mechanisms. The difference between ionising radiation and other physicochemical influences consists in the reduced wavelength (< 100 nm) and higher energy. The ionisation region begins with an energy in excess of 5 eV. The interaction of ionising radiation with matter, including biochemical objects, has been described in numerous monographs.[2-4] Without going into the details of the theoretical aspects of this process, we shall mention here only that the study of the indirect influence of ionising radiation through the radicals formed as a result of the radiolysis of the medium (in particular water) is more important and informative for biochemistry. The principal water radiolysis products are as follows:[5] H, OH, e_{aq}^-, O^{2-}, HO_2, H_2O_2. The radiation-chemical yield G (the amount of product formed per 100 eV of absorbed energy) depends on the presence of impurities (radical donors and acceptors), the pH of the solution, and other factors.[6]

The interaction of a biomolecule with these products leads to a change and degradation of structures, in particular those ensuring the functioning of the organism. The mechanisms of such processes have been described in another review for the simplest biomolecules (peptides, aminoacids, and proteins).[7]

The imbalance in the processes involving the activation and inactivation of enzyme systems, which in the case of low and chronic irradiation doses may not be manifested for a time but accelerates nevertheless the ageing of the systems of the organism, may be regarded as one of the ways in which the vital activity of an organism is disturbed. In view of this, there has been a growth of interest at the present time in the study of phenomena determining the relationship between the functioning of separate systems and combined influences, which presuppose the occurrence of synergism.[8] The necessity for such studies is associated with the sharp impairment of radioecology against the background of a disastrous ecological situation. The problem of discovering the consequences of the influence of small radiation doses as well as chemical reagents (radiomodifiers) on the results of radiolytic processes requires the creation of predictive models. Quite a large number have now been proposed — both purely biological and biochemical, including protease models.[9]

The development of radiotherapy is also closely related to problems of radiobiology and damage to individual portions of cells and microstructures of the organism.[10] This is partly a consequence of the use of new emitters (for example, neutron emitters[11,12] or emitters of beams of heavy ions[13,14]), which requires additional studies in the field of the relative biological effects of this influence on the principal components of the organism and different cells.

It has become evident in recent years that proteases play a decisive role in the processing of protein.[15] Many facts indicate that proteolytic enzymes perform the function of biological control in the organism, influencing objects important for life. A whole series of key metabolic enzymes are controlled directly by proteases. The mechanisms of the regulation of their activity can operate via the activation of zymogens, the inhibitor–protease balance, and the location of the protease with the substrate. It is therefore not surprising that, in the early stages of radiation and thermal lesions, changes were observed in proteolytic activity,[16] this finding being attributed to the pathology of the kallikrein–kinin system.

The aim of the present review is a comprehensive examination of the mechanism of the radiolysis of proteases and the possible use of this process in medicine and bioengineering.

II. Irradiation of proteases in the solid and immobilised states

Irradiation of enzymes in the solid state constitutes the first stage in the study of the mechanism of their radiolysis, since it makes it possible to investigate the consequences of the direct action of radiation and not of the secondary products of the radiolysis of the medium. This also permits in many instances the determination of the relative molecular masses of both the individual enzymes and of complex biological formations. Studies on these lines, initiated in the 1950s,[17] have continued to this day as a result of a new assessment of the possibilities of the radiation method for the determination of relative molecular masses[18,19] and new computational methods.[20,21]

It is believed that, on irradiation of biochemical objects in the dry state, the site acted upon by the radiation is localised at the point of incidence, in contrast to solutions where the effective volume increases as a result of the diffusion of the water radiolysis products. Localisation is partly observed also on irradiation of frozen solutions,[22] although on subsequent heating to room temperature secondary reactions do occur. In all cases, the target theory is applicable[23] and the main quantitative characteristic of the process is the effect–dose relation, which is exponential for proteases. On the other hand, the deviations from the exponential function which are encountered permit inferences about the process mechanism, which may be complicated as a result of energy transfer in the biosystem.

On irradiation of an enzyme system, the energy transfer to the most radiosensitive component of the molecule can greatly increase the effective volume,[24] increasing it to the size of the entire biomolecule and this affects also the relative molecular masses determined. Since the inactivation of the system changes as a rule on raising the temperature, one should introduce a correction to the calculations of the molecular mass. This has been demonstrated.[25,26] The introduction of additives, i.e. irradiation of mixtures containing several components, also changes the degree of inactivation of the enzyme itself. For example, on irradiation of a mixture with glutathione[27] or another radioprotector, a decrease in the degree of inactivation of the enzyme is observed.

Theoretical problems concerning the determination of the sizes of complex equilibrium enzyme systems comprising several identical components[19] or identical functional units[20] have been examined.[19,20] In both cases, simple exponential effect–dose relations and more complex convex-concave curves may be observed, which depends on the oligomer–monomer equilibrium:

$$R + E \underset{}{\overset{K_d}{\rightleftharpoons}} RE ,$$

where R is the regulator unit, E the catalytic unit, and K_d the equilibrium dissociation constant.[9]

Depending on the size and concentrations of the components, the equilibrium constant, the relative activities of the free enzyme and the enzyme complex, and also the distribution of the components between the free and bound forms, the apparent size of the target and hence the relative molecular masses obtained also change during irradiation.

Analysis with the aid of the target theory likewise makes it possible to obtain an idea about the structural organisation of complex systems, which has been demonstrated in relation to a calmodulin-dependent phosphodiesterase[28] and the components of the adenylate cyclase system in erythrocytes.[29] The presence and the influence of the activator or inhibitor can also be determined from the form of the above relation.[20] In many instances it has been suggested that the role of the transfer of the energy of the oligomeric subunits be likewise estimated in this way when the dissociation of the oligomeric complex can be modelled.[20,28,30,31]

Examination of the form of the effect–dose relations and the application of the target theory on irradiation of a pure enzyme and enzyme complexes with different degrees of interaction of their components permit not only the development of a theoretical analysis but also the determination of the influence of the parameters on the cell populations[32] and also an understanding of the mechanism of the inactivation of a particular enzyme, which is itself a complex structural reacting unit.[33] The increase in the popularity of the method of radiation-induced inactivation for the determination of the dimensions of the systems is due to its simplicity, applicability to complex objects, and the possibility of using only partly purified preparations.

There are literature data on the inactivation of dry preparations of proteases: trypsin,[23,34–36] pepsin,[23] chymotrypsin, papain, subtilisin, and carboxypeptidase.[34,35] Two interrelated processes arise on irradiation: radical formation and inactivation. The radiation-chemical yield of radicals is $\sim 1-7$. γ-Irradiation yields information under these conditions about the distribution of carbon-based radicals (for example, in chymotrypsin at 195 K), preceding the secondary radicals observed at 295 K. The carbon-based radicals can be divided into two groups: those formed at a temperature below 195 K and independent of the aminoacid sequence and those formed above 195 K and depending on the conformation of a specific native enzyme.[37] The dose dependences are exponential and the inactivation reaction is first order for γ- and X-irradiation.

In order to investigate the damage caused in molecules by ionising radiation, it is convenient to employ subsequent tritiation, which has been used[38] to determine the changes which had occurred in α-chymotrypsin after γ-irradiation. On the basis of the aminoacid analysis of the tritiated specimens, the authors reached a conclusion about the conformational transformations, which entailed a change in the area of the accessible surface of the molecule and a greater importance of the hydrophobic residues.

In a number of studies, dry enzymes were irradiated in order to elucidate their radiation stabilities as such and to compare them with stabilities in relation to other methods of treatment. Figure 1 presents results characterising the loss of activity by certain dry proteases on irradiation.

It is noteworthy that the observed degree of inactivation of proteases may depend on the method of its determination, which hinders comparison of the results of different studies. In particular, this has been observed for chymotrypsin irradiated in a dry state.[35,36]

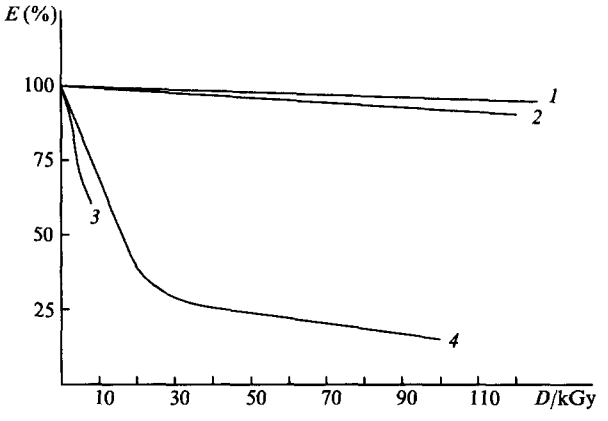

Figure 1. Radiation-induced inactivation of enzymes in the crystalline state: (*1*) α-chymotrypsin (X-rays);[39] (*2*) trypsin (γ-rays);[36] (*3*) glucosidase + catalase (X-rays);[39] (*4*) subtilisin-72 (X-rays).[39]

The stability of enzymes increases following their immobilisation and for this reason immobilised enzymes are actively employed in the national economy, especially in medicine. There exist three aspects of the study of the action of ionising radiation on immobilised enzymes. The first involves the use of ionising radiation for immobilisation itself. There exists an extensive literature on this question, which is not considered in the present review.

The second aspect involves the development of materials for the production of an image (for use in roentgenoscopy, autoradiography, and dosimetry). Thus α-chymotrypsin and subtilisin-72 have been bound[39] to various diazides and the vinylpyrrolidinone–acrolein copolymer on chromatographic paper in order to obtain a latent image and hence to detect X-radiation. The authors tested several versions of the method: solutions of the enzyme (2×10^{-3} M α-chymotrypsin, 1.1×10^{-3} M subtilisin) were deposited on a support and irradiated with X-rays at a dose rate of 200 rad s^{-1}; the enzyme and the diazide were deposited on a support and irradiated with X-rays transformed by a special screen into UV radiation at a wavelength of 365 nm; chromatographic paper was subjected to a preliminary treatment with *p*-azidobenzaldehyde diethyl acetal, the vinylpyrrolidinone–acrolein copolymer (VPA), or VPA modified by azide groups with subsequent exposure together with the enzyme. The subsequent development of the latent image by a suitable dye reveals a difference between the irradiated and nonirradiated sections. Exposure to X-rays of a carrier impregnated with an enzyme solution leads to the immobilisation of 0.05% of α-chymotrypsin and 0.01% of subtilisin.

The use of proteases for the preparation of dosimetric materials has been described.[40] Gelatin films containing small amounts of enzymes (chymotrypsin, papain, trypsin, and subtilisin) were exposed to the low-energy tritium β-radiation and development was carried out after irradiation in solutions of these enzymes. In both cases, irradiation hardly affected the activity of the enzyme but damaged the structure of gelatin, altering the degree of and conditions for its digestion by the enzyme. When the films are dyed, a half-tone image is formed and this method as well as the previous one can therefore be used to detect ionising radiation.

The third aspect of the studies involves an attempt to model the mechanism of the action of ionising radiation on immobilised systems via the investigation of the radicals generated. Such studies have been carried out for trypsin immobilised on dialdehyde-cellulose (DAC) by comparison with pure trypsin.[41,42] The range of γ-irradiation doses was 0.05–10 Mrad (0.5–100 kGy). Comparison of the EPR spectra of the immobilised and native trypsin as well as the support suggested that the increase in the stability of the immobilised trypsin is associated with the recombination of the trypsin radicals with the DAC radicals and with their migration to weakened bonds in the DAC. The activity of the immobilised trypsin does not then change, while native trypsin loses 25% of its activity for a dose of 10 Mrad (100 kGy).[42] Such increase in stability makes it possible to employ immobilised proteases in enzyme therapy using γ-sterilisation,[43] since the activity of γ-irradiated immobilised trypsin does not change during prolonged storage with a simultaneous decrease in the number of radicals. Trypsin immobilised on DAC can be stored under severe conditions for a long time. Comparison of the behaviour of the enzymes on γ-irradiation of their aqueous solutions and the enzymes immobilised on nylon fibres showed[44] that not all enzymes exhibit an appreciable increase in their resistance to radiation in the immobilised state; however, this does not apply to proteases.

III. The effect of ionising radiation on aqueous solutions of proteolytic enzymes

1. Serine proteases

The radiolysis of serine proteases in solution has been studied most fully. Questions associated with the mechanism of the radiation-induced damage to trypsin and chymotrypsin (the enzymes of the pancrease) and certain subtilisins (the enzymes from microorganisms produced by various strains of *B. subtilis*) have been examined in detail in the literature. The blood enzymes (thrombin and plasmin) have been much less investigated and as regards certain enzymes no information is encountered in the literature.

The main feature of the radiolytic damage to serine proteases is a fairly high stability of the active centres, containing a serine residue, in relation to the action of ionising radiation, whilst the conformational stability of the biomolecule is most vulnerable. It has been shown in a number of studies[45,46] that the main contribution to the inactivation of serine proteases comes from OH radicals obtained on radiolysis of water. This has been readily confirmed by irradiating chymotrypsin in N_2O, where the number of OH radicals increases as a result of the reaction

$$e_{aq}^- + N_2O + H_2O \rightarrow OH + OH^- + N_2 . \quad (1)$$

In this case, the corresponding increase in the radiation-chemical yield of the inactivation is observed.

The coefficients of susceptibility to damage (effectiveness of inactivation, i.e. the probability that the attack by a given active influence inactivates the enzyme) of chymotrypsin by various radicals, the number of which was regulated by controlling the irradiation conditions (Tables 1 and 2), have been published.[2,3] The rate constants for reactions with certain water radiolysis products are also known (Table 3). It has been shown that the changes induced by the OH and H radical species involve mainly tryptophan residues in chymotrypsin, while approximately 15%

Table 1. Radiation-chemical yields in radical formation (G_R) and inactivation (G_{in}) reactions in aqueous solutions of chymotrypsin and papain on γ-irradiation under different conditions.

of e^-_{aq} react at the S–S bonds. The next stage of the study was therefore the determination of the relationship between the damage to the tryptophan residues and the conformational stability.

A detailed analysis has been carried out of the mechanism of the inactivation of chymotrypsin.[49-51] A change in the accessible surface of the globule was detected by the $^1H-^3H$ exchange method.[46,50] The rate of exchange increased by 16% compared with the nonirradiated enzyme with increase in the irradiation dose from 30 to 50 Gy. The use of fluorescence, viscometric, and microcalorimetric methods made it possible to determine the radiation-chemical yield of the uncoiled molecules (G_{unc}) and to find the correlation between G_{unc} and the radiation-chemical yield of the damaged tryptophan residues $-G(-Trp)$[49] (Table 4). Data on the binding of proflavin[53] demonstrated the presence of local steric changes around the binding centres. Conformational changes were initially detected only after an irradiation dose of about 2 kGy,[46,49] but later they were discovered also at lower doses (< 1 kGy).[50,51] The change in the fluorescence quantum yield in irradiated chymotrypsin solutions, characterising the number of tryptophan residues, showed[52] that at pH 3 their decrease is correlated with the decrease in catalytic activity. At pH 7.8 (the pH optimum of the esterase activity), an increase in the number of accessible tryptophan residues was observed initially, decreasing following an increase in their dose. These data make it possible to infer the changes in the degree of uncoiling of the chymotrypsin globule as a function of pH. In particular, it appears that at low pH the area of the accessible surface of the globule is greater. The maximum change in this quantity was observed at pH 2.0, whereupon the radiation-chemical yield of the inactivation reaction increases.[53] For doses in excess of 0.6 kGy, the conformational changes became insignificant but the aminoacid composition of the enzyme changed sharply.[51]

Damage to the disulfide bridges occurred at higher irradiation doses and no longer played a significant role in the breakdown of catalytic activity. Thus, for a dose of 0.5 kGy, 5.5 S–S bonds were detected in chymotrypsin,[50] while for a dose of 0.8 kGy the number of such bonds was 4. It was found that the presence of S–S bonds is important for reducing the conformational changes on irradiation. This was demonstrated by comparing the γ-inactivation of chymotrypsin and subtilisin,[52] where the same degree of inactivation in subtilisin entails the decomposition of a smaller number of important aminoacid residues. This conclusion follows from the comparison of the ratios $G(-Trp)/G_{in}$. This quantity is 4.3 times smaller for subtilisin than for chymotrypsin, while G_{in} (subtilisin) is smaller than G_{in} (chymotrypsin) by a factor of 1.4 (Table 4). A similar difference has been observed also between the overall quantities $G(Tyr+Trp)/G_{in}$. The authors see an explanation of this effect in the presence of five S–S bonds in chymotrypsin (subtilisin is a single-stranded enzyme and has no disulfide bridges), which, as it were, 'maintain' the structure of the enzyme under the conditions where the tryptophan residues are damaged.

The change in the aminoacid composition of chymotrypsin for different irradiation doses has been investigated in a number of studies.[50-52] $5\times10^{-6}-10^{-5}$ M solutions at pH 3 (HCl)[50] and 7.8 (tris-HCl buffer)[52] were used. After irradiation with a dose of 0.5 kGy, a decrease in the number of tyrosine residues and, after a dose of 1.2 kGy also, in phenylalanine residues was observed together with the damage to the tryptophan residues.[50] For a dose of about 1.6 kGy, almost all the aminoacid residues are involved. The aminoacid compositions[52] of the irradiated solutions at pH 3 and 7.8 were compared. A common feature of these compositions is a decrease in the number of tyrosine, cysteine, phenylalanine, and lysine residues, but the doses required for this are smaller at pH 3. Thus the decomposition of one tyrosine residue requires about 0.025 kGy at pH 3 and approximately 0.6 kGy at pH 7.8. A greater radiation yield G_{decomp} for chymotrypsin at pH 3 compared with pH 6.9 has been observed.[49] Comparison of data from different studies shows that, by virtue of their more uncoiled conformation, the damage to the aminoacid residues on irradiation with high doses at pH 3 is stochastic and evidently the change in conformation is more important for catalytic activity than the change in the aminoacid composition (except for the aromatic aminoacid residues).

A correlation between the decrease in catalytic activity and the decomposition of tyrosine residues has been observed for irradiated subtilisin-BPN′ and subtilisin-72,[52,54] especially at pH 8.5 (the pH optimum of the activity of the enzyme).[52] At lower pH (for example, 5.5), this correlation is less marked, since there is a dependence on the decomposition of tryptophan residues. The degradation of the histidine residues forming part of the active centre of subtilisin-72 is observed at doses in excess of 5 kGy, whereupon the catalytic activity is almost completely lost. Histidine is more important for the radiation stability of subtilisin-BPN′. After γ-irradiation with a dose of 1.1 kGy, subtilisin-BPN′ loses two tyrosine residues and one tryptophan, one methionine, and one histidine residues[53,54] (Figure 2). The reaction with diisopropyl phosphorofluoridate shows that under these conditions 85% of the active centres are retained. For an irradiation dose of 2.4 kGy, changes appear in the leucine, proline, phenylalanine, serine, and alanine residues. The

Dependence of the change in the catalytic activity of enzymes on the absorbed γ-radiation dose:[33] (a) α-chymotrypsin; (b) trypsin; (c) subtilisin-72; concentration (M): (1) 10^{-4}; (2) 7.5×10^{-6}; (3) 10^{-6}; (4) 10^{-7}; (5) 10^{-5}; (6) 10^{-6}; (7) 5×10^{-5}; (8) 5×10^{-6}; (9) 9×10^{-7}; (10) 3×10^{-7}; (11) 8×10^{-8}.

oxidation of methionine does not then lead to the inactivation of subtilisin-BPN',[54] but is significant for subtilisin-Carlsberg,[55] which differs, according to the data of Alden et al.,[56] from subtilisin-BPN' by the presence of a series of repeating segments in the polypeptide chain. For a dose of 0.55 kGy, the number of degraded tyrosine residues increases in subtilisin-72 compared with subtilisin-BPN', but the histidine residue is not degraded.[52] For a dose of 1.1 kGy, the difference between the numbers of degraded tyrosine residues increases still further. These data led to the conclusion that the tyrosine residues are more accessible in subtilisin-72.

Application of the electrophoretic method to irradiated subtilisin-BPN' demonstrated[53] the presence of a larger electric charge compared with the native enzyme, accompanied by the absence of changes in catalytic activity. This agrees with the earlier hypothesis that small irradiation doses lead to the formation of noninactivated molecules, which, however, differ conformationally from the native ones.

The appearance of active but partly damaged molecules has been confirmed by a change, even for low irradiation doses, in the kinetic parameters — the Michaelis constant (K_M) and the maximum rate of the catalytic reaction (V_{max}). Irradiation of dilute solutions increases K_M and diminishes V_{max} both in the case of chymotrypsin[57,58] and subtilisin-BPN' (Table 5).[54] Since the main damage to serine proteases caused by low doses is conformational damage associated with the disappearance of tryptophan residues (at least in chymotrypsin) and since in ribonuclease, which contains no tryptophan residues, there are no changes in K_M and V_{max},[59] the modification of the molecules is attributed to changes in the tryptophan residues. Other workers arrived at similar conclusions on the basis of the results of the irradiation of chymotrypsin and chymotrypsinogen.[60] The presence of modified molecules is reflected in the nature of the effect–dose relation, in particular deviations of the exponential function appear and the form of the curve depends on the initial enzyme concentration (Figure 3). A change in the radiation-chemical yield of the inactivation as a function of the initial enzyme concentration [E_0] has been observed[61-64] for trypsin and chymotrypsin (Table 6). This relation was described by the equation $G_{in} \simeq [E]^N$, where N is an integer. However, there is no concentration dependence if the active radicals (in this case OH radicals) react with the dissolved enzyme molecules faster than with one another, so that the decisive factor is the ratio of the number of the dissolved molecules to the number of active radicals. For trypsin, chymotrypsin, and subtilisin-72, the concentration ranges in which the dose dependences follow the exponential law have been determined:[33] $3 \times 10^{-6} - 5 \times 10^{-5}$ M for chymotrypsin, $2 \times 10^{-6} - 10^{-4}$ M for subtilisin-72, and above 10^{-6} M for trypsin. At lower concentrations, a deviation towards increasing inactivation is observed, whilst at higher concentrations ($> 10^{-4}$ M for chymotrypsin) an increase in dose

Table 5. The change in the kinetic parameters of irradiated proteolytic enzymes.

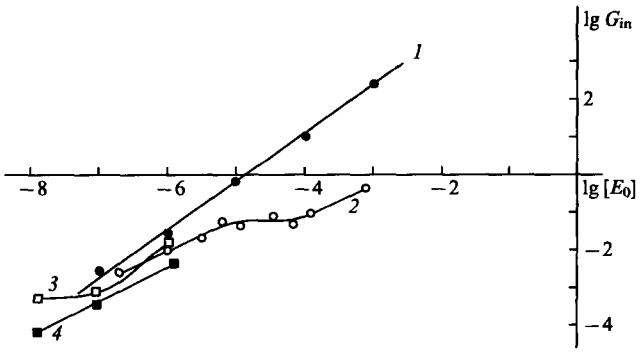

Figure 4. Dependence of the radiation-chemical inactivation yield (G_{in}) on the initial concentrations of chymotrypsin (curves *1* and *2*) and the angiotensin converting enzyme (curves *3* and *4*). For curve *1*, G_{in} was calculated along the initial section of the dose dependence plot and for curve *2* at a dose of 200 Gy; pH: (*1*) and (*2*) 7.8; (*3*) 7.5; (*4*) 9.0.

actually entails a decrease in inactivation compared with the expected value. The simplest calculation of the ratio of the active radicals derived from water and the enzyme molecules for a dose of 20 Gy demonstrated a relation between the observed deviations and the excess of either OH radicals ($< 10^{-6}$ M) or enzyme molecules ($> 10^{-5}$ M). Although the purity of the enzyme and also its possible immobilisation on glass can in fact alter the absolute value of G_{in} under these conditions, they do not affect the nature of the dose dependence. The curve relating G_{in} to the initial enzyme concentration is presented in Figure 4 in terms of logarithmic coordinates. For low doses, it is linear but for a dose of 0.2 kGy there is already a plateau in the chymotrypsin concentration range 5×10^{-6}–6×10^{-4} M. The authors therefore suggest that two inactivation regions, linked to the relation examined above, be distinguished: (1) the number of inactivated molecules is proportional to the initial enzyme concentration (a dose < 20 kGy in the case of chymotrypsin), i.e. a definite fraction of the molecules are inactivated; (2) the number of inactivated molecules ceases to depend on the initial concentration. Very low enzyme concentrations ($< 10^{-7}$ M), at which the excess of radicals is too high, and concentrations above 10^{-3} M, where the direct action of the radiation on the energy transfer process may become important as a result of aggregation, are possible exceptions.

The method used to determine the enzyme activity has a major influence on the value of G_{in} and the form of the effect–dose relation. Lynn[65] pointed out the absence of an exponential dose dependence in the case of trypsin when the catalytic activity was determined with the aid of casein and put forward an explanation based on the methodological characteristics of the determination, namely on the differences between the rates of the tryptic and chymotryptic digestion of the peptides formed.[71] The mixture of peptides varied depending on the degree of irradiation, and its solubility in trichloroacetic acid, used in this method, also varied. As already pointed out above, there are deviations from the exponential relation also when ester substrates are used, in particular, the ethyl ester of *N*-acetyl-L-tyrosine (ATEE).[33,65,71] The reason for and the extent of these differences have been investigated in numerous studies devoted to chymotrypsin,[33,60,65,71,72] trypsin,[65] and subtilisin-BPN′,[53] mainly in relation to casein and ATEE (Table 6). Substrates can be arranged in the following sequence in terms of increasing sensitivity: casein ≪ BTEE < ATEE. This fact confirms the conformational changes on irradiation. By virtue of the difference in the size of the biomolecules, the smallest conformational change affects the ability of the enzyme molecules to bind different substrates. Furthermore, casein apparently has several centres for binding to the enzyme by virtue of its structure, whereas in esters there is only one such centre. The difference between the specificities of ester substrates can be explained by different binding mechanisms.[53] Thus nine ester substrates have been used[72] and it has been shown that for some of them there is a relation between the loss of catalytic activity and the decomposition of the tryptophan derivatives, but this is not true of all substrates. Under these conditions, both catalytic stages—acylation of the active centre as well as deacylation—are acted upon by ionising radiation.

It is noteworthy that in all cases the purities of the enzyme and the substrate are very important for the sensitivity to radiation; this has been demonstrated specially in relation to casein.[65]

The reaction conditions, i.e. the composition of the medium, alter the radiation-chemical yield of active radicals and influence greatly G_{in}. The influence of different buffers on the latter is indicated in Table 6 and for subtilisin-72 has been described in a study[68] where the dependences of G_{in} on the initial enzyme concentration in the acetate buffer and in 0.1 M NaCl solution were compared. At a high enzyme concentration (10^{-4} M), the difference is insignificant, but in 10^{-6} M solution it already increases almost by an order of magnitude. The greatest effect of the acetate buffer on trypsin has been observed by McDonald.[62] On the other hand, the tris-HCl buffer hardly affected G_{in} for chymotrypsin.[51]

The presence of Ca^{2+} ions is important under irradiation. There are data indicating their binding to enzyme molecules (particularly those of the subtilisins), which leads to the observation of a protective effect, G_{in} diminishing for serine proteases as a result of the decrease in G_{unc}. It has been shown[51] that the presence of Ca^{2+} retards the decomposition of the tryptophan residues. The stabilising effect of Ca^{2+} is known also in thermal inactivation.[73] According to Nikol'skaya and coworkers,[51,68] the stabilising effect increases with increase in enzyme concentration; D_{50} (the dose at which 50% of the active enzyme remains) increases by a factor of 2. The stability increases also with increase in pH to 7.8 (D_{50} increases by a factor of 1.5 for a concentration of 10^{-6} M and by a factor of 3 for 10^{-4} M). The joint influence of calcium ions and the acetate buffer has been investigated for subtilisin-72.[68] In this case, competing processes are observed and the protective effect of Ca^{2+} ions is manifested when the effect due to the binding of Ca^{2+} to subtilisin molecules begins to exceed the destabilising effect of the increase in the ionic strength of the solution. There is a region in which the effects cancel out (in the given instance at an enzyme concentration of about 3×10^{-6} M).

The change in the inactivation of chymotrypsin and subtilisin as a function of the type of irradiation has been described[59,67] and is illustrated in Table 7. However, one should bear in mind that such variation depends as a rule on the dose rate of the source, which also influences the radiation stability of enzymes.

Table 7. Dependence of the inactivation constant ($k_{in,eff}$) on the type of radiation.[67]

Enzyme	Medium	pH	Radiation	$10^4\ k_{in,eff}$/min^{-1}
Chymotrypsin, 10^{-5} M	Tris-HCl buffer	7.8	γ	1.0
	Tris-HCl buffer	7.8	γ-n[a]	0.5
Subtilisin-72, 10^{-6} M	0.1 M NaCl	5.5	γ	0.9
	0.1 M NaCl	5.5	γ-n[a]	0.5

[a] Gamma-neutron field.

Many questions are associated with the influence of oxygen on the radiation-induced inactivation process. The results of the irradiation of serine proteases in air and in an inert gas atmosphere have been compared,[50,60] but the conclusions are not unambiguous. It is assumed[65] that, on irradiation in air, the principal role is assumed by OH radicals, whilst under anaerobic conditions it is assumed by both OH and H. According to the

results of Masuda et al.,[74] the yields $G(-SH)$ and $G(-Trp)$ are smaller under anaerobic conditions, whilst in the case of chymotrypsin a greater sensitivity was observed in the absence of oxygen.[57] One of the explanations of differences of this kind may be provided by the dependence on the medium in which the irradiation is carried out (the same competing processes involving the interaction of the enzyme with the active radicals and of the radicals with one another). Thus O_2^- ions are formed faster at pH 5.0 than H atoms and the effectiveness of the inactivation by them is much smaller.[57] The protective role of oxygen on irradiation in air has been observed.[72] In many instances the formation of H_2O_2 is decisive. This has been demonstrated in relation to subtilisin-Carlsberg.[55]

All the data considered above refer to the study of the enzymes *in vitro*. Another version of the study of the changes in the function of the enzyme under influence of ionising radiation constitutes studies *in vivo*. Investigations of this kind[75,76] have been performed to determine the changes in the fibrinolytic metabolism associated with the activity of plasmin. It has been shown that the fibrinolytic activity diminishes with increase in the γ-irradiation dose *in vivo* and this is associated in its turn with the decrease in the reactivity of the plasminogen activator. Unfortunately it was not possible to find any literature data on the mechanism of the radiolysis of the enzymes thrombin and plasmin themselves, but one can postulate that it is common to the serine proteases and involves a change in the conformation of the active centre.

2. Sulfhydryl proteases

Proteases containing cysteine in the active centres are of special interest in the study of their radiosensitivity in connection with the hypothesis of a unique mechanism of radiation sickness associated with the number of free sulfhydryl groups in the organism.[77] The radiolysis of one of the most thoroughly investigated sulfhydryl proteases (papain) has been examined in detail.[78,79] As already pointed out above, the majority of studies on the radiolysis of enzymes have been carried out in the region where the exponential effect–dose relation holds, the latter being as a rule a result of the combination of several nonexponential processes. The kinetics of the inactivation of papain have been described[78] and the following relation between the dose and the degree of inactivation has been obtained:

$$D\alpha = \frac{k' - k_1}{k_0} y + \frac{k_1 E_0 + k'_1 F + k_2 P}{k_0} \ln \frac{E_0}{E_0 - y}, \qquad (2)$$

where D is the dose in Roentgens, α the proportionality coefficient which converts the dose into the number of radicals ($It = \alpha D$), I the number of radicals (mol litre^{-1}) formed per unit time, k' the rate constant for the inactivation of the radicals by the active enzyme, k_1 the rate constant for the inactivation of the radicals by the inactivated enzyme, k_0 the rate constant for the inactivation of the enzyme by the radicals, E_0 the initial enzyme concentration, k'_1 the rate constant for the inactivation of the radicals by contaminants, F the concentration of contaminants in the enzyme, k_2 the rate constant for the inactivation of the radicals by radioprotectors, y the concentration of the inactivated enzyme, and P the concentration of the radioprotectors.

Eqn (2) is in principle applicable to any enzyme. It has linear and logarithmic components. Only when $k' = k_1$, i.e. if the active and inactivated enzymes react with the radicals in the same way, does the exponential relation hold for the dose–effect curves, since we then have

$$E = E_0 \exp(-k_0 D\alpha/[k_1 E_0 + k'_1 F + k_2 P]) = \\ = E_0 \exp(-KD). \qquad (3)$$

However, the authors observed that, for an exponential dose dependence of the X-inactivation of papain, the active enzyme molecules react with the water radiolysis products faster than the inactivated molecules. This made it necessary to examine in greater detail the inactivation kinetics. A family of curves was obtained with an increase in the inactivation yield as a function of the dose, which is associated with the decrease in the importance of the logarithmic part of Eqn (2) as k_0 increases. The theoretical ideas agreed well with the experimental data for the X-inactivation of 1.2×10^{-5} M solutions of papain in phosphate buffer at pH 7.4 and 0 °C. When $k' \neq k_1$, the radiosensitivity parameters change, which usually diminishes the degree of inactivation. Gaucher et al.[80] assumed that, when the enzyme is papain, then, in contrast to serine proteases, it reacts preferentially with the aquated electron e_{aq}^- being an SH-containing enzyme. The fundamental inactivation mechanism involves damage of the active centre by one of the water radiolysis products. Under these conditions, only one active group is important. The interaction of the radical with this group leads to the inactivation of the molecule, i.e. $(k' - k_1)/k_0 = 1$.

The hypothesis that the mechanism of the inactivation of papain (Pa) reduces to damage of the active centre has been confirmed by experiments with modified papain and also by the change in G_{in} in the presence of inhibitors.[81] When cysteamine monosulfoxide, which gives rise to the mixed disulfide Pa–S–S–R, and tetrathionate, forming the Pa–S–$S_2O_3^-$ ion, were used as the modifying agents, an increase in the radiation stability of such papain derivatives was observed (Table 8).[82]

Thus, in contrast to serine proteases, the inactivation of the sulfhydryl enzyme reduces partly to the damage of the active centre, mainly via a single impact mechanism, and this is responsible for the difference between k' and k_1 and leads to the deviation of the dose dependence from the exponential function. One should also note that e_{aq}^- can pass through the protein molecule very effectively, which should hinder the application of the target theory in calculations for SH enzymes. However, by virtue of the appreciable electron affinity of the disulfide bridges, such estimates are nevertheless possible.[48] As already mentioned, the dose curves for the serine proteases, which depend on the direct damage of the serine in the active centre, also do not always correspond to an exponential relation. It is difficult to account for these findings, because the authors[78,79] did not take into account the changes in the conformation of the papain molecule, assuming this process to be of secondary importance. However, it must inevitably occur as a result of the formation under the influence of ionising radiation of S–S bonds and mixed disulfides of the type Pa–S–S–R, which alters (usually strengthens) the molecular structure and inhibits complete degradation by influencing the conformation.

The observed conformational disturbances in papain have been shown[48,87] to occur due to the decomposition of the tyrosine and tryptophan residues with preferential damage to tyrosine residues, two of which (Tyr-61 and Tyr-67) are close to the active centre. In addition, the imidazole–thiol pair (Cys-25 and His-159) plays a major role in the inactivation of papain, which affects the interaction of the enzyme with the substrate.[86] Evidently, as for trypsin-like enzymes, in the case of papain the attack by the OH radicals and the accessibility of aromatic aminoacid residues to the latter are important apart from the effect of e_{aq}^-. Table 9 presents data on the reactivities of various aminoacid residues in papain relative to OH radicals. The tyrosine and tryptophan residues head this list. The overall rate constants for the reactions of papain with OH radicals and e_{aq}^- are listed in Table 3.

Thus the additivity of two processes, namely

$$Cys + e_{aq}^- \rightarrow E_{in},$$

$$Tyr(Trp) + OH \rightarrow E_{in} + E_{ac}^{\bullet},$$

Table 8. Change in the catalytic activity of sulfhydryl proteases on exposure to X-rays (t = 0 °C, substrate—haemoglobin).

[a] The value obtained in the presence of cysteine is indicated in brackets.

(E^*_{ac} are the molecules of active but damaged molecules) generates the papain inactivation pattern. The decrease in the esterase activity of papain under these conditions is associated,[48] as for serine proteases, with the degradation of Trp-177. Furthermore, the abstraction of a H atom from the SH group contributes to the inactivation:

$$OH + Pa{-}SH \rightarrow Pa{-}S^{\cdot} + H_2O\,.$$

If aromatic aminoacid residues are in the vicinity of the S–S bridge, then the probability of inactivation increases to the extent determined by the sum of the processes. As shown by the γ-radiolysis of cysteamine disulfide[48] and cystine,[83,84] the effect of ionising radiation on disulfides and thiols generates numerous products, which then enter into secondary reactions. Similar processes affect also the inactivation of SH enzymes.

It is of interest that papain exhibits a greater radiosensitivity than other SH-containing enzymes, such as alcohol dehydrogenase and glyceraldehyde-3-phosphate dehydrogenase.[81] Its capacity for reactivation by cysteine is also higher. On the other hand, in view of the greater vulnerability of the active centre to the two reactions discussed above, papain is more radiosensitive also compared with serine proteases. However, one should take into

Table 9. The reactivity and accessibility of certain aminoacid residues in papain in relation to OH radicals.[48]

Aminoacid residue	n_{tot}	n_{exp}	$10^{-9}\,k_{(OH+AA)}$/ litre $mol^{-1}\,s^{-1}$	$n_{exp}\,k_{(OH+AA)}$	$\frac{n_{exp}\,k_{(OH+AA)}}{\Sigma\, n_{exp}\,k_{(OH+AA)}}$

Phenylalanine	4	2	5.5	11.0	0.04

account the specific features and the sensitivity of the methods for the determination of catalytic activity, which, as shown in relation to chymotrypsin, are extremely important. Furthermore, in the determination of the activity of papain and in the calculation of G_{in} account must be taken of the fact that about 50% of the papain in the preparation may be in the oxidised (inactive) form, which hinders the comparison of data from different investigations if preliminary reactivation or purification has not been carried out.[85]

Experiments showed[48,80] that the radiation-induced inactivation of papain diminishes greatly following the addition of cysteine after irradiation, partly owing to the reaction

$$Pa^{\cdot} + Cys-SH \rightarrow Pa-H + Cys-S^{\cdot} .$$

The ratio G_{in} (in the presence of cysteine)/G_{in} (in the absence of cysteine) (relative yield) is presented in Figure 5. The protection by cysteine then depends on the real ratio [Pa]/[Cys]. Thus in nitrogen-purified solutions, it should be 1/(2–10). This is caused, apart from the reaction indicated above, by competing reactions with OH radicals and the faster reactions involving e_{aq}^-:

$$e_{aq}^- + R-SH \rightarrow R^{\cdot} + SH^- ,$$

$$Cys^{\cdot} + Cys-SH \rightarrow Cys-H + Cys-S^{\cdot} .$$

The species e_{aq}^- therefore cause a reversible inactivation, whereas OH radicals give rise to an irreversible inactivation.[85]

It is noteworthy that an increase in the pH of the solution increases as a rule G_{in}, although the relation between these quantities is not unambiguous.[81]

The influence of irradiation conditions on the radiation-induced inactivation of papain has been investigated. The authors[85] elucidated the effect on this process of the acetate, isobutyl alcohol, and CNS radicals. It was found that they all increase G_{in} (Table 8), evidently owing to the reaction

$$Pa-SH + R \rightarrow Pa-S^{\cdot} + RH .$$

The influence of hydrogen peroxide on the inactivation of papain has also been observed.[79,85,86] The peroxide gives rise to 60% of the reversible and 40% of the irreversible damage in papain.[85] The elimination of its influence by the addition of catalase diminishes the ionic yield, which hardly changes in air and under a nitrogen atmosphere. The dependence of the degree of inactivation on the presence of H_2O_2 can also be estimated from the increase in the radiation-induced inactivation of papain on reducing the dose rate in the absence of catalase.

Thus the principal difference between the mechanisms of the radiation-induced inactivation of the serine and sulfhydryl proteases consists in the fact that not only a disturbance of the conformation on degradation of the aromatic aminoacid residues but also the competing dominant process involving the single impact inactivation as a result of the damage to the active centre is observed in the latter case.

3. Other classes of proteases

Whereas the radiolysis of the serine and sulfhydryl proteases has been studied fairly completely, the remaining representatives of proteases are mentioned in the literature only incidentally.

The radiolysis of pepsin — an acid protease containing an asparagine residue in the active centre — has been examined.[70] It was shown that the overall characteristics of the inactivation of this enzyme are the same as for trypsin, chymotrypsin, and the subtilisins: in solution, the main reactive species is the OH radical; atomic hydrogen is extremely effective, but it makes a smaller contribution to the inactivation owing to its low yield. The similarity consists also in damage being sustained by the same radiation-sensitive aminoacid residue: Trp and Tyr, which was demonstrated by altering the degree of inactivation in the presence of Br_2^- and $(SCN)_2^-$ ions and also of *tert*-butyl alcohol. The parameters and conditions of the inactivation are presented in Table 6.

Figures 6 and 7 illustrate the inactivation of pepsin in the form of dose dependences and the changes in the pH dependence under various irradiation conditions. The pH dependence varies in the range pH 2–3. Taking into account also the changes for subtilisin[52] and the angiotensin converting enzyme (ACE) (Figure 7), one may say that the radiation-induced inactivation makes it possible to determine the conditions under which conformational changes in the molecule take place.

In the case of carboxypeptidase A, the effectiveness of the action of water radiolysis products on its enzyme activity does not differ from that for serine proteases,[69] despite the fact that the

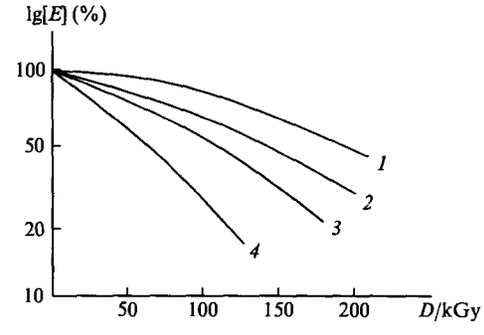

Figure 6. Dependence of the radiosensitivity of pepsin on the irradiation conditions:[69] (*1*) Ar + *tert*-BuOH; (*2*) O_2; (*3*) Ar; (*4*) N_2O.

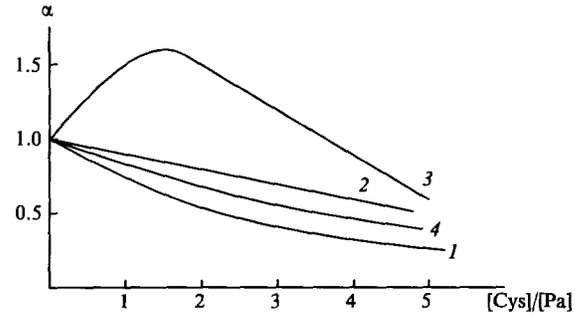

Figure 5. The relative inactivation yield (α) as a function of [Cys]/[Pa]: (*1*) calculated fraction of OH radicals reacting with papain in N_2-saturated solutions; (*2*) irreversible inactivation; (*3*) overall inactivation; (*4*) fraction corresponding to the interaction with papain of both radicals ($OH + e_{aq}^-$) in N_2-saturated solutions.

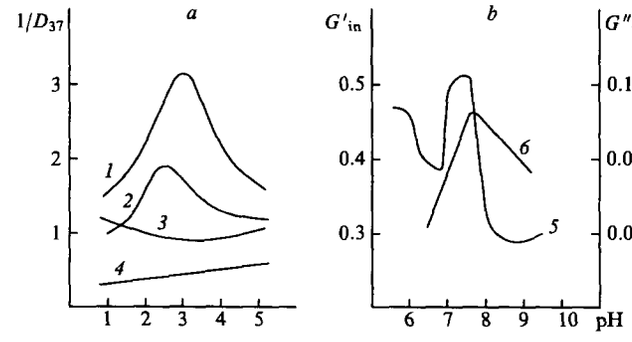

Figure 7. Variation of the radiosensitivity of pepsin[69] (*a*), subtilisin-72 [G'_{in}; curve *5* (*b*)],[52] and the angiotensin converting enzyme (ACE) [G''_{in}; curve *6* (*b*)] under different conditions: (*1*) N_2O + KBr; (*2*) N_2O; (*3*) O_2; (*4*) N_2O + KSCN.

active centre contains in this case a metal (Zn) ion. A similar radiation-chemical yield of the inactivation process is also observed (G_{in}, Table 6). All this confirmed that the inactivation of enzymes of this class takes place primarily via the alteration of the conformation and not via a single impact mechanism involving damage to the active centre. An appreciable dependence of the inactivation on the conformational state of the molecule has been observed also for a Zn-containing hydrolase—ACE, for the stability of which the number of decomposed aromatic aminoacid residues is important. Their decomposition to the extent of ~50% made the active centre accessible to radicals and caused a decrease in enzyme activity (Figure 8).

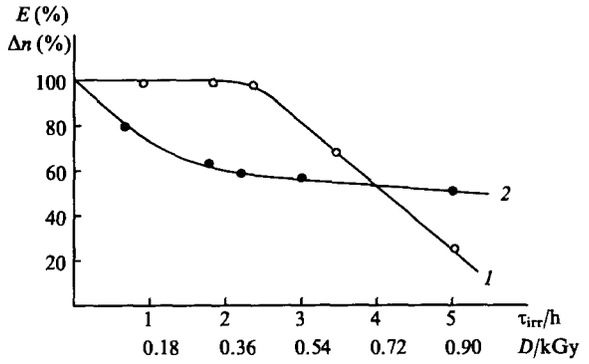

Figure 8. Variation of the catalytic activity E (curve *1*) and of the number of tryptophan and tyrosine residues (curve *2*) in the angiotensin-converting enzyme (γ-irradiation).

Overall, the radiation-induced inactivation of proteases like, incidentally, that of any other enzyme, can be represented by a scheme (Figure 9), the use of which gives rise to a greater complexity of the expressions obtained by Phihl and Sanner[79] and Gaucher et al.[80] Process *4* (Figure 9), which constitutes the mechanism of the inactivation proper, i.e. the modification of the biomolecule, depends on the coefficients of the effectiveness of the action of the water radiolysis products on the given enzyme, involving the active centre itself or its immediate environment. The highest yield and the highest effectiveness are those of the OH radicals and e^-_{aq}. The yield of H atoms, whose effectiveness is a maximum, is insufficient to influence greatly the inactivation, so that OH and e^-_{aq} actually make the main contribution to the given process. On irradiation of the pure enzyme, fundamental differences are observed between SH-containing enzymes and the remaining proteases regardless of whether their active centre contains serine, aspartic acid, or a metal atom. Apart from undergoing conformational damage due to the interaction of OH radicals with tryptophan and tyrosine residues, in the biomolecules containing a SH group the cysteine in the active centre is acted upon directly by e^-_{aq}, which increases their G_{in}. When the mechanism of the inactivation is identical, the area of the accessible surface of the molecule, characterising the extent to which it has been uncoiled, assumes fundamental importance.

Table 10. Accessible surface areas for different classes of proteases.

Enzyme	Accessible surface area/Å²	Ref.
Chymotrypsin	12996	88
Carboxypeptidase A	11260	89
Subtilisin	9790	88
Papain	9210	88

Table 10 presents certain accessible surface areas for metal-containing, SH-containing, and serine proteases. Comparison of the values of G_{in} (Table 6) shows that they are similar for chymotrypsin and carboxypeptidase. For subtilisin, which has a smaller accessible surface area, the radiation-chemical inactivation yield also diminishes. However, for papain, which has a different inactivation mechanism, a higher value of G_{in} is observed despite its smaller accessible surface area. Furthermore, the radiation stability of any protease depends on the accessibility of the aromatic aminoacid residues, especially Trp and Tyr, regardless of the stability in the active centre.

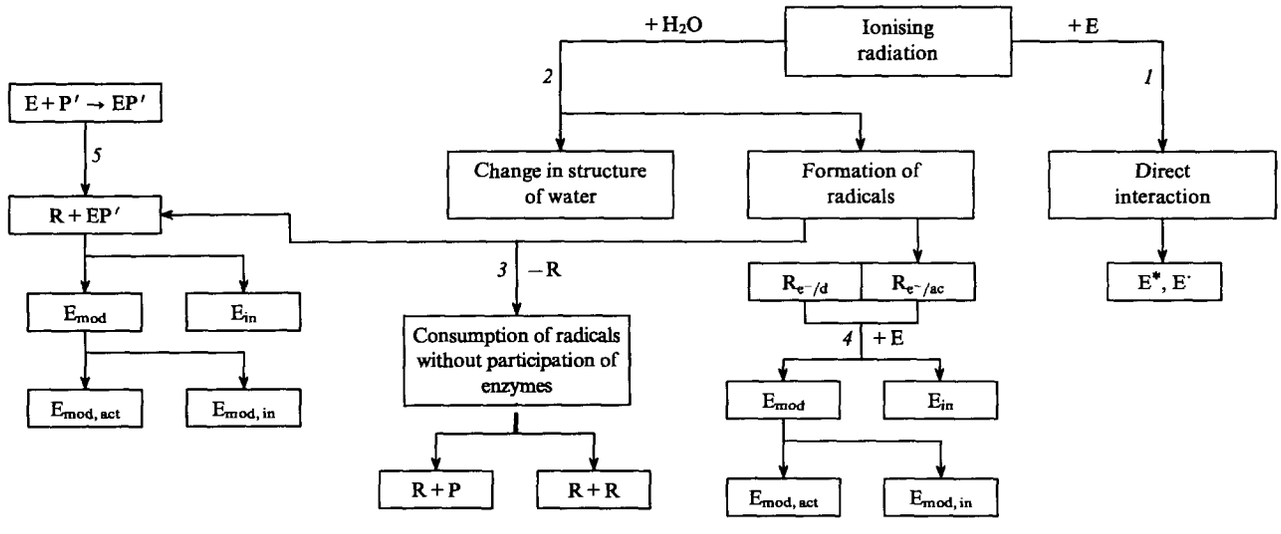

Figure 9. Schematic illustration of the interaction of enzymes with ionising radiation; E = native enzyme, E· = radical fragments of the enzyme molecule, E* = excited enzyme molecules, E_{in} = inactivated enzyme, E_{mod} = enzyme modified in any way, $E_{mod,act}$ = enzyme modified without change in activity, $E_{mod,in}$ = enzyme modified with a change in activity, R = radicals derived from water, $R_{e^-/d}$ = electron-donor radicals, $R_{e^-/ac}$ = electron-acceptor radicals, P and P′ = chemical impurity molecules present in solution.

IV. Application of the method of radiation-induced inactivation of proteolytic enzymes

There are fairly good prospects for the application of the radiation-induced inactivation method. This was partly discussed above.

The oldest and best known application of the radiation-induced inactivation method involves its use in the determination of the molecular masses of biomolecules. The possibility of characterising complex supermolecular formations is of special interest.[18] The application of the method for this purpose has been well developed and has been described in detail.[5,17,18,23,35] It is convenient, reliable, and is fairly widely used.

Medical applications of the results of the study of proteases with the aid of radiation are extremely promising. Immobilised enzymes, which, as stated above, are much more stable than the enzymes in solution, are used in this instance. An important factor is that the action of such materials on the organism is prolonged and requires very low enzyme concentrations.[41-43] Mainly the use of serine proteases, in particular trypsin, has been described. The aim of the preliminary radiation treatment is simultaneous immobilisation and sterilisation virtually without affecting the enzyme activity.

The methods for the generation of half-tone images by exposing protease-containing materials to different types of radiation give rise to extensive possibilities for the creation of dosimetric systems based on them.[40] The sensitivity of such materials can be increased (i.e. the lower limit of the doses determined can be reduced) by altering the material of the support, by introducing additives into the latter, and also by increasing the concentration of the enzymes (the latter is less desirable owing to the increase in the cost of the material and the possibility of partial radiolysis). Apart from purely dosimetric purposes, some of the systems examined[39] can serve as a material which provides an alternative to the X-ray films used in autoradiography and medicine.

In connection with the sharp impairment of the radioecological situation, various biochemical models designed to estimate the degree of risk from ionising radiation simultaneously with the risk from the usual domestic and medical factors (domestic chemistry, fertilisers, pesticides, medicines) have been widely developed in recent years.[8] In addition, another aim of these studies involves the possibility of screening the radioprotectors. In contrast to tests on animals, biochemical models are simpler and yield additional ideas concerning the mechanism of the action of the reagent under certain conditions. Among the models developed, there are also enzyme models, in particular hydrolase models.[9] An attempt was made to use enzyme models in the 1950s, but they proved to be ineffective because of the linear treatment of the results. It was found that the correlation between the effect of radiation on the organism and enzymes is more complex and is associated with the influence of effectors (activators and inhibitors), which leads to a greater or smaller imbalance in the systems of the organism under the influence of ionising radiation or other types of radiation. Figure 10 illustrates the correlation between the constant for the inhibition (K_{in}) of chymotrypsin by certain familiar radioprotectors and the dose characteristic (D_{80}) for which 80% of the enzyme remains active. The type of inhibition (competitive, noncompetitive) does not exert an appreciable influence on the above relation.[90] It must be borne in mind that any compounds used in man's daily life, including food components, medicines, perfumes, etc., may function as effectors. Thus many substances serve as radiomodifying agents, which alter the possible action of any type of radiation. The use of enzyme models may characterise the influence of the radiomodifying agent on a fully defined mechanism of the action of radiation — in particular the protease model yields information about the conformational mechanism.

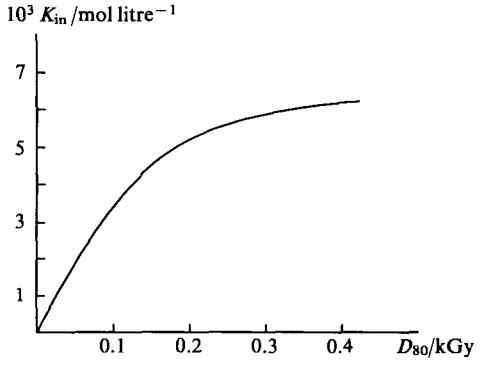

Figure 10. Dependence of the constant for the inhibition of chymotrypsin[90] by radiomodifying agents on D_{80}.

Abstract. Experimental data on the effect of viscosity on the kinetics of elementary chemical reactions of free radicals in solid matrices and viscous solutions are analysed. The dynamic effects in EPR spectroscopy are used for the simultaneous investigation of molecular and chemical dynamics. The intramolecular transformations in free radicals and the spin exchange in biradicals are considered. It is shown that the rates of such intramolecular reactions are controlled by the molecular dynamics of the chemical cage. The bibliography includes 58 references.

I. Introduction

The influence of the viscosity of the medium on the rates of chemical reactions is one of the 'classical' effects in physicochemical kinetics. However, new results, significantly supplementing and modifying the existing ideas, have been obtained in recent years. These ideas refer to diffusion-controlled reactions. If the direct chemical step is rapid, then the rate of a bimolecular reaction is determined by the frequency of the diffusional encounters of the reactants in the 'cage', while the rate of unimolecular decomposition is determined by the frequency of the release of the products from the cage. It has been shown comparatively recently that slow bimolecular reactions, for which the duration of the chemical step is many orders of magnitude greater than the duration of the diffusional approach, can also be controlled by the viscosity of the medium. This can be explained most simply by considering the rotational diffusion of molecules, already involved in an encounter within the cage, as the rate-limiting stage of the process: in this case, the rate of the reaction is proportional to the rotational diffusion coefficient (as in the usual diffusion-controlled processes, the rate is proportional to the translational diffusion coefficient) and is determined unambiguously by the viscosity of the medium.

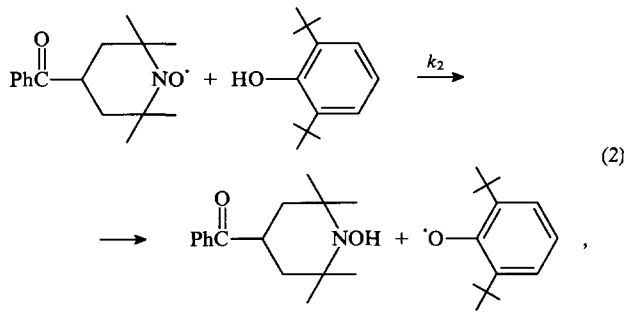
Received 18th January 1993
Uspekhi Khimii **62** (6) 547 – 564 (1993); translated by A K Grzybowski

The influence of the viscosity of the medium on a series of intramolecular processes, which cannot be controlled by rotational mobility, has been observed experimentally in recent years. This necessitates the consideration of the microscopic (at the level of intramolecular dynamics) relation between the viscosity of the medium and the rates of chemical reactions. It was found that the viscosity influences intramolecular processes, which at first sight do not require any intramolecular rearrangements (for example, spin exchange or electron transfer in non-polar media).

The present review is not concerned with 'classical' diffusion-controlled reactions and its subject is only slow bimolecular reactions of free radicals and their intramolecular transformations. As will be shown below, it is precisely in the case of free radicals that the EPR method makes it possible to investigate simultaneously the reaction rates and the molecular mobilities of the reactants, i.e. to compare the frequencies of the molecular motions, whose relation with the viscosity of the medium is evident, with the frequencies of the chemical steps. Attention is concentrated on the analysis of the experimental results obtained in recent years.

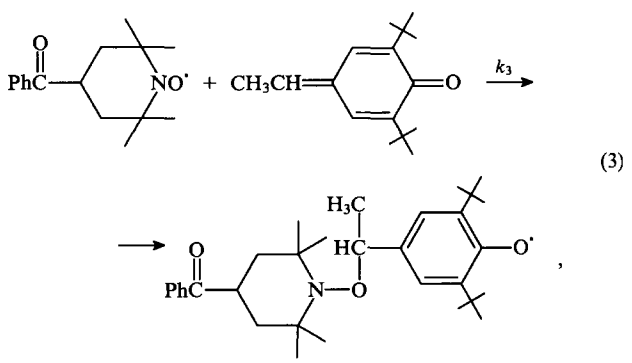
II. The influence of molecular mobility on the kinetics of bimolecular reactions of free radicals



Together with the usual cage effect, consisting in the fact that the relatively immobile species comprising the medium prevent the release of radicals into space, in the case of radical reactions in solid matrices there exists the so called indirect cage effect leading to the retardation of the bimolecular chemical reaction proper.[1] It cannot be explained by diffusional limitations, since the observed bimolecular reaction rate constants are several orders of magnitude lower than the rate constants for the encounters of the reactants. The first effects associated with the influence of the mobility of the medium on the kinetics of slow bimolecular reactions in polymers were observed by Roginskii and coworkers[2–4] and Denisov and coworkers[5–9] The molecular mobility in polymers changed as a result of the change in the external pressure and the plasticisation of the polymer by chemically inert solvents. The interaction of the phenoxyl radical PhO$^{\cdot}$ with a polymeric peroxide, i.e.

$$\mathrm{PhO^{\cdot}} + \mathrm{ROOH} \xrightarrow{k_1} \mathrm{PhOH} + \mathrm{ROO^{\cdot}}, \qquad (1)$$

has been investigated and it has been shown that in polypropylene the reaction is accelerated on plasticisation.[2] The increase in the rate constants k_1 in the polymer is accompanied by a decrease in



the activation energy and in the pre-exponential factor in the Arrhenius equation.

It has been shown[5,8] that the rate constants for bimolecular reactions involving the abstraction of a hydrogen atom by a nitroxyl radical from 2,6-di-*tert*-butylphenol, i.e.

(2)

and the addition of the same radical to the double bond of α-methyl-2,6-di-*tert*-butylmethylenequinone, i.e.

(3)

in plasticised polymers are determined unambiguously by the molecular mobility—the frequency of the rotation of the nitroxyl-radical involved in the reaction.

Another characteristic feature of the radical reactions in polymers is the levelling of the reactivity, i.e. rapid reactions are retarded much more markedly on passing to the solid phase. The levelling is manifested quantitatively by the fact that, for the same chemical reactions (occurring in the kinetic region), the rate constants in the solid phase (k_s) differ much less than those in the liquid phase (k_f) and that the relation $k_s \propto k_f^{1/2}$ holds approximately.[10] If the frequency of the rotation of the spin probe is measured in the same matrices, then the relation $k_s \propto v_c$ is seen to hold in the range of frequencies corresponding to the rotational mobility ($v_c = 10^8 - 10^9\ s^{-1}$). At higher frequencies, this type of relation is not observed.

If one uses indirect data, then the correlation between the rate constant and the mobility of the medium can be found in a much greater number of experiments. For example, a linear relation has been observed[11-13] between $\ln k_s$ and the fraction of the fluctuation volume f. The study of the rotational mobility of spin probes has shown that the same relation holds between $\ln v_c$ and f,[14] so that one may claim that in such cases a correlation is observed between the chemical reaction rate constant and the frequency of molecular reorientations. Data indicating the pressure dependence of k_s and v_c can be compared similarly.[14-16] These relations are of the same type:

$$\ln k_s, \ln v_c \propto -p/c,$$

where p is the pressure and c a coefficient characterising the change in the modulus of bulk compression with increase in pressure. Hence it also follows that $k_s \propto v_c^m$.

Thus the early experiments designed to investigate the influence of molecular mobility on the kinetics of elementary chemical reactions demonstrated the effectiveness of the spin probe method for understanding the kinetics of reactions in polymers.

Bimolecular substitition reactions in solid matrices (inhibition, oxidation chain propagation, etc.) are of special interest to investigators of the structure and stabilisation of polymers.[17] It is then necessary to develop reliable methods for the prediction of reactivities in solid phase reactions, the elementary rate constants of which in the liquid phase are known. It has been shown in relation to the substitution reaction (2)[18] that measurement of the molecular mobility of the spin probe in a solid polymer and the knowledge of the reaction rate constant in the liquid phase k_f make it possible to predict the reaction rate constant in the solid state k_s. The corresponding experimental data can be conveniently represented in the form of the relation between the reciprocal of the rate constant and the correlation time of the rotational mobility $\tau_c = 1/v_c$. For the elementary reactions considered in this review, the above relation can be represented phenomenologically in the following form:

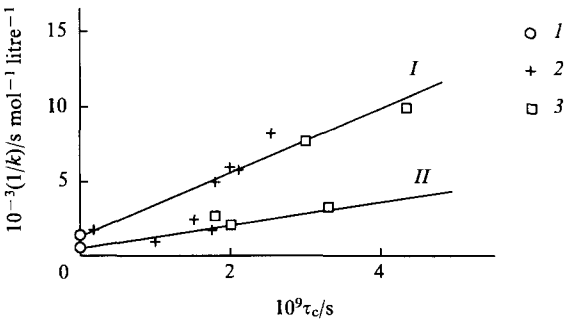
$$\frac{1}{k} = \frac{1}{k_f} + \alpha\tau_c, \qquad (4)$$

where α is an empirical coefficient and k_f the rate constant under the conditions of unlimited molecular mobility ($\tau_c \to 0$), i.e. in a non-viscous solution.

But it is precisely in the case of free radicals that the influence of molecular mobility on the kinetics of elementary chemical reactions can be conveniently investigated from the EPR spectra where one can simultaneously follow the kinetics of chemical reactions and the molecular mobility. The frequency of the motions of the radical which entered into the chemical reaction has been measured for reactions (2) and (3), so one can assume that the parameters τ_c characterise the molecular dynamics of the kinetic cage responsible for the occurrence within it of the elementary reaction (reactants + surrounding molecules of the medium). Fig.1 shows that the variation of the rate constant for reaction (2) can be satisfactorily expressed in a linear form in terms of the variables $1/k$ and τ_c. A similar relation has been observed also for reaction (3), where $1/k_f \simeq 0$, so that the dependence of k on v_c is linear.

Evidently, the characteristics of the kinetics of the elementary chemical reactions examined above are due precisely to the specific features of the phase state of the polymer as a medium with limited molecular mobility. Such features are characteristic also of the elementary chemical reactions in solid matrices and viscous media.[19] It is therefore reasonable to find an analogous experimental approach to the study of the characteristic features of the kinetics of elementary biochemical processes, the most important of which is electron transfer.

The relation between the rate of a chemical reaction and rotational mobility has been investigated[20] for the model reaction



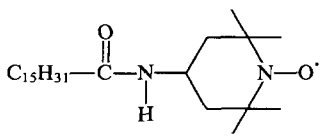


Figure 1. Experimental[7] dependence of the rate constants for the reaction of the nitroxyl radical with phenol on molecular mobility in terms of the variables of Eqn (4): (*1*) benzene; (*2*) polyethylene; (*3*) polypropylene; (*I*) 40 °C; (*II*) 50 °C.

involving the oxidation of the nitroxyl radical by tetranitromethane (TNM). The reaction was carried out in a homogeneous 3:1 water–*tert*-butyl alcohol mixture and in micellar systems based on non-ionogenic surfactants–Tritons X100 and WR1339, the viscous characteristics of which differ greatly. The micellar systems based on the Tritons involve a high degree of molecular organisation and can be regarded as simplified models of biological membranes. The nitroxyl radical

was used as the spin probe. The reaction kinetics were investigated simultaneously in terms of the intensity of the EPR spectrum of the radical.

The radical is used widely in the study of biological membranes and of liposomal and micellar systems. The long hydrophobic hydrocarbon chain of the radical enables it to be thoroughly incorporated in the micelles. In order to determine the location of the nitroxyl radical in the micellar solution, the dependence of the isotropic hyperfine interaction (HFI) constant for the nitrogen nucleus $2A_{iso}$ on the polarity of the medium was employed. It was found that the above quantity in micellar solutions is identical with the value in pure surfactants, which indicates that the radicals are located within the micelles.

The study of the rotational mobility of the nitroxyl radical showed that, on passing from aqueous alcoholic to micellar solutions of Tritons X100 and WR1339 at a constant temperature, the rotation correlation time τ_c increases sharply. It was found that the true rate constant, calculated taking into account the partition coefficient of tetranitromethane between the aqueous phase and the micelles, diminishes appreciably under these conditions. The reaction can be represented by the equations

$$\begin{aligned} R_2NO^{\cdot} + C(NO_2)_4 &\xrightarrow{k} R_2NO^+ + C(NO_2)_3^- + NO_2^{\cdot}, \\ R_2NO^{\cdot} + NO_2^{\cdot} &\xrightarrow{k'} R_2NO^+ + NO_2^-, \end{aligned} \qquad (5)$$

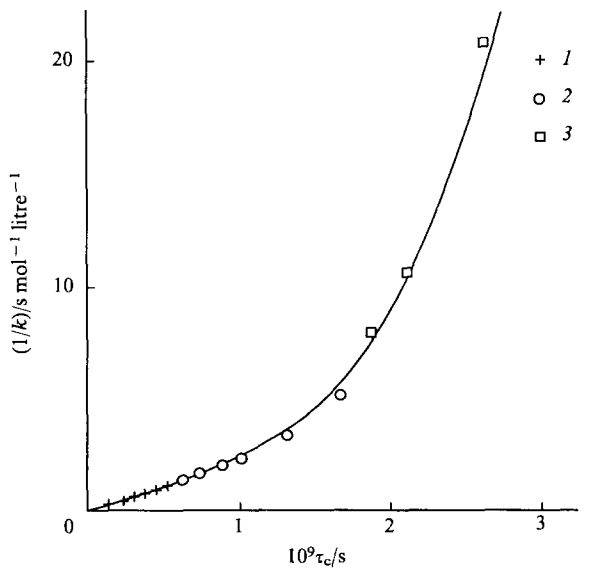

Figure 2. Dependence of the rate constant for reaction (5) on molecular mobility:[20] (*1*) 3:1 water–*tert*-butyl alcohol; (*2*) molecular solution of Triton X100; (*3*) WR1339.

where k is much smaller than k', so that the rate-limiting stage is electron transfer between the nitroxyl radical and the tetranitromethane molecule. Fig. 2 illustrates the dependence of $1/k$ on τ_c. Different values of τ_c at the same temperature are found for the aqueous alcoholic and micellar solutions. In the same medium, the quantity τ_c was varied by varying the temperature in the range 0–50 °C. The non-linearity of the plot in Fig. 2 can be attributed to the temperature dependence of the coefficient α in Eqn (4).

One should note specially that the transition from the homogeneous water–*tert*-butyl alcohol system to micellar systems with molecular organisation is manifested solely by a change in the reorientational mobility of the reactants. In other words, the reactivity is determined unambiguously by the molecular mobility, the measurement of which makes it possible to predict the rates of the elementary reactions even in complex systems such as micellar solutions.

III. The influence of the mobility of the medium on the kinetics of intramolecular radical substitution reactions

We examined above the correlation between the reaction kinetics and the molecular mobility of the reactants for bimolecular processes in which the characteristic reaction time exceeds by several orders of magnitude the characteristic time of rotation of the reactants. The influence of the mobility of the medium on the kinetics of slow bimolecular reactions appears comparatively evident in view of the high stereospecificity of these reactions and the need to assume a favourable mutual orientation of the reactants during the process. The kinetics of such reactions of free radicals have been investigated using the time variation of the intensity of the EPR spectra. The use under these conditions of stable nitroxyl radicals, for which a method of measurement of the rotational mobility correlation time has been well developed, makes it possible to find a relation between the reaction kinetics and the mobility of the medium. The effects associated with the modulation of anisotropic magnetic parameters (HFI constants and the g-factor), which lead to the broadening of the lines, are used to analyse the molecular mobility. In the region of rapid rotations of the radical ($\gamma b_{an}\tau_c \ll 1$, where b_{an} is the parameter of the anisotropy of the EPR spectrum and γ the gyromagnetic ratio for the electron), the line width, which depends on the molecular reorientations, is defined by the relation

$$\delta_m = d\gamma b_{an}^2 \tau_c , \qquad (6)$$

where $d \simeq 1$ is a coefficient. The parameter b_{an} includes the anisotropy of the g-factor and of the HFI constant:

$$b_{an} = H_0 \frac{\Delta g}{g} + \Delta B m , \qquad (7)$$

where H_0 is the external magnetic field, Δg the anisotropy of the g-factor, ΔB the anisotropy of the HFI constant, and m the overall projection of the nuclear spin. The components of the EPR spectrum of the radical with different values of m have different values of b_{an}, so that the degrees of broadening δ_m induced by the rotation of the radical differ for different components of the hyperfine structure.

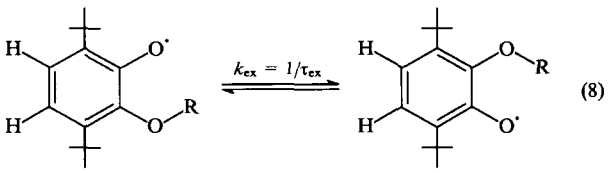
In reality the observed line width Γ_m always includes also an intrinsic width δ_0 which is independent of molecular motions:

$$\Gamma_m = \delta_0 + \delta_m .$$

The contribution to line broadening due to rotation δ_m can be measured provided that $\delta_m > 0.1\delta_0$. The minimum measurable value of τ_c can then be defined thus:

$$\tau_c > 0.1 \frac{\delta}{\gamma d b_{an}^2} .$$

For stable nitroxyl radicals, the anisotropy parameters b_{an} are fairly large and can be measured in the usual 3 cm EPR range. This fact is apparently one of the main reasons for the widescale use of nitroxyl radicals in the study of molecular dynamics — in particular the relation between molecular dynamics and reactivity.



In order to discover this relation, it is essential to extend in experimental measurements the range of the measured rate constants for chemical reactions and to diversify the types of model objects. In particular, the elucidation of the reactivity of phenoxyl radicals in polymers is important in connection with the extensive application of substituted phenols as antioxidants.[21] For example, a purely qualitative correlation between the rate of reaction and the rotation frequency of the phenoxyl radicals in terms of the change in the line form of the EPR spectrum on passing from slow to fast motion has been observed[2] for reaction (1). For the PhO· radical, it is not possible to determine the quantity b_{an} from the EPR spectra in the 3 cm range and it is therefore not possible to obtain the values of τ_c and to compare them with the experimental rate constants, as has been done, for example, for reactions (2), (3), and (5) of nitroxyl radicals.

As 2 mm EPR spectroscopy developed, it became possible to measure the anisotropy parameters for a wide range of organic radicals, in particular, for radicals of the phenoxyl type.[22] This makes it possible to investigate the relation between molecular dynamics and the reactivity of such radicals. Furthermore, they constitute a unique class of free radicals entering into various chemical reactions, the elementary rate constants of which vary within a wide range as a function of the type of reaction and the structure of the radical.[23] In particular, rapid exchange processes, which, like rapid rotational motions of radicals, lead to dynamic effects in the EPR spectra, are characteristic of radicals of this type. However, in contrast to rotational processes, the effects of the chemical line broadening are based on the modulation of the isotropic magnetic parameters of the free radicals.[23] Such effects make it possible to obtain information about the kinetics and thermodynamics of rapid reversible chemical processes occurring with characteristic times $\tau = 1/k = 10^{-9}-10^{-6}$ s. The rotational mobility times τ_c in liquid viscous solutions fall within approximately the same range. This provides a unique possibility, where, by using simultaneously both types of dynamic effects in the EPR spectra of free radicals, one can obtain information under comparable conditions about the kinetics of the elementary chemical reaction and molecular mobility and the characteristic times τ and τ_c have comparable orders of magnitude.

The influence of the mobility of the medium on the kinetics of a series of intramolecular exchange reactions of phenoxyl or *o*-semiquinone radicals, which are intermolecular radical substitution reactions, was first demonstrated in a number of studies.[24-32] The methodological features associated with the corresponding EPR experiments will be examined in greater detail in relation to tin-containing substituted 2-R-oxyphenoxyl radicals. For other systems, we shall discuss only the kinetics of intramolecular reactions in viscous media.

1. EPR study of the molecular and chemical dynamics of free radicals in the 2 mm and 3 cm ranges

The 3,6-di-*tert*-butyl-2-R-oxyphenoxyl radicals were found to be convenient for the simultaneous investigation of the molecular and chemical dynamics of free radicals. A characteristic feature of these phenoxyl radicals is a degenerate tautomerism, which involves the reversible migration of the organoelement fragment R between two oxygen atoms and which constitutes an intramolecular radical substitution reaction.[33]

(8)

The rapid intramolecular migration of the fragment R at high temperatures leads to the equivalence of the two ring protons and a triplet EPR spectrum. At low temperatures, in the absence of chemical exchange the spectrum is represented by a doublet of doublets due to the two non-equivalent protons. In the intermediate temperature range, dynamic effects leading to the exchange broadening of the internal components of the quartet are observed. This makes it possible to find the rate constant or the characteristic time of the chemical exchange $k_{ex} = 1/\tau_{ex}$. We shall consider the possibilities of the EPR method for the simultaneous investigation of the molecular and chemical dynamics of radicals of the type indicated and shall analyse the relation between the quantities τ_{ex} and τ_c.

As noted above, for the calculation of the correlation times of the rotational mobility τ_c it is essential to know the parameters of the anisotropy of the radicals. In the original communications,[24-32] the measured values of τ_c for the radicals are quoted on the basis of rough estimates of the anisotropy parameters derived from poorly resolved 3 cm EPR spectra. The use of 2 mm spectroscopy for a more accurate measurement of the quantity τ_c is extremely important in the quantitative analysis of the influence of molecular mobility on chemical reactivity. The relation between τ_{ex} and τ_c has been investigated[34] with the aid of 2 mm EPR data for tin-containing 3,6-di-*tert*-butyl-2-R-oxyphenoxyl radicals, where R = $SnPh_3$ (**1**) or $SnClMe_2$ (**2**).

Fig. 3*a* presents the EPR spectra of frozen toluene solutions of radical **1** in the 3 cm and 2 mm ranges. Evidently in the former case it is impossible to obtain the anisotropy parameters, while in the latter the canonical components (g_x, g_y, g_z) of the *g*-tensor are manifested quite clearly. Furthermore, the corresponding component B_y of the HFI tensor is manifested in the *y*-orientation. Evidently, the doublet splitting is due to the interaction of the unpaired electron with the aromatic ring proton in the *para*-position relative to the non-coordinated oxygen atom, to which the highest spin density corresponds. The other two components of the HFI tensor (B_x and B_z) were estimated with the aid of computer modelling on the basis of the experimental line widths of the canonical components taking into account the fact that the isotropic HFI constant $a_H^{para} = (B_x + B_y + B_z)/3$ is known from the EPR spectra of the radical in solution. The anisotropy parameters found in this way for radical **1** are

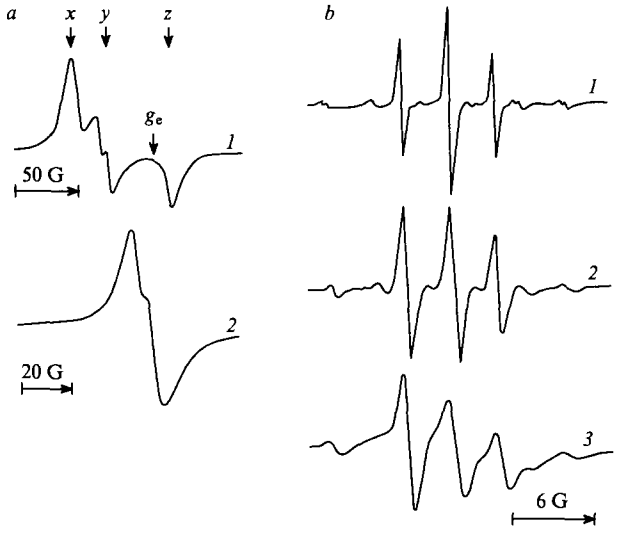


Figure 3. EPR spectra of radical **1**: (*a*) spectra of frozen toluene solutions of the radical in the 2 mm (curve *1*) and 3 cm (curve *2*) ranges; (*b*) spectra in the 3 cm range at 20 °C in the 1:2 (curve *1*) and 1:10 (curve *2*) hexane + liquid paraffin mixtures and in liquid paraffin (curve *3*); the satellite lines are due to the ^{117}Sn and ^{119}Sn isotopes.

as follows:

$$\Delta g_x = 1.88\times10^{-3},\ \Delta g_y = 0.44\times10^{-3},\ \Delta g_z = -2.32\times10^{-3},$$

$$\Delta B_x = 2.6,\ \Delta B_y = -2.6,\ \Delta B_z = 0.0\ \text{G}.$$

The contribution to the line width of the hyperfine structure component with an overall nuclear spin m can be represented in the form[35]

$$\delta_m = \frac{2}{15}\gamma\tau_c \sum_{i=x,y,z}\left(\frac{\Delta g_i H_0}{g} + \Delta B_i m\right)^2.$$

The overall line width for the hyperfine structure component is

$$\Gamma_m = \left(\frac{2}{3}\right)^{1/2}\left[\frac{2}{15}\gamma\tau_c \sum_{i=x,y,z}\left(\frac{\Delta g_i H_0}{g} + \Delta B_i m\right)^2\right] + \delta_0. \qquad (9)$$

It is assumed here that the lines of the hyperfine structure components have the Lorentzian shape and, since the line widths are measured between the points of maximum slope (the first derivative absorption line), it follows that $\Gamma_m = (2/3)^{1/2}(T_2)^{-1}$.

Fig. 3*b* illustrates the EPR spectra of radical **1** in media of different viscosity, which was varied with the aid of hexane–liquid paraffin mixtures having different component ratios. Under the conditions of rapid chemical exchange, the spectrum of this radical remains of the triplet type with a hyperfine structure constant $a = (1/2)\ (a_H^{para} + a_H^{meta})$, but an increase in the viscosity of the medium leads to a non-uniform broadening of the hyperfine structure components corresponding to the overall projection of the nuclear spin $m = -1, 0, +1$. We shall designate the widths of these components by Γ_{-1}, Γ_0, and Γ_{+1} respectively. Since the hyperfine structure constants for the protons in the *para*- and *meta*-positions in the aromatic ring of the radical are negative, the line width Γ_{-1} corresponds to the downfield component ($m = -1$). The following expressions for the line width of the hyperfine structure components can then be obtained from Eqn (9):

$$\Gamma_{-1} = \left(\frac{2}{3}\right)^{1/2}\left[\frac{2}{15}\gamma\tau_c \sum_{i=x,y,z}\left(\frac{\Delta g_i H}{g_0} - \Delta B_i\right)^2\right] + \delta_0,$$

$$\Gamma_0 = \left(\frac{2}{3}\right)^{1/2}\left[\frac{2}{15}\gamma\tau_c \sum_{i=x,y,z}\left(\frac{\Delta g_i H}{g_0}\right)^2\right] + \delta_0, \qquad (10)$$

$$\Gamma_{+1} = \left(\frac{2}{3}\right)^{1/2}\left[\frac{2}{15}\gamma\tau_c \sum_{i=x,y,z}\left(\frac{\Delta g_i H}{g_0} + \Delta B_i\right)^2\right] + \delta_0,$$

where δ_0 is the intrinsic line width and g_0 the isotropic g-factor of the radical.

Measurement of the line width showed that the central component with $m = 0$ is broadened to a much greater extent than predicted by Eqn (10). This is associated with the fact that the contribution to the broadening due to the inhibition of the intramolecular migration of the $SnPh_3$ group in radical **1** must be taken into account for this component. The contribution to the line broadening (only for the component with $m = 0$) due to chemical exchange is defined by the relation[35]

$$\delta_{ex} = \left(\frac{2}{3}\right)^{1/2}\gamma\tau_{ex}\left(\frac{\Delta a^2}{8}\right), \qquad (11)$$

where $\Delta a = a_H^{para} - a_H^{meta}$ is the difference between the hyperfine structure constants due to the protons in the *para*- and *meta*-positions, i.e.

$$\Gamma_0 = \left(\frac{2}{3}\right)^{1/2}\left[\frac{2}{15}\gamma\tau_c \sum_{i=x,y,z}\left(\frac{\Delta g_i H}{g_0}\right)^2\right] + \delta_0 + \delta_{ex}. \qquad (12)$$

The following expressions relating the line widths of the three components to τ_c and τ_{ex} can be obtained from Eqns (10)–(12) taking into account the anisotropies found for the magnetic parameters:

$$\Gamma_{+1} - \Gamma_{-1} = 1.47\gamma\tau_c,$$

$$\Gamma_0 - \Gamma_{-1} = 1.16\gamma\tau_c + 1.39\gamma\tau_{ex}. \qquad (13)$$

The numerical coefficients of τ_c and τ_{ex} have the dimensions G^2.

From the methodological point of view, the measurement of the line amplitude and not the line width is more convenient. The ratios of the integral intensities of the components with $m = -1, 0, +1$ are 1:2:1, i.e. $2I_{-1}\Gamma_{-1}^2 = I_0\Gamma_0^2 = 2I_{+1}\Gamma_{+1}^2$, where I_{-1}, I_0, and I_{+1} are the corresponding amplitudes. In this case, the line amplitudes I_{-1}, I_0, and I_{+1} and the widths of only the downfield component Γ_{-1} must be measured in order to calculate τ_c and τ_{ex}:

$$\left[\left(\frac{I_{-1}}{I_{+1}}\right)^{1/2} - 1\right]\Gamma_{-1} = 1.47\gamma\tau_c,$$

$$\left[\left(\frac{2I_{-1}}{I_0}\right)^{1/2} - 1\right]\Gamma_{-1} = 1.16\gamma\tau_c + 1.39\gamma\tau_{ex}. \qquad (14)$$

Fig. 4 presents the dependence of τ_{ex} on τ_c for radical **1**. The linear correlation $\tau_{ex} = \alpha\tau_c$ is retained, but the coefficient α, which is 3–4 according to the data of Rakhimov et al.,[28] is 0.5–1.0 according to more accurate estimates.[34]

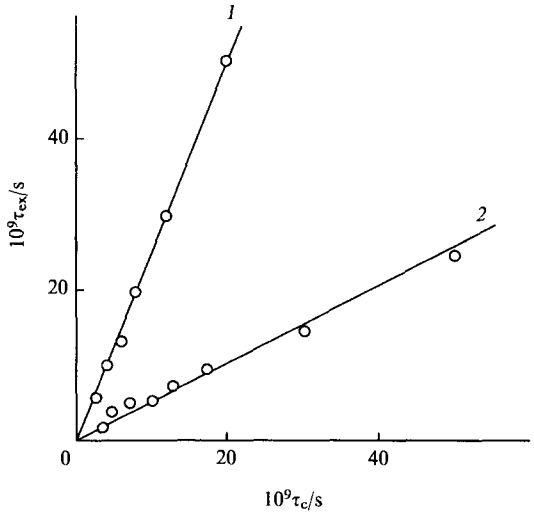

Figure 4. Dependence of τ_{ex} on τ_c for radical **1**: (*1*) according to data of Rakhimov et al.[28]; (*2*) calculation by Eqn (14) from EPR data in the 2 mm range[34] (τ_c was varied by raising the temperature from 0 to 50 °C in liquid paraffin).

The 2 mm EPR spectra of frozen solutions of radicals **1** and **2** are similar, but there is a somewhat different spectral pattern for radical **2**. Under comparable conditions (temperature, viscosity), the frequency of chemical exchange in radical **2** (intramolecular migration of the $SnClMe_2$ group) is smaller by 3–4 orders of magnitude than in radical **1**. As a result of this, the EPR spectra of radical **2** are quartets corresponding to slow and intermediate exchange conditions, where the two inner components of the quartet have undergone exchange broadening (Fig. 5*a*). An increase in the viscosity of the medium lowers the rate of chemical exchange (increases τ_{ex}). As for radical **1**, the extreme components of this spectrum are then non-uniformly broadened, which makes

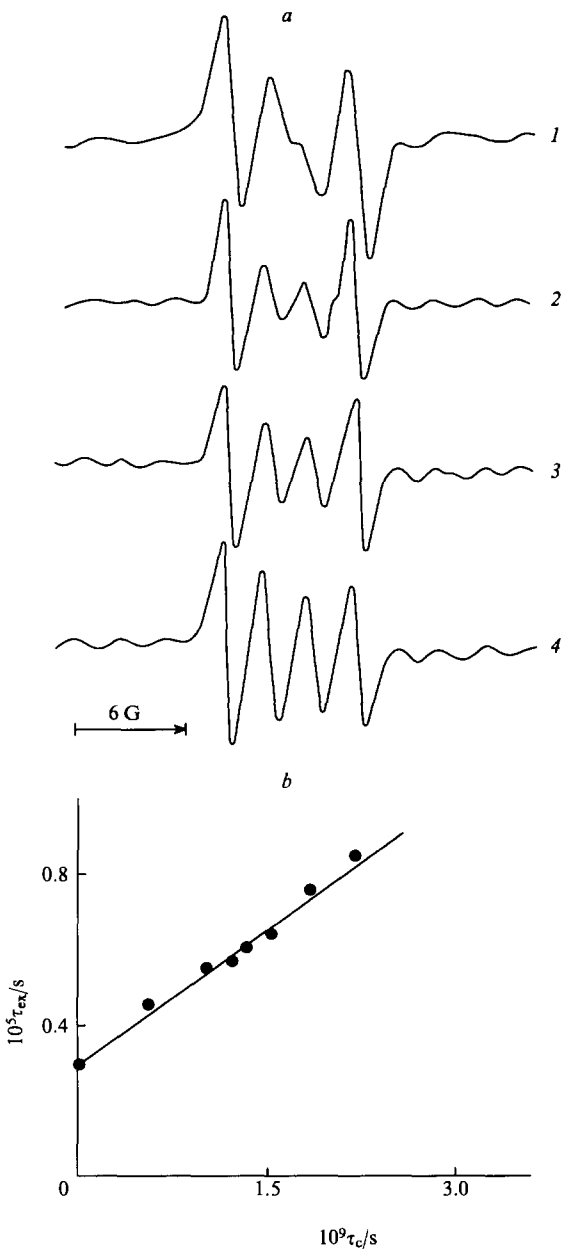

Figure 5. Spectroscopic characteristics of radical **2**: (*a*) EPR spectra in the 3 cm range at 30 °C in hexane (curve *1*), in the 1 : 1 hexane + liquid paraffin mixture (curve *2*), in the 1 : 10 hexane + liquid paraffin mixture (curve *3*), and in liquid paraffin (curve *4*); (*b*) dependence of τ_{ex} on τ_c obtained on varying the viscosity and temperature (from 20 to 30 °C).

it possible to estimate τ_c. The following experimental relation between τ_{ex} and τ_c has been obtained:[29]

$$\tau_{ex} = \tau_f + 8900\tau_c ,$$

where τ_f is the reaction time in a non-viscous medium ($\tau_c \to 0$). The times τ_{ex} and τ_c were found with the aid of the exact values of the anisotropy parameters for radical **2** (Fig. 5*b*). They are described by the relation

$$\tau_{ex} = \tau_f + 2400\tau_c .$$

The intramolecular radical substitution reaction (8) alters the directions of the magnetic axes in space (in particular the *y* axis of radicals **1** and **2** coincides with the axis passing through the C–O· bond involving the non-coordinated oxygen atom[22]). It is therefore impossible to rule out the possibility of the direct influence of chemical exchange on the effects of the modulation of the anisotropy parameters, leading to the broadening of the extreme components of the EPR spectra of radicals of the type considered (with $m = -1, +1$). In the case of radical **2**, the observed correlation between τ_{ex} and τ_c cannot be accounted for by the direct influence of chemical exchange on the measured τ_c, since the characteristic time of the exchange is three orders of magnitude greater than the characteristic time of molecular reorientations.

A completely different situation arises for radical **1**. As shown above, the characteristic times of the chemical exchange and the rotational motions for this radical are comparable ($\tau_{ex} \simeq \tau_c$), so that in the given instance it is necessary to consider the possibility of the direct influence of chemical exchange on the measured τ_c.

In order to elucidate the problem, a quantitative comparison was carried out[36] of the rotational mobilities of radical **1** and the corresponding isomeric radical 3,5-di-*tert*-butyl-2-triphenylstannyloxyphenoxyl **1A**.

Fig. 6 presents the EPR spectra of radicals **1** and **1A** under comparable conditions. In contrast to radical **1**, in radical **1A** there are no intramolecular migrations of the $SnPh_3$ group (because of the difference in the shielding of the oxygen atoms) and its EPR spectrum is a doublet due to the proton in the *meta*-position relative to the non-coordinated oxygen atoms. The non-uniform broadening of the components of the doublet is evidently caused solely by effects associated with the modulation of the anisotropic magnetic parameters of radical **1A** due to rotational motions. The anisotropic parameters of radical **1A** have been found[22] by 2 mm EPR. They make it possible to calculate the times τ_c for a radical in which there is no chemical exchange. The characteristic correlation time for the rotation of a radical without chemical exchange (i.e. radical **1A**) will be designated by τ_c'. Fig. 7 presents the rotation correlation times for radicals **1** (τ_c) and **1A** (τ_c') under comparable conditions. It is essential to note in the first place that the dependence of τ_c on τ_c' is linear: $\tau_c = b\tau_c'$. This means that the linear relation between the characteristic time of the chemical exchange τ_{ex} and the 'true' correlation time of the molecular motions is observed in all cases for radical **1**. In liquid paraffin, in the temperature range from 15 to 50 °C, we have $b = 0.4$, whereas in toluene at appreciably lower temperatures (−100 to −75 °C) we have $b = 0.75$.

Thus the correlation time of the rotational mobility τ_c' of a radical without chemical exchange is greater than that of a radical with chemical exchange. This can be explained by the direct influence of the latter on the measured time τ_c for radical **1**, i.e. if one assumes that τ_c' is the 'true' correlation time of the rotational mobility of the radical, then the measured τ_c for the radical with chemical exchange is reduced compared with τ_c'. Predictably, at high temperatures, where the contribution of chemical exchange increases, the difference between τ_c and τ_c' increases.

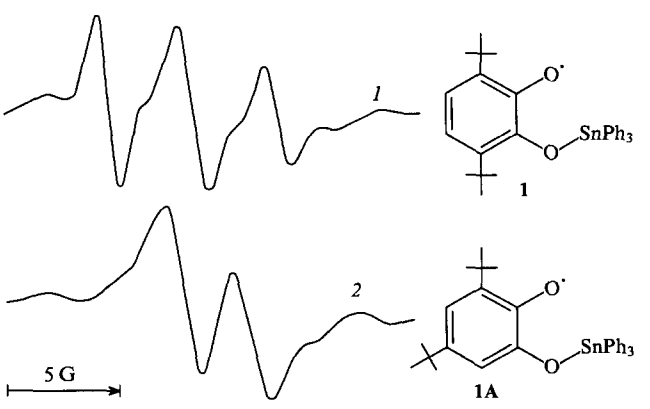

Figure 6. EPR spectra of radicals **1** (curve *1*) and **1A** (curve *2*) in liquid paraffin at 20 °C.

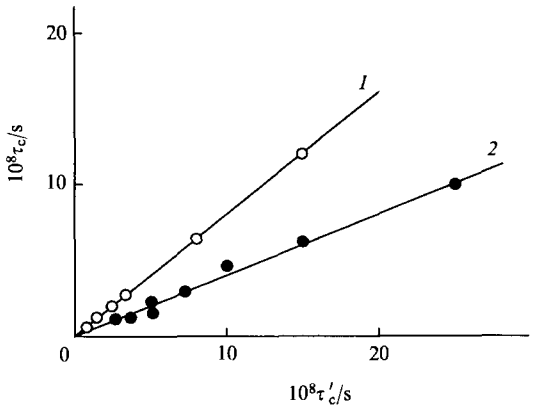

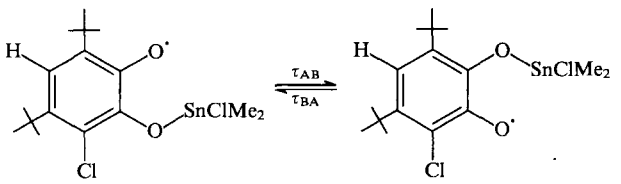

Figure 7. Correlation times of the rotational mobility for radicals **1** and **1A** in toluene for temperatures in the range −100 to −75 °C (line *1*) and in liquid paraffin for temperatures in the range 15 – 20 °C (line *2*).

The examples of the intramolecular reactions of radicals **1** and **2** examined represent chemical exchange between degenerate states (the forward and reverse reactions are identical). In substituted tin-containing oxyphenoxyl radicals with asymmetrically disposed substituents, one may observe reversible intramolecular processes which represent a non-degenerate tautomerism of the free radicals.[37] The influence of the mobility of the medium on the dynamics of the stannotropism of the 3,5-di-*tert*-butyl-2-chlorodimethylstannyloxyphenoxyl radical **3** has been investigated.[30] The chemical exchange process can be represented in this instance in the following form:

3A **3B**

The EPR spectrum of radical **3** in the absence of exchange at low temperatures constitutes a superposition of the spectra of two forms, **3A** and **3B**, differing in the constant for the hyperfine interaction with the aromatic ring proton. In the **A** form, the ring proton is in the *meta*-position relative to the non-coordinated oxygen atom with a_H^A = 2.3 G, whereas in the **B** form the ring proton is in the *para*-position with a_H^B = 4.9 G.[37] For high rates of exchange, an increase in temperature leads to the observation in the EPR spectra of dynamic effects due to transitions between the two forms of radical **3**. The equilibrium constant

$$K = \frac{I_B}{I_A} = \frac{k_{AB}}{k_{BA}} = \frac{\tau_{BA}}{\tau_{AB}}$$

can be determined from the ratio of the integral intensities, and analysis of the line broadening makes it possible to determine the chemical exchange frequency:

$$\nu_{ex} = k_{AB} + k_{BA} = \frac{\tau_{AB}\tau_{BA}}{\tau_{AB} + \tau_{BA}},$$

where $k_{AB} = 1/\tau_{AB}$ and $k_{BA} = 1/\tau_{BA}$ are the rate constants for the forward and reverse reactions respectively. Thus the rate constants for the forward and reverse reactions or the times τ_{AB} and τ_{BA} can be determined separately.

Similar dynamic effects are observed when the viscosity of the medium is varied: the exchange frequency diminishes on passing

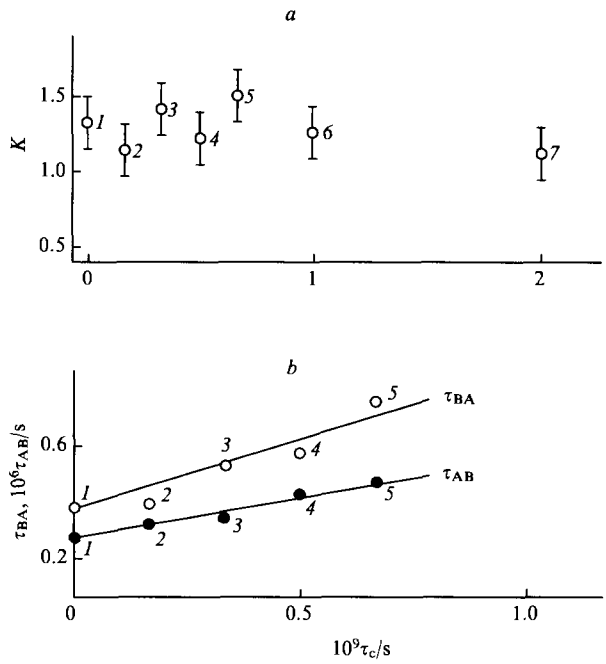

Figure 8. Dependence of the equilibrium constant (*a*) and the characteristic times for the forward (τ_{AB}) and reverse (τ_{BA}) reactions (*b*) on the correlation time of the rotational mobility τ_c at 15 °C: (*1*) hexane; (*2*)–(*6*) 1 : 1 (curve *2*), 1 : 3 (curve *3*), 1 : 5 (curve *4*), 1 : 7 (curve *5*), and 1 : 10 (curve *6*) hexane + liquid paraffin mixtures; (*7*) liquid paraffin; τ_{AB} and τ_{BA} were obtained under the conditions of intermediate exchange; since the spectrum at points *6* and *7* corresponded to slow exchange conditions, τ_{AB} and τ_{BA} were not calculated.

to more viscous media. The rotational mobility correlation time cannot be determined from the EPR spectra of radical **3** because the broadening induced by chemical exchange is much greater than the effects of the modulation of the anisotropic hyperfine interaction. For this reason, the values measured for radical **2** in the same media were adopted as the parameter τ_c. Fig. 8 presents the dependence of the equilibrium constant, τ_{AB}, and τ_{BA} on τ_c. Evidently, a nearly linear relation is observed between the chemical exchange times and the rotational mobility, while the equilibrium constant is independent of molecular mobility within the limits of the accuracy of the measurement.

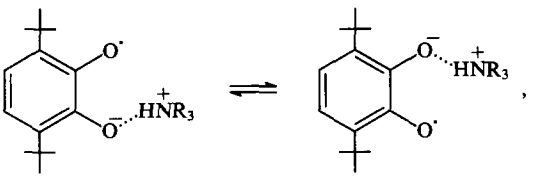
2. Other intramolecular radical substitution reactions

The data presented above indicate a relation between molecular and chemical dynamics also for rapid reversible intramolecular reactions of free radicals. Eqn (4) also holds for such radicals and in the case of unimolecular reactions can be more conveniently expressed in the form

$$\tau = \tau_f + \alpha\tau_c, \qquad (15)$$

where $\tau = 1/k$ and $\tau_f = 1/k_f$.

The influence of molecular mobility on a series of intramolecular radical substitution reactions of type (8) involving other organoelement fragments R in 3,6-di-*tert*-butyl-2-R-oxyphenoxyl radicals, for example, R = ZnAcac (**4**), CdAcac (**5**), ZnS(S)CoBu (**6**), $PbPh_3$ (**7**), H (**8**) $\overset{+}{N}HBu^t_3$ (**9**), and $\overset{+}{N}H_2Bu_2$ (**10**), has been investigated in recent years. Since similar features of the EPR spectra in viscous media (under the conditions of rapid chemical exchange) are characteristic of radicals **4**–**10**, we shall discuss certain phenomenological characteristics of the relation between τ_{ex} and τ_c without going into the details of the EPR experiment.



The study of the elementary reactions in condensed media can be usefully carried out within the framework of a formal-kinetic approach.[19] A characteristic feature of the temperature variations of the rate constants for reactions in condensed media, especially

reactions in the solid phase, is the deviation in certain cases from the Arrhenius relation

$$\ln k = \ln k_0 - \frac{E}{RT}. \quad (16)$$

Furthermore, this deviation is frequently 'masked', being manifested solely by anomalous values of the kinetic parameters—the pre-exponential factor k_0 and the activation energy E. The experimental values of $\ln k_0$ and E for isotypical reactions vary together under these conditions, i.e. the so called compensation effect is observed.[19]

The influence of the mobility of the medium on the kinetics of the intramolecular migration of a hydrogen atom in radical **8** and the kinetics of the migration of the hydrogen bond in the corresponding 3,6-di-*tert*-butyl-*o*-semiquinone radical-anion combined with alkylammonium cations,

where NR_3 = tri-*tert*-butylamine and di-*tert*-butylamine (radicals **9** and **10** respectively) has been investigated.[26]

The corresponding Arrhenius temperature dependences of the times τ_{ex} for media of different viscosity are represented by straight lines, i.e. the chemical reaction time τ_{ex} can be expressed in the form

$$\tau_{ex} = \tau_{ex}^0 \exp\left(\frac{E_{ex}}{RT}\right), \quad (17)$$

where $\tau_{ex}^0 = 1/k_0$ in conformity with Eqn (16) and E_{ex} is the activation energy for the reaction.

Table 1 presents the values of E_{ex} and τ_{ex}^0 for the migration of the hydrogen bond in radical **10** in media of different viscosity. Evidently, with increase in the viscosity of the medium, the quantity E_{ex} diminishes but τ_{ex}^0 increases. Furthermore, similar changes have been observed for a medium of the same composition when the temperature was reduced. Fig. 9 presents the dependence of $\ln \tau_{ex}^0$ on E_{ex}. The linearity of this relation indicates the existence of the compensation effect and the values of E_{ex} and τ_{ex}^0 have therefore no direct physical significance.

The observation of the compensation relation between E_{ex} and τ_{ex}^0 may indicate that the Arrhenius relation in the form of

Table 1. E_{ex} and τ_{ex}^0 for the migration of the hydrogen bond in radical **10** in different media.

Medium[a]	T/°C	E_{ex}/kcal mol^{-1}	τ_{ex}^0/s
LP	5–20	3.5	5.5×10^{-10}
H+LP (1:5)	−10–20	5.5	2.4×10^{-11}
H+LP (1:3)	−10–10	6.3	1.3×10^{-12}
H+LP (1:1)	−10–0	10.7	1.4×10^{-16}
H+LP (1:1)	−60 to −40	2.5	0.8×10^{-9}

[a] H = hexane, LP = liquid paraffin.

Eqn (16) or (17) does not in reality hold. This has been confirmed, in particular, by the temperature variation of τ_{ex} in terms of the Arrhenius variables (Fig. 10). Thus Eqn (17) cannot be used to estimate the elementary rate constants.

Evidently, the sharp change in the kinetic parameters of the reaction is associated with the sharp alteration of the state of the medium (phase or structural transition, etc.). Under these conditions, there is an abrupt change also in the nature of the motion of the radical, i.e. the parallel variation of τ_{ex} and τ_c with temperature is observed (Fig. 10). Consequently, the correlation between the molecular motions and reactivity exists both before and after the phase or structural transition. Despite the fact that the reaction considered is an extremely simple chemical process, occurring in a non-polar medium (hexane + liquid paraffin), the viscosity of the medium exerts a significant influence on its rate. Analysis of the relation between τ_{ex} and τ_c for radical **10** shows that τ_{ex} is approximately two orders of magnitude greater than τ_c. For the intramolecular hydrogen atom transfer reaction in radical **8**, a linear relation is also observed between τ_{ex} and τ_c, but these parameters are similar as regards order of magnitude, so that account must be taken of the possible direct influence of the migration of the hydrogen atom on the measured time τ_c.

A linear relation between τ_{ex} and τ_c for radical **10** is observed when both the temperature and the viscosity of the medium are varied, which can be accounted for by the weak temperature dependence of the coefficient α in Eqn (15). In certain cases, such a relation was observed for radicals of the type considered. As an example, we shall consider the data obtained for radical **7**.

Under conditions where $\tau_c = 0$ (the widths of the lines of the extreme components of the triplet EPR spectrum are identical), the ratios of the amplitudes of the components of the proton hyperfine structure are always 1 : 2 : 1. This means that $\tau_f = 0$, so that the coefficient represents the ratio of the chemical exchange time τ_{ex} and the rotational mobility correlation time τ_c.

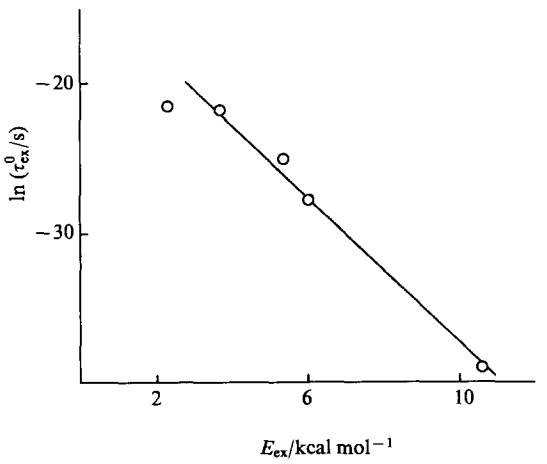


Figure 9. Dependence of $\ln \tau_{ex}^0$ on E_{ex} for radical **10**.

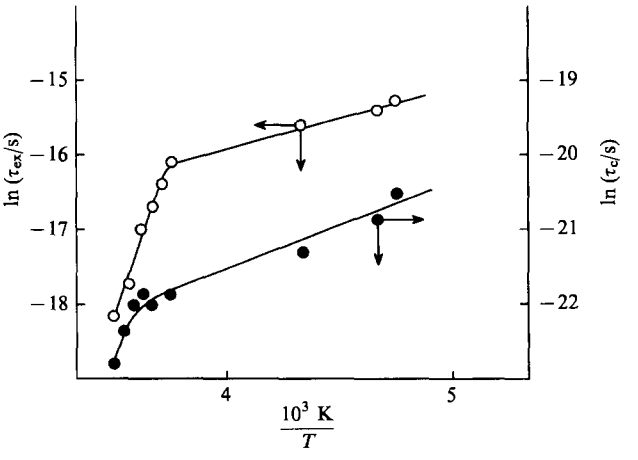

Figure 10. Temperature variation of τ_{ex} and τ_c in terms of the Arrhenius variables for radical **10** in the 1 : 1 hexane + liquid paraffin mixture.

Fig. 11 presents the EPR spectra of radical **7**. Evidently, a decrease in the rate of rotation of the radical leads to the inhibition of the chemical reaction both with increase in the viscosity of the medium and with decrease in temperature. However, comparison of spectra *4* and *5* shows that they correspond approximately to the same value of τ_c for the radical but at a low temperature (−134 °C, pentane) the central line is split, which corresponds to a slow chemical exchange. This means that, for the same value of τ_c, the inequality τ_{ex} (−134 °C) > τ_{ex} (20 °C) holds. This example indicates an increase in the coefficient α with decrease in temperature. Fig. 12 presents the relation between τ_{ex} and τ_c for radical **7**. The variation of τ_c with temperature and composition (viscosity) of the medium leads to a qualitatively different relation between τ_{ex} and τ_c. A satisfactory linear correlation between τ_{ex} and τ_c is observed only for the isothermal variation of the viscosity of the medium. If τ_c varies when the temperature is varied over a wide range, the relation between τ_{ex} and τ_c becomes non-linear and, as was to be expected, a decrease in temperature not only reduces the molecular mobility but also retards the chemical reaction proper, so that the relation between τ_{ex} and τ_c becomes steeper.

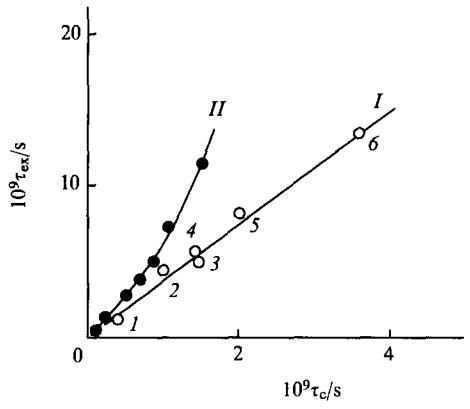

Figure 12. Dependence of τ_{ex} on τ_c for radical **7**: (*I*) variation of the composition of the medium at 20 °C with the aid of 1 : 1 (curve *1*), 1 : 3 (curve *2*), 1 : 5 (curve *3*), 1 : 7 (curve *4*), and 1 : 10 (curve *5*) heptane + liquid paraffin mixtures; (*6*) liquid paraffin; (*II*) variation of temperature in the range −85 to −20 °C in heptane.

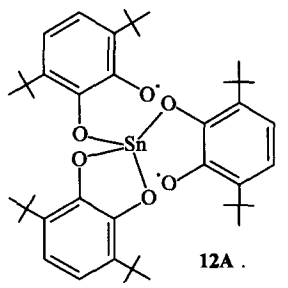
Hitherto we have considered the intramolecular radical substitution reactions in which the centre corresponding to the location of the unpaired electron changed as a result of the intramolecular transfer of an atom or group of atoms (exchange of the unpaired electron and of the bond within one ligand). Another type of intramolecular chemical exchange reactions may be observed for radical complexes of metals with two and three ligands between which the unpaired electron is exchanged (interligand exchange).

A similar interligand exchange of the unpaired electron (and charge) has been observed[38,39] by the EPR method in the radical-anion complexes of zinc and tin.



At low temperatures, the unpaired electron is located on one ligand, which leads to a triplet EPR spectrum determined by the hyperfine interaction with two equivalent protons (within one ligand, the unpaired electron either migrates rapidly between two oxygen atoms or is distributed symmetrically). At high temperatures, the unpaired electron migrates around all the ligands and the EPR spectra show splitting due to all the ligand protons (four protons in complex **11** and six protons in complex **12**). In the intermediate temperature range, the alternation of line widths is observed. Its analysis makes it possible to determine τ_{ex}. Specific line broadening, due to the effects of the modulation of the anisotropic magnetic parameters, has not been observed in the EPR spectra of the radical-anion complexes. This may be associated with the absence of an appreciable anisotropy of the

g-factor and the HFI constant. Therefore, the EPR spectra of the corresponding biradicals have been used[31] to determine τ_c:

11A

12A .

The EPR spectra of biradicals **11A** and **12A** in solution consist of broad singlet lines. In order to determine the rotation correlation time τ_c from the line width in the EPR spectra of the biradicals, the following formula must be used:[35]

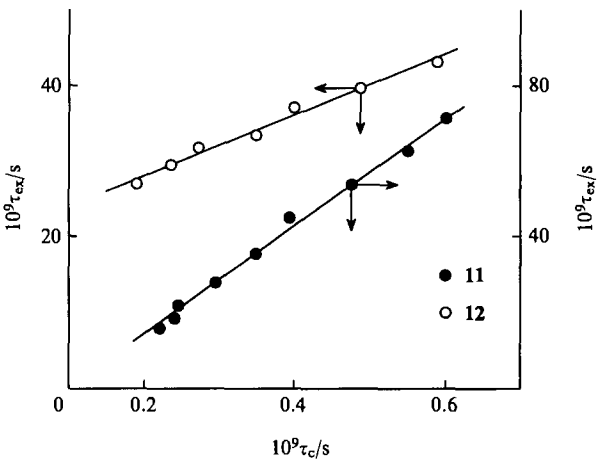
$$T_2^{-1} = \frac{D^2}{20}\left(6\tau_c + \frac{10\tau_c}{1+\omega^2\tau_c^2} + \frac{4\tau_c}{1+\Delta\omega^2\tau_c^2}\right), \qquad (18)$$

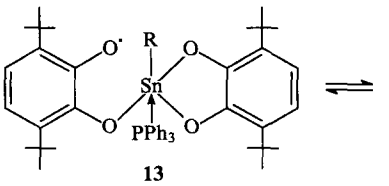
where $D^2 = D_x^2 + D_y^2 + D_z^2$, D_x, D_y, and D_z being the principal values of the dipole–dipole interaction tensor in units of frequency. In our case, $\tau_c \simeq 10^{-9}$ s, so that $\omega\tau_c \gg 1$ and one need retain only the first term in Eqn (18). Having expressed D_x, D_y, and D_z in magnetic induction units, we obtain

$$\tau_c = \frac{5\delta H}{\sqrt{3}\gamma D^2},$$

where δH is the EPR line width of the biradical measured between points of maximum slope.

Fig. 13 presents the EPR spectra of the radical-anion complex **12** and the corresponding biradical **12A**. Evidently, with increase in rotational correlation time (with increase in the line width of the biradical in the EPR spectrum), the chemical exchange time τ_{ex} also increases (broadening of the components of the hyperfine structure with $m = \pm 2, \pm 1$). The relation between τ_{ex} and τ_c for the radical-anionic complexes **11** and **12** is described satisfactorily by Eqn (15). The times τ_{ex} and τ_c were measured in the temperature range -50 to 0 °C in solution in tetrahydrofuran (THF), the temperature variation of τ_{ex} and τ_c satisfying the Arrhenius relation. The kinetic parameters of the chemical exchange and of the rotational mobility for the radical-anionic complex **11** and biradical **11A** were found to be as follows: $E_{ex} = 4.5$ kcal mol^{-1}, $\tau_{ex}^0 = 3.9 \times 10^{-12}$ s, $E_c = 4.0$ kcal mol^{-1}, and $\tau_c^0 = 1.1 \times 10^{-13}$ s; for complexes **12** and **12A**, the corresponding parameters are $E_{ex} = 1.9$ kcal mol^{-1}, $\tau_{ex}^0 = 7.0 \times 10^{-10}$ s, $E_c = 4.6$ kcal mol^{-1}, and $\tau_c^0 = 2.5 \times 10^{-14}$ s (the accuracy of the determination of E_{ex} and E_c is to within 0.3 kcal mol^{-1}). We may note that the quantities E_c for biradicals **11A** and **12A** are actually identical, i.e. under comparable conditions τ_c (**11A**) = $b\tau_c$ (**12A**), where $b = 4$, which confirms the correlation between the rotation frequencies of probe radicals of different types in the same matrix. The quantities E_{ex} and E_c for radicals **11** and **11A** are similar and this is consistent with the observed relation between τ_{ex} and τ_c. For the radical-anionic complex **12**, the quantity E_{ex} is appreciably smaller than E_c, but τ_{ex}^0 is four orders of magnitude greater than τ_c^0. Here we are again dealing with the compensation effect, so that there is no point in discussing the absolute values of E and τ^0 but the correlation (15) nevertheless holds under these conditions.





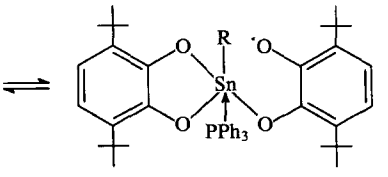


Figure 14. Correlation between τ_{ex} and τ_c for the radical-anionic complexes **11** and **12**.

Subsequently, it was possible to observe a relation between τ_{ex} and τ_c for interligand exchange under conditions where τ_c was varied by varying both the temperature and the viscosity of the medium. The correlation between the rotational mobility and the dynamics of the interligand exchange of the unpaired electron and the bond in radical **13** (R = 3,6-di-*tert*-butyl-2-R-oxyphenoxyl) has been investigated.[32]

13

It follows from the analysis of the EPR spectra of this radical that an increase in the viscosity of the medium leads to a broadening of the components with $m = -1$ and $+1$, i.e. the rate of the interligand exchange diminishes. This is also accompanied by a non-uniform broadening of the extreme

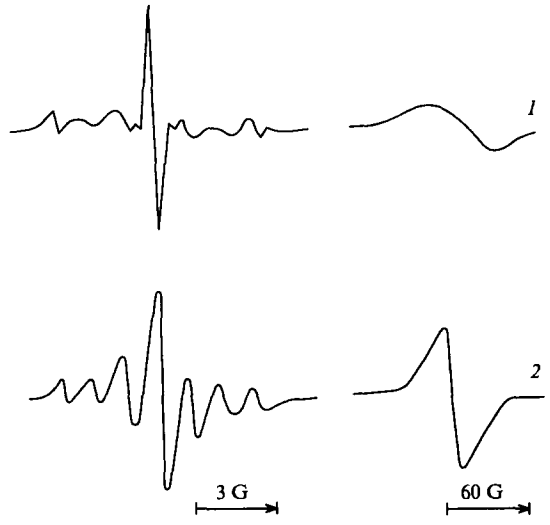

Figure 13. EPR spectra of complex **12** and the biradical **12A** in THF at different temperatures (°C): (*1*) -50; (*2*) 0.

components of the hyperfine structure, which made it possible to estimate also τ_c for radical **13** at the same time. When τ_c is varied by varying the composition of the medium over a comparatively narrow temperature range (0–20 °C), τ_f and α are respectively 0 and 8. When τ_c is varied over a wide temperature range (−90 to 0 °C), the coefficient α becomes 25. Extrapolation of the corresponding straight line to $\tau_c = 0$ yields a negative value of τ_f, which means that the function of τ_{ex} in terms of τ_c is in fact non-linear in this case owing to the temperature dependence of α.

3. Molecular mobility and chemical reactivity. Interpretation of the experimental results

Table 2 presents the parameters of the phenomenological equation (15) for radicals **1**–**13**. For radicals **4**–**10** and **13**, the times τ_c were calculated on the assumption that the EPR spectra of frozen solutions of the radicals are axially symmetrical and that the parameters of the anisotropy are ~1 G, so that the parameters α for these radicals may differ according to the revised data for radicals **1** and **2**, but these differences do not exceed one order of magnitude.

Table 2. Parameters of Eqn (15) for intramolecular radical substitution reactions.

Radical	$10^9\tau_f$/s	α	T/°C	Medium	Ref.
1	0	0.5–1	0–50	LP	34
2	3000	2400	20–30	H + LP	34
3A	400	600	15	H + LP	30
3B	300	300	15	H + LP	30
4, 5	0	7–8	−90 to −10	Toluene	24
6	0.03	0.6–1	0–20	H + LP	24
7	0	4	20	Heptane + LP	27
8	0.8	1	20	H + LP	26
9	0	240	−60–20	H + LP	26
10	0	230	−60–20	H + LP	26
11	0	160	−50–0	THF	31
12	20	40	−50–0	THF	31
13	0	8	0–20	Toluene + LP	29
13	<0	25	−90–0	Toluene	29

Evidently, the phenomenological relation (4), found for the bimolecular reactions (2), (3) and (5) of nitroxyl radicals, may lead to Eqn (15) if the characteristic time of bimolecular reactions $\tau_r \sim 1/k$ is used as the kinetic parameter. The kinetics of these reactions were investigated by measuring the decrease in the intensity of the EPR spectra of the reacting radicals as a function of time under conditions where the initial concentration of free radicals was much lower than the concentration [M] of the molecules with which the free radicals reacted, so that the reaction occurred in a pseudo-unimolecular regime and its characteristic time was $\tau_r = \{k[M]\}^{-1}$.

For the bimolecular reactions considered, the experimental rate constants k are in the range 10^{-4}–10 litre mol^{-1} s^{-1}, which is 10–15 orders of magnitude lower than the rate constants for diffusion-controlled reactions (10^{10}–10^{11} litre mol^{-1} s^{-1}). This actually means that the reaction proceeds in a radical–molecule contact pair R$^{\cdot}$...M surrounded by the molecules of the medium. The time τ_r can therefore be regarded as an analogue of τ_{ex} despite the fact that an electron or an atom is transferred between a radical and a molecule. A table of the parameters α and τ_f for bimolecular reactions was compiled on the basis of experimental data obtained for reactions (2), (3), and (5) (Table 3). The approximate relation[19]

$$\tau_{ex} = \frac{v^*}{k},$$

where v^* is the volume of the cage (usually ~5 litres mol^{-1}), was used.

Table 3. Parameters of Eqn (15) for bimolecular reactions.

Reaction	τ_f/s	α	T/°C	Medium	Ref.
(2)	10^3	10^{13}	40	Polypropylene (or polyethylene) + + benzene	7
(3)	$\ll 10^3$	10^5	28.5	Ditto	8
(5)	0	10^{10}	0–50	Water + *tert*-butyl alcohol (3 : 1)	20
(5)	0	$3\cdot10^{10}$	0–50	Triton X 100 (micellar solution)	20

Thus the EPR method is extremely effective in the study of the characteristic features of the kinetics of elementary reactions in viscous media. The results obtained hitherto have demonstrated convincingly the existence of a relation between molecular mobility (characterised by the time τ_c) and reactivity (characterised by the times τ_{ex} and τ_r) both for rapid intramolecular reversible reactions and for slow intermolecular irreversible chemical processes. In this connection, it becomes necessary to develop a general approach to an adequate explanation of Eqn (15) and an interpretation of experimental parameters of this relation.

Evidently, the classical theory of diffusion-controlled reactions as well as the transition state theory are unsuitable even for a qualitative explanation of the results. The existing models of the elementary chemical reactions in condensed media have been surveyed[19] and it was shown that some of them can be resorted to in order to account for the relation between the elementary rate constants for chemical reactions and the frequencies of molecular motions. One of such models is the Kramers model[14] in which the elementary chemical step is regarded as diffusional passage through the potential barrier in a viscous medium. The familiar expression for the chemical reaction rate constant, valid in a non-viscous medium, i.e.

$$\frac{1}{\tau_f} = \nu_0 \exp\left(-\frac{E}{RT}\right),$$

then assumes the following form for viscous solutions:

$$\frac{1}{\tau_r} = \frac{\beta}{\eta}\exp\left(-\frac{E}{RT}\right),$$

where η is the kinematic viscosity of the solvent and β is a parameter which depends on the frequency of the zero-point vibrations and the size of the reacting molecules.

Since $\tau_c \propto \eta$, the following expression can be obtained for the characteristic time of a chemical reaction:

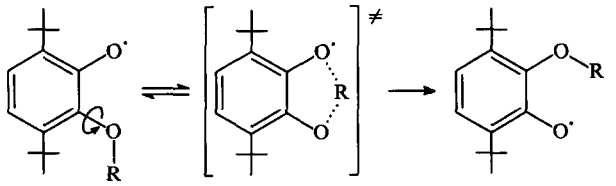
$$\tau_r = b\tau_c \exp\left(\frac{E}{RT}\right).$$

Thus the Kramers model predicts qualitatively a linear correlation between τ_r (or τ_{ex}) and τ_c. The question arises to what extent this model is suitable for a quantitative (within the limits of an order of magnitude) interpretation of experimental results. Evidently, if $E = 0$, $\tau_r \simeq \tau_c$, and $b \simeq 1$ (in reality this coefficient can vary from 0.1 to 10), we have

$$\tau_r = \tau_c \exp\left(\frac{E}{RT}\right). \qquad (19)$$

In order to test this relation, use may be made of experimental results obtained, for example, for radical **2** (Fig. 5). The chemical line broadening effects for this radical are observed also in the limit of rapid molecular reorientations ($\tau_c \to 0$), so that $\tau_{ex} = \tau_f$ and it is possible to investigate the temperature variation of the chemical reaction time in the limit corresponding to the

unrestricted chemical mobility.[29] It was then found that the temperature variation of τ_f is described satisfactorily by the Arrhenius law:



$$\tau_f = \tau_f^0 \exp\left(\frac{E_f}{RT}\right),$$

with $\tau_f^0 = 0.8 \times 10^{-13}$ s and $E_f^0 = E = 10.6$ kcal mol^{-1}. The normal value of the pre-exponential factor τ_f^0 permits the conclusion that the activation energy obtained is close to the true value.[19] Estimation of the ratio τ_{ex}/τ_c at 300 K by Eqn (19) yields $\sim 10^7$. However, it follows from the analysis of the spectroscopic characteristics that $\tau_{ex}/\tau_c \simeq 10^3 - 10^4$ (Fig. 5).

The Kramers model cannot explain also the insignificant difference between the rate constants for chemical reactions at different temperatures, which is reflected by the weak temperature dependence of the coefficient α (Table 2). This model also fails to explain the effect involving the levelling of reactivity observed for a series of bimolecular reactions in viscous media.[10]

A later theory of the electron transfer reactions in condensed media, developed by Marcus,[40] also includes the molecular mobility correlation time in the final expression for the rate constant, but this model deals only with electron transfer reactions in polar media, whereas the present review is concerned with purely homolytic processes in non-polar media. Nevertheless, one can adopt the principal idea of this theory, according to which a reorganisation of solvent molecules is essential for the occurrence of the elementary chemical step. This approach was used subsequently to devise a more general model of the indirect cage effect.[18] The principal idea underlying the model is that, even in the case of homolytic reactions in a non-polar medium, a change in the positions of the atoms and groups in the molecules surrounding the reactants is necessary for the formation of the transition state. Such molecular displacements can be characterised by the correlation time τ_c.

We shall assume that the elementary chemical reaction in a viscous medium proceeds via an intermediate metastable state which corresponds to the structure of the activated complex in a non-viscous medium (free space) but is attained via an additional energy barrier E_c associated with the necessity to reorganise the cages. For the intramolecular radical substitution reactions considered, this scheme can be represented in the form

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A^* \xrightarrow{k_2} A,$$

where A* corresponds to a symmetrical disposition of the organoelement fragment R between two oxygen atoms. This structure of the radical arises as a consequence of the internal rotation about the C–O bond characterised by the barrier E_c. Evidently, the activation energy for the chemical reaction proper E_f corresponds to the barrier to the displacement of the fragment R between two oxygen atoms in the symmetrical structure, which must be overcome regardless of whether the radical is in a dense environment comprising the solvent molecules or in free space. In terms of the approximation of the method of stationary concentrations of A*, the following expression can be obtained for the rate constant:

$$\frac{1}{\tau_r} = k = k_2 \frac{k_1}{k_{-1}(1 + k_2/k_{-1})}.$$

The barrier E_c can be estimated, by a procedure similar to that used by Marcus,[40] as the height of the point of intersection of two parabolic curves. Then

$$E_c = \frac{(E_r + E_f)^2}{4E_r},$$

where E_r is the cage reorganisation energy.[18] Usually $E_f < E_r$ and one can therefore assume that

$$E_c \simeq \frac{E_r}{4} + \frac{E_f}{2}.$$

If $E_f \to 0$, the rate constant corresponds to the frequency of rotational motions, so that

$$\frac{1}{\tau_c} = \nu_0 \exp\left(\frac{E_r}{4RT}\right).$$

The rate constant for the chemical reaction in free space is given by

$$k_f = \frac{1}{\tau_f} = \nu_0 \exp\left(-\frac{E_f}{RT}\right),$$

where ν_0 is the universal pre-exponential factor.

The quantity

$$\frac{1}{\tau_{ex}} = \frac{k_f}{1 + (\nu_0 k_f)^{1/2}\tau_c} \tag{20}$$

or

$$\tau_{ex} = \tau_f + (\nu_0 \tau_f)^{1/2}\tau_c \tag{21}$$

may be found from the equations obtained above.[18] Eqn (21) corresponds exactly to the phenomenological Eqn (15), where

$$\alpha = (\nu_0 \tau_f)^{1/2} = \exp\left(\frac{E_f}{2RT}\right).$$

The model considered predicts, like the Kramers model, a non-linear relation between τ_{ex} and τ_c, but in the case of highly viscous media [i.e. for $\tau_c \gg (\tau_f/\nu_0)^{1/2}$] we obtain, in contrast to Eqn (19), the expression

$$\tau_{ex} = \tau_c \exp\left(\frac{E_f}{2RT}\right), \tag{22}$$

i.e. the model of the indirect cage effect explains the experimental values of τ_{ex}/τ_c, the levelling of reactivity, and the weak temperature dependence of the coefficient α. The energies E_f may be found from the experimental relations between τ_{ex} and τ_c under conditions where the temperature is varied over a wide range.[27, 28]

Thus, despite its approximate nature, the model of the 'reorganisation of the cage' examined above is satisfactorily consistent with the phenomenological relation (15). The experimental relations therefore make it possible to estimate chemical reactivity from molecular mobility data.

IV. Conformational transitions in free radicals. Relation between intramolecular mobility and the mobility of the medium

The rotational mobility correlation time τ_c is not the only parameter characterising molecular mobility. The molecular motions of radicals, leading to the averaging of the magnetic anisotropy, can differ from the motions responsible for the occurrence of the elementary chemical step. The measured quantity τ_c is evidently averaged over different types of motions of the spin probe (the motions around different molecular axes,

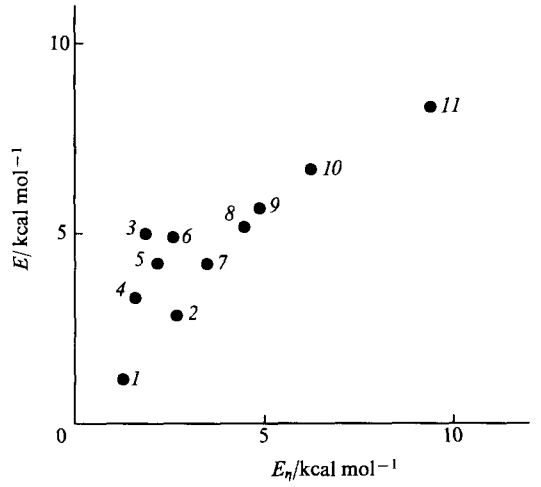


Figure 15. Relation between the activation energy for intramolecular rotations in radical **14** and the activation energy for the viscous flow of the solvent E_η (according to data of Jonkman and Kommandeur[42]): (*1*) carbon disulphide; (*2*) tetrachloroethylene; (*3*) mesitylene; (*4*) n-hexane; (*5*) n-octane; (*6*) n-decane; (*7*) ethanol; (*8*) 1-propanol; (*9*) 1-butanol; (*10*) 1-octanol; (*11*) cyclohexanol.

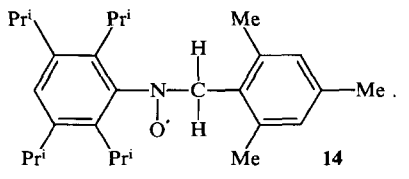
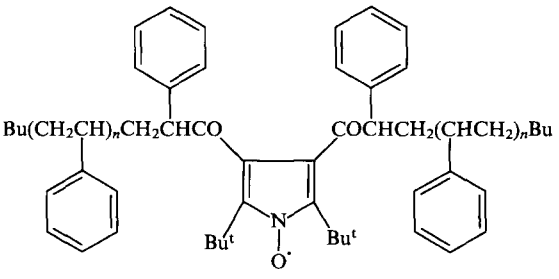


rotation of individual groups in the radical, molecular shifts responsible for the relaxation of the cage, etc.). A correction term must therefore be introduced into the expression for the coefficient α in Eqn (15):

$$\alpha = \alpha_0 \exp\left(\frac{E_f}{2RT}\right). \qquad (23)$$

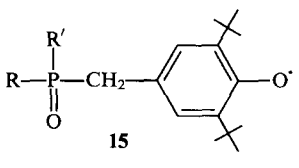
The coefficient α_0 takes into account the correspondence between the molecular motions the average correlation time of which is measured experimentally and the motions leading to the occurrence of the reaction. For this reason, the parameter α_0 may be regarded as the ratio of the frequencies of the molecular motions along the reaction coordinate and the motions leading to the modulation of the anisotropic magnetic interactions of the probe radical. The necessity to take into account the coefficient α_0 in Eqns (4) and (15) makes it necessary to accumulate data on the molecular mobilities of the spin probes and on the relation between molecular motions of different types.

As a result of the development of 2 mm EPR spectroscopy, it has been possible to determine separately the characteristic frequencies of the rotation about different molecular axes for a series of nitroxyl radicals.[41] It was found that the ratio of the rotation correlation times depends only slightly on their absolute values, i.e. is independent of the viscosity of the medium.



Analysis of the available literature data on intramolecular mobility or dynamics of conformational transitions has shown that these processes are also controlled by the molecular dynamics of the medium. As an example, one may consider a nitroxyl radical with the following structure:

14



The EPR spectra of radical **14** indicate the intramolecular rotation of the benzyl group, which is manifested in the HFI modulation due to the two β-protons of this group.[42] Analysis of the line width led to the estimation of the kinetic parameters of the intramolecular rotation and it was shown that the activation energy for the intramolecular motion depends on the viscosity of the solvent. Fig. 15 presents the kinetic parameters of the intramolecular motions in radical **14** . Evidently, there exists a definite relation between the activation energies for the intramolecular motions and the solvent viscosity. The study of the dynamics of the reorientation motions of the spin probes in polymers has also shown that the activation energies for the rotation of radicals are close to the activation energy for segmental motions determined by the NMR method,[43, 44] but the rotation frequencies of the radicals are 2–3 orders of magnitude greater than the frequencies of the segmental motions. Thus a linear correlation of the type $\tau = \alpha\tau_c$, where $\alpha \sim 10^2 - 10^3$, also exists for these motions.

The dynamics of the conformational transitions in a spin-labelled molecule has been investigated[45] by the EPR method. It was found that the experimental results are described satisfactorily within the framework of the Kramers model.

In a study[46] of the relaxation-induced changes in the EPR spectra of a spin-labelled polyvinylpyridine, it was possible to characterise separately the motions of the macromolecule as a whole and the relative motions of the nitroxyl label, i.e. intramolecular motions. In the frequency range $10^8 - 10^9$ s^{-1}, these motions are characterised by the same activation energy, i.e. the mobility is determined in both cases by the solvent viscosity near the boundary of the macromolecule. In other words, the molecular mobility of the reactants (rotational, translational, conformational, etc.) is fully determined by the dynamic properties of the kinetic cage as a whole, including the molecules of the surrounding medium.

The examples considered above, indicating a relation between molecular motions of different types, were based on the parallel temperature variation of the frequencies of these motions. It has been shown[47] that the mobility of the medium exerts a direct influence on the dynamics of intramolecular rotational transitions in phosphorus-containing phenoxyl radicals having the following structure:

15

where R = R′ = Ph, R = Ph and R′ = EtO, or R = R′ = EtO.

The hyperfine interaction of the unpaired electron with the ^{31}P nucleus, the two equivalent protons of the CH_2 group in the *para*-substituent, and the two equivalent protons in the *meta*-positions in the aromatic ring is manifested in the EPR spectra of radicals **15** at high temperatures. As the temperature is reduced, the EPR spectra of radicals **15** exhibit a broadening of the central component of the triplet due to the protons of the CH_2 group of the *para*-substituent. At lower temperatures, these protons become non-equivalent. Such changes in the spectra are fully reversible as the temperature is varied, which indicates the occurrence of intramolecular processes in radical **15** owing to the

hindered rotation of the *para*-substituent around the C–C bond relative to the plane of the aromatic ring. In radicals of this type, the hyperfine interaction with the nuclei of the *para*-substituent takes place via a hyperconjugation mechanism[23] and the HFI constants are described by the relation

$$a = \rho_c^{\pi}(B_0 + B_2 \cos^2 \Theta) ,$$

where B_0 and B_2 are parameters which are respectively 0 and 43.5 G for the protons and 62 and 136 G for phosphorus,[48] $\rho_c^{\pi} = 0.4$ is the spin density in the *para*-position in the phenoxyl radical,[23] and Θ is the angle between the p orbital of the carbon atom in the *para*-position in the aromatic ring and the direction of the C–H or C–P bond. The difference between the HFI constants of the protons of the CH_2 group in the *para*-substituent at low temperatures is due to the difference between the angles Θ for these protons. Analysis of the line width makes it possible to find the characteristic time τ of the intramolecular transitions.

Fig. 16 presents the EPR spectra of radical **15** at the same temperature but in solutions of different viscosity (the viscosity was varied by adding liquid paraffin to toluene). Evidently, the increase in the viscosity of the medium entails a broadening of the central component of the triplets due to the protons of the CH_2 group, which indicates the inhibition of the intramolecular transitions. With increase in the viscosity of the medium, a non-uniform broadening of the components with a hyperfine structure, in particular the components due to the hyperfine interaction with the ^{31}P nucleus, also occurs. If one uses the anisotropic magnetic parameters of radical **15**, this makes it possible to determine the average rotational correlation time τ_c characterising the rotation of the radical as a whole.[47]

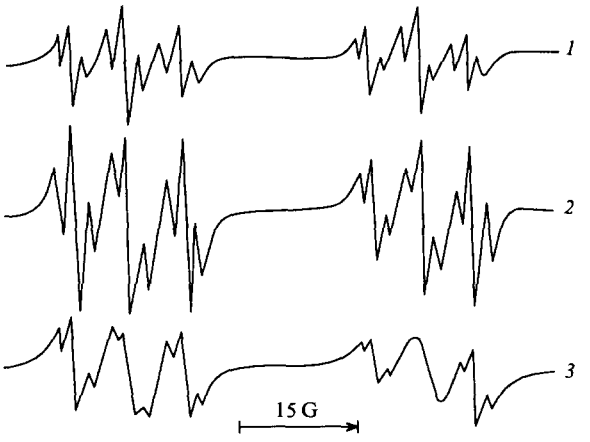


Figure 16. EPR spectra of radical **15** at 0 °C in different solvents: (*1*) toluene; (*2*) 1 : 3 toluene + liquid paraffin mixture; (*3*) 1 : 7 toluene + liquid paraffin mixture.

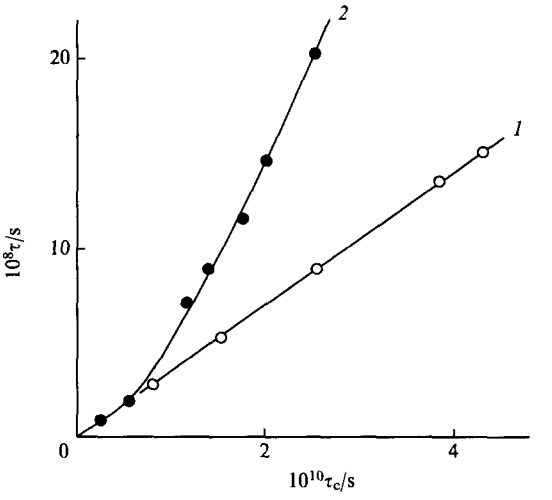
Fig. 17 presents the relation between τ and τ_c obtained on varying the composition of the medium and temperature. Evidently the experimental data are described satisfactorily by Eqn (15) for $\tau_f \ll \tau$. As the viscosity of the medium is varied, the coefficient $\alpha = 400$ remains constant under these conditions, while variation of the temperature over a wide range results in the variation of α in conformity with Eqn (23) ($\alpha_0 \simeq 30$, $E_f \simeq 2.8$ kcal mol^{-1}). The quantity α_0 is of the same order of magnitude as the parameters of the anisotropy of the rotational motions of nitroxyl radicals of complex shape obtained previously.



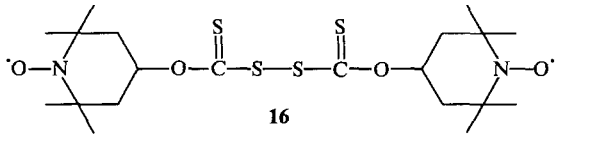


Figure 17. Dependence of τ on τ_c for radical **15**: (*1*) variation of the viscosity of the medium at 0 °C; (*2*) variation of temperature in toluene in the range from −70 to 20 °C.

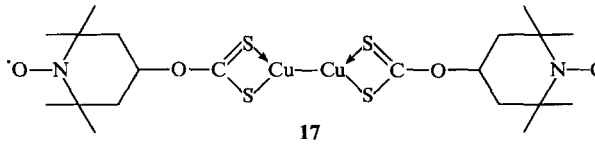
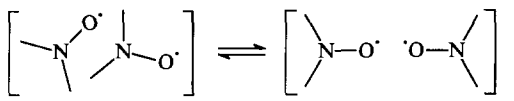


V. Relation between the rotational mobility and the dynamics of spin exchange in nitroxyl biradicals

Spin exchange can be regarded as a model of the electron transfer reaction, which is important in chemical and biochemical processes. The theory and methodological approaches to the study of spin exchange in nitroxyl biradicals have now been quite thoroughly developed.[49] Nitroxyl radicals and biradicals are the most convenient objects for the study of molecular mobility. We therefore regard it as evident that nitroxyl biradicals will also prove to be suitable objects whereby it will be possible to trace the relation between molecular and chemical dynamics — in the given instance the relation between molecular mobility and the dynamics of intramolecular spin exchange.

The influence of the mobility of the medium on the dynamics of spin exchange in biradicals based on a spin-labelled xanthate, having the structure



16

17

has been investigated.[50, 51] Biradicals **16** and **17** have quintet EPR spectra with alternately broadened biradical components.[52] They exist in solution in the form of at least three conformations: the 'extended conformation' with an exchange interaction constant $J = 0$ and two conformations with radical fragments in close proximity, for one of which $J = 0$ and for the other $J \gg a_N$, where a_N are HFI constants for the nitrogen nuclei. The mutual transitions between the conformations are described within the framework of the cage model.[49] According to the ideas of the 'cage' mechanism of exchange interactions in long-chain biradicals, the last two conformations are formed as a result of the mutual approach of the radical fragments, which enter a common 'cage' where they can interact. The elementary spin exchange step then occurs as a result of the direct collision of the radical fragments.

(24)

The alternation of the line widths of the biradical components of the EPR spectrum is caused by the changes in the conditions governing the modulation of the exchange integral within the cage.[49] Measurement of the line widths of the biradical components permits the calculation of the effective spin exchange time τ_{ex}:

$$\tau_{ex} = \frac{4(3)^{1/2}(\Delta H_2 - \Delta H_1)}{\gamma a_N^2}, \quad (25)$$

where ΔH_1 and ΔH_2 are the line widths of the first and second components of the EPR spectrum of the biradical measured between the points of maximum slope.

Since the EPR spectra of biradicals **16** and **17** constitute a superposition of the triplet and quintet spectra, the following formula must be used to determine τ_c for the radical fragments:[23]

$$\tau_c = 6.6 \times 10^{-10} \Delta H_1 \left[\left(\frac{I_1}{I_{1'}} \right)^{1/2} - 1 \right], \quad (26)$$

where I_1 and $I_{1'}$ are the amplitudes of the extreme components (downfield and upfield) of the EPR spectrum of the biradical. As will be shown below, $\tau_{ex} \gg \tau_c$ and the amplitudes of the biradical components and hence their widths remain unchanged. Therefore, in order to determine τ_{ex} one may use Eqn (25), neglecting at the same time the broadening of the biradical components associated with the effects due to the modulation of the anisotropic magnetic interactions by rotational motions.

Analysis of the EPR spectra of biradical **16** in media of different viscosity has shown (Fig. 18) that, with increase in τ_c, the biradical components become broadened and τ_{ex} also increases. The relation between τ_{ex} and τ_c for biradical **16** can be expressed in the form $\tau_{ex} = \alpha\tau_c$ and in the temperature range 0 to 60 °C the coefficient α remains unchanged. This permits the conclusion that the barrier to the activation of the spin exchange is low ($E_f < 2RT \simeq 1$ kcal mol^{-1}) and one can assume that $\alpha = \alpha_0$. For biradicals **16** and **17** in a hexane–liquid paraffin mixture, the parameter $\alpha_0 = 150-170$.[50] The comparatively high values of α_0 can be interpreted as follows: for 150–170 reorientation steps in the radical fragments there is only one spin exchange step, but the additional multiplier α_0 enters into the rate constant k_{ex} as a steric factor. In other words, the coefficient α_0 may be

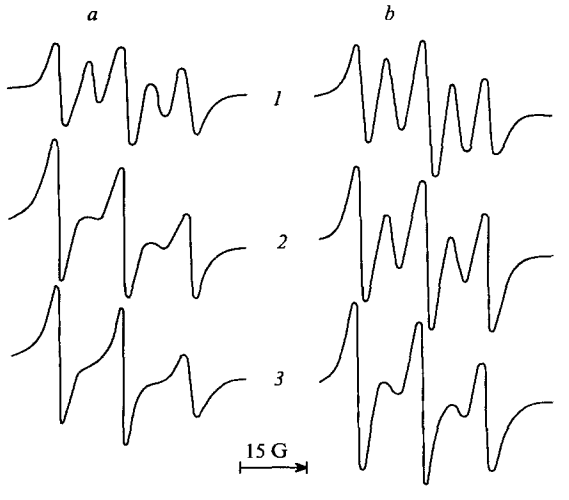


Figure 18. EPR spectra of biradical **16** at 20 °C (*a*) and 60 °C (*b*) in media with different viscosities: (*1*) 1 : 1 hexane + liquid paraffin mixture; (*2*) 1 : 10 hexane + liquid paraffin mixture; (*3*) liquid paraffin.

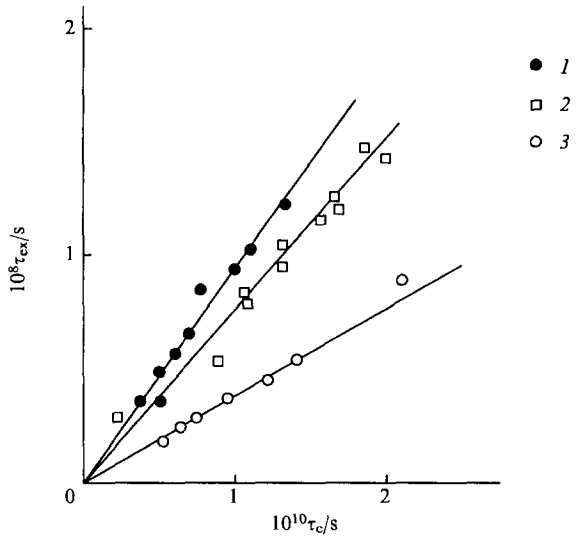

Figure 19. Dependence of τ_{ex} on τ_c for biradical **16** at variable temperatures in different solvents: (*1*) dimethyl sulfoxide; (*2*) 1-butanol; (*3*) THF.

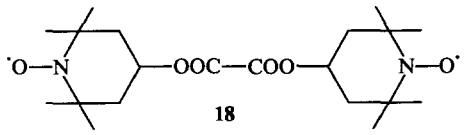
interpreted as a parameter relating the frequencies of molecular motions of different types. For example, the rotation of radical fragments around the axis passing through the N–O bond does not lead to the collision of the radical fragments, as shown in Scheme (24).

The nature of the motion of the probe radicals may be influenced significantly by specific interactions with solvent molecules, so that, by analogy with the parameters of the anisotropy of the rotation of nitroxyl radicals,[41] one may expect changes in the parameters α_0 for biradicals **16** and **17** in different solvents. Fig. 19 illustrates the relation between τ_{ex} and τ_c for biradical **16** in different solvents (τ_c was varied by varying the temperature over a wide range). Evidently the linear correlation between τ_{ex} and τ_c holds satisfactorily, but the proportionality coefficient α_0 depends on the solvent. Table 4 presents the values of α_0 for different solvents together with the pre-exponential factors τ_c^0 and the activation energies E_c for the rotation of the radical fragment in the biradical. In all the solvents investigated, the temperature variation of τ_{ex} and τ_c is described satisfactorily by the Arrhenius relation. In conformity with the linear correlation obtained between τ_{ex} and τ_c, we find that

$$\tau_{ex}^0 = \alpha_0\tau_c^0 \quad \text{and} \quad E_{ex} = E_c .$$

Thus in a viscous medium the activation energy for intramolecular spin exchange in the biradical is identical with the barrier to the rotation of the radical fragment.



Evidently, the equality of the activation energies for different molecular processes frequently occurs in studies by the spin probe method. Some of these data were discussed above. Here one may

Table 4. The parameters α_0, E_c, and τ_c^0 for biradical **16** in different solvents.

Solvent	α_0	E_c/kcal mol^{-1}	τ_c^0/s	T/°C
Toluene	105±11	1.6±0.2	2.6×10^{-12}	−80 – 10
Acetone	100±10	2.2±0.4	7.7×10^{-13}	−60 to −5
DMF	85±8	4.5±1.0	3.4×10^{-14}	−30 – 60
DMSO	96±8	5.0±1.0	2.8×10^{-14}	10 – 80

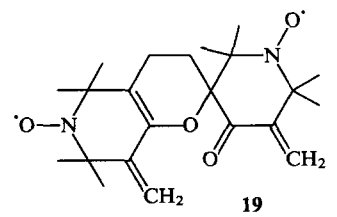
Heptanol	75±15	7.9±1.0	1.1×10^{-15}	30 – 70
Butanol	78±9	3.3±0.5	6.8×10^{-13}	0 – 60
Methanol	50±7	3.7±0.5	1.1×10^{-13}	−50 – 10
THF	38±4	2.8±0.5	4.4×10^{-13}	−70 – 20

quote yet another example illustrating the relation between the dynamics of the intramolecular spin exchange and the rotational mobility.

The spin exchange in a biradical having the structure



18

has been investigated[53, 54] by the double electron–electron resonance (DEER) method. The DEER method makes it possible to observe processes with lower frequencies than is possible when EPR is used. In the EPR spectra of biradical **18**, investigated in liquid paraffin at temperatures in the range −30 to +40 °C, hyperfine interaction with only one nitrogen nucleus is observed, i.e. intramolecular spin exchange is not observed on the EPR time scale. The DEER effect in biradical **18** is due to the intramolecular exchange interaction of the unpaired electron. The temperature variation of the frequency ν_{ex} of this interaction is described by the Arrhenius law with $\nu_{ex}^0 = 10^8\ s^{-1}$ and $E_{ex} = 3.5 \pm 0.7$ kcal mol^{-1}. The rotation frequency of the biradical ν_c, estimated from the EPR spectra as for the monoradical, is also described satisfactorily by the Arrhenius relation with $\nu_c^0 = 10^{11}\ s^{-1}$ and $E_c = 3.9 \pm 1.0$ kcal mol^{-1}. The values ν_{ex} measured for biradical **18** evidently correspond to the frequency of the rare collisions of radical fragments. The similarity of the activation energies for ν_{ex} and ν_c indicates a relation between the rotational and conformational motions of the biradical. Consequently, the relation $\tau_{ex} = \alpha_0\tau_c$, found previously for radicals **16** and **17**, also holds for biradical **18**. For biradical **18**, $\alpha_0 \simeq 1\,000$, which exceeds by an order of magnitude the corresponding values for radicals **16** and **17**.

As mentioned above, the spin exchange in flexible long-chain biradicals, to which biradicals **16**–**18** belong, takes place as a result of the collision between the nitroxyl fragments. Therefore the linear relation between the characteristic spin exchange time and the rotational mobility correlation time reflects the relation between the molecular motions of this type. The study of the relation between molecular mobility and the dynamics of spin exchange in nitroxyl biradicals, where the mutual approach and collision of the radical fragments is impossible and the spin exchange process takes place through the skeleton via an indirect mechanism, is of special interest. This type of spin exchange mechanism has been proposed for rigid nitroxyl biradicals.[49]

The influence of molecular mobility on the dynamics of spin exchange in a nitroxyl biradical having the structure

19

has been investigated.[55] The EPR spectra of biradical **19** have also been investigated.[56] In solutions with a low viscosity, the spectrum consists of a quintet with intensity ratios of 1 : 2 : 3 : 2 : 1 (if the spin had been localised on a single NO fragment, a 1 : 1 : 1 triplet would have been observed). The widths of the biradical components depended only slightly on temperature. This enabled the authors to conclude that an indirect mechanism of exchange via a chain of σ- and π-bonds operates.

The EPR spectra of biradical **19** in viscous solutions in liquid paraffin and in long-chain aliphatic alcohols have been investigated.[55] Fig. 20 shows that an isothermal increase in the viscosity of the medium entails an appreciable broadening of the biradical

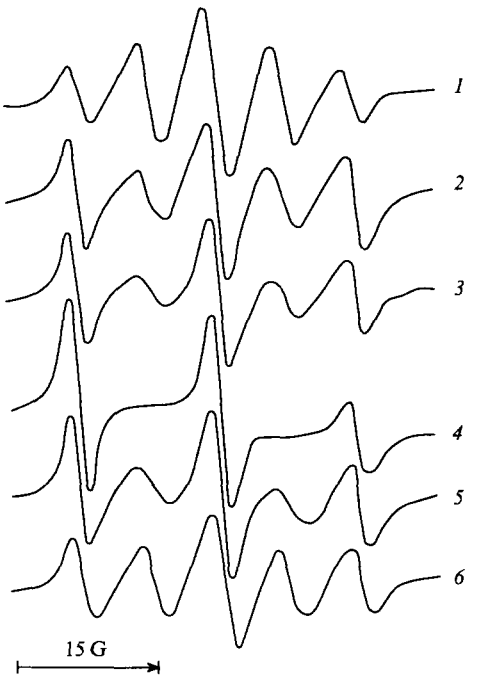


Figure 20. EPR spectra of biradical **19**: (*1*) in hexane at 20 °C; (*2*) in the 1 : 3 hexane + liquid paraffin mixture at 20 °C; (*3*) in the 1 : 5 hexane + liquid paraffin mixture at 20 °C; (*4*) in liquid paraffin at 20 °C; (*5*) in liquid paraffin at 40 °C; (*6*) in liquid paraffin at 60 °C.

components of the EPR spectra. A triplet is observed in the spectra in liquid paraffin, indicating the absence of intramolecular spin exchange on the EPR time scale. With increase in the temperature of the solution of biradical **19** in liquid paraffin, the appearance and subsequent narrowing of the biradical components are observed, which is clearly manifested by the increase in their relative amplitude. The ratios of the integral intensities of all the components of the spectrum always correspond to a binomial distribution. Similar changes are observed when the EPR spectra of biradical **19** in ethanol, butanol, octanol, and decanol are compared. The rate of intramolecular spin exchange falls in the series indicated.

Thus the inhibition of intramolecular spin exchange following a decrease in the mobility of the medium has also been observed for biradical **19**, although it is difficult to imagine what type of motion of the biradical may be responsible for the spin exchange process between the nitroxyl fragments. Despite the relatively rigid structure of biradical **19**, a definite rehybridisation of molecular orbitals, requiring relative shifts of the atoms in the molecule, is apparently necessary for the occurrence of the elementary spin exchange step. In this case, the relatively immobile species comprising the medium, forming 'the walls of the cage', hinder such displacements, which ultimately leads to the retardation of the intramolecular spin exchange. Thus a structural reorganisation of the cage (biradical + surrounding molecules of the medium) is necessary even for the occurrence of the very simple spin exchange step.

The relation between τ_{ex} and τ_c for biradical **19** is also linear (Fig. 21). In an inert medium, $\alpha_0 = 85$, whilst in an alcohol matrix $\alpha_0 = 200$. In solvents with a low viscosity (ethanol, hexane, toluene), the EPR spectrum of biradical **19** remains of the quintet type without appreciable broadening of the biradical components even at low temperatures (−60 to −80 °C), but the amplitudes of the extreme components of the spectrum also do not differ in this instance, which indicates a fairly rapid rotation of the biradical. This fact apparently reflects the characteristics of microscopic organisation of the cage around biradical **19**, since a monotonic decrease in the rotational mobility of nitroxyl fragments with

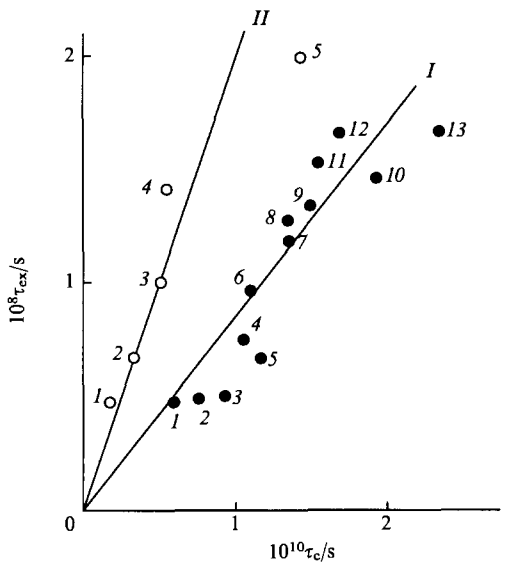

Figure 21. Dependence of τ_{ex} on τ_c for biradical **19**: (*I*) with variation of the composition of the medium (ratio of the concentrations of hexane and liquid paraffin) and temperature (°C): (*1*) 1 : 3, 60; (*2*) 1 : 3, 50; (*3*) 1 : 5, 60; (*4*) 1 : 3, 40; (*5*) 1 : 5, 50; (*6*) liquid paraffin, 60; (*7*) 1 : 5, 40; (*8*) 1 : 3, 30; (*9*) 1 : 5, 30; (*10*) liquid paraffin, 50; (*11*) 1 : 3, 20; (*12*) 1 : 5, 20; (*13*) liquid paraffin, 40. (*II*) In decanol at different temperatures (°C): (*1*) 60; (*2*) 50; (*3*) 40; (*4*) 30; (*5*) 20.

decrease in temperature is observed under these conditions for the 'usual' spin probes, for example, for biradicals **16** and **17**. By virtue of its structural characteristics in low-temperature solvents, biradical **19** can apparently ensure a molecular organisation of the immediate environment with a lower microscopic viscosity.

The data presented above indicate the need to consider the molecular dynamics of the kinetic cage as a whole, including the rotational mobility of the probe and the local motions of the medium. The stable perchlorotriphenylmethyl radical has been investigated[57] in the 2 mm EPR range. The absence of a hyperfine structure simplifies significantly the interpretation of the EPR spectra and the anisotropy of the *g*-factor is sufficient to obtain the necessary information both about the rotation of the spin probe and about the local motion of the medium. In this case, a linear relation was also observed between the characteristic time of the local displacements and the time of the reorientation of the probe molecule by large angles, which constitutes yet another example of the correlation between the frequencies of different processes in one matrix. One can imagine that the complex molecular motions in the condensed phase are effected as a result of the diffusional accumulation n of certain elementary 'quanta' of motion.[58] The frequencies of different types of motion then differ solely by the coefficient n^2 and are linearly correlated with one another. The local displacements of the medium, characterised by Grinberg et al.,[57] can play the role of such elementary motions, which constitutes the basis of the correlation between the frequencies of different molecular processes.

VI. Conclusion

The final aim of studies in the field of chemical physics is, in particular, the elucidation of the relation between the physical and chemical properties of molecules. In relation to chemical processes in condensed media, it is more correct to consider not the physical properties of individual molecules but the properties of the kinetic cage incorporating the reactants and the surrounding molecules of the medium which influence the reactivity. One of the main properties of such a cage is molecular mobility, the quantitative description of which permits the prediction of the difference between the reactivities in an ideal solution and in a real viscous medium of the type of glass, amorphous polymers, and biological structures.

The experimental results presented in this review give rise to the hope that the study of the molecular mobility of free radicals may provide a universal approach to the prediction of reactivity in viscous media and amorphous solids. The results of the investigation may be regarded as the starting point for the construction of microscopic models of chemical reactions in condensed media.

V. Summary	537

Abstract. The results of theoretical and experimental studies of the molecular structure of the oxides of boron and aluminium X_2O_3, X_2O_2, X_2O, and XO_2 (X = B, Al), carried out mainly by spectroscopic methods using matrix-isolation techniques, and also by quantum-mechanical calculations, have been reviewed. The bibliography contains 70 references.

I. Introduction

The present review gives the results of experimental and theoretical studies of the molecular structure of the oxides of boron and aluminium X_mO_n (X = B or Al, $m + n < 6$). The compounds X_mO_n are of both fundamental and applied interest. Thus in the published[1] 'league table' of the chemical elements (involving a comprehensive survey of the importance of the chemical elements in nature, industry, and chemical science), the elements O, B, and Al occupy leading positions.

The literature on the molecular structure of the oxides of boron and aluminium is fairly extensive, and covers a period of more than thirty years. Although it is too early to say that all problems have been resolved, our ideas about the structure of the molecules X_mO_n are fairly well developed. They are based primarily on the results of experimental spectroscopic studies and quantum-chemical calculations. One of the aims of the present review is to show the extent to which it is possible to accept the conclusions of both the experimental and the theoretical studies, which agree with one another in many respects, but not all.

The analysis of the structure of these chemical compounds must involve the question of the similarity and differences in the structure of the oxides of boron and aluminium, and possible explanations. We understand that any 'explanation of the regularities of chemical structure' is provisional, and depends primarily on the level of theory regarded as basic: whether it is sufficient to carry out the analysis using, say, the differences in the electronegativities, dimensions, and polarisabilities of the atoms, or some other parameters, or whether it is necessary to take account of completely different characteristics of the systems.

The theoretical analysis of this present review is based mainly on the molecular orbital model of the theory of electronic structure, with particular attention to the interpretation of the localised molecular orbitals and to such characteristics as the effective charges on the atoms. Analysis of the influence of effects of electron correlation on molecular structure will be regarded as especially important.

II. General characteristics

According to the canonical rules of chemistry, the principal oxide of an element X of group III is X_2O_3. The first studies of the composition of the vapour over solid B_2O_3 and Al_2O_3 showed, however, that oxide molecules with other stoichiometries exist: XO, X_2O, XO_2, and X_2O_2.[2] Later quantum-chemical calculations established that all these systems correspond to stable minima on the potential energy surfaces. Moreover, many of them have several equilibrium configurations of the nuclei. Correspondingly, the experimental spectra relate to different isomers of the molecules. The existence of the higher oxides B_3O_3, Al_3O_3, and Al_2O_4,[3,4] and even exotic species such as Al_3O and Al_4O,[5] has been predicted theoretically. The wide variety of compositions is one of the characteristics of the molecules X_mO_n.

Fig.1 compares the geometric configurations of the most stable isomers of the molecules X_2O, XO_2, X_2O_2, and X_2O_3. The characteristics of the geometric structure of each of the molecules will be discussed in detail later. Here we would only point out that the molecules X_mO_n show not only a variety of compositions but also a variety of geometric forms. It is not always easy to reach a definite conclusion about the geometry of a molecule; this is illustrated by the lively debate about the shape of B_2O_3.[6–9] It is still not completely clear which isomer of AlO_2, linear or cyclic, corresponds to the most stable configuration.[10] The compounds of this class provide a good illustration of one of the traditional problems of the structural chemistry of molecules with 3–5 atoms, namely the question of whether the linear or angular (or cyclic) configuration is preferred. In general, for the oxides X_mO_n we can expect a combination of ionic and covalent bonding, with ionic bonding predominating for the aluminium oxides. Thus linear structures, giving the minimum $O^- - O^-$ and $X^+ - X^+$ repulsion, are generally not unexpected. Angular configurations may be favoured, however, by the effects of sp^2 hybridisation of the boron and oxygen atoms.

Quantum-chemical calculations show that the difficulty of distinguishing between the linear and angular configurations of X_mO_n molecules is related to the flatness of the potential energy surfaces along the deformation coordinates.

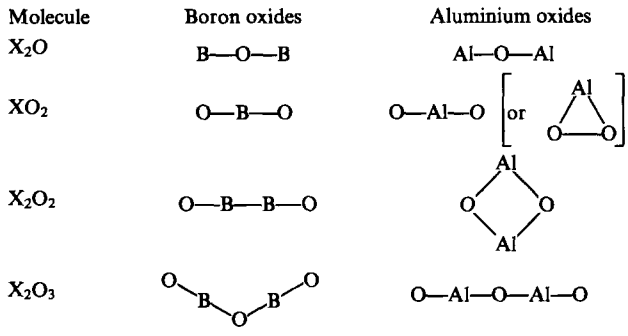

Figure 1. Geometric configurations of the ground-state isomers of the polyatomic molecules X_mO_n.

The structural formulae given in Fig. 1 indicate that the vibrational spectra of the molecules should contain characteristic bands which can be assigned to the groups X—O (in different positions), X—O—X, and O—X—O. The regularities observed in the vibrational spectra, particularly in the high-wavenumber stretching region, represent another characteristic of the molecules of this class.

III. Methods of study

As noted in the Introduction, the present review is based on the results of experimental spectroscopic studies and quantum-chemical calculations. In the present section we shall discuss briefly the possibilities provided by these approaches, mainly to understand how reliable they are for predicting the structure of the molecules B_mO_n and Al_mO_n.

1. Experimental methods

The difficulties in the study of the polyatomic oxides of boron and aluminium are related to the fact that in the equilibrium vapour above the corresponding condensed phases, only the molecules B_2O_3, B_2O_2, and Al_2O are present in quantities sufficient for study by non-resonance spectroscopic methods. Moreover, although resonance methods, for example laser-induced fluorescence (LIF), can be used to study products at low concentrations, with rare exceptions they do not give sufficient information for reaching reliable conclusions about the geometry and vibrational constants of poly-atomic molecules. Thus the data required for the interpretation of the spectra and structure of these materials have been obtained mainly using the methods of the spectroscopy of thermodynamically non-equilibrium systems—inert matrices in which chemical reactions are taking place, and beams obtained by the non-equilibrium (most frequently laser-pulse) volatilisation of appropriate targets. Here we shall discuss mainly data obtained by matrix studies, since almost all the fundamental experimental results on the oxides of boron and aluminium have been obtained from these studies.

The following experimental scheme is now generally accepted.

1. A non-equilibrium situation is created in a system containing boron (or aluminium) and oxygen. This may be a matrix of an inert gas or nitrogen, into which are introduced metal atoms and clusters, volatilised from a Knudsen cell or from the surface of a solid target by a laser, and molecules of an oxidant (oxygen, nitrous oxide, hydrogen peroxide, ozone, etc.). In another version, the products of the non-equilibrium volatilisation of an oxide target are deposited in the matrix.

2. The infrared or Raman spectra of the specimen obtained are recorded by the methods of low-temperature vibrational spectroscopy.

3. The matrix is subjected to external treatment—photolysis, controlled heating ('annealing'), or simple storage for a long time at a constant temperature—after which the changes in the spectra are recorded.

4. When the elements being studied have stable isotopes, the entire cycle of studies is repeated with isotope-enriched specimens.

5. Attempts are then made to obtain an internally consistent assignment of all the bands, or the strongest bands, in all the spectra, relating them to molecules with definite composition.

6. For those molecules whose existence has been established in the previous stage, the experimental wavenumbers and the measured isotope shifts are used to solve the vibrational problem in the harmonic approximation, to determine the symmetry of the equilibrium configuration and to estimate the missing vibrational wavenumbers.

Thus the reliability of the results of the experimental studies depends mainly on the quality of the interpretation of the observed spectra. The complexity of this problem is due to two factors. Firstly, the composition of the products of matrix chemical reactions depends significantly on temperature, the matrix material, and the concentration of the starting materials, and this leads to poor reproducibility of the results. Frequently, papers by different authors give quite different spectra for the same systems. Secondly, the optical properties of the matrices, particularly those containing metals, are very far from ideal, and this leads to various distortions of the spectra, such as displacement and splitting of the bands, and, which is most important, to a significantly non-linear dependence of the intensity of the bands on the concentration of the corresponding products.

We shall not discuss these problems (details can be found elsewhere[11]), and here we merely formulate the general position which we shall subsequently maintain: an individual specific result of an experimental study may prove to be incorrect when a more extensive study or a technically improved study is carried out, but for a sufficiently large number of molecules consisting of the same atoms, the general picture obtained in a systematic study with wide variation of the conditions and methods can apparently be taken as reliable. Thus in the examination of specific molecules we shall try to pick out not the differences between different authors, which naturally represent the principal topic for discussion in experimental and theoretical studies, but the results which can now be regarded as established.

2. Quantum-chemical calculations

According to the present-day ideas, structural data for molecules made up of a small number of atoms from the start of the periodic table should be obtained by non-empirical approaches with allowance for the effects of electron correlation. Calculations of this kind have been carried out for practically all the systems examined in the present review.[3,4,10] It is of course appropriate to discuss the results obtained by other approaches.

When carrying out quantum-chemical calculations, it is necessary to choose correctly the basis set of atomic orbitals (AO) and the method for taking account of electron correlation. It is then necessary, for the given version of the calculation to find the geometric configurations corresponding to stable minima on the potential energy surface (PES) of the molecule, to estimate the differences between the energies of the different minima (if several are found), and to calculate the wavenumbers and intensities for the normal vibrations, for example in the harmonic approximation. This calculation scheme can be simplified, by neglecting correlation effects, that is restricting the treatment to the self-consistent field (SCF) approximation, by introducing pseudo-potentials and excluding explicit consideration of the core electrons, and by using semi-empirical schemes.

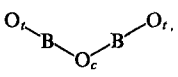
In the discussion of theoretical results and their comparison with experimental data, it is not always easy to estimate the consequences of a given simplification. For example, in calculations of vibrational wavenumbers by the SCF method with scaling, that is in fact with semi-empirical corrections, in a number of cases it is possible to obtain better agreement with the line positions in the experimental spectrum than when various correlation approaches are used.

The structural characteristics of Al_mO_n and B_mO_n molecules have been calculated[3,4] using 6-31GF* basis sets (that is valence-split sets with the addition of polarisation AO) by SCF methods and second-order Moeller–Plesset perturbation theory (MP2). This procedure (MP2/6-31GF*) is now generally accepted, and should give an uncertainty of not more than 2% for the equilibrium geometric parameters and 5% for the vibrational frequencies. For the relative energies of the isomers and all other calculated energy differences, the situation is generally not so favourable, and the upper limit of the uncertainties in the worst cases may be appreciably higher.

The interpretation of the results of calculations of molecular properties in the MO LCAO approximation is facilitated considerably by analysing the electronic structure in terms of the so-called natural bond orbitals.[12] This involves the use of the methods of quantum chemistry to model familiar Lewis structures reflecting the structure of molecules by means of bonds and lone pairs. We shall make extensive use of this representation in the discussion of the properties of the molecules of the oxides of boron and aluminium.

IV. The structure and spectra of X_mO_n molecules

Specific molecular systems X_mO_n will be discussed in the following order. We shall examine first the geometric configuration of the ground-state isomer and its vibrational spectrum, and then other possible geometric configurations (for the boron and aluminium compounds separately). In each concluding section we shall formulate the common and distinguishing details of the structure of the oxides B_mO_n and Al_mO_n mainly on the basis of an analysis of the electronic structure.



1. X_2O_3 molecules

We begin with the principal oxide of group III elements—X_2O_3. Fig. 1 shows that the ground-state isomers of the B_2O_3 and Al_2O_3 molecules have different geometric configurations—angular for B_2O_3 and linear for Al_2O_3. The simple explanation of this result is the more ionic character of the aluminium compounds, leading to the formation of linear structures. The path to this conclusion has been fairly complex, and other configurations, primarily trigonal bipyramidal, have been examined, but the accumulated experimental and theoretical data correspond to the structures given in Fig. 1.

The first studies of the infrared spectra of B_2O_3 vapour were published in the mid nineteen-fifties, when there was interest in the combustion products of boron compounds. Most progress in the study of the structure of the B_2O_3 molecule was made, however, using spectroscopic matrix and electron diffraction methods.[8,9,13–16] The first studies were carried out in the early nineteen-sixties,[13–15] and quantum-chemical calculations to establish the structure of B_2O_3 were carried out at the same time.[6,7,17–19] This was possibly one of the first examples of this complex approach to the solution of problems of molecular structure.

Boric oxide is a fairly convenient material for study by matrix-isolation infrared spectroscopy. The only problem in the assignment of the bands in the spectrum of this molecule was due to the presence of boric acids in the vapour above B_2O_3. This difficulty was overcome by systematic fractional volatilisation.[8] The complete infrared spectrum of natural boric oxide and all isotopic forms of the molecule with ^{10}B and ^{18}O have now been obtained.[8,13] For the molecules obtained by matrix reactions, the degree of reliability which has been achieved in the assignment of the frequencies in the infrared spectrum has not been obtained. Thus the B_2O_3 molecule provides an ideal 'calibration' system for determining the extent of the agreement that can now be obtained between the results of quantum-chemical calculations and the data obtained by infrared spectroscopy and electron diffraction.

The first quantum-chemical calculations for the B_2O_3 molecule by the non-empirical SCF method with a small basis set of AO[17] and by the semi-empirical INDO method[18] gave geometric configurations with C_{2v} symmetry. The results of several independent non-empirical calculations[6,7,19] in the SCF approximation with different AO basis sets, showing fairly good agreement with one another, were published in 1980 and 1981. The latest non-empirical studies of the B_2O_3 molecule were apparently carried out in 1992 (using the SCF method and MP2 perturbation theory with 6-31GF* basis sets),[4] and they did not lead to new qualitative changes in the earlier conclusions about the equilibrium geometry of the molecule

although the quantitative changes in the parameters were appreciable.

Table 1 compares the results of calculations of the equilibrium geometric parameters of the molecule with the C_{2v} configuration with data obtained by electron diffraction.[9] Comparison of the last two rows of Table 1 shows the very good quantitative agreement between the experimental and theoretical approaches. For this example we can estimate the uncertainties in the non-empirical calculations of the equilibrium internuclear distances in the MP2/6-31GF* approximation for the molecules being considered as 0.01 Å (that is about 1%).

It should nevertheless be remembered that the path to these consistent results was complex, and considerable work was required. Thus the electron diffraction data have been repeatedly refined as new measurements were made.[9,15,20,21] Difficulties were also encountered in the calculations; in particular, it has been emphasised that to to obtain a non-linear equilibrium structure it is necessary to include polarisation AO in the basis set.[7]

The vibrational wavenumbers of the B_2O_3 molecule for the principal isotopic form ($^{11}B_2{}^{16}O_3$) are given in Table 2, which compares the values calculated in the harmonic approximation (SCF or MP2 with different basis sets), the results of spectral studies in low-temperature matrices,[8,16] and the results of a combined treatment of data obtained by gas-phase electron diffraction and molecular spectroscopy by an original method which gives an estimate of the frequencies.[19]

The calculated intensities of the infrared bands and a qualitative description of the modes of the B_2O_3 molecule are given in Table 3. The position of the strongest ν_2 band in the infrared spectrum is known from spectroscopic studies of B_2O_3 in inert matrices [2061 cm^{-1} (Ref. 8) or 2062.3 cm^{-1} (Ref. 16)]. Isotope replacement $^{11}B \rightarrow {}^{10}B$ leads to a displacement [2061 → 2128 or 2062.3 → 2130.5 cm^{-1} with $R(10/11) = 1.033$], but the absence from the spectrum of the band corresponding to the mixed composition $^{10}B^{11}BO_3$ remains somewhat puzzling.

Table 1. Calculated and experimental (from gas-phase electron diffraction data) equilibrium geometric parameters of the B_2O_3 molecule (distances R in Å, angles Φ in °).

Method	R_{O_c-B}	R_{B-O_t}	$\Phi(B-O_c-B)$	$\Phi(O_t-B-O_c)$	Ref.
SCF/OST-3GF	1.363	1.237	137.5	176	6

[a] Here and subsequently the column 'SGF(0.9)' gives wavenumbers obtained by the SCF/6-31GF* method by scaling with a factor 0.9.

From MP2/6-31GF* calculations,[4] the isotope shift $^{11}B_2O_3 \rightarrow {}^{10}B_2O_3$ [2125 $cm^{-1} \rightarrow$ 2197 cm^{-1}, $R(10/11) = 1.034$] shows good agreement with the experimental data. Estimates of the intensities with the calculated[4] force-constant matrix show that the band due to the mixed isotopic form $^{10}B^{11}BO_3$ should be fairly close to the $^{10}B_2O_3$ band, and this may make its identification difficult. However, this does not explain the absence of the band due to the mixed isotopic form from the spectrum despite the high intensity expected from the theoretical calculations. Oxygen isotope replacement $B_2^{16}O_3 \rightarrow B_2^{18}O_3$ for the ν_2 band gives a consistent picture for experiment [2062.3 $cm^{-1} \rightarrow$ 2024.1 cm^{-1}, $R(16/18) = 1.019$] and theory [MP2/6-31GF*, 2125 cm^{-1}, 2089 cm^{-1}, $R(16/18) = 1.017$].

For the ν_7 band, the measured[8] isotope shift $^{10}B_2O_3 \rightarrow {}^{11}B_2O_3$ is 489 $cm^{-1} \rightarrow$ 505 cm^{-1}, $R(10/11) = 1.033$; the theoretical (MP2/6-31GF*) shift is 488 $cm^{-1} \rightarrow$ 504 cm^{-1}, $R(10/11) = 1.033$. The experimental shift for oxygen $B_2{}^{16}O_3 \rightarrow B_2{}^{18}O_3$ [489 $cm^{-1} \rightarrow$ 480 cm^{-1}, $R(16/18) = 1.019$] also coincides with the calculated shift [488 $cm^{-1} \rightarrow$ 479 cm^{-1}, $R(16/18) = 1.019$].

Finally, for the ν_5 band the experimental shifts are:[8] for $^{11}B_2O_3 \rightarrow {}^{10}B_2O_3$, 518 $cm^{-1} \rightarrow$ 538 cm^{-1}, $R(10/11) = 1.039$; for $B_2{}^{16}O_3 \rightarrow B_2{}^{18}O_3$, 518 $cm^{-1} \rightarrow$ 510 cm^{-1}, $R(16/18) = 1.016$. The corresponding theoretical estimates are:[4] for $^{11}B_2O_3 \rightarrow {}^{10}B_2O_3$, 529 $cm^{-1} \rightarrow$ 548 cm^{-1}, $R(10/11) = 1.036$, and for $B_2{}^{18}O_3$, 529 $cm^{-1} \rightarrow$ 521 cm^{-1}, $R(16/18) = 1.015$.

The isotope shifts have not been obtained for the remaining two measured frequencies (ν_8 and ν_9).

Since the assignment of the known bands is fairly reliable, it is possible to discuss the accuracy of the theoretical calculations of the wavenumbers of the B_2O_3 molecule. It is appropriate to compare the values calculated by the 4-21GF* and 6-31GF* methods with the experimental spectroscopic data (Table 2). The calculations using the OST-3GF basis set are of considerable historical interest, but the frequencies estimated from experimental electron diffraction data are not all sufficiently reasonable, apparently because of the incorrect choice of reference spectral data.

Table 3. Intensities (km mol^{-1}) of the bands in the infrared spectra and the assignment of the vibrations of the B_2O_3 molecule (the symbols for the modes correspond to those in Table 2).

Mode	Intensities		Assignment
	SCF/4-21GF*	MP2/6-31GF*	
ν_1	68.5	38.0	B–O_t (symmetric stretch)
ν_2	1263.6	963.7	B–O_t (antisymmetric stretch)
ν_3	102.5	108.8	B–O_c (antisymmetric stretch)
ν_4	24.0	13.8	B–O_c (symmetric stretch)
ν_5	131.6	75.1	mixed deformation
ν_6	0	0	anti-phase out of plane
ν_7	16.7	100.6	in-phase out-of-plane
ν_8	21.2	11.6	O_c–B–O_t (deformation)
ν_9	14.0	8.5	B–O_c–B (deformation)

In the SCF approximation, the basis-set effects (the change from 4-21GF* to 6-31GF*) are fairly tyical—the frequencies differ by 10%. The change to the MP2 correlation method lowers the frequencies, and comparison of the data obtained by MP2 and SCF (0.9) methods shows that the use of the popular scaling factor 0.9 for the frequencies calculated in the SCF approximation, covering both correlation and anharmonic corrections,[22,23] in this case leads to values very close to those obtained by the MP2 method (see Table 2). At the very least, the SCF approximation with scaling shows no unique advantages over MP2 in this case, although the frequencies calculated in the SCF approximation with scaling are slightly closer to the experimental data for ν_2, ν_5, and ν_9.

Direct comparison of the calculated and measured wavenumbers is naturally made difficult by the fact that the theoretical values are obtained using the harmonic model and relate to the free molecule, while the experimental data correspond to the real vibrations of the molecule in a matrix environment. It is usually assumed that both the anharmonic and the matrix effects are small, so that the comparison of the frequencies obtained using the MP2 approximation with the experimental spectroscopic data (Table 2) is fully justified. The positions of the strong ν_2, ν_7, and ν_5 bands are effectively reproduced in the MP2/6-31GF* calculation; the differences between the results and the experimental wavenumbers do not exceed 3% (the published[6,9] assignment of the experimental[8] wavenumbers 518 cm^{-1} to B_1 and 462 cm^{-1} to A_1 is incorrect). The values of the ν_8 wavenumbers differ by the same amount. For the B–O_c–B deformation ν_9 with the lowest frequency, slightly greater differences between the experimental and theoretical results are observed, as expected.

The flatness of the PES along the given deformation coordinate (which gives grounds for regarding this molecule as quasi-linear) is responsible for the previously noted difficulties encountered in the quantum-chemical calculations[4,6,7] and for the difficulty in the interpretation of the electron diffraction data.[9,15,20,21] According to published calculations,[6,7] the barrier to inversion, that is the difference between the linear and equilibrium (C_{2v}) configuration, does not exceed 2.5 kcal mol^{-1}. Under these conditions it is fairly difficult to determine the equilibrium valence angle and the frequency of the deformation. Appreciable anharmonicity corrections can also be expected for the ν_9 vibration.

Even by increasing considerably the possible range of uncertainties for the wavenumbers calculated in the MP2/6-31GF* approximation, for example to 10%, it is not

possible to obtain from the calculated data a band in the Raman spectrum in the region of 1062 cm^{-1}, assigned[8] to the B_2O_3 molecule. The absence from the experimental infrared spectrum of the ν_3 band (theoretical wavenumber 1227 cm^{-1}), which should be fairly strong, and the strong ν_2 band due to the mixed isotopic form $^{10}B^{11}BO_3$ also remains unexplained.

An intensive search has been made[4] for other stationary points on the PES of the ground state of B_2O_3, but no structures other than the configuration with C_{2v} symmetry were found.

According to SCF and SCF-X_α SW calculations,[6] the excited states of B_2O_3 are fairly high; the estimated vertical excitation energies are 6–7 eV.

Thus calculation and experiment on the whole give similar pictures of the structure and infrared spectrum of the B_2O_3 molecule. Quantitative agreement is even obtained for the positions and intensities of a number of the spectroscopic bands. The differences noted above are also observed, however.

In contrast to B_2O_3, there are very few experimental data for the Al_2O_3 molecule. The vapour above solid aluminium oxide apparently does not contain free Al_2O_3 molecules.[2] A large number of products are formed in the reaction of atomic aluminium with oxygen in argon and nitrogen matrices.[24–30] Attempts have been made to assign various bands in the infrared and Raman spectra of these products to Al_2O_3. Characteristic features of the infrared spectra of the Al + O_2 system in published studies[26,27] are the 1101, 1095 cm^{-1} doublet in dilute nitrogen matrices, and the 1101, 1095, 1092 cm^{-1} triplet in concentrated matrices. The less intense 502, 492 cm^{-1} doublet is recorded under the same conditions. These two bands have been provisionally assigned to the vibrations of a linear Al_2O_3 molecule with $D_{\infty h}$ symmetry. The doublet band at 1031, 1024 cm^{-1} in the Raman spectrum has been assigned to the same linear molecule.

The band at 1211.2 cm^{-1} in the infrared spectrum of the products of the reaction of aluminium volatilised by a laser from solid Al_2O_3 with oxygen in an argon matrix was recently assigned[30] to the O–Al–O–Al–O molecule. The band at 1101 cm^{-1} was assigned to a molecule with the composition AlO_3 in which two oxygen atoms are joined to one another and the third is a terminal atom. The author cited previously assigned this band to an unsymmetrical aluminium dioxide molecule.

From semi-empirical MNDO quantum-chemical calculations, it was suggested[26] that there exist a number of molecular isomers with the composition Al_2O_3, and the band at 964 cm^{-1} in the infrared spectrum was assigned to one of these which was completely unsymmetrical.

According to non-empirical calculations,[3,31] the ground-state minimum on the PES of Al_2O_3 corresponds to the linear symmetrical $D_{\infty h}$ structure

$$O_t-Al-O_c-Al-O_t\,.$$

Table 4 gives the results of quantum-chemical calculations of the equilibrium internuclear Al–O distances by SCF and MP2 methods. From calculations for the B_2O_3 molecule and other similar molecular systems, the uncertainties in the calculated equilibrium distances in the MP2/6-31GF* approximation should be about 0.01 Å.

Table 4. Equilibrium internuclear distances (Å) in the linear molecule $O_t-Al-O_c-Al-O_t$.

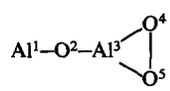
SCF/(12*s*8*p*1*d*,9*s*5*p*1*d*)/[6*s*4*p*1*d*,4*s*2*p*1*d*]	1.657	1.565	31
SCF/6-31GF*	1.666	1.571	3
MP2/6-31GF*	1.691	1.626	3

The wavenumbers and intensities of the vibrations of the linear Al_2O_3 molecule are given in Table 5. The results of two independent calculations by the SCF method with basis sets of comparable quality[3,31] practically coincide. As with B_2O_3, scaling the wavenumbers gives values close to the results obtained in the MP2 approximation with the same basis set. The correlation of the calculated wavenumbers with the experimental spectra in this case, however, is not so successful as in the case of B_2O_3.

Table 6 gives the wavenumbers and the corresponding isotope ratios $R(16/18)$ of the isotopic forms of the Al_2O_3 molecule for those bands in the spectra to which the experimental data are assigned. The band recorded[30] at 1211.2 cm^{-1} apparently in fact corresponds to the $\nu_1(\Sigma_u)$ vibration of O–Al–O–Al–O. The agreement between the isotope ratios is almost quantitative, and the experimentally determined ν_1 wavenumber coincides with that calculated by the SCF method with scaling, and with the wavenumber obtained by the MP2/6-31GF* method to within 3%. The bands observed[26,27] at 1101, 502 (infrared), and 1031 cm^{-1} (Raman) possibly correspond to other compounds or to a molecule with a different structure.

The assignment of the bands is fairly obvious: the pairs ν_1, ν_2 and ν_3, ν_4 correspond to the vibrations of terminal $Al-O_t$ and central $Al-O_c$ groups respectively. All the deformations have fairly low wavenumbers, particularly the ν_7 vibration (40–50 cm^{-1}) describing the deformation about the central oxygen atom. The section of the PES along this coordinate is even flatter than that for B_2O_3.

The question of the isomers of the Al_2O_3 molecule has been examined.[3,26,31] According to quantum-chemical calculations, the at first sight attractive trigonal bipyramidal model must be rejected, since the energy of this configuration is too high compared with the linear form (more than 200 kcal mol^{-1} in the MP2/6-31GF* method); moreover, the D_{3h} structure does not correspond to a minimum on the PES. The configurations found by the semi-empirical MNDO method[26] were not confirmed by subsequent non-empirical calculations.[3]



Of considerable interest is one of the equilibrium configurations of Al_2O_3 found by the SCF/6-31GF* and MP2/6-31GF* methods,[3] namely the planar structure with C_{2v} symmetry

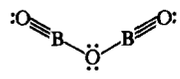
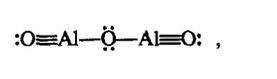
(1.000)					(1.031)		



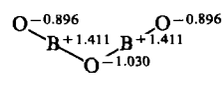


whose energy is higher than that of the linear form by only 11 kcal mol^{-1} in the SCF method, or 32 kcal mol^{-1} in the MP2 method. Experience suggests that the MP2 approximation should give a value for the energy difference which is too large, so that the C_{2v} structure being considered should correspond to an energy of $\sim$20 kcal mol^{-1}, which does not exclude its presence in Al + O_2 matrix reactions. The presence of a similar structure was suggested in the interpretation of electron diffraction data for B_2O_3, but was rejected.[9] According to MP2/6-31GF* data, the equilibrium geometric parameters of the C_{2v} Al_2O_3 molecule are: $R_{Al^1-O^2}$ 1.745, $R_{O^2-Al^3}$ 1.683, $R_{Al^3-O^4}$ and $R_{Al^3-O^5}$ 1.723 Å, $\Phi(O^4-Al^3-O^5)$ 59°.

One of the vibrations of the C_{2v} isomer, 1146 cm^{-1} (MP2/6-31GF*) or 1109 cm^{-1} (SCF/6-31GF* with a scaling of 0.9), should be extremely intense in the infrared spectrum.[3] The corresponding wavenumber might be observed in the experimental spectra.[26,27,30] The electronic structure of this compound is effectively described by the formula $Al^+(AlO_3)^-$.

Thus with reference to the structure of the Al_2O_3 molecule there remain a fairly large number of unanswered questions, particularly regarding the experimental data.

Formally, the Lewis structures of the B_2O_3 and Al_2O_3 molecules coincide:[3,4]



(it is of course possible to use the alternative description

since the boundary between the orbital of the lone pair of the terminal oxygen atom and one of the π-orbitals of the X–O_t bond is somewhat provisional). The pictures of the effective charges on the atoms, obtained by analysis of the populations of the natural orbitals,[3,4] however, differ significantly:

The Mulliken populations[7,31] for systems of this kind give effective charges which are much too low.[12] As expected, the contribution of ionic components to the interaction is greater for aluminium oxide. This also explains the differences in the equilibrium geometric configurations and the lower frequency of the deformation involving the central oxygen atom for Al_2O_3.

The greater contributions of the covalent components to the characteristics of the B–O bonds in B_2O_3 are reflected in the higher values of the force constants (MP2/6-31GF*):

f_{B-O_t} = 13.7 mdyn Å^{-1} $\quad f_{Al-O_t}$ = 6.68 mdyn Å^{-1}

f_{B-O_c} = 7.94 mdyn Å^{-1} $\quad f_{Al-O_c}$ = 4.95 mdyn Å^{-1}

In both molecules, B_2O_3 and Al_2O_3, the dominant correlation effects should be associated with excitations of the type $\pi(X-O_t)\rightarrow\pi^*(X-O_t)$,[3,4,32] leading finally to an increase in the equilibrium internuclear $X-O_t$ distances obtained in the correlation approaches, compared with the results obtained by the SCF method (see Tables 1 and 4). This effect is greater for Al_2O_3 [$\Delta R_{corr}(Al-O_t)$ = 0.06 Å, $\Delta R_{corr}(B-O_t)$ = 0.03 Å]; this can be related to the smaller difference between the energies of the orbitals $\pi(X-O_t)$ and $\pi^*(X-O_t)$ for the Al–O_t bonds, compared with B–O_t.

2. X_2O_2 molecules

Fig. 1 shows that the configurations of the ground-state isomers with the composition X_2O_2 for boron and aluminium are fundamentally different: a linear structure with a B–B bond for B_2O_2 and a cyclic structure for Al_2O_2. Both theoretical and experimental data indicate the existence of other X_2O_2 isomers with low energies. Future more accurate studies will possibly alter present conclusions about the configurations of the ground-state isomers. Nevertheless, it is clear that for oxides with this stoichiometry the differences between the structures of the molecules containing boron and aluminium are considerable.

The B_2O_2 molecule has been studied in parallel with B_2O_3, since mass-spectrometric studies[33] show that when elemental boron is added to solid boric oxide B_2O_3, B_2O_2 molecules predominate in the vapour above the mixture. Until recently, only one isomer had been characterised experimentally. For this isomer, two vibrational wavenumbers were obtained (1898 cm^{-1} and 213 cm^{-1}), and all possible isotope shifts measured. It was concluded that this isomer has a symmetrical linear structure, the force field was calculated, and the frequencies of forbidden transitions in the absorption spectrum were estimated.[34,35] These data were subsequently confirmed[36] in a study of the photoelectron spectra of B_2O_2 vapour. The two bands (at 2048 cm^{-1} and 1408 cm^{-1}) found in recent studies[16,37] of the reactions of atoms in boron clusters with oxygen and water in inert matrices were assigned to the unsymmetrical linear isomer B–O–B–O. In a study of the mass spectra[38] of the vapour above B_2O_3 it was concluded that the compound B_2O_2 corresponds to the unsymmetrical isomer B–O–B–O.

Semi-empirical and non-empirical SCF calculations with the minimum basis set OST-3GF predicted[39,40] that the ground-state

SCF/4-31GF	1.196	1.631	1.337	1.314	1.202	16.8	36
SCF/6-31GF*	1.182	1.667	1.306	1.311	1.190	19.9	4,36
MP3/6-31GF*	1.201	1.647	–	–	–	29.5	36
MP2/6-31GF*	1.218	1.636	1.317	1.332	1.220	40.0	4

Semi-empirical and non-empirical SCF calculations with the minimum basis set OST-3GF predicted[39,40] that the ground-state isomer should have the linear symmetrical structure O–B–B–O.

The parameters of the equilibrium configurations of the linear systems O–B–B–O and B–O–B–O, calculated in a fairly good approximation (SCF and MP with generally accepted basis sets),[4,36] are given in Table 7. As with B_2O_3, we expect that the MP2/6-31GF* method makes it possible to predict internuclear distances with an uncertainty of about 0.01 Å. Comparison with the data in Table 1 shows that for all the molecules (B_2O_3, O–B–B–O, and B–O–B–O) the distances from boron to the terminal oxygen agree within this uncertainty and are equal to 1.22 Å.

The vibrational frequencies and infrared intensities for the two isomers are compared in Table 8. As in the previous examples, noteworthy features are the similarity in the frequencies calculated by the SCF(0.9) and MP2 methods, and the fact that the calculated harmonic frequencies of the MP2/6-31GF* approximation coincide with the measured values in the infrared spectrum (ν_2 and ν_5) for the ground-state isomer O–B–B–O. The published[16,34,35,37] $^{16}O \rightarrow {}^{18}O$ and $^{11}B \rightarrow {}^{10}B$ isotope shifts in different combinations for the ν_2 band are reproduced almost quantitatively by the calculations. The large differences for the ν_3 and ν_4 bands can be explained, since the wavenumbers forbidden in the infrared spectrum were predicted[35] with molecular force constants estimated from known bands. Comparison of the results of different calculations[4,36] shows the very large difference between the ν_1 and ν_2 vibrational wavenumbers obtained by the MP2 and MP3 methods with the same basis set 6-31GF* (in the SCF method, the corresponding values are identical).

The observation[16,37,38] of the unsymmetrical isomer B–O–B–O is also confirmed by non-empirical calculations. From the isotope shifts, the experimental[37] bands at 2048 cm^{-1} and 1408 cm^{-1} agree with the calculated values 2123 cm^{-1} and 1488 cm^{-1} for ν_1 and ν_2 respectively:

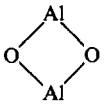
ν_1, $R(16/18) = 1.016$ and $R(10/11) = 1.034$ from experiment, and $R(16/18) = 1.017$ and $R(10/11) = 1.035$ from calculation; ν_2, $R(16/18) = 1.034$ and $R(10/11) = 1.019$ from experiment, and $R(16/18) = 1.035$ and $R(10/11) = 1.019$ from calculation (MP2/6-31GF*).

The differences between the theoretical and experimental wavenumbers are 4% for ν_1 and 6% for ν_2, which are slightly greater than those observed in the previous examples. The question of the magnitude of the energy of the isomer B–O–B–O relative to that of O–B–B–O remains unresolved, that it is not clear whether it is sufficiently low for it to be possible to obtain the isomer B–O–B–O experimentally.

As has been suggested,[40] the cyclic isomers of B_2O_2 also correspond to stationary points on the PES of the ground state,[4,36] but their energies differ from that of the ground-state configuration O–B–B–O by more than 60 kcal mol^{-1}.

The presence of the compound Al_2O_2 in the vapour above solid aluminium oxide has been confirmed by mass spectrometry.[2] The interpretations of the infrared spectra of the products of matrix reactions of aluminium with oxygen, assigned to Al_2O_2, are contradictory. For a long time, the band at 496 cm^{-1} (or 498 cm^{-1}) was assigned to an Al_2O_2 molecule with a rhomb-shaped configuration.[41,42] According to Serebrennikov and coworkers,[24,25] this band belongs to a cyclic isomer of Al_2O_2, and this was confirmed in recent experiments.[30] An infrared band at 691 cm^{-1} and (provisionally) a Raman band at 713/721 cm^{-1} have been assigned[26,28] to a vibration of the square isomer of Al_2O_2; the infrared bands at 640 cm^{-1} and 545 cm^{-1} and the Raman band at 563 cm^{-1} were assigned to the rhomb-shaped isomer. In the work cited,[30] the bands in the infrared spectrum were assigned only for the linear isomer Al–O–Al–O: 1176/1169/1167, 945/943/940 cm^{-1}. The band at about 943 cm^{-1} has been assigned[26] to this isomer.

A number of quantum-chemical calculations have been carried out for Al_2O_2.[3,43–45] SCF calculations using pseudopotentials[43] for the molecule gave three stationary points on the PES: the ground-state isomer corresponds to an almost square configuration with D_{2h} symmetry, the isomer with the rhomb-shaped configuration has an energy 37 kcal mol^{-1} higher, and the third isomer is the linear molecule Al–O–Al–O. From the calculated vibrational wavenumbers it was concluded that the experimental band at 496 cm^{-1} can be assigned to the ground-state square isomer of Al_2O_2. Calculations have been carried out[44] by non-empirical SCF (with different basis sets) and MP2/6-31GF* methods. It was confirmed that the ground-state equilibrium configuration is square, and that the linear Al–O–Al–O (10.2 kcal mol^{-1} higher) and rhomb-shaped (71.5 kcal mol^{-1}) configurations have higher energies. As before, one of the vibrational wavenumbers of the ground-state isomer, found only in the SCF approximation (476 cm^{-1} without scaling), was compared with the experimental data. Attention was drawn[45] to the fact that in the square configuration the energy of the triplet state is fairly close to that of the singlet state.



The equilibrium geometric parameters and the wavenumbers and intensities of the vibrations have been calculated[3] in the SCF and MP2 approximations with the basis set 6-31GF*. For the geometries and wavenumbers in the SCF approximation

and the geometries in the MP2 approximation, the values obtained for the two lower isomers agreed completely with published data.[44] The characteristics of the vibrations calculated in the MP2/6-31GF* approximation, however, make necessary a radical re-examination of the previous interpretation.

The geometric parameters of the Al_2O_2 isomers of lowest energy are given in Table 9. Table 9 does not give results for the second rhomb-shaped configuration, although it is of considerable interest from the viewpoint of structural theory, or results for the other linear isomers obtained, O−Al−Al−O, Al−O−O−Al, and Al−Al−O−O,[3] since the energies of all these configurations are too high compared with the energy of the ground-state isomer (more than 70 kcal mol^{-1}) for them to be observed experimentally.

For the cyclic (almost square) isomer, noteworthy features are, firstly, the small deviations of the valence angles from 90° at the aluminium and oxygen atoms, and, secondly, the similarity in the equilibrium configurations of the molecule in the singlet and triplet states. Comparison of the internuclear distances for the linear isomer $Al_t-O_c-Al_c-O_t$ with the distances in the linear molecule $O_t-Al_c-O_c-Al_c-O_t$ (see Table 4) shows (like the comparison of the data for O−B−B−O and B_2O_3) that the Al_c-O_t distances coincide to within 0.01 Å (1.63 Å, MP2/6-31GF*); the Al_c-O_c distances also coincide (1.69 Å). The Al_t-O_c distance in $Al_t-O_c-Al_c-O_t$ (1.74 Å) is greater than the distance within the fragment O−Al−O. The Al−O bond length in the ring is even longer (1.78 Å).

The relative energies of the lower isomers of Al_2O_2 calculated[3] by the SCF and MP2 methods with the 6-31GF* basis set are shown in Fig. 2. These results show the importance of allowing for the effects of electron correlation in the Al_2O_2 system; on going beyond the one-electron model, the qualitative conclusions about the structure of the molecule change. It is known that the MP2 approximation does not always give energy differences sufficiently accurately, and calculations at a higher level (for example by the MP4 method or the method of bound clusters) may in principle change the relative energies of the linear and cyclic structures. The results obtained, however, provide sufficient grounds for assigning the experimental data to both structures.

Table 10 gives the experimental vibrational wavenumbers for the cyclic Al_2O_2 molecule; the calculated wavenumbers, infrared intensities, and isotope ratios for the singlet and triplet states of the almost square isomer are indicated. As in other examples, the wavenumbers calculated in the SCF/6-31GF* approximation are systematically greater than the corresponding values calculated in the MP2/6-31GF* approximation with a factor close to 0.9. For the ν_3 vibration of the singlet isomer, however, an extremely unusual situation is observed; there is a dramatic change in both the wavenumber (476 →690 cm^{-1}) and intensity of the vibration when corrections for correlation effects are introduced. It is for this reason that earlier attempts to correlate the theoretical wavenumbers calculated in the SCF approximation[43,44] with the experimental data led to an erroneous assignment of the observed band at 496 cm^{-1} to the Al_2O_2 molecule. We shall return to the discussion of the role of correlation effects in the cyclic Al_2O_2 molecule. Meanwhile, we are justified in assigning to the almost square molecule the intense band in the infrared spectrum at 691 cm^{-1}, as previously proposed.[28] The situation is more complex for the other suggestions made in the work cited.[28] The most active vibration in the Raman spectrum is the ν_5 vibration with a wavenumber of about 516 cm^{-1} and an isotope ratio R(16/18) = 1.020. The possibility of assigning the experimental band at 563 cm^{-1} to this vibration[28] cannot be excluded. For the other bands in the infrared and Raman spectra,[28] appropriate assignments were not made.

Table 11 gives the vibrations of the linear Al−O−Al−O molecule. Comparison with experimental data[30] shows that there is practically no doubt about the assignment of the bands at 1176.3 cm^{-1} and 945.5 cm^{-1} (or the bands close to them for

$\nu_3(B_{1u})$	476 {828}	690 {193} (1.036)	691 (1.028)	811	738 {349}
$\nu_4(B_{3g})$	664	622 (1.035)		680	624
$\nu_5(A_g)$	553	516 (1.020)		565	524
$\nu_6(B_{3u})$	327 {45}	308 {51} (1.037)		322	276

(MP2/6-31GF*) frequencies differ by not more than 3%, although the difference between the intensities is much greater.

In contrast to the X_2O_3 systems, the structures of the B_2O_2 and Al_2O_2 molecules differ considerably. The two lowest isomers of B_2O_2 are the Lewis structures of the linear configuration:[4]

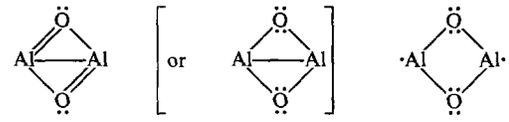
$$:O{\equiv}B-B{\equiv}O: \quad \text{and} \quad :B-\ddot{O}-B{\equiv}O: .$$

The contributions of ionic interactions are not so large, as follows, for example, from the effective natural charges of the ground-state isomer

$$O^{-0.824}-B^{+0.824}-B^{+0.824}-O^{-0.824} .$$

For Al_2O_2 the situation is more interesting. The Lewis structures of the linear isomer Al–O–Al–O obtained with Hartree–Fock and correlation (MP2) electron densities can be represented as follows:

$$:Al:\ddot{O}-Al{\equiv}O: \text{ (SCF)} \qquad :Al{\equiv}O-Al{\equiv}O: \text{ (MP2)},$$



reflecting the general trend in the change in the electronic structure of aluminium oxides—correlation effects lead to an increase in the covalent character of the bond.[3]

Naturally, because of the appreciably higher effective natural charges

$$Al^{+0.867}-O^{-1.595}-Al^{+2.007}-O^{-1.278},$$

the structures with X–X contacts are less favourable for aluminium than for boron (the ground-state linear isomer is O–B–B–O for B_2O_2, and Al–O–Al–O for Al_2O_2). Allowance for correlation effects leads to a lowering of the energy of O–X–X–O relative to X–O–X–O (Table 7 and Fig. 2), but in the case of Al_2O_2 this lowering is insufficient for the O–Al–Al–O isomer to be regarded as sufficiently low-lying. In the limit of a completely ionic description, the linear molecule Al–O–Al–O can be represented as $Al^+[O-Al-O]^-$. The fragment $[O-Al-O]^-$ is identified in the Al_2O_2 and Al_2O_3 molecules both from the geometric parameters and from the vibrational frequencies.

The Lewis structures for the cyclic isomer of Al_2O_2 in the singlet and triplet states can be represented as follows:[3]

singlet triplet

In this picture, the highest occupied and lowest unoccupied MO for the singlet state are the orbitals $\sigma(Al-Al)$ and $\sigma^*(Al-Al)$ with an extremely small energy gap between them (0.1 a.u.). This leads to the marked changes in the energies and in the vibrational wavenumbers of the molecule observed on going beyond the SCF approximation.[3,32] The triplet state corresponds to a biradical structure with unpaired electrons on Al. The rigid framework of Al–O σ-bonds is responsible for the similarity in the geometries and vibrational frequencies of the cyclic Al_2O_2 molecule in the two spin states.

3. X_2O molecules

Of all the polyatomic oxides X_mO_n, the compounds with the composition X_2O are apparently the least puzzling. There is almost no doubt that the ground-state isomers correspond to the linear symmetrical configurations X–O–X. For quantum-chemical calculations, these triatomic systems are not very complex, and sufficiently reliable theoretical results can be expected. From the experimental viewpoint also, there is no doubt about the correctness of the understanding of the structure of the B_2O and Al_2O molecules.

There is only one published experimental study in which, in an investigation of the reaction of atomic boron with water, the bands in the infrared spectrum were assigned to the matrix-isolated B_2O molecule.[37] From the behaviour of the band at about 1420.5 cm^{-1} on isotope replacement it was concluded that the molecule in the matrix has a linear or almost linear symmetrical configuration.

Table 11. Wavenumbers (cm^{-1}) and infrared intensities (in curly brackets, km mol^{-1}) for the linear isomer of Al_2O_2 [the isotope ratios $R(16/18)$ for the replacement $^{16}O \rightarrow {}^{18}O$ are given in round brackets].

Vibration	SCF/6-31GF* [3,44]	MP2/6-31GF* [3]	Experiment [30,26]

MP2/6-311GF**	1456	1043	24			4
Experiment	1420	–	–	1.020	1.033	37

In a study of the gas-phase oxidation of atomic boron by NO_2 and N_2O molecules, the authors[46] tried to assign the chemiluminescence spectrum to the B_2O molecule, supposedly in the form of the unsymmetrical isomer B–B–O (if the vibration with wavenumber 582 cm^{-1} can be associated with this molecule), although the assignment of the experimental spectrum to B_2O_2 is not excluded.

Quantum-mechanical calculations by the SCF method[39,47] predict a linear symmetrical equilibrium configuration, while the energy of the other linear isomer B–B–O should be appreciably higher. According to recent calculations for B_2O, carried out by SCF and MP2 methods,[4] the equilibrium internuclear distance in the linear symmetrical molecule B–O–B is 1.313 (SCF/6-31GF*), 1.333 (MP2/6-31GF*), or 1.329 Å (MP2/6-311GF**), demonstrating again that for these compounds the MP2/6-31GF* method predicts the bond lengths with an uncertainty of not more than 0.01 Å.

The vibrational wavenumbers of the B_2O molecule are compared in Table 12. The experimentally determined wavenumber of the ν_1 vibration is close to that calculated by the MP2/6-31GF* method (error ~5%). Comparison of the wavenumbers calculated by the MP2/6-31GF* and MP2/6-311GF** methods shows that they are fairly sensitive to the basis set, particularly for the ν_3 deformation. The low wavenumber of the deformation indicates a very flat section for the PES along this coordinate, confirming the arguments[37] about the possible quasi-linearity of B–O–B in the matrix. However, the proposed[37] assignment of the emission spectrum[46] to B–O–B is of course excluded. There is more justification for assigning the observed chemiluminescence[46] to the O–B–B–O molecule.

The strong band of the matrix-isolated Al_2O molecule at 992 cm^{-1} (992.8 cm^{-1} according to recent measurements[30] in an argon matrix) with an isotope ratio $R(16/18) = 1.045$, assigned to the antisymmetric stretch, is well known and reliably established.[25,29,30] The electronic spectrum of the gas phase has also been used to estimate the wavenumber of the symmetric stretch (471 cm^{-1}).[48] The bands at 472 cm^{-1} and 475 cm^{-1} in the Raman spectra of the argon and nitrogen matrices were assigned to this vibration.[27,49] In the earliest studies[49] it was pointed out that the wavenumber of the Al–O–Al deformation should be low (below 190 cm^{-1}).

Many non-empirical calculations have been carried out for the Al_2O molecule.[3,5,43,44,50–52] All the data agree in predicting a linear symmetrical equilibrium configuration Al–O–Al. Some of the calculation results are given in Table 13. The positions of the strong ν_1 band in the infrared spectrum and the corresponding isotope ratios $R(16/18)$ obtained by calculation (MP2/6-31GF* or the scaled SCF/6-31GF* wavenumber) and by experiment show very good agreement. The agreement between the calculated ν_2 frequency and that estimated from the electronic spectra is also satisfactory.

Electron diffraction studies of the Al_2O molecule in the gas-phase electron diffraction laboratory of the Chemistry Department of Moscow State University led to the conclusion that the molecule has an angular configuration with an Al–O–Al angle of about 140°. This conclusion is evidently a consequence of the extremely low deformation frequency of the molecule.

Table 13. Equilibrium distance R_{Al-O} (in Å) and vibrational wavenumbers of the Al–O–Al molecule.

Method	R_{A-O}	Wavenumber/cm^{-1}			$R(16/18)$	Ref.
		$\nu_1(\Sigma_u)$	$\nu_2(\Sigma_g)$	$\nu_3(\Pi_u)$

Experiment	–	992.8	471; 472; 475	–	1.045	30, 47, 27, 69

The other possible isomer of the molecule, namely Al–Al–O, has a fairly high energy (more than 80 kcal mol^{-1}) relative to Al–O–Al.[3,5]

Comparison of the details of the electronic structures of the B–O–B and Al–O–Al molecules does not lead to any unexpected features.

The more ionic character of the bonding for Al, which can be seen by comparing the natural charges on the atoms,[3,4]

$$B^{+0.645}-O^{-1.290}-B^{+0.645} \qquad Al^{+0.830}-O^{-1.660}-Al^{+0.830},$$

is responsible for certain differences in the descriptions of the systems. The Lewis structures of aluminium oxide, obtained with the Hartree–Fock (SCF) and correlation (MP2) densities,[3] indicate an increase in the covalent contributions when allowance is made for electron correlation

$$:Al:\ddot{O}:\ Al: \text{ (SCF)} \qquad :Al-\ddot{O}-Al: \text{ (MP2)}.$$

For the boron oxide, the description at the level of the Lewis structures is fairly obvious:

$$B\equiv O-B: \quad \leftrightarrow \quad :B-O\equiv B: .$$

In both molecules, correlation effects are responsible for an increase in the equilibrium internuclear distance X–O (0.02 Å for X = B, 0.03 Å for X = Al), which is slightly smaller than for the other oxides.

4. XO_2 molecules

Species with the composition XO_2 are formed and play an extremely important role in the oxidation of boron and aluminium. A fairly large amount of experimental information on XO_2 molecules has been obtained, including spectral data for the matrix-isolated molecules. From the theoretical viewpoint, the analysis of the XO_2 systems is much more complex than that for the molecules of the other oxides examined above. This is due chiefly to the fact that these molecules have open electron levels; moreover, methods of calculation based on the single-configuration representation of electronic wave-functions are generally speaking inadequate in the present application.

The results of experimental and theoretical studies indicate that the equilibrium configuration of the BO_2 molecule is the linear symmetrical configuration.

The vibrational wavenumbers of the BO_2 molecule, obtained by different methods, are given in Table 14. In this case it is possible to compare the experimental results for the gas phase[53–57] and the matrix-isolated molecules.[14,16,58] Most information has been obtained for the ν_1 antisymmetric stretch. The vibration frequencies of the molecule in the gas phase has been measured extremely accurately, and the shifts observed in matrix-isolation experiments are estimated relative to this quantity. According to the latest measurements,[16] the shifts differ considerably, depending on the material of the matrix and (presumably) on the type of capture position. The maximum deviation from the gas-phase value for ν_1 is ~20 cm^{-1} (not more than 2%).

Thus the characteristic uncertainties in the vibrational wavenumbers calculated by present-day methods of quantum chemistry (MP2/6-31GF*) (about 3%) are close to the relative shifts in the wavenumbers as a result of the matrix environment. For the ν_3 deformation, the matrix shifts have even higher values. Since modelling the matrix shifts is extremely difficult,[60,61] the agreement between the experimental molecular spectra, obtained for these compounds primarily under matrix-isolation conditions, and the theoretically calculated spectra cannot have a higher accuracy than that already noted (3–5%).

There have been few non-empirical calculations of the properties of the BO_2 molecule. For the ground electronic state $X^2\pi_g$, Lomp and coworkers[59] calculated the equilibrium internuclear distance B–O in the linear molecule—1.34 Å (SCF/OST-3GF) and 1.26 Å {SCF/[9*s*5*p*]/(4*s*2*p*)} (experimental value 1.265 Å [53])—and also the harmonic frequencies of the ν_2

Table 14. Vibrational wavenumbers (cm^{-1}) for the BO_2 molecule (the oblique lines separate wavenumbers associated with different positions of capture of the molecule by the matrix).

and ν_3 vibrations (Table 14). In the calculations, considerable difficulty was encountered in obtaining symmetrically stable solutions of the electronic equation.

The AlO_2 molecule has been detected among the products of the reaction of aluminium with oxygen in an argon matrix. For this molecule, a cyclic structure with an O–Al–O angle of 30–50° was proposed, as for all the dioxides of the group III elements.[24] Evidence in support of this interpretation is provided by the presence in the infrared spectrum of a band at 1096 cm^{-1}, close to the wavenumber of the O_2^- vibrations (1089 cm^{-1}). It has been suggested[24] that the molecule has an ionic structure $Al^+O_2^-$. The band at 496 cm^{-1} was assigned to this structure. The remaining wavenumber was estimated at 550 cm^{-1}. Subsequent studies[25,26] showed that in the matrix reactions of aluminium with oxygen, another isomer of the molecule is formed, namely the linear O–Al–O. The wavenumber of the antisymmetric stretch in the infrared spectrum (918 cm^{-1}) was assigned to this isomer, and the laser fluorescence spectra gave the wavenumbers of the symmetric stretch (635 cm^{-1}) and the deformation (70 cm^{-1}).[70]

In other studies of the matrix reactions of aluminium with oxygen,[29] the formation of an unsymmetrical isomer of AlO_2 with a C_s structure was assumed; later,[30] the wavenumber 496.3 cm^{-1} in the infrared spectrum was assigned to a cyclic configuration, and the wavenumber 1129.5 cm^{-1} to the linear O–Al–O isomer.

Nonempirical quantum-mechanical calculations for the AlO_2 molecule are difficult, due to the symmetry instability of the Hartree–Fock equations.[10,62,63] To construct the potential surfaces of this system it is necessary to use many-configuration approximations, and in the last case also considerable difficulties are encountered, particularly in the estimation of the vibrational frequencies. The many-configuration SCF method (MC SCF) combined with the pseudo-potential approximation has been used[62] to model the field of the core electrons. It was established that of the two molecular configurations examined—the cyclic configuration and the linear unsymmetrical Al–O–O—the cyclic form corresponds to the energy minimum. Its equilibrium geometric parameters and the wavenumbers of the harmonic vibrations were estimated (Tables 15 and 16). The methods of configuration interaction (CI) and many-particle perturbation theory (PT) with basis sets of restricted dimensions have been used[63] to examine both the cyclic and the linear symmetric isomers of the AlO_2 molecule. These calculations indicate only that these isomers have similar energies.

Table 15. Geometric parameters of the AlO_2 molecule (distances in Å, angles in °) and difference between the energies (kcal mol^{-1}) of the linear and cyclic isomers.

Method of calculation	Linear isomer R_{Al-O}	Cyclic isomer R_{Al-O}	Cyclic isomer Φ(O–Al–O)	Energy difference	Ref.
MC SCF	–	1.97	38	–	62
CI, PT	1.72	1.88	41	1.2	63
MC SCF	1.67	1.93	42	6.0	10

Table 16. Experimental and calculated vibrational wavenumbers of the AlO_2 molecule (cm^{-1}).

Molecule		Wavenumber/cm^{-1}			Ref.
		ν_1	ν_2	ν_3	
	calculation	1081	591	277	10
		1394	528	242	62
	experiment	1096	496	–	24
		–	496.2	–	30
O–Al–O	calculation	932	582	75	10
		978	659	92	63
	experiment	918	635	70	24

The MC SCF method (the version of the complete configurational space of the active orbitals) was also used by Nemukhin and Almlof,[10] but with allowance for all the electrons, in contrast to the work of Rubio and coworkers.[62] The orbitals were represented using basis sets specially designed for calculations with allowance for correlation effects, the so-called atomic natural orbitals of the type (20*s*13*p*5*d*)/[6*s*5*p*2*d*] for Al and (13*s*8*p*5*d*)/[5*s*4*p*1*d*] for O. It was concluded that on the potential surface of the ground state of the molecule ($^2A_2$) there are two minimum points separated by a high barrier (~60 kcal mol^{-1}), and that the energy of the linear symmetrical form is 6 kcal mol^{-1} lower than that of the cyclic configuration. More accurate estimates of the ratio of the energies of the linear and cyclic forms apparently require additional calculations with a more detailed allowance for correlation effects, but it can be taken as established that both isomers may be formed in matrix reactions of aluminium with oxygen. The linear and cyclic isomers of AlO_2 are described by appreciably different electron configurations, and are characterised by different distributions of the effective charges.[10]

The experimental and theoretical vibrational wavenumbers for the two isomers are compared in Table 16. Unfortunately, the non-empirical calculations for this system were carried out using a scheme different from that used for the other oxides examined (here, generally speaking, the single-configuration SCF and MP2 approximations are inapplicable), so that we cannot use the regularities noted above. Overall, the theoretical and experimental wavenumbers show agreement but the agreement is not yet quantitative.

In the comparison of the properties of BO_2 and AlO_2 in the linear configurations, the significant difference in the wavenumbers of the deformation is noteworthy: 464 cm^{-1} for O–B–O and 70 cm^{-1} for O–Al–O.

5. XO molecules

Information on the diatomic oxides BO and AlO at the level mainly developed in the present review (geometry, vibrational wavenumbers) is already given in reference works,[64] and therefore is not discussed here. In connection with the questions dealt with above, we would merely refer to new spectral studies of matrix-isolated BO and AlO molecules.[16,30,65] From these data it follows

that the experimental matrix shifts for BO and AlO have different signs. For example, in argon matrices the shift of the principal vibrational wavenumber of BO is -7 cm^{-1} (1854.7 cm^{-1} relative to the gas-phase value of 1862.1 cm^{-1}),[16] while that for AlO is 10 cm^{-1} (975 cm^{-1} compared with 965 cm^{-1} for the gas phase).[30,65]

One may also mention fairly detailed studies of the potential energy curves of diatomic oxides by non-empirical methods of quantum chemistry,[66–68] which show significant changes in the electronic structure with change in the internuclear distance.

V. Summary

One of the principal conclusions from the comparison of the results of studies of the oxides X_mO_n (X = B, Al) is that these compounds show a great variety of compositions and molecular geometries. For practically all the systems X_2O_3, X_2O_2, X_2O, and XO_2 we can now formulate definite conclusions about the structure, based on the experimental spectra of the molecules and the results of quantum-chemical calculations. For these compounds it may be concluded that the accuracies of the determination of the equilibrium geometric parameters and the vibrational frequencies from experiment and from calculation are comparable.

Most of the differences in the structures of the oxides of boron and aluminium can be attributed to the more ionic character of the Al–O bond in the compounds Al_mO_n; the balance of the ionic and covalent contributions depends considerably on allowance for correlation effects, which increase the covalent components. Aluminium oxides, to a greater extent than boron oxides, are characterised by the existence of low-lying isomers with the same stoichiometry.

Most of the unresolved theoretical questions remaining relate to the BO_2 and AlO_2 molecules. From the experimental viewpoint, the situation for the Al_2O_3 and Al_2O_2 molecules is least satisfactory.

For a more complete understanding of the processes accompanying the reactions of atoms and clusters of boron and aluminium with oxygen or other oxidants in the gas phase and under matrix-isolation conditions it is extremely important to study systems of the type $(XO)_n$ and $(XO_2)_n$ with $n > 2$.

Abstract. Studies devoted to excimers in organic systems are surveyed. Processes leading to the excitation of the excimer luminescence are examined. Examples of the excimer-like glow of dimers are described. The relation between the structure of the complexes and their fluorescence properties is demonstrated. The bibliography includes 218 references.

I. Introduction

Excimers are dimers a distinctive feature of which is instability in the ground state. Their formation is observed only on photoexcitation of the system. (Here and henceforth physical dimers are considered.) After deactivation of the dimers, the latter dissociate into individual molecules. The term 'excimer' was adopted on the suggestion of Stevens and Hutton[1] and was recommended by the International Symposium on Molecular Luminescence[2] instead of the term 'excited dimer' employed previously. Dimers comprising two different chemical compounds (in particular organic molecules and inorganic species[3,4]) have been called 'exciplexes'.[2] The state of the research into these species has been described in detail in a monograph.[3]

In inorganic systems, excimers were known long before their detection in organic molecules. The atoms of certain metals and noble gases are capable of forming excimers. The optical transitions in their excimers are used for the generation of laser radiation.[5] The excimers of organic compounds were first identified in 1954.[6,7] The class of excimer-forming molecules has not been clearly outlined but it embraces almost all aromatic hydrocarbons with a planar structure and certain compounds with heteroatoms. Certain coordination compounds with organic ligands can be included among them.[8,9]

A characteristic spectroscopic feature of excimers is a luminescence band with an anomalously large Stokes shift (5000 – 12000 cm^{-1}). Its identification is based primarily on the following features. Its intensity relative to that of the monomer (molecular) glow in solutions increases with increase in the concentration of the chromophore. In certain media, such variation may not be observed but a common feature is the absence of visible qualitative changes in the absorption spectra of the test systems, i.e. the absence of aggregation in the ground state. Since the radiative transitions in the excimer lead to an unstable state, the excimer component is represented by a broad structureless spectral band. The overlap of the monomer and excimer components of the luminescence is as a rule appreciable. For example, for pyrene — a typical excimer-forming compound — the short-wavelength emission edge in the spectra of excimers occurs at 375 nm, while the 0 – 0 transition of molecular pyrene occurs at 372 nm, i.e. the excimer component almost fully overlaps the region corresponding to the luminescence of the molecular form.[10]

One of the principal characteristics of excimer-forming systems is the ratio of the excimer luminescence intensity to the intensity of the molecular fluorescence band (I_d/I_m).

The formation of excimers is observed in liquid solutions of monochromophoric molecules, in condensed and gas phases, in polymer matrices, and other media over a wide range of physicochemical conditions. The increased interest in excimer systems is due to their use for the solution of applied problems. In particular, the methods for the structural studies on polymers[11–15] and the determination of the properties of biological systems[16,17] are based on the analysis of excimer fluorescence. The spectroscopic parameters of excimers have attracted the attention of investigators also in connection with the attempts to create effective devices for the concentration of radiation.[18]

There exist also dimers which are stable in the ground state, but exhibit the spectroscopic properties of excimers. Such formations have been designated in various studies as sandwich dimers[19–21] and associated dimers.[22–26] Strictly speaking, their luminescence cannot be identified as excimer luminescence in conformity with the definition adopted[2] and they constitute an example of other forms of aggregation of excimer-forming molecules. The formation of dimers is observed in various media but the number of communications on this topic is small.

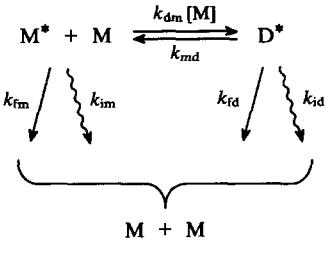
A specific analysis of the recorded excimer-like luminescence was not carried out in all investigations, which suggests that such objects are more common (for example, in the case of many polymers).

II. Excimers in liquid solutions of monochromophoric molecules



The study of processes involving the formation of the excimers of monochromophoric molecules in liquid solutions was carried out particularly vigorously in the 1960s.[27-30]

Eximer formation is determined by the mutual diffusion of molecules. The quenching of the luminescence of the monomer component obeys the Stern–Volmer relation, i.e. the ratio I_d/I_m increases linearly with increase in the dye concentration:

$$\frac{I_d}{I_m} = K[M],$$

where K is the constant of the equilibrium between the monomer and excimer centres and [M] the phosphor concentration. The equilibrium constant K is expressed in terms of the constants of the reactions presented in Scheme 1. This scheme was put forward by Forster[6,7] and was subsequently developed by Birks.[28]

Scheme 1

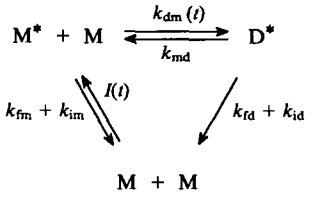
The constants k_{dm} and k_{md} in this scheme correspond to the rates of formation and decomposition of the excimers, k_{fm} and k_{fd} are the constants for the radiative deactivation of the monomers and excimers, and k_{im} and k_{id} are the internal conversion constants for both luminescence centres.

Analysis of the kinetics of the formation of excimers in accordance with Scheme 1 leads to the following definition of the quenching function for the luminescence of the monomer and excimer components after the exciting pulse:[28]

$$I_m(t) = A_1 \exp(-\lambda_1 t) + A_2 \exp(-\lambda_2 t),$$

$$I_d(t) = A_3[\exp(-\lambda_2 t) - \exp(-\lambda_1 t)].$$

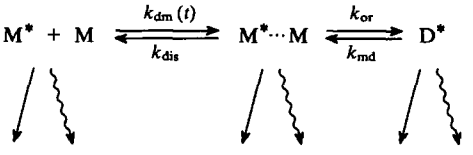
The constants for the process taken into account in Scheme 1 are expressed in terms of the parameters A_1, A_2, A_3, λ_1, and λ_2 and can be determined by various procedures.[31]



Scheme 1 has been hitherto resorted to for the interpretation of the results of experiments,[32-35] but it describes only approximately the excimer formation processes in liquid solutions. The fact that the rate of formation of excimers is assumed to be independent of time in Scheme 1 is most striking. This approximation is justified only for systems after a considerable time has elapsed since the excitation step. Since the rate of formation of excimers is controlled by the diffusion of chromophores, it follows that, in conformity with the theory of diffusion-controlled reactions,[36] it should be expressed in the form

$$k(t) = a(1 + bt^{-1/2}),$$

where $a = 4\pi D N_A R/1000$, $b = R/(\pi D)^{1/2}$, t is the time, N_A the Avogadro number, D the mutual diffusion coefficient of the chromophores, and R the effective reaction radius. The excimer kinetics in various systems have been analysed after adopting this approximation.[37-39] The time variation of the rate of formation of excimers has been called the 'transient effect'.



The development of experimental techniques has made it possible in recent years to obtain data for the construction of better models. In particular, a model has been proposed[40,41] (Scheme 2) in which account is taken of the possibility of the formation of excimers as a result of the reassociation of molecules [the parameter $I(t)$]. The results of calculations taking into account this parameter agree much better with experimental data than those of calculations in accordance with Scheme 1.

Scheme 2

Further improvement of Birks's scheme involved taking into account the orientation processes in the intermediate molecular complexes. Vogelsang and Hauser[42] investigated the kinetics of the quenching of the excimer and monomer luminescence using two approaches: with and without allowance for the time variation of the rate of formation of excimers. The agreement between the calculated and experimental data was better in the first case, but for the initial period both methods yielded results which differed appreciably from the experimental data. The discrepancies were explained by putting forward the following scheme (Scheme 3):[42,43] the excited and unexcited molecules approach one another, after which either excimers are formed as a consequence of the relaxation orientation (constant k_{or}) or the pre-excimer complexes dissociate (constant k_{dis}).

Scheme 3

As already mentioned, excimer formation processes lead to the appearance of physical dimers in which the electronic excitation is delocalised over both molecules.[30] However, a different approach has been developed.[44,45] According to the hypothesis put forward by the author, the appearance of the structureless emission band of the excimers (exciplexes) can be accounted for within the framework of the idea of a fractional energy transfer: as the two molecules approach one another, part of the electronic excitation energy of the first is transformed into the vibrational and rotational excitation of the second, which functions as a quenching agent. The remaining energy is emitted. In this process, the main role is attributed to the interaction of the vibrational states. It has been suggested that this theory possesses quantitative predictive power in relation to the Stokes shift of the excimer luminescence and provides criteria for the assessment of the ability of chromophores to form excimers.

III. Excimer fluorescence of crystals

Excimers are formed not only in liquid solutions but also in media with a greatly restricted mobility of the molecules. In such cases, one is dealing with the so-called excimer-forming centres and the migration of excitation energy towards them. In crystals of organic compounds, the appearance of such centres (predimer sites) is attributed to the presence of structural defects in the bulk phase,[46] the concentration of which can be raised by applying pressure (as a consequence of the sliding of dislocations, neighbouring molecules undergo a reorientation to a productive

geometry similar to the excimer geometry). The activation of these centres is usually explained by the localisation of singlet excitons on them.

The excimer fluorescence of crystals is determined by the temperature. At room temperature, the excimer state in anthracene has a higher energy than the free exciton state and at high temperatures (>400 K) the lattice stabilisation energy is reduced[47] and thermal equilibrium is established between the excimer and free exciton states with appearance of excimer fluorescence.

Typical crystals giving rise to excimer fluorescence under normal conditions are those of pyrene and the α-modification of perylene. In contrast to other polyacenes, the predimer sites in these compounds are not structural defects but regular elements of the crystal lattice—dimers arranged in parallel.[48] The excimer states in such crystals may be populated both by direct excitation and as a consequence of energy migration. The time of the transfer of excitation in pyrene is 5×10^{-5} s and the process activation energy is $\sim8.8\times10^{-21}$ J.[46] Three possible mechanisms of the migration of the excimer state have been proposed:[49] (1) dissociation of excimers into two monomers (in the ground and excited states) with subsequent energy transfer to a neighbouring pair; (2) nondissociative thermal activation of the excimers to a level having the same energy as the S_1 level of the monomer with subsequent energy transfer to a neighbouring pair; (3) the assumption of the pre-excimer geometry by the nonexcited dimeric pair as a result of thermal excitation with subsequent energy transfer from another excited pair.

In the crystals of pyrene and the α-modification of perylene, other excimer states also arise, such as the *B*-state[50] or the *V*-state[51] for pyrene and the *Y*-state[52] for perylene. Fluorescence in the frequency range between the free exciton and normal excimer bands is characteristic of these compounds. In the crystals of the α-form of perylene, normal emission is appreciably quenched below 70 K with the appearance of a new emission band of the excimer type. In the crystals of pyrene at ~120 K, there is a structural transition[48] and normal fluorescence is not quenched as the temperature is reduced. Until recently, the *V*-band was observed only in the time-resolved spectra.[50,53] Mizuno and Matsui[51] were able to obtain a metastable pyrene crystal with the structure of the high-temperature phase at temperatures below the critical temperature. The emission spectra of this and similar specimens are presented in Fig. 1. The *V*-fluorescence of the metastable crystal is recorded by the usual spectroscopic methods.

The dynamics of the excitation of the excimer luminescence in crystals with two excimer states has been investigated.[51,53] Fig. 2 presents the time-resolved spectra of a pyrene crystal in the picosecond range. The *V*-fluorescence is observed most distinctly in the early stage of the development of luminescence, which may indicate the initial relaxation of the excited dimeric pairs to the *V*-state with subsequent transition to the normal excimer state. All the transitions are activated. At high (room) temperatures, the *V*-state gives rise to a relatively indistinct potential minimum in the spectrum, so that the excited state in pyrene under the usual conditions is represented mainly by the free-exciton state and by traps of the normal type.

The situation in the crystals of α-perylene differs only by the rate of the relaxation processes. The relaxation of excitons from the free-exciton state takes place faster than in pyrene, possibly via a tunnel mechanism.[51,53] In the temperature range 4–160 K, the *Y*-state is metastable and lies above the normal excimer state.[54]

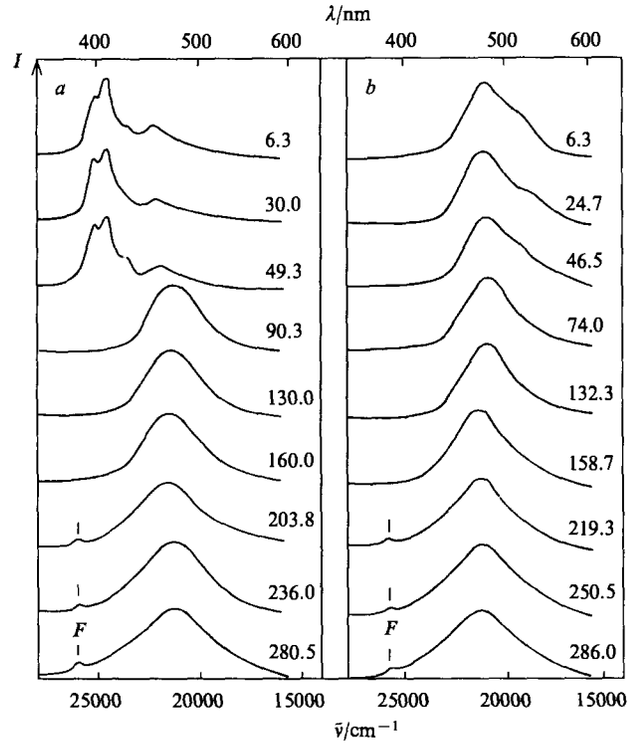


Figure 1. Temperature variation of the fluorescence spectra of crystalline pyrene:[51] (*a*) spectra of the metastable high-temperature phase; (*b*) spectra of the usual crystal; the numerals opposite the curves denote the temperature (K) at which the corresponding spectrum was obtained; *F* denotes the free exciton band.

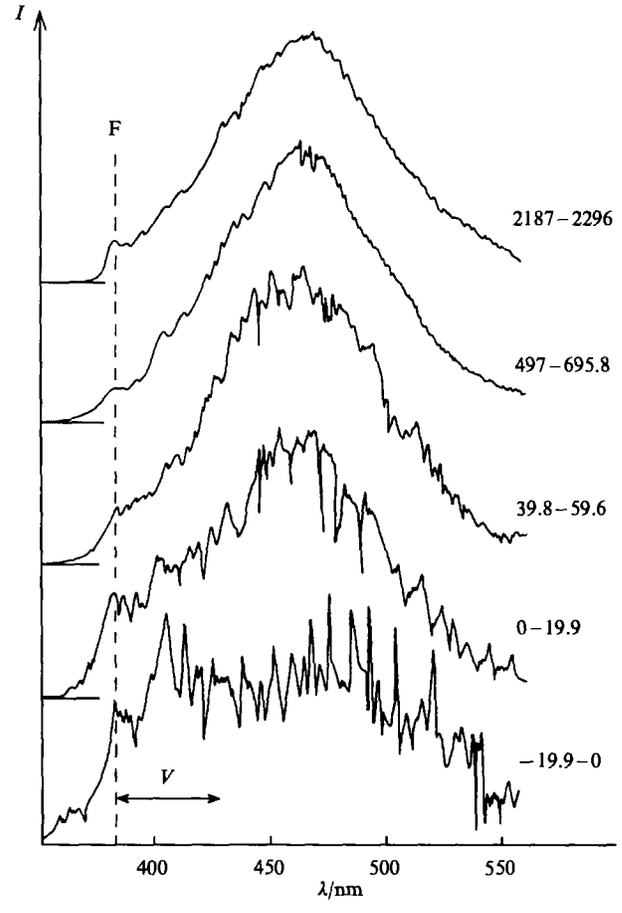

Figure 2. Time-resolved spectra of the pyrene crystal obtained at 293 K. The numbers to the right—time intervals (ps) over which the corresponding curves were integrated; the instant when the exciting laser pulse (λ = 316 nm) reaches maximum intensity is assumed to be the zero time; *F* denotes the free exciton band; *V* denotes the region corresponding to the luminescence of the *V*-centres.[51]

The energy barrier between them is[54] ~ 310 cm^{-1}. It increases following the application of pressure, so that *Y*-fluorescence can be observed also at room temperature.[55]

In melts of organic substances, the specific features of the corresponding crystalline structures are apparently retained. Thus the excimer emission band in the spectra of anthracene melts[47] in the range 460–470 nm is observed only ~ 100 ps after the exciting pulse, which is evidently associated with the necessity for orientation processes on formation of excimers. On the other hand, in the pyrene melt the molecules are evidently in a predimeric state, as in the crystal, because the excimer band is recorded directly after the excitation step.[47] Admittedly, in the temperature range 450–600 K the appearance of a new emission band (390–420 nm) is observed for pyrene. It is either due to the monomolecular form (on the assumption of the thermal dissociation of dimers) or is caused by the formation of yet another kind of excimer complexes.

IV. Excimers in polymers

Almost all the aromatic vinyl polymers, certain heterocyclic polymers, and their various copolymers belong to the excimer-forming class of polymers. Luminescence from both solid specimens and liquid solutions is observed. Similar properties are shown also by solid solutions of excimer-forming molecules in polymer matrices. The excimer luminescence of polymers is due to the presence in their bulk phase of two types of excimer-forming centres.

The excimer-forming centres in polymeric media can be represented both as conformations of sections of polymer chains favourable for the formation of excimers and as sections for which the energy barrier to the assumption of the excimer configuration is very small and which are capable of reorientation during the lifetime of the excited state.[11] The centres of the first type play a major role in solid polymers but they may be formed also in solutions. Neglecting the energy migration processes, the fraction of these centres can be expressed in terms of spectroscopic parameters:[31]

$$f_d = \varphi_{fd}\varphi_{fm} \Big/ \left(\frac{\varphi_{fd}}{\varphi_{fm}} + \frac{q_{fd}}{q_{fm}}\right),$$

where φ_{im} and φ_{id} are the quantum yields of the luminescence of the monomeric† and excimeric centres and $q_{fd}/q_{fm} = Q$ is the ratio of the number of quanta absorbed by the monomeric and excimeric centres. It is assumed here that $\varepsilon_d = 2\varepsilon_m$, ε_m and ε_d being the extinction coefficients of the monomeric and dimeric centres. In this case

$$\frac{I_d}{I_m} = \frac{1}{2}Q\left[(1 + 8[M]_0K)^{1/2} - 1\right],$$

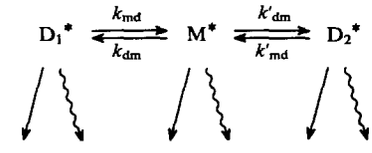
where $[M]_0$ is the overall concentration of the chromophoric fragments and K is the constant of the equilibrium between the dimeric and monomeric forms.

The fraction of conformations favourable for excimer formation is defined by the expression[11]

$$f_d = \frac{W_d \exp(-\Delta E/kT)}{W_m + W_d \exp(-\Delta E/kT)},$$

where W_m and W_d are the multiplicities of the degeneracies of the monomeric and excimeric states and ΔE is the difference between their energies.

† In this section, the monomeric and dimeric centres are understood as isolated chromophores and excimer-forming pairs of chromophores respectively.



Calculations of the structures of poly-2-vinylnaphthalene, polyvinylcarbazole and polystyrene have shown that the fractions of the excimer-forming centres are of the order of 10^{-2}, 10^{-3} and 10^{-3} respectively.[11,56] In the solid polymers, the populations of the excimeric states are determined by the irradiation temperatures of the specimens.

The insignificant concentration of the excimer-forming centres in the polymers together with the observed intensity of the excimer fluorescence lead to the conclusion that the excitation energy is transferred to centres with the monomeric form of the phosphor.[11] The nonradiative migration of energy in solutions may lead to an even greater effect owing to the possibility of the rotational motions of the centres during the lifetime of the excited state of the monomer. Thus the formation of excimers in polymeric systems is a complex process involving the migration of energy and segmental rotation. Furthermore, in solutions there is also a possibility of the macroscopic diffusion of the chromophores, leading to an excimeric configuration, but in polymers these processes are less significant than in solutions of monochromic molecules. For aromatic polymers, the fluorescence of the monomers and excimers is described satisfactorily taking into account the energy migration along the chain[57–62] and in the bulk phase.[63–66] The overall schematic representation of the processes in the polymers taking into account the energy migration and the rotation of the chromophoric fragments has been examined.[59] However, the role of energy migration in polymers still has not been ultimately elucidated. There are experimental facts which cast doubt on its effectiveness. For example, polarisation measurements of the fluorescence of polystyrene films have shown[67,68] that the luminescence retains a high degree of polarisation. This agrees poorly with the hypothesis that energy transfer processes make a significant contribution.

The probability of the formation of excimers in polymeric systems is determined by the structure of the chain and its composition. Attempts have therefore been made in numerous investigations to establish the steric structure of the polymers.[69–82] The formalism of the dynamics of the rotational transitions has been developed[83] for copolymers of the type $A-B_n-A$, where A is the chromophore and B_n are neutral units. In order to establish the possible number of units in contact, computer modelling has been employed.[31,84–86] Studies have also been carried out for low-molecular-mass and bichromophoric analogues of polymers.[87–93]

Among the bichromophoric molecules, one may distinguish two types of compounds—compounds with a flexible linkage between the two chromophores and cyclophane compounds. For the former, the intramolecular excimer formation is preferred to the greatest extent if the chain between the chromophores consists of three carbon atoms.[94] However, this process takes place, albeit with a lower effectiveness, also without the maintenance of this stringent requirement.[95] The formation of intramolecular excimers in bichromophoric molecules is described by two kinetic schemes. In the first case, in the absence of the necessary degree of freedom the excimers are formed only in one steric configuration (see Scheme 1), while in the second (Scheme 4) there is a possibility of two types of complexes.[90] A similar situation is observed also for paracyclophanes,[11] anthracenophanes,[96] pyrenophanes,[97,98] etc.

Scheme 4

The effectiveness of the formation of the excimers of bichromophores in solutions is determined by the kinetics of the conformational changes in the chains linking the chromophores.[11] Depending on the method of formation of the crystals and also on the size and structure of the saturated chains, some of the cyclophanes can give rise to excimer fluorescence also in the solid state.[96]

In individual instances, excimer formation may be an intermediate stage in photochemical reactions. This applies particularly to systems incorporating anthracene chromophores.[31,99-104]

The influence of the composition of the polymer chain on the formation of excimers has been examined for vinylaryl polymers. Fig. 3 presents the dependence of I_d/I_m on the fraction of adjacent chromophores in the chain for solutions of copolymers of the two most typical representatives of this class. The nonzero value of I_d/I_m in the absence of diads in the copolymer chain indicates a finite probability of the formation of excimers between chromophores remote from one another along the chain or between chromophores of different chains. There are also polymers (for example polyacenaphthalene) in which excimers are formed between remote chromophores with a high probability.[31,74,106]

Yet another factor influencing the yield of the excimer luminescence is the molecular mass of the polymers. Typical dependences of I_d/I_m on the chain length for a solution of a copolymer with isolated chromophores and for a solution of a chromopolymer are presented in Fig. 4. Both curves tend to reach a plateau for high molecular masses. However, sometimes, as the length of the polymer chain increases, a decrease in the relative yield of the excimer luminescence is observed. Thus I_d/I_m for dilute solutions of polyindole decreased[86] with increase in chain length and tended to zero already for $N \approx 500$. This result agrees with the results of the calculation of the number of units in contact within the polymer.

Considerable interest in the kinetics of the formation of excimers and polymers has been shown in a large number of studies. The quenching of the luminescence of the monomeric and excimeric components in these media is frequently described by the sum of not two but three or more exponential functions. This shows that the processes in the system cannot be explained within the framework of Scheme 1. One (or several) of the following factors have apparently not been taken into account:[31] the different energy migration distances, the formation of excimeric states as a result of the rotation of segments, and the multiplicity

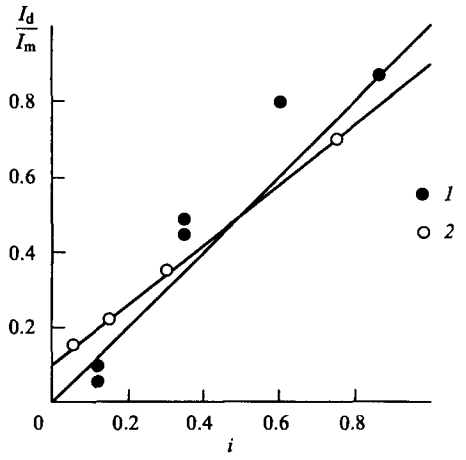


Figure 3. Dependence of I_d/I_m on the fraction of neighbouring chromophores in the chain (i): (*1*) solution of styrene-acrylonitrile in ethanol;[105] (*2*) 2-vinylnaphthalene-dimethyl-maleate in a 3:2 (by volume) tetrahydrofuran–diethyl ether mixture.[71]

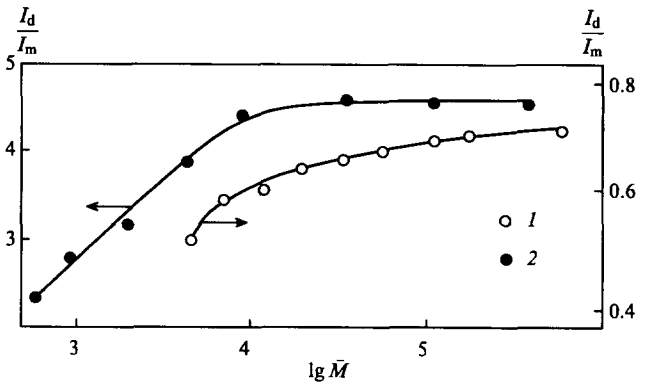

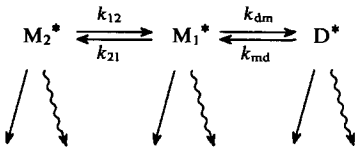

Figure 4. Dependence of I_d/I_m in solution on the molecular mass: (*1*) copolymer of the type $(A-B_n)_N$ (where A = chromophore, B_n = neutral unit, and n = 100) in tetrahydrofuran;[107] (*2*) styrene homopolymer in 1,2-dichloroethane.[11]

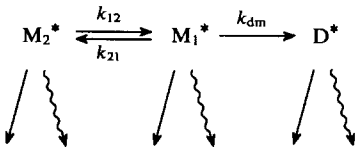
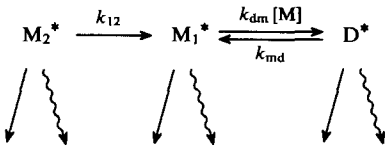
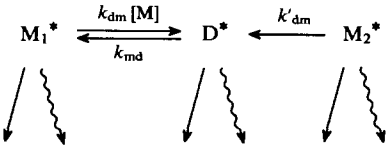


of types of excimeric and monomeric states. Thus models postulating the existence of two different monomeric states have been put forward (Schemes 5–8; M_1 and M_2 designate different conformers).[106,108,109]

In Schemes 5–7, excimers may be formed only from the conformers M_1 as a result of the mutual rotation of the segments. Scheme 8 presupposes their formation also from the conformers M_2 as a result of macroscopic chain motions.

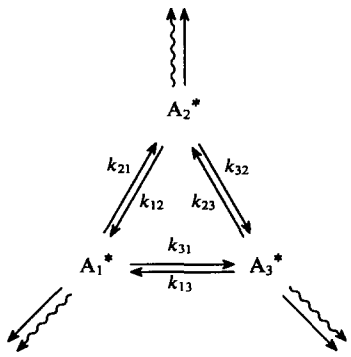


Scheme 5



Scheme 6

Scheme 7

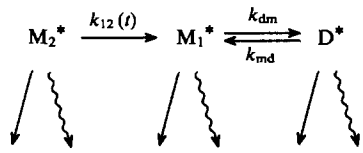


Scheme 8

The formation of several types of excimeric states has been postulated.[110,111] In order to account for the kinetics of the quenching of the luminescence in styrene copolymers, a model with three different monomeric and two excimeric centres, not taking into account the energy migration, was put forward.[112] The general Scheme 9, including three equivalent interconvertible spectral centres A_n, has been analysed.[108]

Scheme 9

However, the models presented in Schemes 5–9 are applicable only to the interpretation of experiments in which the quenching of the luminescence is described by a triexponential function.



Systems in which the quenching of the fluorescence is described more aptly by a tetraexponential relation have been investigated.[111,113,114] The appearance of the fourth component in the expression for $I(t)$ can be attributed to the formation of the fourth luminescence centre, designated as a relaxing monomer or the third excimer. However, the approaches involving allowance for a larger number of luminescence centres for the description of multiexponentially decaying systems have not come to be used widely. Another approach is probably more productive. Thus it has been suggested[59] that the multiexponential decay of fluorescence be regarded as the sum of several dominant energy migration pathways, each of which is represented by the combination of all the possible versions of this process. In this case, the characteristic times of the dominant processes are not related directly to the times of specific physical transformations. Because of this, it has been stated that the excimer kinetics in aromatic polymers must not be described by any kind of phenomenological model on the basis of the number of allowed exponential functions. This approach agrees with the results of studies on the diffusion of energy in nonordered donor–acceptor systems, which indicate the nonexponential nature of the decay of their fluorescence.

A kinetic model based on the initial postulate that chromophores are not constant-energy centres as a consequence of the high dispersion of their relative positions has been developed[65,66] for polyvinylcarbazole films. The excitation energy of the high-energy chromophores migrates to low-lying states with the transfer frequency

$$v(T,t) = v_0 \exp\left[-\left(\frac{T_0}{T}\right)^2\right] + v_1^{\alpha} t^{\alpha-1},$$

where v_0 is the frequency of the transfer of excitation in a hypothetical regular constant-energy polymer, v_1 the discrete step in the variation of the excitation transfer frequency, α a dimensionless parameter assuming values from 0 to 1, T_0 the experimental temperature, and t the time. The dependence of I_d/I_m for the model on λ_{exc}, observed in the region of the long-wavelength edge of the absorption band of polyvinylcarbazole, constitutes experimental confirmation of the proposed model.[65] Scheme 10, which explains the tetraexponential decay of the excimer fluorescence in liquid solutions of polyvinylcarbazole, has also been examined in accordance with this model.[115] If $\alpha = 1/2$, the expression for the transfer frequency formally agrees with the expression for the excimer formation constant, which occurs in the kinetic equations for solutions of monochromic molecules. This approach has been extended to polymer systems.[59,116–120]

Scheme 10

The excimer kinetics have been studied in detail in polyvinylcarbazoles.[121] Studies on polymers of different tacticity by time-resolved spectroscopic methods have in the main confirmed the postulates put forward by Fredriekson and Frank.[59] The existence of two excimeric states has been demonstrated (the formation, together with the usual excimers, of excimeric complexes of yet another kind is observed fairly frequently).[73,76,116,122] The transformations of the high-energy excimeric complexes into normal complexes as a result of the excitation of fluorescence is of interest in this instance.

V. Excimer-forming molecular dimers

So far as we are aware, special studies on dimers of excimer-forming molecules which are stable already in the ground state have not been carried out with the exception of a series of early investigations.[19–21] The spectroscopic manifestations in absorption and emission attributed to such dimers are not subject to clear-cut rules as in the case of excimers. Furthermore, the same compounds have dissimilar optical characteristics under different conditions which can be explained by the nonuniformity of the aggregates formed.

The fact that excimer-forming molecules can be associated in the ground state is not unexpected because attraction forces between the molecules always exist.[123] For example, the interaction energy is $\sim 3.1 \times 10^4$ J mol^{-1} in naphthalene dimers[124] and $\sim 5.9 \times 10^4$ J mol^{-1} in pyrene dimers.[125] Calculations carried out also in other investigations[126] yielded a positive heat of formation of the unexcited excimer-forming dimers. However, quantum-chemical calculations for excited and unexcited dimers have yielded data for the interaction energies of only isolated pairs—a state which is remote from the real conditions. In organic solvents, the potential barrier stabilising the dimeric state vanishes owing to the interaction of the molecules with the solvent,[127] so that the interpretation of the ground and excited states of the pair of chromophores in the form presented in Fig. 5 is in general correct in a qualitative description of the potential energy levels of the excimer-forming system. Dimers stable in the ground state were not detected in special studies of solutions of pyrene in isooctane (10^{-3} M).[10] Presumably the dynamics of the processes in other organic solvents at moderate concentrations of the chromophore is also described satisfactorily by Schemes 1–3. However, even in good solvents one cannot neglect the interaction of the dissolved molecules. As an example, one may quote the result of a study[128] where an anomalously high yield of the excimer fluorescence of dilute solutions of pyrene (10^{-6} M) in ethylene liquefied under pressure and in other solvents was observed. This indicates the existence of a certain degree of long-range order between the chromophores in solution, although naturally one is not dealing in this instance with dimers.

Another picture has been observed in solvents such as water. In aqueous solutions of pyrene, the aggregation of the latter is attributed to its hydrophobic nature. In this case, the maximum of the structureless excimer fluorescence band undergoes a hypsochromic shift by 10–20 nm.[129] The luminescence excitation spectra of the dimeric and monomeric components differ considerably under these conditions. The hydrophobic nature of the chromophores leads to their aggregation in aqueous solutions also in the case of several water-soluble polymers, which is manifested in the absorption spectra.[130–134] The constant of the equilibrium between the monomeric and dimeric centres depends

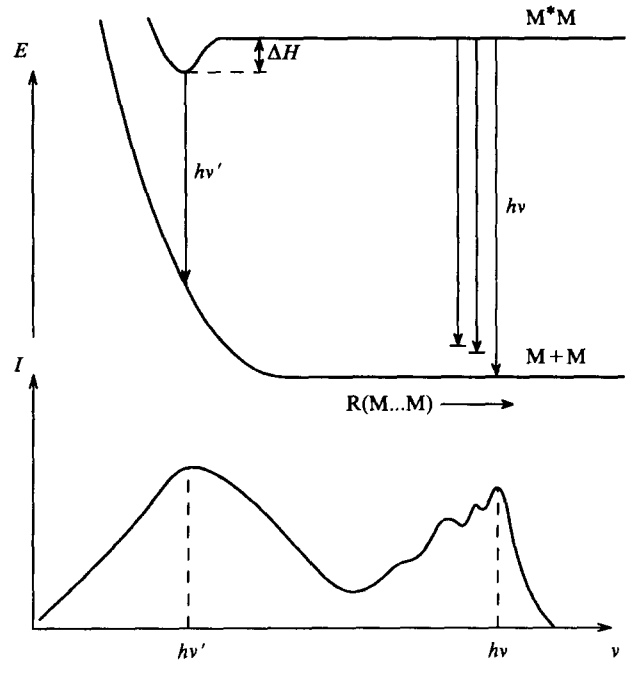


Figure 5. Potential energy (E) diagram for the monomer–excimer system: R(M ... M) = intermolecular distance; ν and ν' = frequencies of radiative transitions in the monomer and excimer respectively; ΔH = heat of formation of the excimers; the upper curve corresponds to the interaction of the molecules in the excimer and the lower to the interaction of the unexcited molecules; the Franck–Condon transitions in the excimer lead to a dissociative ground state which is responsible for the appreciable Stokes shift and the lack of structure in the luminescence.[1]

on temperature. The emission from the phenanthrene dimers has been recorded[135] in the slow fluorescence spectra of solutions in perfluorohexane only at 200 K. On raising the temperature to room temperature, the unexcited dimers dissociated.

There are data indicating the establishment of thermal equilibrium between the excimeric and dimeric centres. Perylene, added to films of the Langmuir–Blodgett type, has been investigated.[136] At room temperature, only the monomeric and dimeric components were recorded in the fluorescence spectra. As the temperature was reduced to 110 K, a new structureless fluorescence band appeared in the long-wavelength region of the spectrum and was attributed to the appearance of excimeric centres.

A pyrene crystal consists of pairs of molecules interacting in the ground state even at room temperature. With decrease in temperature to helium temperature, interaction in the dimers intensifies. Because of this, a new component appears in the absorption spectra of the pyrene crystal in the form of an inflection in the region of 395 nm, which has undergone a bathochromic shift of ~20 nm relative to the molecular absorption band.[49] The existence of pre-excimeric states of this type has been detected also in the absorption spectra of fused anthracene.[137]

Two types of dimers, formed as a result of different processes, have been identified on the basis of the absorption spectra of pyrene single crystals in Shpol'skii's matrices[138] at $T = 4.2-77$ K. The first process, with an activation energy of ~6 cm^{-1}, predominated in the temperature range 4.2–30 K. The formation of excited complexes from aggregates corresponding to the regular crystal structure was postulated in this instance. The second process, with an activation energy of ~70 cm^{-1} and manifested above 30 K, was explained by the presence of defects in the microcrystals, i.e. by the photoexcitation of the dimers, the structure of which differs from the regular crystal structure.

In the emission spectra, the luminescence of the dimers can sometimes be difficult to distinguish from the excimer fluorescence, so that studies on absorption spectra are more reliable for the identification of the dimers. The appearance of an absorption band in the long-wavelength section of the spectrum of the monomolecular form of the phosphor indicates the formation of dimers. As a rule, the new component is indistinct. Fig. 6 presents the absorption spectra of metastable dimers of anthracene and its derivatives obtained by the photochemical decomposition of the chemical dimers in a solid matrix at low temperatures. The luminescence of such species is fully excimer-like, while in the absorption spectrum only a slight bathochromic shift is recorded. Therefore, if both monomeric and dimeric centres absorb radiation in the system, then the fraction of dimers formed can be recorded from the intensity of the absorption band of the molecular S_1 transition.[24, 129, 134, 139] Fig. 7 shows how the optical density in the dimer–monomer system, induced by the displacement of the equilibrium, is redistributed as a function of the solvent composition.

The absorption spectra of the dimers (Fig. 6) demonstrate the general features characteristic of aggregates of this type:[19] the intensity maxima of all the bands due to the dimers have lower energies than the corresponding maxima in the spectra of the monomers (the intensity maximum is represented by the 0–1 transition in the spectra of the dimers and by the 0–0 transition in those of the monomers); an appreciable broadening of the bands in the spectra of the dimers relative to those of the molecules is observed; the total oscillator strength of the transition in the dimer is lower than twice the oscillator strength of the corresponding transition in the monomer.

The greatest number of communications refer to the formation of excimer-like molecular dimers in Langmuir–Blodgett films of different kinds[136, 140–144] or in films obtained by depositing the chromophore onto a solid base[139, 145, 146] and also in fluorescent polymers[130–134, 147, 148] and in solid solutions of the molecules in organic[149] and inorganic[150–152] glasses. Depending on the conditions in the formation of the specimens, the chromophores in such systems can apparently exist in the form of dimers, which may or may not be manifested spectroscopically. If they are not, the excitation of the excimer fluorescence is explained by the migration of energy to the excimer-forming centres.[153–159]

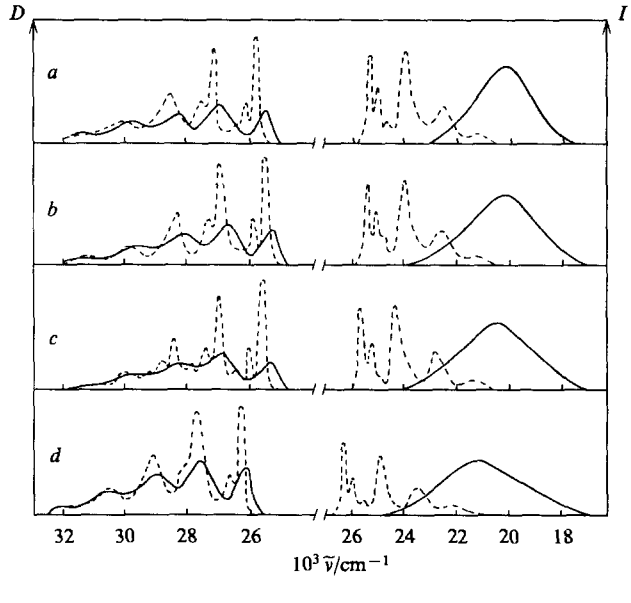

Figure 6. Absorption and emission spectra of the sandwich dimers in methylcyclohexane[19] at 77 K; the spectra of the monomer obtained after unfreezing and refreezing the specimens are indicated by dashed lines: (*a*) 9-methylanthracene; (*b*) 9-bromoanthracene; (*c*) 9-chloroanthracene; (*d*) anthracene.

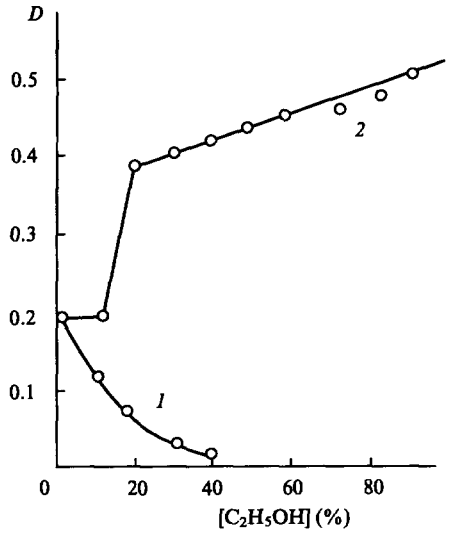

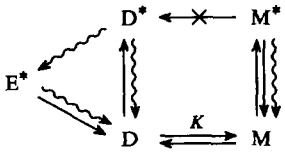

Figure 7. Optical densities of solutions of pyrene in a water–ethanol mixture[129] (phosphor concentration 14×10^{-6} M). Wavelength (nm): (*1*) 360 (S_1 transition in the monomer); (*2*) 319 (S_2 transition in the monomer).

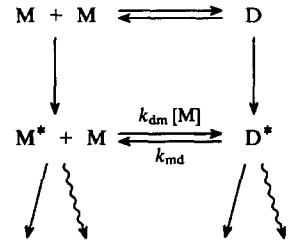
The attempts at a systematic treatment of the observed wide variety of the fluorescence properties of the dimers have demonstrated the following features. Radiation is absorbed by dimers which differ in their interaction energies in the ground state in different systems. Energy transfer processes from isolated chromophores also play a definite role. The type of interaction between the molecules in the ground state of the dimer is close to the type in the excited state,[20] so that the transitions between the levels yield a spectrum which resembles that of molecular fluorescence. If during the excitation period the dimer can relax to the excimer geometry, its spectrum resembles that of the excimer. A structured spectrum of the luminescence due to the dimer has been published.[135] The case of strong interaction has been described for anthracene dimers,[96] the maximum of the excimer-like fluorescence showing a bathochromic shift by ~100 nm relative to the spectrum illustrated in Fig. 6.

Pyrene and naphthalene, adsorbed in the form of dimers (stable in the ground state) on the surface of silica gel, have been investigated.[139,145] Dimerisation was recorded on the basis of the luminescence excitation spectra. The proposed process dynamics is illustrated in Scheme 11.[139]

Scheme 11

It is suggested that the fluorescence arises in the excimeric state, although the dimeric centres absorb. The symbols M* and D* in the scheme denote the monomers and dimers excited respectively from the ground states M and D, E* is the excimer formed as a result of small steric relaxations of the excited dimer, and K is the constant of the equilibrium between the monomeric and dimeric centres in the ground state. It is suggested that, during the lifetime of the excited state of the monomer, there is no energy transfer to the dimeric form. In this case, the dependence of I_d/I_m on the concentration of the chromophores is expressed thus:



$$\frac{I_d}{I_m} = A\left[(1 + 8K[M_0])^{1/2} - 1\right],$$

where $A = \varepsilon_d \varphi_{ed} \varphi_e / 4K\varepsilon_m \varphi_m$ (φ_m and φ_e are the quantum yields of the fluorescence of the monomer and excimer respectively and φ_{ed} is the quantum efficiency of the formation of the excited dimers). The excited dimers relax to the excimeric state very rapidly[145] and the fluorescence arises after less than 1 ns.

These experiments may be compared with studies on the van der Waals fluorene dimers formed in molecular beams on expansion at an ultrasonic velocity.[160,161] The potential energy curves for such systems and the energy transitions are illustrated in Fig. 8. The radiative transitions lead to the dissociated state, although radiation is absorbed by the dimeric form. Similar data are available for benzene[162] and naphthalene derivatives.[163] Excimer-like fluorescence has been recorded under analogous conditions also on excitation of the trimers of 1-cyano-4-methylnaphthalene and its higher-order clusters. The excitation of the stable associated species of 1-cyanonaphthalene with triethylamine[164] and of fluorene with methyl-substituted dienes[165] also led to the appearance of an exciplex-like glow. Comparison of the spectroscopic parameter of the dimers and excimers has shown that the latter are characterised by a greater Stokes shift of the luminescence and a longer lifetime of the excited state (150 and 62 ns for the excimers and dimers of 1-cyano-4-methylnaphthalene respectively).[163]

The excimer-formation processes in liquid-crystal systems began to be studied comparatively recently.[166–168] The formation of excimers in such systems has been unambiguously confirmed by time-resolved spectroscopy.[167] At high chromophore concentrations, one cannot rule out the formation of excimers via the migration of energy to the excimer-forming centres.[168] Subsequent studies on these systems demonstrated the possibility of molecular association in the ground state. In order to explain the experimental results, Scheme 12, including the formation of dimers stable in the ground state, was put forward:[169]

Scheme 12

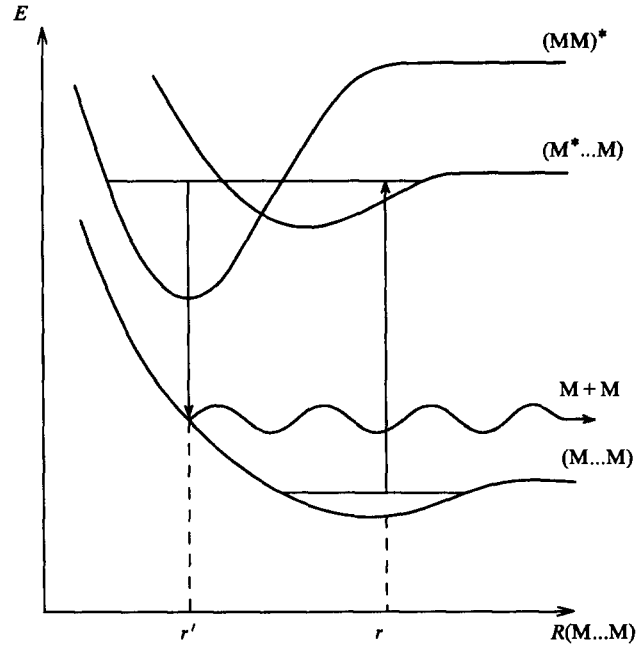


Figure 8. Potential energy curves for the interaction of fluorene molecules.[161]

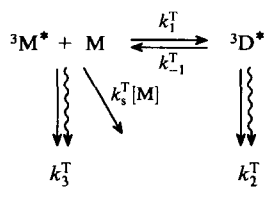
According to this scheme, the decay of the fluorescence of the monomeric and dimeric components is described by a biexponential relation. In all probability, a more complex model of the excitation of the excimer-like luminescence is also possible in liquid-crystal mixtures. The fluorescence of the dimers stable in the ground state has been recorded[170] in time-resolved spectra. A triexponential function best described the decay of the luminescence of the excimer-like component.



The fluorescence properties of the excimer-forming dimeric systems have been described most fully by Yamanaka et al.[152] Solid solutions of pyrene in an inorganic glass exhibit a structured band in the time-resolved spectra due to the fluorescence of the dimers (the *D* band in Fig. 9) with maxima at 381, 399, and 418 nm. At the same time the luminescence of the sandwich (E_2 band) and high-energy (E_1 band) excimers is observed in the spectrum. Isolated molecules emit the *M* band, which is manifested after the decay of the *D* fluorescence.

VI. Excimer phosphorescence and slow excimer fluorescence

The interaction of two excimer-forming molecules, one of which is in the excited triplet state, leads to the appearance of excited triplet dimers. Their phosphorescence was observed in almost all media where the singlet excimers were found to be formed: in liquid solutions, crystals, and polymers.

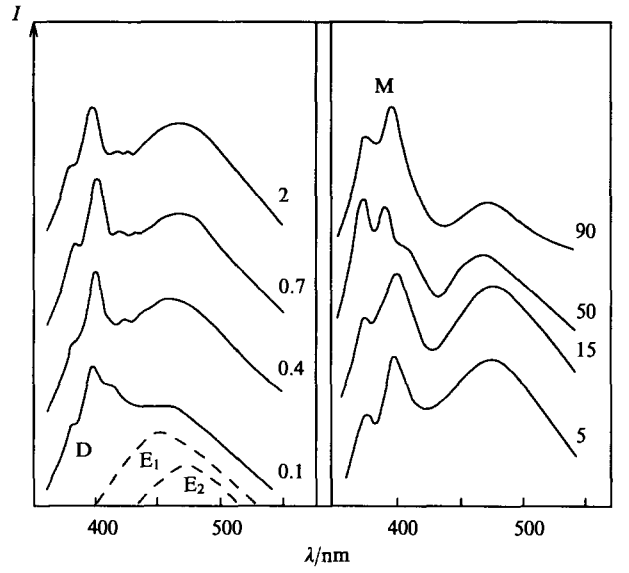
In liquid solutions, the existence of excimer phosphorescence was established on the basis of the following experimental facts:[171,172] the excitation spectrum of this type of phosphorescence is identical with the absorption spectrum of the corresponding monomer; the yield of the excimer phosphorescence increases with increasing solute concentrations; the excimer phosphorescence bands are observed only in liquid solutions and are absent from the spectra of frozen specimens; the phosphorescence of the excimers, like that of the monomers, is quenched by oxygen when the hermetic seal in the cell is broken. Analysis of the kinetics of the formation of the triplet complexes in conformity with Scheme 13 showed that the rate of the process is much lower than the rate of diffusion. It has been suggested that dimers are formed via a stage of intermediate complexes even before the acquisition of the excimer configuration.

Scheme 13

The constants k_1^T and k_{-1}^T in the scheme correspond to the rates of formation and dissociation of the complexes, the constants k_3^T and k_2^T correspond to the rates of the radiative and nonradiative deactivation of the monomers and dimers respectively, and k_s^T is the self-quenching rate constant.

The reliability of data concerning the existence of triplet excimers in liquid solutions has been questioned. Nickel and Prieto[124] reproduced the experiments from a large number of studies (see the list of references in their communication) where the breakdown of triplet phosphorescence had been reported. The reproduced experiments yielded a negative result and it was concluded that the observed luminescence is more likely to be the impurity glow of the solvents. The results lead to the conclusion that the triplet excimers of aromatic hydrocarbons are unstable, although the existence of weakly bound intramolecular triplet excimers in certain diarylalkanes has been admitted.

Such conclusions aroused the active opposition of a number of investigators, which has given rise to a controversy.[173] On the other hand, the presence of triplet excimers in crystals and



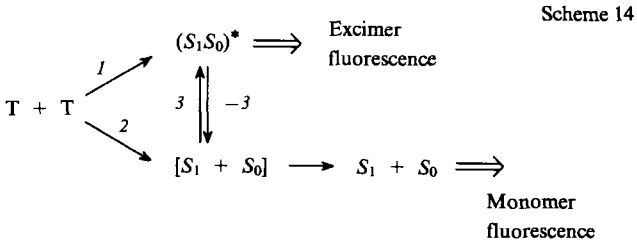


Figure 9. Time-resolved fluorescence spectra of solid solutions of pyrene in a silicate glass[152] (4×10^{-2} M); the numerals opposite the curves represent time (ns).

polymeric media is apparently not open to doubt. Two types of excimers have been detected in pyrene crystals[174-176] and excimer phosphorescence has been observed at low temperatures also in the crystals of halo-derivatives of benzene,[174,177,178] phenanthrene, and naphthalene.[179] Triplet excimers are formed in carbazole-containing[29,180-182] and naphthyl-containing[183-187] polymers.

Apart from the formation of triplet excimers, intersystem crossing processes initiate a slow excimer fluorescence. In the general case, its appearance is a consequence of processes leading to a slow *P* type fluorescence.[27] Different versions of the excimer formation processes on interaction of two triplet molecules in solutions are illustrated in Scheme 14.

Scheme 14

Three pathways leading to the excitation of excimer fluorescence of this type are possible: (1) simultaneous formation of singlet excimers and pairs of monomers (reactions *2* and *1*); (2) formation of singlet excimers with their subsequent dissociation to the monomeric form (reactions *1* and *3*); (3) exclusive formation of monomeric centres with subsequent formation of singlet excimers as a result of the reassociation of the molecules in the ground and excited singlet states (reactions *2* and *3*). Singlet excimers are formed after triplet–triplet annihilation via a stage involving intermediate complexes. The slow excimer fluorescence may be recorded if the rapid excimer fluorescence does not arise.[100,188,189]

The slow excimer fluorescence, induced by the migration of triplet excitons, is also observed both in liquid solutions of polymers and in solid polymer matrix at low temperatures. This confirms data indicating an increase in the intensity of the slow singlet fluorescence relative to phosphorescence with increase in the molecular mass of the homopolymer.[182,187]

VII. The structure of excimeric complexes

Excimers have a structure with a coplanar (sandwich) disposition of the molecular planes and an intermolecular distance of 3–3.5 Å. This conclusion was reached already at an early stage of the research into excimers, which agrees with data on the structures of crystals of the type of pyrene, α-perylene, 1,12-benzoperylene, etc.[19,48,96] The luminescence of such crystals is of the excimer type. This is also confirmed by the results of numerous experiments with flexible bichromophores in liquid solutions: the formation of intramolecular excimers is observed only when the molecule is capable of assuming the sandwich form. This type of structure has been confirmed also by the analyses of the polarised excimer fluorescence,[190] quantum-chemical calculations,[35,126,191–196] and the results of photochemical experiments.[3,11,19,20] However, the structure of the chromophores themselves or the influence of external factors frequently prevent the assumption of this geometry.

The introduction of bulky substituents, crystal structure defects, the morphological characteristics of chromophore-containing polymers, etc. frequently lead to the appearance of several types of excimeric configurations in real systems: in certain cases, it is possible to distinguish spectroscopically, together with excimers of the normal (sandwich) type, also one or several other types of excimers, which can be identified in terms of the polarisation characteristics of the glow, the position of the fluorescence band maximum, and the lifetime of the excited state of the complex. The wavelengths of the luminescence maxima of different types of excimers of certain compounds are listed in Table 1.

Excimers exhibiting luminescence in the region between the molecular band and the band due to normal excimers exist for virtually all classical excimer-forming chromophores (pyrene, naphthalene, anthracene, and carbazole). This type of luminescence is attributed to aggregates, which, in contrast to the normal ones, are characterised by an incomplete overlap of the orbitals of the aromatic nuclei. Such states are designated as high-energy states, second excimers, or dimer-like excimers. Nevertheless, their stabilisation requires a significant degree of overlap of the aromatic rings; for example, a degree of overlap of 25% is insufficient for naphthalene.[204] For more bulky chromophores, the degree of overlap of the electron shells may be smaller compared with compounds with a short conjugation chain.[11] An incomplete sandwich structure may arise also for a not fully parallel relative arrangement of the chromophores in the polymer chain.[86]

Spectroscopic data do not permit the determination of the details of the spatial disposition of the molecules in the excimeric complex, but in the case of polymeric systems the geometry of the excimeric centres may be found from conformational calculations for the chains.[72,78,101,199,203,205,206] The polarisation characteristics of the luminescence of excimers for different helicoidal configurations of the polymer chain have been obtained by computational methods and from the analysis of the fluorescence.[203,207–210] The different structures of the excimers in polymers have been attributed to the positions of the interacting molecules in the chain: the structures of the complexes are different when they are formed between neighbouring and remote sections of the polymer. If the polymer chain contains two types of nonequivalently linked chromophores, the formation of three types of excimeric complexes is noted.[199]

Isolated ('free') isomers are characterised by a finite number of relatively stable states, the population of which is determined by the influence of external factors. Calculations have shown that, for an intermolecular distance of ~3 Å, the excimers of naphthalene, anthracene, and pyrene can assume only two steric configurations. The interaction energy depends on the angle between the long molecular axes in the sandwich dimer and, together with the principal minimum (at 0°), has local minima at 55°[35] or 40°–50°[126] for pyrene, at 75° for naphthalene,[193,194] and at 65° for anthracene.[195]

The ability of molecules to form different excimeric configurations is associated with the contributions of different states to the wave function for the system. The stability of excimeric complexes is determined by the exciton-resonance interaction and the forces arising as a result of charge transfer.[30] In this sense, excimers are regarded as a special case of exciplexes. With increase in the length of conjugation in the benzene–naphthalene–anthracene–pyrene, etc. series, the energy gap between the molecular levels diminishes, which leads to an increase in the role of the exciton–resonance interaction. For example, the interaction due to charge transfer predominates in the benzene complexes,[162] whereas pyrene excimers are described almost entirely by the exciton-resonance component of the wave function.[35,211] Since the charge-resonance interaction is more isotropic, the benzene excimers may be formed in different configurations, although the sandwich configuration is nevertheless the most stable.[162]

In this connection, one should note that there are virtually no literature data on high-lying excited states of the excimers. As a rule, they do not play a significant role in the kinetic process examined in the previous sections. They aroused interest precisely in connection with the study of the two-photon ionisation of benzene. The stabilisation energy of its excimers in the second excited state exceeds by an order of magnitude this parameter for the S_1-excited complexes (1.8×10^4 and 5.9×10^2 J mol^{-1} respectively).[162]

For compounds with a pyrene fragment (i.e. with a long aromatic system), two configurations of excimers, differing by the displaced positions of the molecules in the sandwich complexes relative to one another (by half the length of the benzene ring along the long axes), can be clearly distinguished. Excimers of one of these type are formed in crystals, being retained also in liquid solutions.[28] The centrosymmetric structure of the excimer determines its zero ground state overall dipole moment and hence the forbidden optical transitions. This is reflected in the different fluorescence decay times: ~150 ns for the centrosymmetric model and 60–70 ns for the structure with incomplete overlap of the π-systems of the aromatic rings.[90] The same type of system occurs also in α-perylene crystals. Calculations have shown[191] that an isolated perylene excimer has an energy minimum for the complete overlap of the rings, but dimers of this type do not occur in crystals.

The short decay time of the V and Y components relative to the normal glow in pyrene and α-perylene makes it possible to attribute these types of fluorescence to the formation of weakly bound complexes. It is assumed that such states arise as a consequence of the incomplete relaxation of the molecules in the dimers.[50,54,191] According to Sumi,[52] the nature of these centres can be related to the association of pairs of molecules more remote from one another in the crystal than in the case of the dimeric pairs discussed above.

The relation between the thermodynamic parameters and structure of excimers has been examined.[90] It was shown that the entropy–enthalpy ($\Delta S-\Delta H$) relations are different for different excimeric configurations (Fig. 10). Another conclusion is that the entropy gain may be responsible for the formation of weakly bound complexes with a small or even positive value of ΔH. This accounts for the existence of weakly bound triplet excimers.

The structures of triplet excimers have been calculated, but contradictory results were obtained.[126,192,195,212] According to the data of Padma and coworkers,[126,192] the structure of the naphthalene and anthracene triplet excimers differs from the sandwich structure. For pyrene, the structures of the complexes of both multiplicities were obtained for virtually identical asymmetric configurations. The structure of the triplet state of all the molecules considered is virtually identical with the structure of the corresponding unexcited dimers. This has been explained by the fact that the stability of the triplet structure of excimers is determined by van der Waals forces, as in the unexcited dimers.

Table 1. The fluorescence maxima of the excimers

Chromophore	Experimental conditions	λ_{max}^{fl}/nm	Ref.
Benzene (phenyl)	Liquid state	320	197
	Solution of polystyrene–acrylonitrile copolymer in methanol	325	105
	Solution of polystyrene in 1,2-dichloroethane	332	82
	Solution of low-molecular-mass polystyrene analogues (2,4-diphenylpentane, 2,4,6-triphenylpentane, 2,4,6,8-tetraphenylnonane) in methylene chloride	330	198
	Solutions in dichloromethane		
	of hexaphenoxycyclotriphosphazene	~340	199
	hexacresoxytriphosphazene	~330	199
	polybisphenoxyphosphazene (T = 160–300 K)	305–310	199
	polybis-*p*-cresoxyphosphazene (T = 160–300 K)	320–330	199

	Single crystal	625	52
	Langmuir–Blodgett films		
	excimer	600	144
	band due to dimer	546	144

The differences between the singlet and the corresponding triplet complexes are determined largely by the different contributions of the exciton–resonance interaction.

The geometrical differences between excimers of different multiplicities have been demonstrated experimentally in relation to the following examples. Chandross and Dempster[20] obtained naphthalene sandwich dimers in a methylcyclohexane glass at 77 K. The fluorescence of such dimers was excimer-like whereas the phosphorescence was of the structural type corresponding to the naphthalene monomer. In another study,[213] where solutions of binaphthalene compounds were investigated, only the fluorescence due to the monomer and the triplet excimer glow were actually recorded; the association of the singlet complexes was hindered, whereas the triplet ones might have been formed with an asymmetric configuration.

Calculations of the geometries of the unexcited naphthalene, anthracene, and pyrene dimers showed that[126] the centrosymmetric sandwich conformation does not give rise to a stable ground state. The benzene dimers, which are stable in the ground state, are assumed to be capable of assuming the T-type, sandwich,[214,215] and V-type (house of cards)[216] forms. These states are separated by small potential barriers, so that the geometry of the benzene dimers is very sensitive to external influences.[217]

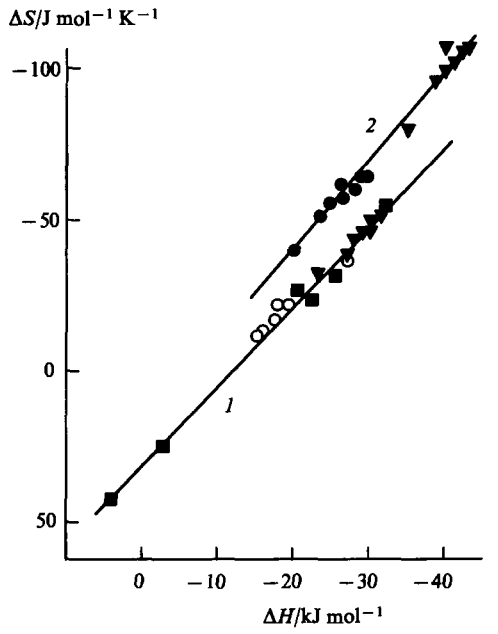

Figure 10. Dependence of ΔS on ΔH for intramolecular excimers of certain dipyrenylalkanes in various solvents.[90] The data plotted along straight line *1* correspond to centrosymmetric complexes with full overlap, while those plotted along line *2* correspond to complexes with displaced molecules (partial overlap).

VIII. Conclusion

In the present review we have attempted to concentrate attention on questions which arose during the last 10–15 years and which have not been adequately analysed in the scientific literature. This concerns primarily the conditions under which various excimer species arise. Unfortunately the available information does not permit a deeper elucidation of this problem. Without accurate calculations of the geometries of the complexes, it is impossible to achieve significant results in studies on the assignment of the spectroscopic manifestations of the excimeric centres to their structure. Such calculations have still not been carried out. Nevertheless steps taken in this direction would make it possible to obtain a more precise method in the field of studies, which have already become traditional (studies on the kinetics and the structure of the medium), using excimer-forming fluorescent probes.

Another problem which has become urgent is due to the unsuccessful definition of excimers adopted in the literature.[2] In particular, one may point to the lack of clear-cut criteria for the assignment of fluorescence to the excimeric or dimeric type. Nevertheless, this is not a fundamental problem. In the literature, there are examples of the study of dimers and excimers from a general standpoint (i.e. when no account is taken of the difference between them).[46,218] However, the simplified consideration of excimers from the standpoint of the somewhat idealised Scheme 1 frequently hinders the understanding of the essential features of the phenomenon. Attention was already drawn to this at an earlier stage. For example, two definitions of excimers have been formulated:[124] kinetic and spectroscopic. The former reflects the dynamic aspect of the formation of the excited complexes, while the latter definition postulates the similarity of the fluorescence characteristics of the excimeric and dimeric centres. The data presented in this review show that the second approach is also limited in character. For example, the low-temperature fluorescence of crystalline pyrene (Fig. 1) is excimeric despite the resolved vibrational structure if its consideration is based on the fact that the excitation is initially localised in a free-exciton state (i.e. in the monomer). In our view, the term excimers should be given to appropriately excited associated species stabilised by resonance interaction, regardless of the nature of the ground state.

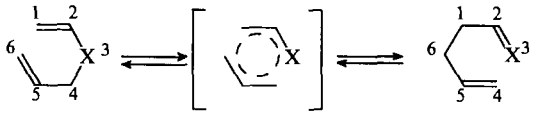
Abstract. Literature data on [3,3]-sigmatropic rearrangements of organofluorine compounds are surveyed and described systematically in terms of the type of substances and intermediates involved in the rearrangements. The characteristic features of these reactions are considered as a function of the structure of the isomerising molecules and the positions in the latter of fluorine atoms and fluorine-containing substituents. The possibilities arising from the use of the [3,3]-sigmatropic rearrangements for the specific synthesis of fluorine-containing compounds belonging to particular classes are assessed. The bibliography includes 180 references.

I. Introduction



The [3,3]-sigmatropic rearrangements, which include the Claisen and Cope rearrangements, as well as their different modifications (Carroll, Ireland–Claisen, Johnson–Claisen, etc. rearrangements) and their numerous versions based on unsaturated compounds with hetero- and functional-group substituents constitute one of the most important synthetic methods in modern organic chemistry.

This type of intramolecular rearrangements was discovered by Claisen[1] in 1912 in relation to the thermal transformations of the allyl ethers of phenol and 2-naphthol into the corresponding *C*-allyl derivatives. Later similar reactions were investigated for a large number of substituted allyl (propargyl) aryl ethers, which made it possible to develop high-temperature synthesis of a wide variety of unsaturated aryl-substituted aliphatic substances (see the relevant reviews[2–4]).

The extension of the Claisen rearrangement to aliphatic and alicyclic systems (ethers, sulfides, and amines) as well as heteroaromatic compounds and the discovery of the Cope rearrangement[5] and its modifications converted the [3,3]-sigmatropic reactions into a universal method for the specific construction of the carbon skeletons of compounds containing multiple bonds in the 1,5-positions relative to one another. The principal advances in the last two decades of the study of the Claisen and Cope rearrangements have been described in a number of reviews[6–13] and numerous data on hetero-[3,3]-sigmatropic rearrangements are available in other reviews.[14–18]

The [3,3]-sigmatropic rearrangements are irreplaceable in the syntheses of many substances with a complex structure. For example, effective methods for the synthesis of polyenes have been developed on the basis of consecutive [3,3]-sigmatropic rearrangements,[13] while certain versions of the Cope aza-rearrangement have been used to synthesise the previously unavailable nitrogen-containing polycyclic systems.[17, 18] However, the importance of these reactions is mainly associated with the total synthesis of polyfunctional unsaturated compounds, the preparation of which by other methods usually involves several stages.

The extensive synthetic possibilities of the [3,3]-sigmatropic reactions are responsible for the continued interest in the theoretical aspects of these reactions. In accordance with the ideas of Woodward and Hoffman,[19] the [3,3]-sigmatropic rearrangements are assigned to the class of unimolecular pericyclic reactions. They take place as thermal concerted processes in accordance with the general **1** → **2** mechanism predominantly via a six-centre quasi-aromatic transition state of type **A***.

1 **A*** **2**

X = CH_2, O, S, Se, NH.

The most preferred pathway in these reactions involves a supra-suprafacial formation of the transition state **A*** in the chair form.[6, 13, 19] This is the reaction for the high effectiveness of the stereochemical control of the rearrangements, which frequently lead to the enantioselective formation of a C–C bond. By virtue of this, they are widely used in asymmetric synthesis,[20, 21] primarily for the preparation of biologically active natural products and their analogues.[22–26]

The formation of the transition state **A*** in the aliphatic Claisen rearrangement (in contrast to the purely carbon systems) is accompanied by an appreciable charge separation,[27] i.e. is a charge-controlled process, which leads to extensive possibilities for controlling it. Thus the rate of the [3,3]-sigmatropic reactions increases by 2–6 orders of magnitude in the presence of polar solvents or catalysts stabilising the zwitter-ionic or ionic states of the intermediates.[9, 10] The principal reagents generating anions

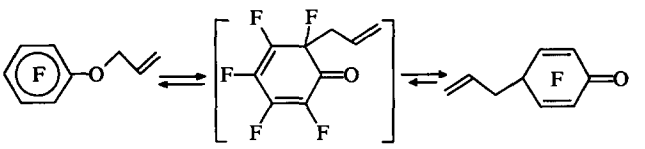
derived from the initial substrates exert an even stronger influence. For example, the rate of the sigmatropic shift in the Cope oxy-rearrangement increases by a factor of $10^{10}-10^{17}$ if the reaction intermediate is the anion formed when the substrate is acted upon by metal hydrides.[28] A similar acceleration is observed in the carbanionic Claisen rearrangements[29-32] and in all these reactions the temperature of the rearrangement is reduced sharply. A similar but less marked effect may be produced by substituents at the multiple bonds of allyl vinyl ethers **1**, which enhance the π-donor properties of the 'vinyl' and/or the π-acceptor properties of the 'allyl' fragments.[29, 33-35] Thus the [3,3]-sigmatropic rearrangements, which had been previously considered as hard thermal processes, can be achieved as soft chemo-, regio-, and stereo-selective transformations of 1,5-diene systems.

The mild conditions and the high rate of the reactions are especially characteristic of the relatively little investigated [3,3]-sigmatropic rearrangements of fluorine-containing unsaturated compounds. The anomalous behaviour of aliphatic fluoro-compounds in reactions of this type was first described in 1967 by Krespan in the paper "Negative substituents in the Claisen rearrangements".[36] The unexpected results of this study, which has since become classical, have served as a powerful stimulus to the more extensive use of [3,3]-sigmatropic rearrangements of compounds of the organofluorine series. It was shown subsequently[37] that not only the specific features of the electronic effects of the fluorine atoms and the fluoroalkyl groups but also the special nature of the double bond in the fluorinated olefins, which tends to combine with fluorine and alkoxide ions to form carbanions, exerts a significant influence on the conditions and nature of the reactions of the fluorine-containing substrates.

The rearrangements of the allyl and propargol ethers of polyfluorophenols polyfluorocycloenols, and aliphatic polyfluorophenols as well as the esters of the polyfluorocarboxylic acids and polyfluoroallyl ethers have been investigated. However, until recently there were no surveys of data concerning the [3,3]-sigmatropic rearrangements as a method of organofluorine synthesis. In the reviews published recently,[37, 38] only individual aspects of the problem are considered which emphasises still further its timeliness.

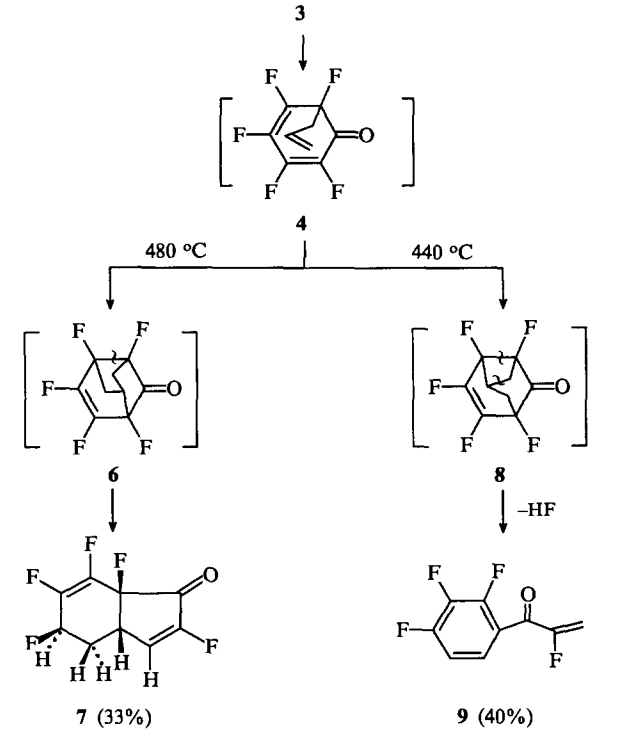


In the present review, an attempt is made for the first time to survey fully and to give systematic account of data on the [3,3]-sigmatropic reactions of fluorine-containing compounds and to assess the possibilities and prospects of their use for the specific synthesis of new organic derivatives of fluorine.

The review is not concerned with the Cope rearrangements (see the relevant communications[38-43]), because studies on the thermodynamic, kinetic, and stereochemical effects of fluorine and the trifluoromethyl group in these reactions are of no preparative value.

II. Rearrangements of polyfluoroaryl ethers

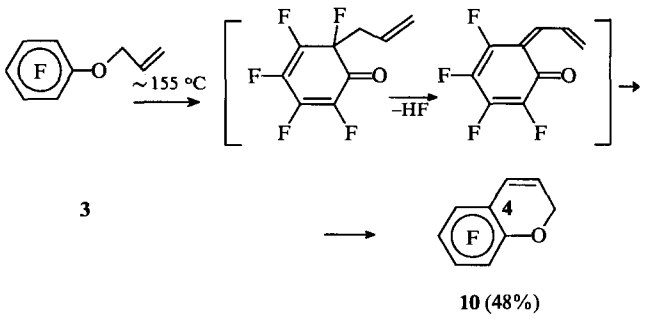
Allyl(propargyl) aryl and allyl heteroaryl ethers and sulfides fully or partly fluorinated in the aromatic ring as well as the corresponding phenyl trifluoromethyl ethers and phenyltrifluoromethylamines have now been involved in the Claisen rearrangement or its different versions. The most interesting results have been obtained in the study of the rearrangements of compounds with aromatic perfluoro-fragments in the gas phase and in solutions. The characteristic features of these reactions were elucidated in an excellent series of studies by Brooke[44-53, 56-60] in relation to perfluorinated phenyl, 2-naphthyl, 2-, 3-, and 4-pyridyl, quinolin-2(4)-yl, and pyrimidin-4-yl ethers.



In contrast to allyl phenyl ether,[6, 54] heating of allyl pentafluorophenyl ether **3** in the gas phase at 137–141 °C (for 13 days) or at 365 °C leads to the *para*-rearrangement product 4-allylpentafluorocyclohexa-2,5-dien-1-one **5** and not to the expected *ortho*-rearrangement product the 2,4-dien-1-one **4**.[44, 45]

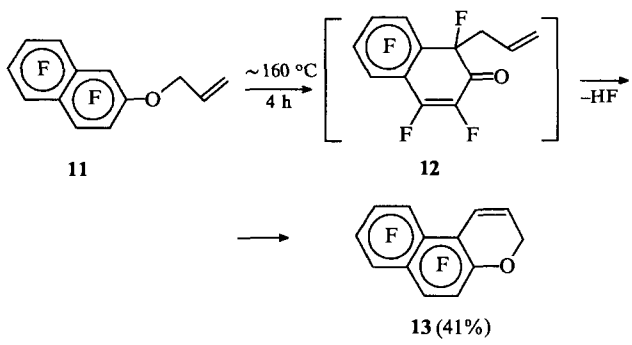
3 **4** **5**

The yield of compound **5** increases from 10% to 32% with increase in temperature. The absence of the dienone **4** among the reaction products is associated with its low thermodynamic stability, its ability to undergo reversible isomerisation to the ether **3**, and also its tendency to undergo side reactions.[45]



Indeed, the gas-phase pyrolysis of compound **3** at 440 °C–480 °C in a quartz tube filled with siloxane fibre affords either pentafluorotetrahydroinden-1-one **7**[46] or 1′-fluorovinyl 2,3,4-trifluorophenyl ketone **9** mixed with compound **7** as the main product.[47] Their appearance is explained by the alternative transformations of the dienone **4** into the intermediate tricycloketones **6** and **8**, which are formed as the stereoisomeric adducts as a result of the intramolecular Diels–Alder [4 + 2]-cycloaddition.[46, 47]

Under these conditions (480 °C), the dienone **5** is also converted into compound **7** in 28% yield, which demonstrates the reversibility of the rearrangements **4** ⇄ **5** under severe conditions.[46]

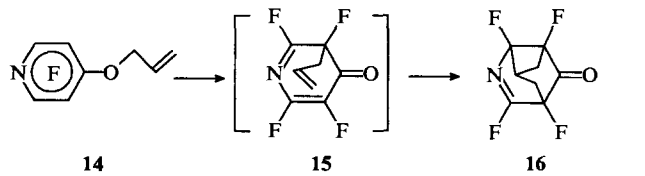


It was possible to isolate the tricyclic ketone **8** after the low-temperature (137–141 °C and 13 days) thermolysis of compound **3** in the gas phase.[48] This compound, which is the first carbocyclic Diels–Alder adduct obtained in the rearrangement of an allyl aryl ether, was characterised by spectroscopic methods and by conversion into a hemihydrate,[48] which was subsequently obtained also from compound **3** but without the intermediate isolation of compound **8**.[45]

Another type of reaction of the ether **3** take place in the liquid phase (DMF, refluxing, 4 h) in the presence of potassium fluoride.[49] In this case, the temperature of the rearrangement of the ether **3** is appreciably reduced compared with the temperature of the isomerisation of the allyl phenyl ether,[6, 54] while the primary *ortho*-rearrangement product **4** undergoes successive dehydrofluorination and intramolecular electrocyclisation to tetrafluoro-2*H*-1-benzopyran **10**.

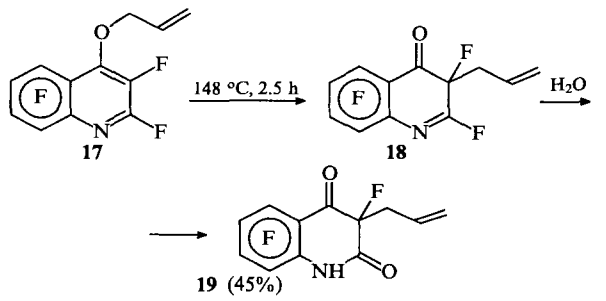
3 10 (48%)

Allyl heptafluoro-2-naphthyl ether **11** is similarly converted into 5,6,7,8,9,10-hexafluoro-2*H*-napththopyran **13** in the KF/sulfolan system.[49]



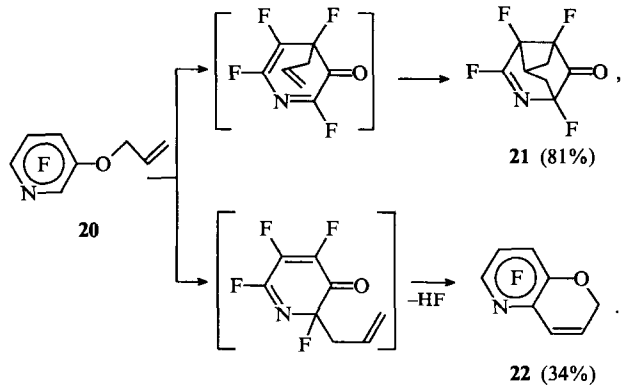
11 **12** **13** (41%)

However, at 135 °C in xylene the ether **11** isomerises smoothly, in 64% yield, to the *ortho*-rearrangement product 1-allylheptafluoronaphthalen-2-one **12**, which is stable, in contrast to compound **4**.[50]



The structural rearrangements occurring in the [3,3]-sigmatropic rearrangements of allyl tretralfluoropyridyl and allyl hexafluoroquinolinyl ethers are in many respects similar to the reactions of allyl perfluoroallyl ethers examined above. The mode of these reactions is determined primarily by the position of the allyloxy-group relative to the nitrogen atom and they occur as a rule under milder conditions than the rearrangements of the non-fluorinated analogues.[6, 12]

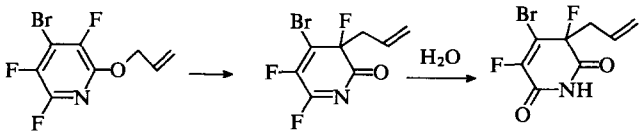
Thus the low-temperature gas-phase thermolysis (138 °C, 10 h) of allyl tetrafluoro-4-pyridyl ether **14** leads to the tricyclic ketone **16** in a yield up to 25%. This compound is formed as a result of the stabilisation via the [4 + 2]-cycloaddition of the product **15** of the *ortho*-rearrangement.[51]



14 **15** **16**

On the other hand, when allyl hexafluoroquinolin-4-yl ether **17** is refluxed in *o*-xylene the stable product of the *ortho*-rearrangement is produced—the quinolinone **18**, which readily hydrolyses to the dione **19** during isolation.[52]

17 **18** **19** (45%)



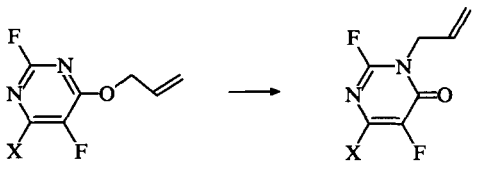
Allyl tetrafluoro-3-pyridyl ether **20** is converted under conditions more severe than for the ether **14** (gas phase, 185 °C, 113 h), into the tricyclic ketone **21**,[51] whilst heating in sulfolan in the presence of KF (nickel flask, 184 °C, 4 h) leads to its conversion into 6,7,8-trifluoro-2*H*-pyranopyridine **22**.[49]

20 **21** (81%) **22** (34%)

The opposite direction of migration of the allyl group in the [3,3]-sigmatropic shift in the second reaction is explained by the strong influence of the protophilic solvent.[49]

It is of interest to note that, in contrast to the ethers **14** and **20**, the rearrangement of allyl 4-bromo-3,5,6,-trifluoro-2-pyridyl ether **23** is completed, even after prolonged heating in the gas phase (160 °C, 139 h), by the formation of the stable product **24** of the *ortho*-C-migration of the allyl group, which is hydrolysed during isolation to 3,4-dehydropiperidinedione **25**. The degree of conversion of the ether **23** is 38%.[51]

23 **24** **25** (7%)

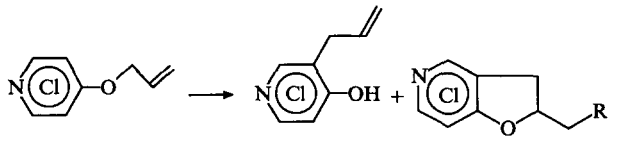


The formation of the *N*-allyl-substituted product was not detected in this reaction.

Nevertheless the migration of the allyl group exclusively to the nitrogen atom is characteristic of the thermal reactions of allyl hexafluoroquinolin-2-yl and allyl hexafluoroisoquinolin-1-yl ethers in tetralin (212 °C, 48 h). These rearrangements result in the formation of fluorine-containing *N*-allylquinolinone **26** and *N*-allylisoquinolinone **27** in satisfactory yields.[52]

26 (69%) **27** (45%)

The rearrangements of allyl polyfluoropyrimidin-4-yl ethers **28** take place with much more difficulty. The products **29** of the [3,3]-sigmatropic shifts were obtained from the ethers **28** in 53%–67% yields only at 440–475 °C under the conditions of gas-phase pulsed pyrolysis.[53]



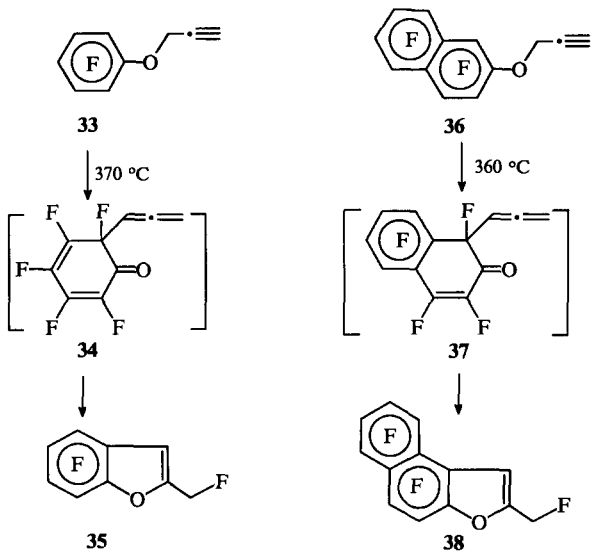
28 29

X = H, F, OMe.

The probability of the migration of the allyl group to the N(3) atom in this reaction proved significantly higher than that of the migration to the C(5) atom, which made it possible to develop on its basis a new approach to the preparative synthesis of derivatives of 5-fluorouracil and barbituric acid.[53]

Evidently the features of the [3,3]-sigmatropic rearrangement of allyl perfluoroaryl and allyl polyfluoroheteroaryl ethers noted above can be explained primarily by the high $+E$ contributions of the fluorine atoms to the aromatic and conjugated cyclohexa-2,4-diene systems and also by the reaction conditions. These factors are responsible, in the first place, for the enhancement of the π-donor properties of the aryl fragment and hence for the appreciably milder, compared with the non-fluorinated analogues, conditions in the Claisen rearrangement, which is completed (in aprotic solvents) by the formation of stable *ortho*-rearrangement products — bicyclic 2-aryl ketones incapable of isomerising to the corresponding *ortho*-hydroxyallyl derivatives. In the second place, they are responsible for the higher probability of the stabilisation of the intermediate 2,4-dienones either (in the gas phase) via the intramolecular [4 + 2]-cycloaddition or (in protophilic media) via dehydrofluorination, with subsequent electrocyclisation.

By virtue of the influence of the fluorine atoms, the Claisen rearrangements of aromatic polyfluoro-compounds and the subsequent reactions of the *ortho*-rearrangement products are unique. Even chlorine, which is very close to fluorine as regards the electromeric contribution, is incapable of altering quite so radically the traditional modes of these reactions. Thus allyl tetrachloro-4-pyridyl ether **30** isomerises under conditions more severe than in the case of compound **14** (sulfolan, 190 °C, 1.5 h).[55] The product of the *ortho*-rearrangement of the ether **30** does not exhibit a tendency to undergo any of the transformations examined above and is stabilised by a homolytic mechanism with formation of a mixture of allyl-2,5,6-trichloro-4-hydroxypyridine **31** and fluoropyridines **32**.

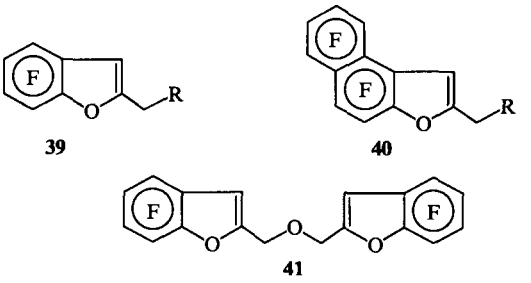


30 31 (26%) 32 (16.5%)

R = H, Cl.

The data obtained by Brooke and coworkers[56-60] in the study of the rearrangements of pentafluorophenyl propargyl ether **33** and heptafluoro-2-naphthyl propargyl ether **36** confirm the strong influence of the perfluoroallyl groups on the nature of the [3,3]-sigmatropic shift. The gas-phase pyrolysis of the ethers **33** and **36** at 360–370 °C leads to tetrafluorobenzofuran **35**[56] and hexafluoronaphthofuran **38**[57, 58] in 8% and 43% yields respectively. The polyfluorofuranes are formed as a result of the electrocyclisation of the intermediate *ortho*-rearrangement products **34** and **37** accompanied by the [1,4]-fluorotropic shift.

In solutions, these rearrangements occur already at 140 °C–150 °C, the structure of the final products being determined under these conditions by the nature of the solvents employed. The maximum selectivity in the formation of compounds **35** (yield 17%) and **38** (yield 81%) is observed in solution in Khladon 113 [Freon 113].[58] In solvents of the π-donor type (benzene, *p*-xylene),



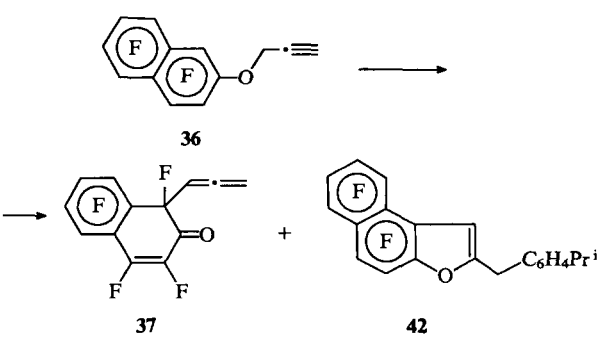
33 36

370 °C 360 °C

34 37

35 38

the products of the incorporation of the solvents into the molecules of the annelated furans **39** and **40** are formed together with compounds **35** and **38**.[56] In addition an appreciable amount (11%–18%) of the ether **41** is formed from the ether **33** in Khladon 113 and benzene.[58, 59]



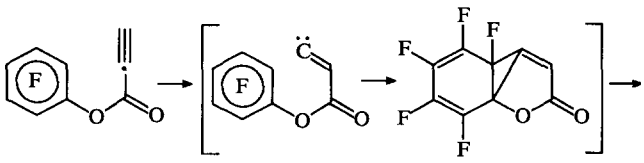
39 40

41

For **39**: R = Ph (28%), 2,5-$Me_2C_6H_3$ (21%);
For **40**: R = Ph (64%), 2,5-$Me_2C_6H_3$ (73%).

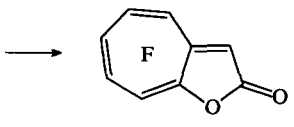
When the ether **33** is isomerised in *N*,*N*-diethylaniline (153 °C, 134 h), the latter solvent is also incorporated into the structure of the final furan, but numerous products of side reactions of the initial compound are mainly formed in the given reaction.[60] On the other hand, the rearrangement of the fluorine-free phenyl propargyl ether in boiling *N*,*N*-diethylaniline proceeds relatively smoothly and affords 2*H*-1-benzopyran (yield 2%) as the main product, formed on cyclisation of the intermediate products of the *ortho*-rearrangement.[6]

Interesting results have been obtained in the study of the rearrangement of the ether **36** in isopropylbenzene (155 °C, 24 h),[59] where the naphthalenone **37**, which is a stable compound, was isolated in 10% yield together with the naphthofuran **42**.



36

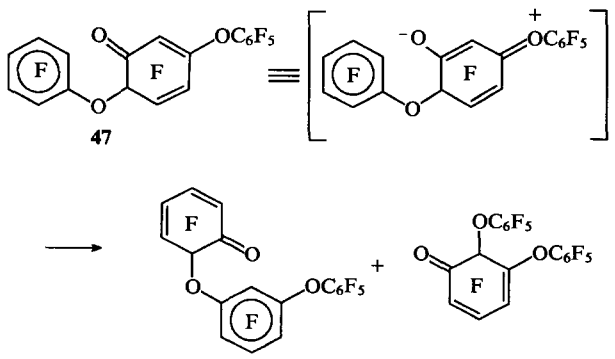
37 42



The appearance of the naphthalenone among the reaction products indicates that the [3,3]-sigmatropic shift is of the usual type in perfluoroaryl propargyl ethers and is accompanied by the inversion of the propargyl group and the acetylene–allene rearrangement. At the same time, the stability of compound **37** suggests that compound **35** and **38–42** would not necessarily be formed solely from the products of the *ortho*-rearrangement of compounds **34** and **37**.[56] Their synthesis is probably ensured also by another pathway — directly from the type **A*** transition state of the reaction. This mode of reaction is associated with the thermodynamically favourable homolytic cleavage of the C–F aromatic bond and a subsequent [1,4]-fluorotropic shift. At any rate, the involvement of arene solvents of the π-donor type (and apparently of traces of moisture) in the formation of the furans **39–42** can be explained solely by a free-radical mechanism of the reactions.

Pentafluorophenyl ethers containing fragments related to the allyl propargyl groups are also capable of undergoing rearrangements, being converted into exotic products under these conditions.

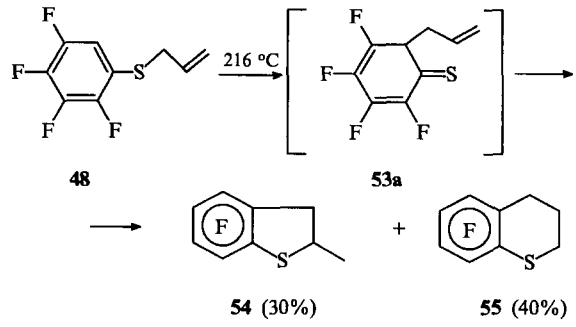
Under the conditions of vacuum pyrolysis (640 °C, 0.01 Torr), pentafluorophenyl propiolate **43** is transformed into 4,5,6,7,8-pentafluoro-2*H*-cycloheptatrieno[*b*]furan-2-one **46**.[61a] The formation of compound **46** is attributed[61a] not to [3,3]-sigmatropic shift[61b] but to the thermal acetylene–methylenecarbene rearrangement[61c] leading to the generation of the carbene **44** in the first stage. The subsequent intramolecular conversion of the pentafluorophenyl group into a cyclopropane derivative and rearrangement of the intermediate oxatricyclodecanone **45** with ring expansion afford the furanone **46** in 8% yield.



43 **44** **45**

46

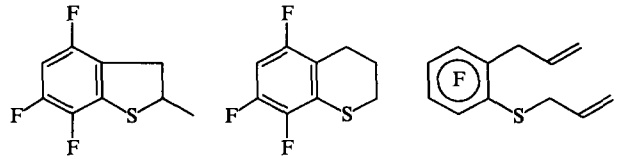
When phenyl propiolate is used as the initial compound in this reaction, the yield of the corresponding furanone reaches 45%.[61b]



It is believed[62] that the O–O′ migration of the C_6F_5 group in the molecule of perfluoro-3,6-diphenoxycyclohexa-2,4-dien-1-one **47** takes place via a mechanism involving the [3,3]-sigmatropic rearrangement under exceptionally mild conditions (CCl_4, 50 °C, 3.5 h). The authors suggest[62] that this reaction is favoured by the appreciable charge separation in the initial compound **47** with the localisation of the excess electron density on the carbonyl oxygen.

47

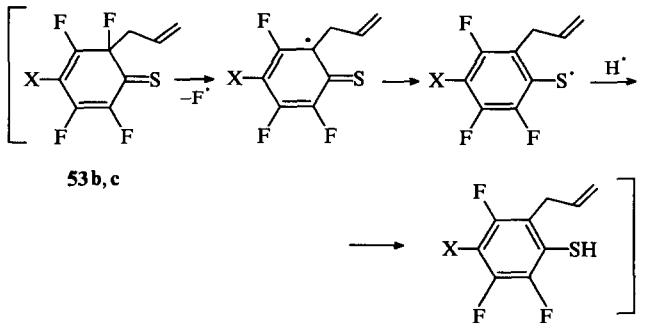
The Claisen thio-rearrangement has been investigated by Brooke and coworkers[49, 63] in relation to allyl 2,3,4,5-tetrafluoro-phenyl sulfide **48**, allyl 2,3,5,6-tetrafluorophenyl sulfide **49**, allyl pentafluorophenyl sulfide **50**, pentafluorophenyl propargyl sulfide **51**, and heptafluoro-2-naphthyl propargyl sulfide **52**.[64]



The rearrangement of the sulfide **48** proceeds smoothly in boiling *N*,*N*-diethylaniline with the intermediate formation of the 2,4-diene-1-thione **53a**, which cyclises, after a [1,3]-prototropic shift, to the dihydrobenzothiophene **54** and the dihydrobenzothiopyran **55**.[63]

48 **53a**

54 (30%) **55** (40%)

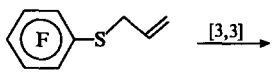


The thiophene **56** and the thiopyran **57** were obtained under the same conditions from the sulfide **49** in 5% and 12% respectively. The reaction of sulfide **50** in *N*, *N*-diethylaniline, which led to the isolation of compounds **54** and **55** in an overall yield of 7% and of the sulfide **58** (yield 8%) is just as ambiguous.[63]

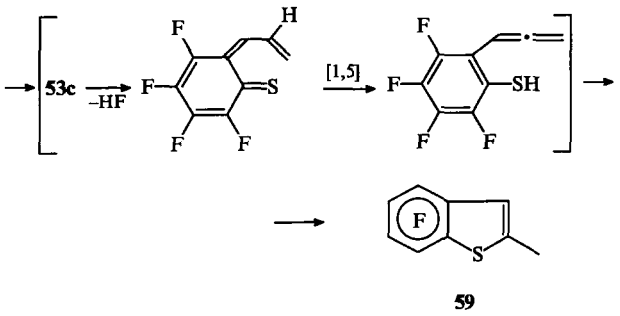
56 **57** **58**

Furthermore, the rearrangements of the sulfides **49** and **50** result in the formation of appreciable amounts of ethyl polyfluorophenyl sulfides, which indicates the dominant role of *N*,*N*-diethylaniline in the side reactions.

In contrast to the thione **53a**, the *ortho*-rearrangement products **53b** and **53c**, formed initially from the sulfides **49** and **50** respectively, undergo subsequently reductive defluorination. The homolysis of the aliphatic C–F bond is favoured by the biradical nature of the thiocarbonyl group in compounds **53b** and **53c** and by the presence of a highly electron-donating solvent in the reaction sphere.[63]



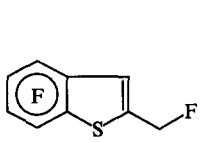
53b,c



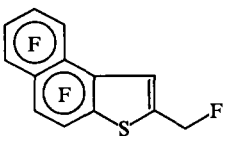
X = H (b), F (c).

On heat treatment of the sulfide **50** in the KF-sulfolan system (nickel flask, 192 °C, 22 h), the reaction proceeds via a different pathway.[49] In this case, only 4,5,6,7-tetrafluoro-2-methylbenzo-[*b*]thiophene **59** was isolated in 9% yield from a complex mixture of final products. According to Brooke,[49] the intermediate **53c** is

initially dehydrofluorinated, the process being accompanied by the [1,5]-migration of the vinyl hydrogen atom to the terminal heteroatom.

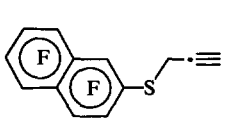


50

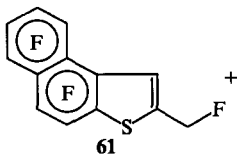


59

The rearrangements of the perfluoroaryl propargyl sulfides **51** and **52** in Khladon 113 at 160–180 °C lead to the thiophene **60** and **61** in 13% and 14% yields respectively.[64] Evidently, as in the case of perfluoroaryl propargyl ethers, these reactions are accompanied by a [1,4]-fluorotropic shift.

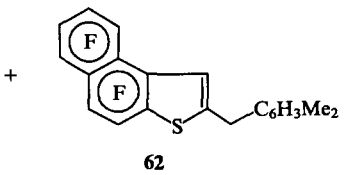


60



61

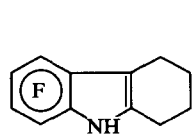
In the gas phase at 360 °C, the yield of the thiophene **61** reaches 81%.



The thermal reactions of the sulfide **52** in *p*-xylene make it possible to obtain either mainly the thiophene **61** (nickel flask, yield 61%) or exclusively the product **62** of incorporation of *p*-xylene (glass bulb, yield up to 85%), depending on the material of the reactor.[64]

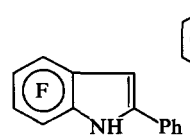
52

61



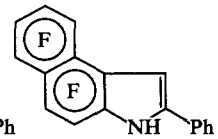
62

The mode of the rearrangement of the sulfide **52** probably depends on the ability of the reactor wall to sorb fluorine atoms, which determines the probability of the involvement of the arene in the transformation of the reaction intermediate.



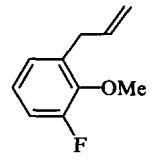
The Cope 3,4-diaza-rearrangement, which is a key stage in the Fischer synthesis of indoles,[17] has been investigated in relation to 2,3,4,5-tetrafluorophenyl-, pentafluorophenyl-, and heptafluoro-2-naphthylhydrazones.[65–67]

On refluxing in concentrated hydrochloric acid, cyclohexanone tetrafluorophenylhydrazone is converted smoothly into 5,6,7,8-tetrafluoro-1,2,3,4-tetrahydrocarbazole **63** (yield 50%), while acetophenone tetrafluorophenylhydrazone in converted on heating (215 °C) with $ZnCl_2$ into tetrafluoro-2-phenylindole **64** in 15% yield.[65]

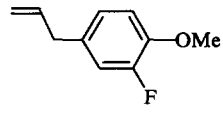


The indole **64** is the main product (yield 12%) also on refluxing acetophenone pentafluorophenylhydrazone in tetralin (208 °C) in the absence of any catalyst or condensing agents.[66] The non-catalysed thermolysis of acetophenone heptafluoro-2-naphthylhydrazone is more effective under the same conditions: the product of this reaction — hexafluoro-2-phenylbenzo[*e*]indole **65** — was isolated in 37% yield.[66] The corresponding fluorinated indoles were obtained by a similar procedure from the pentafluorophenyl- and heptafluoro-2-naphthyl-hydrazones of various aldehydes and ketones.[67] It has been noted[67] that the presence of a fluorine atom in the *ortho*-position relative to the nitrogen atom in the initial hydrazones accelerates their conversion into products of the Fischer reaction. The formation of polyfluoroindoles is apparently formally associated under these conditions with the reductive defluorination of the primary products of the *ortho*-rearrangement.

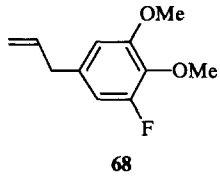
63



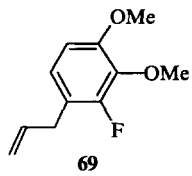
64



65



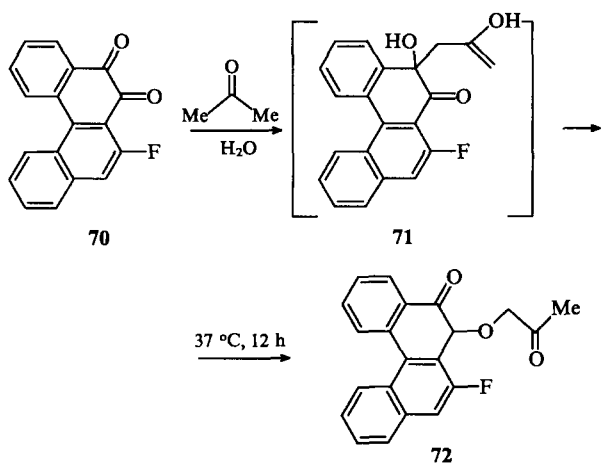
The [3,3]-sigmatropic rearrangements of the partly fluorinated allyl aryl ethers have been less investigated. It has been shown[68a] that allyl 2-fluorophenyl ether is converted in *N*-methylpyrrolidinone (195 °C, 3.5 h) preferentially into the *ortho*-rearrangement product **66** with an admixture of the *para*-rearrangement product **67**. On the other hand, heat treatment of allyl 2-fluoro-6-methoxyphenyl ether does not lead to its isomerisation, but in the presence of Lewis acids as the catalysts a mixture of the *para*-isomer **68** and the *meta*-isomer **69** is formed from this ether even at −20 °C, the latter compound being an unusual product of the Claisen rearrangement.[68b] All the compounds obtained in the above studies[68a, 68b] were isolated in the form of the corresponding methyl ethers.



66

67

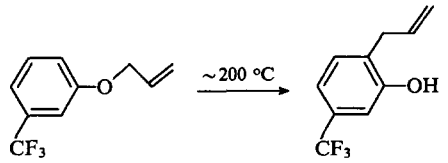
68



69

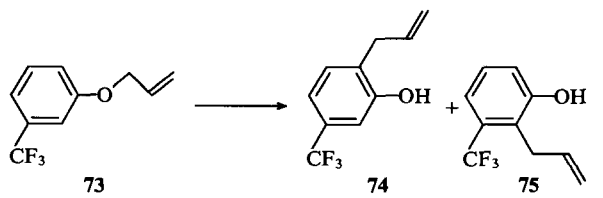
The rearrangement of 3-fluoro-substituted aryl penta-2′,4′-dienyl ethers takes place just as readily in the presence of $AlCl_3$ etherate.[69]

Interestingly, the presence of Lewis acids (which lower the reaction temperatures and accelerate not only the Claisen rearrangement[68b, 69] but also the Claisen retro-rearrangement[13]) is not required for the Claisen retro-rearrangement of the monofluroro-derivative of a quinone.[70] The aldol condensation of 7-fluoro-benzo[*c*]phenanthrene-5,6-quinone **70** with an excess of water-containing acetone leads to the primary formation of two regioisomeric intermediates **71** of the aldol type (one regioisomer is illustrated). The intermediate aldols **71** undergo the spontaneous



Claisen retro-rearrangement with formation of acetylmethyl ethers **72** (one regioisomer is shown).[70]

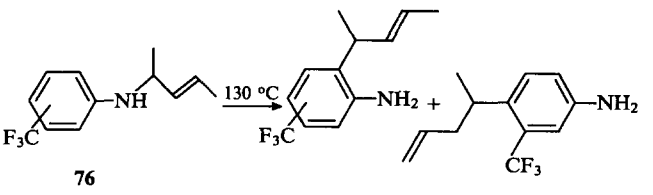
70 **71** **72**



The interaction of the 7-fluoroquinone **70** with acetophenone in solution in $MeCN/H_2O$, reaching completion in the stage involving the formation of the corresponding aldol which is incapable of undergoing the Claisen retro-rearrangement, constitutes an indirect confirmation of the reaction mechanism proposed by the authors.[70]

The influence of the trifluoromethyl group in the *meta*-position relative to the allyl group in allyl phenyl and methylallyl phenyl ethers on the rate and conditions of the Claisen rearrangement has been investigated. On refluxing (without a solvent) under a CO_2 atmosphere, methylallyl 3-trifluoromethylphenyl ether does not rearrange, while allyl 3-trifluoromethylphenyl ether **73** gives rise to the *ortho*-rearrangement product **74** at a rate lower by a factor of 15 than the fluorine-free analogue.[71]

73 **74**

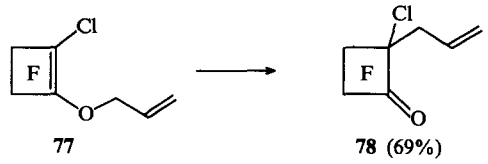


In dimethylformamide at 220 °C, the difference between the rates of rearrangement of the ether **73** and of its non-fluorinated analogue is abolished and, together with the phenol **74**, an equal amount of its regioisomer **75** is formed in an overall yield of the rearrangement products of 81%.[72a]

73 **74** **75**

A mixture of the same composition was obtained when the above reaction was catalysed by boron trichloride and under the conditions of an electric discharge, the induction of which increases, according to the authors' calculations,[73] the rate of the [3,3]-sigmatropic shift by tens of orders of magnitude.

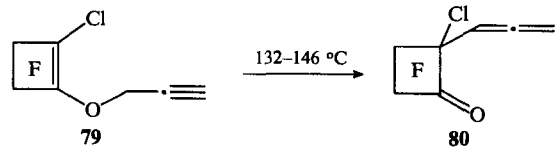
The CF_3 group exerts a greater influence, compared with the rearrangement of the ether **73**, on the rate of the Claisen amino-rearrangement. Thus, in solution in nitrobenzene, the hydrochlorides of *N*-alkenyl-3(4)-trifluoromethyl-anilines **76** rearrange 100 times more slowly than the hydrochloride of *N*-(1-methyl-but-2-enyl)aniline.[74]



76

Thus the CF_3 group lowers the rate of isomerisation of compounds **73** and **76** similarly to other electron-accepting substituent in the *meta*-position[72a] or the *para*-position[72b] in the aromatic ring and has a negative influence on the rate of the Claisen rearrangement and on the conversion of the initial allyl aryl ethers (up to their decomposition).

III. Rearrangements of polyfluorocycloalkenyl ethers



The [3,3]-sigmatropic rearrangements of compounds of this class have been investigated in relation to derivatives of polyfluorinated cyclobut-1-enols, cyclopent-1-enols, and cyclohex-1-enols as well as five-membered heterocycles with one or two heteroatoms. The sigmatropic shift in these systems takes place much more readily (at 25–150 °C) than in the case of allyl(propargyl) polyfluoroaryl ethers. The ring size, the effects of the substituents at the C(1) atom of the 'vinyl' fragment, the nature of the 'allyl' fragment of the molecule, and probably the degree of aromaticity of the ring in the initial compounds have a decisive influence on the conditions and rate of the rearrangement.

In the series of ally(propargyl) cycloalkenyl ethers, the polyfluorocyclobutenyl ethers enter into the Claisen rearrangement with the greatest difficulty. Thus allyl 2-chlorotetrafluorocyclobut-1-enyl ether **77**[75] is converted at an appreciable rate into chlorotetrafluorocyclobutanone **78** only at 120–130 °C.[36] The reaction is completed in 8 h.

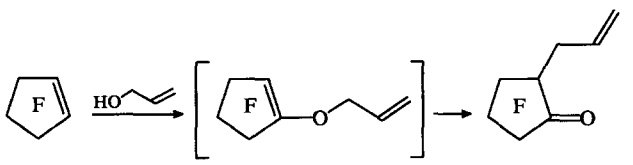
77 **78** (69%)

The propargyl ether **79** isomerises with much greater difficulty. Under these conditions, the [3,3]-sigmatropic shift is accompanied by the acetylene–allene rearrangement and the formation of the cyclobutanone **80** in 55% yield.[36]

79 **80**

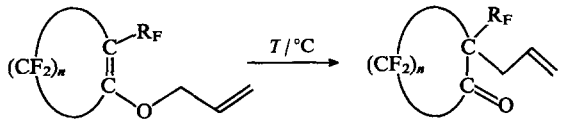
The presence of the fluorine atom and other electron-donating substituents at the C(1) atom apparently hardly lowers the thermodynamic stability of allyl polyfluorocyclobutenyl ethers. Thus allyl perfluorocyclobutenyl ether **81** and the 2X-substituted ether **82** synthesised from it distil without change at a reduced pressure and temperature up to 75 °C.[76]

81 **82**



X = H, OMe, NEt_2 .

Ring expansion leads to appreciably milder conditions and acceleration of the Claisen rearrangement. Allyl 2-chlorohexafluorocyclopent-1-enyl ether **83** isomerises smoothly to the cyclopentanone **84** even at 95 °C.[77]

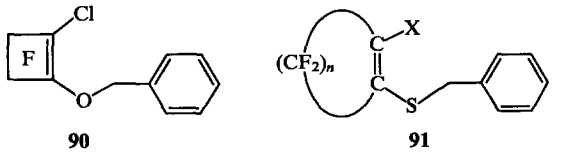


83 **84**

Allyl perfluorocyclopentenyl ether **86**, formed in the reaction of perfluorocyclopentene **85** with allyl alcohol in the presence of KOH, probably rearranges under similar conditions. After the reaction mass had been heated for a short time up to 106 °C, only the product of the rearrangement of the ether **86**—2-allylperfluorocyclopentanone **87**—was isolated from it.[36]

85 **86** **87** (35%)

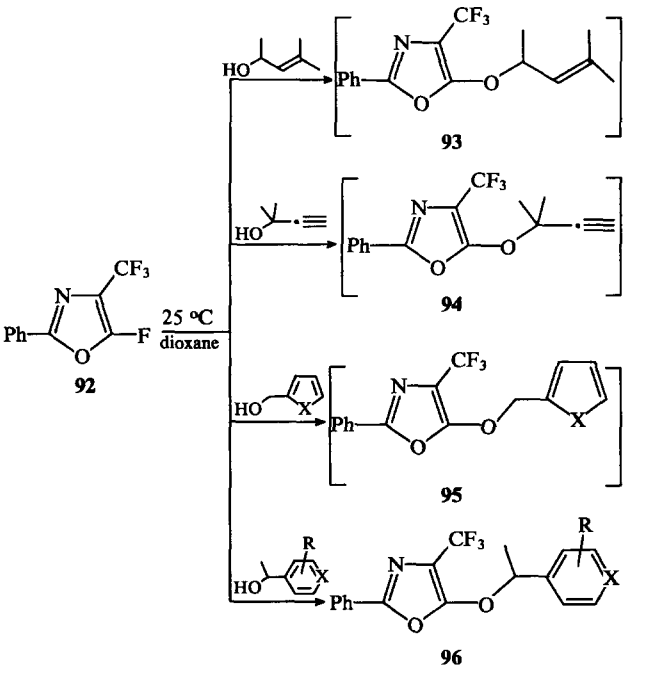
The influence of ring size and of the perfluoroalkyl groups at the C(1) atom on the conditions and rate of the rearrangement of allyl ethers **88** has also been investigated.[78, 79] An appreciable increase in the rate and a decrease in the temperature of the reaction in parallel with a decrease in ring strain were noted. The yield of 2-allylperfluorocycloalkanones **89** is 90%–94%.[78, 79] The bulky perfluoroethyl group hinders the [3,3]-sigmatropic shift. The equal half-reaction times ($\tau_{1/2}$ = 1.0–1.5 h at 100 °C) for the cyclopentenyl ether **88b** and the cyclohexenyl ether **88c** have been attributed to the inhibiting effect of the C_2F_5 group, which compensates for the increase in the rate of the rearrangement on passing from the five-membered to the six-membered ring.[78, 79]



88 **89**

Compound	n	R_F	T/°C
a	2	C_2F_5	130
b	3	CF_3	100
c	4	C_2F_5	100

It is noteworthy that benzyl ethers (sulfides) derived from polyfluorocycloenols do not enter into the Claisen rearrangement, in contrast to allyl ethers. All the attempts to subject the rearrangement of the benzyl ether **90** to radical or anionic catalysis, including those under photolytic conditions, were unsuccessful.[36]

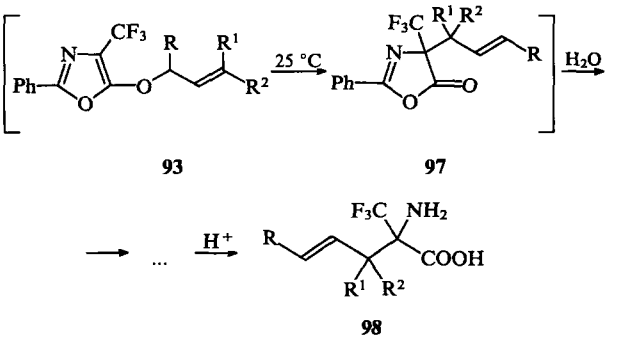


Benzyl polyfluorocycloalkenyl sulfides **91**, formed in the reactions of the corresponding cycloalkenes with toluene-α-thiol in the presence of triethyl-amine, are evidently just as stable.[80]

90 **91**

n = 2, X = F; n = 3, X = CF_3; n = 4, X = Cl.

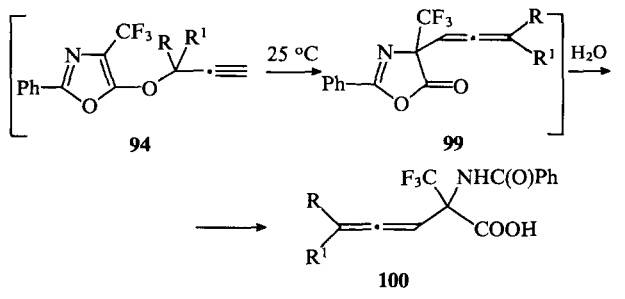
Unexpected results were obtained by Burger and coworkers[81–86] in the study of the reactions of polyfluoroheterocycloallenes with 2,3-unsaturated alcohols. 5-Fluoro-2-phenyl-4-trifluoromethyl-1,3-oxazole **92**,[87] reacting exothermically in the presence of KOH with allyl type alcohols which involves the primary formation of the ethers **93**–**96**, proved to be a convenient model for the study of certain characteristics of the low-temperature [3,3]-sigmatropic rearrangement observed in these reactions and for the development of new approaches to the synthesis of trifluoromethyl substituted α-aminoacids.[81, 82, 84, 85]



92 **93** **94** **95** **96**

5-Allyloxy-1,3-oxazoles, which do not have pronounced aromatic properties, are known[88] to enter more readily than allyl aryl ethers into the [3,3]-sigmatropic reaction (the oxazole–oxazolone rearrangement or the Steglich–Claisen rearrangement). The allyl group then migrate initially to the 4-position in the ring and then to the 2-position.

In contrast to the non-fluorinated analogues, 4-trifluoromethyl-1,3-oxazoles **93**–**95** undergo the spontaneous Steglich–Claisen rearrangement under the conditions of their synthesis even at 25 °C. The rearrangement is completed by the shift of the 'allyl' fragment of the molecule only to the 4-position.

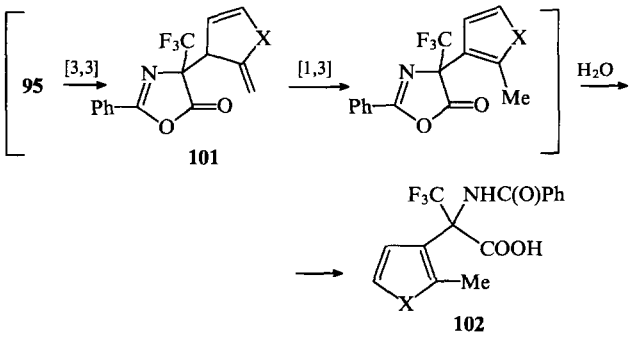


The conditions in the rearrangement of the allyl ethers **93** are almost independent of the numbers of substituents in the allyl group. The oxazolones **97** formed as a result of the rearrangement are hydrolysed without isolation (the reaction was followed by ^{19}F NMR spectroscopy) to give a satisfactory yield (up to 78%) of 2-alkenyl-3,3,3-trifluoroalanines **98**.[81]

93 **97** **98**

R, R^1, R^2 = H, Me, Et, Pr^n.

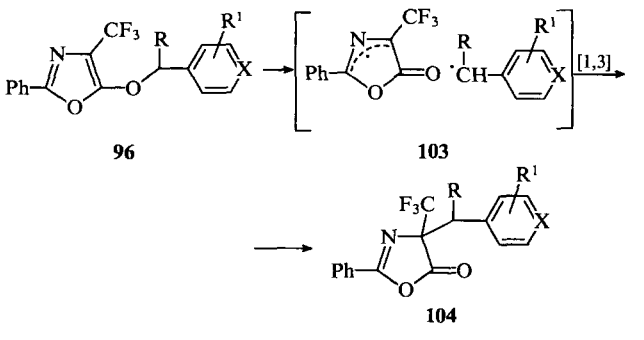
The propargyl ethers **94** isomerise just as smoothly to the oxazolones **99**, the hydrolysis of which leads to derivatives of 2-alkadienyl-3,3,3-trifluoroalanines **100** in yields up to 64%.[81]



94 **99** **100**

R, R^1 = H, Me, Et.

The [3,3]-sigmatropic rearrangements of the furfuryl and thienyl ethers **95** are accompanied by a [1,3]-prototropic shift.[84]

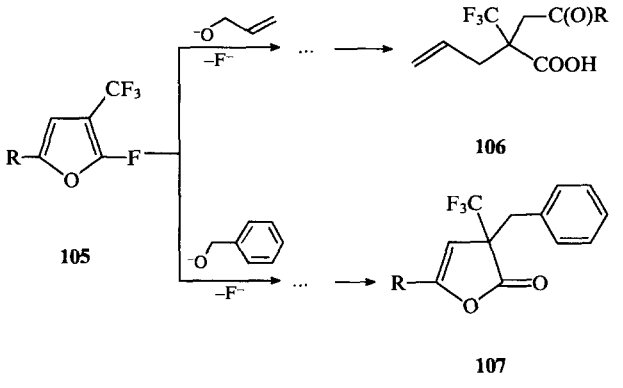


The high reactivity of the *exo*-methylene intermediates **101** is apparently the reason for the low-yield of the final products **102a** (47%) and **102b** (30%).

101 **102**

X = O(**a**), S(**b**).

The rearrangement of the benzyl ethers **96**, which is a key stage in a new method of synthesis of fluorine-containing derivatives of phenylalanine developed by Burger and coworkers,[82-85] constitutes a special case. In contrast to the oxazoles **93-95**, the benzyl derivatives **96** can be isolated in a free state although some of them are extremely thermolabile and isomerise to the corresponding oxazolones **104** at room temperature even in the crystalline state.[83, 84]

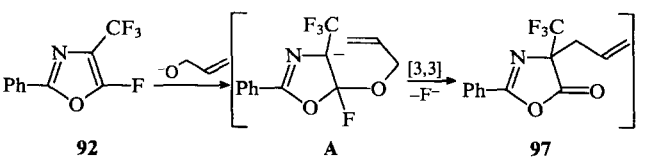


96 **103** **104**

X = CR^2, N; R = H, Me, COOH;
R^1 = H, OMe; R^2 = H, F, Cl, Br, NO_2, OMe, Ph.

The temperature range of this reaction is fairly wide (25 °C–120 °C). However, its main feature consists in the fact that, according to the authors,[84] it is not a concerted [3,3]-sigmatropic process and takes place as a result of the [1,3]-shift of the benzyl group, formed on thermal dissociation of the ethers **96** into the radical pair **103**. This mode of reaction has been demonstrated by the isolation of the mixed products in 'cross-experiments'.[84] The absence of the inversion of the benzyl fragment is also evidence in support of this mechanism.

The slight enhancement of the aromatic properties of the 'vinyl' component on replacement of the fluorine-containing oxazole fragment by the furan fragment apparently also exerts only a slight influence on the rearrangement conditions. The reactions of 2-fluoro-3-trifluoromethyl-5R-furans **105** with allyl and benzyl alcohols in the presence of HF acceptors leads either to the products of the low-temperature Claisen rearrangement (with subsequent ring opening), namely the ketoacids **106**, or to the products of the [1,3]-benzyl shift—the butenolides **107**.[86] The isolation of the intermediates in the nucleophilic substitution of the fluorine atom was not reported.

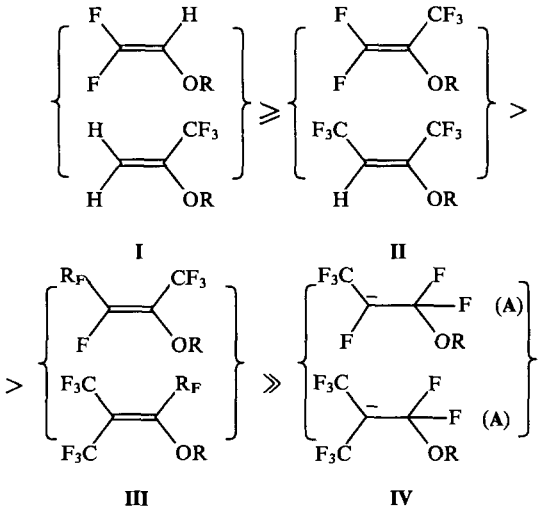


105 **106** **107**

One may postulate that the corresponding allyl and benzyl ethers obtained from 2-fluoro-3-trifluoromethylthiophene[86] can exhibit an increased thermal stability (which is characteristic of, for example, 5-benzyloxy- and 5-benzylthio-4-trifluoromethyl-1,3-thiazoles[87]) as a consequence of the much greater aromacity of the thiophene ring compared with the furan ring.

The [3,3]-sigmatropic rearrangements of derivatives of polyfluorinated cycloenols and heterocycloenols examined above made it possible to synthesise previously unavailable organofluorine compounds such as polyfluorocycloalkenones containing the allyl and 1,2-dienyl groups and CF_3-containing carboxylic 4-ketoacids, butenolides, and oxazolones. The last compounds proved to be promising precursors of a wide variety of trifluoromethylated α-aminoacids[81, 82, 84] (including derivatives of aspartic acid[89]), which were used in their turn for the modification of biologically active peptides.[85, 90]

The instances of the low-temperature Steglich–Claisen rearrangement in the reactions of the oxazole **92** with 2,3-unsaturated alcohols are of special theoretical interest. In our view, the spontaneous transformations of the intermediates are caused, in the first place, by the synchronous influence of the electron-accepting CF_3 group in the C(1) position and the electron-donating substituents (fluorine and oxygen) at the C(2) atom on the kinetic lability of the multiple bond of the oxazole **92**, as a result of which these reactions apparently occur via a carbanionic mechanism. The concerted effects of the substituents in the molecule of the oxazole **92** at the instant of attack by the alkoxide ion favour the stabilisation of the carbanionic intermediate A and the subsequent [3,3]-sigmatropic shift coupled with the elimination of the fluoride ion.



92 **A** **97**

IV. Rearrangements of polyfluorovinyl ethers

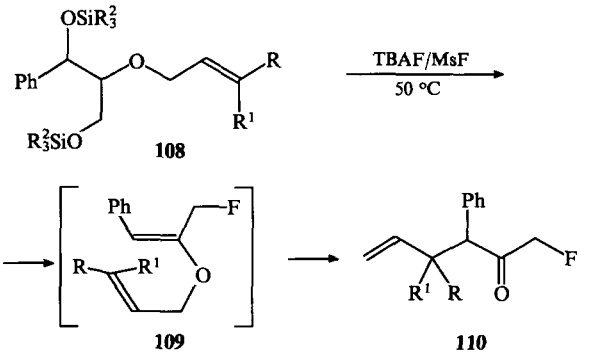
The allyl and propargyl ethers of acyclic polyfluoroenols enter into the Claisen rearrangement even more readily than the derivatives of polyfluorocycloenols, because in this case the fluorine atoms and the fluorine-containing substituents exert the maximum influence on the properties of the vinyl fragment.

According to Dolbier's data,[41, 91a] the conjugation of the geminal fluorine atoms with the sp^3 orbitals of carbon is thermodynamically more favourable (almost to the extent of 5 kcal mol^{-1}) than the conjugation with the sp^2 orbitals, which gives rise to, for example, the mild conditions in the rearrangement of allyl difluorovinyl ethers.[92] On the other hand, the trifluoromethyl group, which increases the thermodynamic stability of unsaturated compounds, the same time increases greatly the kinetic lability of the unsaturated bond.[91b] The combination of the effects of these substituents, which depends on their number and positions, leads to a sharp differentiation of polyfluorovinyl ethers (PFVE) in terms of their tendency to undergo the [3,3]-sigmatropic shift, which is manifested most clearly under the conditions of the rearrangement of these compounds.

In conformity with this finding, the PFVE can be divided into four groups (I–IV) in order of decreasing temperature and apparently in order of increasing rate of rearrangement of the compounds. The first two groups (I and II) contain relatively stable CFVE, which isomerise as a rule at 50–100 °C.

I II

III IV



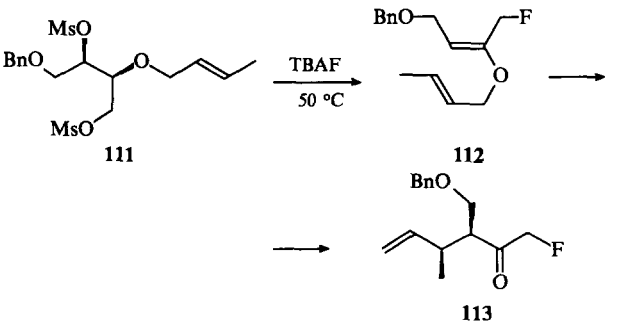
R_F = CF_3, C_2F_5; R = CH_2CH = CH_2.

As the CF_3 groups accumulate in the C(1) position, the rearrangement temperature falls to 20–40 °C (group III), whilst, following the appearance in the PFVE of the capacity to stabilise carbanionic states, the changes in the rate under the conditions of the reactions become dramatic: the fluorocarbanions A (group IV) undergo a spontaneous rearrangement in the instant of generation even on strong cooling.

1. Rearrangements of stable polyfluorovinyl ethers

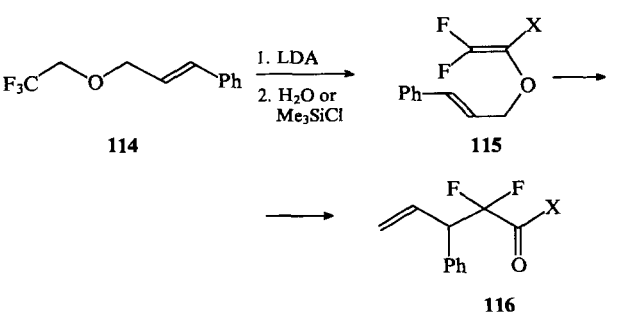
The synthesis of stable PFVE has been determined only in recent years and for this reason there are few examples of rearrangements of compounds of this kind. The monofluoro- and difluoro-substituted vinyl ethers, capable of undergoing the Claisen rearrangement with formation of α-fluoroketones, are usually obtained by three methods.

In the first method, developed by Japanese workers[93, 94] and called 'fluoroolefin formation', the starting materials employed are alkyl allyl ethers, the alkyl fragment of which contains two readily removable groups (for example, trimethylsiloxy- or methanesulfonyloxy-groups), one of which is exchanged for fluorine. Thus treatment of alkenyl 2-phenyl-2,2'-bis(trimethylsiloxy)isopropyl ethers **108** with a mixture of tetrabutylammonium fluoride (TBAF) and methanesulfonyl fluoride (MsF) in tetrahydrofuran (THF) leads regiospecifically to alkenyl 1-fluoromethyl-2-phenylvinyl ethers **109** which are either transformed *in situ* in the fluoroolefin formation process (THF), 50 °C, 12–36 h) or are converted into monofluoromethyl ketones **110** under more severe conditions (toluene, refluxing, 2 h).[93]



108 **109** **110**

R = R^1 = H (95%);
R = H, R^1 = Me (89%);
R = R^1 = Me (53%).

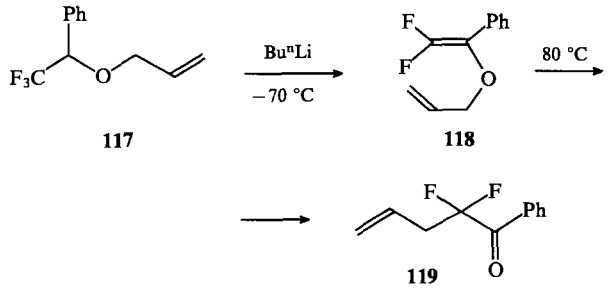


Benzyl 1-fluoromethyl-2-phenylvinyl ether synthesised in this way[93] proved to be a stable compound incapable of undergoing the Claisen rearrangement.

The monofluoromethyl ketone **113**, which is a key compound in the multistage stereospecific synthesis of (±)-fluorobotriodiplodin — a fluoride containing analogue of a natural micotoxin — was obtained by a procedure similar to that used for the ketones **110**.[94] The fluoroolefin formation reaction involving crotyl 2-2'-bis(methanesulfonyloxy)isobutyl ether **111** affords crotyl 1-fluoromethylvinyl ether **112** in 70% yield. Compound **112** rearranges in boiling xylene to compound **113** in 92% yield and with a high degree of stereoselectivity.

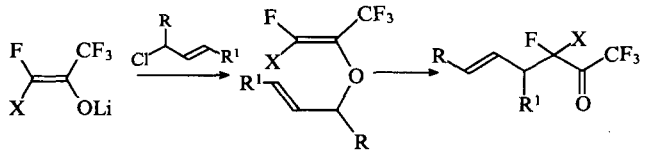
111 **112** **113**

The second method is based on the dehydrofluorination of allyl trifluoroethyl ethers, formed on alkenylation of 2,2,2-trifluoro-IR-ethanols.[92] For example, the trifluoroethyl ether **114**, synthesised by the reaction of sodium trifluoroethoxide with cinnamyl chloride, is readily (THF, −70 °C) dehydrofluorinated



114 **115** **116**

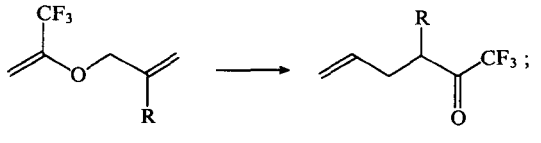
X = H (**a**), AR (**b**).



by lithium diisopropylamide (LDA). The resulting cinnamyl 2,2-di-fluorovinyl ethers **115** fully isomerise to the 2,2-difluoro-substituted aldehyde **116a** or the ketone **116b** on refluxing in CCl_4 (80 °C, 1 h).[92] It is remarkable that the cinnamyl vinyl ether rearranges only at 200 °C.[95]

Butyllithium is also a convenient dehydrofluorinating agent in these reactions. Treatment of allyl 1-phenyltrifluoroethyl ether **117** with this reagent affords the ether **118**, which is converted on subsequent heating into the difluoroketone **119** in 41% yield.[92]

117 **118** **119**



The third method of synthesis of stable PFVE is extremely promising and is applicable only in organofluorine synthesis. It consists in the *O*-alkenylation of the lithium salts of stable polyfluorophenols such as the enol of pentafluoroacetone and its analogues **120**. The alkenyl 2-fluoro-1-trifluoromethylvinyl ethers **121** obtained in this way undergo the Claisen rearrangement at 40–65 °C with formation of trifluoromethyl ketones **122**.[96]

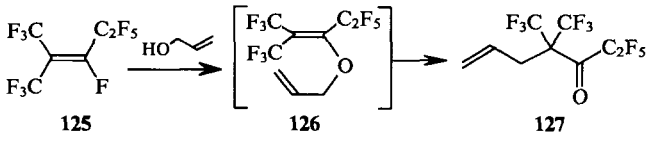
120 **121** **122**

X = F, Bu, Ph .

Evidently the CF_3 group in the C(2) position does not prevent the [3,3]-sigmatropic shift. The influence of the trifluoromethyl group at the C(2) atom on the rate of the Claisen rearrangement has been studied in greater detail by Gajewski et al.[35] They established that allyl 1-trifluoromethylvinyl ether **123a** is converted into the trifluoromethyl ketone **124a** in cyclohexane (61–98.5 °C, $\tau_{1/2}$ = 7.5 h) 73 times faster than the non-fluorinated analogue in a similar reaction.

123 **124**

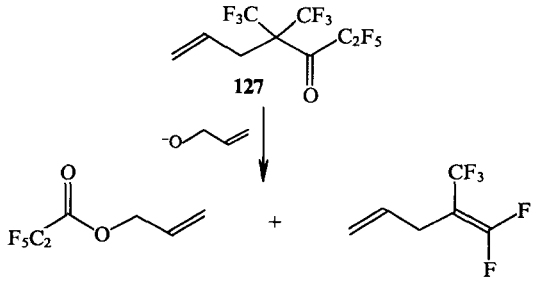
R = H(**a**), Ar(**b**).



On the other hand, a similar effect is not observed in the Cope rearrangement of *cis*-2-trifluoromethylocta-1,5-diene. According to the authors,[35] the acceleration of the rearrangement of the ether **123a** is associated with the destabilisation of the ground state of the molecule under the influence of the CF_3 group and with the increase in the polarity of the transition state. Indeed the rate of the rearrangement of the ether **123a** in a polar solvent (DMSO, 80 °C, $\tau_{1/2} \simeq 2.4$ h) is higher almost by a factor of 3.[35]

For comparison, one may note that the methoxycarbonyl group in the C(2) position accelerates the Claisen rearrangement by a factor of 79,[97] while the CN group in the same position causes an acceleration by a factor of 111,[33] the gain in the free energy of activation for the C(2)-substituted substrate amounting to 2.0–2.5 kcal mol^{-1}.[35]

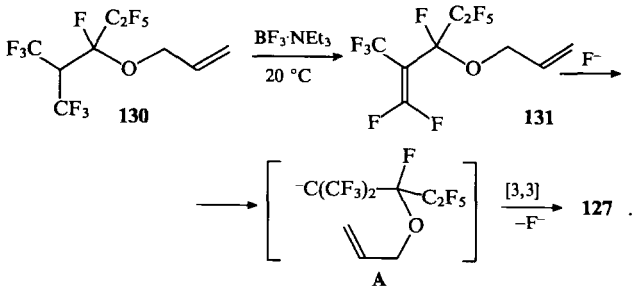
2. Rearrangements in the reactions of internal polyfluoroalkenes



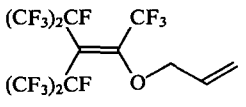
The interaction of 2,3-unsaturated alcohols with internal polyfluoroalkenes (PFA) and fluorinated alkynes and cumulenes leads to the ethers of poly(fluoroalkyl)enols, which isomerise more readily than monofluoro-, difluoro-, and monotrifluoromethyl-substituted vinyl ethers.

Thus the ether **126**, formed in a mixture with other products by the reaction of perfluoro-2-methylpent-2-ene **125** with allyl alcohol in the presence of NEt_3, rearranges to the ketone **127** already under the conditions of the synthesis (Et_2O, 20 °C, 2 h).[98]

125 **126** **127**

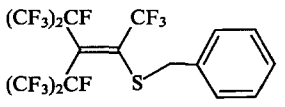


The half-conversion time for the ether **126** at 36 °C, established by ^{19}F NMR, is ~1 h. As the ketone **127** accumulates, it undergoes a partial 'haloform' cleavage under these conditions by the allylate anion to allyl perfluoropropionate **128** (yield 28%) and pentafluoropentadiene **129**.[98]



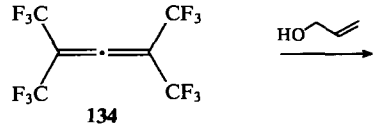
128 **129**

In a polar medium, the rate of conversion of the pentene **125** into the propionate **128** increases, so that, when the reaction of the pentene **125** with allyl alcohol is carried out in acetonitrile (NEt_3, 60 °C),[99] the propionate **128** is formed in 65% yield, while the ketone **127** is not isolated at all.

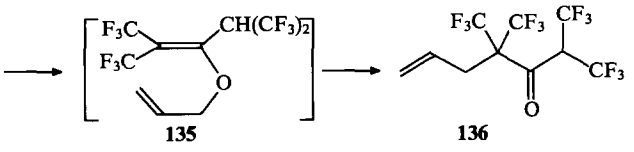


It is essential to emphasise that, under the conditions of the above study,[98] the rearrangement of the ether **126** takes place in the presence of fluoride ions, so that the smooth formation of the ketone **127** can be explained also by a carbanionic reaction mechanism. The latter probably operates in the reaction with the fluoride ion of the stable allyl pentafluoroalkenyl ether **130** — one of the products of the reaction of the pentene **125** with allyl alcohol.[98] However, one cannot rule out the possibility that the formation of the ketone **127** as a side product (yield 25%) in this reaction is altogether independent of the synthesis of the ether **131** and takes place in a reaction competing with the formation of the latter in the instant of the deprotonation of the initial adduct via the mechanism **130** → **A** → **127**.

The stability of tris(polyfluoroalkyl)vinyl ethers depends significantly on the steric effects of the fluoroalkyl groups and their position. For example, the allyl ether **132**[100] and the sulfide **133**,[101] substituted in the C(1) position by the bulky $(CF_3)_2CF$ groups, do not undergo the Claisen rearrangement.

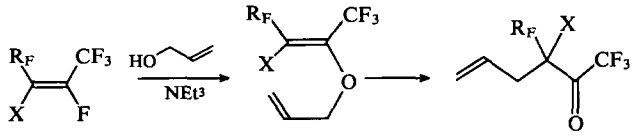


132



133

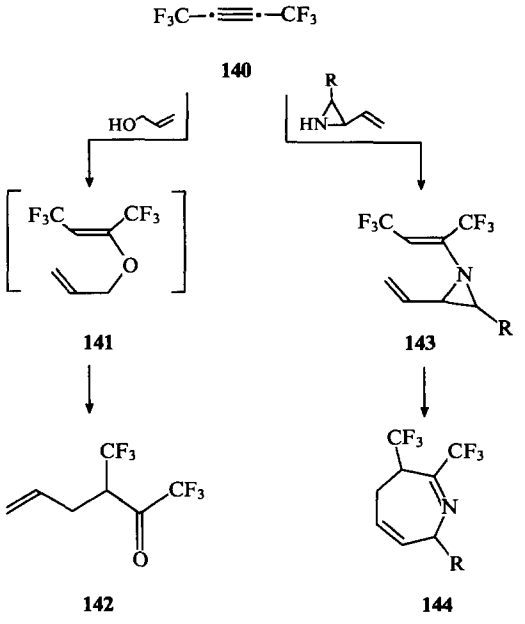
The steric effects of the substituents at the C(2) atom exert a much smaller influence on the tendency towards their rearrangement. Allyl 1-(α-*H*-hexafluoroisopropyl)-2,2-bis(trifluoromethyl)-vinyl ether **135**, obtained by the addition of allyl alcohol to tetrakis(trifluoromethyl)allene **134**, isomerises slowly to the ketone **136** even at 36 °C. At 65–72 °C, the ether **135** is fully converted after 1.5 h into the ketone **136**, the yield of which reaches 71%.[102]



134

135 **136**

Vicinal bis(perfluoroalkyl)-substituted vinyl ethers proved to be, like the ethers **126** and **135**, thermodynamically unstable. The allyl ethers **138a** and **138b**, obtained from 2-chloroheptafluoro-but-2-ene **137a** and perfluoropent-2-ene **137b** can be isolated only by vacuum fractionation at 30–35 °C.[79] At 36 °C, they are slowly transformed into the ketones **139a** and **139b** with half conversion periods of 24 h (**a**) and 72 h (**b**).[79]



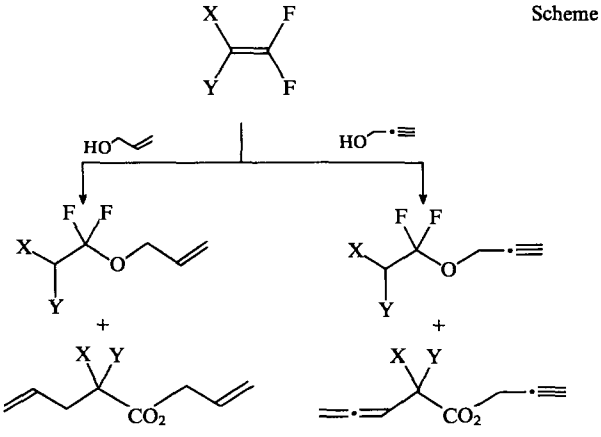
137 **138** **139**

$R_F = CF_3$, X = Cl(**a**) ;
$R_F = C_2F_5$, X = F(**b**) .

The mild conditions in the rearrangement of ethers **138** are appreciably influenced apparently by the halogen atom in the C(1) position, because allyl 1,2-bis(trifluoromethyl)vinyl ether **141**, formed in the reaction of perfluorobut-2-yne **140** with allyl alcohol (catalysed by NaOH), rearranges to the ketone **142** (yield 74%) on heating to 89 °C.[36]

The low-temperature Claisen amino-rearrangement is observed in the reaction of perfluorobutyne **140** with 2-vinyl-aziridines.[103] The adducts **143** isomerise at room temperature or on slight heating (50 °C) to CF_3-containing azepines **144**, which are rare products of the [3,3]-sigmatropic rearrangement, by virtue of the involvement of the aziridine ring in the latter.

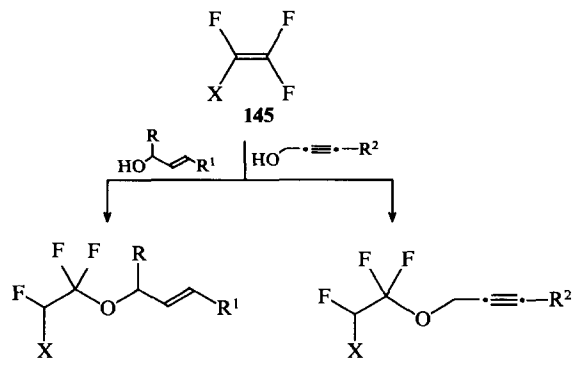
140 **141** **142** **143** **144**



R = H, CH = CH_2.

3. Rearrangements in the reactions of terminal polyfluoroalkenes

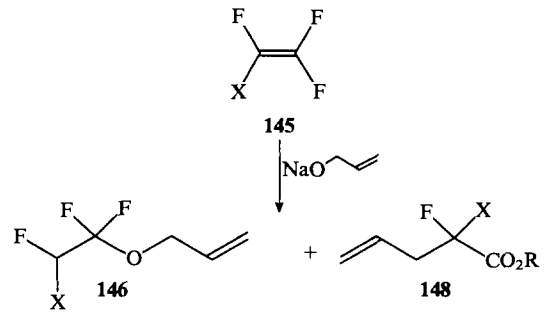
The interaction of terminal PFA with unsaturated alcohols proceeds via intermediate fluorocarbanions and leads to either adducts of the initial reactants or to alkyl polyfluorovinyl ethers†.[104, 105a, 106] The latter pathway operates as a rule in the presence of favourable conditions for the transformation of the carbanionic intermediates via the elimination of the fluoride ion, for example, in the reactions of PFA with alkoxides in protophilic or aprotic solvents.



Accordingly, in the reactions of terminal PFA with 2,3-unsaturated alcohols one might have expected the generation in the first stage of the fluorocarbanions **A** (see p. 562, group IV) with the subsequent formation of allyl(propargyl) polyfluorovinyl ethers capable of undergoing the non-catalysed thermal Claisen rearrangement. However, in none of the reactions investigated was it possible to isolate the corresponding PFVE. The products of these reactions were found to be exclusively the adducts of the initial compounds and the rearrangement products — derivatives of fluorine-containing alk-4-ene(alka-3,4-diene)carboxylic acids (Scheme 1), the proportions of which depend on the structure of the PFA and the conditions of its interaction with the alcohol.

Scheme 1

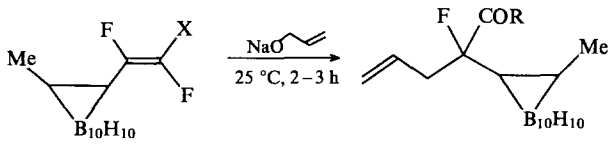
† The products of the substitution of the allylic fluorine atom are sometimes formed.[104, 106]



The tetrafluoroethylene **145a** and chlorotrifluoroethylene **145b** interact with allyl[107-112] and propargyl[113-116] alcohols‡ in the presence of KOH,[107, 108, 115, 116] catalytic amounts of metallic sodium,[110-113] or ion exchange resin[114] or at a low§ pressure[108] with formation of only adducts — allyl 2-*H*-polyfluoroethyl ether **146** and propargyl 2-*H*-polyfluoroethyl ether **147**.

145 **146** **147**

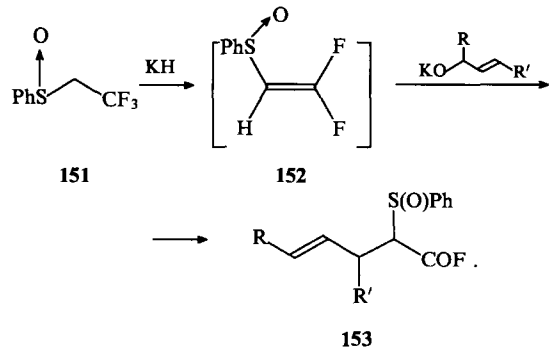
X = F(**a**), Cl(**b**); R = H, Me; R^1 = H, Me, Ph; R^2 = H, Cl, Br, I.



In the reactions of the polyflurorethylenes **145** with sodium allylate,[110, 117] which take place particularly readily (0 °C) in THF,[110] the products of the rearrangement — derivatives of 2-fluoropent-4-enoic acid **148** (yield 16%-34%) — were obtained together with the ethers **146** (yield 22%-25%).

145 **146** **148**

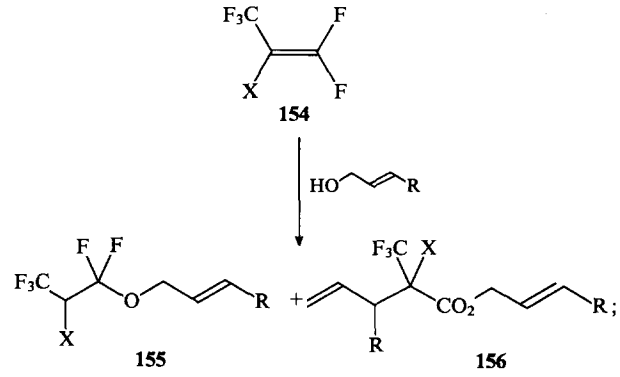
X = F(**a**), R = H; X = Cl(**b**), R = $CH_2CH=CH_2$.



Fluoroethylenes with functional group-substituents interact unambiguously with allylates. Thus the reaction of 1-methyl-2-polyfluoroalkenyl-*o*-carbaboranes **149** with sodium allylate results in the formation of only the rearrangement products **150** in 40% (**a**) and 44% (**b**) yields.[118]

149 **150**

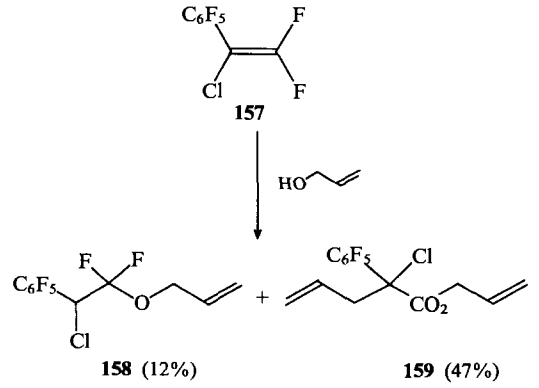
X = Cl, R = $OCH_2CH=CH_2$(**a**); X = R = CF_3 (**b**).



The reaction of allylates with *gem*-difluorovinyl phenyl sulfoxide **152**, generated *in situ* from trifluoroethyl phenyl sulfoxide **151** with the aid of potassium hydride, under mild

151 **152** **153**

conditions (THF, 0-5 °C, 0.5-2.0 h) also leads exclusively to the rearrangement products — the acid fluorides 153.[199]



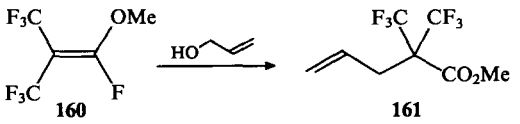
The terminal PFA **154**, which are more electrophilic than the perfluoroethylene **145a**, interact with 2,3-unsaturated alcohols to form a mixture of adducts and rearrangement products. In the reaction of hexafluoropropene **154a** with allyl alcohol (catalysed by KOH, 20-30 °C¶), allyl 2-fluoro-2-trifluoromethylpent-4-enoate **156a** was isolated in 5% yield together with allyl 2-*H*-hexafluoropropyl ether **155a**.[120]

154 **155** **156**

X = F, R = H(**a**); X = CF_3, R = H, Me(**b**), X = SMe, R = H(**c**).

α-Chloroperfluorostyrene **157** reacts under similar conditions (KOH, 20-45 °C, 0.5-1.0 h) with allyl alcohol to form preferentially the rearrangement product — allyl 2-chloro-2-pentafluorophenylpent-4-enoate **159**.[121] The adduct — allyl β-chloro-β-*H*-heptafluorophenylethyl ether **158** — is formed in an insignificant amount.

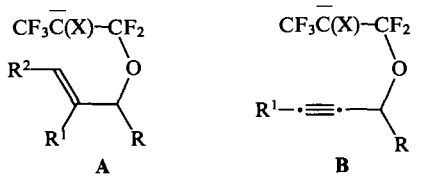
157 **158** (12%) **159** (47%)



In the reaction of the perfluoroisobutene **154b** with allyl alcohol (0-50 °C)[36] even in the absence of bases, the yield of the rearrangement product — allyl 2,2-bis(trifluoromethyl)pent-4-

‡ The reaction of propargyl alcohols with *gem*-bromochlorodifluoroethylene, formed under the conditions of phase transfer catalysis from $CF_3CHBrCl$, has been investigated.[116]

§ The reaction of compound **145a** with allyl alcohol at a pressure of 500 atm affords a product of the cyclodimerisation of the initial

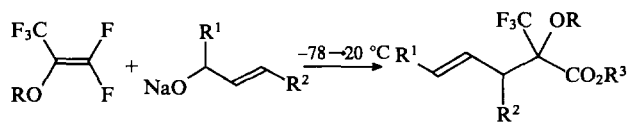


¶ In the absence of bases, the polyfluoroalkenes **154a** and **157** do not interact with allyl alcohol.

enoate **156b** (R = H)† — reaches 15%. 1-Methoxy heptafluoroisobutene **160** reacts with allyl alcohol just as smoothly in the presence of KOH, being converted into methyl 2,2-bis(trifluoromethyl)pent-4-enoate **161** in 39% yield.[36]

160 **161**

In the examples examined above, the yield of the rearrangement products is correlated with the ability of the internal PFA to generate stable fluorocarbanions‡, which are transformed into PFVE after the elimination of the fluoride ion. However, these intermediates could not be detected in the reaction medium by ^{19}F NMR even at −30 °C.[120] It was therefore natural to suppose[37, 120, 123] that the precursors of the rearrangement products in these reactions are the fluorocarbanions **A** or **B**, which at the instant of formation undergo, at a high rate, a spontaneous [3,3]-sigmatropic rearrangement coupled with the elimination of the fluoride ion.



A **B**

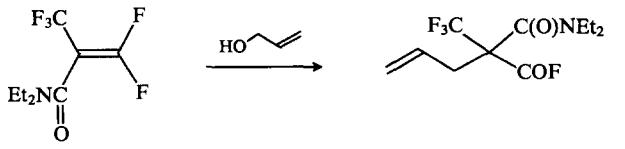
The probability of the [3,3]-sigmatropic shift is determined by the structural features of the fluorocarbanions and their lifetime necessary for the formation of the transition state of type **A***.

Indeed in protophilic solvents [DMF, DMSO, hexamethylphosphoramide (HMPA)], which tend to stabilise carbanionic intermediates, and in the presence of 'mild' HF acceptors, for example potassium fluoride, the reactions of the perfluoroisobutene **154b** with allyl and crotyl alcohols proceed unusually easily (−30 to −10 °C), the formation of the rearrangement products **156b** being the main pathway§ (yield up to 70%).[37, 120, 123] Under similar conditions (KF/DMF, 5–20 °C), in the interaction of allyl alcohol with hexafluoropropene **154a**[120, 123] and 2-methylthiopentafluoropropene **154c**[124] the rearrangement products **156a** and **156c** were obtained in 15% and 32% yields respectively.

Another approach to the stabilisation of the intermediate fluorocarbanions is associated with the use of powerful nucleophiles such as alkoxides. Derivatives of 2-alkoxy-2-trifluoromethylalk-4-enoic acids **163** were obtained in this way from 2-alkoxy-pentafluoropropenes **162** in a yield up to 66%.[125, 126]

162 **163**

R = CH_2OMe,  ; R^1, R^2 = H, Me, Ph;

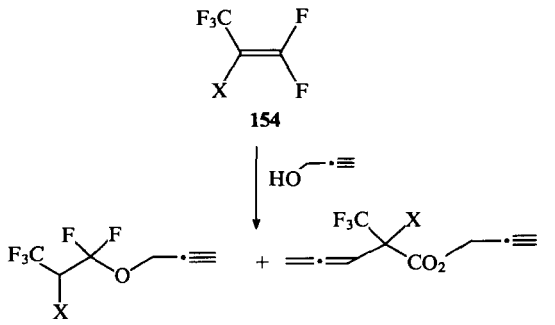


R^3 = H, $CH(R^1)CH = CHR^2$.

† It was believed previously[122] that the side product in this reaction is not the pentenoate **156b** but *O,O*-diallylbis(trifluoromethyl)ketenal.

‡ For the influence of fluorine atoms and CF_3 and CO_2R groups on the stability of the fluorocarbanions, see Refs 106 and 127a, b.

§ The corresponding adducts **115** and a fairly large amount of $(CF_3)_2CHX$ — the adducts of HF and the initial PFA — are also formed in these reactions.

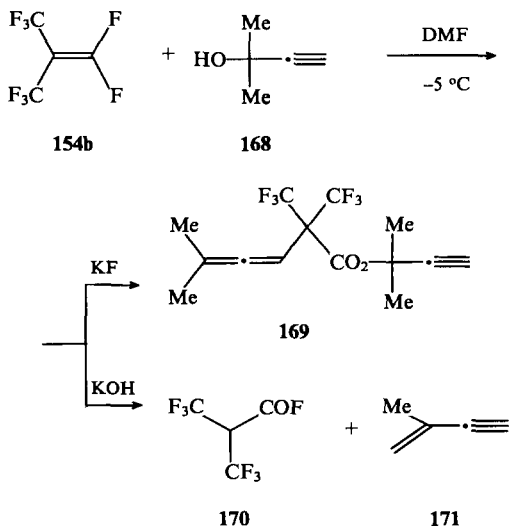


Under the conditions of effective intermolecular stabilisation of the carbanionic states, there is no need to use protophilic solvents, HF acceptors, or alkoxides. In the absence of any kind of reagents, the reaction of perfluoromethacrylic acid diethylamide **164**, the amide group of which stabilises the adjoining carbanionic centre,[127a] with allyl alcohol leads chemospecifically to the rearrangement product — the acid fluoride **165** (yield up to 90%).[128] The excess of the amide **164** serves as the HF acceptor in this reaction.

164 **165**

Terminal PFA reacts similarly with acetylenic alcohols.[120, 123, 129]

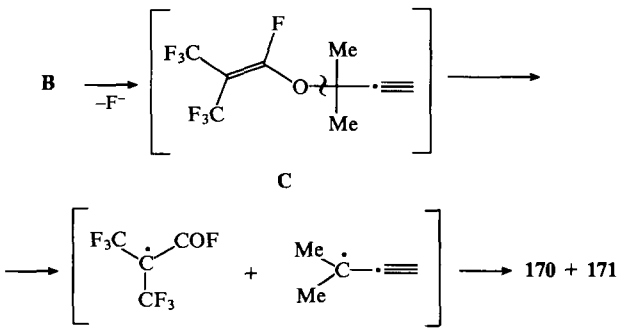
In a protophilic medium (KF/DMF), the reactions of perfluoroalkenes **154a** and **154b** with propargyl alcohol take place at −10 to 0 °C, while the [3,3]-sigmatropic shift in the intermediate **B** is accompanied by the acetylene–allyne rearrangement, which makes it possible to obtain CF_3-substituted penta-3,4-dienoates **167** in yields of 13% (**a**) and 59% (**b**) together with 2-*H*-polyfluoroalkyl propargyl ethers **166**.[120, 123]



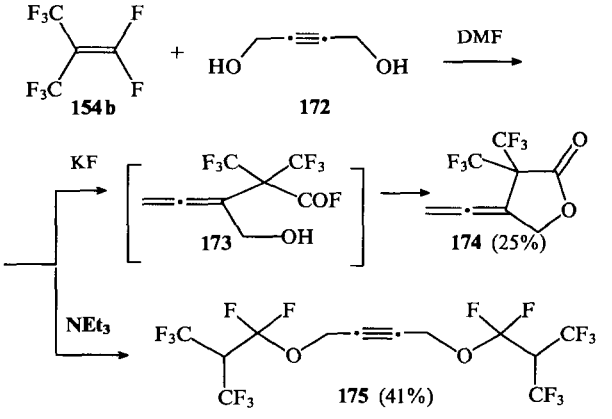
154

166 **167**

X = F (**a**), CF_3(**b**).

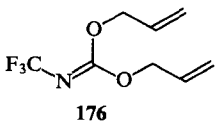


In a number of instances, the influence of the nature of the base employed on the mode of the reactions of PFA with homologues of propargyl alcohol has been noted. The reaction of the perfluoroisobutene **154b** with 1,1-dimethylprop-2-yn-1-ol **168**

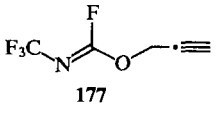


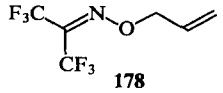
154b **168** **169** **170** **171**

under optimum conditions (KF/DMF) leads to the rearrangement product **169** (yield 48%), while the reaction catalysed by KOH affords a mixture of the acid fluoride **170** and isopropenylacetylene **171**.[129]

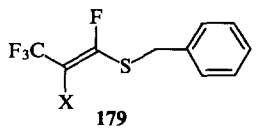


Apparently in the presence of a strong base the elimination of the fluoride ion from the intermediate **B** is faster that its rearrangement and the resulting polyfluorovinyl ether **C** undergoes homolytic decomposition owing to the steric hindrance to the [3,3]-sigmatropic shift.

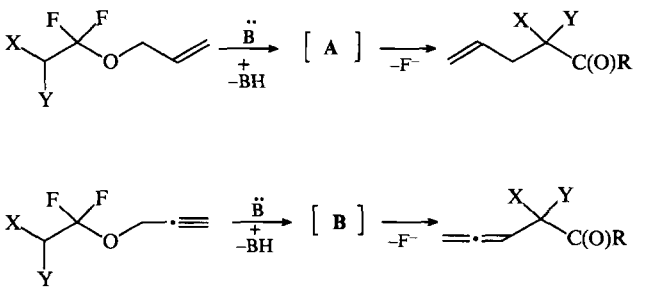




Two pathways operate also in the reaction of the perfluoroisobutene **154b** with but-2-yne-1,4-diol **172**.[129] In the presence of an excess of KF, the main product is 2,2-bis(trifluoromethyl)-3-vinylidene-4-butanolide **174**, formed on lactonisation of the intermediate **173** in the rearrangement, but, when this reaction was catalysed by triethylamine, only the adduct **175** was obtained.



It is noteworthy that, in the reactions of a terminal azaalkene such as perfluoro-2-azapropene with allyl and propargyl alcohols, the products of the [3,3]-sigmatropic rearrangement are not formed at all and allyl polyfluoro-2-azapropenyl ether **176** and propargyl polyfluoro-2-azapropenyl ether **177** do not isomerise even at 150 °C.[130] The *O*-allyl ether of hexafluoroacetone oxime **178** is just as stable.[130]

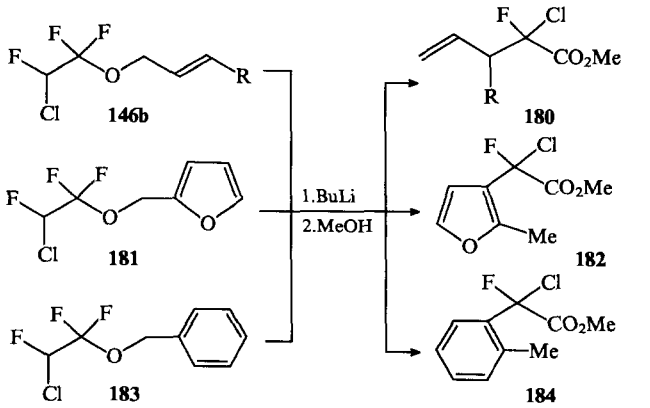


X= CF_3, $C(O)NMe_2$.

The benzyl sulfides **179**, obtained in the reactions of toluene-α-thiol with perfluoroisobutene[131] and perfluoromethacrylic acid dimethylamide,[132] also proved to be thermodynamically stable.

4. Rearrangements on deprotonation of 2-*H*-polyfluoroalkyl ethers

Another preparative method of synthesis of alkyl polyfluorovinyl ethers is based on the dehydrofluorination of the products of the addition of alcohols to terminal PFA, for example, to perfluoroisobutene.[133] On the other hand, the dehydrofluorination of the adducts of 2,3-unsaturated alcohols and terminal PFA—allyl(propargyl)2-*H*-polyfluoroalkyl ethers—leads not to the expected polyfluoroenols but to the rearrangement products—derivatives of fluorine-containing alk-4-enoic and alka-3,4-dienoic acids. The fluorocarbanions **A** or **B**, generated at the instant of the deprotonation of the initial CH acids, are probably the direct precursors of the rearrangement products in this case too (Scheme 2).

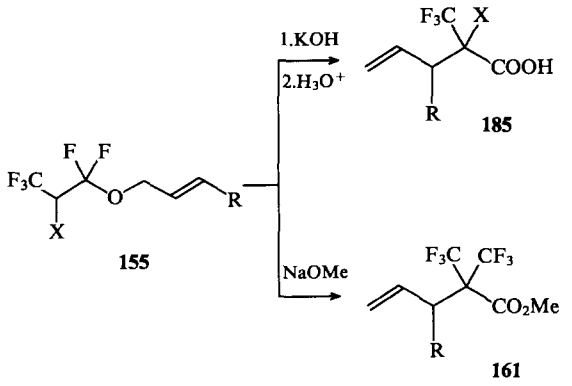


Scheme 2

R = F, OH, OMe.

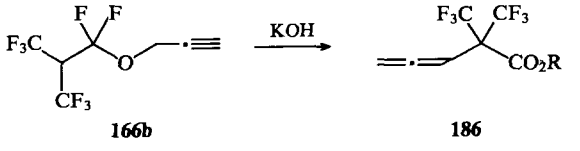
This method of synthesis of unsaturated carboxylic fluoroacids and their derivatives was first used by Normant and coworkers[110, 111] in relation to the initial 2-*H*-chlorotrifluoroethyl ethers. The use of butyllithium as the deprotonating agent made it possible to obtain from the adducts of chlorotrifluoroethylene with allyl, crotyl, cinnamyl (compound **146b**; R = H, Me, Ph), furfuryl (compound **181**), and benzyl (compound **183**) alcohols at negative temperatures the corresponding products **180**, **182**, and **184** of the [3,3]-sigmatropic rearrangement in satisfactory yields.

The low-temperature preparative syntheses of derivatives of 2,2-difluoropent-4-enoic acid were subsequently developed on the basis of Normant's method.[112, 134]



R = H, Me, Ph.

According to Normant and coworkers,[110, 111] the products of the rearrangement in the reactions described above are formed from the intermediate PFVE. However, it is difficult to explain from this standpoint the very high rate of the Claisen rearrangement of the above intermediates even at −70 °C,[111, 134] whereas cinnamyl 2,2-difluorovinyl ether **115a** is extremely stable.[92]

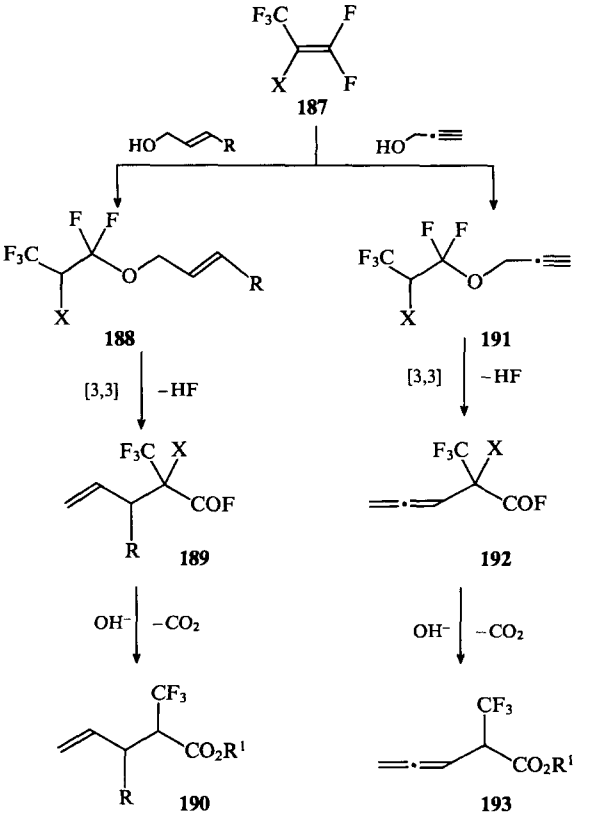


Even stronger CH acids, for example the 2-*H*-hexafluoropropyl ether **155a**, the 2-*H*-octafluoroisobutyl ether **155b**, and 2-methylthio-2-*H*-pentafluoropropyl ether **155c** are depronated by potassium hydroxide, being converted into 2-trifluoromethylpent-4-enoic acids **185** in yields of 32% (**a**), 60%–78% (**b**), and 67% (**c**).[123, 124, 135]

Methyl 2,2-bis(trifluoromethyl)pent-4-enoates **161** have been synthesised from the ether **155b** with the use of sodium methoxide or Claisen's alkali (a solution of KOH in dry methanol) as the deprotonating agents.[120]

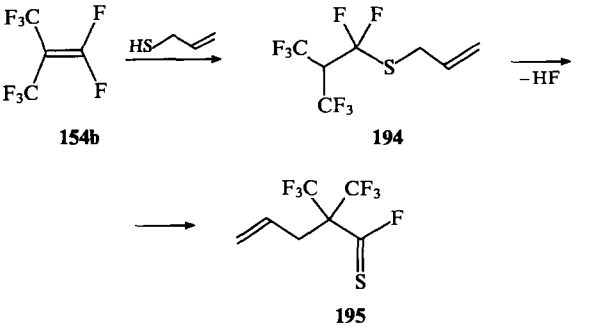
X = F, R = H (**a**) (DMSO, 60–65 °C);
X = CF_3, R = H, Me (**b**) (Et_2O, 30–35 °C);
X = SMe, R = H (**c**) (THF, 60–65 °C).

The propargyl ether **166b** is converted into 2,2-bis(trifluoromethyl)pent-3,4-dieonoic acid **186** (R = H) on reaction with KOH in diethyl ether (35 °C, 2 h),[136] whilst in methanol the reaction affords the ethyl ester of the acid **186** (R = Me).[120]



R = H (54%), Me (51%).

Allyl 2-*X*–2-*H*-pentafluoropropyl ether **188** and propargyl 2-*X*–2-*H*-pentafluoropropyl ether **191**, obtained by the addition of 2,3-unsaturated alcohols to highly electrophilic PFA with functional-group substituents in the 2-position, namely methyl perfluoromethacrylate **187a**, perfluoromethacryloyl fluoride **187b**, and 2-fluorosulfonylpentafluoropropene **187c**, are particularly readily deprotonated. Being strong CH acids, the adducts **188** and **191** interact smoothly with a weak base such as the complex $BF_3 \cdot NEt_3$. Depending on the strength of the initial CH acid, the deprotonation begins at 25–30 °C (**c**),[137, 138] 40–45 °C (**b**),[138] or 70–80 °C (**a**).[123, 128] The subsequent [3,3]-sigmatropic rearrangements of the fluorocarbanions **A** or **B** take place almost instantaneously and with evolution of much heat, leading to the selective formation of the acid fluorides **189** and **192** in 85%–90% at 65%–85% yields respectively.

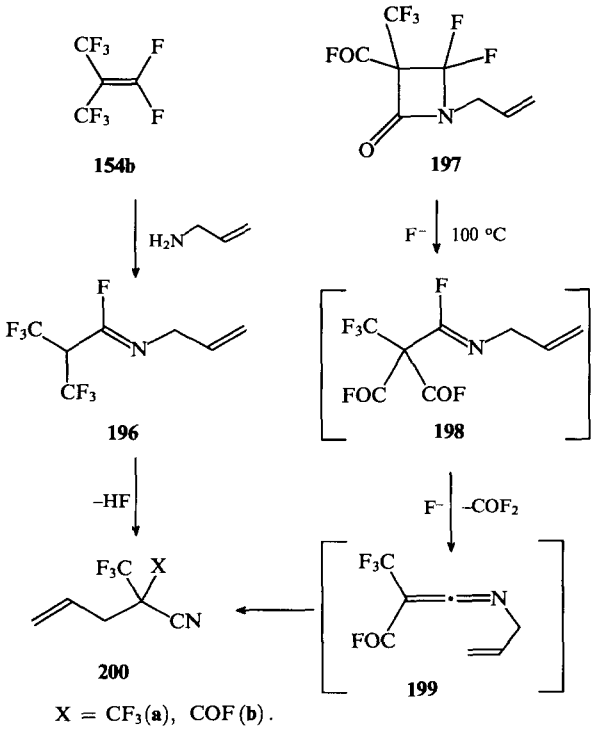


On alkaline hydrolysis, the acid fluorides **189a,b** and **192a,b** are readily decarboylated, being transformed into the 2-trifluoromethylpent-4-enoic acid **190** (R = R^1 = H) and 2-trifluoromethylpenta-3,4-dienoic acid **193** (R^1 = H) or their methyl esters.[139] The latter can be obtained under the conditions of phase transfer catalysis directly from 2-methoxycarbonyl-2-*H*-pentafluoropropyl ethers, namely from compound **191a**,[139] by-passing the stage involving the isolation of the corresponding acid fluorides.

The thio- and amino-[3,3]-sigmatropic rearrangements proceed with greater difficulty on deprotonation of the adducts of perfluoroisobutene with propene-3-thiol [allyl mercaptan] **194**

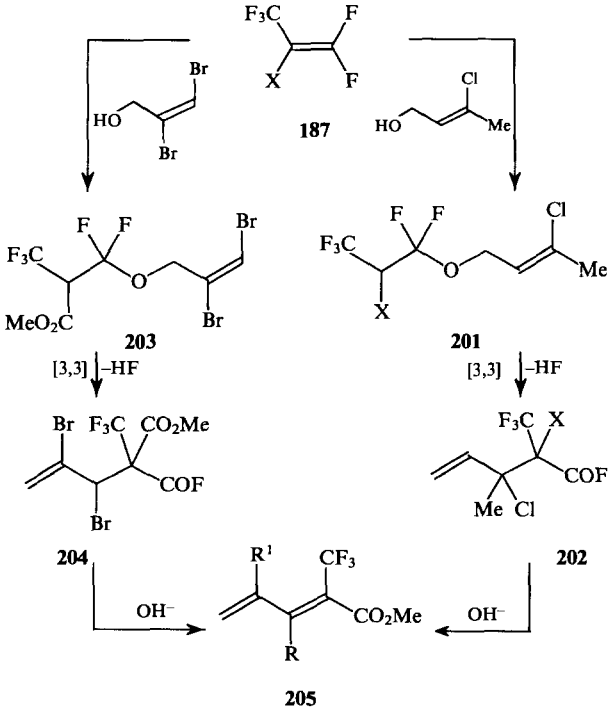
X = CO_2Me (**a**), COF (**b**), SO_2F (**c**); R = H, Ph; R^1 = H, Me.

and allylamine **196**¶. The sulfide **194** is converted into 2,2-bis(trifluoromethyl)pent-4-enethioyl fluoride **195** in 70% yield only on heating with the complex $BF_3 \cdot NEt_3$ to 100–110 °C.[140]



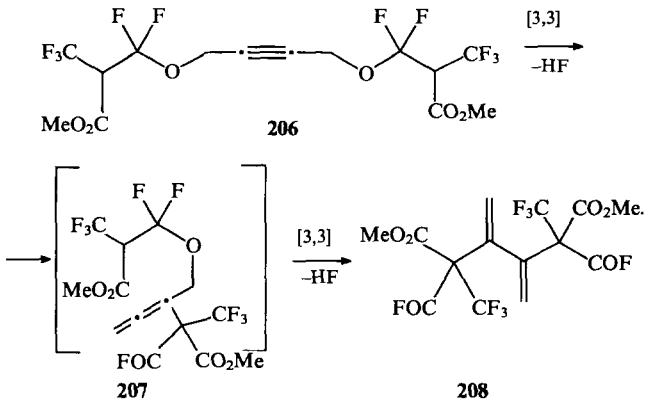
The thermolysis of the imidoyl fluoride **196** at 120 °C leads to the nitrile of 2,2-bis(trifluoromethyl)pent-4-enoic acid **200a** (yield 53%) in the absence of deprotonating agents.[141]

It is of interest that the reaction of the β-lactam **197** with caesium fluoride also involves the formation of the nitrile of 2-trifluoromethylpent-4-enoic acid **200b** in a low yield.[142] According to the authors, the ketene imine **199** — the product of the opening of the lactam ring and of the 'haloform' cleavage of the intermediate imidoyl fluoride **198** by the fluoride ion — is a precursor of compound **200b**.



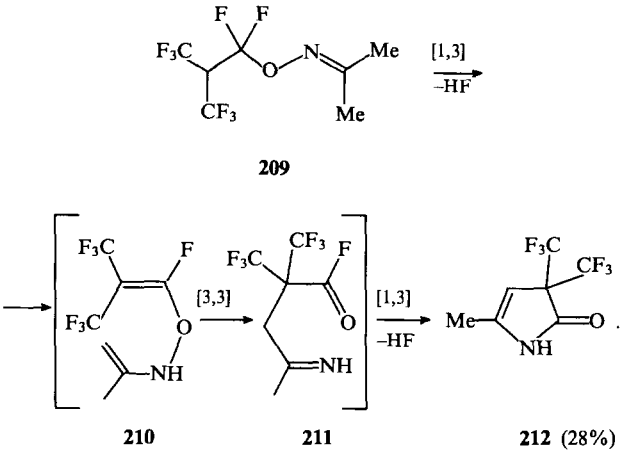
The deprotonation of 2-*H*-polyfluoroalkyl ethers proved to be a convenient method of synthesis of not only derivatives of fluorine-containing alk-4-ene- and alka-3,4-diene-carboxylic acids

¶ The rearrangement products are formed in extremely insignificant amounts in the reactions of perfluoroisobutene **154b** with propene-3-thiol and allylamine.[120]



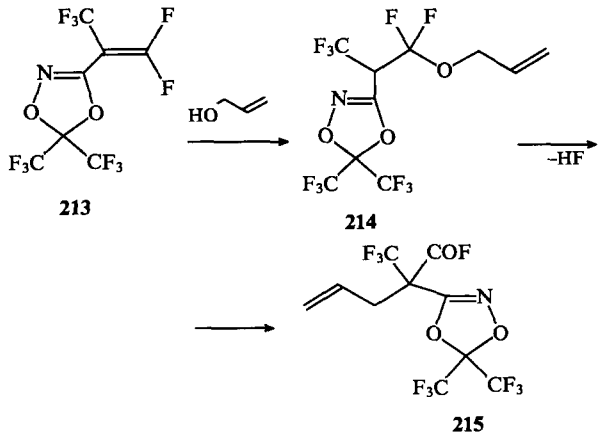
but also of the corresponding dienoates.[143, 144] Furthermore, the possibility of using this method for the synthesis of new[145] or the modification of the already available fluorinated heterocycles[146] has been demonstrated in individual instances. In all cases, the use of $BF_3 \cdot NEt_3$ as the deprotonating agent is most effective.

The adducts **201** and **203**, obtained by the addition of 3-chloro(bromo)allyl alcohols to the perfluoromethacrylates **187a,b** on heating with $BF_3 \cdot NEt_3$ to 85–110 °C, are converted into the acid fluorides **202** and **204** containing an allylic halogen atom.



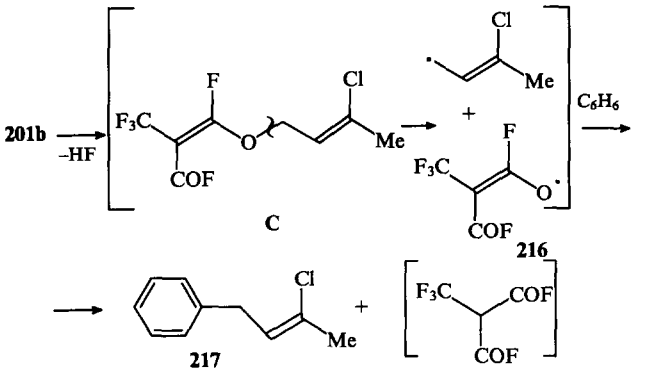
The formation of a vicinal (in relation to this atom) CH acid centre during the mild hydrolysis of the acid fluorides **202** and **204** is therefore accompanied by dehydrohalogenation with formation of methyl 2-trifluoromethylpenta-2,4-dienoates **205**† in yields up to 80%.[143]

When the 2:1 adduct of methyl perfluoromethacrylate and butynediol **206** is heated (85 °C) with the complex $BF_3 \cdot NEt_3$, the difluoride of 3,4-dimethylenehexane-1,6-dioic acid **208**—the product of the sequential [3,3]-sigmatropic reaction—is formed in 34% yield.[144] The relatively high selectivity of this reaction is achieved despite the significant steric hindrance to the [3,3]-sigmatropic shifts, especially in the deprotonation of the intermediate **207**.



Sequential shifts in the intermediate structures occur also in the reaction of acetone *O*-(2-*H*-perfluoroisobutyl)oxime **209** with bases (KOH or $BF_3 \cdot NEt_3$). According to Zeifman et al.,[145] the dehydrofluorination of compound **209** is accompanied by a [1,3]-prototropic shift in the oxime part of the molecule with formation of the enamine **210**, which undergoes at 20 °C the Cope 3-oxa-4-aza-rearrangement to the imino-substituted acid fluoride **211**. The latter cyclises under the reaction conditions to the pyrrolinone **212**.[145]

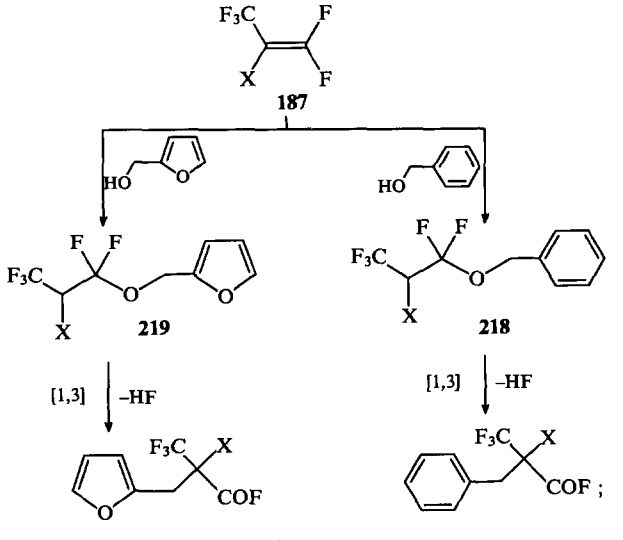
The mild deprotonation conditions and the high rate of rearrangement, characteristic of strong fluorine-containing CH acids, have been used successfully for the modification of the pentafluoroisopropenyl-substituted 1,4,2-dioxazoline **213**.[146] The allyl ether **214** obtained from it is readily transformed on treatment with $BF_3 \cdot NEt_3$ into the acid fluoride **215**. There is no doubt that this method may prove to be extremely promising for the modification of other 2-heteroarylpentafluoropropenes.



In a number of instances, the interaction of 2-*H*-polyfluoroalkyl ethers with bases is complicated by radical reactions. When 3-chlorocrotyl 2-fluorocarbonyl-2-*H*-pentafluoropropyl

† Derivatives of 2,4-dienecarboxylic acids have also been obtained in other studies[111, 119, 147, 148, 167, 169] as a result of the [3,3]-sigmatropic[111, 119, 147, 167, 169] or [2,3]-sigmatropic[148] rearrangements.

213 214 215

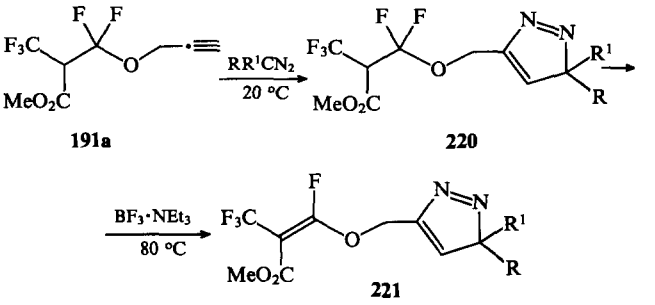


ether **201b** is heated with $BF_3 \cdot NEt_3$ in benzene, 3-chlorocrotylbenzene **217** is formed together with the rearrangement products **202b**.[143] Apparently, owing to the steric effect of the substituents at the double bond of the allyl group, stabilisation of the intermediate fluorocarbanion **A** is achieved in this instance not only via a [3,3]-sigmatropic shift but also via the elimination of a fluoride ion with subsequent homolytic cleavage of the tetrafluoropropenyl ether **C** to give the radical pair **216**.[143]

C **216** **217**

It must be emphasised that, on deprotonation of the ether **201a**, a similar reaction is not observed, evidently as a consequence of the greater stability of the corresponding carbanion.

The free radical reactions apparently occur also on dehydrofluorination of the very unstable adducts **218** and **219** formed in the reactions of the perfluoromethacrylates **187a,b** with benzyl and furfuryl alcohols.[37] [1,3] Shifts of benzyl (furfuryl) radical



187 **219** **218**

X = CO_2Me (**a**), COF (**b**).

occur in these reactions, similar to those observed by Burger et al.[84] for benzyl ethers **96**.

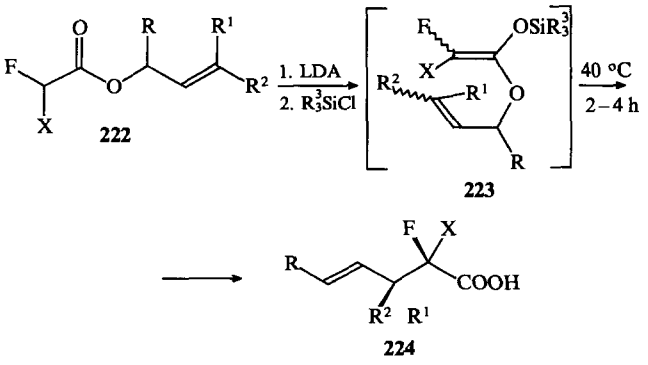
On the other hand, the dehydrofluorination of the adduct **220**, obtained in the reaction of the propargyl ether **191a** with bis(trifluoromethyl)diazomethane or ethyl diazoacetate, afford the very stable 3'-pyrazolylmethyl tetrafluoropropenyl ethers **221**, the structure of which does not change even on heating to 150 °C.[149]

191a **220** **221**

R = R^1 = CF_3; R = H, R^1 = CO_2Et.

On the whole, it is essential to emphasise that the high rate and chemoselectivity, satisfactory yields, and the simplicity of the apparatus provide grounds for the claim that the deprotonation of the corresponding 2-*H*-polyfluoroalkyl ethers is the most convenient and most suitable for technological synthesis of a wide variety of aliphatic fluoro-products of the [3,3]-sigmatropic rearrangement —in the first place fluorine-containing alk-4-ene; and alka-3,4-dienecarboxylic acids and their derivatives. The choice of the deprotonating agent and of the conditions in the rearrangement are determined by the CH acid properties of the initial adducts.

The unsaturated carboxylic fluoroacids and their derivatives, which have become available as a result of the use of this method, are promising synthons for the synthesis of a large number of analogues of biologically active natural products of practical value, for example fluorine-containing 4-butanolides.[111, 136, 139, 150]

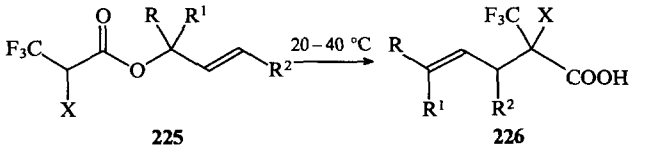


V. Rearrangements of polyfluorocarboxylic acid esters

The [3,3]-sigmatropic rearrangement of the alkenyl esters of 2-*H*-carboxylic acids, known as the Ireland–Claisen rearrangement,[151] usually occurs under mild conditions after the transformation of the alkenyl carboxylates under the influence of organolithium reagents into the corresponding lithium enolates or *O'*-alkenyl-*O*-trialkylsilylketenals. This method, characterised by an exceptionally high diastereoselectivity, is believed to be one of the best for the synthesis of alk-4-enecarboxylic acids.[152] In recent years, the Ireland–Claisen rearrangement has been successfully extended also to the allyl esters of 2-*H*-fluorocarboxylic acids as a result of the efforts of Welch and coworkers.[153–155]

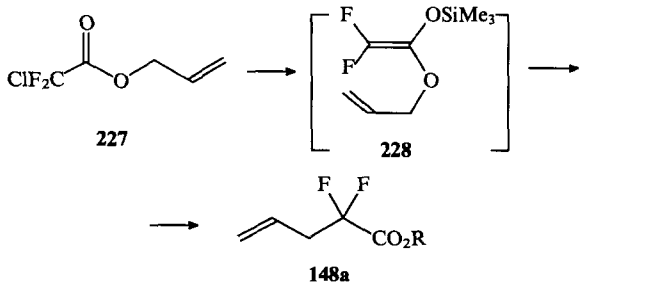
The allyl esters of fluoroacetic acid **222a** and 1-fluoropropionic acid **222b** are stereoselectively deprotonated in THF (−100 to −78 °C) by lithium amides (the best of which is lithium diisopropylamide) with formation of 2-fluoropent-4-enoic acids **224**‡ in 15%–97% yield.[153, 154] The use of silylating agents as enolate traps in the second stage made it possible to establish that the (*E*)-form of the intermediate fluoroketenals **223** participates in the rearrangement.[153, 154]

The presence of fluorine atoms in the molecules of the fluoroketenals **223** apparently facilitates somewhat, and accelerates, their rearrangement. This is indicated by the half-reaction time ($\tau_{1/2}$ = 40 min at 40 °C) measured for compound **223a** (R = R^1 = H, R^2 = Me) and also by the fact that the ketenals **223** can be isolated in a free state,[153] in contrast to the non fluorinated analogues.[152]



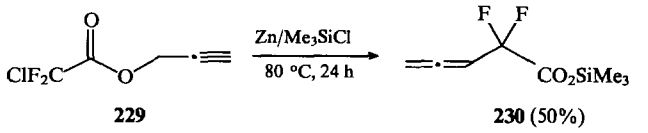
‡ 2-Fluoro-4-butanolides have also been obtained by converting the acids **224** into lactones.[153–155]

X = H(a), Me(b); R, R¹, R² = H, Me.



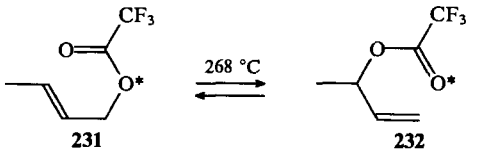
Equimolar mixtures of triethylamine and trialkylsilyl triflates (R_3SiOTf) are more convenient reagents for the generation of silylated fluoroketenals. In this case, the reactions do not require ultralow temperatures. The suitability of the Ireland–Claisen rearrangement for the synthesis in a satisfactory yield of not only the 2-monofluoro-substituted unsaturated acids[96, 155] but also of the polyfluorinated acids of this kind[96, 156, 157] must be regarded as its advantage.

Nakai and coworkers[156, 157] found that 2-trifluoromethylalk-4-ene carboxylic acid **226a** and 2-fluoro-2-trifluoromethylalk-4-enecarboxylic acid **226b** are formed smoothly when alkenyl polyfluoropropionates **225** are treated with a mixture of NEt_3 and Me_3SiOTf in methylene chloride with subsequent refluxing of the reaction solution for 5–12 h (**a**) or its stirring (at 20 °C) for 36 h (**b**).



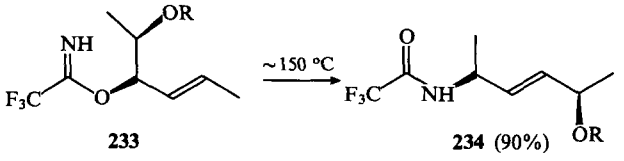
X = H (**a**), F (**b**); R, R¹, R² = H, Me.

Allyl chlorodifluoroacetate **227** undergoes the [3,3]-sigmatropic rearrangement only under the conditions of the Reformatskii reaction. When a mixture of compound **227**, freshly activated zinc, and chlorotrimethylsilane is heated in acetonitrile (100 °C, 20 h), derivatives of 2,2-difluoropent-4-enoic acid **148a** are formed after the rearrangement of the intermediate ketenal **228** and the appropriate treatment.[158]

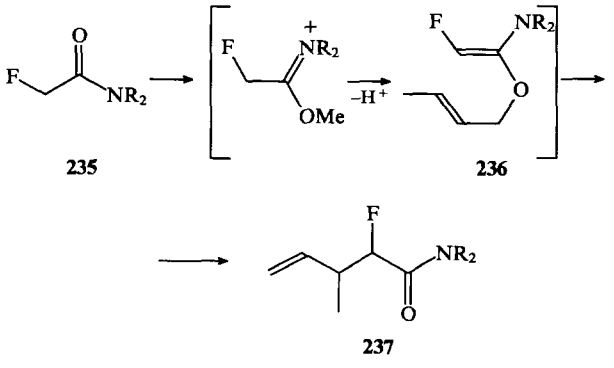


R = H (78 %), Et (60 %), $SiMe_3$ (95 %).

Other 2,2-difluoroalk-4-enecarboxylic acids, including some extremely difficult to obtain, are also formed under these conditions form the corresponding esters of chlorodifluoroacetic acid. In addition, the ester of 2,2-difluoropenta-3,4-dienoic acid **230** was obtained from propargyl chlorodifluoroacetate **229**.[158]

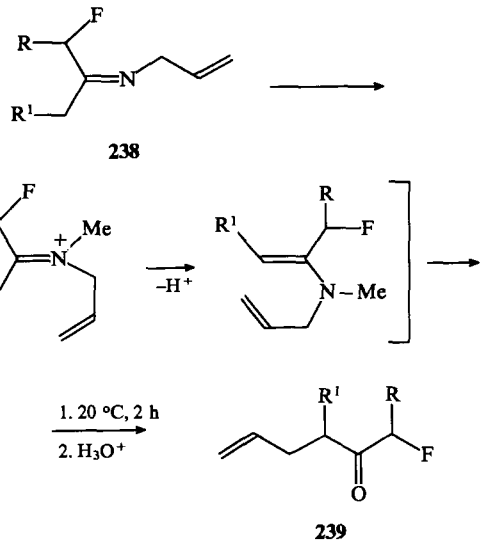


The allyl esters of trifluoroacetic acid are incapable of entering into a similar reaction. However, it has been shown with the oxygen-labelled crotyl trifluoroacetate **231**[159] that, when the latter compound is heated in the gas phase, a reversible [3,3]-sigmatropic rearrangement of this compound to the 1-methylallyl ester **232** takes place.



On the other hand, the trifluoroacetic acid iminoester **233** undergoes smoothly and stereoselectively the Cope 1-aza-3-oxa-rearrangement, on heating in xylene (20 h), to *N*-alkenyltrifluoroacetamide **234**, which is a precursor of an optically active polyoxamic acid.[160]

The analogous iminoester of trichloroacetic acid isomerises after more prolonged refluxing in xylene (48 h), but the yield of the final trichloroacetamide does not exceed 40%.[160]

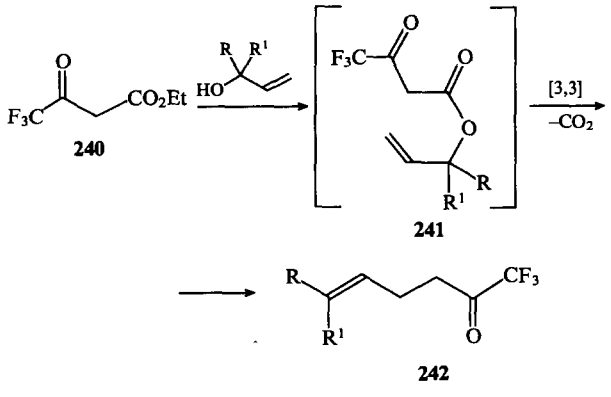


The optically active amides of monofluoro-substituted alk-4-enecarboxylic acids are obtained under milder conditions via intermediate aminoketenals, for example, compound **236**.[161a] The fluoroacetamides **235** are alkylated in the first stage with methyl triflate (MeOTf) or dimethyl sulfate, after which the product is treated with the lithium salt of the geometrically pure crotyl alcohol. The products of the rearrangement (the amides **237**) are isolated in 23%–78% yield (depending on the configuration of crotyl alcohol) after stirring the reaction solution (THF or methylene chloride, at 225 °C) for at least 14 h.

R = Me, $-(CH_2)_4-$, Pr^i.

The optically active *N*-(2′-fluoro-3′-methylpent-4′-enoyl)-2,5-dimethylpyrrolidine was obtained in the same way (at 20 °C, 24 h) in 61% yield.[161b]

The Claisen amino-rearrangement (the Cope 3-aza-rearrangement) of the α-halogenated and non-halogenated ketimines proceeds via a similar mechanism with participation of the quaternised nitrogen atom.[162] Successive treatment of *N*-fluoroalkylideneallylamines **238** with alkylating (MeOTf) and deprotonating [solution of 1,8-bis(dimethylamino)naphthalene in MeCN] agents under mild conditions leads to the monofluoroketones **239**.



238

239

R = Me, R^1 = H (54%); R, R^1 = $-(CH_2)_3-$ (31%).

The high regioselectivity of these reactions[162] permits their use as a convenient method of synthesis of α-halogenated 4,5-unsaturated ketones.

Camps and coworkers[163, 164] investigated in relation to several examples the behaviour of the esters of fluorine-containing acids in the base-catalysed Carroll rearrangement. Ethyl 4,4,4-trifluoroacetoacetate **240** was used as the starting compound in this rearrangement. The transesterification of the acetate **240** with 1-substituted allyl alcohols is carried out in the presence of catalytic amounts of sodium acetate (150 °C, 15 h). The allyl ethers **241**, generated as a result of this reaction, undergo *in situ* a [3,3]-sigmatropic shift, coupled with decarboxylation and formation of CF_3-substituted 4,5-unsaturated ketones **242**.[163]

240

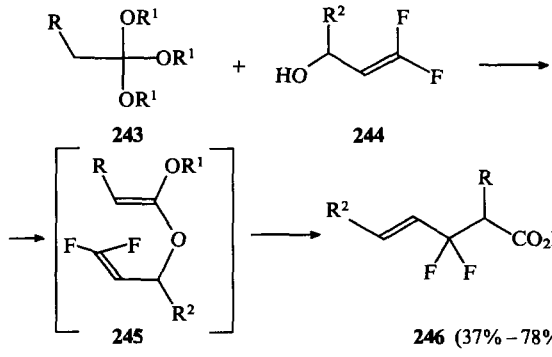
241

242

R = R^1 = Me (80%); R = Me, R^1 = $(CH_2)_2CH$ = CMe_2 (84%).

It has been noted[163] that the presence of the CF_3 group in the acetate **240** is responsible for the less severe reaction conditions compared with those which obtain in the Carroll rearrangement of ethyl acetoacetate.[165]

Although this method is not distinguished by a high stereoselectivity, it makes it possible to obtain in satisfactory yields certain compounds of practical value, for example geranyltrifluoroacetone,[164] which is a trifluoro-analogue of juvenile hormone.



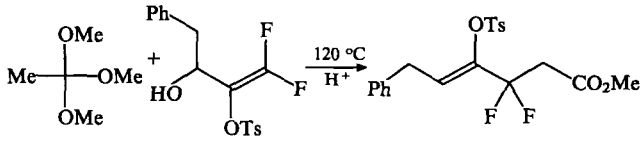
VI. Rearrangements of polyfluoroallyl ethers

Fluorine-containing 2,3-unsaturated alcohols are precursors of polyfluoroallyl vinyl ethers which undergo *in situ* [3,3]-sigmatropic transformations, involving Johnson–Claisen, Claisen, and Ireland–Claisen rearrangements. Preparative syntheses of fluorinated allyl and propargyl alcohols began to be actively developed only during the last decade and one can therefore postulate that there are good prospects for the development of methods of synthesis of unsaturated compounds based on the rearrangements of the corresponding polyfluoroallyl ethers.

The initial components in the Johnson–Claisen rearrangement[166] are trialkyl orthoacetates and allyl alcohols. The high stereoselectivity of the rearrangement requires the use of geometrically pure alcohols, whilst its fairly severe conditions (110 °C–150 °C, the presence of an acid catalyst generating the vinyl component) permit the involvement of highly substituted unsaturated alcohols in these reactions.

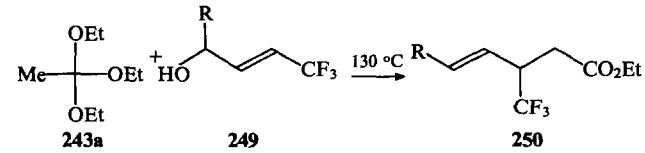
Among fluorinated alcohols, only the most readily available 3,3-difluoroallyl and trifluoromethylated allyl and propargyl alcohols have been made to undergo the Johnson–Claisen rearrangement.

The 3,3-difluoroallyl alcohols **244** react with the orthoesters **243** in boiling toluene in the presence of catalytic amounts of propionic acid. The resulting difluoroallyl vinyl ethers **245** isomerise under the reaction conditions (115 °C, 5 h) to the esters of 4,5-dialkyl-3,3-difluoroalk-4-enecarboxylic acids **246**.[167] Under the influence of alkali, the esters **246** are readily dehydrofluorinated, being converted into alkyl 3-fluoro-5R^2-penta-2,4-dienoates.[167]



243 **244**

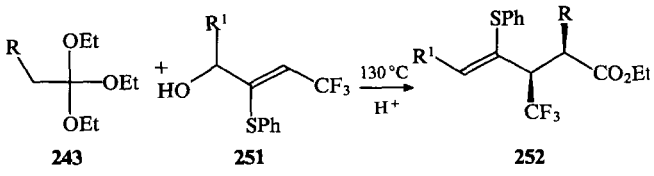
245 **246** (37%–78%)



R = H (**a**), Me (**b**); R^1 = Me, Et; R^2 = H, CH_2CH_2Ph, C_5H_{11}.

The analogous reaction of the orthoester **243a** (R^1 = Me) with 1-benzyl-3,3-difluoro-2-tosyloxyallyl alcohol **247** is smoothly completed after 1.5 h by the formation of the ester **248** in 84% yield.[92]

243a **247** **248**

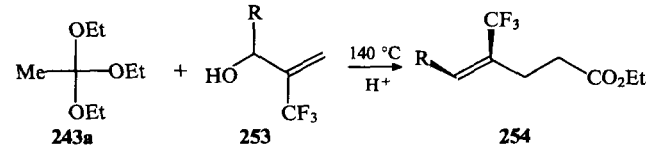


Trifluoromethyl-substituted unsaturated alcohols undergo the Johnson–Claisen rearrangements under virtually the same conditions. Japanese workers have shown[147, 168, 169] that these reactions constitute a convenient method for the stereoselective synthesis of the esters of 3- and 4-CF_3-substituted unsaturated acids. Thus, ethyl 3-trifluoromethyl-5R-pent-4-enoates **250** have been obtained by heating 1-alkyl-3-trifluoromethylallyl alcohols **249** in a large excess of the orthoester **243a** (R^1 = Et) in the presence of a catalyst (EtCOOH).[147]

243a **249** **250**

R = CH_2CH_2Ph (71%), CH_2OCH_2Ph (45%), n-C_6H_{13} (81%).

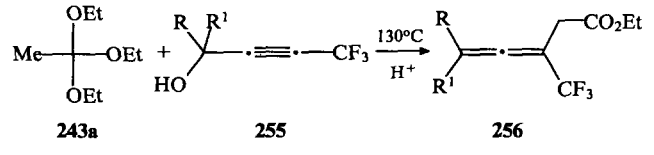
The reactions of 2-phenylthio-3-trifluoromethylallyl alcohols **251** with the orthoesters **243** lead stereoselectively to the esters of 4-phenylthio-3-trifluoromethylalk-4-ene carboxylic acids **252** in 55%–87% yield.[168]



243 **251** **252**

R = H, Me; R¹ = Me, Et, Pr^i, Ph.

The presence of the phenylthio-group at the double bond in the alcohol **251** does not exert a significant influence on the conditions of the rearrangement.

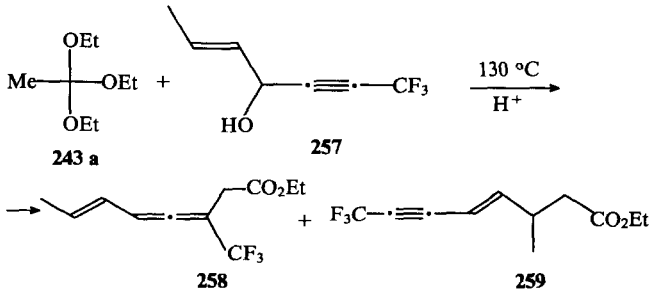


2-Trifluoromethylallyl alcohols **253** react with the orthoester **243a** under somewhat more severe conditions. The esters of 4-trifluoromethylalk-4-enecarboxylic acid **254** are formed stereoselectively as the final products in this instance.[169]

243a **253** **254**

R = CH_2CH_2Ph (86%), CH_2OCH_2Ph (73%).

Trifluoromethyl-substituted acetylenic alcohols also enter into a reaction of a similar type. Interaction of 1-R-3-trifluoromethylpropargyl alcohols **255** with the orthoester **243a** leads to derivatives of 3-trifluoromethylpenta-3,-4-dienoic acid **256** in 32%–55% yields.[147]

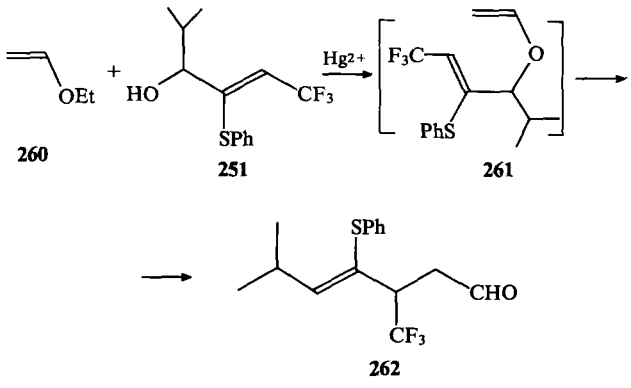


243a **255** **256**

R = CH_2CH_2Ph, CH_2OCH_2Ph, *n*-C_6H_{13}, R¹ = H; R = R¹ = $-(CH_2)_5-$.

The base-catalysed isomerisation of compound **256** affords 3-trifluoromethyl-5-R-penta-2,4-dienoate (R = CH_2OCH_2Ph).[147]

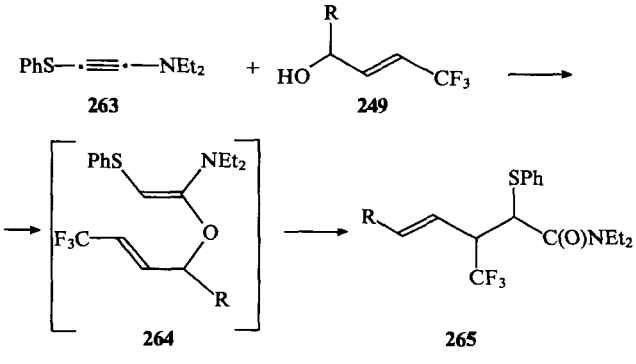
It is of interest that allyl and propargyl alcohols exhibit the same tendency to undergo the Johnson–Claisen rearrangement. The use of 1-propenyl-3-trifluoromethylpropargyl alcohol **257** in this reaction leads to a mixture of the esters of 3-trifluoromethylocta-3,4,6-trienoic acid **258** and 7-trifluoromethylhept-4-en-6-ynoic acid **259** in proportions of 1 : 1.[147]



243 a **257**

258 **259**

At the same time, an attempt to involve 1-(4′-methoxyphenyl-2′,3′,6′-trimethyl)-3-trifluoromethylpropargyl alcohol in the Johnson–Claisen rearrangement was unsuccessful,[170] apparently owing to the powerful steric effect of the bulky substituent in the 1-position.

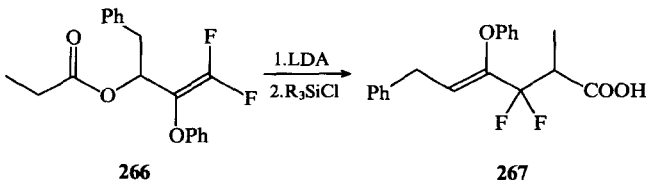


The ability of polyfluoroallyl ethers to enter into the Claisen and Ireland–Claisen rearrangements has also been investigated.

The thermal condensation (150 °C) of ethyl vinyl ether **260** and 3-trifluoromethylallyl alcohol **251** (R = Pr^i) catalysed by mercury acetate affords 3-trifluoromethylheptenal **262** in 50% yield.[168] At temperatures below 150 °C, the Claisen rearrangement of the initial 3-trifluoromethyl vinyl ether **261** does not occur.

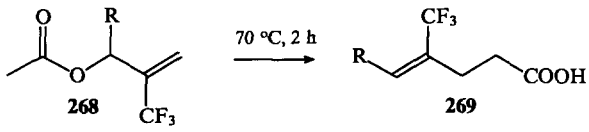
260 **251** **261** **262**

Another method of generation of the intermediate Claisen substrate is involved in the reaction of phenylthioalkynamine **263** with trifluoromethylallyl alcohol **249**.[147] The adduct **264** of these reactants isomerises on refluxing in toluene to the amide **265**, which is subsequently oxidised to 3-trifluoromethylalk-2,4-dienoate. The use of (*Z*)-**249** instead of (*E*)-**249** lowers the yield of the amide **265** from 62% to 35%.



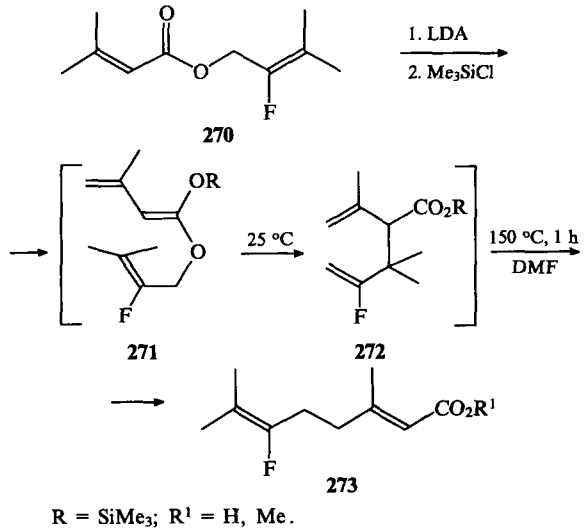
263 **249** **264** **265**

R = CH_2OCH_2Ph.



The polyfluoroallyl esters of carboxylic acids undergo the Ireland–Claisen rearrangement under standard conditions, although unsuccessful attempts to involve certain difluoroallyl carboxylates in this reaction have been noted.[167]

The difluoroallyl propionate **266** is readily transformed into 3,3-difluoro-2-methylalk-4-enecarboxylic acid **267** in 57% yield on successive treatment with lithium diisopropylamide and trialkylchlorosilane.[92]

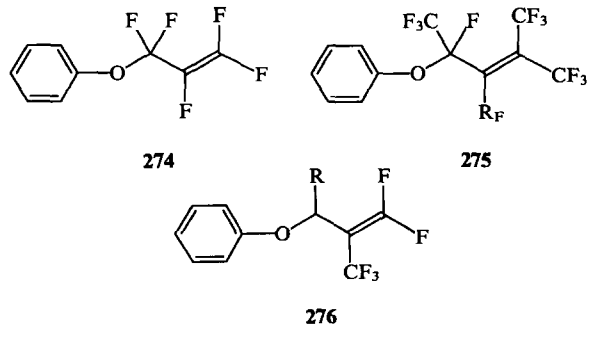


266 **267**

On treatment with lithium isopropylcyclohexylamide and *tert*-butylchlorodimethylsilane in hexamethylphosphoramide, 2-trifluoromethylallyl acetates **268** are similarly converted into 4-trifluoromethylalk-4-enecarboxylic acid **269** (in yields up to 86%).[169]

R = CH_2CH_2Ph, CH_2OCH_2Ph.

The tandem Ireland–Claisen/Cope rearrangement used by Camps et al.[171] is a key stage in the multistage synthesis of the monofluoro-analogues of one of the juvenile hormones from 2-fluoroallyl acrylate **270**.



R = $SiMe_3$; R^1 = H, Me.

When these reactions are carried out in one stage without the isolation of the intermediates **271** and **272**, it is possible to obtain the ester of 6-fluoro-3,7-dimethyl-octa-2,6-dienoic acid **273** in 78% yield.[171]

Overall, one may note that the fluorine atoms and the trifluoromethyl group apparently do not exert a significant influence on the conditions and rate of the [3,3]-sigmatropic rearrangements of polyfluoroallyl ethers. This has been confirmed by the calculations of Gajewski et al.,[35] who determined the activation parameters for the Claisen rearrangement of 1-trifluoromethylallyl vinyl ether. According to the authors' data,[35] the CF_3 group at the C(4) atom does not have an appreciable influence on the rate of the rearrangement, in contrast to, for example, the CN group, which ensures a gain in activation free energy of 3.5 kcal mol^{-1} in this position.[33]

The thermodynamic stability of phenyl polyfluoroallyl ethers is evidently also close to that of the fluorine-free allyl ethers of phenols. Indeed, perfluoroallyl phenyl ether **274**[172] and phenyl polyfluoroalkenyl ethers **275**[100] and **276**[173] have fairly high thermal stabilities and do not isomerise after prolonged storage or on heating under the reaction conditions.

R_F = $CF(CF_3)_2$, R = $CF_2(CH_2CF_2)_nF$.

The absence of positive effects by the fluorine atoms on the CF_3 group in the [3,3]-sigmatropic rearrangements of polyfluoroallyl vinyl ethers in no way reduces the preparative value of these compounds. They make it possible to synthesise highly stereoselectively, and in a satisfactory yield, 3- and 4-fluoro(trifluoromethyl)-substituted unsaturated acids and their derivatives which are otherwise difficult to obtain.

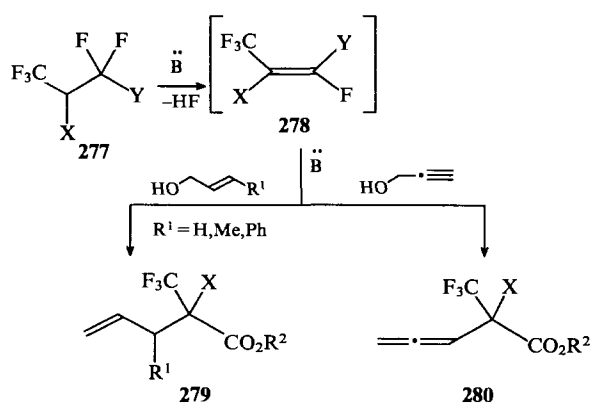
VII. Conclusion

Whereas only two studies[35, 44] devoted to the Claisen rearrangement were mentioned in Hudlicky's fundamental monograph[105b] in 1976, towards the end of the 1980s the continuous growth in the number of studies on the [3,3]-sigmatropic rearrangements of organofluorine compounds already made it possible to recognise these reactions as one of the important methods of synthesis of fluorine-containing synthons.[174] Analysis of the data presented in this review permits an assessment at a deeper level of the applied and theoretical importance of the [3,3]-sigmatropic rearrangements of compounds of the organofluorine series.

In the first place, one should note their undoubted applied value. At the present time, this method is used to synthesise many organofluorine compounds of different classes. They include perfluorinated aromatic or heteroaromatic fragments of pyrans, furans, thiophens, and pyrroles condensed with a benzene ring, polyfluorinated 4,5-unsaturated ketones, derivatives of alk-4-ene, alka-3,4-diene-, and alka-2,4-diene-carboxylic acids, alkenylmalonic and carboxylic 4-ketoacids, furans, thiophens oxazolones, 4-butanolides, and compounds of other types. At the same time, the [3,3]-sigmatropic rearrangements have been used successfully in the preparative syntheses of fluorine-containing[81, 82, 84, 89] and non-fluorinated[160] α-aminoacids and fluorine- and trifluoromethyl-modified micotoxins,[94] phospholipids,[112] nucleosides,[155] juvenile hormones,[164, 171] and new medicinal[53, 157] and pesticidal[77, 157] preparations.

In addition, the considerable potential possibilities of the [3,3]-sigmatropic rearrangements as a universal method for the formation of the C–C bond can probably find applications in the solution of certain problems in the industrial chemistry of fluorine of current interest. For example, in the large-scale manufacture of hexafluoropropene, they can be used for the selective removal of a highly toxic impurity, namely perfluoroisobutene, from the main product with the simultaneous synthesis of the products of the rearrangement of the impurity. The same rearrangements can be used for the ecologically clean assimilation of the existing industrial manufacture of ozone-damaging Khladons (Freons), which are capable of being transformed into polyhaloalkenes under certain conditions.[175]

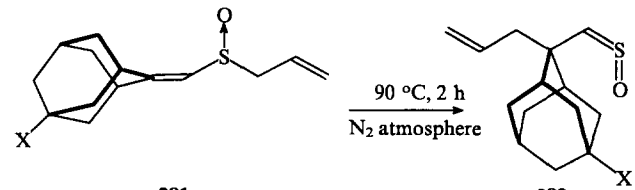
Theoretical studies on the [3,3]-sigmatropic rearrangements of organofluorine compounds have also proved extremely fruitful. By virtue of the unique effect of the fluorine atoms and the fluoroalkyl groups on the electronic system of the double bond of the 'vinyl' fragment in the series of 2,3-unsaturated ethers of polyfluoroalkenols and polyfluorocycloalkenols, compounds with a broad spectrum of reactivities were obtained (ranging from compounds thermodynamically stable at 150 °C to compounds which isomerise spontaneously under the conditions of their synthesis even on intense cooling). It has been shown that the probability and conditions of the rearrangement are determined primarily by the level of the population of the π-orbital of the vinyl bond, its capacity for polarisation from the C(2) to the C(1) atom, and the steric effect of the bulky fluorine-containing substituents in the C(1) position. The necessary preconditions for the prediction of the behaviour of the corresponding ethers of polyfluoroalkenols (polyfluorocycloalkenols) in the [3,3]-sigmatropic rearrangement and for the control of this process were thus created.



The phenomenon of the low-temperature anionic Claisen and Cope rearrangements, widely discussed in recent years,[9, 13, 28-32] has been manifested particularly clearly in the study of the [3,3]-sigmatropic rearrangements of fluorocarbanions.[37] The general features of an anionotropic [3,3]-sigmatropic process, the driving force of which is the highly effective symmetry-allowed charge-controlled pπ interactions, are characteristic of these rearrangements. However, instances of the easiest sigmatropic shifts have been noted precisely in the reactions of certain polyfluoroalkenes (perfluoroisobutene, perfluoromethacrylic acid diethylamide) with 2,3-unsaturated alcohols even in the absence of basic reagents.

The results in the study of the [3,3]-sigmatropic rearrangements of fluorine-containing compounds obtained hitherto indicate the appearance of a new modern method of organofluorine synthesis which reflects the unusual character of the fluorine chemistry as a whole. These results constitute a good practical and theoretical basis for further still more vigorous development of this field of chemistry.

* *
*

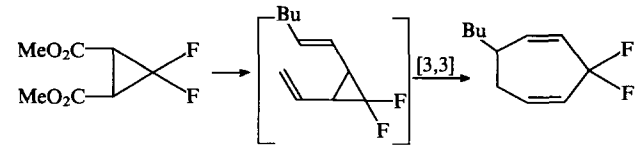


The studies published during the brief period of the preparation of the present review for the press confirm the steady interest of investigators in the problem considered. In one of the latest monographs devoted to fluorine chemistry, a review by Welch et al.[176] was published in which the Claisen rearrangements of the acetals of fluoroacetamides (fluorine-containing aminoketenals) are considered as an effective instrument for asymmetric synthesis.

A new convenient method of synthesis of derivatives of 2-trifluoromethyl-substituted unsaturated acids has been developed recently.[177] The fluorinated CH acids **277** interact in the presence of bases (B̈) with allyl and propargyl alcohols to form the products of the [3,3]-sigmatropic rearrangement — the esters of 2-trifluoromethylpent-4-enoic acid **279** and 2-trifluoromethylpenta-3,4-dienoic acid **280**. The reaction conditions and yields of the final products **279** and **280** are determined by the strength of the CH acids **277**, from which the polyfluoroalkenes **278** are generated initially. The latter undergo further reactions *in situ*. The new method[177] makes it possible to obtain in one stage the derivatives of unsaturated fluorocarboxylic acids, by-passing the laborious syntheses of polyfluroalkenes and their adducts with 2,3-unsaturated alcohols.

X = CF_3, CO_2R; Y = F, OR;
R = Me, Et; R^2 = R, $CH_2CH = CHR^1$, $CH_2C{\equiv}CH$.

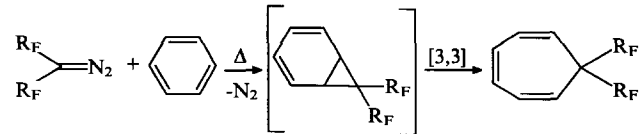
American investigators[178] studied the thio-[3,3]-sigmatropic rearrangement of the unsubstituted and 5-fluoro-substituted adamantylidenemethyl allyl sulfoxides **281**, which leads to a mixture of the stereoisomeric sulfines **282** [the stable (*Z*)-form is illustrated]. The introduction of a fluorine atom in the 5-position does not alter the reaction conditions, but increases the number of diastereoisomers formed from 2 to 4.



281 **282**

X = H, F.

It was established[178] that the steric and electronic effects of the substituents in compound **281** influence equally the stereochemistry of the process, in contrast to the Cope oxy-rearrangement,[43] investigated by the same workers, in which the influence of the steric factor predominated.



One of the few examples of the practical use of the Cope rearrangement has been described in a study[179] devoted to the preparative synthesis of fluorinated analogues of cycloheptadiene pheromones present in brown seaweed. The di(methoxycarbonyl)-substituted *gem*-difluorocyclopropane **283** was used as the synthon for the synthesis of the *trans*-dialkenyl-substituted *gem*-difluorocyclopropane **284**. The extreme instability of the cyclopropane **284**, which rearranges spontaneously at room temperature to 3,3-difluorocyclohepta-1,4-diene **285**, was unexpected.

283 **284** **285**

The kinetic parameters of the isomerisation of compound **284** to **285**, determined by the authors,[179] made it possible to discover the marked influence of the geminal fluorine atoms, weakening the opposite bond of the cyclopropane ring and leading to milder reaction conditions.

It is essential to note that a similar rearrangement had been observed earlier in relation to *gem*-perfluoroalkylnorcaradienes **287**. Krespan and coworkers[180] showed that the pyrolysis of the perflurodiazoalkanes **286** in an excess of benzene (150 °C–200 °C, 8 h) affords 7,7-bis(perfluoroalkyl)cyclohepta-1,3,5-trienes **288** as the main products in yields of 62% (**a**) and only 22% (**b**). Compounds **288** are formed as a result of the Cope rearrangement of the intermediate norcaradienes **287**.

286 **287** **288**

R_F = CF_3 (**a**), C_2F_5 (**b**).

The cycloheptatriene **288a** is formed as a side product in 11% yield on photolysis of bis(trifluoromethyl)diazomethane **286a** (benzene, 40 h).[180]

The preparative value of the Cope rearrangement of substrates of the type of compounds **284** and **287** increases sharply if this process is considered as a convenient approach to the synthesis of tropylidene structures containing fluorine and fluoroalkyl substituents, which are otherwise difficult to obtain.

V.	Decyclisation of glycals as a basis for synthesis of natural products and their structural analogues	596

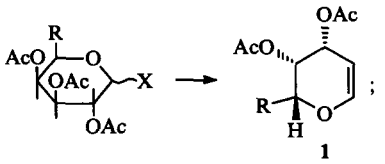
Abstract. The reactions of 1,2-unsaturated sugars (glycals) are considered in this review in relation to problems of the enantiospecific synthesis of natural products, their fragments, and their analogues. The reactions occurring both with retention of the heterocycle and those carried out with the aim of obtaining open chain chiral units are discussed. It is shown that the use of glycals as a stock of chiral substances which determine the configuration of the asymmetric centres in the target products of multistage synthesis is promising. Schemes for the synthesis of natural products of different types are considered: *O*- and *C*-glycosides, nucleosides, oligosaccharides, pheromones, antibiotics, toxins, glycosphingolipids, etc. The bibliography includes 161 references.

I. Introduction

Glycals — 1,2-unsaturated derivatives of pentoses and hexoses — were first obtained by Fischer and Zach.[1] The factual data on the chemistry of glycals accumulated during several decades have been surveyed in two reviews.[2, 3] Since a detailed description of the results of studies during the last twenty years would have exceeded the available space in the present review, it appears useful to concentrate attention on the most important and interesting aspects of the chemistry of glycals which are of value for fine organic synthesis.

The main principles of the enantiospecific synthesis of natural products using chiral building blocks obtained from carbohydrates were formulated at the beginning of the 1970s. The excellent book by Kochetkov et al.[4] and a number of reviews[5–7] are devoted to this question. On the other hand, a detailed study of the literature enabled us to note that, until the beginning of the 1980s, there were only a few isolated examples of the use of natural sugars such as glycals in the total synthesis of natural products. A notable feature of this decade has been an increasing interest in the chemistry of glycals in connection with problems of enantiospecific synthesis.

At the present time the glycal approach is regarded as one of the promising methods of synthesis of *O*- and *C*-glycosides and oligosaccharides. Reactions involving electrophilic addition to the double bond in glycals are important in this connection. Glycals are completely irreplaceable in the synthesis of natural metabolites incorporating in their structure oxygen-containing heterocycles (ionophoric antibiotics, sea toxins, etc.). The Ferrier reaction,[8] which proceeds as S_N2' substitution accompanied by the allyl rearrangement, has been noted among the reactions which are specially important for the specific modification of glycals. The reactions of alcohols and thiols under the influence of Lewis acids, *C*-glycosylation by cation-active alkenes, allylsilanes, and silyl ethers of enols, the coupling with arenes, malonates, and aryl halides in the presence of metal complex catalysts, and the synthesis of *N*-nucleosides proceed in precisely this way. The reactions of glycals based on the Claisen rearrangement are distinguished by a high enantiospecificity in the formation of new oxygen–carbon bonds. The [2+2]-, [3+2]-, and [4+2]-cycloaddition reactions, which make it possible to obtain cyclic systems and also to achieve the stereospecific introduction of heteroatomic functional groups, are finding applications to an increasing extent. A very promising approach, which has so far been little developed, involves the use of organometallic derivatives of glycals of vinyl type. The products of the oxidation reactions of glycals have acquired great synthetic value. The decyclisation reactions, which make it possible to obtain open chain chiral units, are widely used. Having restricted the present review to the discussion of the methods of synthesis of natural products, we intend at the same time to give a description, which is as detailed and systematic as possible, of the characteristic reactions of glycals and also to include a bibliography, which, although not necessarily referring to the synthesis of natural products and their molecular fragments, is nevertheless of interest to a wide range of readers.



II. Synthesis of glycals

The characteristics of the classical method of synthesis of glycals, which involves treatment of the corresponding acylglycosyl bromides with zinc dust, are given in the paper of Fischer and Zach[1] and in the reviews by Ferrier.[2, 3] The method involves fairly mild conditions, since it makes it possible to obtain in satisfactory yields glycals from disaccharides, for example gentiobial,[9] and modified type **1** glycals from 6-deoxy-6-substituted galactopyranosides (Scheme 1).[10, 11]

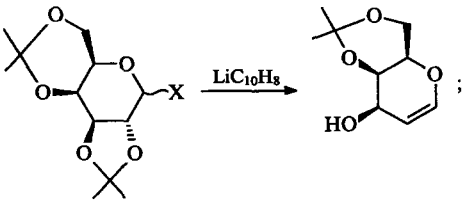
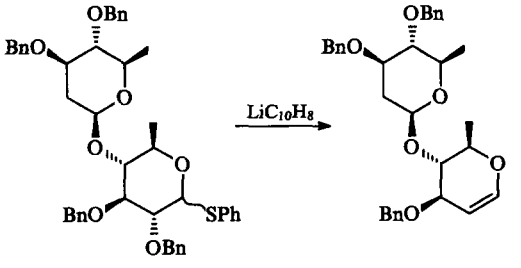
Scheme 1



1

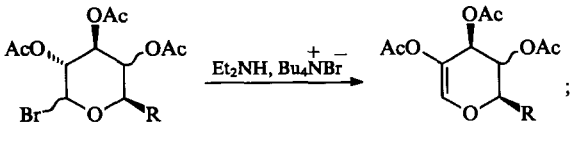
X = OAc, Br ;



R = 

A number of studies have been devoted to the improvement of the method of synthesis of glycals.[12-14] The possibility of a significant increase in yields when the zinc–silver or the zinc–copper couple,[15, 16] aluminium amalgam,[17] a divalent chromium salt,[18] and lithium in liquid ammonia[19-21] are used was demonstrated. Lithium naphthalide was used successfully in the synthesis of glycals from *S*-glycosides and their oxidised derivatives (Scheme 2).[22, 23]

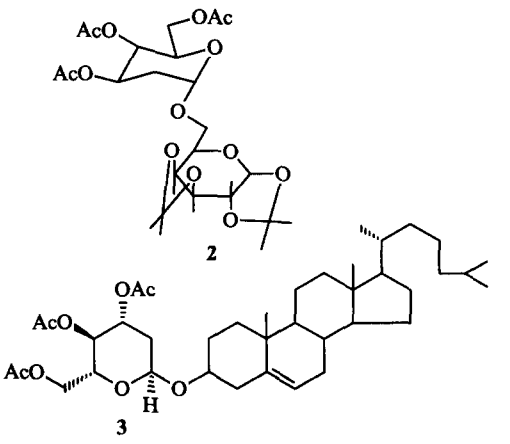
Scheme 2



X = PhS, $PhSO_2$.

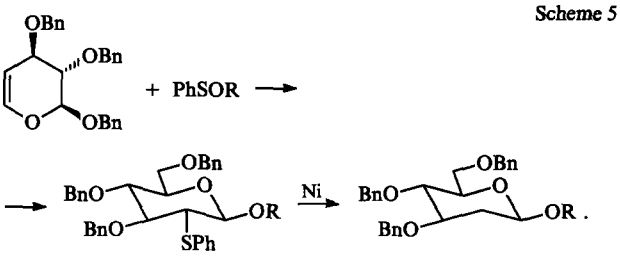
Derivatives of 2-deoxysugars, containing leaving groups of the type OMs, Cl, and SOPh at the C(1) atom are used in many instances.[24-26] 2-Acyloxyglycals, obtained by treating the corresponding acylglycosyl bromides with diethylamine in the presence of quaternary ammonium salts, have been acquiring increasing importance in the synthesis of natural products (Scheme 3).[27]

Scheme 3



R = H, Me, CH_2OAc .

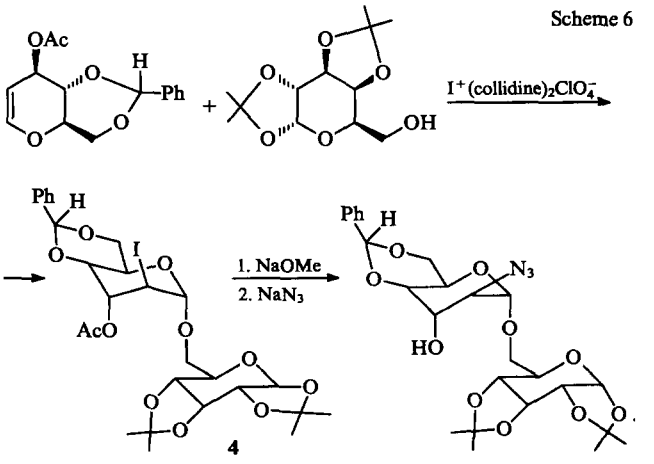
III. A brief description of the reactions of glycals which have found applications in the synthesis of natural products



The addition of electrophiles to the double bond of glycals is used in the synthesis of *O*- and *C*-glycosides and oligosaccharides. According to Sabegam and Neira,[28] the very simple reaction involving the addition of water and alcohols is best catalysed by an acid cation exchanger and LiBr. The reactions in the presence of the complex $PPh_3 \cdot HBr$ take place with a high α-stereoselectivity.[29] The α-*O*-glycosides **2** and **3** were synthesised in this way from tri-*O*-acetyl-D-glucal, diisopropylgalactopyranose, and cholesterol (Scheme 4).[2, 3]

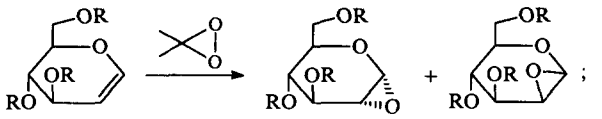
Scheme 4

The addition to glycals of benzenesulfenic acid esters, synthesised from PhSCl and the corresponding alcohols, is resorted to in order to obtain the β-*O*-glycosides of 2-deoxysugars (Scheme 5).[30]



Scheme 5

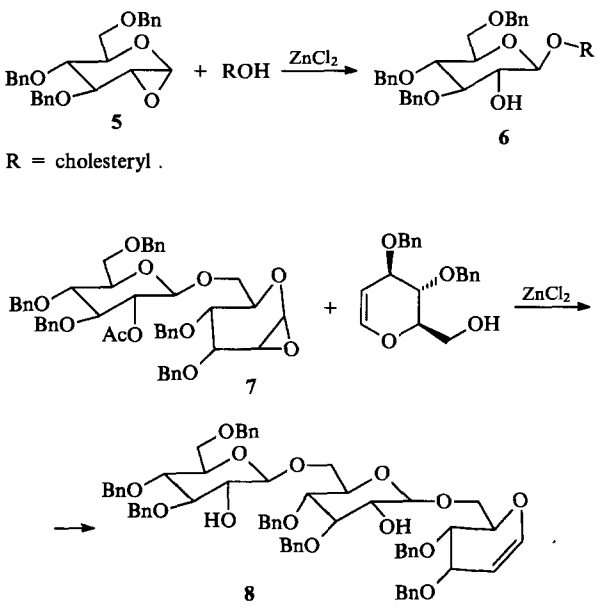
Phenyl selenyl chloride[31, 32] and phosphorodithioic acid esters[33] can also be used for such purposes.



The method based on the addition of alcohols to glycals in the presence of donors of iodonium ions proved to be extremely promising. The complex $I^+(collidine)_2ClO_4^-$ or iodosuccinimide is used as a donor of this kind.[34, 35] The presence of the iodine atom in the adduct **4** makes it possible to introduce nucleophilic groups, in particular the azido-group (Scheme 6).[36]

Scheme 6

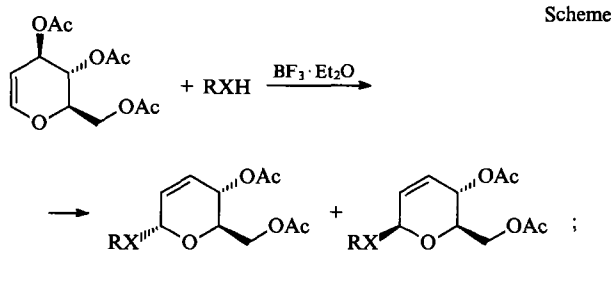
The use of 1,2-epoxysugars, obtained by epoxidising glycals with dimethyldioxiran (Scheme 7), has led to extensive prospects.[37, 38]



Scheme 7

R = Ac, Bn, Bu^{t}Me$_2$Si (TBS).

The great synthetic possibilities of this method are demonstrated in Scheme 8. Here the opening of the epoxide ring in compounds **5** and **7** by alcohols in the presence of $ZnCl_2$ proceeds regiospecifically with formation of the individual *O*-glycosides **6** and **8**. The configuration of the latter is determined by the stereochemistry of the initial epoxides.

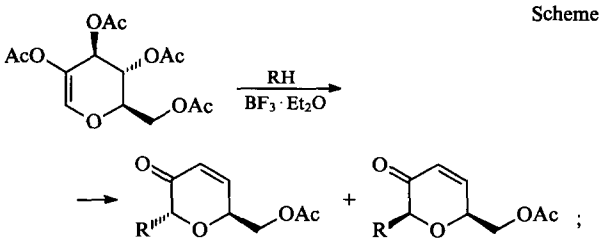


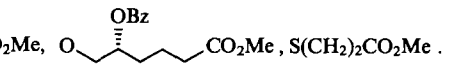
Scheme 8

R = cholesteryl.

The reactions of glycals accompanied by the allyl rearrangement have found wide scale application. The first of these, the so called Ferrier rearrangement, takes place with participation of alcohols and thiols in the presence of Lewis acids (Scheme 9).[2, 3, 8]

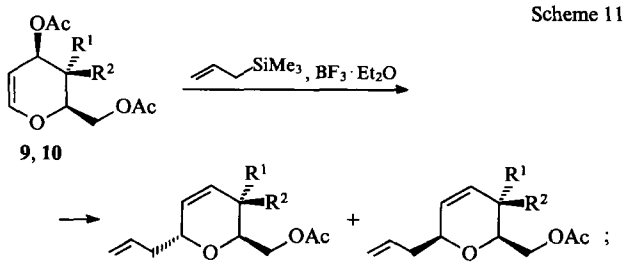
Scheme 9





X = O, S.

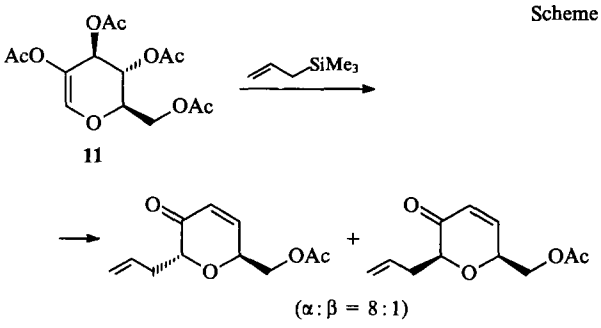
This reaction is used to synthesise substituted 3-oxo-2*H*-pyrans from 2-acetoxyglycals (Scheme 10).[39, 40]



The synthesis of *C*-glycosides is of considerable interest because of the possibility of obtaining 2,6-disubstituted dihydropyrans — important building blocks in the total synthesis of many heterocyclic natural products. The reaction of allyltrimethylsilane with glycals is sensitive to steric factors, which follows from the greater α-stereoselectivity of the interaction of tri-*O*-acetyl-D-galactal **9** compared with tri-*O*-acetyl-D-glucal **10** (Scheme 11).[41]

Scheme 10

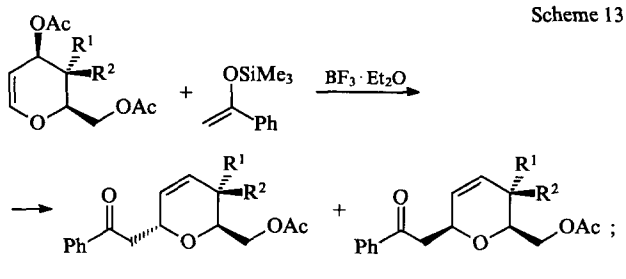
R = OCH_2CO_2Me,  , $S(CH_2)_2CO_2Me$.



Scheme 11

R^1 = H, R^2 = OAc (**9**) (α:β = 30:1);
R^1 = OAc, R^2 = H (**10**) (α:β = 16:1).

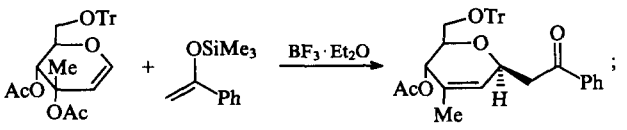
It has been shown that the 2-acetoxyglucal **11** reacts with allyltrimethylsilane in the presence of $BF_2 \cdot OEt_2$ as the catalyst with formation of a mixture of anomeric 3-oxo-*C*-glycosides (Scheme 12).[39]



Scheme 12

(α:β = 8:1)

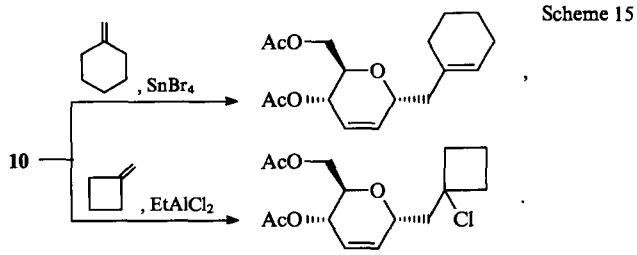
1-Trimethylsiloxystyrene interacts with glycal acetates in the presence of Lewis acids, affording a mixture of isomeric ketones (Scheme 13).[42]



Scheme 13

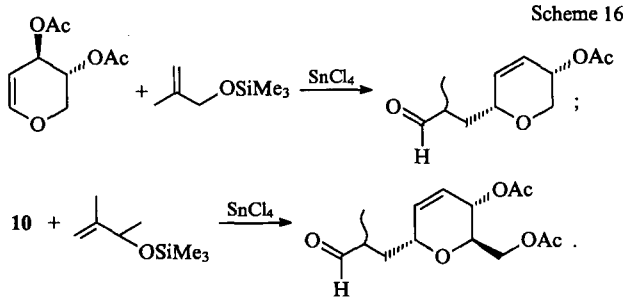
R^1 = H, R^2 = OAc (α:β = 7:1);
R^1 = OAc, R^2 = H (α:β = 4:1).

This reaction can be carried out α-stereospecifically if a bulky substituent, screening the β-position, can be introduced into the molecule of the initial glycal at the C(6) atom (Scheme 14).[43]



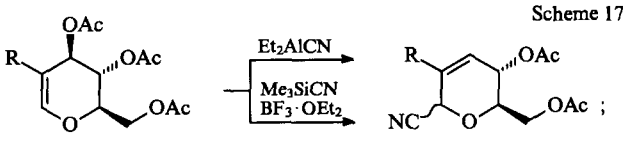
Scheme 14

Tr = Ph_3C .



The reactions of cation-active alkenes with various glycals, which occur in the presence of $SnBr_4$ or $BF_3 \cdot OEt_2$, are surprisingly α-stereospecific. If they are carried out in the presence of $EtAlCl_2$ or $TiCl_4$ as catalysts, their products are chloro-substituted *C*-glycosides which also have exclusively the α-configuration (Scheme 15).[44]

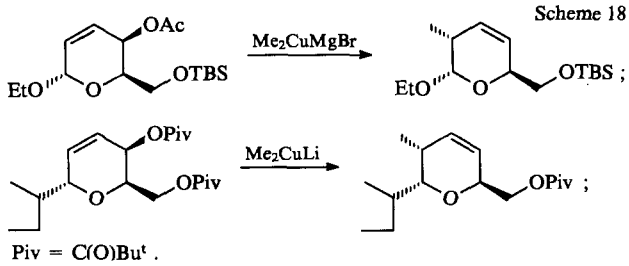
Scheme 15



The reactions of glycal acetates with the silyl ethers of methylallyl alcohol and 2-methyl-3-siloxybut-1-ene lead with a high overall yield (77%–96%) to aldehydes in the form of a mixture of (*R*, *S*)-stereoisomers in relation to the side chain (Scheme 16).[45]

Scheme 16

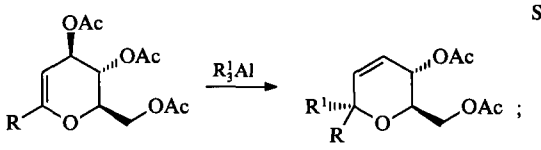
The direct introduction of the cyano-group into glycal ethers by treatment with Et_2AlCN –[46] or $Me_3SiCN - BF_3 \cdot OEt_2$[47] also leads to the allyl rearrangement, affording the corresponding nitriles as a mixture of the α- and β-anomers (Scheme 17).



Scheme 17

R = H, OAc .

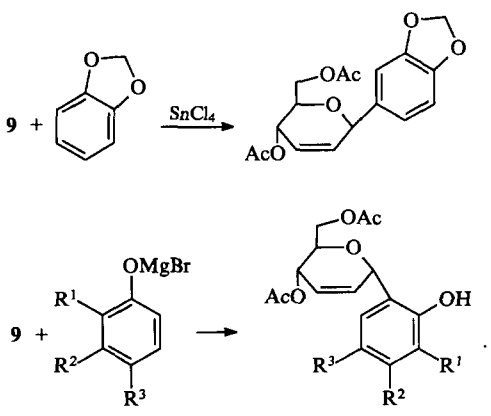
It is noteworthy that the application of organoelement reagents in the chemistry of glycals does not have particularly distinctive features. Nevertheless the cross-coupling of magnesium and lithium cuprate reagents with derivatives of glycals made it possible to obtain a series of important synthons (Scheme 18).[48, 49]



Scheme 18

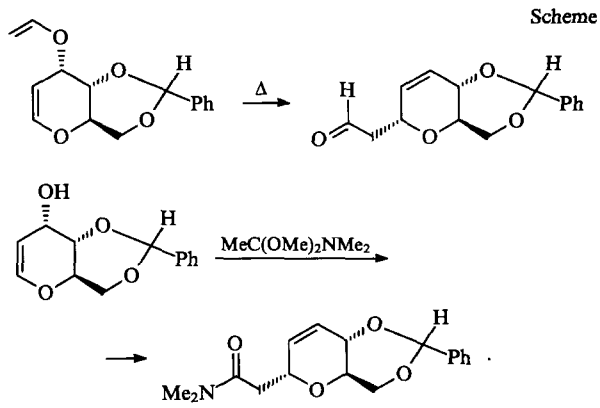
Piv = C(O)Bu^t .

According to the data of Nicolaou et al.,[50] the $TiCl_4$-catalysed reaction of 1-substituted glycals with organoaluminium compounds proceeds stereospecifically (Scheme 19).



Scheme 19

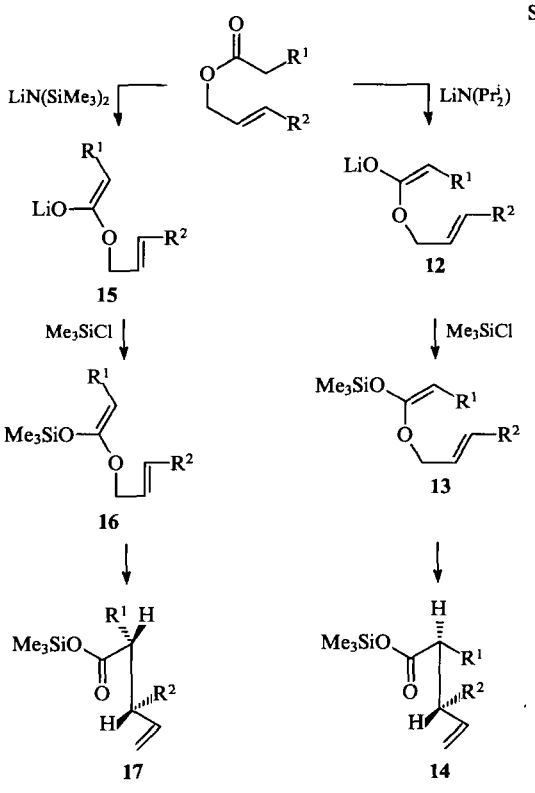
R = Me, $CH_2CH{=}CH_2$;
R^1 = Me, Et .



C-Arylglycosides of natural origin can be obtained from glycals. The reaction takes place with the Ferrier rearrangement and the stereochemistry of the product depends on the method selected for this purpose (Scheme 20).[51–56]

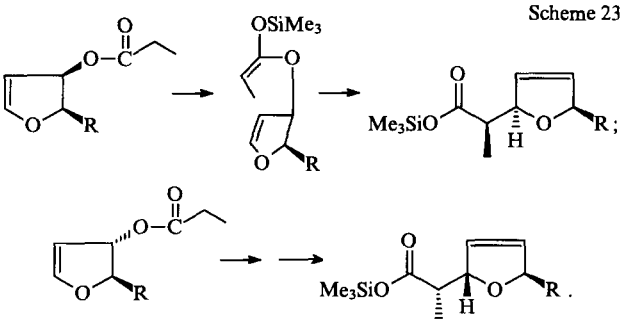
Scheme 20

The Claisen rearrangement with participation of glycal derivatives has been extended with the stereocontrolled formation of a new C–C bond. The thermal rearrangement involves the preliminary formation of the vinyl ethers of glycals or the direct reaction of the latter with the dimethyl acetal of *N*,*N*-dimethylacetamide (Scheme 21).[57]



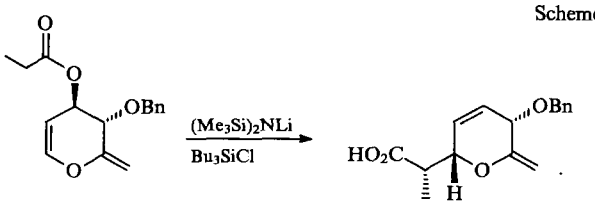
Scheme 21

However, this method is extremely restricted by the choice of the vinyl fragments and one cannot claim that it is widely used. Ireland and coworkers[58–60] found a general approach guaranteeing a high stereoselectivity of the reaction. It is striking that the stereochemistry of the target product can be regulated by altering the nature of the enolisable reagent. Thus the deprotonation of the ethers of allyl alcohols with lithium diisopropylamide in solution in tetrahydrofuran affords the (*Z*)-lithium enolate **12**, the treatment of which with Me_3SiCl leads to the (*E*)-ketene silyl acetal **13**. If the reaction is carried out in hexamethylphosphoramide or lithium bis-(trimethylsilyl)amide is used, then (*E*)-lithium enolate **15** and afterwards the (*Z*)-ketene silyl acetal **16** are formed.



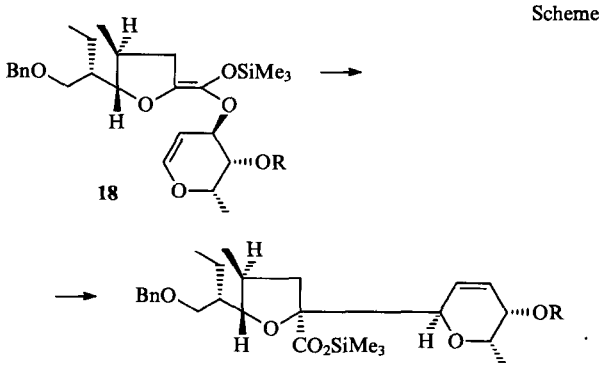
The [3,3]-sigmatropic rearrangement of silyl acetal takes place at −78 °C, the (*E*)-silyl acetal **13** and the (*Z*)-acetal **16** affording respectively the *erythro*-isomer **14** and the *threo*-isomer **17** (Scheme 22).

Scheme 22



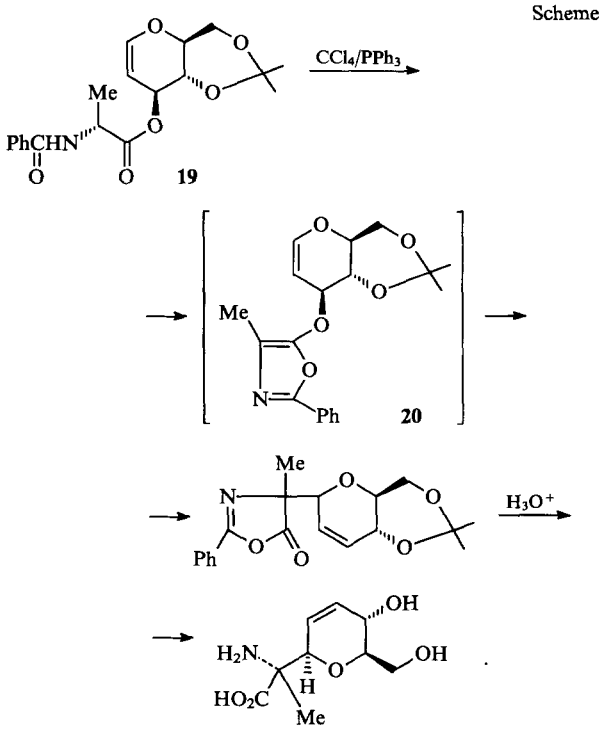
These principles have been clearly demonstrated in relation to the rearrangement of the silyl acetals prepared from the corresponding propionates of furanoglycals (Scheme 23).[60]

Scheme 23



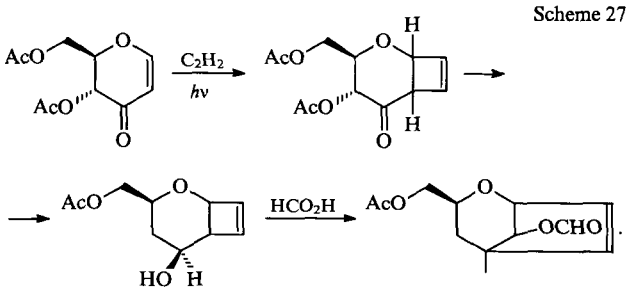
Unfortunately the stereospecificity of the formation of the chiral centre in the side chain breaks down for the propionates of pyranoglycals. For example, a mixture of *C*-glycosides enriched in the α-epimer (up to 86%) was obtained in one of the stages of the synthesis of streptolic acid (Scheme 24).[61]

Scheme 24



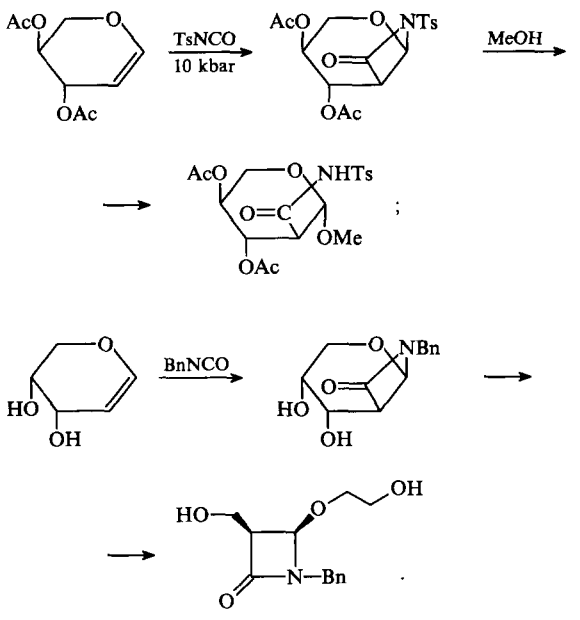
The synthetic possibilities of Ireland's method can be inferred in relation to the rearrangements of the silyl acetal **18**, which has a complex structure (Scheme 25).[62]

Scheme 25



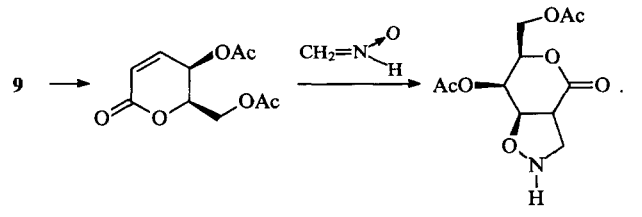
The enolisation of the esters of *N*-benzamidoacids of type **19** makes it possible to achieve an extremely interesting reaction via the oxazole intermediate **20** (Scheme 26).[63]

Scheme 26



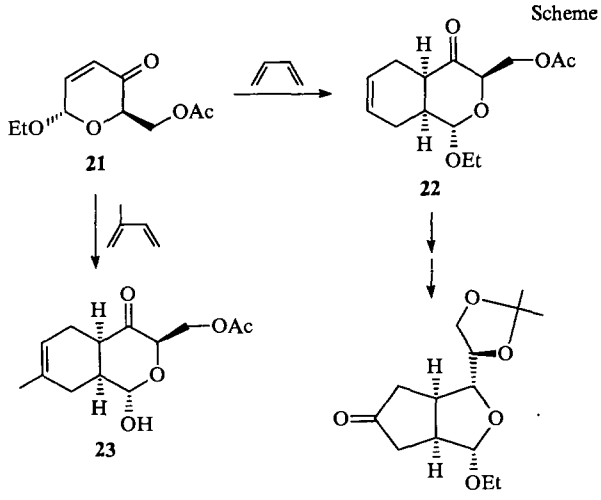
The cycloaddition reactions of glycals and their derivatives have found their place in the stereoselective synthesis of a series of useful bicyclic synthons. Thus the photocycloaddition of acetylene to glycal derivatives via the [2 + 2]-mechanism is regarded as a promising method of constructing the skeleton of trichothecene (Scheme 27).[64, 65]

Scheme 27



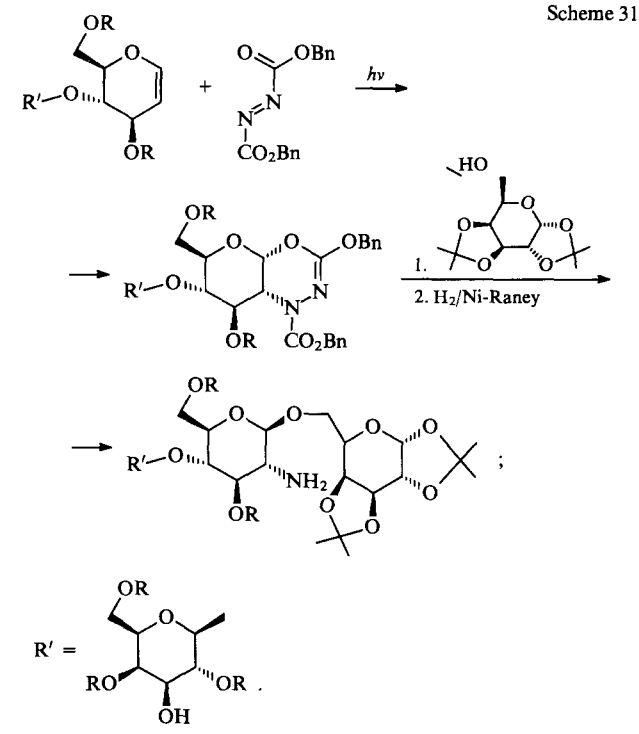
Acyl and sulfonyl isocyanates add to glycals at a pressure of several kilobars, affording [2 + 2]-adducts. The latter have been used in the synthesis of 2-carboxysugars[66, 67] and optically active β-lactams (Scheme 28).[68]

Scheme 28



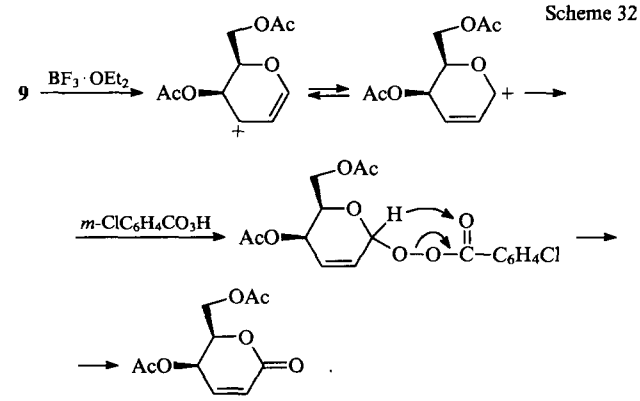
Glycals and their derivatives, which are active 1,3-dipolarophiles, combine with nitrile oxides,[69] nitrones,[70] and formaldoxime (Scheme 29).[71]

Scheme 29



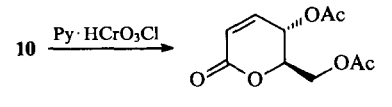
Chiral synthons have been obtained by the [4+2]-cycloaddition reactions of glycals and their derivatives with dienes. Thus the interaction of the enone **21** with butadiene results in the formation of the product **22**, which is used as the starting compound for the synthesis of cyclopentanoid compounds of the type of brefeldin.[72] The Lewis acid-controlled condensation of the enone **21** with isoprene makes it possible to obtain fairly readily compound **23** (Scheme 30).[73]

Scheme 30



The approach to the synthesis of 2-amino-2-deoxysugars developed by Leblanc and Rokach is of great preparative value.[74-76] The photoinitiated reaction of glycals with dibenzyl azodicarboxylate proceeds as a [4+2]-addition. Treatment of the adducts with alcohols in the presence of toluene-*p*-sulfonic acid affords *O*-glycosides, which are converted after hydrogenolysis into 2-aminosugars (Scheme 31).

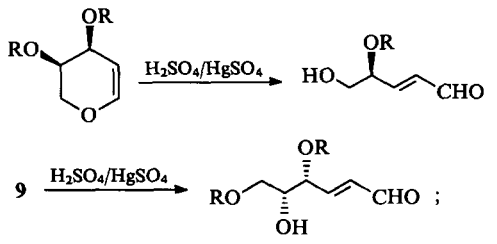
Scheme 31



Among the oxidation reactions of glycals, their single-stage conversion into unsaturated lactones on treatment with *m*-chloroperbenzoic acid in the presence of $BF_3 \cdot OEt_2$ is striking.[77, 78] The proposed mechanism of the oxidation reaction is illustrated in Scheme 32.

Scheme 32

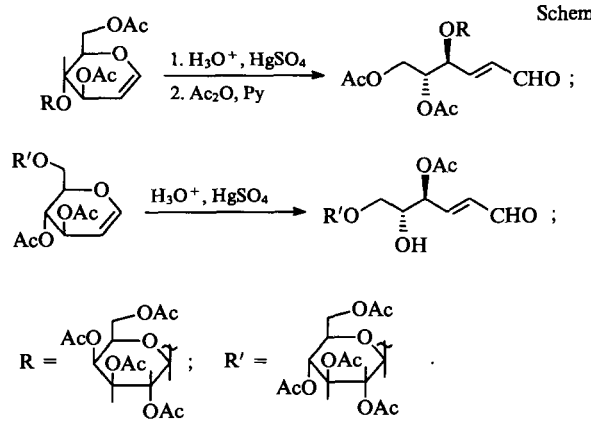
Glycals are oxidised similarly by the complex $Py \cdot HCrO_3Cl$. It has been pointed out[79, 80] that the yields of the lactones are higher than in oxidation with peracids (Scheme 33).



Scheme 33

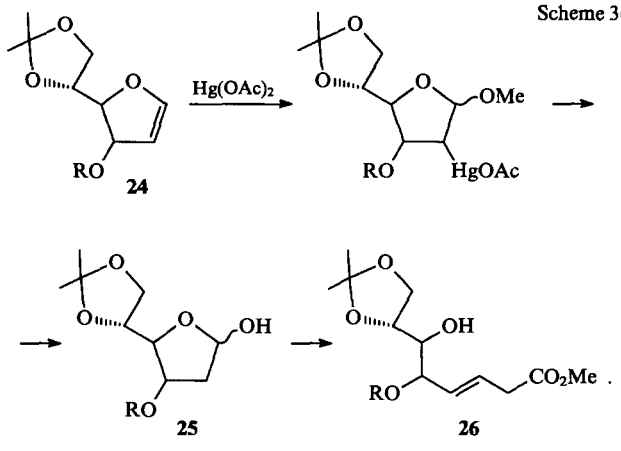
The decyclisation reaction of glycals has been recently used with increasing frequency in enantiospecific synthesis. Several methods of synthesis of open chain synthons from glycals are known. One of these has been developed by Perlin and coworkers.[81, 82] On treatment with Hg^{2+} salts in an acid

medium, glycal acetates are converted into partial acetates of α,β-unsaturated hydroxyaldehydes. According to Tolstikov et al.[83] and Hirata et al.,[84] the ring is opened similarly to benzyl ethers of glycals based on pentoses and hexoses (Scheme 34).



Scheme 34

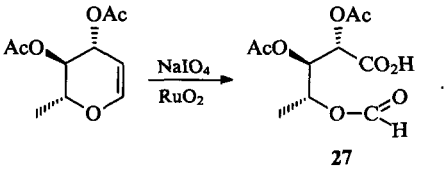
R = Ac, Bn .



The acid $HgSO_4$-catalysed decyclisation of the full acetates of glycals derived from disaccharides leads to *O*-glycosylated α,β-unsaturated acetoxyaldehydes (Scheme 35).[85–88]

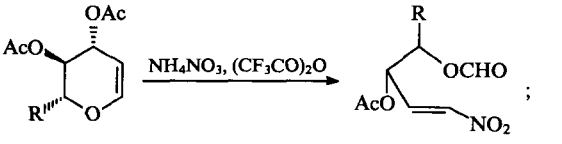
Scheme 35

A convenient method of decyclisation is based on the conversion of glycals into 2-deoxysugars with their subsequent conversion into olefins. Thus the 2-deoxysugar **25** was obtained from the furanoglycal **24** via a methoxymercuration stage, after which the unsaturated ester **26** was prepared (Scheme 36).[89]



Scheme 36

This approach will probably be used in a specific synthesis, because the method proposed recently for the direct hydration of glycals[90] obviates the need for mercury salts.



Oxidative degradation involving the double bond of glycals makes it possible to obtain nor-derivatives. For example, the RuO_2-catalysed oxidation of di-*O*-acetyl-D-rhamnal with $NaIO_4$ led to a 5-deoxyarabinonic acid ester **27** (Scheme 37).[91]

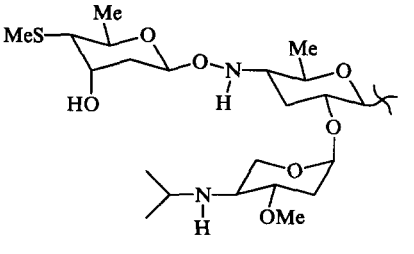
Scheme 37

An interesting oxidation reaction takes place when glycals are treated with ammonium nitrate in trifluoroacetic anhydride (Scheme 38).[92]

Scheme 38

R = CH_2OAc, Me .

As can be seen from the data presented, the reactions of glycals are distinguished by high stereoselectivity and in many cases conditions have been found for a stereospecific course of the reaction. Naturally, this characteristic of glycols cannot fail to draw attention to them in the selection of synthons used in the enantiospecific synthesis of natural products.

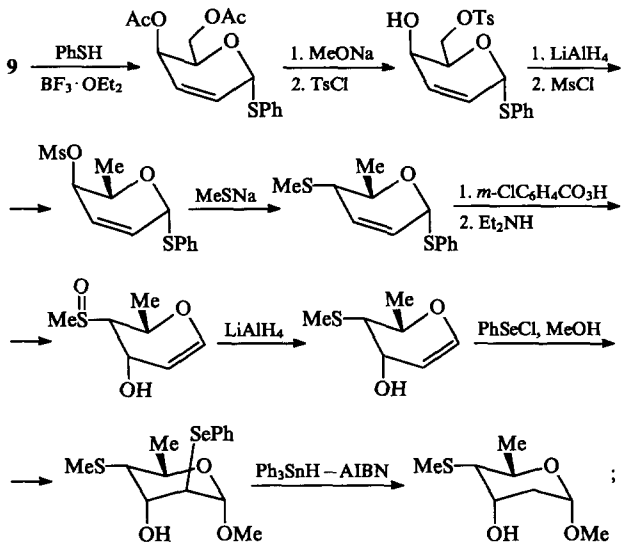


IV. Glycals in the synthesis of natural products with a cyclic structure and their fragments

1. Derivatives of monosaccharides. *O*- and *C*-glycosides

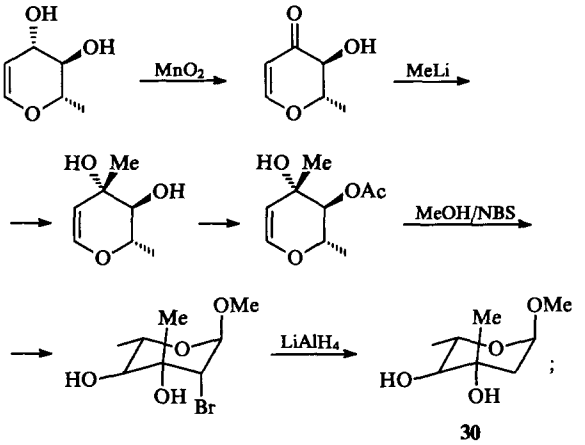
Glycals are being used to an increasing extent in the synthesis of rare mono-, di-, and oligo-saccharides and also *O*-glycosides with aglycones of different structural types. The examples described below convincingly demonstrate the extensive possibilities of the glycal approach.

The recently discovered carcinostatic enediyne antibiotics are distinguished by an abundance of functional groups and an unusual structure of the glycoside fragments. Thus esperamicin contains the trisaccharide fragment **28** incorporating thio- and amino-sugars (Scheme 39).



Scheme 39

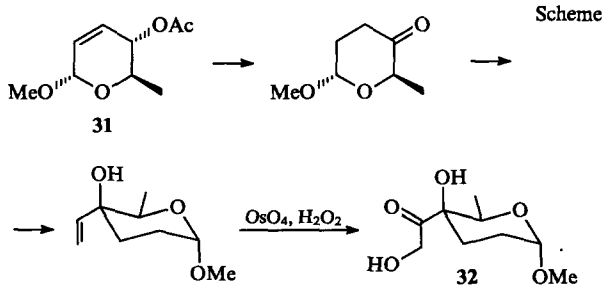
The scheme for the synthesis of the thiosugar **29**, which forms part of the composition of the trisaccharide fragment of the antibiotic, based on the tri-*O*-acetyl-D-galactal **9**, is attractive because of the stereospecificity of all the stages and the twofold use of the reagent by virtue of the presence of a double bond of the glycal type (Scheme 40).[93]



The antibiotics olivomycin and chromomycin contain L-olivomycose **30** as part of the composition of the trisaccharide fragment. Its synthesis from L-rhamnal consists of only a few stages (Scheme 41).[94]

Scheme 40

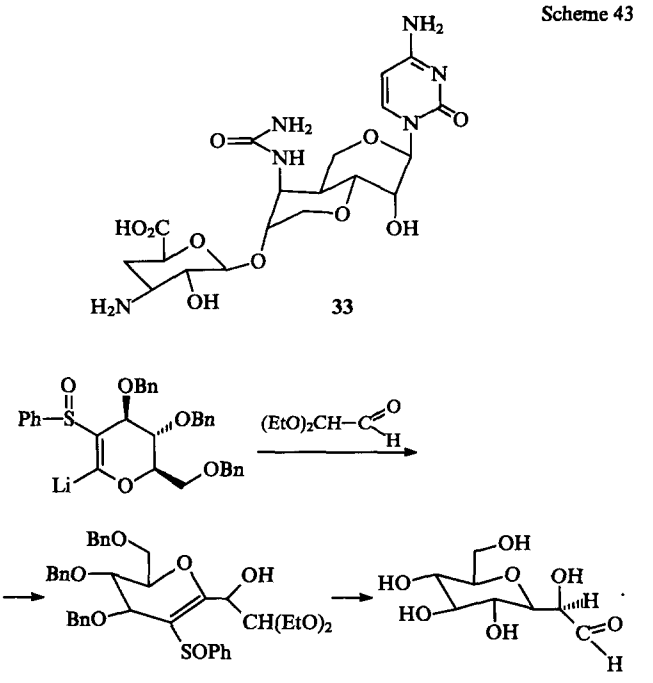
AIBN = azoisobutyronitrile.



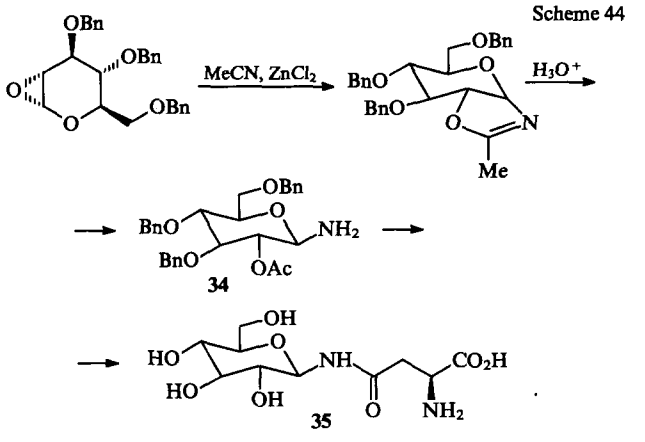
Scheme 41

NBS = *N*-bromosuccinimide.

Pillaromycin A—an antibiotic with anticancer activity—contains a deoxysugar—pillarose **32**, which has been synthesised from the Ferrier glycoside **31** (Scheme 42).[95]



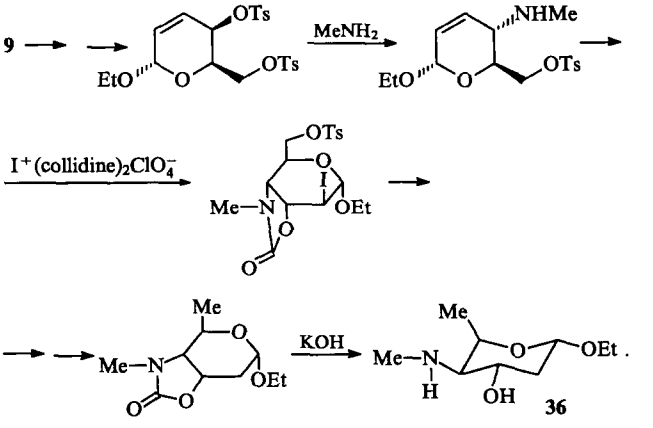
Scheme 42



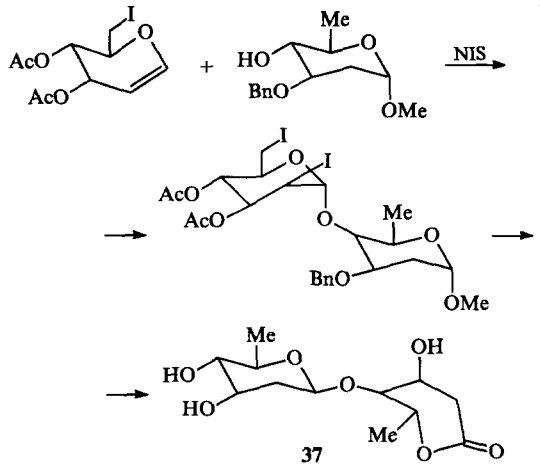
A derivative of vinyllithium, obtained by the direct introduction of lithium into tri-*O*-benzyl-2-benzenesulfoxygalactal, was used in the synthesis of the antibiotic ezomycin **33** from tri-*O*-benzyl-D-glycal. The reaction with the diethyl acetal of glyoxal took place smoothly with subsequent formation of the D-glucose *C*-glycoside as the key synthon (Scheme 43).[96]

Glucosylasparagine **35** was synthesised with the use of the epoxide of tri-*O*-benzyl-D-glucal (Scheme 44).[97] The formation of the indi-vidual β-glucosylamine **34** is striking.

Scheme 43

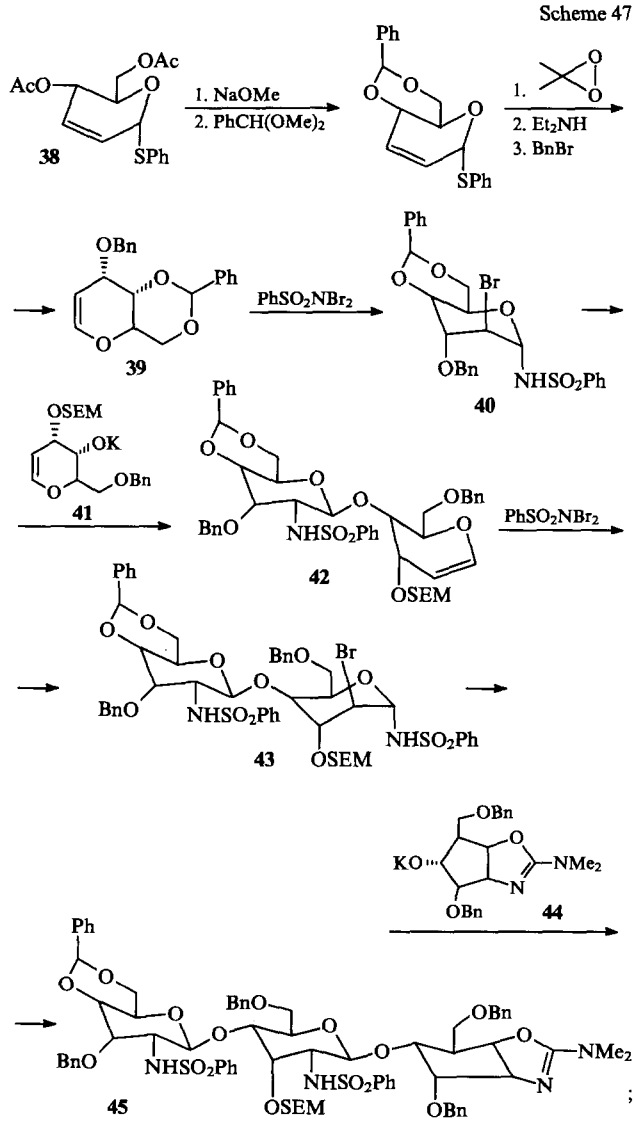


Scheme 44



The aminosugar holacosamine **36**, which forms part of the composition of the steroid glycosides holacurtine and holarosine, has been synthesised from tri-*O*-acetyl-D-galactal **9** (Scheme 45).[98]

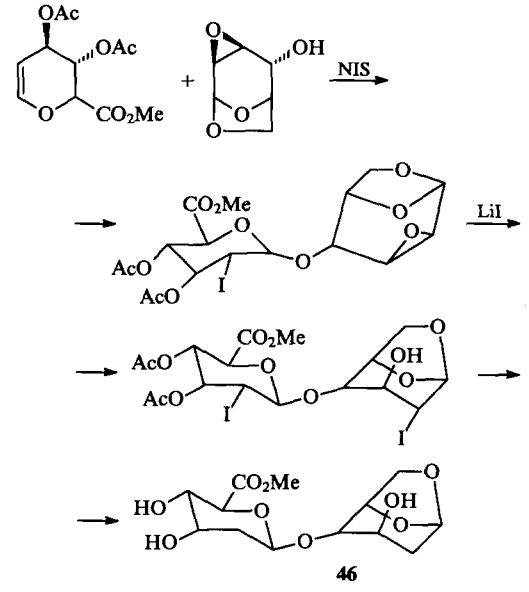
Scheme 45



The formation of the glycosidic linkage with the aid of *N*-iodosuccinimide (NIS) has been used successfully in the synthesis of bamflalactone **37** (Scheme 46).[99]

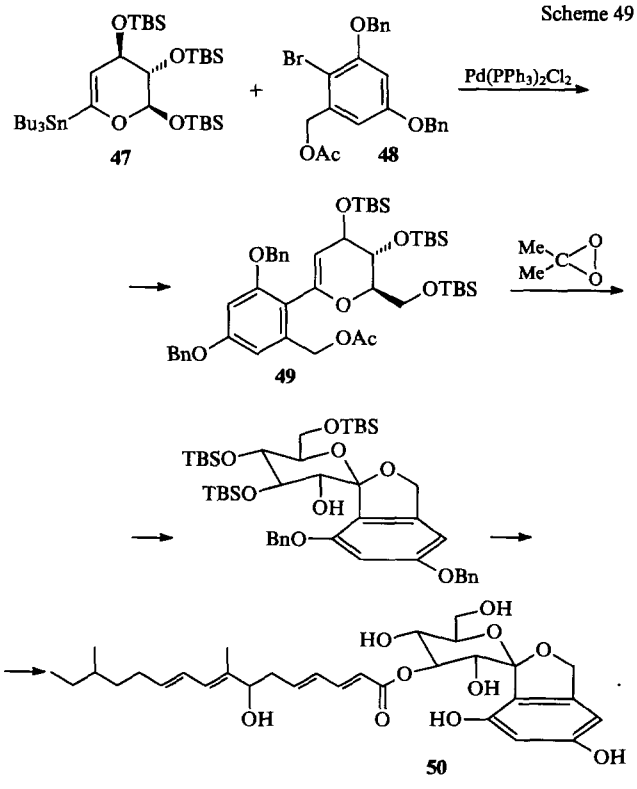
Scheme 46

The glycoside allosamidin (compound **45** is its derivative), isolated the from *Streptomyces* mycelium, is a selective inhibitor of chitinase. Its synthesis represents a very characteristic example of the application of the varied reactivity of glycals. The phenylthioglycoside **38** was converted into the key synthon **39** via a stage involving oxidation to the sulfoxide and the subsequent sulfoxide rearrangement. The reaction of the synthon with *N*-dibromobenzenesulfonamide affords the bromosulfonamide **40**, which readily condenses with the potassium alkoxide derived from the glycal **41**.



Scheme 47

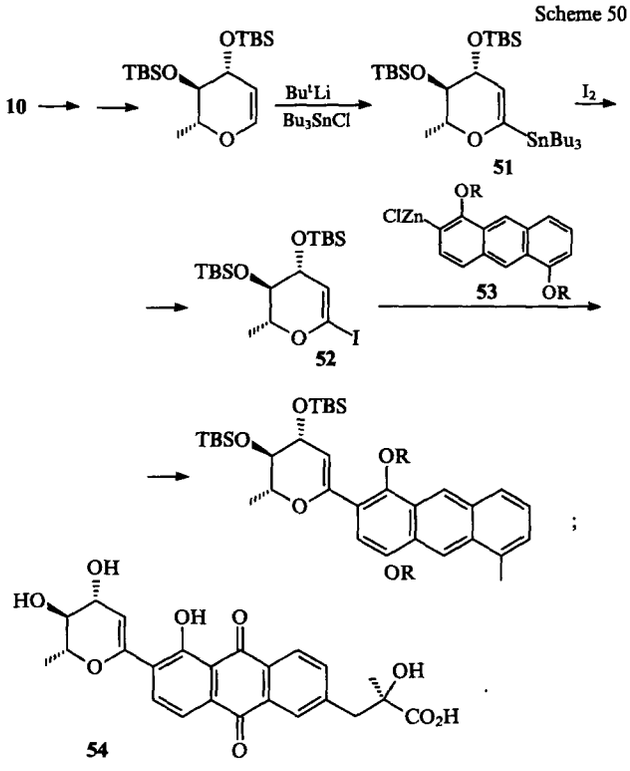
The repeated reaction of compound **42** with the dibromosulfonamide and the condensation of the product **43** with the potassium alkoxide derived from the aglycone **44** made it possible to obtain the target glycoside **45** (Scheme 47).[100]



The disaccharide **46**, which forms part of the structure of the heptasaccharide orthosomycin, has been obtained from the glycal of glucuronic acid (Scheme 48).[101]

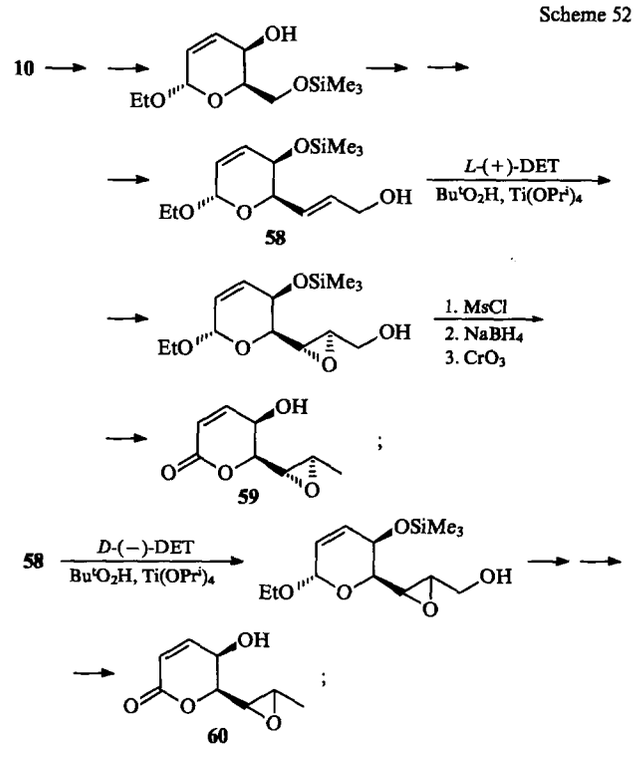
Scheme 48

Papulacandin **50** is one of the promising fungistatic agents. In the synthesis of the glycoside components of its molecule, the cross-coupling of the organotin glucal derivative **47** with the aryl bromide **48** and the oxidation of the *C*-arylglucal **49** by dimethyldioxiran constitute remarkable stages (Scheme 49).[102]



Scheme 49

SEM = β-(trimethylsilyl)ethoxymethyl .

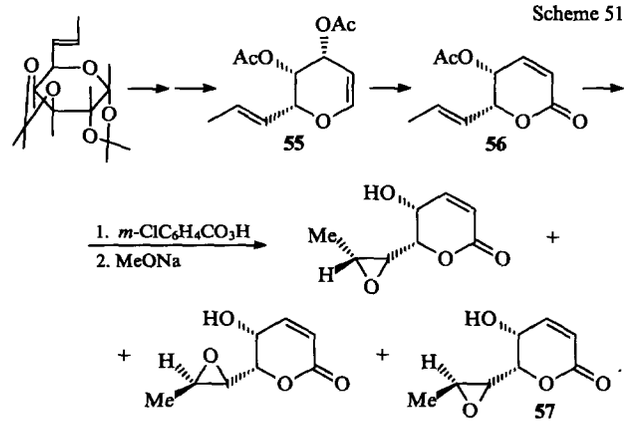


It has been suggested that tri-*O*-acetyl-D-glucal **10** be used for the synthesis of vineomycinone B_2 **54**. Compound **10** was converted in four stages into the organotin derivative **51** and then into the vinyl iodide **52**. The key stage—the coupling of compound **52** with the arylzinc **53**—is catalysed by a palladium complex (Scheme 50).[103]

Scheme 50

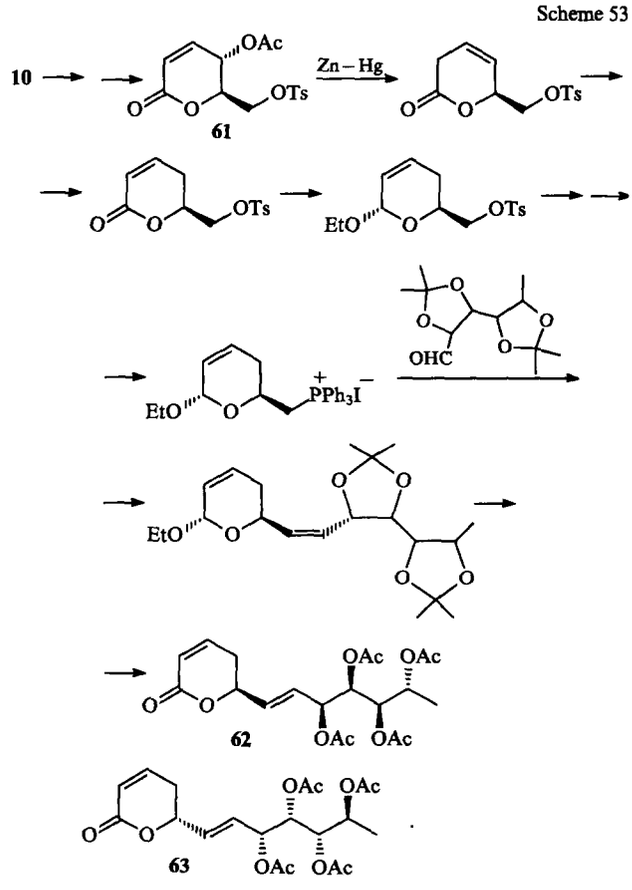
The weak point of this scheme is the stage involving the non-stereospecific epoxidation of the precursor **56**. Valverde et al.[104] were able to synthesise the isomers (6*R*, 7*S*)-**59** and (6*S*, 7*R*)-**60** of asperlin with a high optical purity by the asymmetric epoxidation of the allyl alcohol **58** obtained from tri-*O*-acetyl-D-glucal **10** (Scheme 52).

Scheme 52



DET = diethyl tartrate .

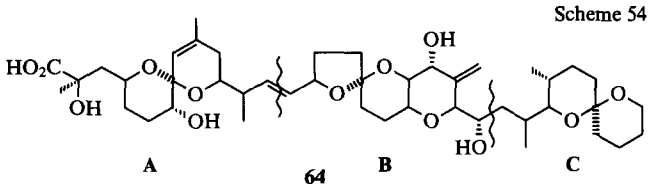
2. Synthesis of natural products containing a hydropyran fragment



Compounds containing a hydropyran fragment are fairly common in nature. The total synthesis of many of them constitutes a fairly complex problem and is itself of interest as a stage in the development of the enantiospecific synthesis of compounds with a large number of chiral centres. The use of glycals makes it possible to obtain synthons containing up to five chiral centres with a specific configuration. It is noteworthy that compounds combining a high biological activity with a relative simplicity of structure, which renders their synthesis of practical interest, have been found with increasing frequency among natural hydropyrans.

Thus a series of studies have been devoted to the synthesis of the dihydropyran antibiotic asperlin, which exhibits carcinostatic activity. The D-enantiomer of asperlin **57** has been obtained from the modified galactal **55** (Scheme 51).[7]

Scheme 51

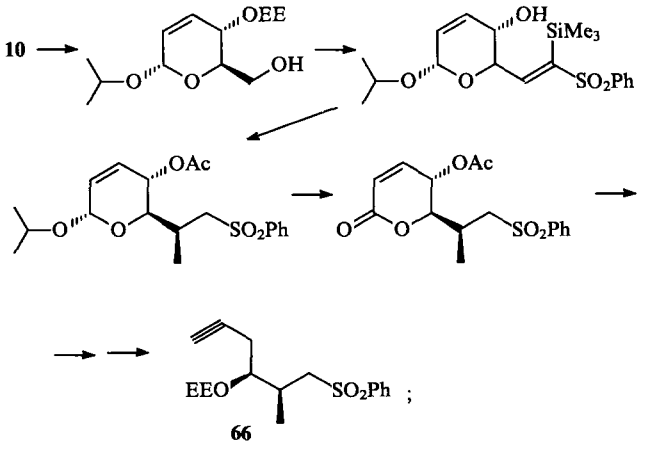


Scheme 53

Anamarin **63**, isolated from a plant of the genus *Hyptis*, has the (*R*)-configuration in the pyranoid ring and an unusual α-gluco-structure of the C(6)-side chain. The enantiomeric (−)-anamarin **62** was synthesised from the unsaturated lactone **61** obtained from tri-*O*-acetyl-D-glucal **10** (Scheme 53).[105]

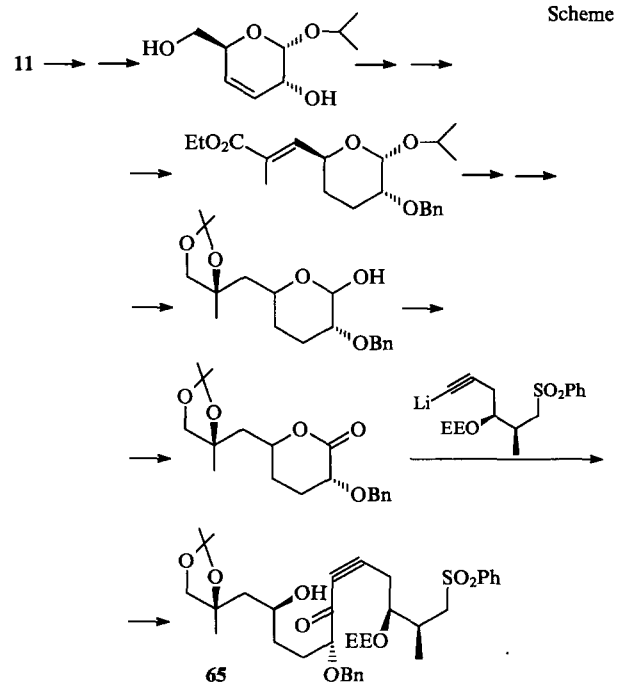
Okadaic acid **64**, isolated from the sea sponge *Halichondria okadai*, is one of the specially complex compounds whose total synthesis has been undertaken (Scheme 54).

Scheme 54



64

Isobe and coworkers described the synthesis of the **A**, **B**, and **C** fragments of the toxin molecule in a series of brilliant studies.[106–109]

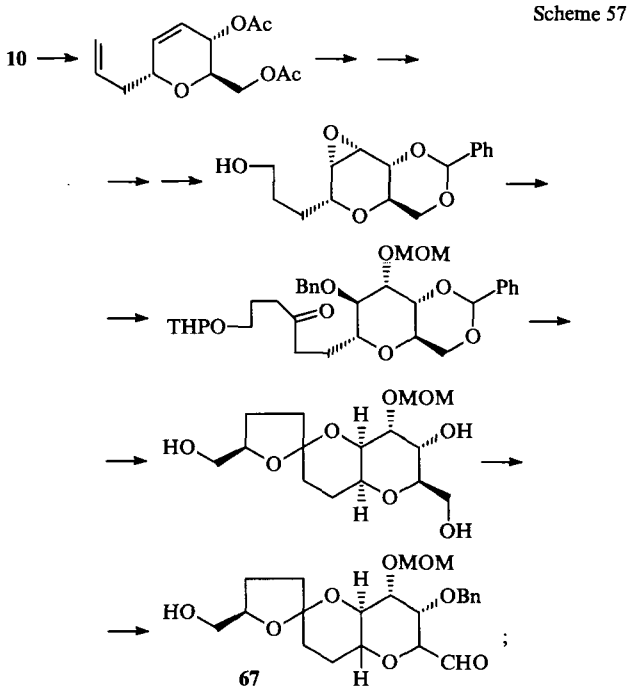


The synthesis of the fragment **A** (compound **65**) involves the preparation of two synthons based on tri-*O*-acetyl-D-glucal **10**

Scheme 55

EE = $EtOC_2H_4$.

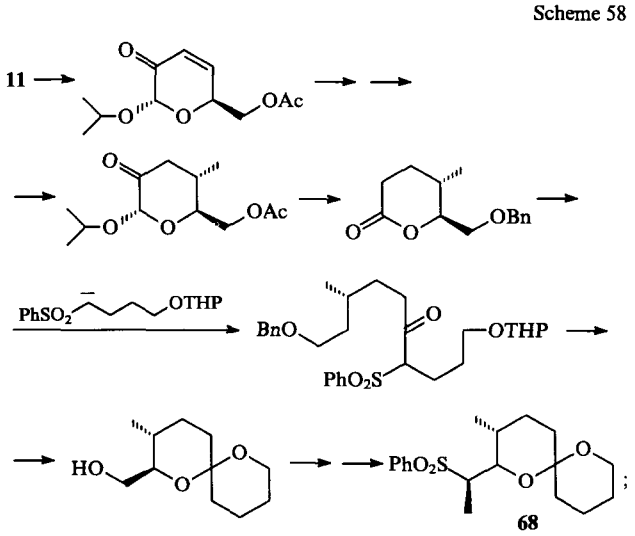
Scheme 56



and tetra-*O*-acetyl-2-hydroxy-D-glucal **11**. As can be seen from Scheme 55, the configuration of the carbon atom to which a methyl group is attached in the molecule of the target acetylenic sulfone **66** is specified in conformity with the directing effect of the oxygen-containing functional groups in the 1,4-addition of lithium dimethylcuprate to the silicon-containing unsaturated sulfone.

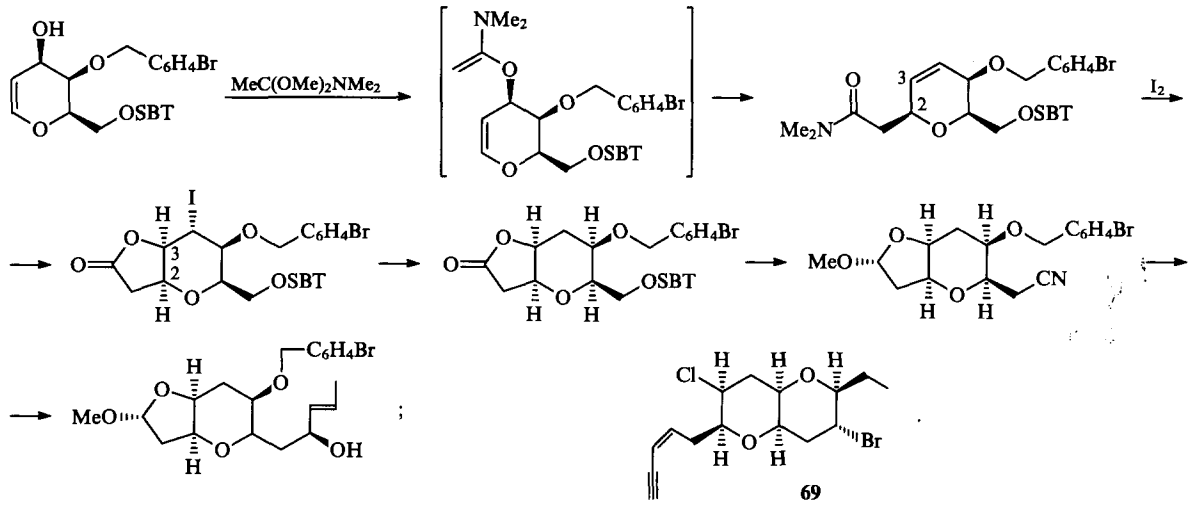
The key stage in the synthesis of the fragment **A** is the reaction of the lithium derivative of the acetylenic sulfone with the lactone obtained from tetra-*O*-acetyl-2-hydroxy-D-glucal **11** (Scheme 56).[106]

The construction of the segment **B** (compound **67**) begins with the reaction of tri-*O*-acetyl-D-glucal **10** with allyltrimethylsilane. The key stages of this synthesis are presented in Scheme 57.[107]



Scheme 57

MOM = $MeOCH_2^-$.

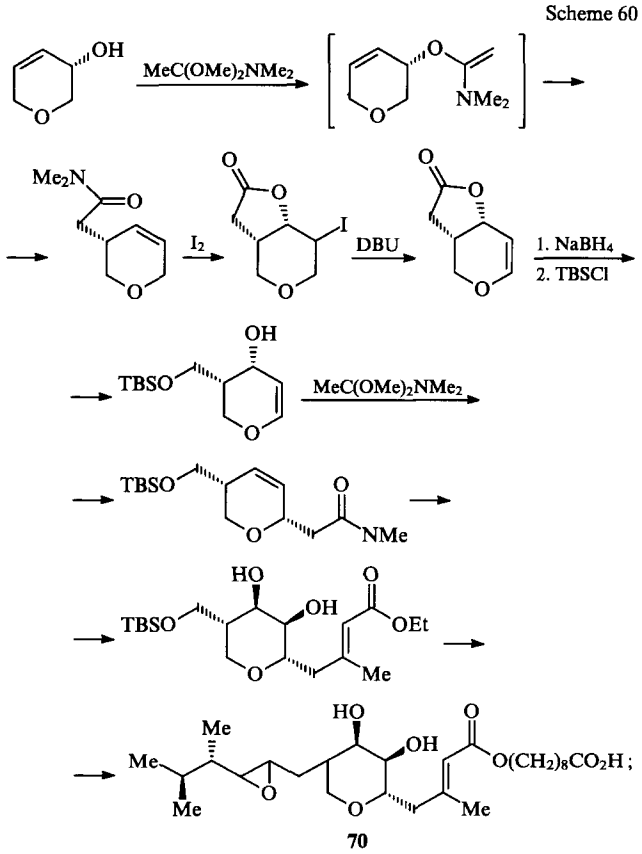


The synthesis of the comparatively simple segment **C** (compound **68**) is also based on the reactions of the 2-acetoxy-glucal **11** (Scheme 58).[108, 109]

Scheme 58

THP = tetrahydropyran-2-yl.

Scheme 59

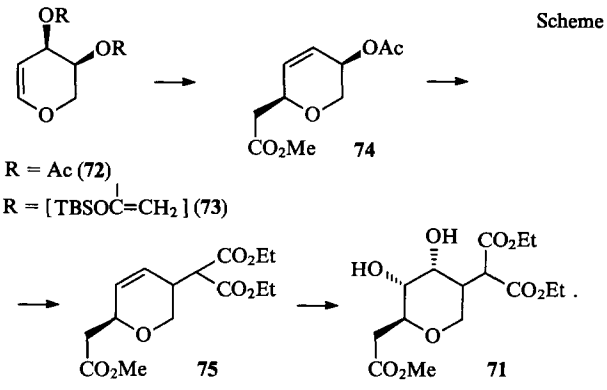


69

(3*E*)- and (3*Z*)-Dactomelynes **69**, pyranopyran derivatives isolated from the sea hare *Aplysia daktylomela*, exhibit a valuable biological activity. The chiral centres at C(2) and C(3) are formed by the enantiospecific stages of the Claisen rearrangement involving the dimethyl acetal of *N*,*N*-dimethylacetamide and conversion into an iodolactone. These steps have been incorporated into the synthesis of dactomelynes (Scheme 59).[110]

The Claisen rearrangement of natural glycals is used twice in the scheme for the synthesis of pseudomonic acid **70** (Scheme 60).[111]

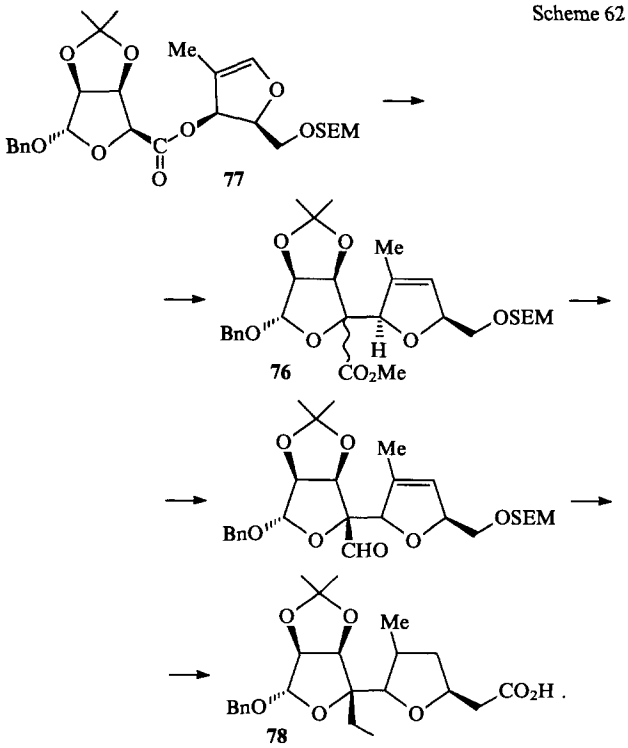
Scheme 60



70

DBU = 1,5-diazabicyclo[5.4.0]undec-5-ene.

A short pathway to the key chiral intermediate **71**, essential for the synthesis of pseudomonic acid, has been proposed.[112] Di-*O*-acetyl-L-arabinal **72** was proposed as the initial chiral compound. It was converted via the rearrangement of the bisketene silyl acetal **73** into compound **74** and further into the ester **75** (Scheme 61).

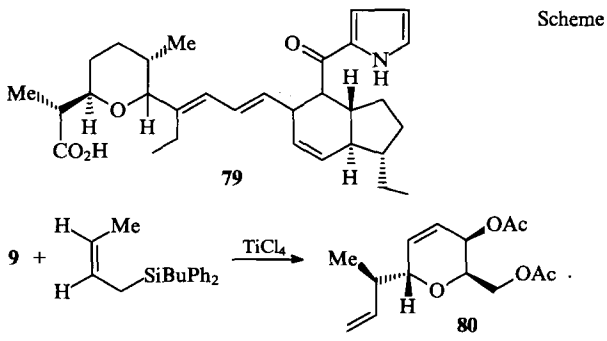


Scheme 61

R = Ac (**72**)

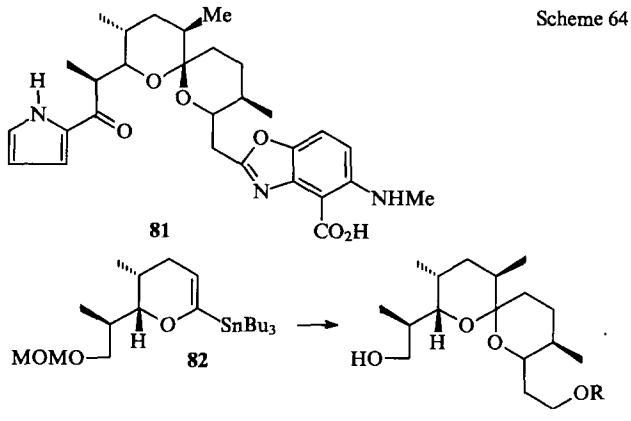
R = [TBSOC(=CH$_2$)] (**73**)

Scheme 62



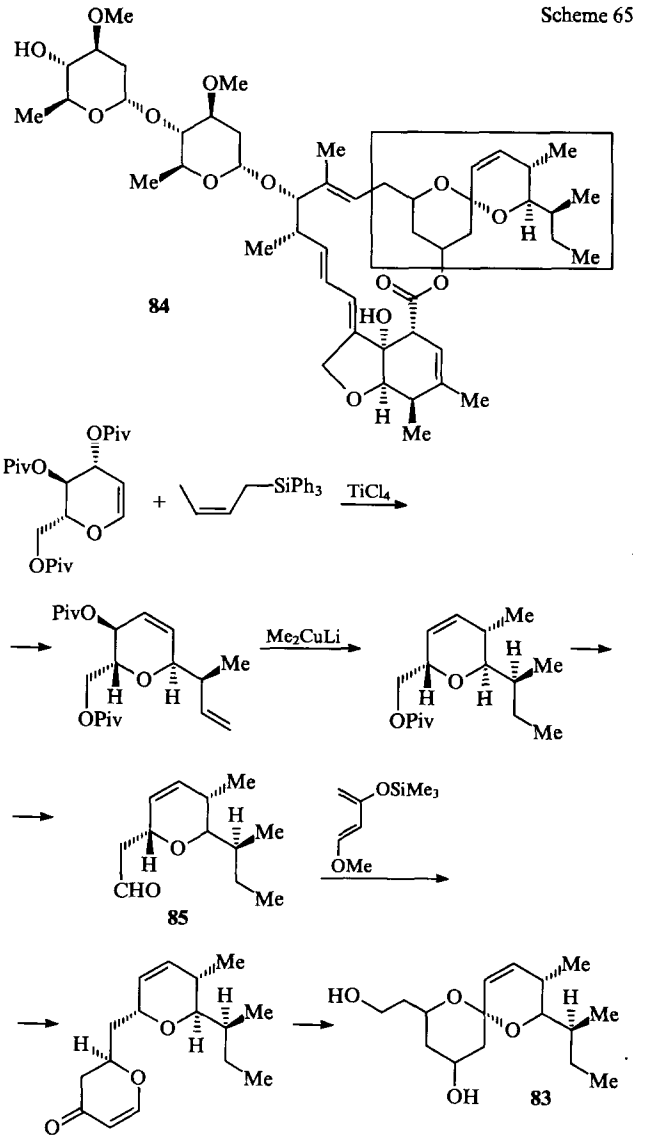
The use of the Claisen rearrangement in the synthesis of antibiotics of the hydropyran type, namely lasalocid, tirandamycin,[7] and monensin,[113] has been described. A strikingly high yield of compound **76** in the rearrangement of the ester **77**, constructed from two furanoid fragments, was noted in the synthesis of the last

compound.[114] One of the key units (compound **78**) necessary for the construction of the monensin molecule was obtained as a result of this reaction (Scheme 62).

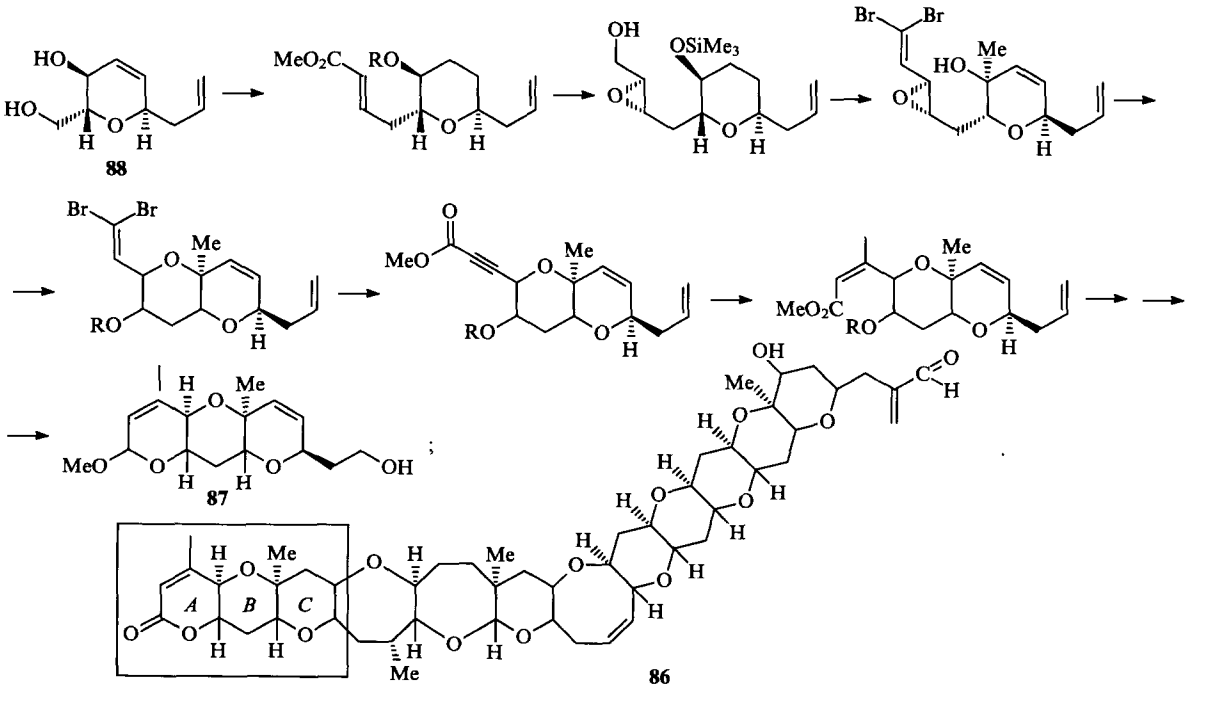


As mentioned above, the stereoselective reaction of glycal acetates with allylsilanes is one of the effective methods of synthesis of chiral building blocks.[41] In the synthesis of the antibiotic indanomycin **79**, the necessary dihydropyran synthon unit **80** was obtained by the reaction of tri-*O*-acetyl-D-galactal **9** with (*Z*)-crotylsilane (Scheme 63).[115]

Scheme 63



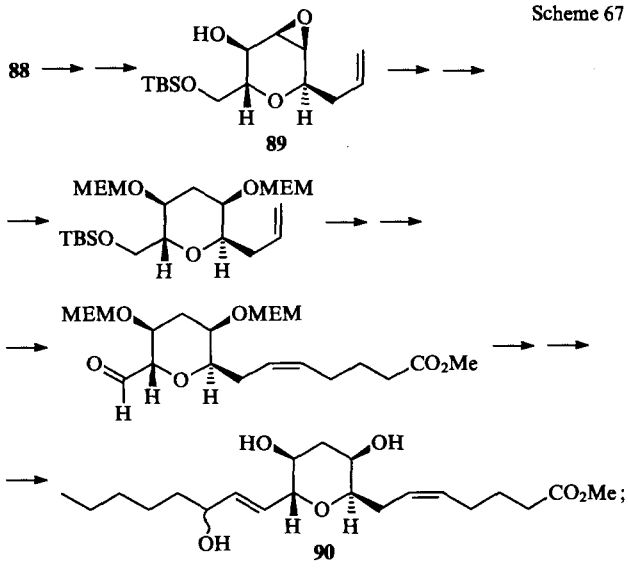
An organotin glycal derivative **82** has been used to synthesise the ionophor calcimycin **81** (Scheme 64).[24]



Scheme 64

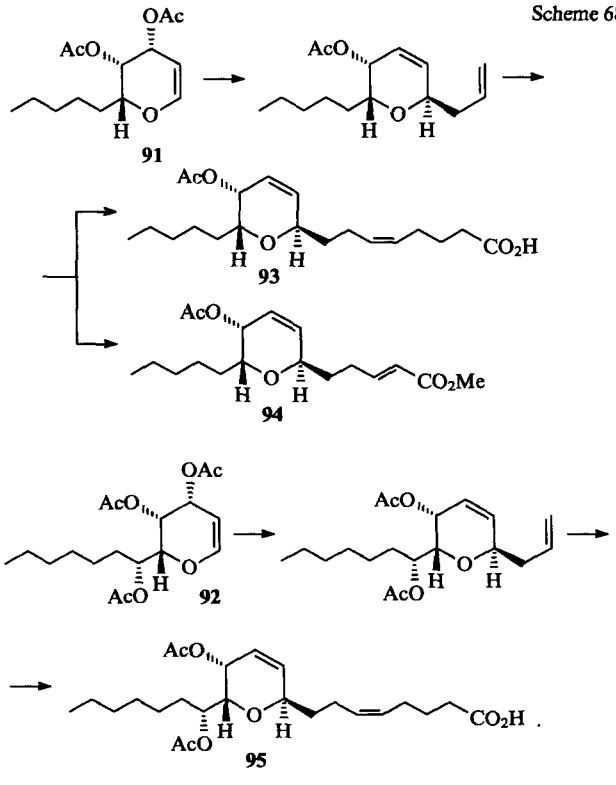
Scheme 65

Scheme 66



The strategy used in the synthesis of the spiroketal unit **83** of the insecticide avermectin **84** includes the reaction of tri-*O*-pivaloyl-D-glucal with (*Z*)-crotyltriphenylsilane and the [4+2]-addition of the so called Danishevskii's diene to the aldehyde **85** (Scheme 65).[116-118]

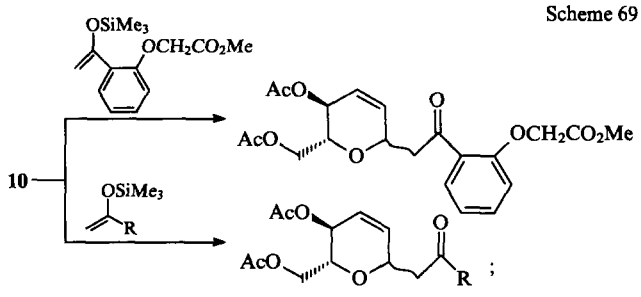
The total synthesis of one of the most powerful of the natural toxins — brevetoxin **86** — is extremely complex. The **ABC** fragment **87** of its structure was synthesised from (2*R*, 3*S*, 6*R*)-6-allyl-3,6-dihydro-3-hydroxy-2-hydroxymethyl-2*H*-pyran **88** — the product of the coupling of tri-*O*-acetyl-D-glucal **10** with allyltrimethylsilane (Scheme 66).[119, 120]



The substituted dihydroxy-2*H*-pyran **88** and its epoxide **89** have also been used as the starting compounds in the synthesis of (8*R*, 9*R*, 11*S*, 12*R*, 15*R*, *S*, 5*Z*, 13*E*)-9,11,15-trihydroxy-8,12-oxy-5,13-eicosadienoic acid **90** — a stereoisomer of the natural metabolite of arachidonic acid (Scheme 67).[121]

Scheme 67

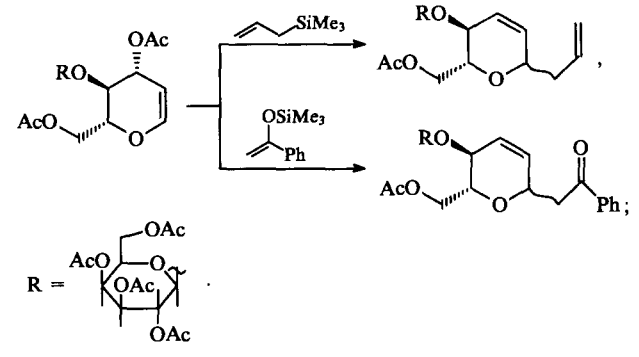
MEM = $MeOC_2H_4OCH_2$.



Scheme 68

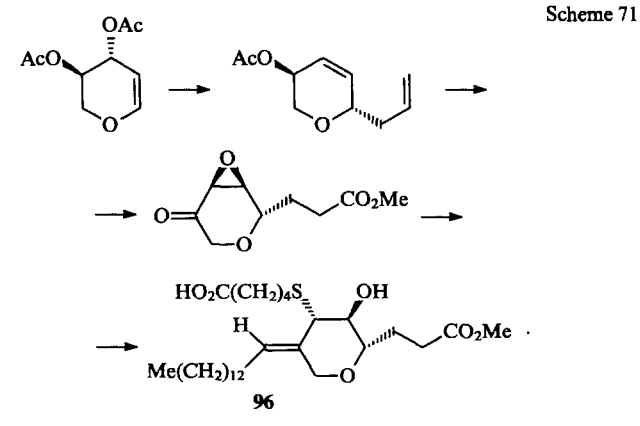
The stereospecific reaction of the modified glycals **91** and **92** with allyltrimethylsilane served as the key reaction for the synthesis of unsaturated carboxylic hydroxyacids **93**–**95** — structural analogues of arachidonic acid (Scheme 68).[122, 123]

New chiral building blocks, which are promising for the synthesis of the oxo-analogues of the cyclic metabolites of arachidonic acid, have been obtained by coupling silyl ethers of enols with tri-*O*-acetyl-D-glucal **10** (Scheme 69).[124]



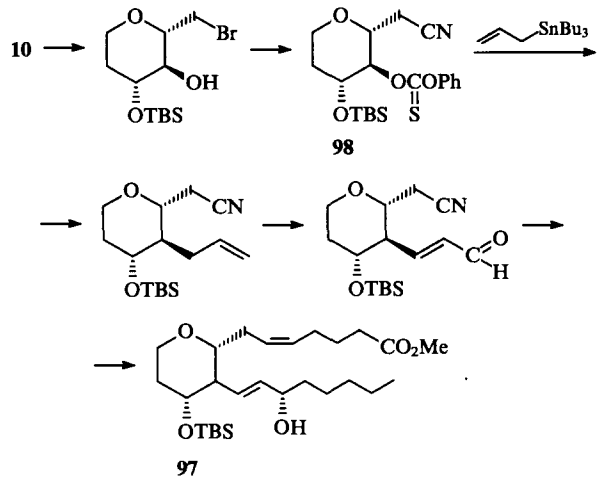
Scheme 69

R = $(CH_2)_nCO_2Me$.



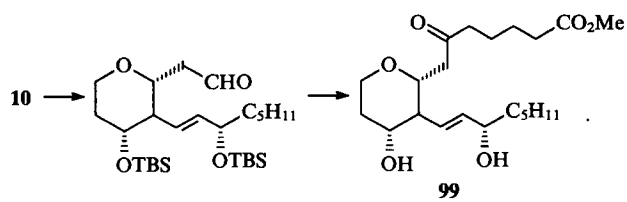
Hexa-*O*-acetyl-D-lactal reacts smoothly on treatment with $BF_3 \cdot OEt_2$ both with allylsilanes and with siloxyethers, affording units suitable for the synthesis of glycosylated derivatives of hydropyran (Scheme 70).[125]

Scheme 70



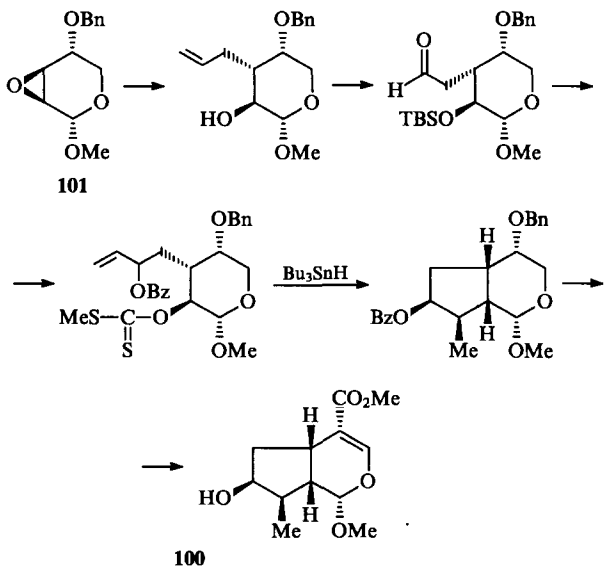
Compound **96**, the synthesis of which from xylal is fairly simple, is able to inhibit the biosynthesis of leucotriene D_4 (Scheme 71).[126]

Scheme 71



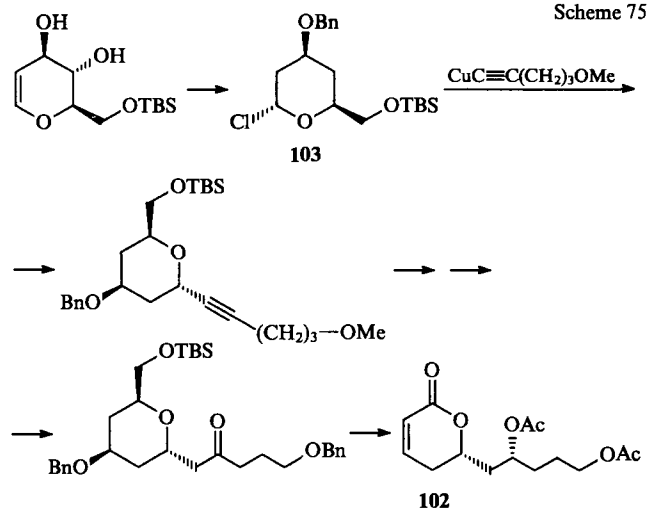
The key stage in the synthesis of the tetrahydropyran analogue of prostaglandin $F_{2\alpha}$ **97** from tri-*O*-acetyl-D-glucal **10** is the free-radical allylation of the intermediate phenyl thiocarbonate **98** by treatment with allyltributyltin (Scheme 72).[127]

Scheme 72



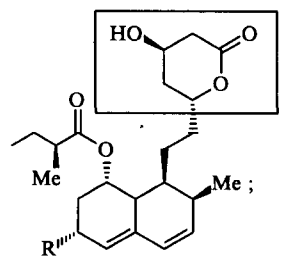
An analogous reaction of tri-*O*-acetyl-D-glucal **10** has been used to synthesise the 6-oxoprostanoid **99** (Scheme 73).[128]

Scheme 73



Various approaches have been used in applying the schemes for the synthesis of hydropyran fragments in a series of natural products. Thus in the scheme for the synthesis of α-*O*-methylloganin **100**, in which the starting material is compound **101**, the free-radical cyclisation stage is noteworthy. It affords a cyclopentane fragment with four chiral centres, each having a rigorously defined configuration (Scheme 74).[129]

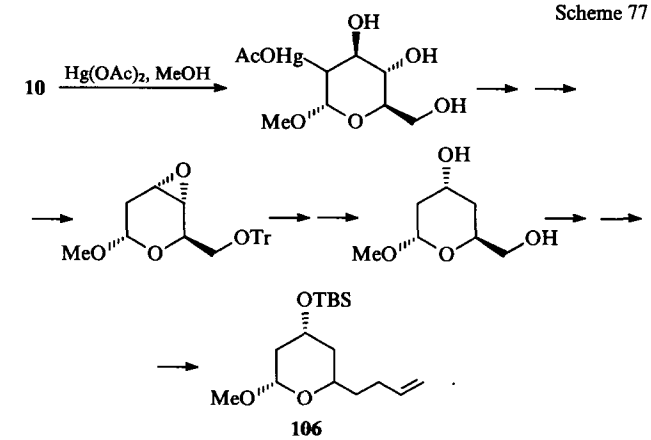
Scheme 74



One of the fragments (compound **102**) of the antibiotic nystatin has been obtained by coupling copper acetylide with the chloro-derivative **103** obtained from the monosilyl ether of D-glucal (Scheme 75).[130]

Scheme 75

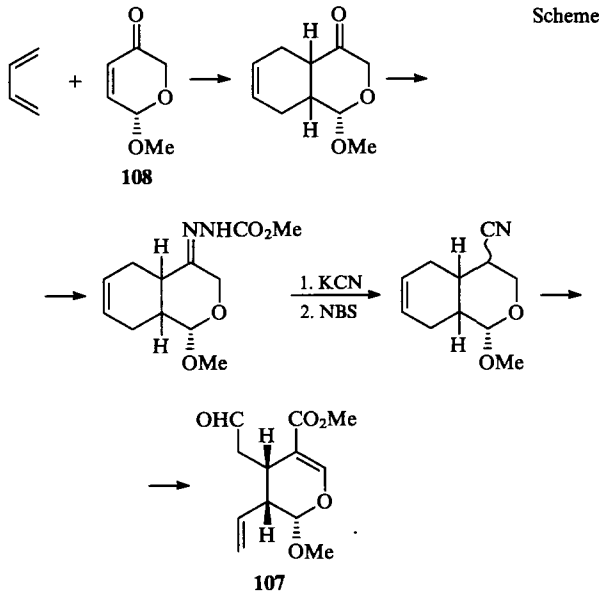
In the last decade, much attention has been devoted to the synthesis of mevinoids — substances which inhibit the biosynthesis of cholesterol. Analogues of commercial value as medicinal drugs reducing the cholesterol content in the blood have been described. An important element of the structure of compactin **104** and mevinolin **105** as well as their structural analogues is a pyranoid lactone fragment, the synthesis of which has aroused considerable interest (Scheme 76).



Scheme 76

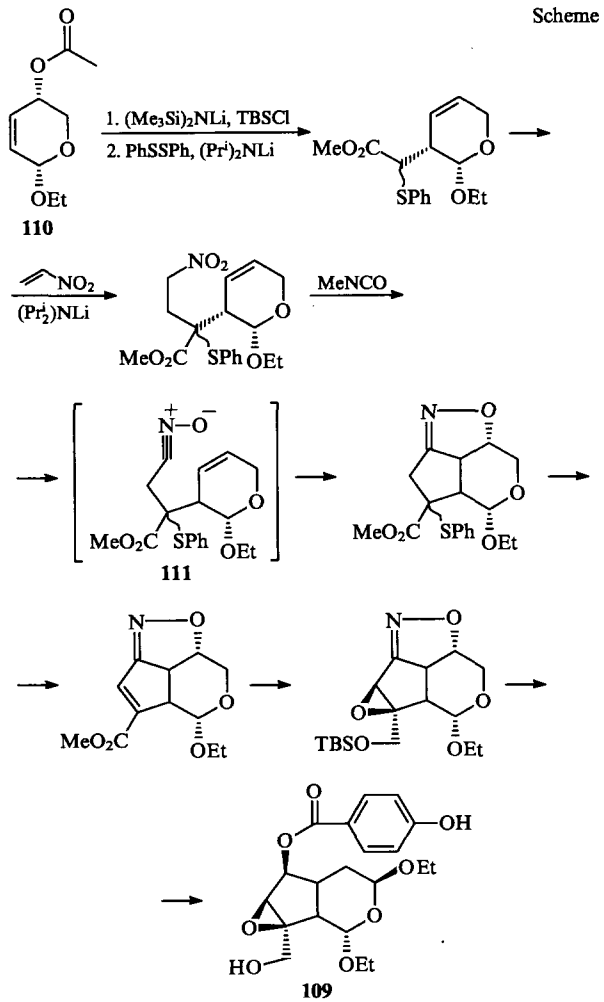
R = H (**104**), R = Me (**105**).

One of the approaches to the synthesis of the lactone fragment **106** of the (+)-compactin molecule presupposes[131] the methoxymercuration of the initial tri-*O*-acetyl-D-glucal **10** with subsequent transformation of the intermediate epoxide in accordance with Scheme 77.



Scheme 77

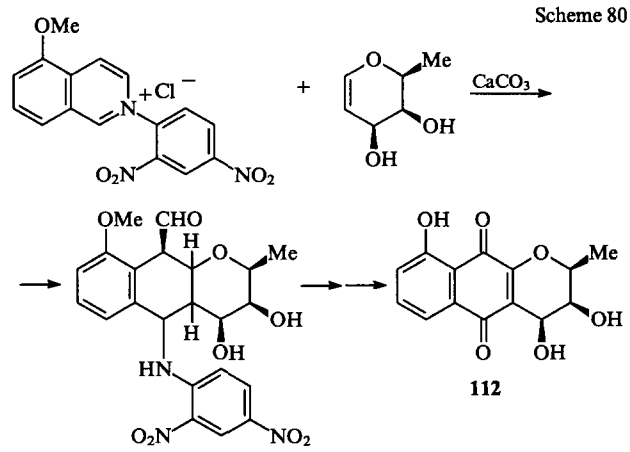
The [4+2]- and [3+2]-cycloaddition reactions with participation of glycals and their derivatives have served as key reactions in the synthesis of a series of polycyclic natural products containing a hydropyran fragment. Thus the aglycone of the



iridoid secologanin **107** has been obtained by the reaction of the methoxyenone **108** with butadiene (Scheme 78).[132]

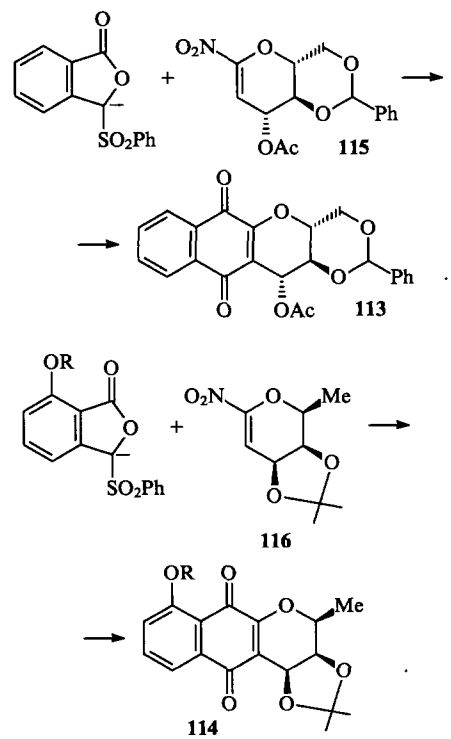
Scheme 78

Bicyclic iridoids are a group of natural products of interest from the practical point of view. Substances with antileukemic and antimicrobial activities have been found among them. The characteristic cyclopentanopyran skeleton of iridoids determines the approaches to the synthesis based on the use of carbohydrates.



Scheme 79

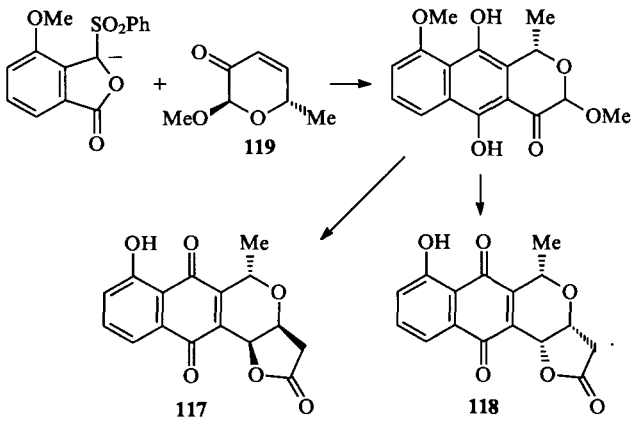
Specionin **109** is regarded as a promising antifeedant. The multistage scheme for its synthesis includes reaction such as the Ireland–Claisen rearrangement of (*E*)-ketene silyl acetal derived from the D-xylal **110** and the dipolar [3 + 2]-addition of the nitrile oxide **111**, which ensures the stereospecific synthesis of the polyfunctional cyclopentane ring (Scheme 79).[133, 134]



The generation of quinodimethanes from isoquinoline salts has led to extensive possibilities for the synthesis of polycyclic structures based on the [4 + 2]-cyclo-addition reaction. In Scheme 80 for the synthesis of the fungal metabolite cryptosporin **112**, which is active against gram-positive bacteria, the above reaction constitutes the key stage.[135]

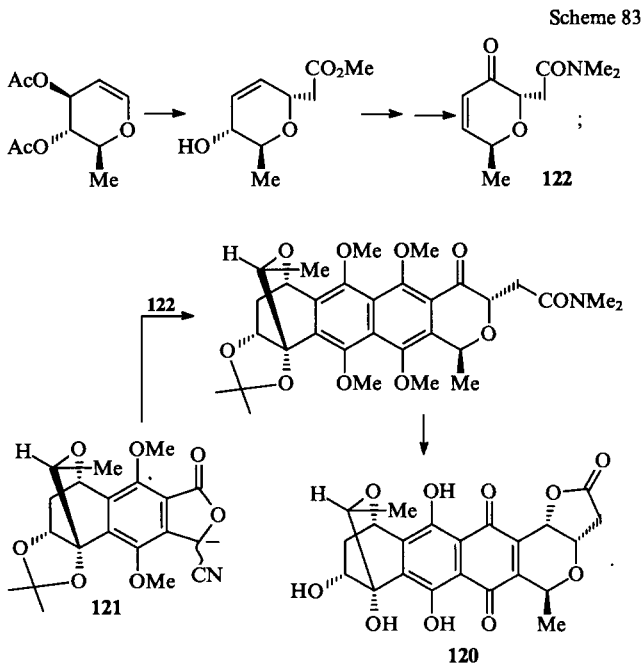
Scheme 80

The reaction of glycals with the anions of arenesulfonyl- or cyano-phthalides, which formally constitutes [4 + 2]-addition, has found an application in the synthesis of natural metabolites of the quinone type. In particular, the derivatives **113** and **114** of the cryptosporin mentioned above have been obtained by reaction with the nitroglycals **115** and **116** (Scheme 81).[136]



Scheme 81

Nanaomycine **117** and its natural stereoisomer kalafungin **118** have attracted attention by their high antimicrobial and anticancer activities. Japanese investigators developed a synthesis based



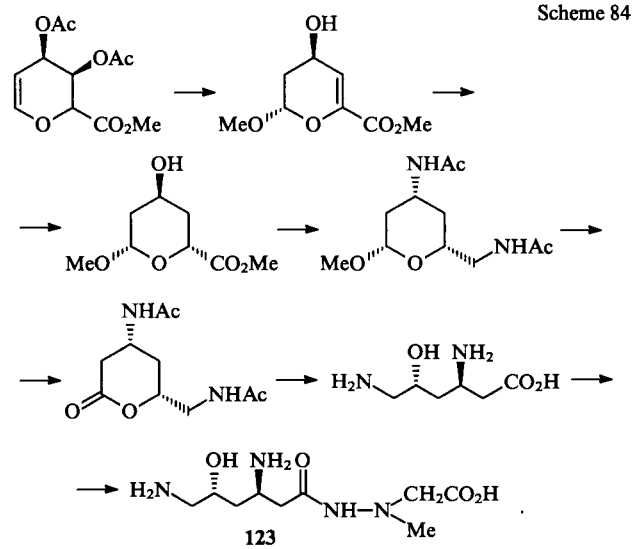
on the reaction of benzenesulfonylmethoxyphthalide with the methoxyenone **119** obtained from L-rhamnal (Scheme 82).[137]

Scheme 82

Scheme 83 for the synthesis of the antibiotic granaticin **120** includes a stage involving the condensation of the cyanophthalide **121** with the ketoamide **122** obtained from di-*O*-acetyl-D-rhamnal.[138]

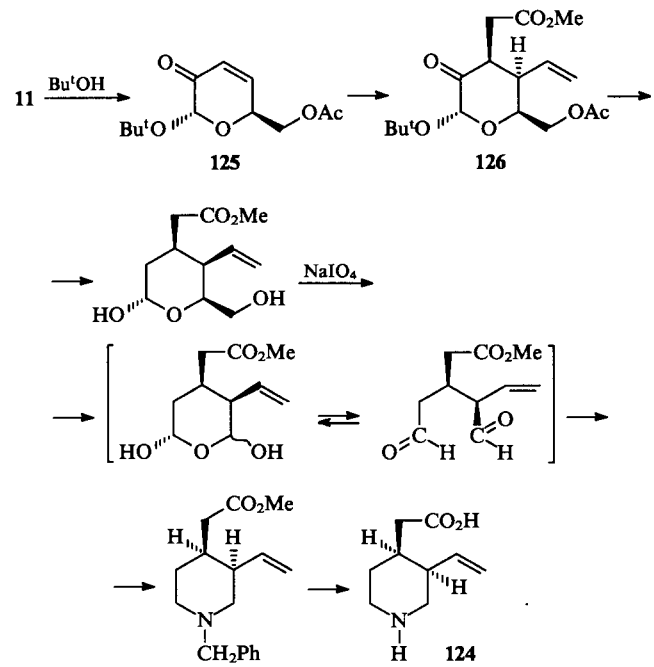
Scheme 83

3. Synthesis of nitrogen-containing compounds



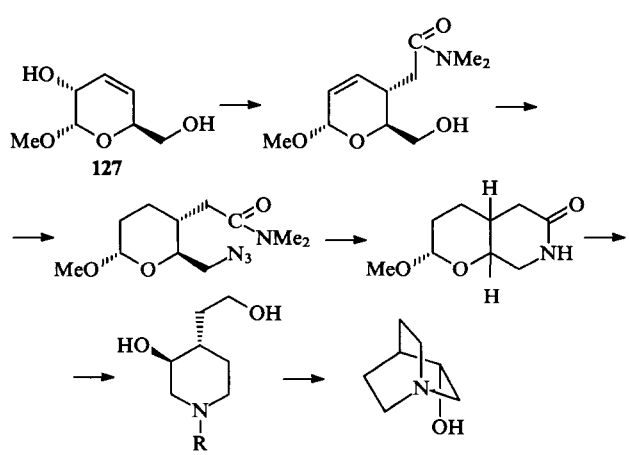
The use of glycals in the synthesis of nitrogen-containing natural products so far covers only a small number of examples. However, the schemes described in the literature are fairly interesting and demonstrate new possibilities in the chemistry of glycals.

The antibiotic negamycin **123** belongs to the class of hydrazine derivatives which are rarely encountered in nature. Its synthesis from the glycal of D-galacturonic acid includes more than ten stages,[139] some of which are presented in Scheme 84.



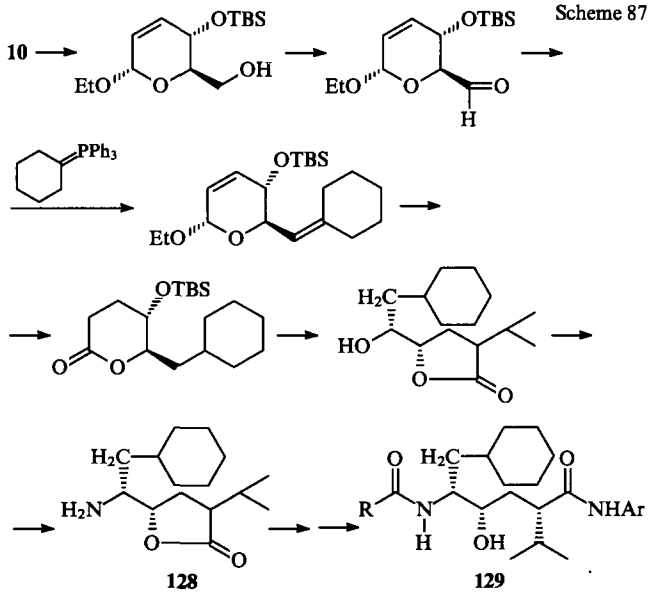
In Scheme 85 for the synthesis of meroquinene **124** from tetra-*O*-acetyl-2-hydroxy-D-glucal **11**, there is a stereospecific stage including the conversion of the enone **125** into the ketoester **126**, which involves the 1,4-addition of the vinylcuprate reagent and the alkylation of the enolate with methyl bromoacetate.[140]

The quinuclidine fragment enters into the structures of a whole series of important alkaloids. One of the approaches to the synthesis of optically active quinuclidines is based on the use of the natural D-glucal **127** (Scheme 86).



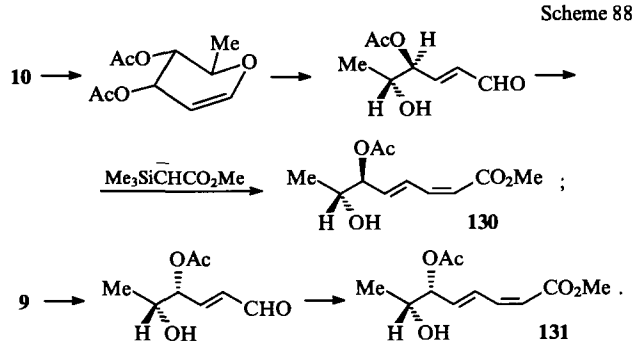
Scheme 84

Scheme 85



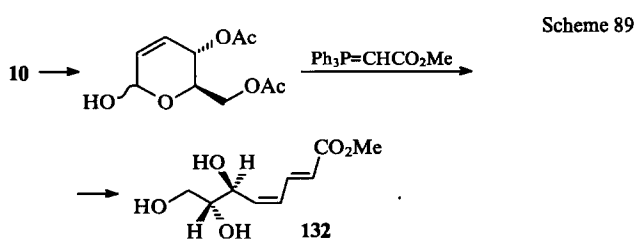
Scheme 86

The inhibitors of renin belonging to the group of low molecular mass peptides are regarded as highly effective antihypertensive agents. The aminolactone **128**, which is a key synthon unit for the construction of peptides of type **129**, was synthesised from tri-*O*-acetyl-D-glucal **10** (Scheme 87).[142]



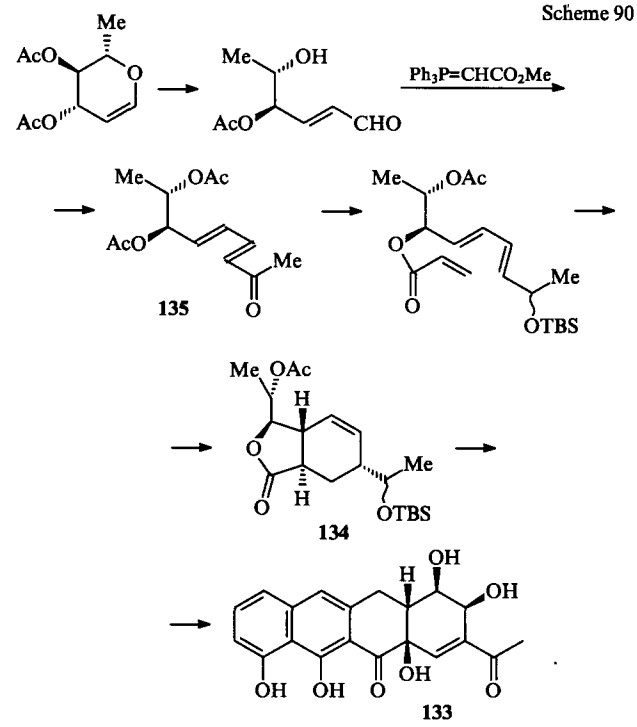
Scheme 87

V. Decyclisation of glycals as a basis for synthesis of natural products and their structural analogues



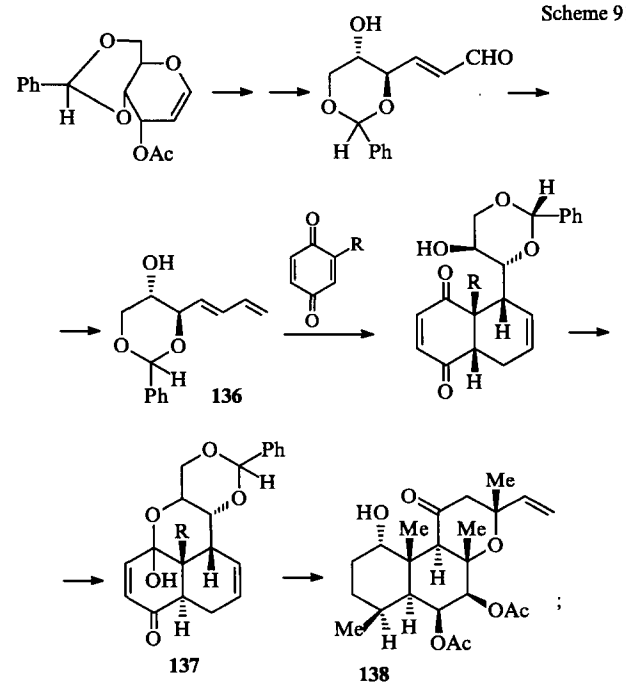
The products of the decyclisation of glycals were not considered for a long time as objects meriting attention in designing schemes for enantiospecific synthesis. The situation began to change after the publication of a study[143] devoted to the synthesis of 6,7-dihydroxyocta-2,4-dienoic acids, which form part of the structures of a series of toxins of the trichothecane series. Thus (6*R*, 7*R*)- and (6*S*, 7*R*)-dihydroxyacids **130** and **131** with the (2*Z*, 4*E*)-configuration of the double bonds have been synthesised from tri-*O*-acetyl-D-glucal **10** and tri-*O*-acetyl-D-galactal **9** (Scheme 88).[143, 144]

Scheme 88



The method of synthesis of the (2*E*, 4*Z*)-isomer **132** is based on the two-stage conversion of tri-*O*-acetyl-D-glucal **10**. Derivatives of compound **132** have been used in the synthesis of trichoverrol B and trichoverrin B (Scheme 89).[144]

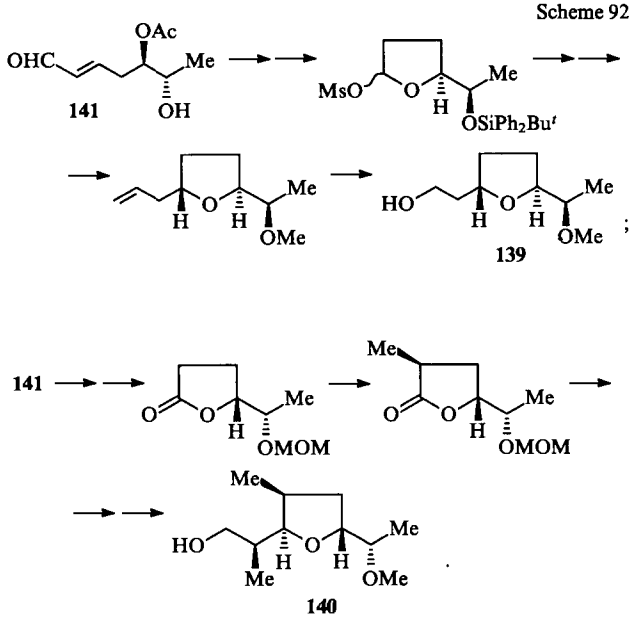
Scheme 89



The synthesis of (+)-pillaromycinone **133** includes a stage involving the intramolecular Diels–Alder reaction, which leads to the key cyclic adduct **134**. The diene component **135** was obtained from di-*O*-acetyl-L-rhamnal (Scheme 90).[145]

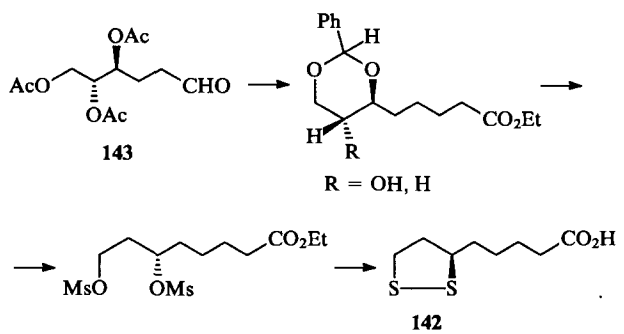
Scheme 90

The reaction of 2-methoxycarbonylquinone with the diene **136**, synthesised from 3-*O*-acetyl-4,6-*O*-benzylidene-D-allal, has been proposed as a convenient method of synthesis of compound **137**—an intermediate for the construction of the molecule of the diterpenoid forskolin **138** with an exceptionally valuable biological activity (Scheme 91).[146]



Scheme 91

R = CO_2Me.

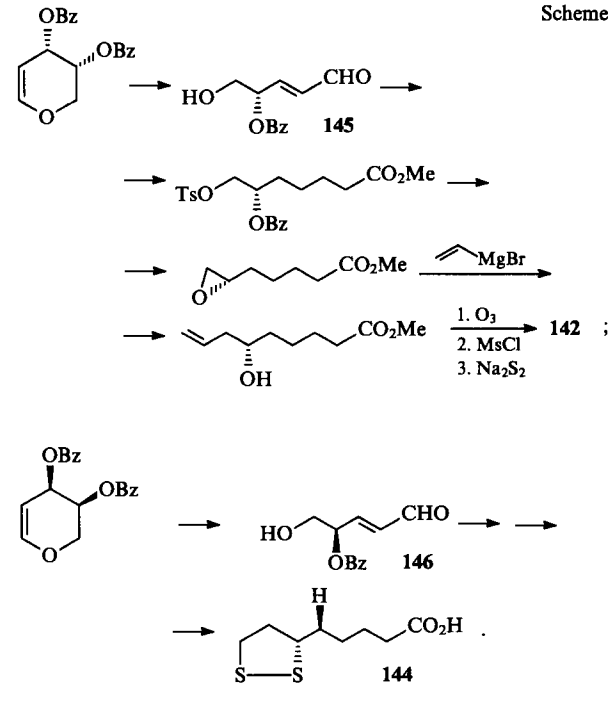


The tetrahydrofuran fragments **139** and **140** of the antibiotics tetronasin and tetronomycin have been synthesised from the heptenal **141**—a product of the decyclisation of di-*O*-acetyl-L-rhamnal (Scheme 92).[147]

Scheme 92

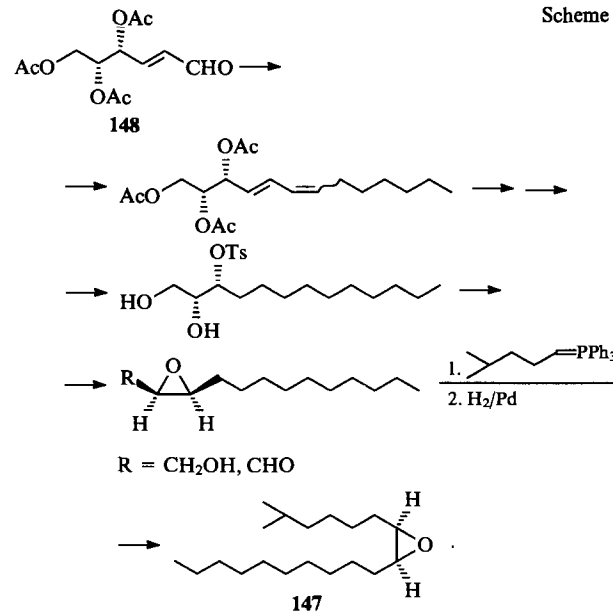
The syntheses of (*R*)-(+)-α-lipoic acid and its (*S*)-(−)-enantiomer from the products of the opening of the dihydropyran ring in glycals based on hexoses and pentoses have been described. The scheme for the synthesis of (*R*)-(+)-α-lipoic acid **142**, in which the triacetoxyhexenal **143**, obtained from tri-*O*-acetyl-D-glucal, was used, has been realised in practice (Scheme 93).[148]

Scheme 93



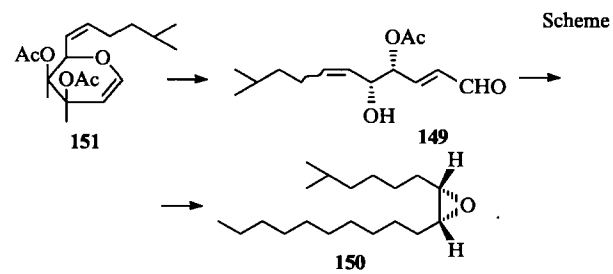
According to Tolstikov et al.,[149] (R)-(+)-α-lipoic acid and its (*S*)-(−)-enantiomer **144** can be obtained from the pentenals **145** and **146** synthesised from di-*O*-benzoyl-D-arabinal and di-*O*-benzoyl-L-arabinal (Scheme 94).

The products of the acid decyclisation of glycal esters proved to be convenient starting materials for the synthesis of open-chain insect pheromones. Thus the gypsy moth pheromone (+)-*cis*-disparlure **147** was synthesised from (4*R*, 5*R*)-4,5,6-triacetoxy-(2*E*)-hexenal **148**—a derivative of tri-*O*-acetyl-D-galactal (Scheme 95).[150, 151]



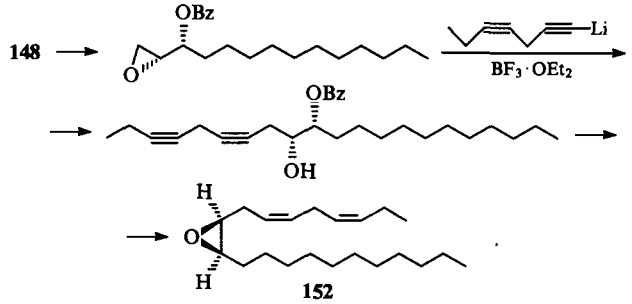
The key synthon **149** for (−)-*cis*-disparlure **150** has been obtained by decyclising a modified D-galactal **151** (Scheme 96).[10]

The α,β-unsaturated aldehyde **148** served as the initial compound in the synthesis of (3*Z*, 6*Z*, 9*S*, 10*R*)-*cis*-9,10-epoxyheneicosa-3,6-diene **152**—the principal component of the sex pheromone of the American white butterfly *Hyphantria cunea drury* (Scheme 97).[152]

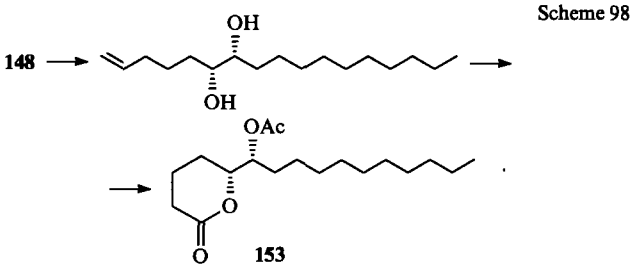


Scheme 94

Scheme 95

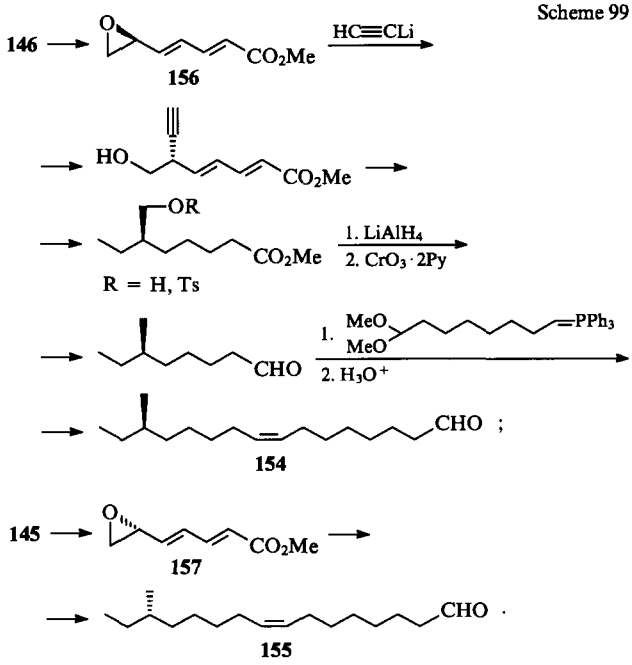


Scheme 96



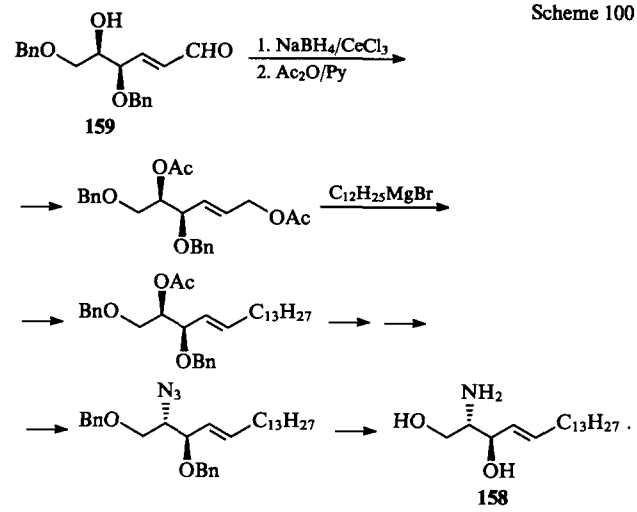
The hexenal **148** has also been used to synthesise (5*R*, 6*R*)-6-acetoxy-5-hexadecanolide **153**—the stereoisomer of the oviposition of pheromone of the gnat *Culexpipiens fatigans* (Scheme 98).[153]

Scheme 97

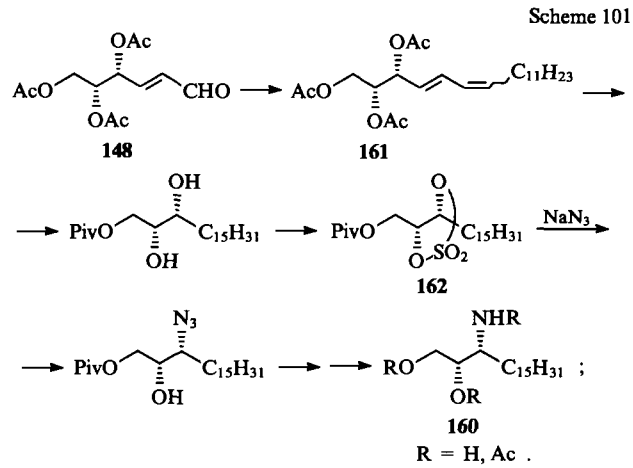


Scheme 98

The key stage in the synthesis of the aggregation pheromone of the leather eating beetles of the genus *Trogoderma*, namely (14*R*, 8*Z*)-trogodermal **154** and its (14*S*, 8*Z*)-enantiomer **155**, from the aldehydes **145** and **146** is the stereospecific reaction of their derivatives, i.e. (6*S*, 2*E*, 4*E*)- and (6*R*, 2*E*, 4*E*)-methyl-6,7-epoxyhepta-2,4-dienoates **156** and **157** respectively, with ethynyllithium. An approach to the synthesis of the enantiomerically pure methyl-branched synthons has been developed in relation to this reaction (Scheme 99).[154]



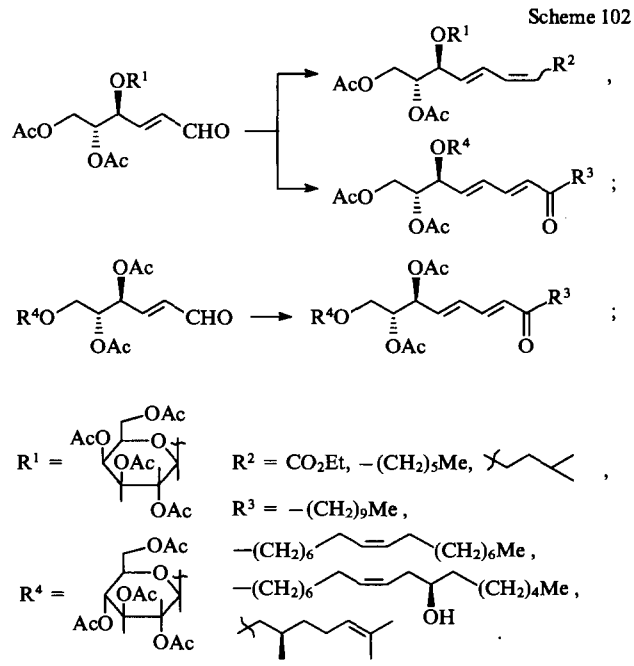
Scheme 99



Six-carbon units with two chiral centres, obtained from glycals based on hexoses, have been used in the synthesis of sphingolipids. Thus a highly effective stereocontrolled synthesis of D-*erythro*-C_{18}-sphingosine **158**, based on the transformations of (4*R*, 5*R*, 2*E*)-4,6-di-*O*-benzyl-5-hydroxyhex-2-enal **159**, has been described (Scheme 100).[84]

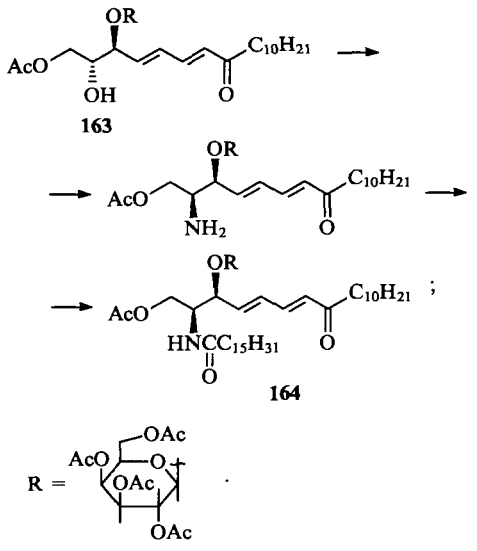
The synthesis of the regioisomer of dihydrosphingosine **160** presupposes the use of the triacetoxydiene **161** obtained by converting the familiar hexenal **148** into an olefin (Scheme 101).[155]

Scheme 100



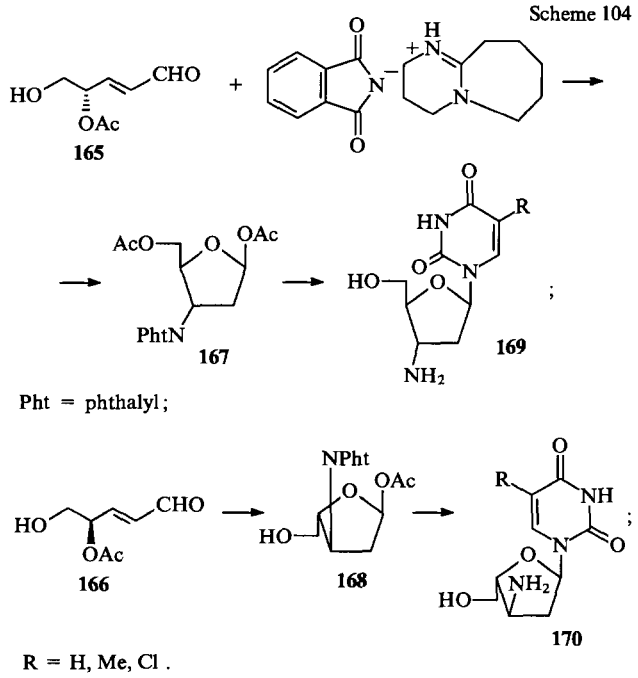
Scheme 101

The stage involving the regiospecific opening of the cyclic sulfate ester **162** on treatment with sodium azide is noteworthy.



The *O*-glycosylated α,β-unsaturated aldehydes, synthesised by the decyclisation of glycals derived from disaccharides, enter fairly readily into the olefin formation reaction with various phosphoranes and 2-oxophosphonates (Scheme 102).[9, 85–88]

Scheme 102

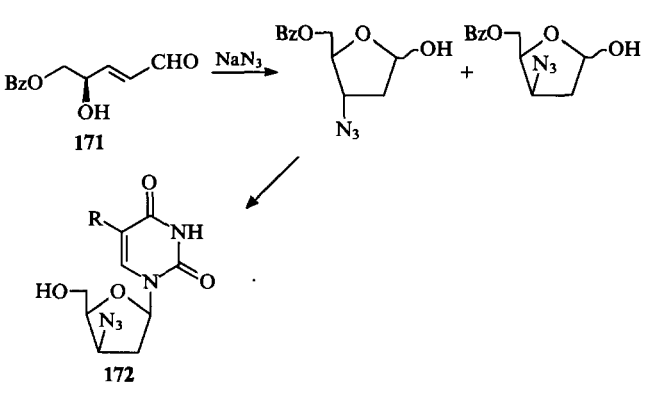


The glycoside **163**, obtained in this way, has been used in the synthesis of the pentaacetate of (2*S*, 3*S*, 4*E*, 6*E*)-3-*O*-(β-D-galactopyranosyl)-2-*N*-hexadecanoyl-8-oxosphinga-4,6-diene **164** — a structural analogue of the membrane galactocenebroside (Scheme 103).[156]

Scheme 103

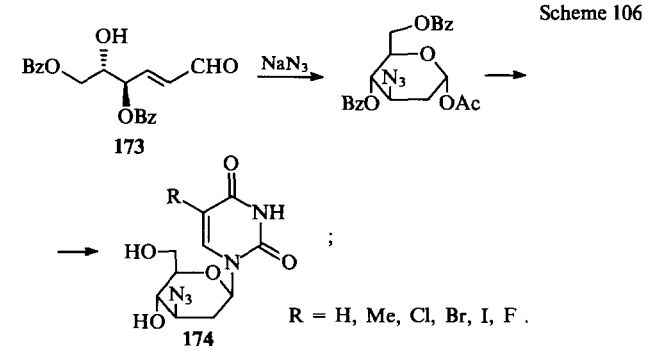
The monoacetates of the α,β-unsaturated dihydroxypentenals **165** and **166**, obtained by the decyclisation of di-*O*-acetyl-D-xylal and di-*O*-acetyl-L-arabinal, react with phthalimide in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene via a recyclisation mechanism, affording the phthalimido-2',3'-dideoxypentoses **167** and **168**. The latter have been used in the synthesis of 3'-amino-3'-deoxythymidine **169**[157] and L-3'-amino-2',3'-dideoxyuridines **170** (Scheme 104).[158]

Scheme 104



Pht = phthalyl;

R = H, Me, Cl .



The cyclisation of the benzoyloxypentenal **171** on treatment with NaN_3 leads to stereoisomeric azidopentoses, one of which has been used to synthesise azidothymidine **172**, which possesses a high antiviral activity (Scheme 105).[159]

3'-Azido-2',3'-dideoxyhexosouridines **174** have been synthesised from the aldehyde **173** in accordance with a similar scheme (Scheme 106).[160]

Scheme 105

Scheme 106

R = H, Me, Cl, Br, I, F .

The syntheses of analogues of azidothymidine from the products of the decyclisation of glycal esters derived from hexoses have been described.[161]

As can be seen from the present review, the study of the reactions of glycals has outgrown the framework of the chemistry of carbohydrates proper and has made it possible to discover their extensive possibilities in relation to enantiospecific synthesis. One cannot fail to draw attention to the fact that synthon units of special preparative value by virtue of the enantiomeric purity of the natural and synthesised chiral centres and the presence of the reactive functional groups most suitable for subsequent transformations can be obtained precisely from the glycals. Judging from the rate of growth of the publications during the last five years, glycals are rapidly occupying an honourable place among the series of sources of chiral carbon which are of general importance for the synthesis of complex natural products, their analogues, and their derivatives.

New aspects of the problem of the ageing and stabilisation of polymers

G E Zaikov, A Ya Polishchuk

Contents

I. Introduction 603
II. Thermodynamic and kinetic aspects of the photo- and radiation-induced ageing and photostabilisation of polymers 603
III. Stability of elastomers and water-soluble polymers. Their applications in medicine and petrochemistry 609
IV. New approaches to the fundamental investigation and practical application of polymer degradation and stabilisation processes 613

Abstract. The results of the most recent studies in the field of the ageing and stabilisation of polymers are presented. The review deals with the questions of the photo-ozone and radiation induced ageing of polymers, and thermo-oxidative degradation and stabilisation of elastomers, various aspects of the interaction of polymers with corrosive media, the problems of the synthesis and efficiency of natural and synthetic stabilisers, and various applications of polymers and polymer blends. New approaches and methods for the investigation of the degradation of polymers are described. The bibliography includes 78 references.

I. Introduction

The regulation of the lifetime of polymer articles is not only a chemical but also a social problem of current interest. On the one hand, prolongation of the duration of use and of storage life is equivalent to an increase in the output of polymeric articles and an improvement in their quality.[1] On the other hand, the accumulation of polymer waste brings to the fore problems of the protection of the environment and of the utilisation of polymeric products.[2] The search for a new method for the modification of polymeric articles in order to improve their operational characteristics (in the first place, in order to modify the properties of their surface) and for the synthesis of polymers with a controllable lifetime has not lost its interest.[3]

Studies on the diffusion, sorption, and desorption of low-molecular-mass compounds in a polymer phase are of interest. This is associated not only with the problem of the protection of polymeric materials against the loss of stabilisers but also with the use of polymers in medicine and the creation of new polymeric long-acting medicinal systems.

The present review deals with problems of regulating the duration of the use and storage and the ageing and stabilisation of polymers as well as the search for ways of prolonging and shortening the lifetime of polymeric articles within the framework of studies carried out in our country during recent years. The review includes also information concerning the prediction of a reliable operating lifetime, which will permit a fuller use of polymeric articles without risk of their premature breakdown.

II. Thermodynamic and kinetic aspects of the photo- and radiation-induced ageing and photostabilisation of polymers

1. Photo-ozone ageing of polymers

The ageing of polymers under natural conditions takes place under the simultaneous influence of many factors (light, ozone, heat, etc.). Ivanov and Shlyapintokh[4] showed recently that synergism may be observed in photo-ozone ageing. Thus it was observed in a study of the ageing of rubbers based on polydieneurethanes that, under the simultaneous influence of ozone and light, cracks arise much faster than on exposure to ozone alone, while exposure to light alone does not lead to the formation of cracks during the period of observation (Fig. 1*a*).

The synergistic effect of light and ozone is also manifested on non-stabilised resins and resins containing antiozonants and photostabilisers. The mechanisms of the action of these influences are then different. Fig. 1*b* shows that an antiozonant of the class of *p*-phenylenediamine, which protects the polymer against ozone quite effectively, becomes inactivated when acted upon by light and ozone simultaneously. On the other hand, a photostabiliser of the class of azo-compounds actually accelerates the ozone-induced ageing process, which is apparently due to its catalytic properties. At the same time, when one uses a mixture of this photostabiliser with an antiozonant acting in accordance with a physical mechanism, a synergistic enhancement of the protective effect is observed. Thus, during the photoozone-induced ageing of a polymer, synergistic phenomena of two types are manifested: the synergistic effect of UV light and ozone; the mutual synergistic influence of antiozonants and photostabilisers.

2. A special type of kinetics in the photochemical oxidation of polyamides

A series of independent tests confirmed[5] the hypothesis, put forward by Postnikov, of the ketoimide mechanism of the oxidation of aliphatic polyamides (PA). An unusual type of kinetics, for which there are as yet no analogues in the photochemical oxidation of other polymers, of the variation of the concentrations of the principal intermediates, i.e. the ketoimide fragment of the macromolecule ($\sim CONHCOCOCH_2 \sim$) and the structurally similar unsaturated ketone, correspond to this new mechanism. Both products have dual functions: under the influence of light, they behave as photoinitiators of the oxidation chains and at the same time, regardless of the influence of light, they participate in kinetic chain transfer with dissociation of the macromolecule accompanied by the alternation of radicals of two types.

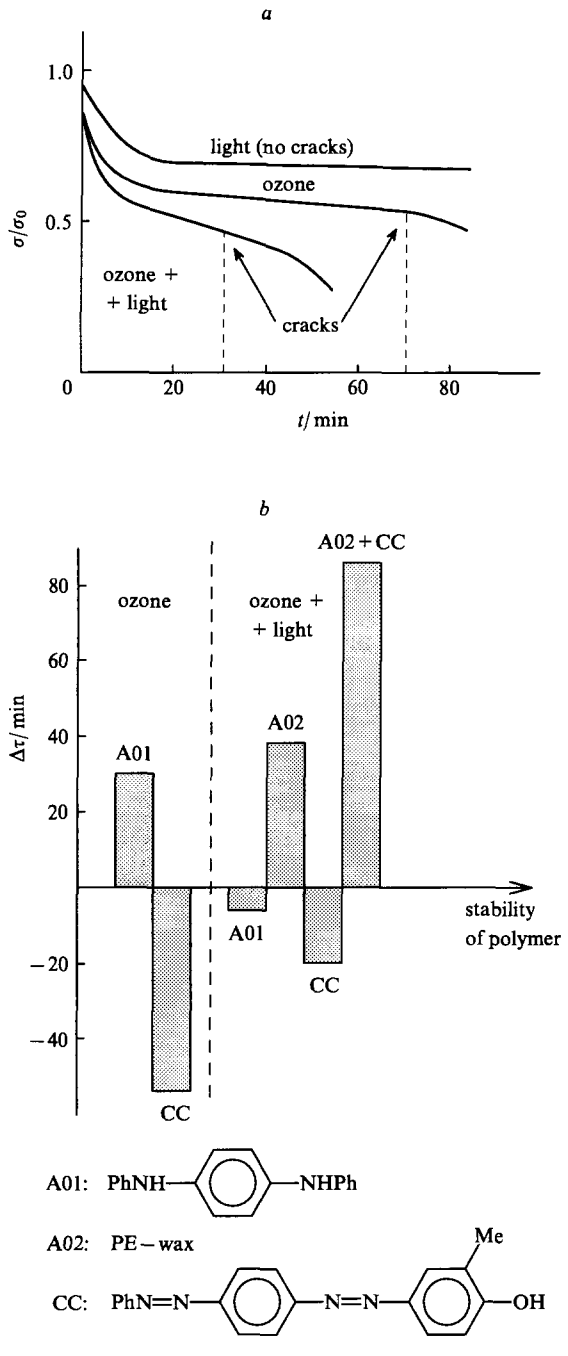

Figure 1. The synergistic effect of UV light and ozone in the ageing of polydieneurethanes: (*a*) kinetics of the relaxation of stresses; (*b*) kinetics of the formation of cracks.

Under any conditions of the photochemical oxidation of polyamides the stationary concentrations of these products are established after a time and for deliberate regulation of the process it is necessary to discover the quantitative parameters which determine both the stationary concentrations themselves and the kinetics of their attainment. The ketone mechanism explained for the first time the known kinetics of the photochemical oxidation of polyamides under all irradiation conditions of practical interest.

The kinetics of the approach to a stationary regime in the case where a polyamide is acted upon by the longest-wavelength light still capable of inducing photooxidative degradation may serve as a clear example of the importance of the above findings. Under such conditions, the kinetic chain is transferred by intermediates (K and K′), but the photoinitiator is only one of them (the ketoimide K). The kinetics of the variation of their concentrations from the initial (K_0 and K'_0) to the stationary (K_{st} and K'_{st}) values are then described by the following functions:

$$K = K_{st}\left[\coth\left(\frac{F+Gt}{2}\right)\right]^2,$$

$$K' = K_{st} - (K'_{st} - K'_0)\times$$

$$\times\left[\left(\sinh\left(\frac{F+Gt}{2}\right)\right)^{Ak'_5/G} \Big/ \sinh\left(\frac{F}{2}\right)\right],$$

where F, G, A, and k'_5 are familiar parameters with a known physical significance:

$$F = \ln\left|\frac{(K_0)^{1/2} - (K_{st})^{1/2}}{(K'_0)^{1/2} - (K'_{st})^{1/2}}\right|,$$

$$G = -\left[\frac{k_7}{k_5}I_0\left(\frac{k_7}{k_5}I_0 + 4\frac{k_2}{k_6}\right)\right]^{1/2}\frac{k_5}{2},$$

$$A = 2\frac{k_2}{k_3}\left(\frac{k_3k_7I_0}{k_6k_2}K_{st}\right)^{1/2},$$

$$PO_2 + PA \xrightarrow{+O_2} POOH + PO_2^{\cdot}, \quad (1)$$

$$PO_2^{\cdot} \longrightarrow A + r^{\cdot}, \quad (2)$$

$$PO_2^{\cdot} \longrightarrow B + r^{\cdot}, \quad (2')$$

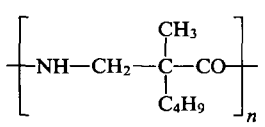
$$r^{\cdot} + PA \xrightarrow{+O_2} rH + PO_2^{\cdot}, \quad (3)$$

$$A \xrightarrow{+2O_2} K, \quad (4)$$

$$A \xrightarrow{+2O_2} K', \quad (4')$$

$$K + r \longrightarrow PO_2 + S, \quad (5)$$

$$K' + r \longrightarrow PO_2 + S, \quad (5')$$



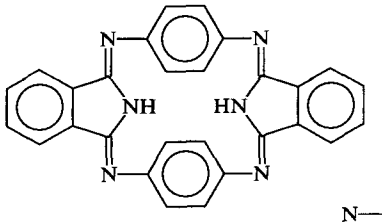
$$PO_2 + r \xrightarrow{-O_2} S, \quad (6)$$

$$K \xrightarrow{+I_0+2O_2} 2PO_2 + S. \quad (7)$$

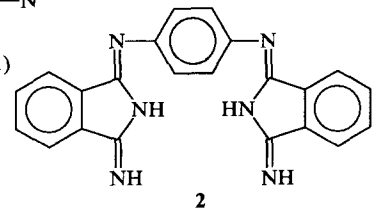
Here k_i is the rate constant, the subscript i corresponding to the ordinal number of the reaction in the mechanism, I_0 is the light intensity, P is a polymer radical, PO_2 are the peroxide macroradicals $\sim CH_2CONHCH(OO^{\cdot})CH_2\sim$, r are low-molecular-mass radicals $HO_2^{\cdot}$ or O_2^{-}, A, K, and K′ are intermediate molecular products, B is the final product, and S denotes the dissociation of the macromolecule.

Functional relations of this type have not so far been considered in the kinetics of the photodegradation of polymers. Such relations help in the rational selection of photostabilisers. Previously stabilisers were selected without taking into account the actual mechanism of the photochemical oxidation of polyamides.

The observed mechanism is valid for different industrially manufactured aliphatic polyamides regardless of the number of CH_2 units. However, it ceases to operate in the absence of hydrogen atoms attached to the α- or β-carbon atom, for example, when they are substituted by alkyl groups, because the formation of the ketoimides

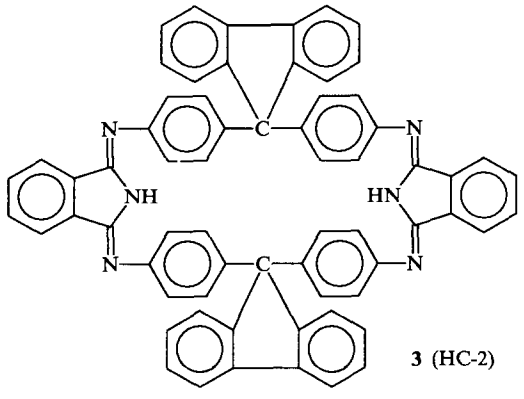


becomes impossible. As a result of this, the photochemical oxidation of poly(3-butyl-3-methylazetidine) follows completely different kinetics.



3. A new class of photostabiliser

Cellulose acetates (CA) are widely used nowadays in different branches of industry, but, owing to their inadequate photostability, the operating characteristics of articles made from this material become strongly impaired after a time. Therefore, despite the great variety of cellulose acetate stabilisers, the search for effective photostabilisers is still a timely problem.[6, 7]



A new class of photostabilisers based on macroheterocyclic substances — hexaazacyclanes (HC) — has been developed.[8] Among different derivatives of hexaazacyclanes, phthalonitrile and its derivatives comprising *p*-phenylenediamine (a conjugated substance — compound **1** or HC-1) and 9,9-bis(4-dianilino)fluorene (a non-conjugated substance — compound **3** or HC-2) were selected for study. In order to determine the influence of the structure of the macrocyclic stabiliser on its properties, the product of the linear condensation of phthalonitrile and *p*-phenylenediamine (compound **2**) was also investigated. All the substances are powders with different colours (depending on the structure) ranging from yellow to brown. They are fairly compatible with cellulose acetate and do not impair the operating properties of the latter at concentrations in the range 5–7.5 mass%.

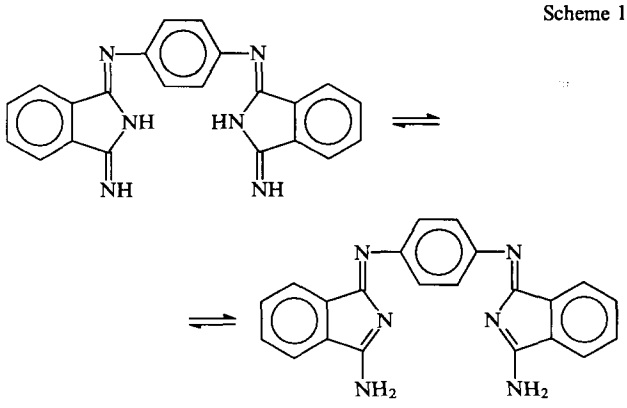
1 (HC-1)

2

3 (HC-2)

The proposed photostabiliser can act simultaneously via several mechanisms, among which the most important involve shielding from UV light, inhibition, and photosensitivity. The contribution of UV shielding to the overall effect of the stabiliser is calculated using the formula proposed by the present authors:[4]

$$i_p = \frac{D_{d+st}(1 - 10^{-D_d})}{D_d(1 - 10^{-D_{d+st}})},$$



where D_d and D_{d+st} are the optical densities of the non-stabilised and stabilised films respectively. The coefficient i_p characterises the quantitative decrease in light absorption by the polymer owing to the presence of the stabiliser. Thus, if the effect of the stabiliser is limited to the absorption of UV light, then the rate of degradation falls by factor i_p relative to the amount of absorbed light.

The principal product of the degradation of cellulose acetate by UV radiation is acetic acid, the rate of formation of which characterises the photostability of the material. The overall effect of the increase in stability (A) is determined by the ratio of the rates of formation of acetic acid without stabiliser (W_0) and in its presence (W_{st}):

$$A = \frac{i_p W_0}{W_{st}}.$$

Data concerning the influence of the structure of the photostabiliser on the overall increase in the photostability of the composition are presented in Table 1. For all stabilisers, $A < 1$. Consequently these stabilisers not only provide a shield against UV light but they also operate as photosensitive elements.[9] The highest photosensitivity is shown by compound **2**. The point is that this substance has two resonance states (see Scheme 1 below), one of which contains amino-groups. Evidently these amino-groups act as photostabilisers in relation to the photodegradation of cellulose acetate, in agreement with the present authors data.[4]

Scheme 1

In terms of its photostabilising properties, HC-2 is superior to compound **2** but is inferior to HC-1. This is probably associated with the shorter length of the conjugated chain and the smaller number of aromatic groups in the structure of HC-2.

HC-1 is the most effective stabiliser. Its effective photostabilising properties could be accounted for by the simultaneous shielding and inhibiting activities. In order to estimate the possible contribution of the inhibition mechanism to the overall effect of HC-1, measurements were made of the kinetic parameters of the photochemical oxidation of unstabilised cellulose acetate and cellulose acetate stabilised by HC-1. These parameters are the chain oxidation parameters $k_p[PH]k_t^{-1/2}$ and the photoinitiation quantum yield P_i.

The results are presented in Table 2. The HC-1 stabiliser does not influence the cellulose acetate chain oxidation parameter or, in other words, it is not an inhibitor interacting with polymer radicals. On the other hand, the photoinitiation quantum yield P_i diminishes sharply in the presence of HC-1. This means that transition from the pure to the stabilised cellulose acetate alters the initiation mechanism, i.e. the stabiliser becomes the initiator instead of cellulose acetate. However, the significant decrease in P_i in the presence of HC-1 is also responsible for the overall protection against light. Thus HC-1 introduced into cellulose

acetate acts both as a screen against UV light and as a photosensitive element.

The stabilising properties of HC-1 have been confirmed by comparative data, presented in Table 3, and the decrease in the viscosity of cellulose acetate solutions in acetone after the UV irradiation of films stabilised by HC-1 and one of the most effective stabilisers—carbazole-5,10,12-trisulfonamide (CTS). The stabilising properties of HC-1 are significantly more effective than those of CTS. The protective effect of HC-1 begins to be manifested at its relatively low concentrations (0.5 mass%), the maximum effect being attained at a concentration of 3 mass%. The high stabilising effect under the conditions of prolonged irradiation is also remarkable.

The photostabilising properties of polyhexaazacyclanes (PHC) have been investigated in cellulose acetate and polycaproamide (PA). The photostabilising activity of PHC was estimated from the change in the viscosity of a 5% solution of cellulose acetate in dimethylformamide (DMF) and a solution of polycaproamide in formic acid. Comparative data on the photostability of cellulose acetate and polycaproamide films stabilised by PHC over a period of 24 h are presented in Table 4. They show that PHC is a stabiliser in relation to the photooxidative degradation of both cellulose acetate and polycaproamide, its photostabilising properties in relation to cellulose acetate being more effective than those in relation to polycaproamide. Comparison of the data presented in Tables 3 and 4 demonstrates that the photostabilising properties of HC-1 are significantly more effective than the analogous properties of PHC.

A further search for new effective stabilisers for cellulose acetate and polycaproamide should be continued among macrocyclic aromatic substances with an extensive conjugated chain and a nearly planar structure. A characteristic feature of all macrocyclic stabilisers is their ability to colour textiles yellow, red, and brown depending on the nature and amount of the stabiliser.

4. Certain problems of the photodegradation and photostabilisation of polymers

Mel'nikov et al.[10] showed in relation to the photooxidative ageing of polystyrene that the photochemical reactions of the peroxyl radicals formed from the central macroradicals

$$\sim CH_2\underset{\displaystyle C_6H_5}{\overset{|}{C}}(O\dot{O})CH_2\sim$$

lead to the disruption of the main polymer chain. The spectroscopic characteristics of this reaction are presented in Fig. 2. The quantum yield of the reaction, accompanied by the formation of low-molecular-weight transfer agents (OH· radicals), is 10^{-3} at 77 K. The photochemical reactions of radicals of other types—cyclohexadienyl radicals, central macroradicals, peroxyl radicals obtained from cyclohexadienyl radicals—have quantum yields ranging from 10^{-1} to 2×10^{-5}; they lead to the migration of the free valence and the formation of low-molecular-mass products without involving the main chain.

The photochemical reactions of radical-anions and polymers such as poly(vinyl acetate), polyacetals, and aliphatic polyurethanes do not exert any significant influence on the molecular mass distribution of the polymers indicated.[11]

In the study of the mechanisms of the photochemical reactions of peroxyl radicals of different types grafted to the surface of chemically activated silicon dioxide, it was possible to show[12] that the primary step in the photolysis involves dissociation at the O–O bond (Table 5).

$$R\dot{O}_2 \longrightarrow [R\dot{O} + O] .$$

The subsequent course of the process is determined by the behaviour of the [RO· + O] pair formed. In particular, the energy evolved in the reverse reaction (250 kJ mol^{-1}) exceeds the energy of the C–O bonds in the peroxyl radicals and hence the vibrationally excited radical may decompose:

$$[R\dot{O} + O] \longrightarrow [RO_2] \longrightarrow \dot{R} + O_2 .$$

The extent of the reaction should be correlated with the strength of the C–O bond in the peroxyl radicals. These results are important for the interpretation of many data on the photooxidative ageing of polymers.

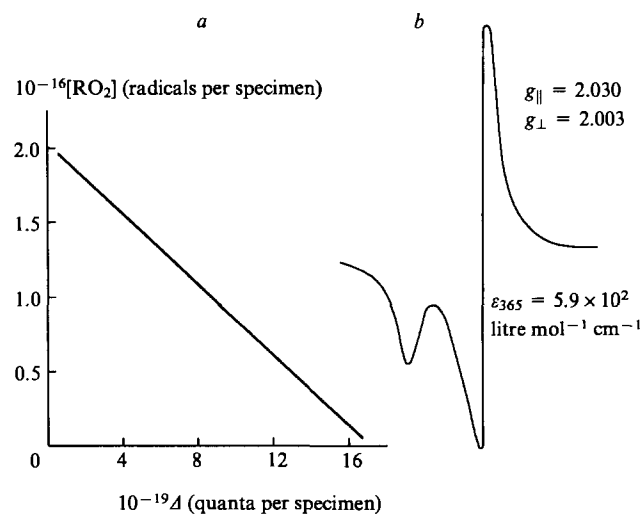

Figure 2. Dependence of the concentration of the RO_2 radicals on the irradiation dose (*a*) and the absorption spectrum at a wavelength of 365 nm (*b*).

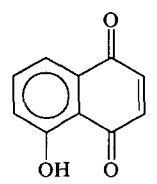
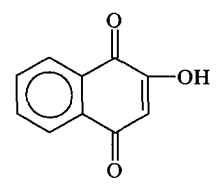
5. Photostabilisation of cellulose diacetate and cellulose paper by natural products

The problem of the photostabilisation of cellulose diacetate (CDA) and cellulose paper (CP) by compounds of natural origin has become of primary importance, since it is directly associated with the protection of the environment and the utilisation of waste.

Studies of the use as stabilisers of flavanoids (isorhamnetin **4** and quercetin **5**) as well as extracts of the walnut, henna, and the total dyes of the polypore (bracken fungus) (TDP) have been carried out by Kalontarov, Niyazi, and coworkers.[13] The walnut extracts contain 25% of juglone and the henna extracts contain 1.85% – 2.23% of lawsone.



4



5

These natural products are coloured antioxidants. This permits their use as dyes and photostabilisers for cellulose and its acetates.

juglone

lawsone

It is known that, during the photoageing of cellulose materials, the degree of their polymerisation (DP) diminishes, the concentration of >C=O groups increases, and their physico-chemical properties are impaired.[14] The results of certain tests are presented in Table 6. The introduction of such additives retards the decrease in the degree of polymerisation and the formation of

[a] The concentration of the dye or its dilution is quoted.

Note. The following notation has been adopted here and in Table 7: (I) before irradiation; (II) after irradiation.

carboxy- and aldehyde groups. The stabilising effect of the additives is manifested to the greatest extent in the case of quercetin.

In order to investigate the mechanism of action of the additives, transparent films of cellulose diacetate into which these additives had been introduced were obtained. The results of tests on the retention of viscosity are presented in Table 7.

Table 7 shows that all the additives promote the retention of viscosity after irradiation for 24 h. The best result has been achieved with isorhamnetin (78%). After UV irradiation of cellulose diacetate films containing isorhamnetin, a change in is colour is observed — decolorisation as a consequence of the consumption of the dye. The rate constant for the consumption of isorhamnetin was determined from the initial portion of the kinetic optical density curve. Since this relation is linear in terms of logarithmic variables (Fig. 3), the rate constant was calculated from the equation for a first order reaction.[15]

Fig. 3 shows that the rate of consumption of isorhamnetin is inversely proportional to the concentration of the additive. Isorhamnetin is consumed at the lowest experimentally determined rate when its concentration is 3 mass%. These data agree with the literature.[13, 14] According to Kalontarov, at low concentrations the molecules of the additive are distributed in the polymer, forming a monolayer. With increase in the isorhamnetin concentration, the forces of the interaction between the additive and the polymer are overcome and ultimately the isorhamnetin molecules are converted into aggregates, which are decolorised more slowly as a consequence of the effect of the concentration-induced quenching.[16]

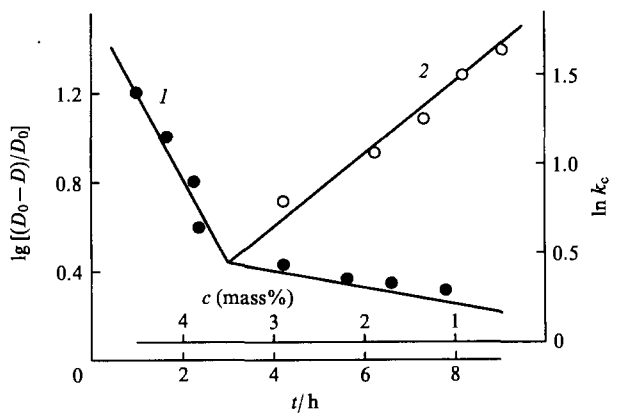

Figure 3. Kinetics of the consumption of isorhamnetin under UV irradiation: (*1*) $\lg[D_0-D)/D_0] = f(t)$; (*2*) $\ln k_c = f(c)$; k_c is the consumption rate constant, D_0 and D are the initial and current optical densities, and c is the concentration of the additive.

6. Laser-induced degradation of polymers

Kalontarov and Marupov investigated in recent years[17-21] the degradation of certain materials — poly(vinyl alcohol) (PVA), polyacrylonitrile (PAN), and polyimide (PI) — by the continuous radiation from an argon laser (514.5 nm). It was shown that the laser-induced degradation process is determined by the kinetics of the accumulation of the products of the thermal decomposition of the macromolecules. Typical dependences of the absorbances of the polymer films on the duration of the laser irradiation are illustrated in Fig. 4. The figure shows that the laser-induced degradation process has two stages: the activation stage (for the duration t_a) and the stage involving a sharp increase in absorption (for the duration t_b), which is completed by the breakdown of the film. The avalanche-like nature of the decomposition is due to the establishment of a positive feedback between the heating of the polymer and the absorption of radiation in the degradation zone. The phenomenon of the sharp increase in absorption and temperature on laser decomposition of polymers has been called photothermochemical instability (PTCI). The first and second stages of the laser-induced degradation (Fig. 4) are therefore called respectively the activation phase and the PTCI development phase. The duration of both phases (t_a and t_b) depends on the power of the absorbed radiation.

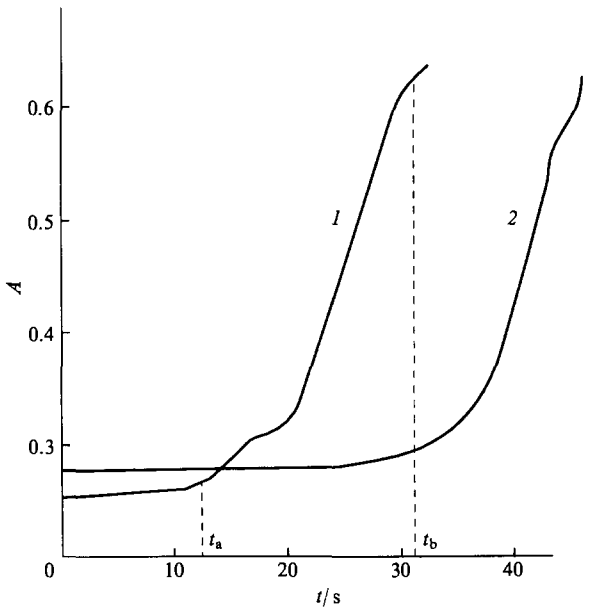

Figure 4. Kinetics of the variation of the absorbance of dyed PVA during laser irradiation for a solid solution of the dye (curve *1*) and for the dye bound chemically to the polymer (curve *2*).

A model of PTCI based on the non-stationary approximation has been constructed[17] and the temperature variation of t_a has been obtained:

$$t_a = \left(\frac{2T_0}{\alpha\gamma}\right)^{1/2} \exp\frac{\alpha}{2}, \quad (8)$$

where $T_0 = \mu P + T_a$ is the temperature of the specimen in the field of the irradiation before the development of the PTCI, P = the power of the incident radiation, T_a the ambient temperature, μ a coefficient, $\alpha = E/RT_0$, $\gamma = (P\varepsilon v)/(\rho C_p S)$, E and v are the activation energy and the pre-exponential factor for the rate of accumulation of the thermal degradation products, C_p is the heat capacity of the polymer film, and ε the extinction coefficient. It has been shown[17] that the activation times calculated by Eqn (8) agree with data for the laser-induced degradation of PVA (Fig. 5).

It has been observed[19, 20] that the duration of the second phase is determined by the rate of development of the PTCI and obeys the following empirical relation:

$$t_b = \tau_0 \exp(-\beta T_0), \quad (9)$$

where τ_0 and β are constants.

The difference between the $t_b(T_0)$ and $t_a(T_0)$ relations is of greatest interest. Eqn (8) was derived on the hypothesis that the Arrhenius equation holds for the chemical reaction rate constant. The fact that the experimental values of t_a are described satisfactorily by Eqn (8) confirms the validity of the Arrhenius equation for the initial stage of the laser-induced degradation when the changes in the temperature and concentration of the degradation products are still small. The qualitative PTCI model shows[20] that the process involving the development of instability is significantly non-stationary. Under these conditions, the Arrhenius kinetics break down, which is reflected in its turn in the dependence of the time of the development of the PTCI on the temperature T_0 [Eqn (9)].

The non-linear thermochemical processes in polymers under the conditions of the thermal effect of the laser radiation have been investigated.[21, 22] The effect involving the self-stabilisation of the laser-induced dehydration of PVA, the propagation of travelling degradation waves, and the vibrational and random dynamics of the evolution of volatile products during the laser-induced decomposition of polymers have been observed.

The effect of the radiation of a Nd : YAG continuous wave laser (1064 nm) on the colour of the PVA film has been investigated.[23, 24] It has been established by mass-spectrometric analysis[23] that the qualitative composition of the volatile products on thermal and laser decomposition is virtually the same, but the relative contributions of the individual components can differ significantly. It was concluded that the laser-induced decomposition of polymers takes place on the whole via a thermal mechanism, although the dynamics of the laser-induced processes differ from the dynamics of the usual thermal degradation. It has been shown[24] that the laser stability of the coloured PVA depends both on the type of the dye introduced and on the way in which the dye is bonded to the polymer. It has also been observed that the resonance effect of the radiation decomposes polymers much more effectively than the non-resonance effect.

III. Stability of elastomers and water-soluble polymers. Their applications in medicine and petrochemistry

1. A new method for estimating the thermal and radiation stabilities of elastomers

The existing methods for the determination of the lifetime (τ) of elastomers, widely used in practice and based on thermal ageing, take a long time, consume a large amount of materials, and are unsuitable for high temperatures. A new method, developed by Prokopchuk et al.,[25] is free from these disadvantages and makes it possible to estimate the contributions of different factors in the external medium to the decrease in the lifetime of rubbers. A distinctive feature of the new method involves the thermooxidative degradation of elastomers in a field of a tensile mechanical stress. The method is based on a single relation (Fig. 6) between the lifetime and the activation energy U_0, established on the basis of extensive experimental data obtained by the existing thermal ageing method. It includes also a high-speed method for the estimation of the values of U_0 from the temperature variation of the breaking stress when the thermooxidative degradation takes place with the specimen being acted upon simultaneously by heat, atmospheric oxygen, and a mechanical tensile stress, i.e. is accelerated by the applied field of mechanical forces.

The lifetimes of 20 types of rubbers, based on different polymers and having different compositions, have been determined by the above method.[25] The results agree with data obtained by the existing method in parallel experiments.

In order to estimate the contribution of ionising radiation to the decrease in the lifetime of rubbers based on butadienenitrile (SKN-18SM) and chloroprene (nairit M) raw rubbers,[26] their specimens were irradiated with ^{60}Co γ-rays. The radiation dose was 500 kGy (50 Mrad) and the dose rate was 4 Gy s^{-1} (400 rad s^{-1}). The results of the investigation are presented in Table 8.

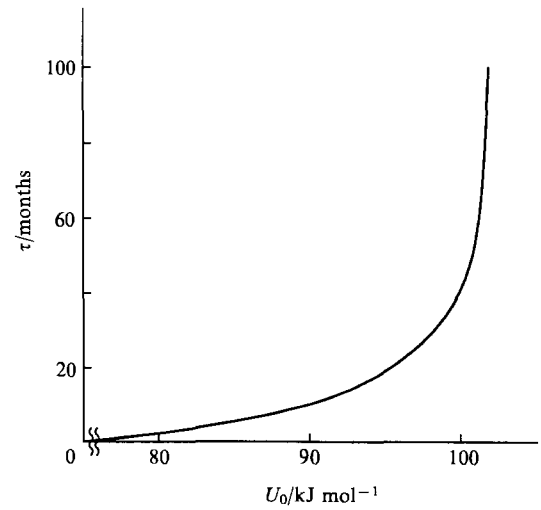

Figure 6. Dependence of the lifetime of rubbers in air at 25 °C on the activation energy for their thermal ageing.

Table 8. Changes in the properties of rubbers under the influence of ionising radiation.

Polymer	Initial specimen			Specimen after irradiation		
	$\sigma(1+\varepsilon)$/ MPA	U_0/ kJ mol^{-1}	τ^a/ months	$\sigma(1+\varepsilon)$/ MPA	U_0/ kJ mol^{-1}	τ^a/ months
SKN-18SM	30	109	190	14.2	102	68
Nairit M	75	121	1103	22.2	105	106

[a] Lifetime at 25 °C.

It follows from the above table that the breaking stress $\sigma(1 + \varepsilon)$ is reduced on irradiation by a factor of 2.1 for the SKN-18SM specimens and by a factor of 3.4 for the nairit M specimens, the activation energies for the thermooxidative degradation U_0 being reduced by 7 and 16 kJ mol^{-1} respectively. The quantity U_0 is a critical parameter for the determination of the lifetimes of rubbers.[25] The influence of γ-radiation on the lifetimes of rubbers with a different polymer base varies: the value of t for irradiated SKN-18SM specimens is 35% of the values for the initial specimens, while for nairit M it is only 9.6%. However, the lifetimes of both rubbers are fairly long after irradiation with a dose of 500 KGy and they meet fully the technical requirements for rubbers serving as components of different technological objects.[25]

2. Elastomers in medicine

Highly elastic materials employed in the manufacture of articles for medical purposes play an important role among polymers. In the first place, these are elastomers based on *cis*-1,4-polyisoprene and obtained mainly from natural rubber (NR) and natural latex (NL). Apart from their natural origin, one may include among their advantages a unique set of properties associated with strength and elasticity. The latex technology based on the natural latex ensures an ecologically safe manufacture of articles for mass consumption and makes it possible to obtain articles with a specified thickness and with a complex configuration.

However, owing to their low resistance to different types of ageing and the risk of toxic effects of different low-molecular-mass substances used for the vulcanisation of polyisoprene, the materials based on it have come to be regarded as undesirable or unsuitable for prolonged contact with living tissues. Nevertheless, because of the lack of systematic studies, existing ideas about the biocompatibility of these materials are fairly contradictory.

Khodzhaeva et al.[27] investigated in recent years the influence of prolonged contact between polyisoprene and a biologically active medium (blood serum). The structure and properties of the polyisoprene, vulcanised polyisoprenes, and latex materials were studied. The relative contributions of several factors influencing the above materials were estimated in parallel experiments: water, salt (isotonic) solution, proteins, at the temperature of living tissues (~40 °C).

The following results of the above study are of greatest interest and importance.

It was established that the biological medium does not exert a specific disruptive influence on natural rubber. Water and the protein components of the blood serum, adsorbed on the polymer surface, protect it against the thermooxidative degradation gradually developing at 40 °C. After being kept in blood serum for 2 years, polyisoprene retains a high molecular mass, while in air the latter diminishes (Fig. 7).

Biologically stable highly elastic materials can be obtained from natural rubbers. For this purpose, it is essential that the vulcanisation network should be resistant to thermooxidation at 40 °C and that the composition of the material should ensure a minimal level of sorption of the components of the medium. The cross-linking density of natural rubbers changed little in the course two years of contact with different media and they retained a high strength and elasticity (Table 9).

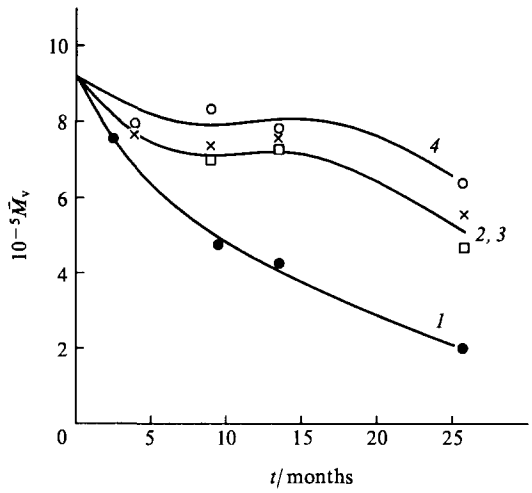

Figure 7. Variation of the molecular mass of *cis*-1,4-polyisoprene under conditions of prolonged contact at 40 °C with air (curve *1*), water (curve *2*), isotonic solution (curve *3*), and blood serum (curve *4*).

For latex materials, which are on the whole inferior to vulcanised block polyisoprene as regards resistance to thermooxidation, the most active disruptive factors during prolonged contact with a biological medium are the absorption of water and the effect of temperature. The negative effect of these factors can be to a large extent abolished by the specific regulation of the microstructure and composition of the material.[28] The application of these principles made it possible to obtain from natural latexes thin-walled film articles which retain highly effective properties during contact with aqueous and biological media in the course of a year.

Table 9. Changes in the properties of vulcanised natural rubbers on exposure to air, in isotonic solution, and in blood serum at 40 °C.

Time/months	$10^5(1/M_s)$/mol cm^{-3}	f_{700}/ MPa	f_r/ MPa	ε(%)
	Initial specimen			
0	12.9	17.5	32.8	880
	Specimen maintained in air			
12.0	16.1	24.6	35.0	820
22.2	12.5	24.2	29.8	750
	Specimen maintained in isotonic solution			
12.0	12.2	12.1	34.9	920
22.2	13.3	14.9	29.8	810
	Specimen maintained in blood serum			
12.0	14.8	13.8	30.7	850
22.2	15.6	13.4	29.8	890

Note. $1/M_s$ = density of cross-linking; f_{700} = modulus of elasticity; f_r = tensile strength; ε = relative elongation on rupture.

Materials and articles for medical purposes with thromboresistant properties have been developed on the basis of natural latexes; the characteristics of the structure of the latex gel and the presence in the latter of protein components served as a basis for the improvement of the method of ionic-covalent immobilisation of heparin.[29-31]

In order to increase the biological compatibility of latex articles and to impart to the latter new functional properties, procedures have been developed for the preparation of composite materials based on the combination of a natural latex with an aqueous dispersion of a high-molecular-mass polyorganosiloxane[32] and on the surface modification by coatings consisting of segmented polyesterurethanes.[33]

The present state of the problem of the biological compatibility of highly elastic materials based on *cis*-1,4-polyisoprene and also the advances in the field of their preparation and application have been surveyed in a review.[34]

3. Stabilisation of coatings in biochemically active media

The problem of the stabilisation of the protective properties of coatings used in biochemically active media is of great theoretical and practical importance.

The complexity of the solution of the problem arises from the fact that the protective properties of coatings depend on many physicochemical factors: the adhesion strength of the bond between the coating and the support; the magnitude and the kinetics of the growth of internal stresses, arising during their formation and use, which are comparable to the adhesion and cohesion strengths; the barrier properties of coatings; the ability of polymers to inhibit electrochemical processes at the interface; the resistance of polymers to the effect of the microflora in undertakings for the food industry.

In order to stabilise the structures and properties of protective coatings used in biochemically active media, Rozantsev[36] developed structure-forming additives for the industrially produced compositions based on organoelement and other compounds with an aromatic conjugation system, which promote the creation in the coatings of an ordered structure of the mesomorphic type. The influence of these additives on the specific features of the structure formation during the production of epoxide coatings as well as the internal stresses and the physicomechanical protective properties of the coatings have been investigated.

It has been shown by the NMR method and electron microscopy that the introduction of these additives in small amounts (1–2 mass%) promotes the formation of structures of the nematic type made up of uncoiled macromolecules with a coplanar orientation in the plane of the support. The mesomorphic level of order in the structure ensures a kinetically convenient order for the involvement of the functional groups in the adhesion and cohesion interactions.

Table 10 presents data concerning the influence of an organosilicon additive on the stability of the properties of epoxide coatings in corrosive media. Modifying agents based on derivatives of the piperidinoxyl (PPO) radical have been developed for the stabilisation of the properties of the coatings in acid media.[36] It was shown that they are capable of retarding strongly the rates of oxidation processes at the interface and in the bulk of the polymer.

Table 10. The mechanical and adhesive properties of polymeric coatings.

Properties	Without additive	With additive
Internal stress/ MPa	4.0	1.5
Adhesion scale points		
initial	1	1
after ageing		
in 3% lactic acid solution	4	2
in 1.5% NaOH solution	2	1
Impact strength/ N m		
initial	5	5
after ageing		
in 3% lactic acid solution	1	3.5
in 1.5% NaOH solution	1.5	4
Lifetime/days		
in 3% lactic acid solution	7	350
in 1.5% NaOH solution	34	400

The introduction of small amounts of the PPO into the corrosive medium increases the corrosion stability of the material as a result of the adsorption of the inhibitor molecules on the surface and a change in the kinetics of the electrochemical reactions (Table 11). The effectiveness of the inhibitor (W) is estimated from the formula

$$W = \frac{i_k - i_k''}{i_k},$$

where i_k and i_k'' are the corrosion currents without and with the inhibitor.

Table 11 shows that the introduction of PPO into electrolyte solutions in an amount of 0.5–2 mass% shifts the stationary potential in the positive direction by 100–120 mV, lowers the maximum dissolution currents by a factor of 8, and increases the degree of protection to 80%–85%.

Similar features have been observed after the introduction of PPO in an amount of 0.5–1 mass% into perphthalic, perchlorovinyl, and epoxide coatings. The modified coatings have already found practical applications for the protection of equipment in the food industry.

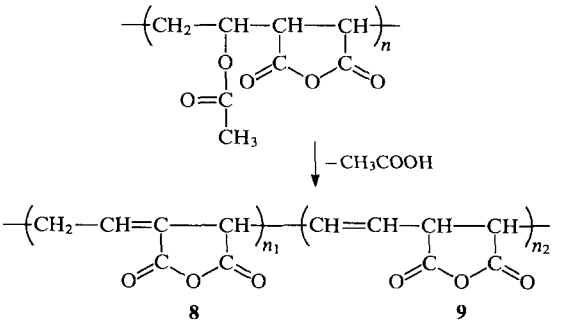

Table 11. The influence of piperidine oxide on the electrochemical characteristics of steel (ST-3).

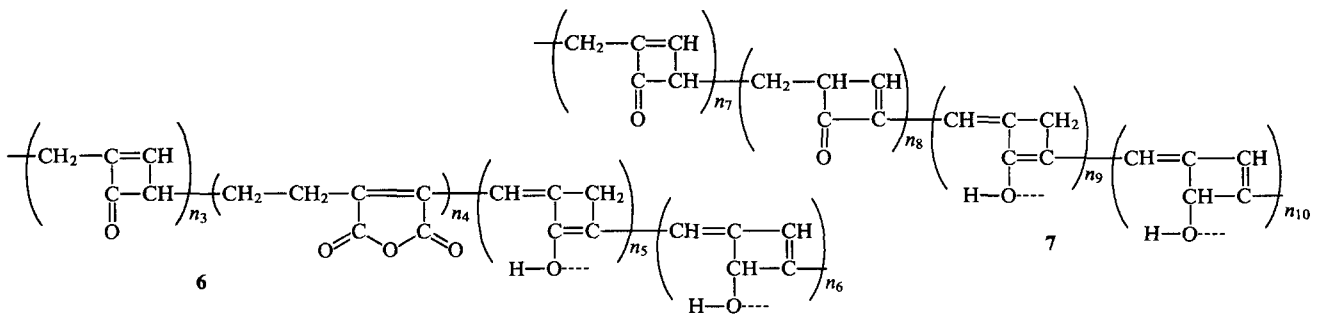
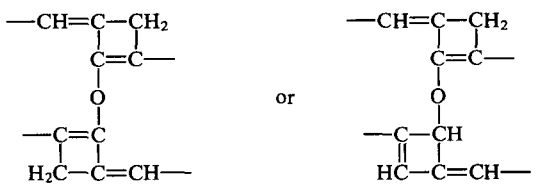
PPO content (%)	Stationary potential/mV		Maximum dissolution current/mA cm^{-2}		Degree of protection (%)	
	I	II	I	II	I	II
0	−500	−600	16.7	80.0	0	0
0.5	500	−600	10.0	62.0	39	25
1.0	−450	−570	2.2	43.0	80	50
1.5	−450	−500	3.0	15.0	66	80
2.5	−450	−480	4.4	10.0	66	85
3.0	−550	−530	25.0	80.0	–	0



Note. Electrolyte: (I) 0.5 N Na_2SO_4; (II) 5% HCl.

4. Regulation of the liberation of medicinal preparations by the controlled degradation of polymers

Among various applications of the degradation of polymers, yet another has been discovered in the study of the copolymer of maleic anhydride and vinyl acetate (MA/VA). The present authors investigated the thermal degradation of this copolymer jointly with McNeill using his method for the thermal analysis of the volatile degradation products (TV/ATVA).[37, 38] The results showed that the first stage of the isothermal degradation at 205 °C can be represented in the form



8 9

6 7

The next stage involves rearrangements of structures **8** and **9** without the evolution of carbon dioxide or as a result of such evolution, which leads to structure **6**†. The last stage of the isothermal degradation involves the decomposition of the anhydride ring, which leads to structure **7**.

The quantities n in the above structures can vary and we have no adequate grounds for attributing any definite values to them. The appearance of a cyclic structure in the side chain diminishes the mobility of the latter and is one of the causes of the decrease in solubility. Another cause may be the cross-linking of the polymer as a result of the dehydration of the hydroxy-groups. This explanation has been confirmed by the liberation of water as a consequence of isothermal degradation. This type of reaction may lead to the cross-linking of individual units.

Conclusions concerning the presence of the above structures were based on data obtained by UV, IR, and NMR spectroscopic and mass-spectrometric methods and also by gas chromatography.

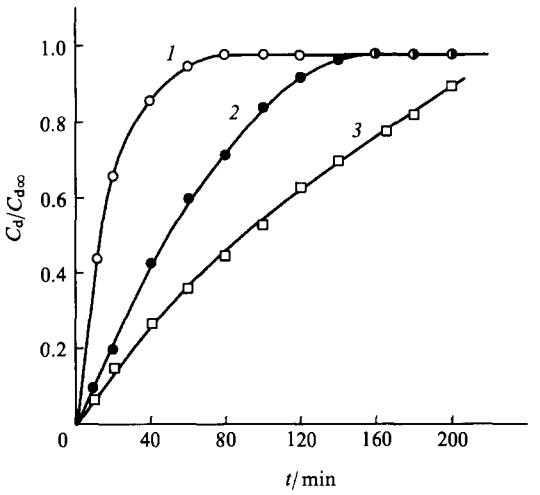
Apart from thermal degradation, the behaviour of the polymer in the presence of water was also investigated. In the first place, the question to what extent the sorption of the polymer can be regulated by its controlled degradation was elucidated.

The first stage of the interaction of water vapour with the polymer involved reversible sorption up to an equilibrium value. The increase in the activity of water vapour induced its irreversible binding accompanied by the rupture of the chemical bonds in the copolymer chain with subsequent dissolution. The critical concentration for hydrolysis was attained only for an activity of water vapour close to unity (liquid phase). The general characteristics of the sorption of water by partly degraded polymers are the same as for the initial material and the observed differences are associated with the degree of structural rearrangement as a consequence of the equilibrium sorption. The specimens obtained after degradation for 10 and 20 min are insoluble in water, although their partial hydrolysis was observed. After degradation for 30 min, a swollen polymer was obtained for which the irreversible sorption stage was limited.

The change in the hydrophilicity of the copolymer as a result of the different degrees of its degradation has been used to create a system where it was necessary to regulate the hydrophilic-hydrophobic balance in the polymer matrix, namely a system for the controlled liberation of medicinal preparations.[39]

We investigated a multicomponent system incorporating polyamide coated by a mixture of the MA/VA copolymer with furacilin. The redistribution of the drug between the two polymers controls the multistage process involving is liberation, which includes desorption from the moderately hydrophilic polyamide and subsequent transfer in the swollen or dissolving copolymer.

The retardation of the liberation of the medicinal preparation as a result of the partial degradation of the polymer is illustrated in Fig. 8, which describes the kinetics of the liberation of furacilin from the above system containing the initial or degraded copolymer.



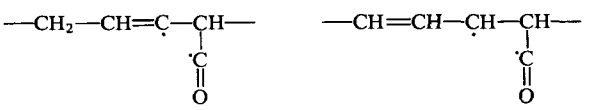


Figure 8. Kinetics of the liberation of furacilin from polyamide coated by the initial (curve *1*) and partially degraded copolymer of maleic anhydride and vinyl acetate. Thermodegradation time (min): (*2*) 10; (*3*) 20.

Following the appearance of the possibility of the simultaneous monitoring of the polymer structure and of its transport properties, good prospects have arisen for the development of new systems in which it will be possible to regulate the rate of liberation of medicinal drugs.

5. Regulation of the stability of water-soluble polymers

Studies by Golubev and coworkers[40, 41] on the regulation of the stability of water-soluble polymers have been published recently. These investigations were undertaken because of the expanding use of such substances in the petroleum industry to make good the non-uniformities in the productive stratum and to increase its coverage when it is flooded. Polymers based on acrylamide are used widely for this purpose. The employment of polyacrylamide

† In the last case, one can postulate the following intermediate states of the chain fragments:

The 1755 cm^{-1} absorption band in the IR spectrum of the partly degraded polymer as well as the appearance of signals at 3.0 and 23 ppm in its ^1H and ^{13}C NMR spectra respectively allow the assumption that the structure of a four-membered ring ketone is more probable than that of other ketones and aldehydes. On this hypothesis, we obtain structure **6**.

(PAA) to increase the extraction of petroleum from the strata has a number of advantages, but at the same time it suffers from a series of important disadvantages. The principal disadvantage is the degradation of PAA under the conditions of joint exposure to elevated temperatures and pressures, shear stresses, as well as metal salts, oxygen, and hydrogen sulfide dissolved in the water within the strata.

Studies on numerous commercial PAA specimens showed that, even when the polymer contains traditional stabilisers, a sharp impairment of the viscous characteristics of aqueous PAA solutions is observed in the presence of iron ions and hydrogen sulfide, especially at elevated temperatures.

The decrease in the viscosity of PAA solutions under the conditions in the strata is associated not only with the degradation of the polymer molecules as such, accompanied by a decrease in the molecular mass, but also with a series of more complex intramolecular and intermolecular processes, cross-links, and conformational changes, which diminish the volume of the macromolecular coil with retention and even an increase in the molecular mass. This has been confirmed by independent methods of measurement, such as viscometry, light scattering, and sedimentation (Table 12).

Table 12. The molecular mass characteristics of polyacrylamide.

Type of influence		Molecular mass/ 10^6 M			
T/ °C	$[Fe^{3+}]$/mg litre^{-1}	M_η	M_w	M_s	$M_{s\eta}$
20	–	8.5 (0)	7.4 (0)	8.3 (0)	8.5 (0)
45	–	1.1 (28)	8.84 (28)	0.91 (28)	0.96 (28)
20	10	3.2 (16)	8.92 (10)	10.8 (16)	8.65 (16)
45	10	3.6 (12)	5.43 (12)	8.52 (45)	10.14 (45)

Note. The molecular mass characteristics were determined for a zero degree of hydrolysis at a PAA concentration of 0.005 mass%; the subscripts to M correspond to the methods used: η = viscometry, w = light scattering; s = sedimentation; the numbers in brackets denote time in days.

Different classes of new PAA stabilisers and metal deactivators, the joint application of which makes it possible to improve significantly the viscous characteristics of aqueous PAA solutions under the conditions of the saturation of the polymer with water, have been investigated.[41]

The copolymers of acrylamide with cationic monomers (dialkyldiallylammonium halides, aminoesters) possess effective flocculating properties. This permits their use in the extraction of petroleum to restrict the inflow of water and also to solve ecological problems, for example, that of the purification of petroleum-containing waste waters. However, it has been established that, during processing in storage, these polymers can lose their solubility in water, probably as a consequence of structure formation in them or they can be degraded, which diminishes their molecular mass.

A study was therefore made of the influence of a series of additives on the stability of polymers in the course of their processing. It was found that mercaptobenz-imidazole and thiourea exhibit a high stabilising activity. Polymers containing 0.3 mass% of these additives do not lose their solubility in water during processing and storage. The intrinsic viscosity of solutions of these polymers is higher than that for polymers processed in the absence of stabilisers.

IV. New approaches to the fundamental investigation and practical application of polymer degradation and stabilisation processes

1. A new approach to the estimation of the physical and thermal parameters of polymers

Askadskii developed in recent years an approach to the estimation of the physical and thermal characteristics of polymers based on the chemical structure of the repeating unit.[42-46] According to this approach, the repeating unit of the polymer consists of a set of anharmonic oscillators each of which consists of a pair of interacting atoms. In order to estimate properties such as the glass and melting points and the coefficient of volume expansion, intermolecular interactions at different levels have been considered: weak (dispersion) and strong (dipole–dipole interaction, hydrogen bonds) due to the presence of polar groups. The temperature corresponding to the loss of stability of such an oscillator characterises the glass and melting points of the polymer.

In order to estimate the temperatures of the onset of the intense thermal degradation of the polymer, when the loss of stability by the set of anharmonic oscillators is due to the dissociation of chemical bonds, chemical reactions are considered. As a result, it is possible to calculate on the basis of the chemical structure of the repeating unit of the polymer, apart from the temperature of the onset of the intense thermal degradation, chemical characteristics such as the glass and melting points as well as a number of other properties—density, refractive index, dielectric constant, the coefficient of the optical sensitivity to stress, the Hildebrand solubility parameter, and the criterion of the solubility of polymers.

In the case of thermal degradation, there is a possibility of estimating by means of the proposed approach the influence of the end groups on the thermal stability of the polymer as well as the influence of other 'weak points' in the composition of the repeating unit.

The possibility, in principle, of synthesising polymers with glass points which are much higher than the temperature of the onset of the intense thermal degradation has been demonstrated.

Askadskii's ideas have been successfully applied to the prediction of the properties of polymer networks, particularly for highly cross-linked polymers, which constitute the basis of many polymeric building materials. In the case of a dense network, the thermal stability of the network nodes themselves and not only the internodal fragments begins to play a major role.

The application of this approach made it possible, in particular, to predict the possibility of obtaining highly cross-linked polymers with extremely unusual properties. Networks containing massive nodes and very short flexible linear fragments between them can have any prespecified modulus of elasticity in the range from 3 MPa to 3 GPa. Despite the fact that these values of the modulus of elasticity are in the intermediate range between those characterising the vitreous and viscoelastic states, such materials have elastic properties and not viscoelastic properties like the majority of polymers.

2. The influence of organic acids on the effectiveness of phenolic inhibitors of the oxidation of polymers

Higher organic acids may be present in the polymer for various reasons: they may be the products of the oxidation of the polymer and can also be present in mixtures of antioxidants. Unfortunately, the contribution of higher organic acids to the effectiveness of the inhibition of the oxidation of polymers has not yet been adequately described in the literature.

The studies of Shlyapnikov and coworkers[47, 48] were devoted to the influence of stearic acid on the effectiveness of antioxidants—2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) (MBP) and the ester of 3,5-di-*tert*-butyl-4-hydroxyphenylpropyldiethyleneglycolic acid (fenozan 28)—in the oxidation of fused isotactic polypropylene (PP).

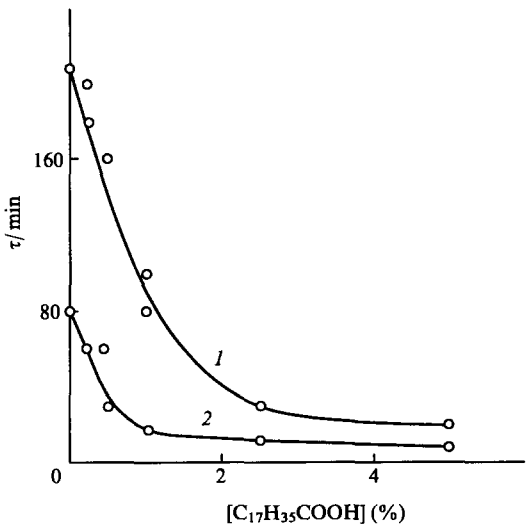

Figure 9. Dependence of the induction period in the oxidation of polypropylene on the concentration of stearic acid in the presence of 0.015 mol kg^{-1} MBP (curve *1*) and fenozan 28 (curve *2*); T = 200 °C; P = 300 torr.

At the same initial concentration of the antioxidant, the induction period in the oxidation of PP diminishes appreciably with increase in the concentration of the acid, the action of the latter on the oxidation process being opposed to that of the antioxidant (Fig. 9).

The dependence of the induction period on the initial concentration of MBP is characterised by the fact that in the initial stage at low concentrations of the antioxidant and MBP the latter slightly retards the oxidation reaction and, after the attainment of a definite critical MBP concentration, the induction period increases (Fig. 10). The critical MBP concentration depends on the amount of acid and increases from 0.0012 mol kg^{-1} (in the absence of the acid) to 0.0053 mol kg^{-1} (at a stearic acid concentration of 0.06 mol kg^{-1}). It is suggested that the acid binds the antioxidant into complexes which do not retard the oxidation process. This leads in its turn to an increase in the critical concentration.

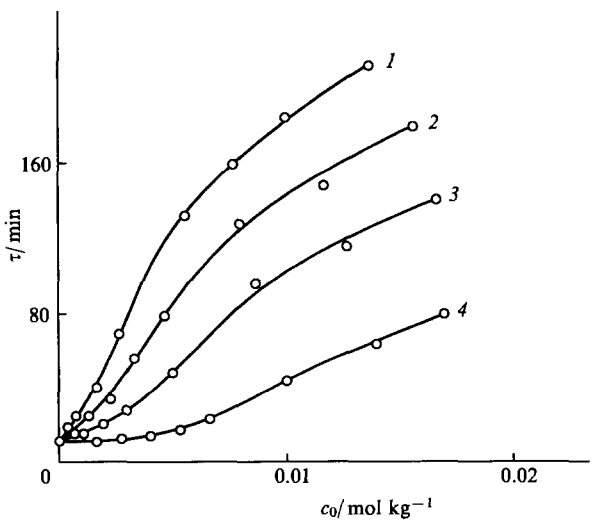

Figure 10. Dependence of the induction period in the oxidation of polypropylene on the MBP concentration in the absence (curve *1*) and in the presence of stearic acid at different concentrations (mol kg^{-1}): (*2*) 0.015; (*3*) 0.03; (*4*) 0.06.

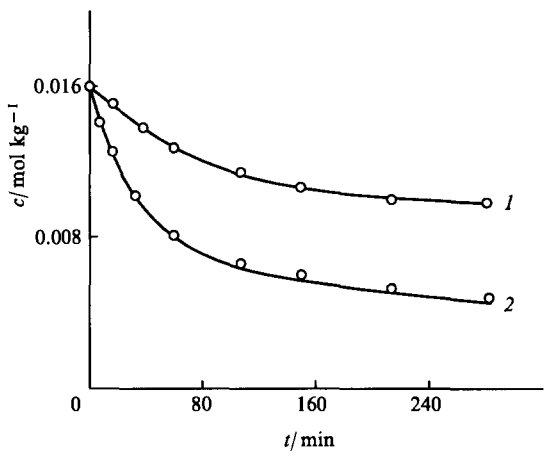

Figure 11. Kinetics of the consumption of MBP in the course of its reaction with stearic acid in polypropylene at 200 °C; initial stearic acid concentration (mol kg^{-1}): (*1*) 0.03; (*2*) 0.06.

Another cause of the observed effect may be the esterification of phenol by stearic acid. In order to confirm the latter hypothesis, specimens of PP containing phenol and stearic acid were heated under a nitrogen atmosphere to 200 °C. In the presence of stearic acid, a slight consumption of phenol was observed, its rate increasing with increase in the initial acid concentration (Fig. 11). A sharp decrease in the induction period and in the critical antioxidant concentration was not observed.

The above phenomena may be explained by the formation of complexes between phenol and the acid and also by the slow reaction between these substances. This leads to the synthesis of the ester, the contribution of which becomes significant only in later stages of the process.

The formation of phenol–acid complexes has been confirmed by the IR spectra of solutions of these substances in CCl_4. A mixture of MBP with stearic acid is characterised by absorption bands at 3840 cm^{-1} (isolated OH groups) and 3520 cm^{-1} (bound OH groups). The absorption of bound OH groups diminishes on complex formation, whilst the absorption band due to isolated hydroxy-groups shifts to (3540 cm^{-1}).

3. Estimation of the effectiveness of antioxidants

The estimation of the effectiveness of antioxidants in polymer systems is a problem the solution of which is of considerable interest from both theoretical and practical points of view. The attempts to find a unique parameter determining the activity of the antioxidant, such as, for example, the oxidation-reduction potential or the rate constant for the reaction of the inhibitor with the peroxyl radical derived from the substrate, have not yielded positive results. The reason for this is primarily the fact that the process involving the consumption of the antioxidant is complex and includes a whole series of reactions involving the antioxidant itself as well as radical and molecular products of its conversion.

According to Shanina,[49, 50] the effectiveness of the antioxidant can be estimated by studying the kinetics of its consumption. The kinetic curves reflect the entire wide variety of the processes occurring in the polymer containing the antioxidant. Comparison of the results obtained at different initial concentrations of the antioxidant makes it possible to estimate the contribution of side reactions, whilst comparison of the kinetic curves for its consumption in the polymer and in an inert medium permits the estimation of the contribution of the inhibitor oxidation process (apparently the main one among side processes which significantly reduce the effectiveness of the antioxidants).

We shall consider two examples of the kinetics of the consumption of phenolic antioxidants in polymer systems.

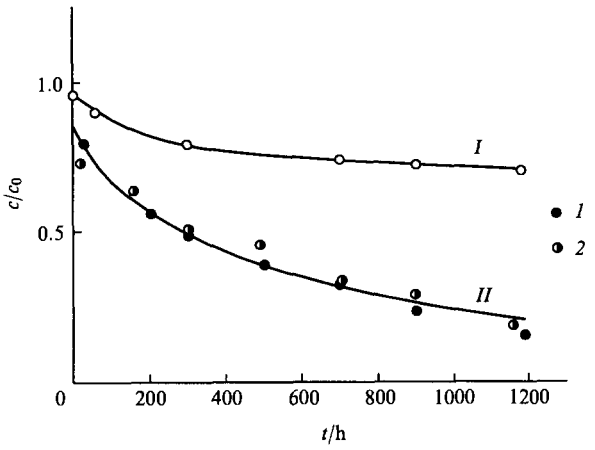

Figure 12. Kinetics of the consumption of antioxidants in isotactic polypropylene (I) Irganox 1076; (II) Topanol CA; concentration (mol kg^{-1}): (*1*) 10^{-2}; (*2*) 2×10^{-3}.

Fig. 12 presents kinetic curves for the consumption in isotactic polypropylene of two industrial antioxidants produced by the Himont Company. Evidently, under experimental conditions in air at 130 °C, the Irganox 1076 stabiliser is consumed much more slowly than Topanol CA. The lower effectiveness of the latter can apparently be accounted for by its slightly sterically hindered structure, which is known to facilitate the occurrence of side reactions. Experimental data confirm this hypothesis. Points corresponding to an initial concentration of 2×10^{-3} mol kg^{-1} were plotted on the curve for the consumption of Topanol CA, obtained at an initial stabiliser concentration of 10^{-2} mol kg^{-1} (relative concentrations of the stabilisers were plotted along the ordinate axis). Despite the fact that the initial concentrations differ by a factor of 5, these points fit satisfactorily on a single curve, i.e. the initial sections of the consumption curves virtually coincide. This shows that an appreciable proportion of the stabiliser is consumed in side processes.

Fig. 13 presents kinetic curves for the consumption of the Nonox WSP stabiliser in the polyethylene–polypropylene (PE/PP) composition at different temperatures. This composition is used in the cable industry for the insulation of optical cable. It is important to note that in the PE/PP blend the antioxidant is consumed at a higher rate than in each of its constituent polymers, which may indicate a higher rate of oxidation of the blend compared with its components.

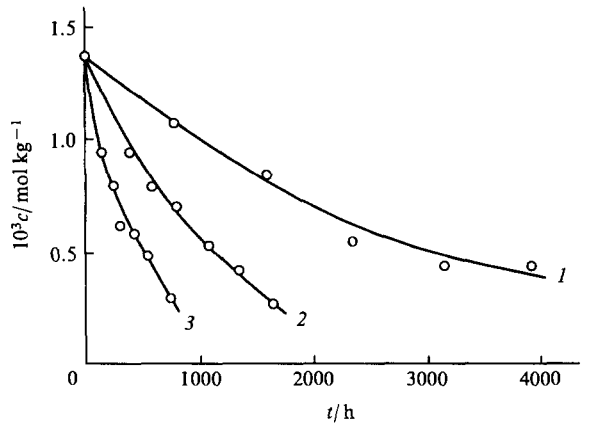

Figure 13. The influence of temperature on the kinetics of the consumption of the antioxidant Nonox WSP in the PE/PP blend; T (°C): (*1*) 60; (*2*) 80; (*3*) 105.

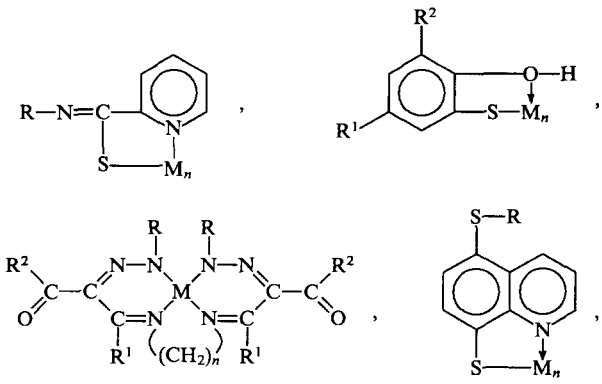
The results permit the estimation of the time required for the consumption of the antioxidant until the attainment of the critical concentration. The accuracy of such an estimate is not very high, but it can serve as a guide in determining the operating stability of the material. Furthermore, the knowledge of the temperature dependence of the rate of consumption makes it possible to extrapolate these rates to any temperatures corresponding to the real operating conditions.



4. The inhibiting properties of heavy metal chelates

Studies on the inhibiting properties of heavy metal chelates have been prosecuted in the course of a number of years by Vinogradova and coworkers.[51–53]

A range of problems associated with the deactivation of alkyl and peroxyl radicals by metal chelate complexes of different classes have ben investigated. Chelates differing in the composition and structure of the chelate units as well as in the nature of the substituents in the ligands and their reactions of the type

$$RO_2^{\cdot} + ML_x \longrightarrow \text{termination},$$
$$R^{\cdot} + ML_x \longrightarrow \text{termination},$$

were investigated. The reactivities of both well known compounds (dithiocarbamates and salicylideneamine complexes) as well as new compounds with N,N-, S,N-, and S,O-containing chelate units, for example

were studied.

The influence of added chelates was investigated in two types of model autoxidation systems: in the oxidation of solutions of polyoxyethylene and its low-molecular-mass analogues, hydrocarbons, and ethers, and in the polymerisation of styrene in solution.

It was shown that the inhibiting activity of the chelates is determined by the composition and hence the properties of the radicals propagating the oxidation chain. The inhibiting activity is different for different oxidation substrates: in ethers and hydrocarbons, only chelates containing sulfur (or selenium) atoms in the chelate units are active, some of them (the copper and antimony chelates) being characterised by a high activity, which is independent of the nature of the substrate. In the oxidation of polyoxyethylenes having different molecular masses, a high inhibiting activity was shown, apart from the sulfur-containing chelates, by compounds with N,N-units. For sulfur-containing chelates in such systems, there is a sharp increase (by more than an order of magnitude) in the inhibiting activity of the chelates. Data have been obtained indicating the possibility of the repeated termination of the oxidation chains of polyoxyethylene involving copper and cobalt chelates and/or their reaction products.

The structure of the ligands of the majority of the chelates investigated contains no functional groups capable of the classical hydrogen atom transfer reaction, which deactivates the peroxyl radicals $RO_2^{\cdot}$ (the OH an NH atoms in phenols and amides). Inhibition is due to the redox mechanism of the interaction between the peroxyl radicals and the chelate units of the complexes.

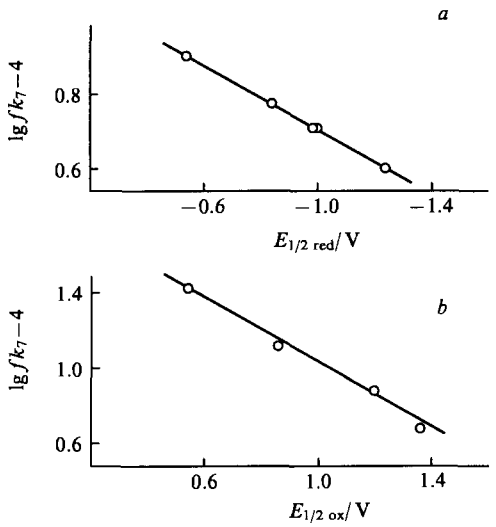


Figure 14. Dependence of the chain termination rate constant on the reduction potentials of copper complexes (*a*) and the oxidation potentials of cobalt complexes (*b*).

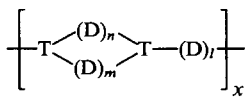
Comparison of the rate constants for the chain termination in the interaction of the $RO_2^{\bullet}$ radical derived from polyoxyethylene with chelates and of the half-wave potentials for the electrochemical oxidation and reduction of the chelates demonstrates the presence of a relation between the 'antiradical' activity of the chelates and the oxidation and reduction potentials of the metal complexes (Fig. 14). This correlation indicates that the peroxyl radicals responsible for the oxidation of polyoxyethylene have dual, i.e. oxidising and reducing, properties.

In the interaction with arylalkyl radical R$^{\bullet}$ (in the polymerisation of styrene), the highest reactivity is manifested by the sulfur-containing copper(II) and iron(III) chelates. The inhibiting properties are also characteristic of the cobalt analogues of the above chelate complexes. Copper chelates with nitrogen and oxygen atoms in the chelate unit exhibit catalytic properties.



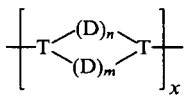
Comparison of the oxidation-reduction properties of chelates and their activities in the inhibition of the polymerisation of styrene showed that in this instance two mechanisms of the interaction of the chelates with the R$^{\bullet}$ radicals operate — a redox mechanism accompanied by the reduction of copper(II) to copper(I) and a mechanism involving the transfer of a hydrogen atom from the activated ligand in the chelate.

5. Stabilisation of polydimethylsiloxanes by the introduction of cyclic fragments into the linear chain

The stabilisation of linear polyorganosiloxanes by the introduction of cyclic fragments both into the chain and into the side groups has been the subject of the latest studies by Khananashvili and coworkers.

It is known that the introduction of various cyclic fragments into the linear dimethylsiloxane chain leads to the decomposition of the helical structure of the polymers and hence alters their physicochemical properties. The glass point can be varied within a wide range by merely altering the organic groups attached to the silicon atoms in the linear macromolecules. As a result of the extensive possibilities for the structural modification of polysiloxane chains by the introduction into the latter of polyfunctional branching centres, mono- and poly-cyclic fragments having a different structure [spirocycles and condensed rings (for example sections corresponding to a 'ladder' structure)], and others, polysiloxanes occupy an exceptional position as excellent model systems for the creation of polymeric materials with a set of physicochemical properties capable of being varied over a wide range.

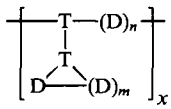
The influence of the introduction into the dimethylsiloxane chain of organocyclotetrasiloxanes, organocyclopentasiloxanes, and organocyclohexasiloxane with a 1,5- and 1,7-disposition of the organocyclohexasiloxane fragments in a chain of the following composition has been demonstrated:



$n, m = 1, 2, 3; n \neq m,$
$l = 2-50$

where D are siloxane units and T are silsesquioxane units.

The principal process leading to the degradation of such copolymers begins at a temperature higher by 80–100 °C than for linear polydimethylsiloxanes.[54–56] A similar result was achieved by introducing cyclocarbosiloxanes and bissiloxaindan fragments into the dimethylsiloxane chain.[57, 58]



When cyclic fragments are introduced into the linear dimethylsiloxane chain, the copolymers are stabilised, since the cyclic fragments prevent, during depolymerisation, the chain transfer, which proceeds with formation of type D organocyclosiloxanes.

The synthesis of a new class of copolymers, occupying an intermediate position between linear and ladder polymers, has been described.[59, 60] The ratio of the D and T units can be varied in such copolymers. It was shown that, by varying the ratio of the D and T units in the atactic polymer, it is possible to vary the properties of copolymers having the following composition:

$n, m = 1, 2; n \neq m.$

Studies have also been carried out on the synthesis of new copolymers in which the branching segments are organocyclosiloxanes distributed regularly in the side chain.[61, 62]

$m = 1, 2, 3;$
$n = 2-30.$

It has been shown that, with increase in the bulk of the cyclic fragments, the thermooxidative stability of the copolymers diminishes. In addition it has been demonstrated that copolymers with cyclic fragments in a side chain behave in the same way as copolymers with cyclic fragments within the main chain.

6. The ageing of the ABS plastic under atmospheric conditions

In the latest studies by Seitablaev and Kalontarov[63, 64] the influence of climatic factors on the physicomechanical, electrical, and structural properties of acrylonitrilebutadienestyrene (ABS) plastic of type 2020 S were investigated under the conditions of prolonged exposure to the atmosphere in various regions of Tajikistan at different heights above sea level: in the mountain settlement Gissar, 800 m, non-industrial zone; in Dushanbe, 890 m, industrial zone; in the mountain gorge Varzob, 1 700 m; on the mountain pass Anzob, 3 372 m.

It was established experimentally that, during the initial period of the climatic tests on the ABS plastic specimens, the degradation processes predominate greatly over structure formation processes. During the first 1.5–2 months of atmospheric ageing, the decrease in the breaking stress (σ_r) is 28% – 30% and the relative deformation leading to rupture (ε_d) is reduced to 80%. This is followed over the three years by slow ageing processes, whilst towards the fourth year an increase in σ_d is observed. IR spectroscopic studies showed that, during the first 100–200 h of atmospheric ageing, the formation of C=O groups takes place most vigorously (the 1720 cm^{-1} band). After the saturation of

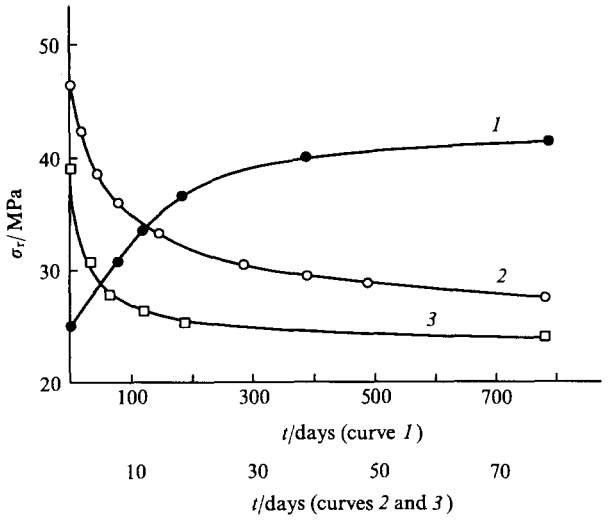


Figure 15. Dependence of the breaking stress (σ_r) for the ABS plastic on the exposure time in an enclosed space (curve *1*) and in open areas (curves *2* and *3*).

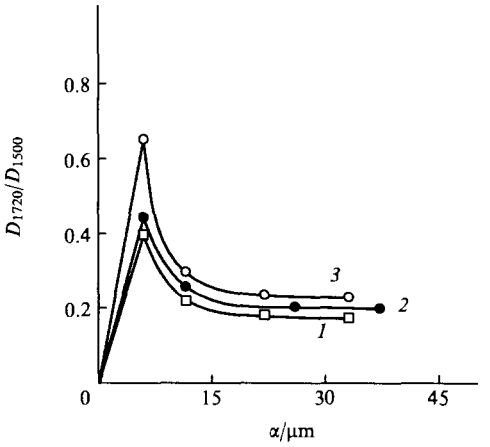

Figure 16. Dependence of the ratios of the optical densities on the thickness of the layer of the ABS plastic undergoing degradation in tests in the Dushanbe climatic area in the course of different periods (days): (*1*) 4; (*2*) 7; (*3*) 13.

surface layers by oxygen-containing products and the closure of the so called channels for the free access of oxygen into the deeper layers of the plastic, a monotonic decrease in σ_d is observed. Under the conditions of prolonged 'oxygen starvation', dark reactions begin to be manifested. Their occurrence is indicated by the increase in σ_d after ageing for 3 years on open areas exposed to the atmosphere. A similar situation has been observed also in specimens stored for a long time under laboratory conditions after climatic tests.

Thus under the conditions of natural ageing of the plastic, dark reactions are manifested towards the fourth year of exposure, whilst under conditions where the influence of atmospheric factors has ceased they become apparent towards the beginning of the 'rest' period. The tensile strength of the plastic after a year's 'rest' is restored to 87% of its initial value, i.e. an increase in σ_d by 34% is observed (Fig. 15).

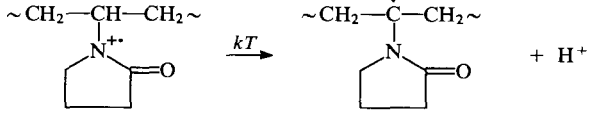
A considerable accumulation of defects in the first stage of the ageing process is known to be associated with the intense degradation processes in the surface layers of the plastic. It has been established experimentally that, as the surface layer of specimens aged for a short time (2–3 months) is removed, both the strength and viscous properties are restored. On the other hand, in the specimens subjected to prolonged climatic influences (for a year and more), this is not observed and subsequently quasi-brittle decomposition takes place. This finding is explained by the predominance in the bulk of the plastic of cross-linking reactions over degradation processes, which has been confirmed by studies on gel formation. During the first 12 months of ageing, the content of the gel fraction diminishes by 10%–30%, while after an increase in the ageing period from 12 to 48 months, the content of the insoluble fraction rises by 30%–40%. Furthermore, in the specimens aged in the Dushanbe climatic area the degree of gel formation is higher than in the specimens aged in other areas. The high degree of contamination of the atmosphere and the increased temperature of the air probably have an effect here. IR spectroscopic studies on different layers of the plastics showed that the dependence of the ratio of the optical densities D_{1720}/D_{1500} on the thickness of the degraded layer is exponential and, furthermore, with increase in the duration of the exposure during the initial ageing period the degradation processes proceed most vigorously in a surface layer having a depth up to 10 μm, where the C=O groups mainly accumulate (Fig. 16).

Fractographic analysis of the specimens after natural climatic ageing showed that the structure of the surface of the plastic has undergone appreciable changes—microcracks appeared. This is characteristic of all the regions where the specimens were tested. With increase in the ageing period, the number of microcracks and their density also increase.

Thus it has been established that the nature of the decomposition of the ABS plastic under different climatic conditions is determined by processes leading to the degradation of the surface layers and structure formation in the bulk of the material.

7. Radical processes in filled polymers

In filled polymers, boundary layers, the properties of which differ appreciably from the polymer bulk phase, are formed near the surface of the filler particles. It has been shown that the structural features of the boundary layers affect the kinetics of the elementary radical reactions. Thus a dependence of the effectiveness of the thermal reaction of the radical-cations generated at 77 K by the photochemical reduction of iron(III) chloride in polyvinylpyrrolidinone (PVP) on the content of the aerosil filler has been observed.[65, 66]



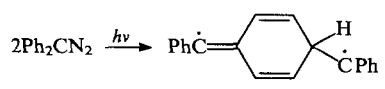


Fig. 17 presents the relative concentrations of macroradicals during the thermal reaction of the radical-cation in PVP without a filler and with 15 and 50 mass% of aerosil. The maximum relative amounts of the macroradicals characterise the fraction of their precursors stabilised at 77 K during the reduction of iron(III) chloride. It was found that in the highly filled specimens (~50% of aerosil) only 10% of the radical-cations are stabilised at 77 K, whereas in the unfilled specimens approximately 70% are stabilised.

In solid polymers [polycarbonate, poly(methyl methacrylate)], the dimerisation of diphenylcarbenes in the quasi-clusters of the added diphenyldiazomethane (DDM), accompanied by the formation of biradicals in which the distance between the unpaired electrons is $r \simeq 5$ Å, was observed.

The relative yield of the biradicals, recorded by the EPR method, serves as a quantitative characteristic of the non-uniformity of the distribution of the low-molecular-mass additive.

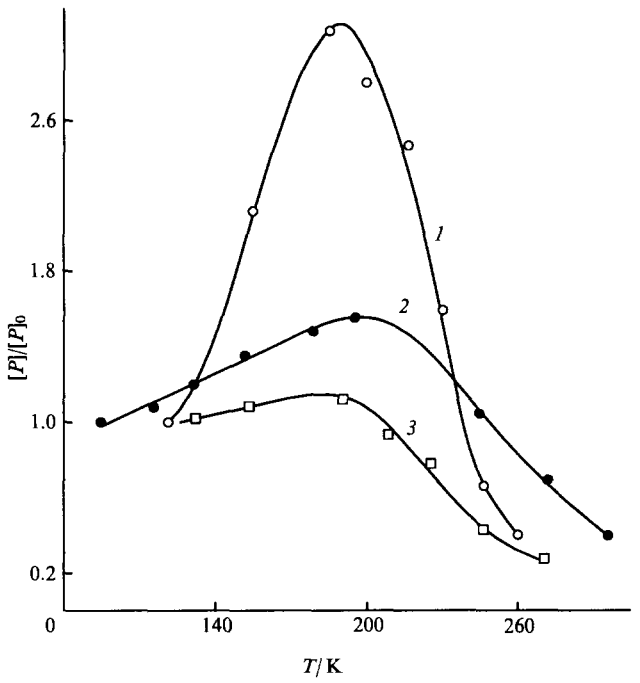

Figure 17. Variation of the concentration of macroradicals during the heating of PVP with $FeCl_3$ irradiated at 77 K: (*1*) without filler; (*2*) 15 mass% of aerosil; (*3*) 50 mass% of aerosil.

Fig. 18 presents the dependence of the yield of the biradicals in the polymer on the additive concentration. At fairly high concentrations (~0.1 M), biradicals with $r \simeq 10$ Å were detected. They are formed in larger quasi-clusters. The study of the dependence of the yield of the biradicals made it possible to estimate the non-uniformity of the distribution of various low-molecular-mass additives whose structures is similar to that of diphenyldiazomethane, for example, photostabilisers, antioxidants, and photosensitisers (salicylates, bisphenols, and benzophenones).

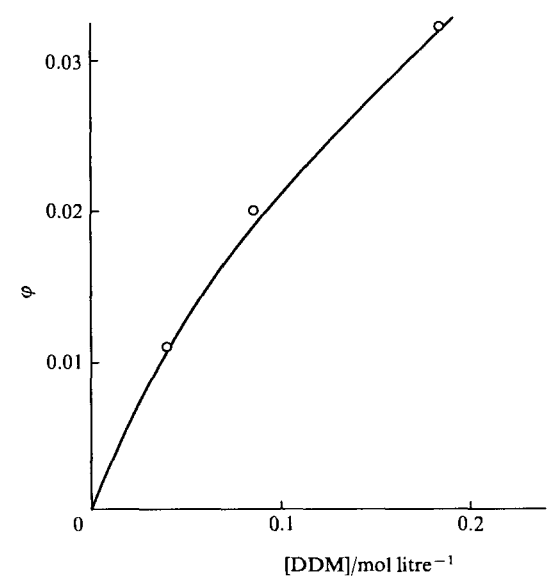

Figure 18. Dependence of the yield of biradicals on the concentration of diphenyldiazomethane in polycarbonate.

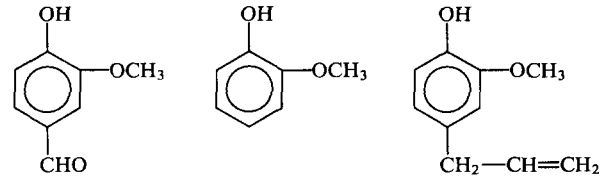
8. The inhibiting capacity of natural phenols in radical reactions

Askarov and Saidov[67] estimated the reactivities of a series of natural phenols such as vanillin, guaiacol, eugenol, and gossypol in the model cumene oxidation reaction. Their approach makes it possible to estimate rapidly and quantitatively the ability of various additives to inhibit radical reactions and to reach thereby a preliminary conclusion about the usefulness of the further employment of such substances as stabilisers for polymeric materials. These compounds are also interesting because they can be obtained from reproducible sources — plants and seeds.

In the initiated chain reaction involving the oxidation of cumene (isopropylbenzene), the inhibiting capacity of the additive is estimated in terms of the rate of constant k_7 in the classical oxidation mechanism. For this purpose, the induction period is determined in a preliminary step from the slope of the kinetic oxidation curve under the conditions of fairly long chains:



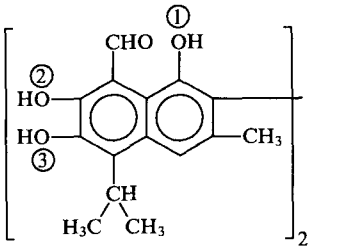
$$\tau = f_n \frac{[\mathrm{InH}]}{W_i},$$

where n is the number of inhibiting groups in the inhibitor molecule, f the inhibition coefficient for one group, [InH] the initial inhibitor concentration, and W_i the rate of initiation.

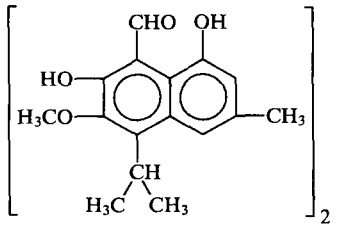
The inhibition rate constant k_7 is then determined from the relation

$$\frac{[\mathrm{O_2}]}{[\mathrm{RH}]} = -\frac{k_3}{k_7} \ln\left(1 - \frac{t}{\tau}\right),$$

where $[O_2]$ is the amount of absorbed oxygen (mol litre^{-1}), [RH] the amount of cumene taken for the reaction (mol litre^{-1}), and k_3 the chain propagation rate constant (for cumene at 60 °C, $k_3 = 1.75$ litre mol^{-1} s^{-1}).

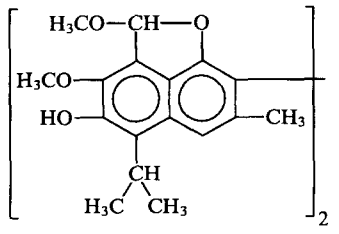


vanillin $k_7 = 3.6 \times 10^{-3}$, guaiacol $k_7 = 5 \times 10^{-3}$, eugenol $k_7 = 1 \times 10^{-4}$.

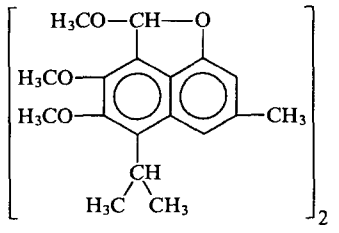


A typical initiated and inhibited cumene oxidation curve as well as its logarithmic form are presented in Fig. 19. The ratio k_3/k_7 is determined from the slope of the logarithmic plot and then k_7 is found. The corresponding calculations yielded the following inhibition rate constants (litre mol^{-1} s^{-1}):

These data make it possible to reach a conclusion about the nature of the influence of the substituent in the *para*-position (with the inevitable presence of a methoxy-group in the *ortho*-position). The transition from the electron-accepting aldehyde group to the electron-donating allyl group leads to a successive increase in k_7. This provides grounds for the assumption that the role of the substituents must always be taken into account in predicting the subsequent application of substances as inhibitors. The Hammett constant of the substituent permits a preliminary conclusion about the usefulness of the antioxidant for the inhibition of the oxidation of particular polymers.



The study of gossypol and its derivatives concerned mainly the determination of their physiological properties. The use of gossypol as an antioxidant in the oxidation of various classes of substances, including polymers, appears promising. In the first place, this is associated with the enormous renewable raw materials base for its preparation. For a detailed estimation of the reactivity of each of the numbered hydroxy-groups, a series of derivatives of the methyl ethers of gossypol were obtained.



Gossypol
T_m = 282–284 °C ,

Dimethylgossypol
T_m = 168–170 °C ,

Tetramethylgossypol
T_m = 205–207 °C ,

Hexamethylgossypol
T_m = 210–215 °C .

It is noteworthy that hexamethylgossypol does not exhibit an inhibiting effect on the initiated oxidation of cumene.

The subsequent study of the role of the hydroxy-groups responsible for the inhibition of the oxidation reaction can be conveniently begun with tetramethylgossypol. Calculation based on the results presented in Fig. 19 yielded $k_7 = (0.83 \pm 0.03) \times 10^{-4}$ litre mol^{-1} s^{-1} for this compound. When cumene is oxidised in the presence of dimethylgossypol, we are apparently dealing with hydroxy-groups differing in their reactivity. This conclusion was reached on the grounds that a break point is clearly observed on the logarithmic form of the curve (Fig. 20). This shows that, after the consumption of the 'stronger' hydroxy-groups during the induction period, the 'weaker' groups begin to be consumed. From the slope of the logarithmic curve, we obtain respectively for the initial and final sections of the kinetic curve

$$k_7 = (5 \pm 0.04) \times 10^{-4} \text{ litre mol}^{-1} \text{ s}^{-1} ,$$

$$k_7 = (0.85 \pm 0.04) \times 10^{-4} \text{ litre mol}^{-1} \text{ s}^{-1} .$$

There is also only one point of inflection on the logarithmic form of the cumene oxidation curve in the presence of gossypol. This justifies the conclusion that one pair of hydroxy-groups have approximately the same reactivity. If all three types of hydroxy-groups had different reactivities, two points of inflections with three sections of the logarithmic plot would have appeared. Calculation of k_7 for gossypol yielded the following values:

$$(5.2 \pm 0.05) \times 10^{-4} \text{ and } (0.8 \pm 0.04) \times 10^{-4} \text{ litre mol}^{-1} \text{ s}^{-1} .$$

It appears logical to assume that the hydroxy-groups in the 2- and 3-positions have the same reactivities.

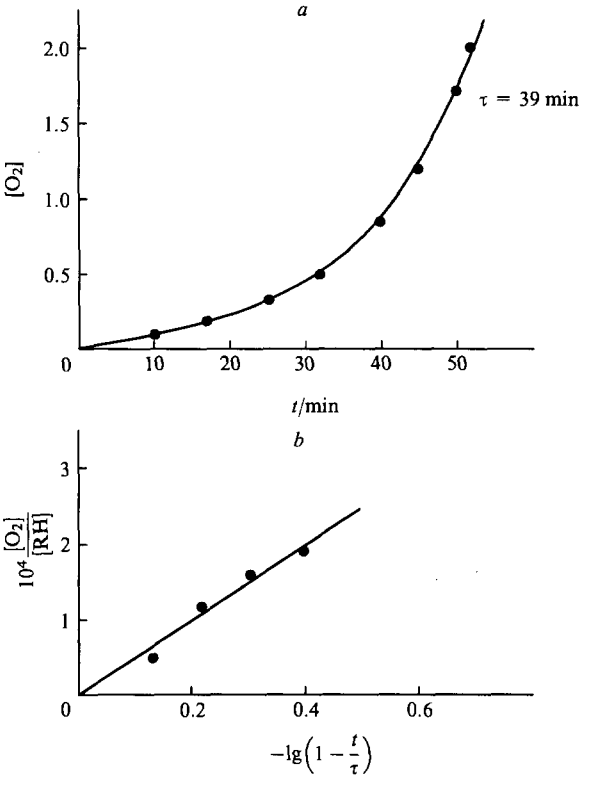


Figure 19. Curve for the initiated oxidation of cumene in the presence of tetramethylgossypol (*a*) and its logarithmic form (*b*); [InH] = 10^{-5} M; $W_i = 1.26 \times 10^{-8}$ mol litre^{-1} s^{-1}.

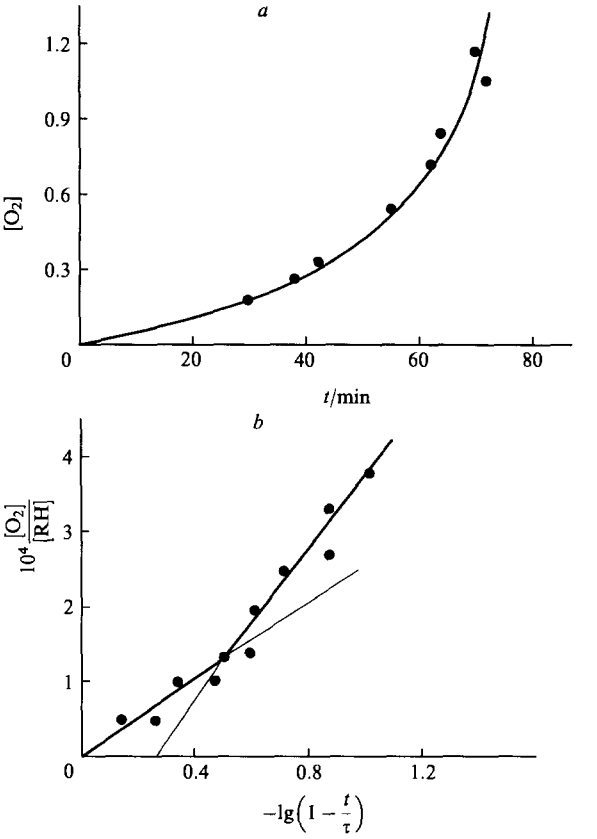

Figure 20. Curve for the initiated oxidation of cumene in the presence of dimethylgossypol (*a*) and its logarithmic form (*b*); [InH] = 1.2×10^{-1} M; $W_i = 5.44 \times 10^{-8}$ mol litre^{-1} s^{-1}.

Since $k_7 = (0.83 \pm 0.03) \times 10^{-4}$ litre mol^{-1} s^{-1} for the OH group in the 3-position (tetramethylgossypol), it is difficult to postulate that $k_7 = (5 \pm 0.04) \times 10^{-4}$ litre mol^{-1} s^{-1} can be assigned to the hydroxy-group in the 2-position. This becomes particularly evident if the constants k_7 for gossypol and its derivatives are compared with the corresponding values for vanillin, guaiacol, and eugenol taking into account the nature of the substituents in the corresponding positions relative to the hydroxy-group. Therefore $k_7 = (5.2 \pm 0.05) \times 10^{-4}$ litre mol^{-1} s^{-1} should be assigned to the hydroxy-group in the 1-position.

In contrast to synthetic sterically hindered phenols, for the majority of which the inhibition rate constant (of the order of 10^{-4} litre mol^{-1} s^{-1}) depends little on the nature of the substituents (provided that they are not highly polar), in the case of sterically unhindered phenols the role of substituents is more pronounced. If the chemical formula of a potential stabiliser (antioxidant) of radical processes is known, then, taking into account the nature and positions of the substituents, it is possible to predict the behaviour of the compound. It must be emphasised that the estimates are preliminary. The final conclusion about the usefulness of a particular compound as a stabiliser can be reached only taking into account the results of technological tests.

9. Structural model of the autoxidation of polypropylene

The autoxidation model proposed by Mikheev and coworkers[68-71] includes heterophase-coupled reaction chains distributed among non-uniform structural zones of the polymer being oxidised. The operation of the heterophase mechanism had been demonstrated previously in relation to the modification of polymers by benzoyl peroxide.

The autoxidation of PP has a number of characteristic features which cannot be explained within the framework of the traditional mechanism of the homogeneous oxidation of hydrocarbons. Some of these features have become the subject of acute controversy in the literature, whilst others remained unnoticed. The latter include the presence of kinetic macroscopic stages due to the change in the reaction order with respect to the hydroperoxide (HP). It is possible to distinguish three stages.[72]

In the first stage, which is of average duration (induction period), the oxidation proceeds via an unbranched chain reaction and the accumulating hydroperoxide does not catalyse the process. The hydroperoxide becomes a catalyst (branching agent) in the second stage. To date theoretical studies have been concentrated on the second stage. It is brief and the degree of oxidation during this period is small. This period is convenient for the conservative employment of the established oxidation mechanism for liquid hydrocarbons.

The third stage of the oxidation of PP is prolonged and is characterised by a zero reaction order with respect to the hydroperoxide. The latter is the principal process initiator in this stage. A similar situation had been observed earlier for the oxidation of poly(ethylene oxide) and was accounted for by a heterophase mechanism.[73, 74]

Furthermore, the oxidation of PP exhibits a specific dependence of the rate on the oxygen pressure P. The dependence is different for the initial and subsequent stages. Namely, during the induction period the rate of oxidation increases gradually over a very large range of values of P but it reaches saturation rapidly as a function of P in the subsequent stages. This property has not been explained.

The problem of the mechanism of the degradation of macromolecules in the oxidation process also remained unsolved. It was established that the rate of degradation in the initiated process is directly proportional to the rate of initiation (macroradicals are destroyed). A mechanism was proposed for the degradation of polymer chains in the oxidation chain with quadratic termination steps. However, this mechanism does not explain the effect of inhibitors. Degradation is known to occur even when the inhibitor fully suppresses the oxidation chains.

The above features agree with the heterophase mechanism based on the micellar-cellular model of the supermolecular structure of the non-crystalline polymer (the oxidation reaction involves primarily the non-crystalline PP phase).[75, 76]

The model is based on the consideration of two structural zones within the polymer globules made up a large number of macromolecules. The point is that the polymer chains encapsulated in the globule form a conglomerate of micropores. The surface forces operating in this conglomerate compress the internal micropores (the v-zone) but at the same time stretch and increase the size of other micropores adjoining the rigid envelope of the globules (the s-zone). This alters in its turn the reactivity of the reactants belonging to different micropores and is the cause of the kinetic polychromaticity. In particular, the narrow v-micropores suppress the reactivity as regards dissociation of the hydroperoxide and the impurity initiator. Dissociation takes place in the spacious s-micropores. Furthermore, elastic mechanical forces suppress the macroradical decomposition steps in the compressed v-zone but promote degradation in the extended sections of the chains of the s-zone.

The primary formation reactions of macroradicals as well as their degradation and destruction take place in the micropores of the s-zone. The s-mechanism should not include the hydroperoxide formation reaction. The latter occurs in another reaction chain, in the v-zone, by virtue of the interzonal s–v transfer of the free valence.

$$PH_s + O_{2s} \xrightarrow{k_{0s}} \delta_1 P_s^{\bullet}, \qquad P_s^{\bullet} \longrightarrow R_s^{\bullet}\text{(degradation)},$$

$$R_s^{\bullet} \xrightarrow{k_{1s}} R_{1s}^{\bullet}\text{(isomerisation)}, \qquad R_s^{\bullet} + R_{1s}^{\bullet} \longrightarrow \text{(products)}.$$

The mechanism of the s–v transfer includes steps (which occur with a low probability) involving the transfer to the thermal $R_s^{\bullet}$ radicals from the lattice structure of the s-micropore and conversely as well as the oxidation of $R_m^{\bullet}$ within the volume of the micropore and the ejection of HO$^{\bullet}$.

$$R_s^{\bullet} \underset{k_{-m}}{\overset{k_m}{\rightleftharpoons}} R_m^{\bullet},$$

$$R_m^{\bullet} + O_{2s} \xrightarrow{k_{tr}} RO_{2m}^{\bullet} \longrightarrow HO_m^{\bullet}.$$

The light hydroxyl penetrating into the v-zone initiates the oxidation chains

$$HO_m^{\bullet} \longrightarrow HO^{\bullet} \xrightarrow{PH} P^{\bullet}, \qquad P^{\bullet} + O_2 \xrightarrow{k_1} PO_2^{\bullet},$$

$$PO_2^{\bullet} + PH \xrightarrow{k_2} POOH + P^{\bullet}, \qquad 2PO_2^{\bullet} \xrightarrow{k_3} \text{termination}.$$

As it accumulates, the hydroperoxide begins to pass from the v-zone to the s-zone, i.e.

$$HP_v \xrightarrow{k_{vs}} HP_s,$$

as a consequence of which steps involving the generation of the radicals HP_5, i.e.

$$HP_s \xrightarrow{k_{0s}} \delta P_s^{\bullet},$$

and the heterogeneous non-radical bimolecular reaction

$$HP_v + HP_s \xrightarrow{k''} \text{molecular products},$$

are included in the process. The latter reaction limits the rate of generation of the radicals and ensures the attainment of a stationary rate of the oxidation process in a zero order reaction with respect to the hydroperoxide.

The above mechanism reproduces the principle of the heterophase conjugation of the s- and v-reaction chains and entails the non-equivalent involvement in the chains of the oxygen dissolved in the polymer. The O_2 molecules (like those of other low molecular mass compounds) are localised within the micropores under the influence of surface forces. This results in steric hindrance to the oxidation reaction, which promotes within the micropores of the s-zone the destructive pathway competing with the oxidation reaction and involving the conversion of alkyl macroradicals into $P_s^{\cdot}$. On the other hand, in the v-zone the destruction of the $P^{\cdot}$ radicals is suppressed by the change in structure and the radicals are oxidised.

In the initial stage of the heterophase reaction, oxygen participates twice in the stages determining the rate of the process: in the radical generation steps with participation of CH_2 groups and in the s–v free valence transfer steps. As a consequence of such 'double initiation', the rate of oxidation is initially

$$W^{(1)} = k_2[\mathrm{PH}][\mathrm{PO}_2^{\cdot}]_1 = \frac{aP}{\sqrt{b+P}} \simeq \tau_{\mathrm{ind}}^{-1},$$

where a and b are constants subject to the condition that the microporous structure does not change in the course of the oxidation reaction.

As a result of the migration of the hydroperoxide into the s-zone, the hydroperoxide becomes the main source of radicals and after a time increases the rate of reaction as a result of the increase in the rate of initiation:

$$W^{(2)} = \frac{\delta k_{0s} k_{vs} g}{(k_{0s} + k'' g)} \gg \delta_1 k'_{0s}[\mathrm{PH_s}][\mathrm{O_{2s}}],$$

where g is the hydroperoxide concentration, but after a short autoaccelerated stage, the maximum rate of initiation is established for a long period:

$$W_i^{(3)} = \frac{\delta k_{0s} k_{vs}}{k_{0s}}.$$

It is independent of the overall hydroperoxide content. In stages (2) and (3), the role of oxygen in the generation of radicals is negligible, but it retains its influence as a participant in the interzonal transfer of radicals.

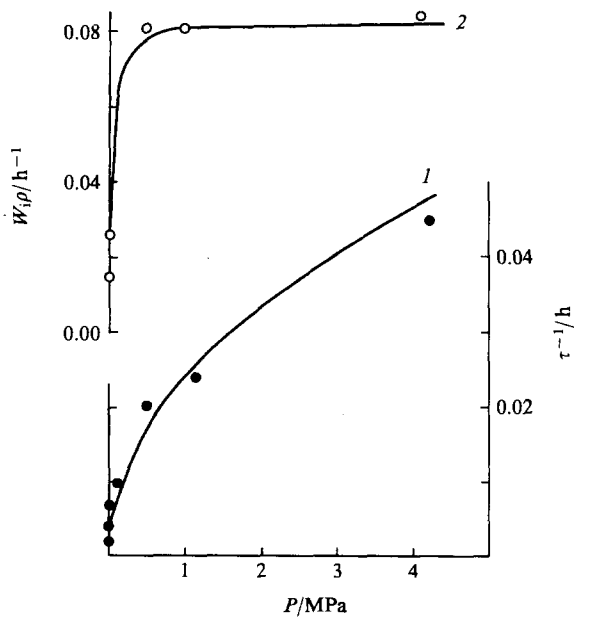

Figure 21. Dependence of the induction period (curve *1*) and of the maximum rate of oxidation of polypropylene (curve *2*) on the oxygen pressure; T = 90 °C.

The rate of oxidation is now described by the expressions

$$W^{(2)} \simeq \left(\frac{P_0}{b+P}\right)^{0.5} \left(\frac{\delta k_{0s} k_{vs}}{c+g}\right)^{0.5},$$

$$W^{(3)} \simeq \left(\frac{P}{b+P}\right)^{0.5},$$

where b and c are constants and $W^{(2)}$ and $W^{(3)}$ differ from $W^{(1)}$ by faster saturation as a function of P.

The calculated $W^{(1)}(P)$ and $W^{(3)}(P)$ curves for PP and polyethylene (PE) oxidation are presented in Figs 21 and 22. Experimental data have been obtained for PP films[77] and for a PE melt.[78] The unique mechanism of the oxidation in all stages of the process is confirmed by the finding that the expressions for $W^{(2)}$ and $W^{(3)}$ include the same value of b: 0.1 MPa for PP and 10, 50, and 200 torr for PE at 141 °C, 157 °C, and 165 °C respectively.

The observed correspondence between the calculated curves and the experimental points permits the conclusion that the heterophase mechanism predominates over the traditional homogeneous oxidation mechanism in relation to a hydrocarbon polymer, which differs fundamentally from a homogeneous liquid by its supermolecular organisation.

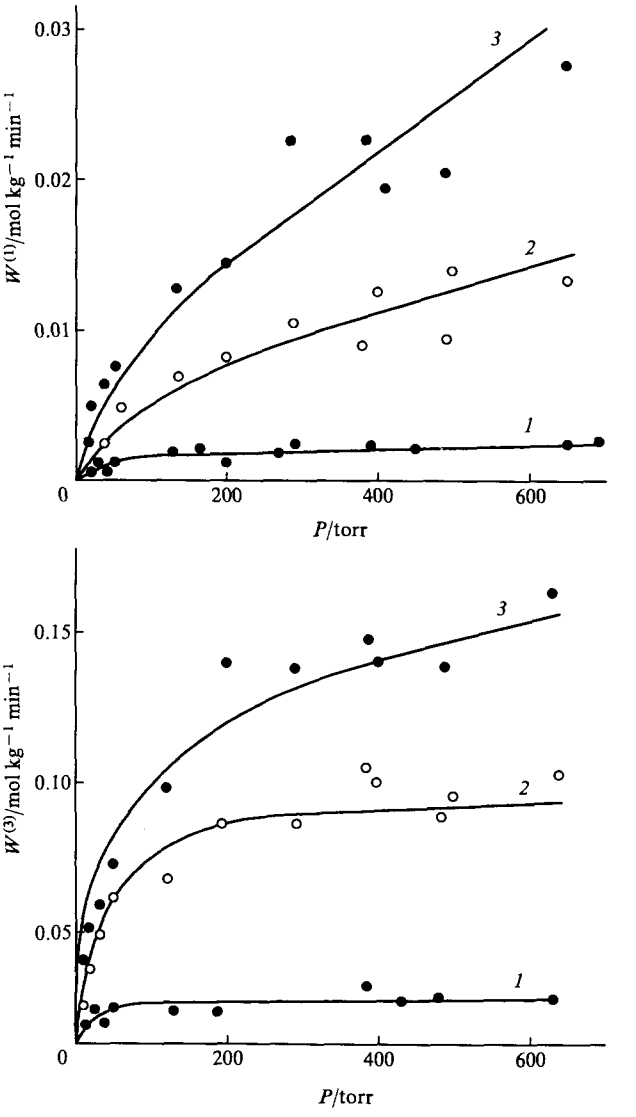

Figure 22. Dependence of the rate of oxidation of polyethylene on the oxygen pressure; T(°C): (*1*) 141; (*2*) 157; (*3*) 165.

Abstract. Recent data on the effect of the polarity of the medium on the state of solute molecules having different types of chemical bond are reviewed. The changes in electronic structure and in the energetics of the molecules are discussed, and their influence on the physicochemical properties and role of the molecules in various liquid-phase processes (tautomeric and con-formational transformations, nucleophilic substitution, proton transfer) is examined. Special attention is paid to the new concept of preferential stabilisation of molecular and of ionic forms of salts and of complexes with intermolecular hydrogen bonds in media of different polarity. The bibliography includes 98 references.

I. Introduction

The influence of the medium on the state and properties of substances in solution (a problem first formulated towards the end of the last century) continues to stimulate the interest of research workers, because the properties of the solvent play a substantial (and often a dominant) role in the thermodynamics and kinetics of many important liquid-phase processes. Various aspects of the effects of solvation on the energetics and dynamics of these processes, the role of structural changes in the solvent, and the influence of the solvent on the reaction kinetics and on the physicochemical characteristics of dissolved substances have been discussed in several reviews and monographs.[1-13] However, like many of the original papers, the review literature fails (in our view) to give due weight to the influence of solvation on the electronic and the geometrical structure of the solute molecules. Thus, recent studies have shown that the transfer of molecules from the gas phase to a strongly solvating medium can result in marked structural changes, due to electron donor–acceptor (EDA) interactions between the solvent and the solute molecules (specific solvation) or to the polarising effect of the medium (nonspecific solvation).

Both experimental and calculated results suggest that the role of nonspecific solvation in the structural change of dissolved molecules can be as important as the role of specific solvation. Thus, in a very polar solvent a substantial charge separation can take place in easily polarisable molecules, leading to a transition to the ionic state. Furthermore the interaction with the polar medium also affects the electronic structure of the molecular complexes produced by the EDA interaction. As has been reported,[14-21] an increase in the dielectric permittivity (ε) of the medium increases the intermolecular charge transfer in these complexes, which can lead to the creation of ionic forms in specifically solvating media with a high value of ε. Large changes in the relative acidity and basicity of compounds, in the rates of (electron or proton) charge transfer reactions, and shifts in the tautomeric and other equilibria are also possible.

The aim of the present review was to highlight the general features of changes in the electronic and the geometrical structure of molecules under the influence of a polar medium and to show how these changes are reflected in the physicochemical properties of the molecules (such as dipole moments, spectral characteristics, etc.), in their solvation energy, and in their ionisation in solutions, and also in processes which are controlled by these properties.

II. Theoretical approaches to the problem

The rapid developments in theoretical methods of studying solvation effects during the last two decades[1-4] created a much wider understanding of the nature of changes stimulated in various systems by the presence of a solvent. However, even the most recent theoretical studies[1, 2] have not allowed adequately for the polarising effect of the medium on the electronic structure of molecules and of molecular complexes in solution. Three basically different approaches can be identified among the computational methods used in studies of solvation processes: statistical calculations by the Monte Carlo method (MC) and by molecular dynamics (MD), quantum-chemical calculations on the molecule to be solvated and on its nearest-neighbour solvent molecules (treated as a single super-molecule), and lastly calculations in the continuum approximation, in which the solute molecule is treated as surrounded by a continuous medium with a known value of ε. The polarising effect of the medium is usually ignored in the MC and MD methods, which treat the solvated molecule as a geometrically rigid species with an invariant electronic structure, whereas in the super-molecule approach no allowance is made for the influence of the whole volume of the polar solvent on intermolecular charge transfer.

Simkin and Sheikhet have described the theoretical methods of calculating the solvation effects, and have compared their

prospects when applied to various aspects of the problem, in a recently published monograph[2] as well as in earlier reviews.[3, 4] As they clearly state,[4] no one method can be classified as 'good' or 'bad': the most important consideration is that the method should be adequately matched to the problem of interest.

Since the structure of the solvent and the mobility of its molecules in the solvation shell can be analysed only by the MC and MD methods, whereas the supermolecular approach is better suited to studies of specific solvation, in the absence of specific solvation it is more rational to use quantum-chemical calculations (which allow for the effect of the medium in the continuum approximation) in studies of the effect of the polarity of the medium on the electronic structure of solute molecules.

The distribution of electron density and the energy of a molecule immersed in a dielectric continuum are calculated by the Schrödinger equation in one of its approximations, defining the Hamiltonian of the molecule immersed in the medium as

$$\hat{H} = \hat{H}_0 + \hat{U}; \tag{1}$$

$\hat{H}_0$ is the Hamiltonian of the molecule in a vacuum and $\hat{U}$ is an operator describing the interaction of the molecule with the medium.

Eqn (1) provides the foundations of a wide range of methods of calculation, described in the review literature[2-4, 22-24] as well as in the original papers.[25-46] Therefore we shall only dwell on the most significant differences between the methods adopted in these approaches to construct the operator $\hat{U}$, since our further discussion requires the differences to be explicitly stated. The operator $\hat{U}$ is usually expressed in terms of the classical Born, Onsager, and Kirkwood theories of the electrostatic interaction between charged or polar particles and the medium. The Born equation (2) (E_B) and the Onsager equation (3) (E_{Ons}) are the most frequently used:

$$E_B = \frac{\varepsilon - 1}{2\varepsilon} \frac{q_i q_j}{r_{ij}}, \tag{2}$$

where q_i, q_j, and r_{ij} are (respectively) the charges on the interacting particles and the distance between them, and

$$E_{Ons} = \frac{\varepsilon - 1}{2\varepsilon + 1} \frac{\mu^2}{a^3}, \tag{3}$$

where μ is the dipole moment of the solute molecule, and a is the radius of the cavity which this molecule produces in the solvent.

Eqn (2), derived by Born in order to calculate the interaction energy of ions in a solution, found an interesting application in Klopman's solvaton model,[25] which provided a new impetus for the development of quantum-chemical methods of calculation allowing for the effect of the medium. In this model each atom A of a molecule immersed in the medium is conjugated with a solvaton C, at a distance r_{AC} and having a charge q_C equal to the charge of the atom A (Z_A) but of opposite sign. It is assumed that the solvatons do not mutually interact, and that the energy of the interaction between the atom and the solvaton is described by Eqn (2) in the form

$$E = \frac{\varepsilon - 1}{2\varepsilon} \frac{q_C Z_A}{r_{AC}}. \tag{4}$$

In this case the operator $\hat{U}$ becomes

$$\hat{U} = \frac{\varepsilon - 1}{2\varepsilon} \left[\sum_{C=1}^{N} \sum_{i=1}^{M} \frac{q_C}{r_{C_i}} - \sum_{C=1}^{N} \sum_{A=1}^{M} \frac{q_C Z_A}{r_{AC}} \right], \tag{5}$$

where N and M are the numbers of atoms and of electrons in the molecule respectively. Various modifications of the solvaton model[26-29] converge towards the ideas underlying the models of molecular perturbation by point dipoles[36] and of 'virtual charges'.[37-39]

An essentially different approach to the construction of the operator $\hat{U}$ was used by Tapia and coworkers,[38-42] who developed the self-consistent reactive field (SCRF) theory by analogy with Onsager's reactive field model. This approach allows not only for the effect of the polar medium on the molecule immersed in it (resulting in a redistribution of the charges in the molecule and therefore also in a change in the dipole moment), but also for the polarising interaction of this dipole with the surrounding medium, which produces the so-called 'reactive' Onsager field (R) in the medium. The quantum-chemical analogue of the classical electrostatic interaction energy ($E = -\mu R$) in the SCRF model is the operator $\hat{U}$, in the form

$$\hat{U} = -\hat{\mu} g \langle \Psi | \hat{\mu} | \Psi \rangle, \tag{6}$$

where $\hat{\mu}$ is the operator of the dipole moment vector, Ψ is the wave function of the molecule in a medium with a dielectric constant ε, and g is a tensor which defines the susceptibility of the reaction field, expressed [by analogy with Eqn (3)] as

$$g = \frac{\varepsilon - 1}{2\varepsilon + 1} \frac{2}{a^3}. \tag{7}$$

It is assumed that the molecule occupies a spherical cavity of radius a, within which ε is equal to 1.

The assumption of a spherical cavity seriously restricts the application of the SCRF model when the molecules of interest are asymmetric. In this case an improved Onsager model is used, in which the cavity produced by the molecule in the surrounding dielectric continuum has the same shape as the molecule.[30, 43-46] The molecule in its cavity is treated as a system of charges, defined by the distribution of electron density $\rho(x)$, which induce in the boundary surface S of the cavity the charges $\sigma(S)$ responsible for the reactive field.[44-46] Under these conditions the perturbation operator takes the form

$$\hat{U} = \sum_i q_i \int \frac{\sigma(S)}{r_i - S} \mathrm{d}S, \tag{8}$$

where q_i and r_i are the charge and the position of the ith particle respectively. The density of the surface charges $\sigma(S)$ is determined by the polarisation of the inner (P_+) and of the outer (P_-) boundary surface of the cavity:

$$\sigma(S) = P_+ \boldsymbol{n} + P_- \boldsymbol{n}, \tag{9}$$

where $\boldsymbol{n}$ is a unit vector perpendicular to the boundary surface at the point S. The polarisation vector is related to the ε value for the medium by the Maxwell relation

$$P = \frac{1}{4\pi}(\varepsilon - 1)E. \tag{10}$$

The electric field E is determined by the electrostatic potential Φ generated by the distributions $\rho(x)$ and $\sigma(S)$:

$$\Phi(r) = \int \frac{\rho(x)}{r - x} \mathrm{d}x + \int \frac{\sigma(S)}{r - S} \mathrm{d}S. \tag{11}$$

Thus in the SCRF model proposed by Miertuš[30] and subsequently developed by Hochi[44-46] and by Bazilevskii[47] the reactive field is created by the charges induced by the molecule in the surrounding dielectric, and the interaction of the molecule with the dielectric is described by its interaction with these charges. This approach brings the SCRF model close to the solvaton or virtual charges model described above.

Eqns (1)-(11) show that the Hamiltonian (1), in which the perturbation operator allows for the electrostatic interaction with the medium, can be used to solve the Schrödinger equation for an arbitrary value of ε. This allows the quantum-chemical calculations to be used to determine the electronic structure and the geometry of the molecules, and their physicochemical parameters, as a function of the ε value for the medium. As in the case of isolated molecules, these calculations have been carried out in both nonempirical[30-35] and semiempirical variants.[27-29, 45-49] In spite of the great sensitivity of the calculated results to the method used in the approximate solution of the Schrödinger equation and to the model chosen for the effect of the medium this approach usually gives a correct description of the general trends seen in the changes in electronic structure and in the properties and the

energetics of the molecules under the influence of a polar medium, and (as will be shown below) they are acceptably consistent with experimental data. The good agreement between calculations by different methods is shown in Table 1, where changes in the total energy (ΔE) and in the Helmholtz free energy (ΔF) of various molecules when transferred from a vacuum or from a gas phase to a medium with $\varepsilon = 80$ are compared.

The difference between the total energies of a molecule calculated for a medium with a given value of ε (E) and for a vacuum (E_0) can be used as a measure of the stabilisation energy experienced by the molecule in the polar medium as a result of electrostatic interactions.

III. Changes in the electronic structure, energetics, and physicochemical properties of molecules under the influence of a polar medium

Quantum-chemical calculations followed by an analysis of the Mulliken populations of the orbitals show that when a molecule is transferred from the gas phase ($\varepsilon = 1$) to a solution ($\varepsilon > 1$) the charges on almost all its atoms change by an amount which is greater, the greater the ε value of the medium. The most substantial changes are seen in easily polarisable bonds. Thus, in the case of the C=O bond in some carbonyl compounds (Table 2) it was established that a change in ε from 1 to 80 markedly

[a] The distances between the carbon atom of the CO group and the neighbouring C atoms of the benzene rings are quoted.

increases the electron density on the O atoms and lowers it on the C atoms. In particular, polarisation of the C=O bond in dimethylformamide lowers its population, whereas the population of the neighbouring C–N bond increases: the lengths of these bonds are altered,[50, 51] and the dipole moment of the molecule shows a large increase. In *N*-nitrosodimethylamine changes in electron density on the O, N^1, and N^2 atoms lower the population of the $N^1=O$ bond and increase that of the N^1-N^2 bond in proportion to the ε value of the medium. Similar results were obtained for benzophenone, showing that an increase in ε stretches the C=O bond and shortens the C–C bond between the carbon atoms of the carbonyl group and the benzene rings (Table 3). Thus the polarisation of the surrounding medium affects the geometry of the molecule by causing a redistribution of charge in the molecule.

The changes in the charges of the individual atoms of the molecule caused by an increase in ε are also reflected by the screening parameters (σ) of the nuclei, which are correlated with the chemical shifts (δ) in the NMR spectra. For example, the decrease in electron density (Δq) on the C^1, C^3, and C^4 carbon atoms of crotonaldehyde (see Table 2) caused by increasing ε for the medium from 1 to 80 results in a deshielding (Δσ) of the nuclei of these atoms, which is consistent with the shift of the corresponding ^{13}C NMR signals (Δδ) towards weak fields on going from pentane (ε = 1.8) to DMSO (ε = 49.6), whereas an increase in the negative charge on the C^2 atom corresponds to a shift of the ^{13}C NMR signal towards strong fields.[46]

An extensive experimental and theoretical study[52–54] of the effect of the polarity of the medium on the screening parameters and on the ^{14}N NMR chemical shifts in nitrogen compounds with chemical bonds of different types involving the N atom has been reported. It was shown, in particular, that the change from a nonpolar medium (ε < 2) to a polar medium increases the screening of the nitrogen nuclei in nitriles, whereas the opposite effect (deshielding) is found in compounds where the N atom is attached to an O atom or to a C=S group, in complete agreement with the changes in electron density on the nitrogen atoms in these compounds. Both effects increase with the ε value of the medium (Table 4).

The results of quantum-chemical calculations are satisfactorily consistent with experimental data on the ^{14}N NMR chemical shifts, which are described by the relation[52–54]

$$\delta = \delta_0 + S(\pi^* + d\delta) + a\alpha + b\beta , \quad (12)$$

where δ and δ_0 are the ^{14}N NMR chemical shifts (relative to nitromethane) of the experimental compound in this solvent and in the standard (ε ~ 2) respectively; *S*, *a*, and *b* are parameters which characterise the polarisability, the proton-donor, and the electron-donor strength of the compound, π^*, α, and β are parameters which characterise the polarising strength and the proton-donor and electron-donor strength of the medium respectively,[55] dδ is a correction for polychlorinated (δ = 0.5) and for aromatic solvents (δ = 1). Comparing the *S* values for the compounds shown in Table 4 shows that both theory and experiment suggest a large increase in the screening of the N nuclei as a result of the polarisation of the C=N bond in nitriles (compounds 1–4), whereas in *tert*-butyl nitrite (compound 5) the most marked effect is the deshielding of the nitrogen nuclei caused by the polarisation of the N=O bonds.

Good agreement between calculations by the CNDO/2–solvaton method and experiment (^{29}Si NMR) has been reported[56] for the chlorosilane series. The changes in the deshielding parameter (σ) and the shift of the ^{29}Si NMR signals towards weaker fields relative to TMS are described by the equation

$$\delta(-\sigma) = A\frac{\varepsilon - 1}{2\varepsilon} + B . \quad (13)$$

The agreement between calculated and experimental values of *A* in Eqn (13) is acceptably good.[56]

The observed deshielding of the nuclei as ε for the medium is increased can be attributed to the polarisation of the Si–Cl bonds, the effect decreasing in the following sequence: Me_3SiCl (μ = 2.09) > Me_2SiCl_2 (μ = 1.89) > $MeSiCl_3$ (μ = 1.87) > $SiCl_4$ (μ = 0); Me_2HSiCl (μ = 1.8) > $MeHSiCl_2$ (μ = 1.7) > $HSiCl_3$ (μ = 1.0) > $SiCl_4$ (μ = 0). Obviously, these effects are related to the decreases in the same sequence of the μ values for these compounds and to the consequent strengthening of the electrostatic interaction of the molecules with the polar medium.

The results of the quantum-chemical calculations show that the polarising effect of the medium and the associated redistribution of the charges in the molecule usually result in an increase in the dipole moments and therefore also in the ε values of the medium (Tables 1 and 2). Experimental data on the μ values of molecules in a series of solvents with different ε values point to the same conclusion. For example, in a molecule such as triphenylchloromethane (Ph_3CCl), which contains the covalent (in a nonpolar medium) but easily polarisable C–Cl bond the μ value increases from 1.9 to 12.2 D when ε for the solvent is increased from 2 to 65 (Table 5).

The change in electronic structure produced by the polarising effect of the solvent strongly influences the energy characteristics of the molecules. An analysis of the data in Tables 1, 2, 6, and 7 identifies the three most important types of change in the

Notes. DN is the Gutmann donor number of the solvent;[58] δ^2 is the cohesion energy density of the solvent;[59] μ/D is the dipole moment of Ph_3CCl; ΔH_s/kJ mol^{-1} is the solvation enthalpy of Ph_3CCl; ΔE_{cav}/kJ mol^{-1} is the energy of formation of a cavity; ΔE_{int}/kJ mol^{-1} is the energy of interaction of Ph_3CCl with the solvent.

energetics of molecules induced by an increase in the polarity of the medium:

1. A decrease in the energy of the molecule (E), and therefore in its stabilisation energy (E_{st}), resulting from the transfer of the molecule from the gas to the solution.

2. A change in the energy of the highest occupied (n, π) and the lowest unoccupied (π^*) MO, and therefore in the energies of the singlet $n-\pi^*$ and $\pi-\pi^*$ transitions.

3. An increase in the barriers to internal rotation round the bonds (C–N in amides, N^1-N^2 in nitrosamines), whose population increases.

These changes have a marked effect on the physicochemical characteristics of molecules and of processes involving those molecules in solutions.

The stabilisation energy of molecules in polar media (Table 1) is higher for molecules with a high intrinsic dipole moment. The parameter μ increases with the ε value of the medium, with a corresponding increase in the stabilisation energy of the molecule. This justifies the conclusion that the stabilisation energy in polar media is strongly dependent on the dipole–dipole interaction between the solute and the solvent molecules, and that this contribution increases with the polarities of both the participants. The same conclusion follows directly from Onsager's classical reactive field model in conjunction with Eqn (3), and is confirmed by Monte-Carlo modelling[60] of the dependence of the electrostatic interaction energy of solute molecules with the medium (ΔE_{int}) on their dipole moment.

Neither the lack of dependence of the enthalpy of solvation (ΔH_s) on μ for the solute molecules[61] nor the lack of a definite dependence of ΔH_s on μ and ε for the solvent (Table 5) can be interpreted as proof of the absence of a stabilising effect from dipole–dipole interaction. We must allow for the energy used to cut out the cavity (ΔE_{cav}), which makes a substantial endothermic contribution to ΔH_s. By introducing the correction $\Delta E_{cav} = \delta^2 V$ (where δ is Hildebrand's parameter and V is the molar volume of the solute) we can present the data in Table 5 as a linear dependence of ΔE_{int} on the μ value of the solute (Fig. 1). It is noteworthy that the solvents under study give two almost parallel straight lines, of which the lower corresponds to the solvents 5–7 and 11 (which according to their Gutmann donor numbers have the strongest specific solvation power). A possible explanation is the failure to allow for the contribution to ΔH_s from the reorganisation of the solvent associated with the creation of solvation shells in the calculation of ΔE_{int} from ΔH_s. In the case of specific solvation, which is accompanied by the formation of more rigid shells, this reorganisation requires a more substantial

Notes. E(a.u.) is the total energy of the molecule; ΔE/kJ mol^{-1} is the barrier to rotation round the C–N or N–N bond,; $\Delta\mu$/D is the change in dipole moment caused by the change from the planar to the nonplanar form (i.e. by a 90° rotation).

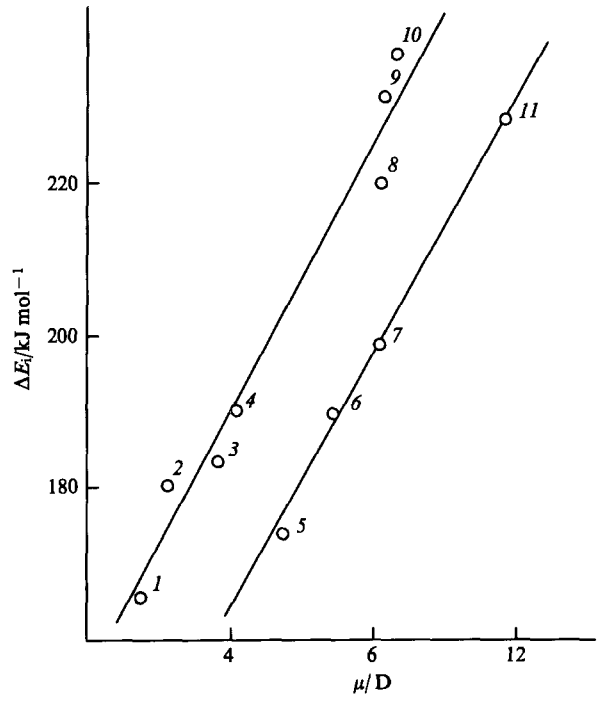

Figure 1. Plots of the interaction energy ΔE_{int} of triphenylchloromethane with the medium against its dipole moment for different ε values of the solvents (numbered as in Table 5).

consumption of energy than in nonspecific solvation. The important role of the formation of the cavity in solvation processes is also made clear by the reported[62] linear dependence

$$\ln \tau = a + b\Delta E_{cav} , \quad (14)$$

where τ is the dielectric relaxation time, which characterises the rotational mobility of the solute molecules.

Eqn (14) is consistent with the rotational diffusion model, in which the molecule can undergo discontinuous changes in its axis of rotation by overcoming a potential barrier equal to the cavity formation energy, i.e. by passing from one cavity into the next.

The dependence of the stabilisation energy of the molecules of the polar medium on their dipole moment is reflected by the nature of the dependence of ε for the solvent on the position of the absorption bands in the electronic spectra of the dissolved substances. Theoretical calculations[28, 48, 50] and experimental data[63-65] show that an increase in ε for the medium can either raise or lower the energy of the electronic transitions. CNDO/S calculations for benzophenone[50] have confirmed that the transition to the excited state can be accompanied by either an increase or a decrease in the dipole moment of the molecule (Table 8), as suggested by the experimental data.[65] Under these conditions the

energy of the $n-\pi^*$ transition increases, and that of the $\pi-\pi^*$ transition decreases, in keeping with data on the blue and the red shift of the corresponding spectral bands produced by an increase in ε for the solvent (Table 9). The increase in the $n-\pi^*$ transition energy calculated theoretically[43] agrees with the experimentally observed[64] blue shift of pyridine and of acetone: in the latter compound a decrease in the energy of the $\pi-\pi^*$ transition consistent with the red shift of the absorption band has also been reported.[48, 64] The change in the transition energy combined with a decrease in μ (shown schematically in Fig. 2) can be explained by postulating that when ε is increased the stabilisation of the ground state is more marked than that of the less polar excited state. The opposite state of affairs is observed when the transition involves an increase in μ during excitation.

The change in the electronic structure and in the energetics of molecules under the influence of a polar medium strongly affects the processes taking place in solutions, and in particular the tautomeric and conformational equilibria.[2, 48]

Low-barrier intramolecular proton transfer processes (prototropic tautomerism) have attracted wide interest because of their dominant role in many important processes such as the activity of living cells. An example of this type of tautomerism can be found in the keto–enol equilibria between 2-pyridone and 2-hydroxypyridine, or between uracil and 4-hydroxyuracil. The equilibrium constants of these processes, which determine the concentration ratio of the keto and the hydroxy form, can vary by several orders of magnitude when the system is transferred from the gas phase to a strongly polar solvent.[2, 48] This shift in the equilibrium is largely due to the preferential stabilisation by the polar medium of the tautomeric form having the higher dipole moment. For example, whereas in the pair of tautomers uracil and 4-hydroxyuracil, which have similar μ values in the gas phase, the uracil (keto form) is predominant, in aqueous solutions we find mainly 4-hydroxyuracil, which is not observed in the gas phase.[66] This is because the increase in μ, and therefore the decrease in E in media of high polarity is more marked for the hydroxy form than for uracil, and this form becomes the more stable when $\varepsilon > 8$ (see Table 10).

Table 9. Absorption bands (in nm) in the electronic spectra of benzophenone and energies (in eV) of the corresponding transitions in solvents of different polarities.[50]

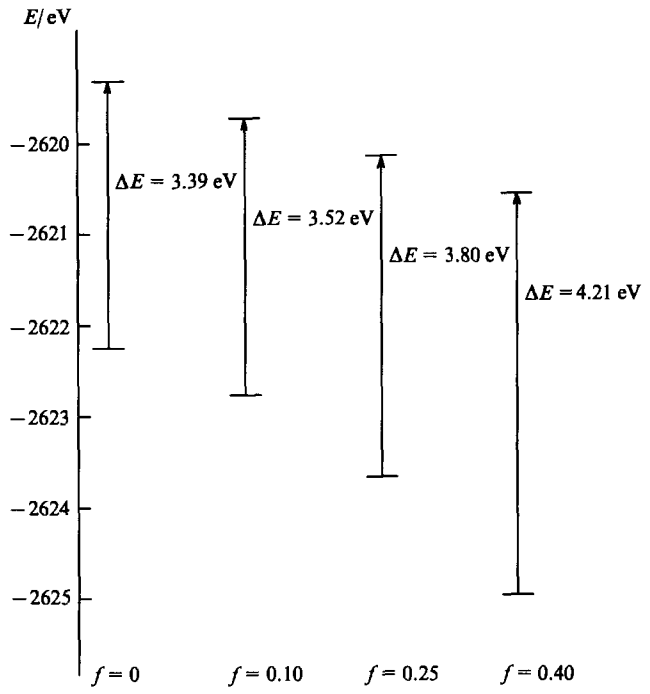

Figure 2. Changes in the energies of the ground and the excited states of benzophenone corresponding to the $n \rightarrow \pi^*$ transition, and energies of this transition as a function of the polarity of the solvent (f values, see Table 8).

The effect of a polar medium on the conformational equilibria is associated with a change in the energy of the barriers opposing the interconversion of the isomers. Thus, the conversion of *N,N*-dimethylformamide and *N*-nitrosodimethylamine from the planar to the nonplanar form (by a 90° rotation) requires surmounting barriers to internal rotation round the C–N and N^1–N^2 bonds whose height increases with the ε value of the medium. This may be due to two possible factors: the stabilisation of the more polar, planar conformer and the increased population (Table 2) of the bonds round which the rotation takes place. The difference between the dipole moments ($\Delta\mu$) of the planar and the nonplanar form increases with the ε value of the medium (see Table 6), and this effect should be accompanied by a relative stabilisation of the first form and a shift of the equilibrium towards it. An increase in the height of the barriers to internal rotation with increase in ε for the medium has been established also for formamide on the basis of INDO and CNDO/2 calculations, allowing for the effect of the medium in the solvaton formalism.[48, 67] The calculated results are acceptably consistent with the experimental determination of the barrier to internal rotation round the C–N bond in amides.[48, 68–70] For example, the barriers to rotation in formamide found by NMR increase from 70 to 80 kJ mol^{-1} when the compound is transferred from a nonpolar solvent (ε = 2) to water (ε = 80), whereas the calculated values increase from 87 to 90–100 kJ mol^{-1} when ε increases from 1 to 40 (see Ref. 48).

IV. Molecular and ionic forms of H complexes in media with different dielectric permittivities

Compounds which are easily polarised in solutions include complexes with an intermolecular hydrogen bond, formed by acids AH and bases B and existing in a molecular (AH · B) or an ionic form (A^-HB^+). In the molecular form we observe intermolecular charge transfer from the B molecule to the AH molecule, acting as electron n-donor and σ-acceptor respectively,[71–74] whereas in the ionic form proton transfer from the AH to the B molecule takes place, with formation of an ion pair. Problems concerning the role of charge transfer in the stabilisation of the molecular forms of H complexes and the role of the effect of the polarity of the medium on the transfer of a proton and on the formation of ionic forms have been widely discussed in the literature on the nature of the hydrogen bond. The many theoretical and experimental approaches aimed at solving these problems have been examined in depth in a series of recently published monographs and reviews.[14, 16, 75–81]

There are two fundamentally different ways of describing the hydrogen bond. According to the first[14, 75, 76, 80] the molecular forms of H complexes are stabilised only through the electrostatic interaction of the component molecules, and the substantial increase in the dipole moment resulting from the formation of the H complexes is attributed to the equilibrium between the low-polarity molecular form and the high-polarity ionic form:

$$AH + B \rightleftarrows AH \cdot B \rightleftarrows A^-HB^+ . \qquad (15)$$

According to the second concept of the hydrogen bond,[71–74] based on the EDA interaction between the AH and the B molecule, the increase in μ accompanying the formation of the H complexes is due to the intermolecular charge transfer or to the shift of electron density from B to AH. Evidence in favour of this interpretation is provided by the experimentally[71, 72] and theoretically well established[73, 74] linear relationship between the energy (ΔE_c) or enthalpy (ΔH_c) of formation of the H complexes and the extent of the charge transfer (Δq_{ct}) in low-polarity media. However, as regards the equilibrium (15), the ionic forms have never been observed in the gas phase or in low polarity media.[17] The erroneous conclusions stipulating the presence of this equilibrium are often based on the observation of two minima on the potential curves. However, in amine–hydrogen halide systems in a vacuum it has been shown that two minima can be obtained on the potential curve even in very strict nonempirical calculations if no allowance is made for the electronic correlations or for the dispersion interaction of the component molecules.[82–84] Allowance for electron correlations results in the merging of the two minima into a single, wide minimum, corresponding to the molecular form of the H complex. Zundel and coworkers have shown[16, 85, 86] that the second minimum experimentally found on the potential curves of AH · B systems is due to the polarising effect of the solvent.

Quantum-chemical calculations on systems with H bonds, allowing for the solvent,[15, 19, 21, 87–89] have shown that changing from the gas phase to a polar medium has a marked effect on the shape of the potential curves, consistent with the change in electronic and geometrical structure resulting from complex formation. As shown by the increase in the μ value for the H complexes, and as in the case of individual molecules, the charge separation under the influence of the medium is greatest in media with the highest dielectric permittivity. For example, the dipole moment of the complex $Bu_3N \cdot HCl$ increases from 8 to 13 D as ε for the medium is increased from 2.3 to 35, the μ and ε values being related by the expression[19]

$$\mu = 13.6 - \frac{12.7}{\varepsilon} \quad (r = 0.985) . \qquad (16)$$

The intermolecular charge transfer (Δq_{ct}) calculated for μ = 8 D and the enthalpy of formation of the complex $Bu_3N \cdot HCl$ in benzene (ε = 2.3) satisfy the linear relation between ΔH_c^0 and Δq_{ct}

which characterises the EDA complexes.[72] The value 8 D agrees well with the μ value (7.2 D) calculated by the CNDO/2 method for the model complex $Me_3N \cdot HCl$ in the gas phase, which gives only one minimum on the potential curve (for $\varepsilon = 1$, Fig. 3*a*). In the same figure we show the potential curves calculated with allowance for the effect of the medium by the solvaton model. Under these conditions a second minimum appears on the potential curves: it corresponds to the ionic form, and its depth increases with the ε value for the medium. The calculations for the molecular and the ionic form of the complex indicate large differences between their geometric (and their charge) characteristics (Table 11). The N–Cl distance in the molecular form is much shorter than in the ionic form. Whereas the binding of the HCl molecule in the $Me_3N \cdot HCl$ complex lengthens the H–Cl bond by only 0.14 Å the H–Cl distance in the ionised complex reaches 2.3 Å. Essentially this implies the breaking of the H–Cl bond, as shown by the decrease in its population (P_{H-Cl}) almost to zero. The intermolecular distance N...H in the molecular complex is 0.2 Å longer than the corresponding distance in the ionic form, whose value is close to the length of the N–H bond in the Me_3NH^+ ion. The binding Me_3N and HCl molecules into a molecular complex lowers the population of the orbital of the unshared pair (P_{up}) on the N atom and increases P_{up} for the Cl atom (calculated as already described[90]) by an amount close to Δq_{ct}. This state of affairs is consistent with the normal behaviour of molecular H complexes with charge transfer from the unshared pair (UP) of the hetero-atom in the donor molecule to the electronegative atom attached to the proton in the acid. The transition to the ionic form increases P_{up} for the Cl atom to a value corresponding to the formation of a Cl^- ion. As could have been expected in this type of complex,[90] the population of the N...H bond is substantially less than unity, but in the ionic form it is very close to unity. The same is true of the charge on the Cl atom (q_{Cl}). However, the q_{Cl} value in $Me_3NH^+Cl^-$ is less than unity by approximately 0.15, and the μ value (13.03 D) is smaller than the value calculated for the contact ion pair with unit charges on the cation and the anion (16.3 D for $r_{N-Cl} = 3.4$ Å). This suggests the presence of interionic charge transfer from the Cl^- anion to the Me_3NH^+ cation.[91, 92] We note that μ for the ionic form is close to the value given by Eqn (16) for $Bu_3N \cdot HCl$ with $\varepsilon \to \infty$.

Table 11. Parameters of the molecular and the ionic forms of the $Me_3N \cdot HCl$ complex and of their components, calculated by the CNDO/2 method.[19]

Parameter	$Me_3N \cdot HCl$	$Me_3NH^+Cl^-$	Me_3N	HCl	Me_3NH^+
r_{N-Cl}/Å	2.75	3.40	–	–	–
r_{N-H}/Å	1.31	1.10	–	–	1.08
r_{H-Cl}/Å	1.44	2.30	–	1.30	–
q_{Cl}	−0.42	−0.86	–	−0.09	–
P_{N-H}	0.24	0.85	–	–	–

P_{up} (N)	1.72	1.39	1.94	–	–
P_{up} (Cl)	1.42	1.91	–	1.09	–
μ/D	7.17	13.04	1.43	2.48	0.48
Δq_{ct}	0.27	–	–	–	–
$-\Delta E_c$/ kJ mol^{-1}	115	–	–	–	–

The results in Table 12 shows that the μ values of both the molecular and the ionic form of the H complex increase with the ε value of the medium: this is due mainly to an increase in the level of intermolecular charge transfer, and also to an increase in the level of charge separation.[90, 91] An increase in Δq_{ct} (and therefore in ΔH_c) for the complexes with a Y...H–X intermolecular hydrogen bond (where Y is the heteroatom with an UP in the B molecule and X is the electronegative atom bound to the H atom in the acid molecule) shortens the Y...H distances and lengthens the X–H bond. These changes in the geometry of the H complexes are observed also when the increase in Δq_{ct} is due to an increase in the polarity of the medium, as shown in particular by *ab initio*

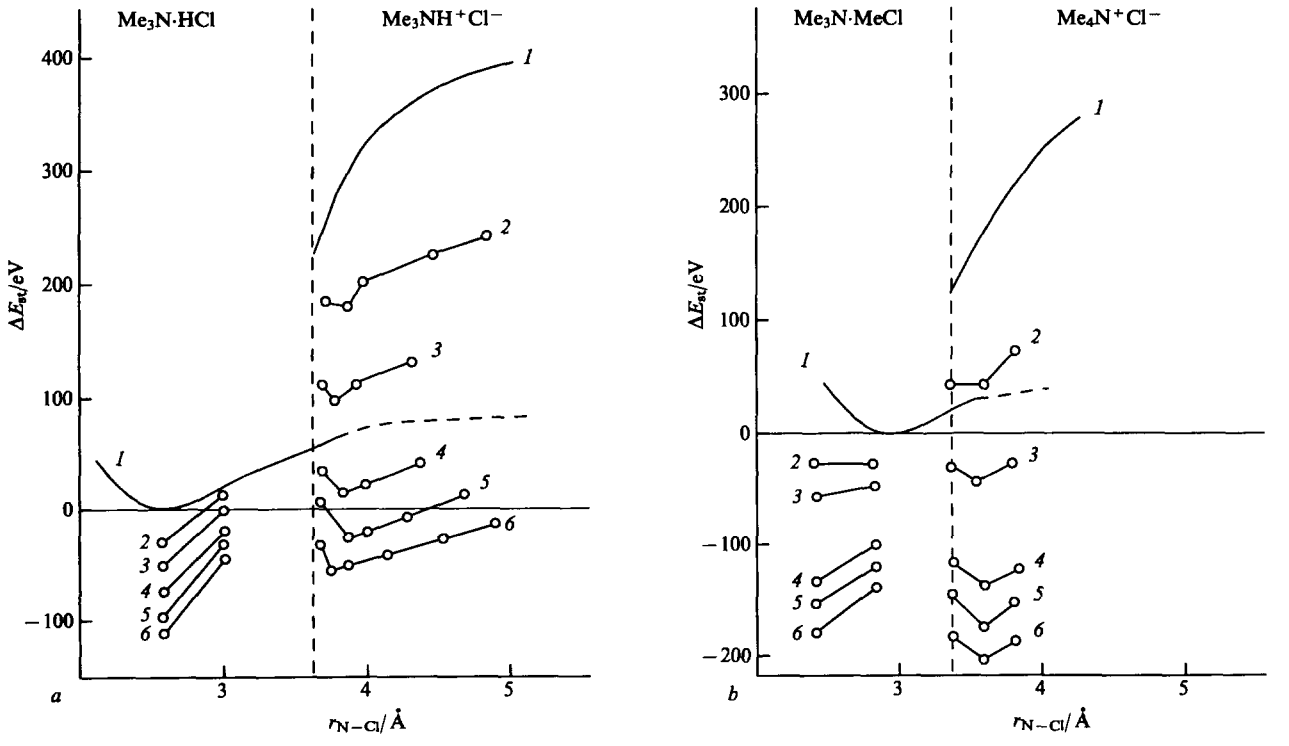

Figure 3. Plots of ΔE_{st} against r_{N-Cl} for Me_3NHCl (*a*) and Me_4NCl (*b*) in media with different ε: (*1*) 1; (*2*) 1.5; (*3*) 2.3; (*4*) 5.6; (*5*) 10; (*6*) 40.

Table 12. Dipole moments (μ/ D), charges on the Cl atoms (q_{Cl}), stabilisation energies (ΔE_{st}/ kJ mol^{-1}) of the molecular and the ionic forms of the complex of Me_3N with HCl contributed by the medium, and energies of interaction with the medium (ΔE_{int}) as a function of ε (CNDO/2 and CNDO/2–solvatons methods[19]).

ε	$Me_3N{\cdot}HCl$ (r_{N-Cl} = 2.75 Å)			$Me_3NH^+Cl^-$ (r_{N-Cl} = 3.4 Å)

calculations[21] allowing for the effect of the medium in the SCRF formalism for the $Me_nH_{3-n}N{\cdot}HX$ series of model complexes, where X = F, Cl, or Br, and n = 0–3.[21] In the gas phase the energy of formation of these complexes (ΔE_c) increases with n in the series Br > Cl > F. The N–H distances decrease in the same sequence, and the H–X bonds become longer. However, even in the most stable complexes (n = 3, X = Br, Cl) the r_{N-H} lengths do not reach the very low values found in the $Me_nH_{4-n}N^+$ cations.

Allowing for the polarising effect of the medium shortens r_{N-H} and lengthens r_{H-X} in all the complexes by an amount which increases with ε for the medium. Conversion of the molecular complexes into the ionic form $Me_nH_{4-n}N^+X^-$ was observed only for X = Cl or Br and in media of relatively high polarity ($\varepsilon > 10$), the $Me_nH_{3-n}N{\cdot}HCl$ complexes giving the ionic form less readily than their HBr analogues. An analysis of the potential curves (Fig. 3) shows that the change from the gas phase to a polar medium stabilises the ionic form only when $\varepsilon > 10$. This effect is caused by the need to expend energy in rearranging the molecular structure into an ionic structure (mainly, in breaking the H–X bond). These energies are quite substantial: for example, 283 kJ mol^{-1} for $Me_3N{\cdot}HCl$.[19] The total stabilisation energy (ΔE_{st}) resulting from the change from the gas to a solution can be expressed as the sum of terms for the rearrangement (ΔE_r) and for the interaction with the medium (ΔE_{int}):

$$\Delta E_{st} = \Delta E_r + \Delta E_{int} . \quad (17)$$

The energy of the electrostatic interaction with the medium is higher for the more polar ionic form of the complex than for the molecular form, but in both forms $-\Delta E_{int}$ increases with the ε value of the medium as it does in the individual molecules (Table 12). The lack of stabilisation of the ionic forms in media with $\varepsilon < 10$ is due to the fact that in these cases $|\Delta E_r| > |\Delta E_{int}|$.

V. Electronic structure of salts in media with different polarities

Studies of the simplest members of this class of compounds, such as the alkali metal halides and the tetra-alkylammonium salts,[19, 90–93] have shown that in the gas phase and in nonpolar solvents their dipole moments are much lower and their interionic distances are much shorter than the values expected for ion pairs (Table 13). An attempt to explain these differences by the mutual polarisation of ions model[94] was unsuccessful, as can be seen by comparing the experimental values of the dipole moments observed in the gas phase (Table 13) with those calculated for the ion pairs (μ_{ip}) by the equation

$$\mu_{ip} = er^3\left[1 - \frac{r(\alpha_+ + \alpha_-) + 4\alpha_+\alpha_-}{r^6 - 4\alpha_+\alpha_-}\right] . \quad (18)$$

Mulliken's model, which treats the ion pairs as EDA complexes in which the anion acts as the electron donor and the cation as the electron acceptor,[95] proved more successful. This approach accounted for the decrease in μ for the ion pair in terms of the oppositely oriented dipole moment resulting from the interionic charge transfer, and the shortening of the bond between the ions was ascribed to the additional stabilisation of the pair.

Calculations on the LiCl and Me_4 NCl molecules by CNDO/2 method (in a vacuum) with full optimisation of the geometry showed[90] that in both compounds the charges on the Cl atoms (q_{Cl}) are close to 0.5 of a unit charge, and the dipole moments and interionic distances are much lower than those expected for ion pairs. Under these conditions the distance between the C and Cl atoms in Me_4NCl (Table 14) is almost equal to the sum of their covalent radii (0.99 Å for Cl and 0.77 Å for C), and the N–C distance exceeds the sum of the covalent radii of C and N (1.47 Å)

Table 13. Dipole moments (μ_r/ D) and interatomic distances (r_r/ Å) of the alkali metal halides measured in the gas phase, and values of these parameters expected for contact ion pairs (μ_{ip}, r_{ip}).[93]

[b] Energy of the rearrangement of MeCl during the formation of a complex with Me_3N.

by only 0.16 Å. All these observations indicate a molecular (rather than an ionic) structure for the compounds in the gas phase and in nonpolar solvents.

The R_4NX compounds are electronic analogues of the $R_3N \cdot HX$ H complexes. In particular, the potential curves for Me_3NHCl and Me_4NCl (Fig. 3) are identical. Both gas-phase curves show a single minimum which in the case of Me_4NCl can be assigned to the molecular $Me_3N \cdot MeCl$ $n\sigma$ complex, with the alkyl halide acting (like HCl) as a σ acceptor. The geometric and the charge characteristics of the N–C and C–Cl bonds, calculated by the CNDO/2 method in a vacuum with full optimisation of the geometry of Me_4NCl (Fig. 3*b*, minimum on curve *1*), are also consistent with the EDA interpretation of the N...C–Cl bond and with the assumed analogy of this bond with the N...H–Cl bond in $Me_3N \cdot HCl$. Comparing the data in Tables 11 and 14 shows that the C–Cl (or H–Cl) bonds in the σ-acceptor molecules MeCl (or HCl) are only slightly stretched by the formation of molecular complexes with Me_3N, and that their population, though decreased, remains close to 1, whereas the population of intermolecular N–C and N–H is substantially less than 1. In the ionic structures the geometric and the charge characteristics of the N–C, C–Cl, N–H, and H–Cl bonds are markedly different. The C–Cl and H–Cl bonds are effectively broken, as shown by their elongation to 2.3 Å and by the decrease of their population to practically zero. Under these conditions the N–C and N–H bonds are shortened to values close to the r_{N-C} or r_{N-H} distances in the cations Me_4N^+ or Me_3NH^+ respectively.

The binding of the MeCl molecule in a complex with Me_3N is accompanied by an increase in the HCH bond angle from 111° to 120°, while the N–C–Cl fragment ion in the molecular complex adopts a trigonal bipyramidal structure with a planar CH_3 group, corresponding to sp^2 hybridisation of the C atom. This rearrangement of the MeCl molecule requires an energy expenditure of ~113 kJ mol^{-1}, which explains the much lower energy of formation of the $Me_3N \cdot MeCl$ complex (as compared with $Me_3N \cdot HCl$) for similar Δq_{ct} values of the two complexes. Applying a correction for the rearrangement energy gives similar values of ΔE_c (Tables 11 and 14). The conversion of the $Me_3N \cdot MeCl$ complex into the ionic form decreases the HCH angle in the methyl group to 107°, corresponding to the Me_4N^+ cation with a Walden inversion of the carbon tetrahedron relative to the methyl group in the free MeCl molecule.

As in the case of the $Me_3N \cdot HCl$ complex (Table 14) the dipole moments of the molecular and of the ionic form of Me_4NCl increase with the polarity of the medium (Table 15) as a result of the increase in the intermolecular charge transfer in the former and of the decrease in the interionic charge transfer in the latter. Corresponding increases in the energy of the electrostatic interaction with the medium take place: these are substantially higher for the more polar ionic form than for the molecular form. The energy of the rearrangement of the molecular structure $Me_3N \cdot MeCl$ into the ionic structure (151 kJ mol^{-1}) is substantially lower than for $Me_3N \cdot HCl$ (283 kJ mol^{-1}), and therefore the stabilising effect of the polar medium is higher in the former than in the latter (see Fig. 3). Whereas in Me_4NCl the minimum for the ionic form is deeper than that of the molecular form when $\varepsilon > 5.6$, in Me_3NHCl the effect is not observed even for $\varepsilon = 40$.[19] The validity of the theoretical predictions has been confirmed by a dielectrometric and conductimetric study of R_4NX (X = Cl or Br) and $R_3N \cdot HCl$.[19, 90, 91]

Studies of several organic chlorides and hexachloroantimonates[90, 91, 96–98] by the dielectrometry of conducting media method[92] showed that as ε for the solvent is increased from 2 to 10 the dipole moments of the salts rapidly increase to values of the same order as μ_{ip} for $\varepsilon = 35$, the dependence of μ on $1/\varepsilon$ taking the linear form

$$\mu = \mu_{ip} - \frac{A}{\varepsilon}. \qquad (19)$$

The parameter A characterises the sensitivity of the electronic structure of the given salt to the polarising effect of the medium. In the light of the theoretical ideas discussed above this type of dependence [Eqn (19)] can be explained by a transition from a molecular $n\sigma$ or $n\nu$ complex (a halogen complex of a metal with an n donor in Mulliken's terminology) to a complex with interionic charge transfer, followed by charge separation up to the formation of contact ion pairs with unit charges on the cation and the anion. Whereas the quaternary ammonium halides in nonpolar solvents have an $n\sigma$ complex structure the molecular

Table 15. Dipole moments (μ/D), charges on the Cl atoms, stabilisation energies (ΔE_{st}/kJ mol^{-1}) of the molecular and the ionic forms of the complex of Me_3N with MeCl provided by the medium, and energies of the interaction with the medium (ΔE_{int}) as a function of ε (CNDO/2-solvatons method[19]).

[a] Gas phase

form of the hexachloroantimonates is an $n\nu$ complex in which the intermolecular bond is formed by the UP of the Cl atom, bound to the cation, and the unoccupied sp^3d^2 orbital of the $SbCl_5$ molecule, known as a very strong V electron acceptor.[17, 58] The similarity of the electronic structure and of its changes under the influence of a polar medium which we have established for the salts and the H complexes offers the possibility of a unified treatment of the mechanism of two types of reaction: the bimolecular nucleophilic substitution (S_N2) and the proton transfer reaction in solutions, by the interaction of bases B with alkyl halides X–C in the first case and with bases A–H in the second:

$$X-C + B = C-B^+ + X^- , \quad (20)$$

$$A-H + B = H-B^+ + A^- . \quad (21)$$

In both these reactions two types of complex behave as intermediates: molecular (X–C...B or A–H...B) and ionic ($X^-...C-B^+$ or $A^-...H-B^+$). The reactions (20) and (21) produce a transition from molecular to ionic complexes by surmounting an activation barrier as the system moves along the reaction coordinate.[2]

Molecular complexes stable in the gas phase and in low-polarity solvents are formed by intermolecular charge transfer from the electron donor B to the electron acceptor (alkyl halide or acid). The complete transfer of an electron from the molecule B to the alkyl halide or acid, accompanied by the breaking of the X–C or A–H bond and by the addition of an alkyl radical or of a proton to the B molecule, leads to ionic complexes, stabilised mainly by the contribution from the interionic charge transfer. The formation of an ionic complex is a necessary precursor of the appearance of free ions.[87]

The conversion of a molecular complex into the ionic form is accomplished by using the energy of the interaction of the molecular complex with the polar solvent (ΔE_{int}), which increases with the ε value of the medium.

When ΔE_{int} exceeds ΔE_r the ionic complex becomes more stable than the molecular, the dissociation into free ions becomes possible. The dielectric permittivity (ε) of the solvent for which dissociation is possible depends on the properties of the system, as can be seen from the results of the experimental and theoretical study of the tri- and tetra-alkylammonium halides discussed above.

The important role of the polarising effect of the medium in controlling reactions such as (20) is underlined by a study of the interaction of various azoles with alkyl halides.[98] The stable products of this reaction in low-polarity solvents are molecular $n\sigma$ complexes, and in more polar solvents they are quaternary azolium salts. The quaternisation of azoles (like that of tertiary amines) during their interaction with alkyl halides is accompanied by Walden inversion of the tetrahedron of carbon atoms, which contributes to the formation of N–C bonds in the azolium cation. This is preceded by the formation of a molecular complex having a structure close to trigonal bipyramidal. Evidence for the EDA nature of the interaction of azoles with alkyl halides comes from the fact that only one of the several N atoms in the azole heterocycles acts as a reaction centre: it has n-donor properties, whose theoretically calculated indices for a series of azoles of different structure are linearly correlated with the logarithms of the rate constants of their interaction with methyl iodide in acetonitrile.

VI. Conclusions

The above discussion demonstrates the importance of effects from the polar medium in determining the distribution of electron density and the energetics of the molecules dissolved in the medium. Obviously, the mechanisms of liquid-phase processes cannot be described correctly without allowing for this effect.

The charge separation in the solute molecules and the stabilisation of their more polar forms under the influence of polar media are reflected in the changes of their physicochemical characteristics, which play an important role in many processes taking place in solutions. The shift of tautomeric or conformational equilibria towards the more polar forms and the increase in the rate constant of S_N2 or proton transfer reactions in solvents with a high dielectric permittivity are largely the result of an increase in the charge separation and in the stabilisation energy of the reacting molecules, of the intermediates, or of the reaction products. Processes involving the conversion of various compounds from the molecular into the ionic form take place at a reasonably high rate only in highly polar solvents, which induce an effective charge separation in the relevant molecules up to the formation of ion pairs.

Obviously, liquid-phase processes cannot be correctly described without allowing for these factors. We must therefore take careful note of the results and conclusions of theoretical studies of the mechanisms and kinetics of reactions in solutions which allow for solvation effects only in the approximation of structurally rigid reactant molecules.

Iron-subgroup metal carbonyls in reactions with olefins having functional group substituents

L V Rybin, M I Rybinskaya

Contents

I. Introduction 637
II. η^2-Olefin complexes of iron carbonyls. Synthesis and properties 637
III. Reactions of ruthenium and osmium carbonyl complexes with olefins having functional group substituents 644

Abstract. The review covers the results of studies on the reactions of iron, ruthenium, and osmium carbonyls with olefins having functional group substituents, the behaviour of which differs significantly from that of simple olefins. Such studies have made it possible to create a new aspect of the chemistry of olefin complexes. The development of this field has led to the synthesis of previously unknown mononuclear and polynuclear complexes and to the discovery of unusual rearrangements of the complex compounds. The reactions of iron carbonyls differ from those of ruthenium and osmium carbonyls. In the last case, the hapticity of the unsaturated ligands increases and the ligands are found to be capable of giving rise to extremely unexpected structures. The present review surveys mainly the results of studies by the authors, who made a significant contribution to the development of this field. The bibliography includes 73 references.

I. Introduction

η^2-Olefin complexes occupy a special position in the chemistry of organometallic compounds of transition metals as the simplest compounds with a metal–organic ligand π-bond. They have served as a model for the development of the theory of the π-complex linkage. Furthermore, they are key intermediates in the catalytic reactions of olefins in the presence of transition metal compounds. Studies on such complexes have promoted the development of ideas about the mechanisms of catalytic hydrogenation, isomerisation, carbonylation, oligomerisation, and polymerisation of olefins. The chemistry of olefin complexes has therefore attracted for many years the attention of investigators.[1, 2] However, attention has been concentrated on the study of the properties of the complexes with ethylene and its homologues and to a lesser extent the complexes with olefins containing functional group substituents.

In the course of a number of years, we have carried out systematic studies on the thermal reactions of iron carbonyls with olefins having functional group substituents XCH=CHY and showed that the electronic nature of the substituents influences significantly the course of the reactions and the formation of the complexes $Fe(CO)_4$ (η^2-olefin).

These investigations have also shown that the coordination of an olefin to the $Fe(CO)_4$ group increases the electron density at the double bonds and the functional group adjoining it. The chemical reactions of these groups in the complexes have been used successfully to achieve the transition from η^2-olefin compounds to η^3-allyl or η^3-elementaallyl compounds, which made it possible to develop methods of synthesis of previously unknown organoiron compounds and also to discover and investigate new types of haptotropic rearrangements.

In order to deduce the general pattern for all the iron-subgroup metals, we included in the reactions with olefins having functional group substituents also ruthenium and osmium carbonyls. It was found as a result that, in contrast to iron carbonyls, which readily form the mononuclear complexes $Fe(CO)_4$ (η^2-olefin), the less reactive ruthenium and osmium carbonyls react with α,β-unsaturated ketones and esters under severe thermal conditions to form polynuclear compounds. The reactions proceed non-selectively and frequently lead to multicomponent mixtures which are difficult to separate. The elucidation of the structures of the complexes formed proved to be extremely useful, because it throws light on the possibility of the coordination of a polymetallic fragment to the organic ligand. The ligand in the sphere of the polynuclear fragment not only undergoes an increase in its hapticity compared with the mononuclear complexes but also proves capable of giving rise to different and frequently unexpected structures.

The data obtained are of interest for the understanding of the mechanisms of catalysis on clusters and, what is particularly important, heterogeneous catalysis on metallic surfaces.

II. η^2-Olefin complexes of iron carbonyls. Synthesis and properties

1. Interaction of iron carbonyls with substituted olefins

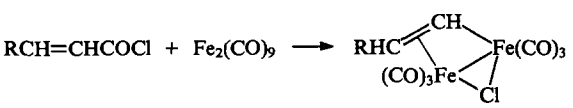
β-Substituted unsaturated ketones, acids and their derivatives[3–17] as well as the vinyl compounds of transition metals, silicon, and germanium,[18–29] have been used in the reactions with iron carbonyls as mono- and di-substituted olefins: XCH=CHY, where X and (or) Y = COR, COOH, COOR, COCl, COF, CONRR′, C(=NR)OEt, $C^+(OEt)NR_2$, CONHNHR, CONRNR′CO, $CON^-N^+R_3$, Cl, I, SPh, SO_2R, NR_2, NO_2, CF_3, SiRR′R″, $GeRR'_2$, $CpFeC_5H_4$, $Fe(CO)_2Cp$, $W(CO)_3Cp$, $Re(CO)_5$, etc.

The majority of these mono- and disubstituted olefins form η^2-olefin complexes:

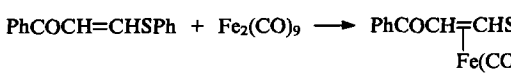
$$XCH{=}CHY + Fe_2(CO)_9 \longrightarrow Fe(CO)_4(\eta^2\text{-}CHX{=}CHY)\,.$$

In certain cases, the substituents at the double bond can influence significantly the mode of these reactions and the nature of the products formed. It has been established[8] that, depending on the electronic effects of the substituent X, the unsaturated

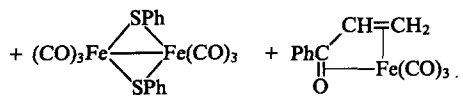
L V Rybin, M I Rybinskaya A N Nesmeyanov Institute of Organoelement Compounds, Russian Academy of Sciences, ul. Vavilova 28, 117813 Moscow. Fax (7-095) 135 50 85.



Received 15 April 1993
Uspekhi Khimii **62** (7) 680–689 (1993); translated by A K Grzybowski

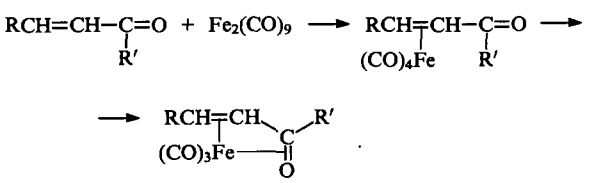


ketones RCOCH = CHX can give rise to qualitatively different results in reactions with iron carbonyls. When the substituent X is a strong electron-donating group, for example, the amino-group, a π-complex is not formed. When there are two strong electron-accepting groups at the double bond, as happens, for example, in β-nitrovinyl ketone, the reaction with iron carbonyls proceeds extremely vigorously but a polymeric product is formed. Vinyl ketones having substituents with stronger electron-donating or electron-accepting properties (X = Cl, H, COOR, etc.) form olefin complexes.

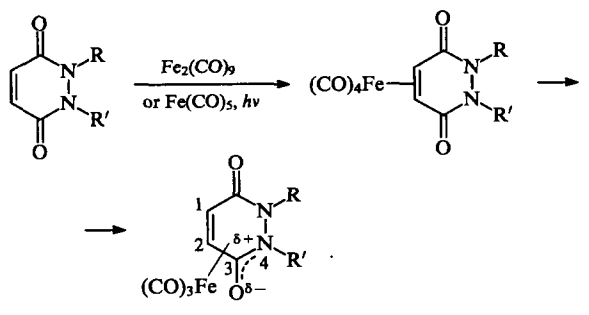


Such differences are determined by the difference between the energies of the lowest unoccupied π* orbital of the olefin and the 3*d* and 4*s* orbitals of iron. According to calculated data,[8] the unoccupied π* orbital is highest in amonovinyl ketone. For this reason, the formation of a π-complex by the latter is unlikely. The lowest orbital occurs in nitrovinyl ketone and in this instance there is a possibility of complete electron transfer from the metal to the ligand with subsequent polymerisation of the latter.

The energy of the π* orbitals in β-chlorovinyl ketone occupies an intermediate position, which ensures adequate reverse electron donation from the metal to the ligand and hence permits the formation of a stable π-bond.

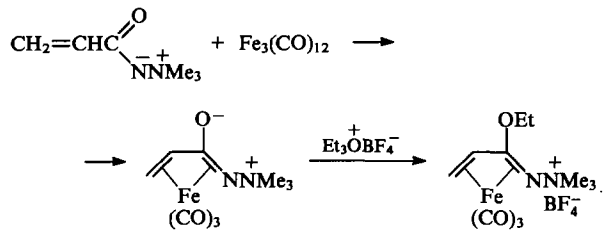


Certain substituents complicate the synthesis of η^2-olefin complexes by participating in reactions with iron carbonyls, for example:[14, 30]



If the substituted olefins contain a heterodiene bond system, there is a possibility of the formation of heterodiene tricarbonyl complexes as a result of the $\eta^2 \rightarrow \eta^4$ transition in the initial η^2-olefin complexes:[5-9, 11, 31]

$\eta^2 \rightarrow \eta^4$ transition of this type have been observed also by other investigators.[32-34]



In the study of the reactions of unsaturated acid amides and related compounds with iron carbonyls, the possibility of the coordination of the metal to the amide fragment in the unsaturated ligand was demonstrated for the first time.[15] This was established unambiguously in the study of the reactions of cyclic maleic acid hydrazides with iron carbonyls.[17]

1

The structure of the η^4-complexes **1** was established by X-ray diffraction. The iron atom in complex **1** is linked to four neighbouring C(1), C(2), C(3), and N(4) ring atoms, i.e. the maleic acid hydrazide can be regarded as an azadiene ligand.

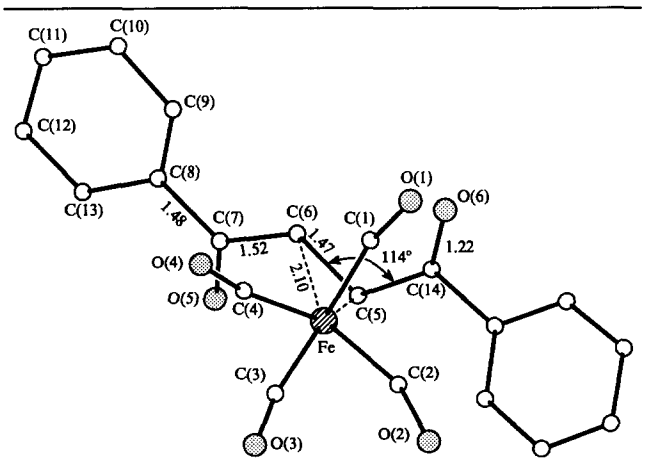
A stable η^4-complex of the azadiene type was also obtained for an open-chain compound, namely for the acrylic acid aminoimide.[15]

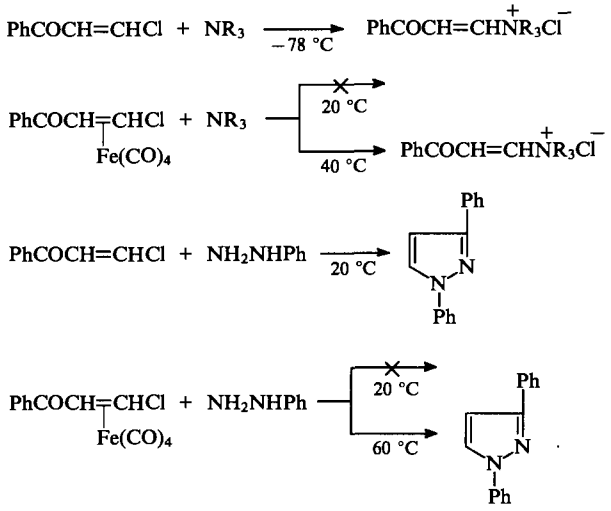
The interaction of the unsaturated acid amides themselves with iron carbonyls results in the formation, together with the complexes $Fe(CO)_4(\eta^2\text{-RCH}=\text{CHCONR'R''})$ as the main product of extremely unstable iron tricarbonyl compounds which can be characterised only with the aid of IR spectra. On the basis of the analogy between unsaturated amides, on the one hand, and maleic hydrazides and acrylic acid aminoimide on the other, one can postulate that the unstable $Fe(CO)_3$ complexes of unsaturated amides also have the η^4-azadiene structure. This hypothesis agrees with calculated data.[15]

2. The change in the properties of substituted olefins on π-coordination to zerovalent iron

Coordination to the iron carbonyl group entails significant changes in the electronic state, structural parameters, and reactivity of the η^2-olefin ligand with functional group substituents.

X-Ray diffraction study[35] of the complex $Fe(CO)_4$ (η^2-PhCOCH = CHCOPh) demonstrated a significant increase in the length of the coordinated double bond to 1.47 Å and a decrease in the bond angles of the olefinic carbon atoms by 5° – 6° (Fig. 1). These structural changes indicate a decrease in the order of the double bond and partial sp^2-sp^3-rehybridisation of the olefinic carbon atoms, which is probably a result of the significant back-donation of electrons from the metal to the ligand in such complexes. A similar conclusion can be arrived at by analysing the spectroscopic data for the complexes $Fe(CO)_4$ (η^2-XCH = CHY).





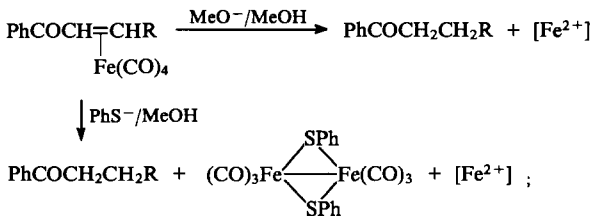


Figure 1. The structure of the $Fe(CO)_4(\eta^2\text{-PhCOCH}=\text{CHCOPh})$ molecule.

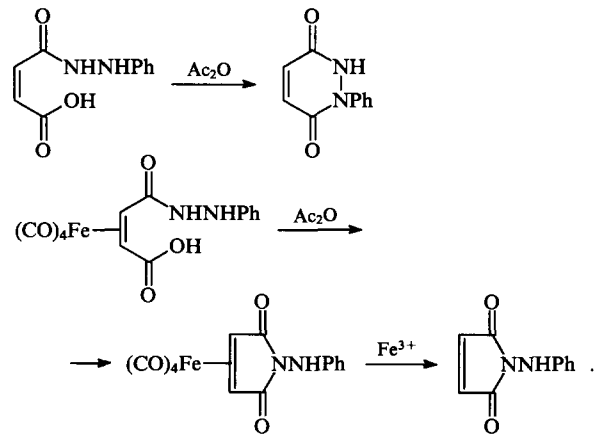
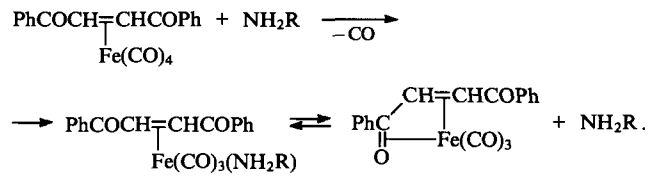
Such changes are reflected in the chemical properties of the olefin ligand and are manifested by a decrease in the electrophilicity of the double bond and of the functional groups in the ligand. For example, β-chlorovinyl ketones are known to react readily with nitrogen-containing bases,[36, 37] but their $Fe(CO)_4$ complexes are resistant under mild conditions to the action of these nucleophiles and the iron–olefin bond is ruptured only on heating.[16]



The cleavage of the π-bond accompanied by the reduction of the unsaturated ligand on treatment of stable olefin complexes with anionic nucleophiles has been observed.[30, 31]

Free β-substituted vinyl ketones combine with nucleophiles under these conditions.[38]

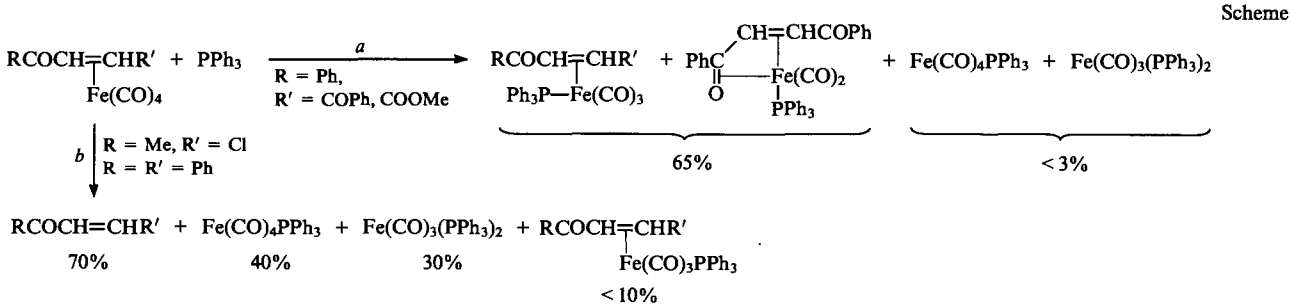


R = COPh, COOMe.

The change in the chemical properties of the unsaturated ligand on coordination to the $Fe(CO)_4$ group is manifested in the cyclisation of β-carboxyacryloylhydrazines: in the case of the substitution of the free olefin, six-membered rings are formed, whilst in the case of its $Fe(CO)_4$ complex the products are five-membered rings.[16]

This factor has been used for synthetic purposes in order to obtain substituted maleimides.

In addition, reactions due to the presence of iron carbonyl groups, for example, the reaction involving the substitution of CO ligands with retention of the metal–olefin bond, are characteristic of complexes of substituted olefins.[39]

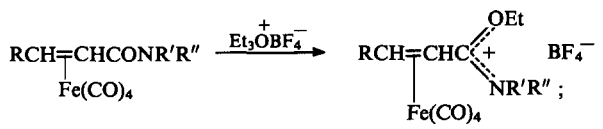


The reactions with triphenylphosphine may be used for the comparative characterisation of the strength of the Fe–CO and Fe–olefin bonds. It has been shown that the enhancement of the electron-accepting properties of the olefin and hence the increase in the strength of the π-bond alter the mode of the substitution reactions.[10] Thus the interaction of the complexes of α,β-dibenzoylethylene and methyl β-benzoylacrylate with PPh_3 results in the formation mainly of the products of the substitution of the CO ligand (Scheme 1, pathway *a*), whereas treatment of the less stable complexes of chalcone and methyl β-chlorovinyl ketone with phosphine leads to the preferential substitution of the unsaturated ligand (Scheme 1, pathway *b*).

3. The formation of the olefin, allyl, and elementaallyl structures in the iron carbonyl complexes. Haptotropic rearrangements.

The question of the interaction of the metal with the substituents is important in the study of complexes with substituted olefins. One can imagine two limiting cases: complexes of the η^2-olefin type **A** in which there is no such interaction and complexes **B** in which the metal is bound to the substituent.

Scheme 1

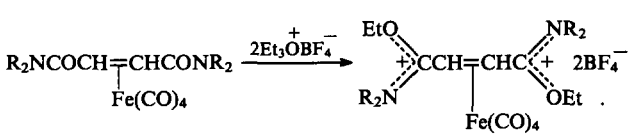


A B

In the general cases complexes **B** can be assigned to the η^3-allyl type if the metal is linked to X via a carbon atom, or to the η^3-elementaallyl type if the bond between the metal and the substituent X is formed via a non-carbon atom.

The question of the formation of the olefin and allyl structures has been investigated for complexes containing a positively charged substituent at the double bond. It was assumed that the degree of delocalisation of the charge can influence significantly the structure of such compounds.

a. Olefin complexes

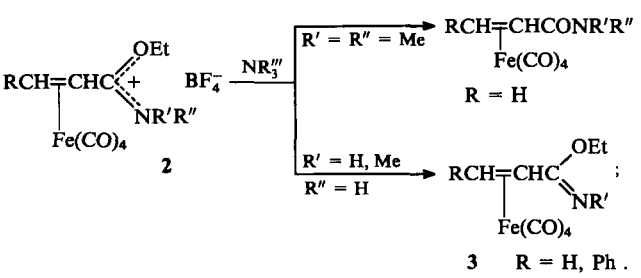


The olefin complexes with a positively charged substituent in the ligand can be synthesised by ethylating the amide group in the iron tetracarbonyl complexes of unsaturated acid amides.[40-42]

2

R = R′ = R″ = H; R = H, R′ = R″ = Me;
R = R′ = H, R″ = Me; R = Ph, R′ = R″ = H.

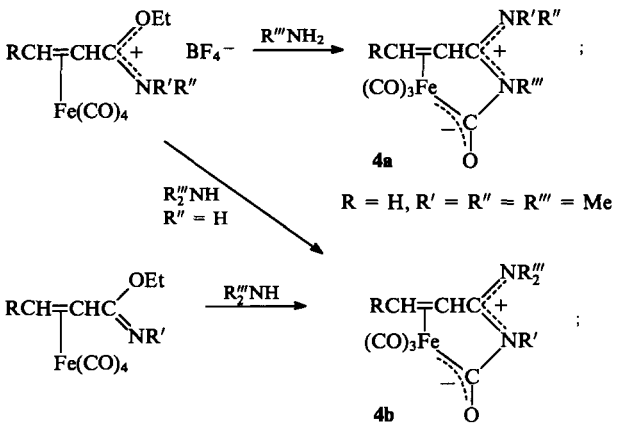
In the case of dibasic acid amides, dicationic complexes were obtained.



2a

Complexes **2** have the η^2-olefin structure. The signal of the α-carbon atom in the ^{13}C NMR spectra is significantly displaced downfield ($\delta \approx 180$ ppm) in comparison with the signals of olefinic carbon atoms (δ = 130–140 ppm), i.e. into the region characteristic of carbonium ions.

Complexes **2** were the first olefin complexes with a positively charged substituent.



The reactions of complexes **2** with amines proceed with retention of the Fe–C(olefin) and Fe–C(carbonyl) bonds, which constitutes a fundamental difference between them and the reactions of the neutral olefin complexes of iron considered previously. Tertiary amines are dealkylating or deprotonating agents.

The deprotonation of the imidate group in the η^2-ligand in complexes **2** constitutes a method of synthesis of complexes of unsaturated acid iminoesters **3**. These complexes cannot be obtained directly from the iminoesters and iron carbonyls, whereas coordination to the $Fe(CO)_4$ group stabilises the unstable acrylic iminoesters.

2 **3** R = H, Ph.

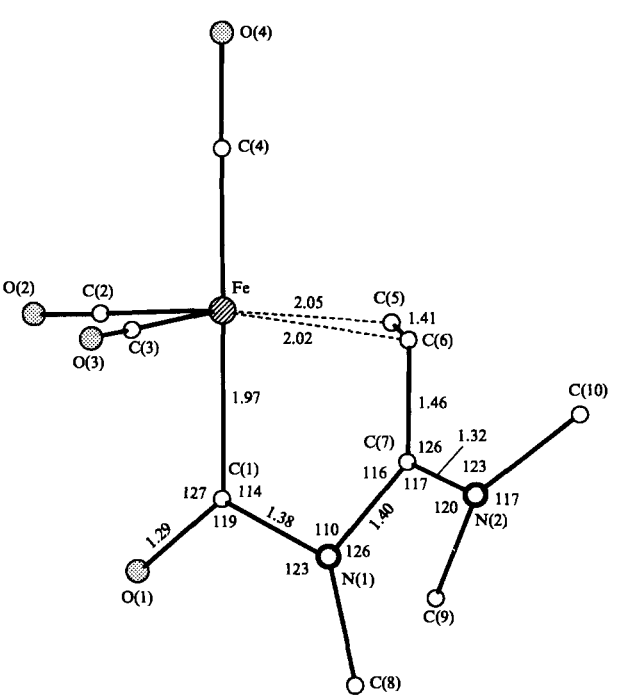
The dipolar chelate olefincarbamylate complexes **4** are formed in the reactions of the complexes of the iminoesters and their salts with primary and secondary amines.[40, 41, 49]

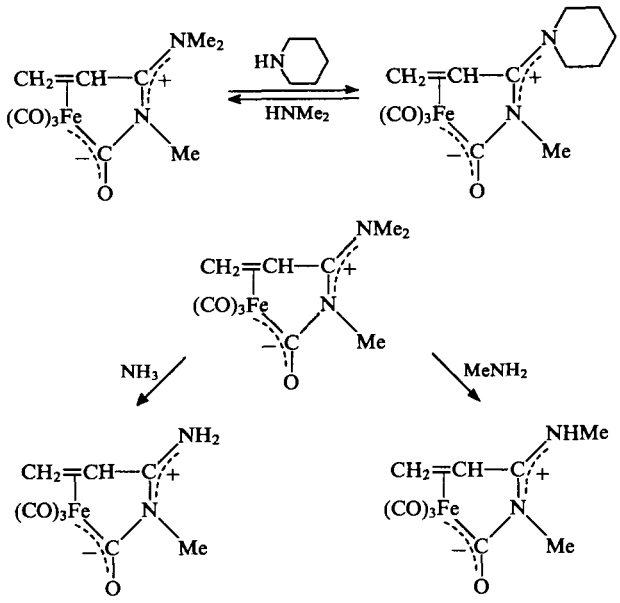
4a **4b**

R = H, R′ = R″ = R‴ = Me

R = H, R′ = R‴ = Me, H; R′ = H, R‴ = Me;
R′ = Me, R_2''' = $(CH_2)_5$; R′ = H, R_2''' = $(CH_2)_5$;
R = Ph, R′ = H, R‴ = Me.

The structure of the chelate complexes **4** has been established by X-ray diffraction (Fig. 2).[40, 44]





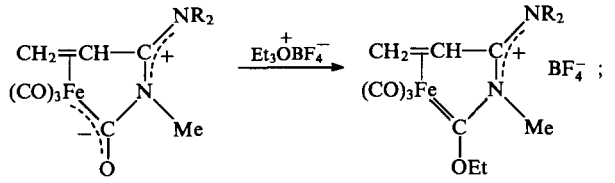


Figure 2. The structure of the molecule of complex **4** (R = H, R′ = R″ = R‴ = Me).

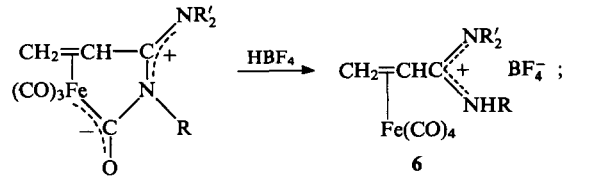
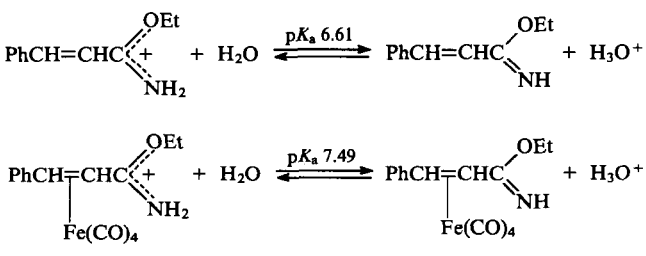
In conformity with the dipolar structure, complexes **4** react both with nucleophiles and electrophiles. The transamination reactions, which make it possible to convert a more readily available complex into others which are less easy to obtain, are important for synthetic purposes.[43]



The reactions with electrophiles, for example, with the triethyloxonium cation and acids, lead to new olefin complexes with an α-cationic centre[40, 41, 43] — the vinylcarbene complex **5** and the acrylamidinium complex **6**.

R = Me, $R_2 = (CH_2)_5$.

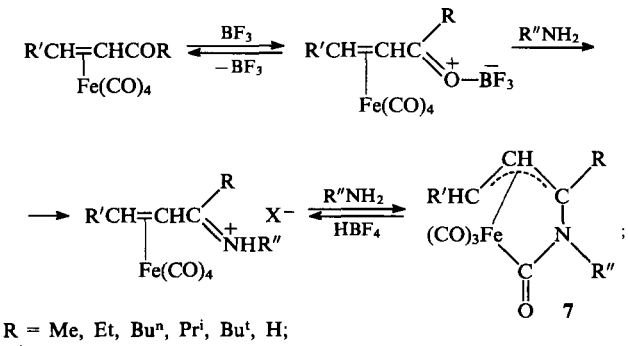


5

R = R′ = Me; R = Me, $R'_2 = (CH_2)_5$;
R = H, R′ = Me.

Examination of the characteristic features of the structures of complexes **2**–**6** permits the conclusion that the olefin structure with direct interaction between the metal and the cationic centre occurs in those cases where the charge is delocalised to a large extent owing to the presence of strong electron-donating substituents, for example, amino-groups.

The stabilising effect of the $Fe(CO)_4$ group in olefin complexes with a cationic centre has been estimated quantitatively by measuring and comparing the pK_a of ethyl cinnamidate and the corresponding iron tetracarbonyl complex.[45]



Comparison of the pK_a indicates a powerful electron-donating effect of the $Fe(CO)_4$ group, which more than compensates for the loss of conjugation as a result of the π-coordination.

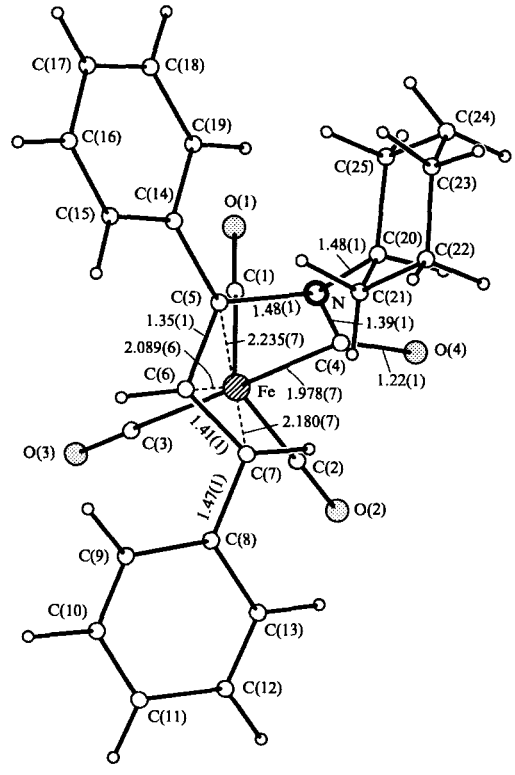
b. Allyl complexes.

$\eta^3:\eta^1 \rightleftarrows \eta^2$-Tautomerism and the $\eta^2 \rightarrow \eta^1$(N) rearrangement.

The replacement of the strong electron-donating amino-group at the cationic centre in the olefincarbamylate complexes **4** by a weaker electron-donating group — an alkyl or aryl group — alters their structure, namely leads to a transition to compounds of the allyl type. Such compounds have been synthesised from the $Fe(CO)_4$ complexes of unsaturated ketones and cinnamaldehyde via their adducts with BF_3 and the subsequent reaction with amines.[39, 46, 47]

R = Me, Et, Bu^n, Pr^i, Bu^t, H;
R′ = Ph, PhCO, H;
R″ = H, Me, Et, Pr^i, Bu^n, Bu^t, n-C_6H_{13}, cyclo-C_6H_{11}, CH_2Ph .

The structure of the chelate $\eta^3:\eta^1$-allylcarbamoyl complexes **7** in the solid state has been established by X-ray diffraction (Fig. 3).[46, 48]



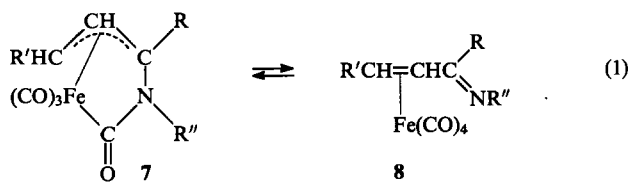


Figure 3. The structure of the molecule of complex **7** (R = R′ = Ph, R″ = cyclo-C_6H_{11}).

Table 1. Thermodynamic parameters of the equilibrium **7** ⇄ **8** (R = Me, R′ = Ph, R″ = cyclo-C_6H_{11}).

Solvent	ΔH/kJ mol^{-1}	ΔS/J mol^{-1} deg^{-1}	ΔG/kJ mol^{-1}		
			295 K	250 K	210 K
Hexane	11.8	49.5	−2.8	−0.6	1.4
Hexane-CH_2Cl_2 (96:4)	20.3	72.8	−1.2	2.1	–

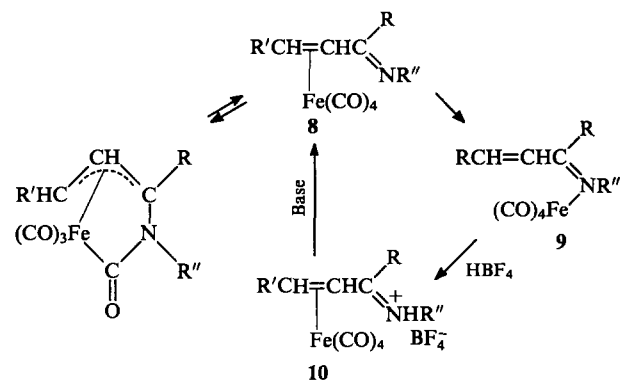
In solutions, complexes **7** rearrange reversibly to the isomeric η^2-olefin complexes **8**.[12, 41, 47]

(1)

7 **8**

The IR spectra of complex **7** with R = Me or n-alkyl, R′ = Ph or H, R″ = Me, Et, Pr^i, Bu^n, cyclo-C_6H_{11}, or CH_2Ph in non-polar solvents, for example in hexane, are seen to contain not only the three $\nu(C\equiv O)$ bands referring to the allylcarbamoyl form (~2065, 2010, and 1990 cm^{-1}) but also additional bands (~2085, 2020, 2010, and 1985 cm^{-1}), the positions and relative intensities of which indicate the presence in the molecule of the complex of the $Fe(CO)_4$ group η^2-linked to the olefin ligand.

The formation in solution of the η^2-olefin complexes **8** has been confirmed also by NMR spectroscopic data. Thus equilibrium (1) with R = Me, R′ = H, and R″ = Pr^i is displaced to the right so much that the ^{13}C NMR spectrum shows only signals due to the olefin form [$\delta(C_{olef})$ = 148.97 and 140.06 ppm and $\delta(C_\alpha)$ = 146.06 ppm; cyclopentane; 10 °C]. The ^1H NMR spectra can also serve as a demonstration of the appearance in solutions of the η^2-olefin form **8**. However, complex **8** could not be isolated in a pure state.



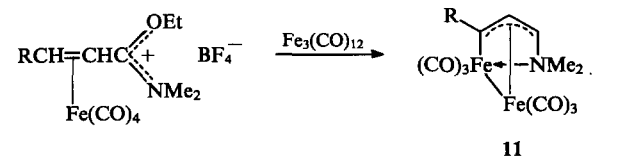
The dependence of the equilibrium position on the temperature, the solvent polarity, and the nature of the substituent in the ligand has been investigated quantitatively by IR spectroscopy.[12, 49]

The thermodynamic parameters of the reversible transition from the cyclic allyl form to the open-chain olefin form for the complex with R = Me, R′ = Ph, and R″ = cyclo-C_6H_{11} are presented in Table 1. With decrease in temperature, the equilibrium shifts towards the formation of the chelate form. The positive entropy change can probably be accounted for by the transition from the rigid chelate molecule to the more mobile molecule with an open chain. On passing to a more polar solvent, the relative stability of the more readily solvated chelate form also increases. The lower limit of the rate constant for the forward reaction ($k > 2.3 \times 10^{-3}$ s^{-1}) and the corresponding upper limit to the activation energy ($\Delta G^{\neq} < 90$ kJ mol^{-1}) were estimated.

The thermodynamic and kinetic parameters of the equilibrium isomerisation of the chelate alkylcarbamoyl complexes to the open-chain olefin complexes are within the limits of the corresponding scales for the tautomeric transformations.[50] Such isomerisation can be regarded as the first example of the ring–chain valence $\eta^3:\eta^1 \rightleftarrows \eta^2$-tautomerism. A characteristic feature of this process consists in the fact that, simultaneously with the opening and closure of the ring, the hapto-binding of the metal to the unsaturated ligand and the formal oxidation state of the metal change.

The steric requirements of the substituents R at the α-carbon atom and R″ at the nitrogen atom exert a significant influence on the equilibrium position.[12] An increase in the bulk of the substituent R leads to a sharp shift of the equilibrium towards the cyclic form. As a consequence of the increase in the bulk of the substituents R″ at the nitrogen atom, there is a smaller shift in the opposite direction.

The η^2-olefin complexes **8**, formed as a result of the tautomeric shift, are capable of rearranging further to the η^1(N)-complexes **9**.[51] Such $\eta^2 \rightarrow \eta^1$(N) rearrangement occurs when the substituents R and R″ are small alkyl groups or one of them is a hydrogen atom. The rate of the rearrangement is appreciably lower than the rate of the tautomeric transformations. Complexes with R = H rearrange faster. The reverse η^1(N) → η^2 rearrangement occurs on protonation of complexes **9**. The deprotonation of the η^2-complexes **10** formed again opens the way to the $\eta^3:\eta^1 \rightleftarrows \eta^2$ tautomerism and the η^1(N) → η^2 rearrangement.



10

R = H, R″ = Me, cyclo-C_6H_{11}, Ph; R = Me, R″ = Me, Et; R = Et, Bu^n, R″ = Me, Et, Bu^n; R = Ph, Bu^t, R″ = H.

The tautomeric transformations and rearrangements investigated are characterised by the ease of the interconversions of various types of complexes containing unsaturated ligands with functional group substituents.

The conversion of the acrylimidate η^2-complexes **2** into the dinuclear η^3-aminoallyl† complexes **11** on heating with $Fe_3(CO)_{12}$ can also be formally classified as a hapto-transition.[42, 52]

11

The structure of these complexes was established by X-ray diffraction.[52]

c. Olefin and elementaallyl complexes

σ-Vinyl derivatives of elements of the type $RCH{=}CHER'_n$ occupy a special place among substituted olefins. The reactions of such compounds with iron carbonyls open the way to the synthesis of dinuclear and polynuclear complexes with a η^2-olefin or η^3-elementaallyl structure.

† Complexes **11** can also be regarded as compounds containing the azaferra-ring, which is η^4-coordinated to the other iron atom via its ferradiene system.

The structure of the complexes formed is influenced by the nature of the element. Thus the interaction of the σ-ketovinylrhenium compound with $Fe_2(CO)_9$ results in the formation of only the η^2-olefin complex without the Re–Fe bond.[26]

$$(CO)_5Re(\sigma\text{-}CH{=}CHCOMe) + Fe_2(CO)_9 \longrightarrow \longrightarrow MeCOCH{=}CHRe(CO)_5 \; . \quad | \; Fe(CO)_4$$

The σ-ketovinyltungsten derivative affords under the same conditions the tungstaallyl complex with an intermetallic bond together with the olefin and oxadiene complexes.[24]

$$Cp(CO)_3W(\sigma\text{-}CH{=}CHCOPh) + Fe_2(CO)_9 \longrightarrow \longrightarrow PhCOCH{=}CHW(CO)_3Cp + \; | \; Fe(CO)_4$$

$$+ \; PhC(O)CH{=}CHW(CO)_3Cp + PhCOCH{=}CHW(CO)_2Cp \; . \quad Fe(CO)_3 \qquad (CO)_3Fe{-}CO$$

On the other hand, in the case of the σ-vinyl derivatives of iron, the metallallyl complexes are the only reaction products.[23, 25, 26, 53]

$$Cp(CO)_2Fe(\sigma\text{-}CH{=}CHR) + Fe_2(CO)_9 \longrightarrow \longrightarrow RCH{=}CHFe(CO)Cp \; ; \quad (CO)_3Fe \; CO$$

R = H, Ph, COMe, COPh, CON⬡.

The structure of the ferraallyl complexes was established by X-ray diffraction.

The reactions of $Fe_2(CO)_9$ with various σ-vinyl derivatives of metals described above are the first examples of π-complex formation involving a σ-linked unsaturated ligand.

The nature of the complexes formed changes when the olefin contains two σ-linked iron carbonyl groups.[28]

In this case, a trinuclear complex with a bridging carbyne ligand, the formation of which requires an extensive rearrangement of the acryloyl ligand, was isolated together with the olefin and ferraallyl complexes. Its structure was demonstrated by X-ray diffraction (Fig. 4).[28]

$$Cp(CO)_2FeCOCH{=}CHFe(CO)_2Cp + Fe_2(CO)_9 \longrightarrow \longrightarrow Cp(CO)_2FeCOCH{=}CHFe(CO)_2Cp + \; | \; Fe(CO)_4$$

48%

$$+ Cp(CO)_2FeCOCH{=}CHFe(CO)Cp + MeC{\equiv}CFeCp \; . \quad (CO)_3Fe{-}CO \qquad Fe{-}CO \; (CO)_3$$

15% 2%

π-Complexes could not be obtained in the reactions of iron carbonyls with substituted σ-vinylpalladium(II) compounds.[29] At the same time it was found that, on heating in benzene, the σ-alkoxycarbonylvinylpalladium complexes undergo the $\eta^1 \rightarrow \eta^2$ rearrangement.

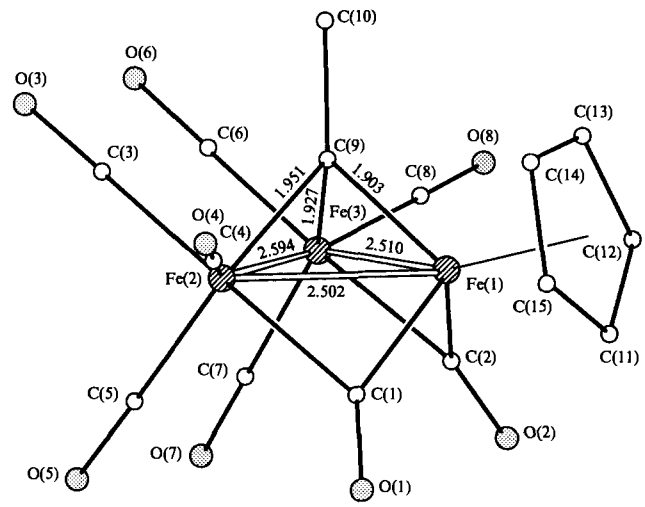


Figure 4. The structure of the molecule of the μ_3-ethylidyneoctacarbonyltriiron complex.

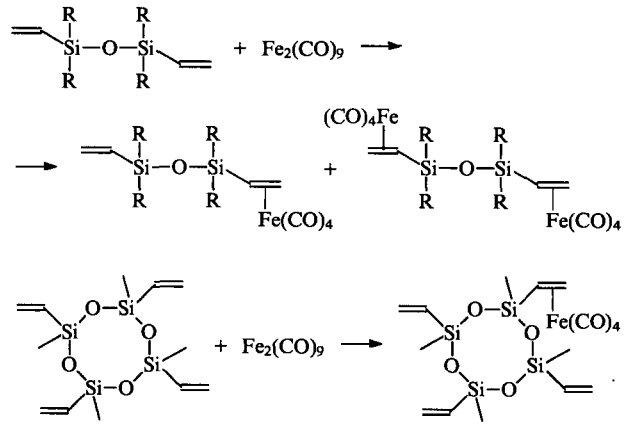
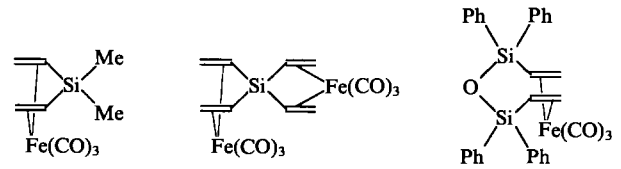
$$Ph_3P(X)Pd(CH{=}CHCOOR) \xrightarrow{80\ ^\circ C} X(Ph_3P)Pd^{-}(CH{-}PPh_3)^{+} \; ; \quad CH{-}COOR$$



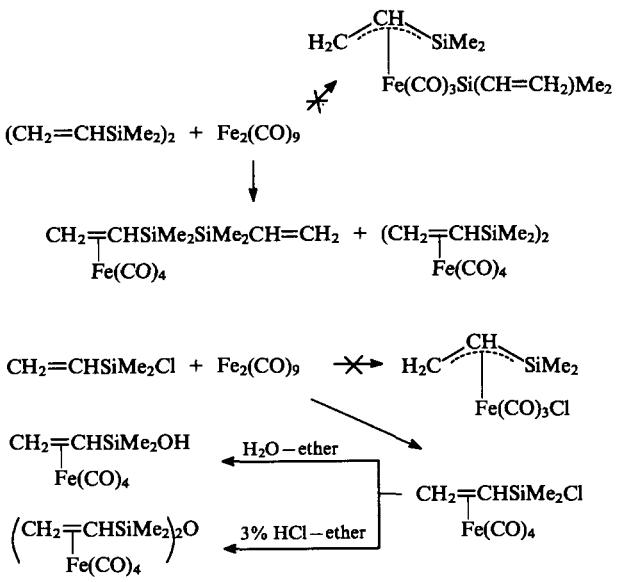
R = Me, Et; X = Cl, I.

Complexes in which the metal is coordinated only to the carbon–carbon double bonds have been obtained in the reactions of various vinyl compounds of silicon with iron carbonyls.[19, 20]



$$CH_2{=}CHSiRR'_2 + Fe_2(CO)_9 \longrightarrow CH_2{=}CHSiRR'_2 \; ; \quad | \; Fe(CO)_4$$

R = R′ = Me, OMe;



R = CH=CH$_2$, R′ = Me; R = R′ = CHCH$_2$;

η^4-Diene complexes have been obtained from dimethyldivinyl- and tetravinyl-silanes and also from 1,3-divinyltetraphenyldisiloxane and iron carbonyls.[20, 55]

η^3-Silaallyl complexes could not be obtained from divinyldisilanes or chlorovinylsilane.[18]

The absence of compounds of the silaallyl type among the reaction products can probably be explained by the fact that the stabilisation as a result of the formation of a π-complex with a metal is insufficient for the formation of stable structures with silicon–carbon multiple bonds.

The reactions of vinylgermanes and digermanes with $Fe_2(CO)_9$ also lead to complexes of the olefin type.[21]

$$CH_2{=}CHGeR_2R' + Fe_2(CO)_9 \xrightarrow{30-40\ ^\circ C} CH_2{=}\underset{\displaystyle Fe(CO)_4}{CH}{-}GeR_2R';$$

R = R′ = Et, $CH{=}CH_2$;

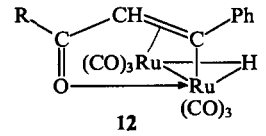
R = $CH{=}CH_2$, R′ = $Ge(CH{=}CH_2)_3$.

The interaction of iron carbonyls with germanes containing at least one vinyl group leads, under more severe conditions, to the elimination of all the organic groups from germanium and the formation of an iron-germanium cluster.[21, 22]

$$CH_2{=}CHGeR_2R' + \begin{matrix} Fe_2(CO)_9 \\ \text{or} \\ Fe_3(CO)_{12} \end{matrix} \xrightarrow{110\ ^\circ C} (CO)_4Fe\!-\!Ge\!-\!Fe(CO)_4$$

III. Reactions of ruthenium and osmium carbonyl complexes with olefins having functional group substituents

The reactions of ruthenium and osmium carbonyl compounds with substituted olefins have been less investigated than those of their iron analogues. The main cause of the slow development of this field is apparently not only the high cost of the compounds of the above metals but also the specific features of the behaviour of the most readily available carbonyls $M_3(CO)_{12}$, the chemical properties of which are determined by the greater strength of their M–M and M–CO bonds compared with iron carbonyls (Table 2).[56]



The products formed initially undergo further reactions under severe thermal conditions. This frequently results in the formation of mixtures of complexes which are difficult to separate. The metallic M_3 skeleton is either retained in these reactions or actually increases, whilst unsaturated hydrocarbons are dehydrogenated and undergo oxidative addition to the metal with formation of structures containing allyl, allenyl, alkyne, and vinylidene ligands.[57]

Table 2. The bond enthalpies in the carbonyls $M_3(CO)_{12}$ (in kJ mol^{-1}).

Bond	Fe	Ru	Os
M–M	80.37	117.2	130.2
M–CO	117.6	172.5	191.7

Trinuclear ruthenium and osmium carbanions react with olefins also under photochemical conditions. On UV irradiation, the M–M bonds are ruptured and mononuclear η^2-olefin complexes, similar to the η^2-olefiniron complexes already examined, are formed.[58–60]

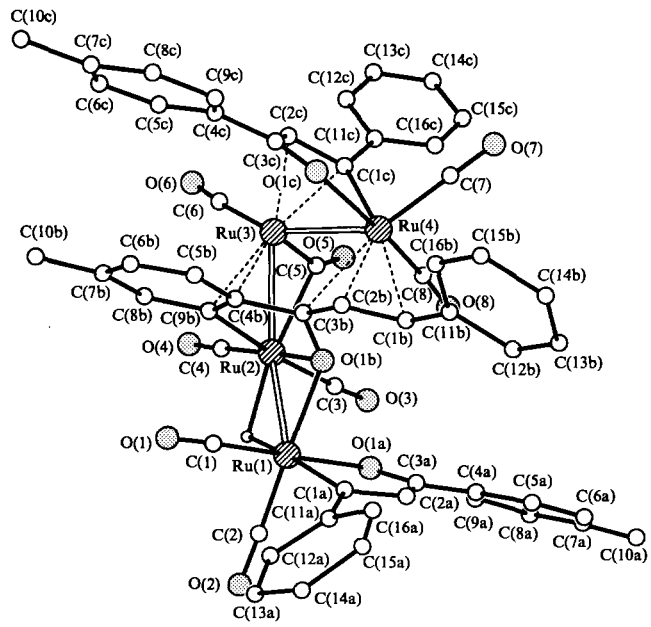
The pattern becomes even more complicated after the introduction of functional groups into the olefin molecule. The study of the thermal reactions of $M_3(CO)_{12}$ (M = Ru, Os) with organic unsaturated carbonyl compounds showed that such systems can be coordinated in different ways to the polynuclear fragment. Thus, in the interaction of the unsaturated ketones $PhCH{=}CHCOR$ (R = Me, p-MeC_6H_4) with $Ru_3(CO)_{12}$ in boiling hydrocarbons (hexane, benzene, heptane), dinuclear complexes **12** are formed as the main products.[61]

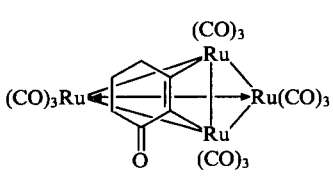
12

12a: R = Me;
12b: R = p-MeC_6H_4.

The structure of complex **12a** was established by X-ray diffraction. Previously this complex had been obtained by the reaction of benzylideneacetone with mononuclear (η^4-cycloocta-1,5-diene)tricarbonylruthenium.[62] The ruthenium atoms in complex **12a** are linked by a metal–metal bond, a μ-hydride ligand, and an enone ligand which has lost one hydrogen atom. The last ligand chelates one Ru atom via the β-carbon atom (σ-bond) and the ketone oxygen atom (n-donor bond). The other ruthenium atom is η^2-coordinated to the same ligand.

Apart form complexes **12**, a series of other complexes are also formed in the reaction of $Ru_3(CO)_{12}$ with $PhCH{=}CHCOR$. The structure of one of them, namely complex **13**, was determined by X-ray diffraction (Fig. 5).[61]





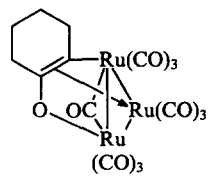


Figure 5. The structure of the molecule of complex **13**.

The molecule of complex **13** includes a chain made up of four ruthenium atoms and three organic ligands. One $PhC=CHCOC_6H_4Me$ ligand at the edge chelates the Ru(1) atom via the β-carbon atom (σ-bond) and the oxygen atom of the keto-group (n-donor bond), forming a five-membered metallocycle. Another similar ligand chelates the Ru(4) atom via the formation of σ-bonds with carbon and oxygen atoms and is also η^2-linked to Ru(3) via the C=C double bond.

The central ligand serves as a μ^4-bridge between all the ruthenium atoms and is linked to them in various ways. Its oxadiene fragment is converted into the hydroxyallyl fragment, which is η^3-linked to Ru(4) and is σ-O-linked to Ru(1) and Ru(2). In addition, Ru(2) forms a σ-bond with the *ortho*-carbon atom of the tolyl substituent and Ru(3) is involved in π-olefin coordination with the same substituent. Thus the ways in which the α,β-unsaturated ketones are coordinated in the ruthenium clusters are extremely varied. They depend primarily on the structure of the unsaturated ketone. When cyclohex-2-en-1-one was used in the thermal reaction with $Ru_3(CO)_{12}$, complexes **14** and **15** were obtained.[63, 64]

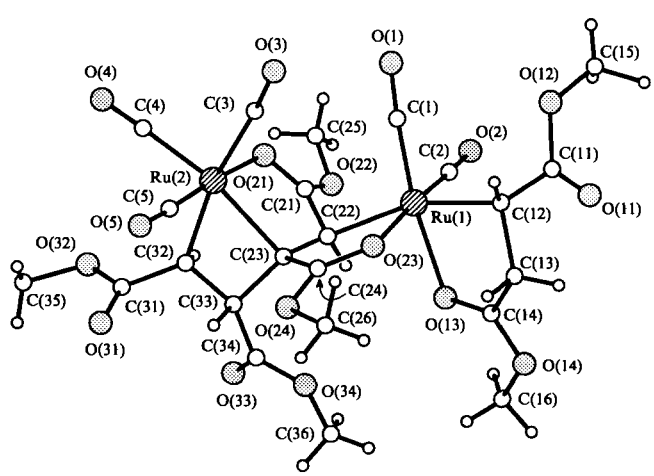
14

15

In complex **14**, the four ruthenium atoms form the 'butterfly' configuration. The metal atoms 'at the ends of the wings' are π-linked, while the axial metal atoms are σ-linked to the dehydrogenated cyclohexene.

Interesting examples of the wide variety of the ways in which bonding takes place in the ruthenium clusters are provided by the complexes formed in the reactions of unsaturated aldehyde imines (azadienes) with $Ru_3(CO)_{12}$.[65-69] Various types of bonds between the metal and the organic ligand are formed in these polynuclear compounds: σ-N, σ-C, η^2-C = C, η^2-C = N, η^3-allyl, and η^3-azaallyl.

Complex **16**, in which there is no intermetallic bond and the metal atoms are linked only to the common organic ligand, is formed in the reaction of $Ru_3(CO)_{12}$ with dimethylfumarate.[70] According to X-ray diffraction data (Fig. 6), the double bonds in the three dimethylfumarate ligands in complex **16** were opened [partly dissociated?] and two ligands dimerised with formation of three condensed metallacycles. One hydrogen atom was then transferred to the third ligand forming the fourth metallacycle.



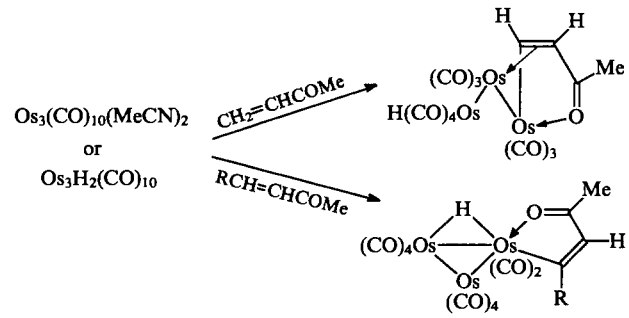


Figure 6. The structure of the molecule of complex **16**.

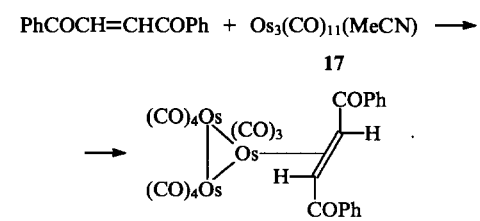

Several other complexes were obtained in this reaction, including the mononuclear complex $Ru(CO)_4(\eta_2$-MeOCOCH=CHCOOMe).

The examples examined above show that organic α,β-unsaturated carbonyl compounds in the ruthenium carbonyl complexes exhibit a tendency towards many-centre bonding, including the formation of σ-Ru–O and σ-Ru–C_β bonds.

The situation is similar also in the case of reactions of osmium carbonyl complexes with unsaturated ketones.[71]

For this reason, relatively few simple η^2-olefin complexes of transition metal clusters are known. In order to obtain a η^2-olefinosmium cluster complex, the monoacetonitrile derivative $Os_3(CO)_{11}(MeCN)$ **17** was used. The latter is normally employed for the synthesis of undecacarbonylosmium compounds.[72] When compound **17** was refluxed with *trans*-α,β-dibenzoylethylene in hexane, the η^2-olefin complex **18**, in which the Os_3 cluster skeleton is retained, was obtained.[73]

Abstract. The scientific-technical and patent literature on the synthesis of derivatives of diphosphonic acids is surveyed. Various methods of synthesis of diphosphonate, phosphonylphosphinyl, and phosphonophosphate compounds are described. The principal aspects of the use of the above compounds in medicine, biochemistry, and agriculture are examined. The bibliography includes 174 references.

I. Introduction

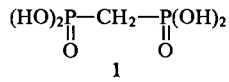
In recent years, many investigators have shown interest in the method of synthesis and the detection of biological activity of phosphonic acids and their derivatives, which can be regarded as analogues of natural phosphates. Pyrophosphates containing the P–O–P linkage are known to be natural regulators of the metabolism of calcium at the cellular level. Attempts have been made to use inorganic pyrophosphates in the treatment of diseases associated with the breakdown of the calcium metabolism, but the desired results were not achieved owing to the hydrolysis of the above compounds by pyro- and polyphosphatases. Synthetic analogues of pyrophosphates, namely diphosphonates, which are not metabolised because of the presence of P–C–P linkages, attracted the attention of investigators. There exists a series of monographs and reviews in which the methods of synthesis, properties, and the results of biochemical and clinical tests on diphosphonates are considered. However, these studies were devoted as a rule either only to the synthesis of these compounds[1,2] or only to the analysis of their pharmacological properties.[3–10] In a series of investigations attention was devoted merely to the narrow subclass of biphosphoryl substances.[11,12]

The biologically active derivatives of diphosphonic acids known at the present time, which contain two phosphorus atoms in the molecule, can be divided into the following main groups:

1. Compounds with geminal or vicinal phosphonate groups:

2. Polyalkylpolyaminodiphosphonic acids.

3. Phosphonylphosphinyl compounds containing the P–C–P–C linkages.



4. The phosphonophosphate compounds P–C–O–P.

The methods of synthesis and biological activities of such compounds are the subject of the present review.

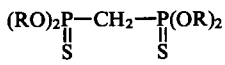
II. Biological activity and synthesis of compounds with geminal phosphonate groups

1. Methylenediphosphonic acid and its halo-derivatives

The closest analogue of inorganic pyrophosphates is methylenediphosphonic acid **1** (MDP), which is capable of forming stable complexes with alkaline earth, transition, and heavy metals. This property of the above compound is used to prevent the deposition of calcium in living tissues.[2]

1

Methylenediphosphonic acid forms part of the composition of many disinfecting and radiopharmaceutical preparations.[13] The radioisotopes of certain metals, for example ^{99}Tc, capable of fulfilling the function of a radioactive probe, are used as the main components of such preparations. Chelation of the cations of the above isotopes by MDP makes it possible to increase their toxicological acceptability to the organism, to facilitate their transport, and to ensure the selectivity of their concentration in particular organs.



MDP can add to adenosine triphosphate and can also inhibit the incorporation of inorganic phosphate in nucleoside polyphosphates and phosphorolysis;[2,14] MDP acts on the immune system, inhibiting inorganic pyrophosphatase as a consequence of competition for the substrate and a decrease in the concentration of the activator (Mg^{2+}) and the substrate.[15] It has been observed that MDP exerts a mutagenic effect on plants.[16] A review has been devoted to the structure, properties,

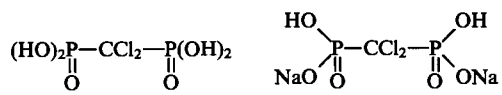
Received 26th January 1993
Uspekhi Khimii **62** (7) 691 – 703 (1973); translated by A K Grzybowski



synthesis, and application of MDP and its full and mixed esters.[13] The main reaction leading to the synthesis of MDP and its derivatives is the Arbuzov reaction in its various versions. Another method incorporates the Michaelis–Bekker reaction of a dihaloalkane or a haloalkylphosphonate with a metal dialkyl phosphite in several modifications.[1,13,17] A consecutive method of synthesis using initially the Arbuzov reaction and then the Michaelis–Bekker reaction, which affords the products in an acceptable yield, has also been reported.[2] An exchange reaction between $CH_2(AlCl_2)_2$ and PCl_3, leading to $CH_2(PCl_2)_2$, has been proposed. The acid dichloride of MDP and methylenediphosphonite $CH_2[P(OR)_2]_2$, has been proposed. The acid dichloride of MDP and methylenediphosphonite $CH_2[P(OR)_2]_2$ have been synthesised from the latter and their oxidation in dimethyl sulfoxide (DMSO) afforded the corresponding MDP esters.[13] There exists a method of synthesis of MDP by the oxidation of the readily available methylenediphosphine $CH_2(PH_2)_2$ with nitric acid.[2]

A patent[18] describes a reaction in which the starting materials for the synthesis of MDP esters are white phosphorus, epoxyethane, and sodium alkoxide. MDP esters can also be obtained from tetraalkylmethylenebisphosphonites by a reaction with carbonyl compounds.[19,20] Any phosphonate can be converted into the acid by acid hydrolysis or via trimethylsilyl esters (by reaction with Me_3SiHal). The esters of methylenephosphonodithionic acid **2** are intermediates in the synthesis of biologically active substances. It has been suggested[21] that they can be obtained by the Michaelis–Bekker reaction induced by UV radiation at reduced temperatures in liquid ammonia.

2

Dichloromethylenediphosphonic acid **3** (DCMDP) and its disodium salt **4**, known as clodronic acid, are used to prevent the excess resorption of bone and the calcification of soft tissues, to regulate calcium metabolism at the cellular level, and to treat osteoporosis.[3,4,22]

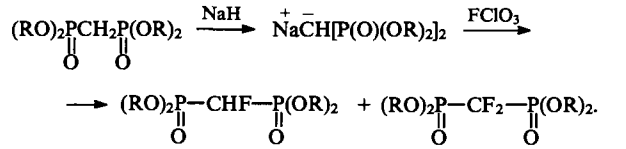
3 **4**

It has been established that DCMDP prevents the spreading of the metastases of bone tumours.[23,24] By regulating the permeability of membranes, this compound also assists in the transport of antitumour drugs into the cell, preventing thereby the disintegration of bone tissue and suppressing the growth of tumours without manifesting toxic properties.[25]

In a study of the effect of dihalomethylenediphosphonates on the activity of alkaline phosphatase and the oxidation of aliphatic acids in cell cultures, it was shown that DCMDP is the most powerful stimulator of the above enzyme compared with the dibromo- and difluoro-derivatives of MDP. The monohalo-derivatives of MDP and the non-halogenated acids are less active in relation to phosphatase and are inactive or inhibit the oxidation of aliphatic acids.[26]

DCMDP can be obtained from trialkyl phosphite, bromotrichloromethane, and an excess of sodium hypochlorite[1] and also as a result of the radical reaction with carbon tetrachloride[27,28] or with $Cl_3CP(O)(OEt)_2$.[29,30]

Difluoromethylenediphosphonic acid (DFMDP) has been proposed as a therapeutic preparation for the treatment of diseases associated with increased desorption of bone. By virtue of the presence of fluorine, this compound can also be used as an experimental means for the investigation of the way in which all diphosphonates act.[31] It has been noted that monofluoro- and difluoro-methylenediphosphonic acids are isopolar analogues of pyrophosphoric acid.[32]

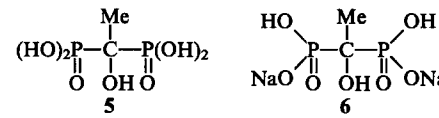


Both symmetrical and asymmetric difluoromethylene-diphosphonates can be obtained by the Michaelis–Bekker reaction[32,33]

$$(RO)_2P(O)M + CF_2XY \longrightarrow (RO)_2P(O)CF_2P(O)(OR)_2,$$

or by the reaction

$$(RO)_2P(O)M + XCF_2P(O)(OR^1)_2 \longrightarrow (RO)_2P(O)CF_2P(O)(OR^1)_2,$$



where X, Y = Cl, Br, or I; M = Na or K; and R, R^1 = alkyl. Another version of the synthesis of fluoromethylene-diphosphonates involves the use of methylenediphosphonic acid esters, which are treated with butyllithium, sodium hydride, or potassium *tert*-butoxide,[1,32,34,35] the carbanions $\bar{C}H(PO_3R_2)_2$ formed being subsequently fluorinated by perchloryl fluoride:[32,34,35]

The esters obtained can be hydrolysed to the corresponding acids.

2. Hydroxyethylidenediphosphonic acid

The best known compounds among diphosphonic acids used in medicine are hydroxyethylidenediphosphonic acid **5** (HEDP) and its disodium salt **6**, called etidronate.

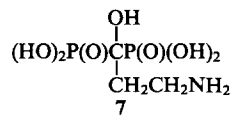
5 **6**

The study of the complex-forming properties of HEDP showed that the combination in the molecule of this compound of two acid phosphono-groups and the hydroxy-group with its comparatively high basicity gives rise to the possibility of the formation by this ligand of stable complexes with alkaline earth, transition, and lanthanide metals. The stability constants of the HEDP complexes of certain metals[12] differ little from the corresponding constants of the MDP complexes. Therefore, by virtue of their ability to reduce the degree of resorption of bone and to diminish the liberation of hydroxyproline, HEDP and etidronate are used as regulators of calcium metabolism at the cellular level in the treatment of Paget's disease.[3,36] In minimal doses, HEDP increases the incorporation of calcium into bone tissue, prevents the development of various types of osteoporosis and myositis and prevents the destruction of the peridontal membrane and of the transplanted bone in animals.[12] HEDP inhibits the formation and growth of calcium oxalate stones in kidneys. The addition of HEDP to dental preparations and toothpastes is an excellent means whereby the formation of plaque and caries can be prevented.[3,11] The use of xydiphone — the potassium sodium salt of HEDP — for the treatment of urinary calculus as an anticalcifying and antiinflammatory agent has been permitted.[37] It has been suggested in the USA that HEDP be used as a pharmaceutical preparation for the treatment of persons suffering from metastatic bone cancer.[38]

The extremely high selectivity of the complex forming capacity of HEDP in relation to beryllium is notewothy.[12] Its introduction into the organism poisoned by Be^{2+} ions eliminates the inhibition of the activity of alkaline phosphates. As stabilisers of cell membranes, HEDP and its salts can be effective prophylactic

agents in diseases such as bronchial asthma and hyperglycemia. By virtue of its ability to reduce to the normal level the concentration of cholesterol and triglycerides in the plasma and also its ability to be incorporated in the phospholipids of cell membranes, HEDP prevents the accumulation of peroxide compounds in erythrocytes.[3,39]

HEDP is widely used for the treatment of rheumatoid diseases. It is particularly effective as an antiarthritic agent in combination with antiinflammatory agents. The antiatherosclerotic effect of HEDP has been described: it was found that it influences the immune system, the genetic apparatus of the cell, the biosynthesis of prostaglandins, the stimulation of the citric acid cycle,[16,40] the metabolism of vitamin D,[2,41] and the embryotropic effect of the latter.[42]



HEDP salts increase the bactericidal activity of phenolic compounds, which permits their use in disinfectants, shampoos, mouth washes, and other similar products. A series of publications have been devoted to the use of HEDP in cosmetics. HEDP esters are employed as pesticides.[11]

Thus comprehensive studies on the properties of HEDP and its salts have led to an extremely wide range of their applications, some of which have been successfully realised in practice.

The practical interest in HEDP is determined primarily also by the ready availability of the starting material and the comparative simplicity of its synthesis, which permitted the industrial manufacture of this product. The reaction of PCl_3 or H_3PO_3 (or their mixture) with acetic acid (or a mixture of acetic acid and acetic anhydride) as well as the reaction of H_3PO_3 with acetic anhydride or carboxylic acid chlorides have been used to synthesise HEDP. Numerous versions of the acylation of phosphorus(III) compounds differ in the reaction conditions, the reactant ratios, and the yields of the target product.[1,11,12,43-51] A method of synthesis of HEDP by the hydrolysis and acidolysis of dimethyl phosphite to H_3PO_3 followed by acetylation with acetic anhydride or acetyl chloride, affording a yield up to 96%, has been developed.[52] It has been suggested that the still residue remaining after the distillation of dimethyl phosphite, which is a waste product in the manufacture of chlorofos, be used as the starting material. An improved version of the synthesis of HEDP from dimethyl phosphite and acetic anhydride in solution in acetic acid has been described.[53] The methods of synthesis of HEDP introduced into industrial production have been considered in detail in a review.[54] A high yield of HEDP (97%) has been achieved in the synthesis based on the interaction of PCl_3 and acetic acid using a zinc catalyst.[55,56] A method has been proposed for the continuous synthesis of HEDP with a purity of 99.2% by the reaction of P_4O_6 with carboxylic acids[57] and also by the reaction of a mixture of phosphorus oxides, obtained as side products in the synthesis of P_4O_6, with acetic acid.[58] If the reaction of P_4O_6 with acetic acid is carried out in the presence of urea under a nitrogen atmosphere,[59] then the yield of HEDP increases to 97%. A procedure has been proposed for the synthesis of HEDP and its analogues by the nitrosation of aminodiphosphonic acid $H_2NC(R)(PO_3H_2)_2$ with nitrous acid or substances forming HNO_2 during the reaction (nitrogen oxides, nitrous fumes, NOCl, $NaNO_2$, and aqua regia).[60] The initial aminoalkylidenediphosphonic acid is obtained by the reaction of PCl_3 with acid amides in the presence of H_3PO_3 and subsequent hydrolysis; HEDP is isolated as the hydrate in yields up to 100%.

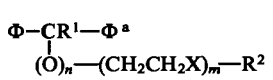
3. Aminohydroxyalkylidenediphosphonic acids

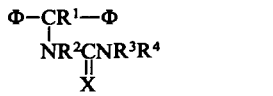
Compounds such as 3-amino-1-hydroxy-1,1-propylidenediphosphonic acid **7** (APD), 4-amino-1-hydroxy-1,1-butylidenediphosphonic acid (ABD), 6-amino-1-hydroxy-1,1-hexylidenediphosphonic acid, and 6-amino-1,1-hexylidenediphosphonic acid are used as regulators of the calcium metabolism for the prevention of the deposition of calcium in the soft tissues and the resorption of bone and for the treatment of poisoning by metal salts and alcohol.[3,4,12]

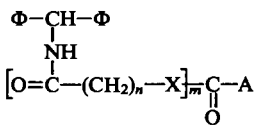
7

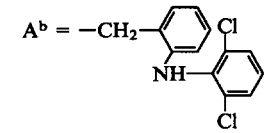
Their complexes with alkaline earth, transition, and lanthanide metals exhibit an enhanced solubility by virtue of the presence in the molecule, together with two acid phosphono-groups, of hydroxy- and amino-groups, which play the role of a basic centre in the molecule.[11] The use of the above compounds in the treatment of Paget's disease is based on this property. It has been established that APD has minimal side effects;[61] ABD is used in the treatment of urinary calculus.[62,63] It has been shown in experiments *in vivo* and *in vitro* that APD is 100–300 times more active than DCMDP as the inhibitor of the resorption of bone.[63] The acid **7** and other diphosphonates having a terminal amino-group are readily incorporated into the structure of cell membranes and into phospholipids. They also prevent the accumulation of peroxide compounds in erythrocytes.[39] APD and ABD participate in the metabolism of dihydroxyvitamin D. They effectively normalise the level of calcium in the blood in patients suffering from malignant hyperglycemia.[63,64] Synergistic compositions containing cytostatic or hormonal antitumour agents (melphalan, chlorambucil, methotrexate, etc.) and geminal diphosphonates such as ABD have been proposed for the treatment of metastatic bone cancer.[65]

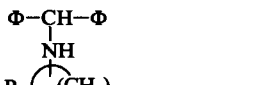
Hydroxyalkylidenediphosphonic acids containing an amino-group have been synthesised from the corresponding carboxylic aminoacids by treatment with a mixture of H_3PO_4 and PCl_3 [3,66-71] or a mixture of H_3PO_3 and PCl_3 [63,72] and subsequent hydrolysis. If a sulfonic acid is added in the latter version,[73] then the yield of the product can be increased to 90%. It has also been suggested that P_4O_6,[74] a mixture of H_3PO_4 and P_4O_6,[75] and a mixture of H_3PO_3 and $POCl_3$ [62] be used as the phosphorus-containing reagents.

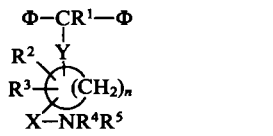


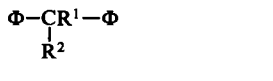


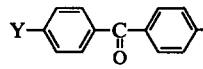


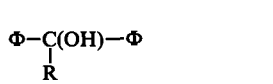


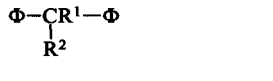


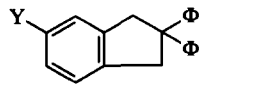


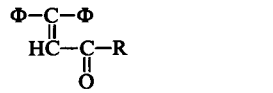


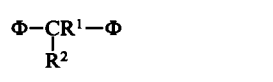


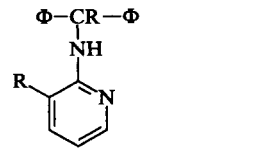












4. Inhibitors of the resorption of bone and antiinflammatory, antiarthritic, and antirheumatoid agents

Because of the ability of diphosphonic acids to form stable complexes with metal ions, they can be used in the treatment of diseases associated with the breakdown of calcium metabolism. A large number of new compounds of this class which can form part of pharmaceutical preparations for the treatment of the above diseases, have been synthesised in recent years. Furthermore, if the diphosphonic acid molecule includes a carboxylic acid residue with antiinflammatory and antipyretic activities, then the use of such a compound as an antiinflammatory agent is particularly effective.

Investigators followed the path leading to an increase in the complexity of the structures of compounds with known pharmacological activities (DCMDP, HEDP, APD, ABD) by introducing into the structure of the given substance all possible cyclic and acyclic hydrocarbon fragments and heterocycles. The synthesis of new compounds are based on the known phosphonylation methods (the Arbuzov and Michaelis–Bekker reactions, addition of di- and tri-alkyl phosphites to unsaturated bonds, phosphonylation of carboxylic acids and their derivatives)[1] in combination with various procedures for the further development of the structure which do not involve the phosphonate groups.

The principal representatives of the geminal diphosphonic acids and their salts and esters obtained during the last 20 years, which exhibit antiresorptive, antiinflammatory, and antiarthritic activities, are presented in Table 1.

Table 1. Geminal diphosphonic acids and their derivatives exhibiting antiresorptive, antiinflammatory, antiarthritic, and antirheumatoid activities.

Formula	Substituents	Ref.

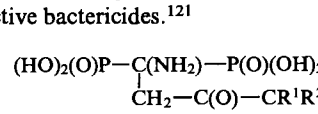
5. Bactericidal, antiviral, and antitumour agents

Diphosphonic acids are capable of acting also upon bacteria. Thus the amidinodiphosphonic acids **8** and **9**, which possess bacteriostatic activity, have been patented.[120]

8, n = 0, 1;

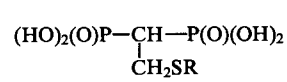


9, R = H, Me, Et.

They were obtained by the reaction of aminomethylenediphosphonates with formamides and $POCl_3$.

$$H_2NCH(PO_3H_2)_2 + HCONH_2 + POCl_3 \longrightarrow$$
$$\longrightarrow H_2N{-}CH{=}N{-}CH(PO_3H_2)_2$$

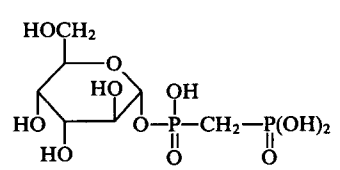
Compounds with the structure **10**, obtained by the phosphonylation of the 3-oxonitrile $R^1R^2R^3CC(O)CH_2CN$ with a mixture of H_3PO_3 and PBr_3 and subsequent hydrolysis, are effective bactericides.[121]



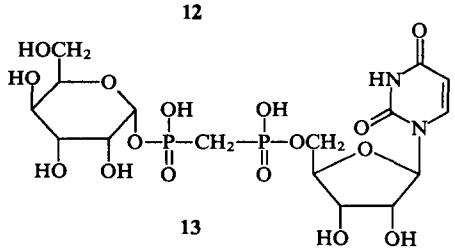
10

R^1 = Alk(C_{1-8}); R^2, R^3 = Me, Et.

The alkali metal salts of compound **10** exhibited an antimicrobial activity.[122]



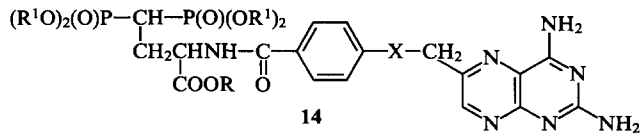
It is believed[123] that compounds with the structure **11** are potential inhibitors of the replication of the influenza A virus. They have been obtained by adding S-nucleophiles, such as thiophenol, 2-mercaptoethanol, ethanethiol, propane-1-thiol, and dodecane-1-thiol, to tetralkyl ethenylidenediphosphonates.



11

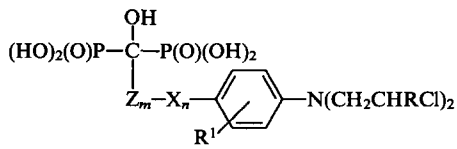
R = Et, Pr, Ph.

A series of geminal α-amino- and α-hydroxy-propylidene-α,α-diphosphonic acids derived from purines and pyrimidines (thymine, uracil, 6-methyluracil, and 5-fluorouracil) have been synthesised. They showed a low antiviral and a moderate antitumour activity on certain strains of tumours.[124] The synthesis and the results of biochemical studies on potential substrate inhibitors of glycosyltransferase on the surfaces of the membranes of cancer cells — the phosphonate analogues of nucleoside diphosphate sugars — have been described.[125] It was shown that, among all the intermediate and final products of synthesis, compound **12** exhibits a weak activity against the rhinovirus, while compound **13** inhibits competitively glycoproteingalactosyltransferase.



12

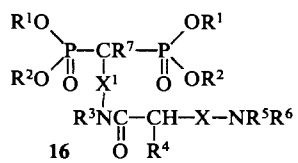
13



Geminal diphosphonic analogues of aminopterin (methotrexate) **14**, derivatives of 10*H*-deazamethopterin, and pharmaceutical compositions based on them have been proposed for the treatment of bone carcinomas, rheumatic psoriasis, different types of polymyositis, Reiter's disease, and rheumatic polyarthritis.[126]

14

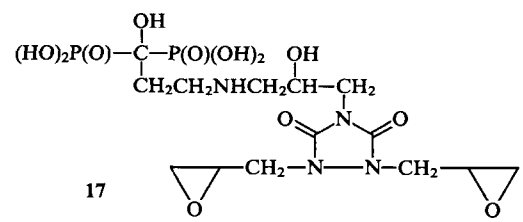
X = NR or CHR^2; R, R^1 = Alk; R^2 = H, Alk.



On the basis of the analysis of the structures of active diphosphonic acids, the authors of a patent application[127] proposed compounds **15**, containing two geminal phosphonate groups, a hydroxy-group, and a terminal amino-group in the hydrocarbon chain, as in ABD and APD [as antitumour agents? (Ed. of Translation)].

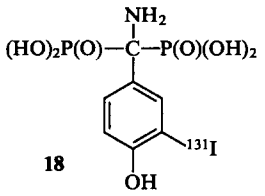
15

R = H, Me; R^1 = H, Hal, NH_2, OAlk, Alk;
Z = alkylene, aminoalkylene;
X = O, S, NH;
m, n = 0, 1.



It was established that, as a result of their accumulation in bone tumours and metastases, compounds **15** induce a significant inhibition of the growth of tumours and increase the survival rate among rats. The rapid calcification of osteosarcoma and lung metastases was confirmed.[38] A patent has also been obtained for a method of synthesis of compounds **15** and pharmaceutical preparations based on them for the treatment of bone tumours.[128] It was shown that joint therapy using compounds **15**, APD, and melphalan yields the best results.[129] Compounds **16**, with an analogous structure, which are also inhibitors of malignant neoplasms, have been patented.[130]

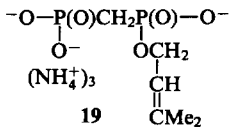
16



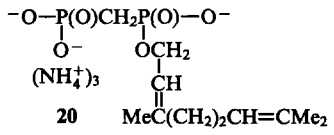
R^1, R^2 = H, Alk; R^3 = H, Alk, cyclo-Alk, Bn, Ph, MeO-  -CH_2;
R^4 = H, Alk, NH_2; R^5, R^6 = $HalCH_2CH_2$;
NR^5R^6 = aziridinyl; R^7 = H, Hal, OH, Alk;
X = alkylene, phenylene, arylalkylene;
X^1 = bond, alkylene, cycloalkylalkylene, arylalkylene.

It has been reported[131] that compound **17** also exhibits an appreciable antitumour activity and that the best results in the treatment of osteolytic metastases in rats were achieved by preliminary treatment with APD.

17



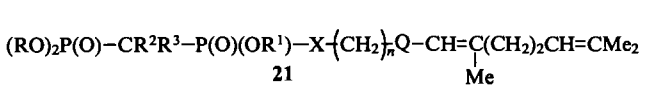
α-Amino-[3-^{131}I]-4-hydroxybenzylidenediphosphonate **18** was synthesised[132] in order to analgise and treat bone metastases. It proved to be the most effective among a series of analogues.[133,134] It has been noted that compound **18** accumulates in bone tissues and that its content is higher in diseased tissues than in healthy tissues. The β-emission from the compound has a smaller effect on bone marrow than the radiopharmaceutical preparations used previously.



18

6. Artificial substrates and inhibitors of various enzymes

The search for synthetic substrates and inhibitors of various enzymes has continued. Thus the synthesis, properties, and the results of biochemical studies of dimethylallyl- and geranylmethylenediphosphonates **19** and **20**, which can serve as artificial substrates for prenyltransferase, have been described.[135]

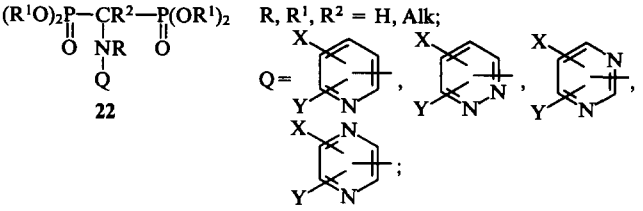


19

20

The ammonium salts of compounds **19** and **20** were synthesised by the reaction of $[HOPO_2CH_2PO_3]^{3-}(NBu_4^+)_3$ with $Me_2C{=}CHCH_2Br$ or geranyl chloride, which is obtained by treating geraniol with *N*-chlorosuccinamide and dimethyl sulfide. It has been established with the aid of compounds **19** and **20** that the presence of the high-energy O–P–O linkage is not important for enzymic reactions, but the structure containing two phosphorus atoms is topologically important for them. The behaviour of geranyl- and geranyldifluoro-methylenediphosphonates in reactions with various enzymes has been investigated.[136]

The synthesis of compounds **21**, used as inhibitors of squalene synthetase, has been described.[137]

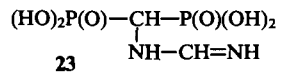


21

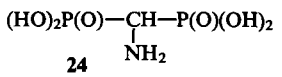
R, R^1 = M, H, Alk, alkenyl; R^2, R^3 = H, Hal; X = O, NH, NR^4; R^4 = Alk; Q = $-CH_2CH_2C(Me)=CH-$, bond; n = 1–4; when X = O, n = 2–4.

$(MeO)_2P(O)CH_2P(O)(OMe)OH$ in methylene chloride and ethyldiisopropylamine are treated with diphenylphosphoric acid chloride, after which farnesylamine is added and compounds **21** are obtained.

7. Herbicides



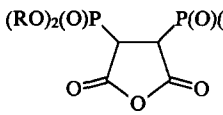
Diphosphonic acids exhibit also a herbicidal activity. Thus the syntheses and herbicidal properties of 46 compounds having the structure **22** have been described in patent applications.[138,139] The synthesis of compounds **22** is based on the reaction between the amino-derivatives of a N-containing heterocycle, $R^2C(OR^3)_3$, and dialkyl phosphite followed by the hydrolysis of the intermediates. (*N*-Pyridyl)aminomethylenediphosphonic acids **22** (R = R^1 = R^2 = H; Q = 3-X-2-pyridyl, X = H, alkyl, Hal; Y = H) and their salts are particularly effective in the fight against perennial weeds.[140]



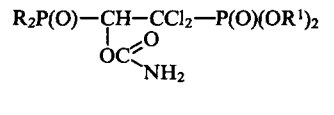
22

X, Y = H, Alk, Hal, NO_2, AcNH, CO_2H, CO_2Me, OH, OMe.

The formamidino- and aminomethylene-diphosphonic acids **23** and **24**, obtained from P_4O_6, anhydrous H_3PO_3, and $HCONH_2$ and by subsequent hydrolysis of the reaction mixture, are suitable as herbicides.[141]

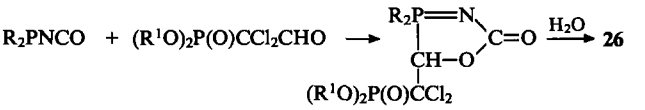


23

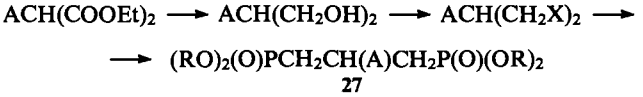


24

III. Vicinal diphosphonic acids



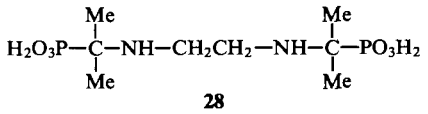
Among the biologically active diphosphonic acids, compounds with a vicinal structure occupy a modest place. Nevertheless, several representatives of substances of this class, which exhibit various types of activity, have been synthesised in recent years. Thus, 3,4-bis(dialkylphosphono)tetrahydrofuran-2,5-diones **25**, used as insecticides and acaricides, have been described in a patent.[142] The synthesis of compounds **26**, which, for R = BuO or Ph and R^1 = Et, exhibit weak pesticidal properties and affect the rate of plant growth, has been reported.[143] These compounds were synthesised by the reaction of phosphorus (III) acid isocyanates with phosphorylated acetaldehydes.



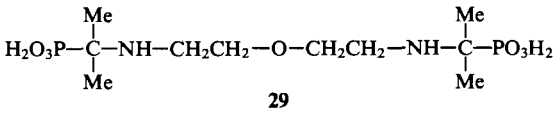
25

26

Specific inhibition of calcium metabolism at the celullar level is induced by the 1,3-diphosphonates **27**, synthesised in accordance with the following scheme;[144,145]



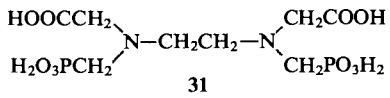
27



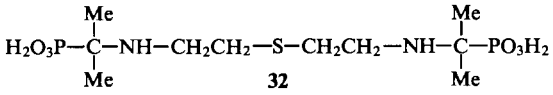
X = Hal, OTs; A = alkyl, arylalkyl, aryloxyalkyl; R = alkyl.

IV. Polyalkylpolyaminodiphosphonic acids

This group includes organophosphorus compounds containing a nitrogen atom in the alkylene chain adjoining the two PO_3H_2 groups. They are capable of activating certain enzymes. Nitrogen-containing diphosphonic acids such as ethylenediaminebisisopropylidenephosphonic acid **28** (phosphicine), 3-oxapentylenediamine-*N*,*N*′-bisisopropylidenephosphonic acid **29**, ethylenediamine-*N*,*N*′-bismethylenephosphonic acid **30**, ethylenediamine-*N*,*N*′-diacetic-*N*,*N*′-bismethylenephosphonic acid **31**, and 3-thiapentylenediamine-*N*,*N*′-bisisopropylidenephosphonic acid **32** possess this property.[12]



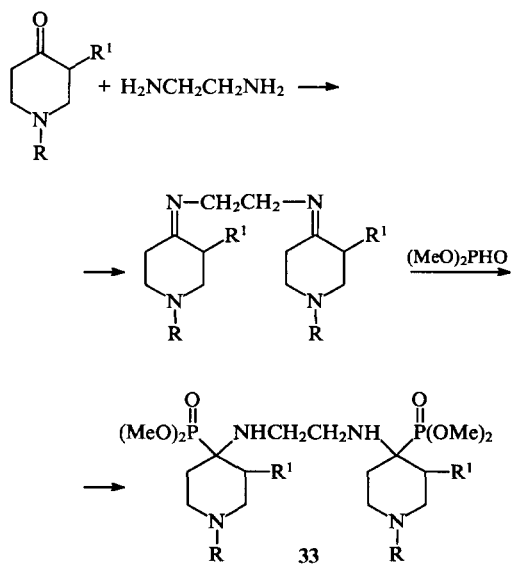
28



29

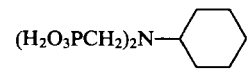
30

31



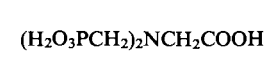
32

A systematic study of the biological properties of alkylenediaminebisalkylenephosphonic acids led to the discovery of the possibility of using substances of this type for the removal from the organism of incorporated toxic metals and also made it possible to discover the influence of these compounds on the removal of certain biologically important elements and on the state of metal complexes in the organism.



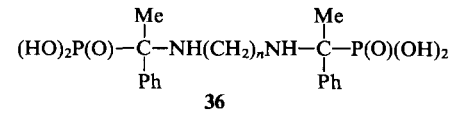
A characteristic feature of organophosphorus ligands containing a nitrogen atom in the alkylene chain linking the two PO_3H_2 groups is the preferential formation of complexes with cations having a small (Be, Fe) or large (lanthanides) radius but not with alkaline earth metals.[12] A unique property of substances of this group is the virtual absence of toxicity. By virtue of their ability to remove copper from the organism, they are used for the treatment of hepatocerebral dystrophy. Phosphicine is particularly effective for the removal of beryllium from the organism, without affecting calcium metabolism, and also for the removal of lead and uranium[11] and for the treatment of poisoning with alcohol.[4]

Phosphicine and its analogues have been synthesised by condensing the corresponding amine with the carbonyl group in aldehydes, ketones, piperidinones, etc. and with trivalent phosphorus compounds.[3] For example, treatment of alkylpiperidinones with ethylenediamine in benzene afforded[146] the corresponding bis-Schiff bases, which are made to react with dimethyl phosphite, whereby bis(phosphonylpiperidinyl)-ethylenediamines **33** are obtained.

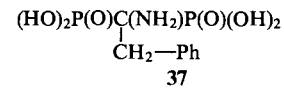


33

The syntheses of complexones **34** and **35** by the reaction of PCl_3 with glycine or cyclohexylamine in the presence of water followed by the interaction of the resulting intermediate with an aldehyde have been described.[147]

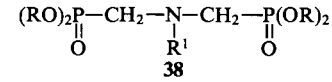


34



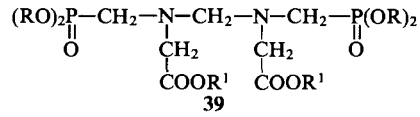
35

The alkylenediaminediphosphonic acids **36** (n = 2, 6), used to inhibit calcium salts, have been synthesised via the intermediate sodium ammonium salts.[148] It has been suggested[149] that 1-amino-2-phenylethylidenediphosphonic acid **37**, obtained by the reaction of $PhCH_2CN$ with PCl_3 and H_3PO_3, be used for the removal of toxic elements from the organism.



36

37

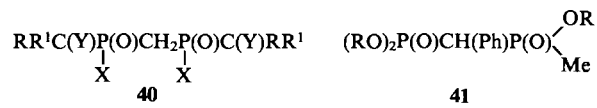


Phosphorus-containing complexones **38** have found extensive applications in medicine.[150-153]

38

R = H, M; R^1 = H, Alk, Ph, Bn, cyclo-C_6H_{11}.

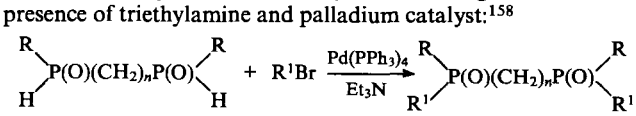
Compounds **39**, which exhibit a herbicidal activity, have been patented.[154]



39

R = Ph; R^1 = Alk, arylalkyl.

V. Phosphonophosphinates and diphosphinates

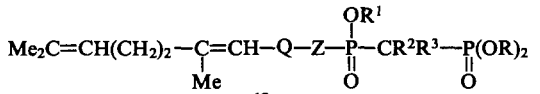


The reaction of esters of methylenediphosphonous acids with carbonyl compounds, which lead (after the hydrolysis) to the corresponding bis[α-hydroxyalkyl(aryl)]methylenediphosphinic acids **40**, has been investigated.[155,156] Compounds **40** are obtained also in the reaction of trialkylmethylenediphosphonite with benzaldehyde in the presence of a base. α-Phosphorus-substituted benzylphosphonate **41** is also formed in this reaction as an addition product.[155]

40 41

X = Cl, Alk, OAlk, OH; Y = Cl, OH; R = H, Me, Et;
R^1 = Alk(C_{2-6}), Ph.

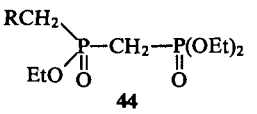
Systematic study of the pesticidal activity of the derivatives of methylenediphosphorus acids showed that they can exhibit growth regulating, herbicidal, and fungicidal activities.[157] It has been suggested that diphosphonates with tetra- and hexamethylene bridges be obtained by the following reaction in the presence of triethylamine and palladium catalyst:[158]



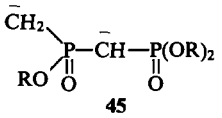
R = EtO, Ph; R_1 = Ph, 4-ClC_6H_4, 4-$Me_2NC_6H_4$, 4-$NO_2C_6H_4$, 4-AcC_6H_4, 2-naphthyl, etc.

Compounds **42**, which strengthen the bone tissue and can be used in stomatology, have been described.[159] They are synthesised by the reaction of $Ph_2P(O)CF_2Br$ with PCl_3 in the presence of zinc dust followed by hydrolysis and the oxidation of the intermediate with distilled water.

$$Ph_2P(O)-CF_2-P(O)(OH)_2$$
42



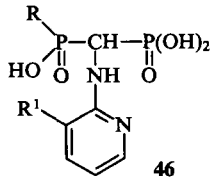
Alkenylphosphinylmethylphosphonates **43** are inhibitors of squalene synthetase, which are used as agents reducing the level of cholesterol.[160]



43

R, R^1 = H, Alk, M; R^2, R^3 = H, Hal; Z = $(CH_2)_n$, $(CH_2)_pCH=CH(CH_2)_m$; Q = $CH_2CH_2C(Me)=CH$, bond; n = 1–5, m,p = 0–2.

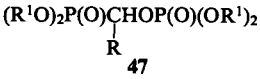
It has been suggested that the phosphinylphosphonyl compounds **44**, obtained by the Arbuzov reaction involving $(EtO)_2PCH_2P(O)(OEt)_2$ and the corresponding alkyl halides RCH_2Br [R = $CH_2CH_2C(Me)=CH_2$ or $Me_2C=CHCH_2$] be used as analogues of natural isoprenoids—isopentenyl and dimethylallyl diphosphates. The ammonium salts of both analogues are competitive inhibitors of the [1′,4]-condensation of isopentenyl diphosphate and geranyl diphosphate catalysed by diphosphate synthetase.[161] Furthermore, it has been reported[162] that the phosphinylphosphonyl dianion **45** is capable of undergoing the alkylation reaction with a multiplicity of electrophiles such as ethyl iodide, geranyl bromide, benzyl bromide, etc., which permits its use in the synthesis of analogues of natural diphosphates.



44

45

It has been established[94] that, in contrast to pyridylaminomethylenediphosphinates and the corresponding diphosphonates, pyridylaminomethylenephosphonoalkylphosphinates **46** exhibit a satisfactory antiresorptive activity.



46

R = Me, Bu, $Ph(CH_2)_4$; R^1 = H, Me.

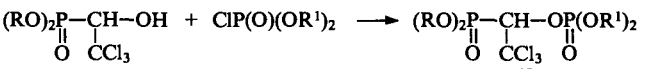
The synthesis of compounds **46** is based on the reaction of equimolar amounts of $(EtO)_2P(O)CH(OEt)_2$, EtO(R)P(O)H, and 2-aminopyridine (or 2-amino-3-methylpyridine) and subsequent hydrolysis.

VI. Phosphonophosphates

Nguyen Lan et al.[89] synthesised and investigated the medical and biological properties of geminal diphosphonates and phosphonophosphates **47**. It was established that, in relation to plasma lipids, these compounds exhibit the maximum pharmacological activity among all the substances of a similar type obtained and they are therefore potential antiatherosclerotic agents.

47

R^1 = H, Alk; R = Alk, Ph, $PhCMe_2$, $PhOCMe_2$, $PhCH_2CMe_2$, $ClC_6H_4C(O)C_6H_4$, cyclo-C_6H_{11}, 2-naphthyl, biphenylyl.

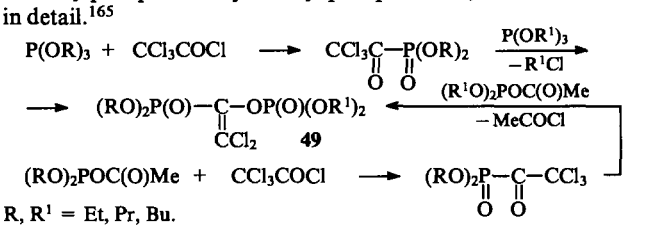


These compounds increase the concentration of the high density lipoprotein cholesterol, the amount of phospholipids, and the ratio of α-cholesterol to β-cholesterol. Compound **47** (R^1 = Me, R = 4-ClC_6H_4) was selected for further pharmacological and clinical studies.

Two methods were used to obtain these compounds, each of which begins with the formation of acylphosphonates $RC(O)P(O)(OR^1)_2$ via the reaction of RCOCl with trialkyl phosphite at 0 °C without a solvent.

The interaction of acylphosphonate with dialkyl phosphites in the presence of 80–100 mol% of dialkylamine at 0 °C in diethyl ether leads to geminal phosphonophosphates,[163] while in the presence of the catalytic amount (~5%) of an amine it affords geminal hydroxyldiphosphonates $RC(OH)[P(O)(OR^1)_2]_2$, which isomerise to phosphonophosphates on refluxing in alcohol.

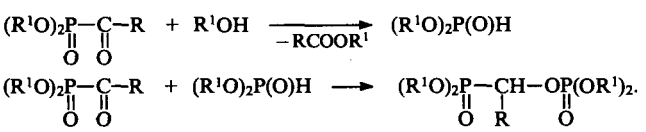
The interaction of acylphosphonate with dialkyl phosphites at 80 °C without a solvent leads to geminal phosphonophosphates.[89]



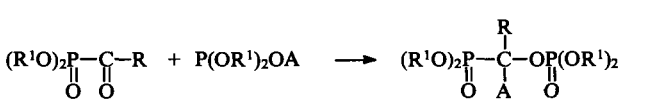
The synthesis of esters of α-(dialkylphosphono)-β,β,β-trichloroethylphosphoric acid **48** from the esters of α-hydroxy-β,β,β-trichloroethylphosphonic acid and the chlorides of dialkylphosphoric acids in the presence of triethylamine were described as early as 1958.[164]

48

R, R^1 = Alk(C_{1-4}).



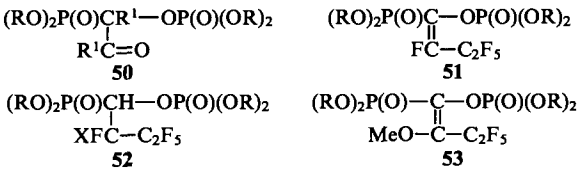
The esters showed strong insecticidal properties and also acted on certain species of stinging insects. The mechanism of the reactions of trialkyl phosphites and dialkyl acetyl phosphites with the chlorides of chloroacetic acids, leading to the formation of α-dialkylphosphonovinyl dialkyl phosphates **49**, has been studied in detail.[165]



49

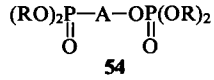
R, R^1 = Et, Pr, Bu.

It has been noted[166] that dialkyl α-dialkylphosphonoalkyl phosphates **47** are formed in the reaction of esters of α-ketophosphonic acids with alcohols and amines in 55% yield.



In a review devoted to esters of α-ketophosphonic acids,[167] the latter compounds are regarded as the most convenient initial reagents for the synthesis of phosphonophosphates in accordance with the following scheme:

A = Alk, C(O)Me.

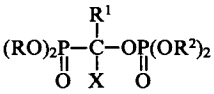


Yet another method of synthesis of phosphonophosphates in yields of above 50% from the esters of α-ketophosphonic acids involves the interaction of the latter with $LiN(CPr^i)_2$ or NaH in tetrahydrofuran.[168] A method of synthesis of phosphonophosphates by the reaction of trialkyl phosphite and R'C(O)X (X = Hal, Ac, NH_2, alkylamino-group, or alkoxy-group) below 45 °C, involving treatment of the intermediate with dialkyl phosphite in the presence of an organic base (NMe_3, NEt_3, Py) in a catalytic amount, has been patented.[169] The yield of the phosphonophosphates reaches 96% in this process. It has been suggested[170] that the reaction of tetraalkyl pyrophosphites $(RO)_2POP(OR)_2$ (R = Pr, Et) or dialkyl acyl phosphite with trifluoroacetic acid in acetonitrile be used for the synthesis of fluorinated phosphonophosphates. The synthesis of fluorine-containing phosphonophosphates **50** in yields in excess of 60% by the reaction of dialkyl phosphites with perfluorinated carboxylic acid anhydrides $(R^1CO)_2O$ ($R^1 = CF_3$, C_2F_5, C_3F_7) has been described.[171] The synthesis of the fluorinated phosphono-phosphates **51**, **52** (X = F, OMe), and **53** has also been investigated.[172]

50 **51**

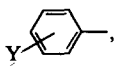
52 **53**

The halogenated phosphonophosphates **54** have been obtained from PCl_3 and epoxyethane in the presence of $TiCl_4$ and by subsequent treatment of the intermediate with the chloride of monochloroacetic acid.[173]

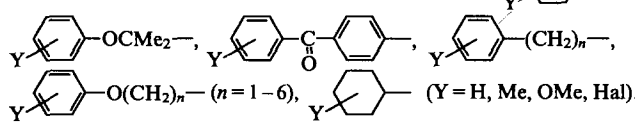


54

R = haloalkyl, for example CH_2CH_2Cl; A = CR^1R^2, $HC{=}CR^1$; R^1 = H, Hal, Alk; R^2 = H, Hal.

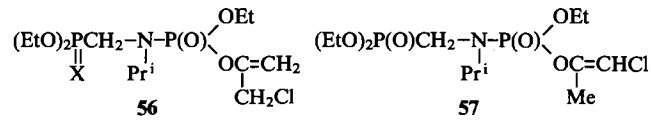


The phosphonates **55** have been obtained in yields of about 92% in two ways.



1. By the reaction of dialkyl phosphite with the corresponding acyl chloride in the presence of dialkylamine and the subsequent interaction of the resulting acylphosphonate with a phosphonite.

2. By the reaction of the corresponding aryl or aroyl halide with methylenediphosphonate and subsequent treatment of the resulting aryl or aroyl diphosphonate.



55

X = H, OH, OAc, NH_2; R, R^2 = H, Alk; R^1 = Bu^t,  ,

(Y = H, Me, OMe, Hal).

These compounds act on lipids and the lipid metabolism, lower the level of free aliphatic acids and triglycerides in the serum, increase the amount of phospholipids, and regulate the concentration of cholesterol. The acids **55** and their salts diminish the amount of calcium in the rat serum. Some of the derivatives are antiatherosclerotic and hypoglycemic agents.[85,86] The effect of compounds **56** and **57** on the enzymes of the Colorado beetle has been reported.[174]

56 **57**

X = O, S.

The above compounds inhibit arylesterase, carboxylesterase, acetylcholinesterase, and butyrylcholinesterase of insects, inducing 50% – 100%, mortality in 24 h.

* * *

Analysis of the scientific-technical and patent literature for the last two decades has shown that derivatives of phosphonic acids containing two phosphorus atoms (MDP, HEDP, diphosphonic analogues of amethopterin, phosphicine) have found extensive applications in medicine. These compounds are used as radiopharmaceutical preparations for the treatment of bone diseases and malignant tumours. The practical interest attaching to the physiological properties of compounds containing two phosphorus atoms has led to a vigorous search for ways of synthesising them. Although the syntheses of new preparations are usually based on known phosphonylation methods (the Arbuzov, Michaelis–Bekker, Kabachnik–Fields, Todd–Atherton, etc. methods), an expansion of the range of the initial reagents and the optimisation of the conditions in the above reactions are to be expected in the next few years. This is because the mechanisms and modes of many phosphonylation reactions depend to a considerable extent on the initial conditions. Furthermore, the use of organophosphorus compounds containing specific groups (formyl, amino-, epoxy-, etc.) is promising, which will permit a wider employment of 'non-phosphorus' reactions for the synthesis of diphosphonates and phosphonophosphates.

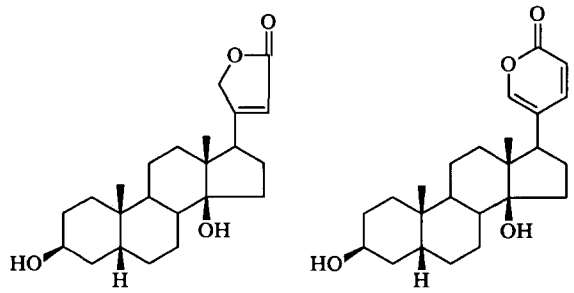
IV. Synthesis of steroids containing a heterocycle in the C(22) position	672
V. Syntheses of the side chains of steroids including the transformation of heterocyclic structures	674

Abstract. The latest data on the methods for the formation of the side chains of steroids containing a heterocyclic fragment are surveyed and described systematically. Attention is concentrated on the methods for the transformation of heterocycles in order to achieve the stereoselective formation of chiral centres in the side chain characteristic of a series of natural polyhydroxysteroids — ecdysones, brassinosteroids, vitamin D metabolites, etc. The bibliography includes 133 references.

I. Introduction

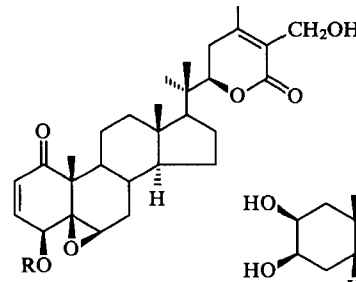
A series of steroids, characterised by a high physiological activity, contain a heterocyclic fragment or a polyfunctionalised side chain as a structural element. Cardenolides, withanolides, ecdysones, etc. can be included among steroids of this kind.



The present review is devoted to the formation and transformations of the steroid side chains containing a heterocyclic fragment and covers the literature for the last 15 years. Additional information on this problem can be found in other communications.[1-10]

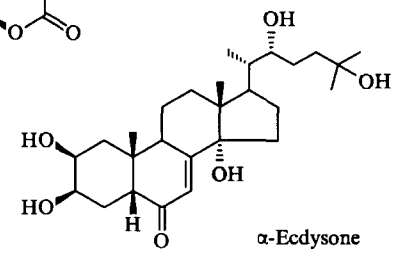
The review includes problems concerning five-membered, six-membered, and the fairly rare four-membered heterocycles. The scope of the review precludes the consideration of steroid alkaloids and 17-spiroheterocycles. Dioxolans and acetonides, which actually constitute protective groups, are also excluded.

II. Synthesis of steroids containing a heterocycle in the C(17) position

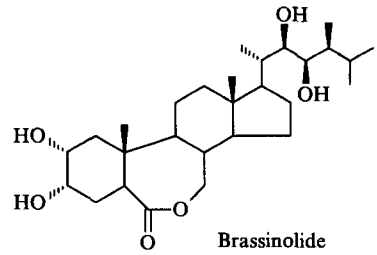


The synthesis of steroids having a heterocyclic substituent in the 17β-position involves mainly the development of convenient methods of construction of the side chain in cardenolides (five-membered lactones), bufadienolides (six-membered lactones), or their analogues, which are distinguished by a broad spectrum of biological activity.

The following most general approaches to their synthesis can be differentiated: (a) cyclisation of 21-derivatives of 20-keto-steroids involving a change in a functional group — primarily in the 21-position; (b) condensation of the reagent initially with the carbonyl group of the 21-derivatives of 20-ketosteroids followed by cyclisation; (c) addition of lithio-derivatives of heterocycles to the carbonyl group of 17-ketosteroids with subsequent transformation of the products.



Digitoxigenin

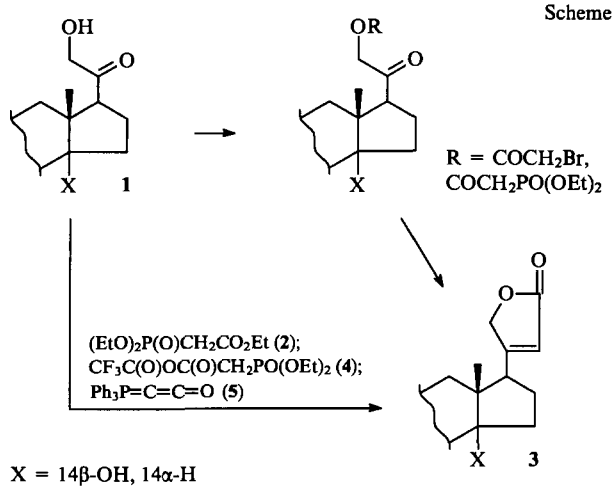


Bufalin

Withaferin A

α-Ecdysone

Brassinolide



One of the main problems in the synthesis of cardiac aglycones is the formation of the butenolide side chain under mild conditions. The Horner–Emmons intermolecular condensation method is most attractive for this purpose. It includes either the esterification of the α-ketol **1** to the bromoacetate and the formation from the latter of a Wittig reagent and its cyclisation[3] or esterification[11-13] of the α-ketol with triethyl phosphonacetate **2** with simultaneous cyclisation to the lactone **3**. However, the

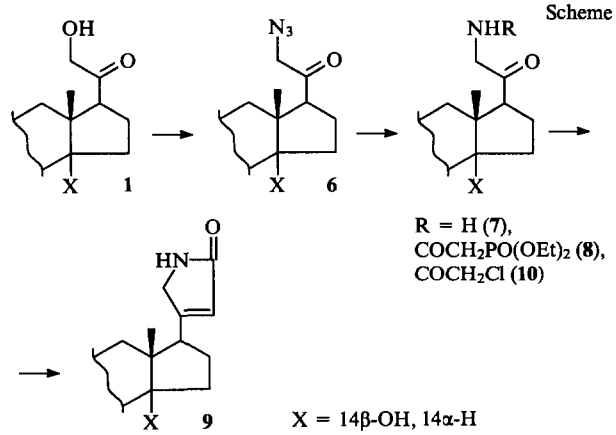
Uspekhi Khimii **62** (7) 704 – 725 (1993); translated by A K Grzybowski

large number of stages, which reduces the yield, in the first case and the poor reproducibility in the second hinder the use of this method. Attempts at improvement of the procedure by using new reagents have therefore not ceased. One of the versions involves the use of the mixed anhydride of trifluoroacetic and diethyl phosphonoacetic acids **4**.[14] Treatment of the ketol **1** with this reagent in the presence of potassium carbonate results in the formation of the lactone **3**. High yields of the lactone **3** have been obtained also using the ketene triphenylphosphoranylide **5**. Treatment of the ketol **1** with the latter results in the formation of the five-membered lactone **3** in one stage.[15] It is remarkable that this reaction does not involve the tertiary hydroxy-groups of the steroid (Scheme 1).

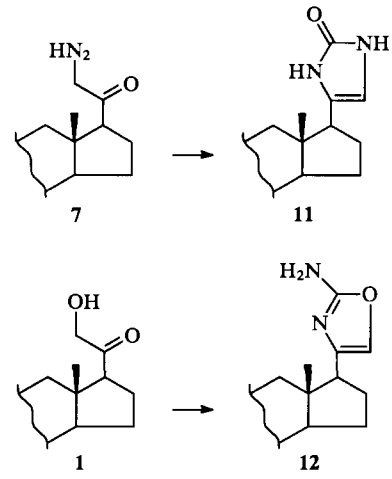
Scheme 1



X = 14β-OH, 14α-H

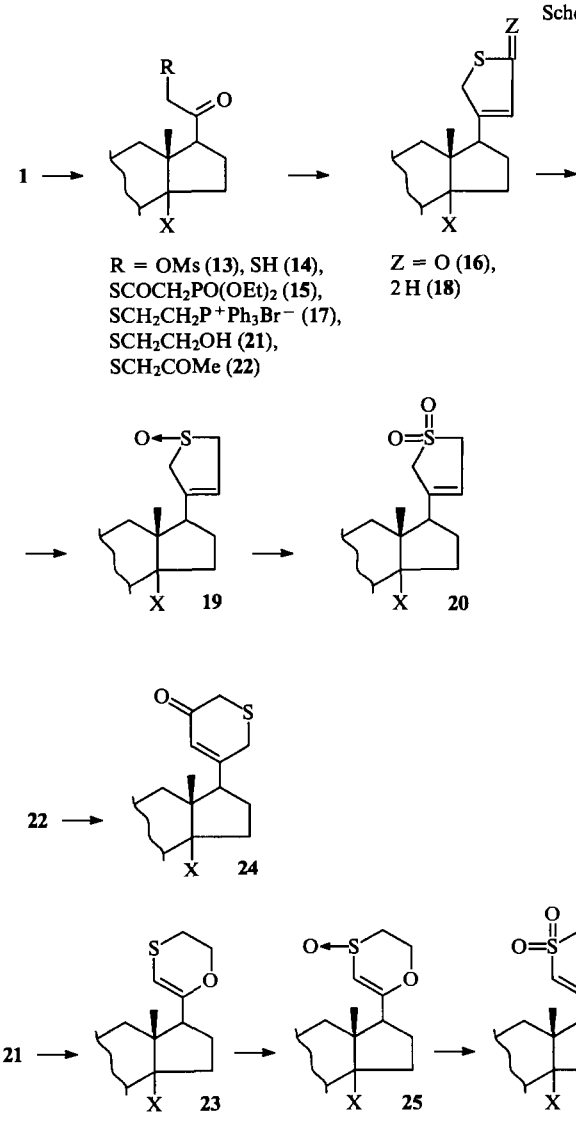
The replacement of the hydroxy-group in the ketol **1** by the azide group or its conversion into the methanesulfonate or toluene-*p*-sulfonate, which undergo nucleophilic substitution, makes it possible to obtain a series of sulfur- and nitrogen-containing derivatives which afford heterocycles — analogues of digitoxigenin and bufalin — under mild conditions.

The reduction of the azide **6** to the amine **7** and acetylation of the latter with diethylphosphonacetic acid in the presence of dicyclohexylcarbodiimide lead[16] to the amide **8** and, after cyclisation, to the lactam **9**. This lactam is obtained by hydrogenating the azide **6** over $Pd/CaCO_3$ in the presence of chloroacetic anhydride.[17,18] The resulting chloroacetamide **10** is converted into a phosphonium salt and subjected to Wittig cyclisation (Scheme 2).



Scheme 2

X = 14β-OH, 14α-H

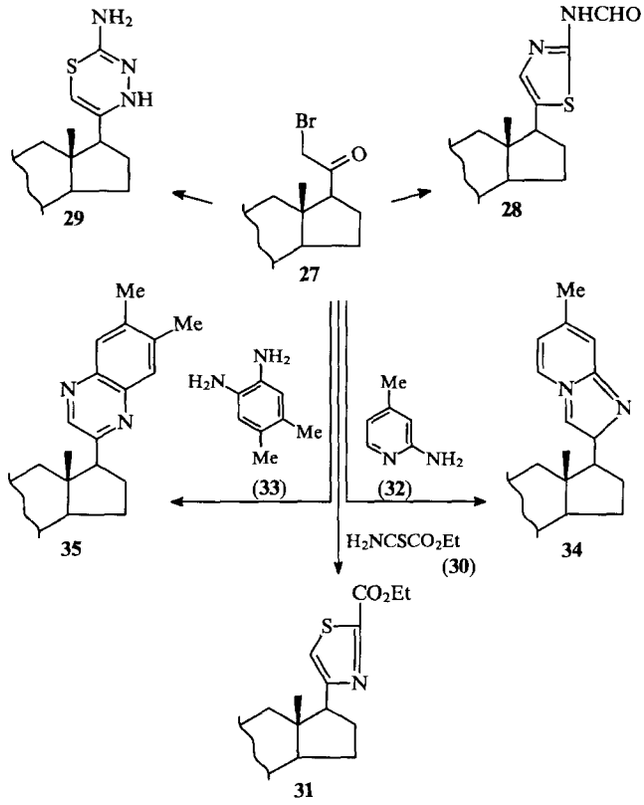


The imidazoline derivatives **11** were obtained from the amine **7** and were treated with carbamoyl chloride with subsequent cyclocondensation.[19] The aminooxazole **12** can be synthesised directly from the ketol **1** by treating the latter with cyanamide (Scheme 3).[20]

Scheme 3

The ease of the nucleophilic substitution of the methanesulfonate **13** makes it possible to form cyclic structures with the sulfur atom. The thiolactone **16** is formed via the phosphonate **15** from the thiol **14**, obtained by the reaction of the methanesulfonate **13** with sodium hydrogen sulfide. The 2,5-dihydrothiophene **18** is synthesised by substituting the methanesulfonate

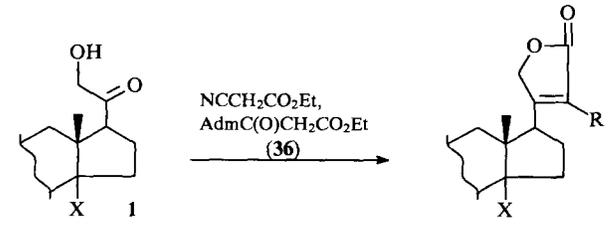
Scheme 4



X = 14β-OH, 14α-H

group in compound **13** by the sodium salt of 2-mercaptoethyltriphenylphosphonium bromide and cyclisation of the intermediate **17**. The dihydrothiophene **18** is readily oxidised by sodium periodate to the sulfoxides **19** and the latter are oxidised in their turn to the sulfone **20** with *m*-chloroperbenzoic acid. Similar substitution of the methanesulfonate group in compound **13** by thiols can afford the derivatives **21** and **22**. The cyclisation of the former to the oxathiine **23** is achieved on treatment with acids, whilst cyclisation of the latter to the thiopyranone **24** is carried out in the presence of sodium methoxide. Similarly the oxathiine **23** can be oxidised[16,21] to the sulfoxides **25** and the sulfones **26** (Scheme 4).

The α-bromoketones **27** are used widely to synthesise steroids of different kinds with diaza- and thiaza-heterocycles in the side chain.[22-26] For example, their condensation with thiourea[22] in dimethylformamide (DMF) affords the thiazole **28**, the condensation with thiosemicarbazide[23] affords the thiadiazine **29**, the condensation with ethyl thioxamate[24] **30** gives rise to the thiazole **31**, while the condensation with aminopyridine[25] **32** or the diamine[26] **33** affords compounds **34** and **35** respectively (Scheme 5).

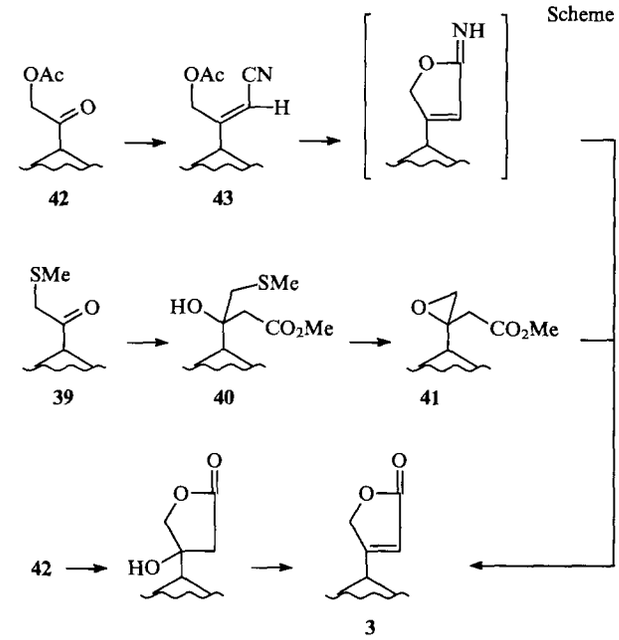


Scheme 5

In the cases considered, cyclisation to a heterocycle was preceded by reactions which did not involve the carbonyl group at C(20). Syntheses involving addition of various reagents to this centre and subsequent cyclisation are described below. They are mainly intended to produce the side chain in compounds related to digitoxigenin and its derivatives. Thus the condensation of the ketol **1** with cyanoacetic ester[27] or the acetoacetic ester derivative **36** affords the unsaturated cyanolactone **37** and the acyllactone **38** (Scheme 6).[28]

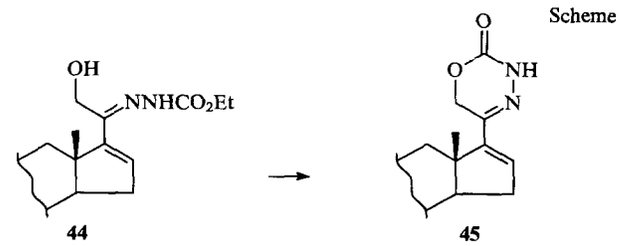
The lactone **3** ring was obtained from the ketosulfide **39** by reaction with bromoacetic ester in the presence of activated zinc.[29] The diastereoisomers **40** are converted, without separation, into the epoxyesters **41** via a methylsulfonium salt. The passage of the esters through a column with basic alumina led to cyclisation to the required lactone **3**. The Reformatskii reaction has been used successfully to synthesise the lactone **3** from the ketoacetate **42**.[30]

Scheme 6



X = 14β-OH, 14α-H
Adm = Adamantine

R = CN (**37**),
C(O)Adm (**38**)

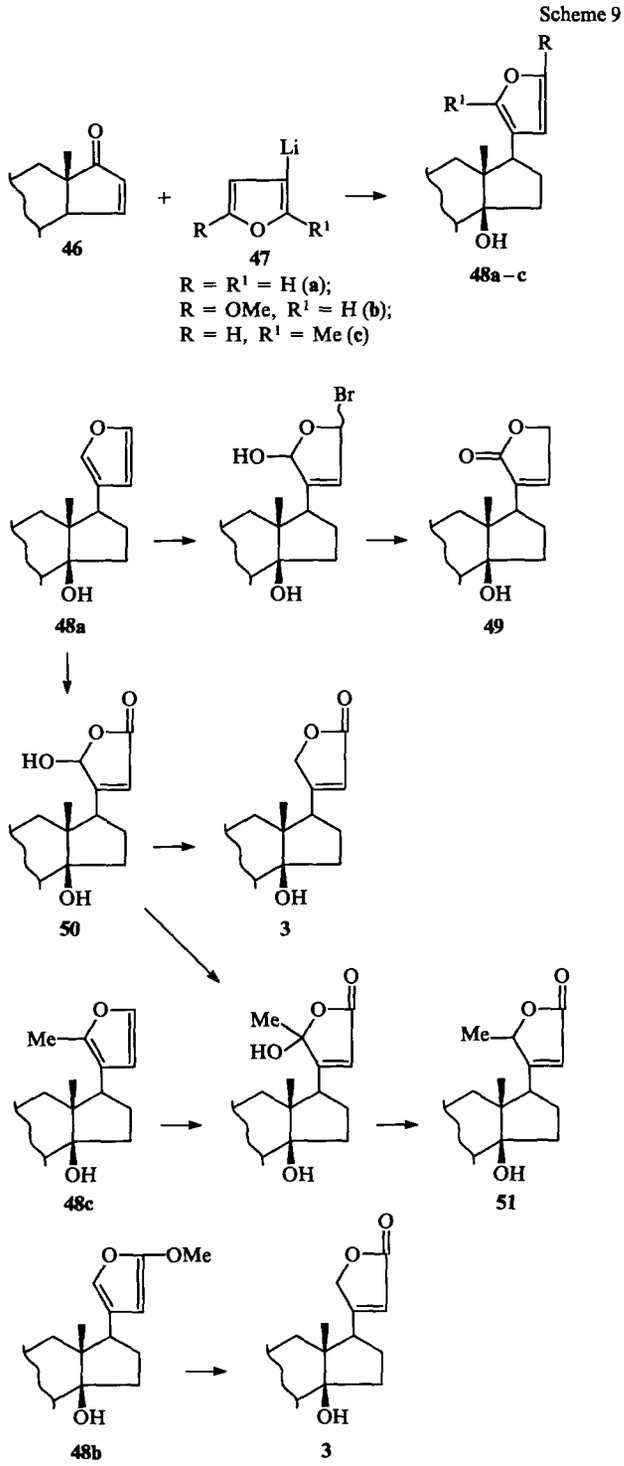


A more effective method, using the chemistry of phosphoranes, has been proposed.[31] The condensation of the ketoacetate **42** with diethyl cyanomethylphosphonate and subsequent treatment of the resulting nitrile **43** with toluene-*p*-sulfonic acid made it possible to isolate directly the lactone **3** (Scheme 7).

Scheme 7

An aza-analogue of cardiotonic steroids **45** of the type of bufalin has been obtained[32] by the alkaline treatment of the ethoxycarbonylhydrazone **44**. Evidently only the (*Z*)-isomers are capable of this kind of cyclisation (Scheme 8).

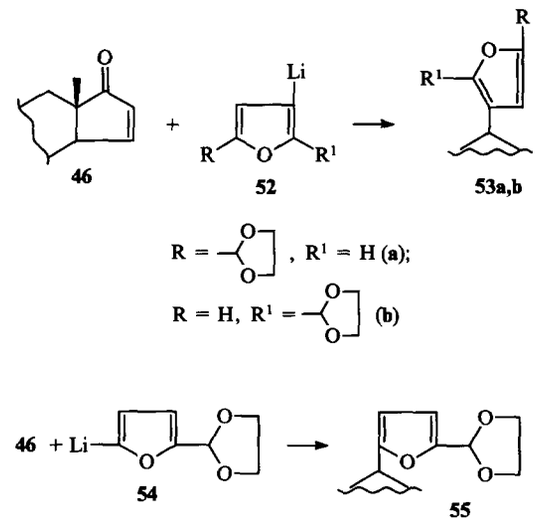
Scheme 8



The chemistry of furan derivatives provides extensive possibilities for the synthesis of the lactone rings in cardenolides and bufadienolides. Thus the cardenolides **3**, the isocardenolide **49**, and the 21-hydroxy- and 21-methyl analogues **50** and **51** have been obtained by alkylating the 17-ketones with 3-lithiofurans and the transformation of the furylsteroids.[33-35]

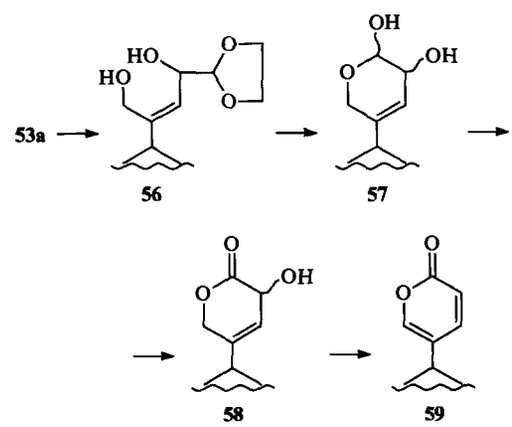
These compounds were synthesised in the following way. As a result of the addition of 3-lithiofurans **47** to the ketone **46** and a series of transformations of the D ring of the steroid molecule, the

furyl steroids **48** were obtained. Oxidation of the furylsteroid **48a** with *m*-chloroperbenzoic acid and the reduction with $NaBH_4$ of the primary product—the hydroxylactone **50**—afforded the cardenolide **3**,[33] which can also be obtained as a result of the acid hydrolysis of the methoxy-group in the furyl steroid **48b**.[34] On the other hand, the oxidation of compound **48a** with *N*-bromosuccinimide leads to the lactone **49** which is isomeric with respect to compound **3** (Scheme 9).[33]



Scheme 9

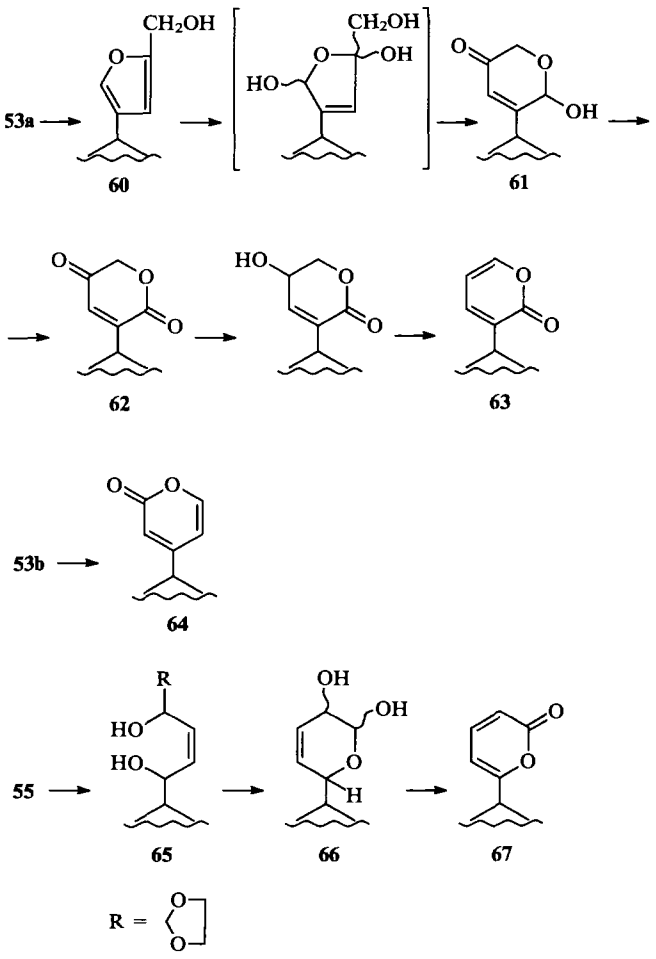
Successive oxidation with *m*-chloroperbenzoic acid and reduction with $NaBH_4$ of the furylsteroid **48c** affords the 21-methyl derivative **51**. Another method of synthesis[35] of the cardenolide **51** involves the alkylation of the hydroxylactone **50** with methyllithium.



The method involving the alkylation of ketones by furans is suitable also for the synthesis of the lactone component of the bufalin and its α-, α′-, and β-isomers.[36–39] Thus alkylation of the ketone **46** by 3-lithiofurans **52a, b** or 2-lithiofuran **54** and subsequent transformations lead to the furylsteroids **53a, b** and **55** respectively (Scheme 10).

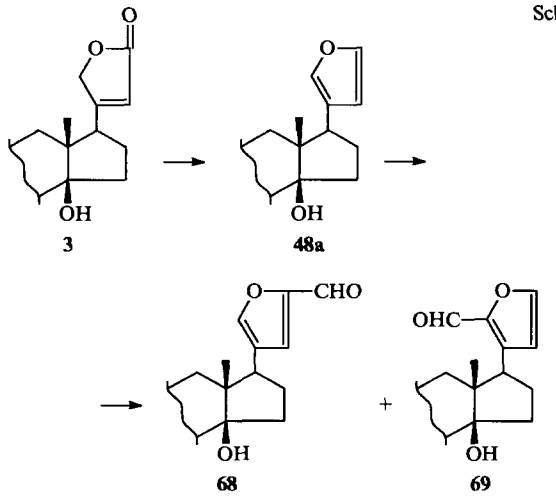
Scheme 10

The furylsteroid **53a** served as an intermediate in the synthesis of the pyrone fragment of bufalin[36,37] **59** and β-isobufalin[38,39] **63**. In the synthesis of bufalin, the furan **53a** was oxidised with oxygen in the presence of a sensitiser and the primary product—an endoperoxide—was cleaved with dimethyl sulfide to give an unstable ketoaldehyde. Without being isolated, the aldehyde was reduced with $NaBH_4$ to the hydroxyacetal **56**. Next the acetal was hydrolysed with hydrochloric acid, affording the six-membered lactol **57**, which was oxidised with silver carbonate on celite to the hydroxylactone **58**. The fragment **58** was converted into the lactone fragment of bufalin by refluxing its methanesulfonate with diazabicyclononene (Scheme 11).



Scheme 11

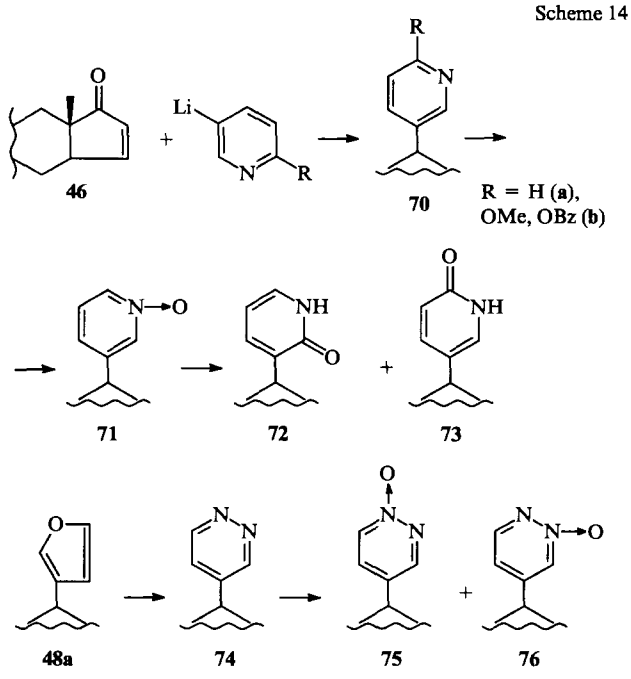
In order to convert the furan ring of compound **53** into the lactone fragment of β-isobufalin, the acetal group was hydrolysed and the resulting aldehyde was reduced with $NaBH_4$ to the alcohol **60**. Oxidation of the alcohol **60** with *m*-chloroperbenzoic acid led to the ketolactol **61**, which was oxidised with chromic acid to the ketolactone **62** and the keto-group was then reduced selectively with zinc tetrahydroborate. The subsequent transformations into the pyrone ring of β-isobufalin were achieved via the methanesulfonate. A similar sequence of reactions in the case of the furan **53b** leads[38,39] to α-isobufalin **64**. In order to obtain α′-isobufalin



67, the furylsteroid **55** is oxidised with *N*-bromosuccinimide and the oxidation product is reduced with $NaBH_4$ to the diol **65**, the acetal group of which is hydrolysed to the lactol **66**, from which the lactone **67** is obtained in accordance with Scheme 12.

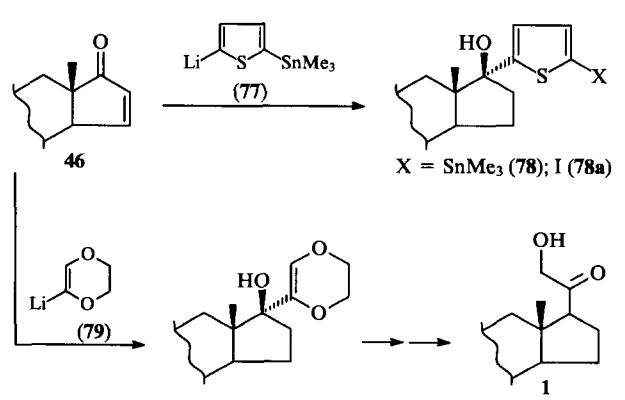
Scheme 12

Treatment of the lactone ring in compounds **3** with $LiAlH_4$ results in the formation[40] of the furan **48a**. This reaction has been used by Wiesner and coworkers[41,42] to synthesise bufalin and α- and β-isobufalins. Formylation of the furan **48a** gives rise to the aldehydes **68** and **69** (Scheme 13).



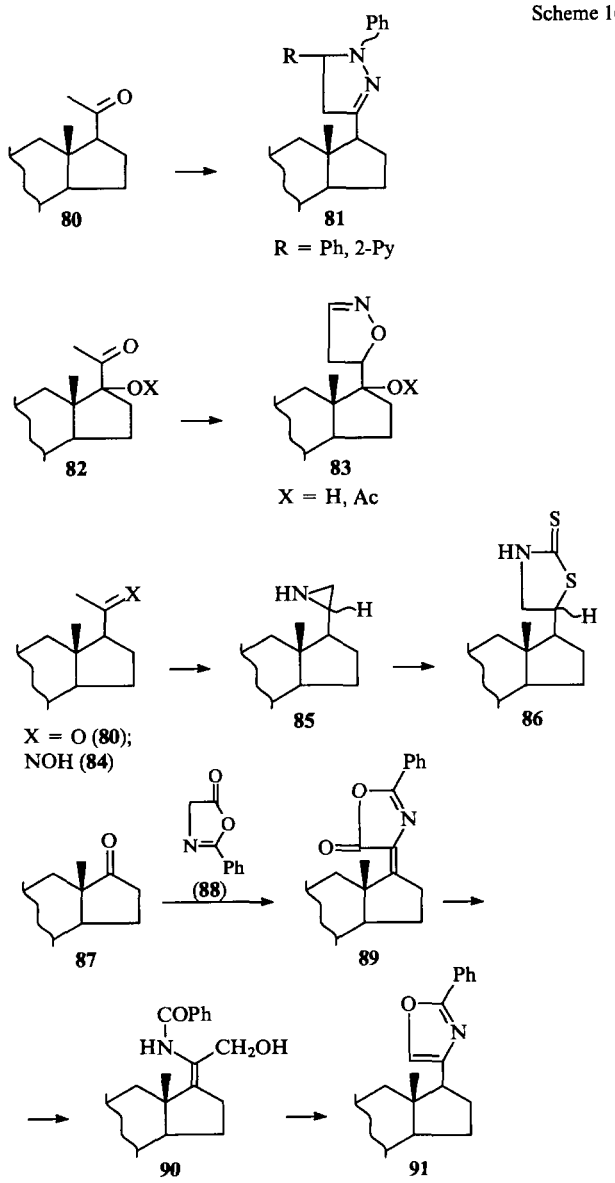
Scheme 13

The introduction of the acetal protective group into the aldehyde **68** leads to the furan **53a**, the subsequent transformations of which afford bufalin, while the reduction of the furans **68** and **69** with $NaBH_4$ affords the corresponding alcohols, from which α- and β-isobufalins were obtained.



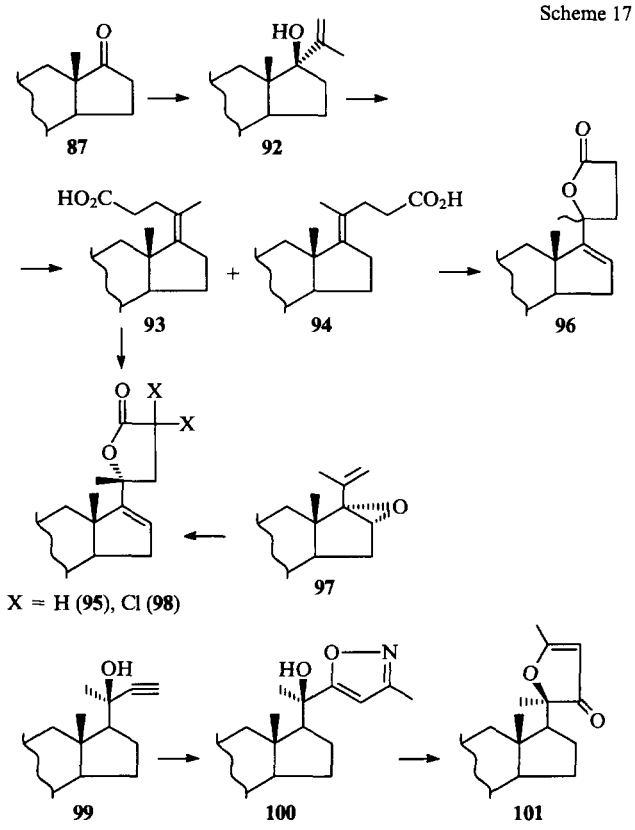
A series of aza-analogues of bufalin were obtained by alkylating the 17-ketosteroids **46** with 3-lithiopyridines. The transition from the pyridine to the pyridone ring was achieved by oxidising the pyridine **70a** with *m*-chloroperbenzoic acid to the *N*-oxide **71**, which afforded the pyridones **72** and **73** in equal proportions on refluxing in acetic anhydride and subsequent alkaline hydrolysis. In the case of compound **70b**, the pyridone **73** is formed as a result of the hydrogenolysis of the ether.[43-47] The reaction of the furan **48a** with *N*-bromosuccinimide and subsequent interaction of the oxidation product with hydrazine hydrate afford compound **74**, the treatment of which with *m*-chloroperbenzoic acid leads to a mixture of the *N*-oxides **75** and **76** in proportions of 3 : 2 (Scheme 14).[48,49]

Scheme 14



The alkylation of 17-ketosteroids by other heterocycles takes place just as readily. For example, the addition of the thiophene **77** gives rise to the product **78**, the ease of substitution of tin in which by iodine and other halogens makes it possible to obtain compounds with functional group substituents and to introduce radioactive isotopes.[50] Androstanes can be converted into pregnanes by reaction with the lithio-derivative **79** (Scheme 15)[51] (for a more detailed treatment, see Section V).

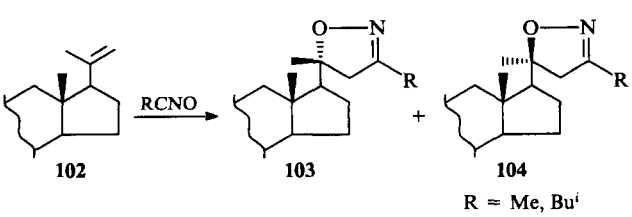
Scheme 15



The synthetic possibilities of 20- and 17-ketosteroids for the construction of heterocycles containing nitrogen or sulfur are not limited to the examples described above. Thus the condensation of the ketosteroid **80** with benzaldehyde or 2-formylpyridine and subsequent treatment of the condensation product with phenylhydrazine afford the pyrazolines **81**.[52,53] When the ketol **82** or its acetate was refluxed in formamide in the presence of perchloric acid, the isoxazolines **83** were obtained.[54] The reduction of the oxime **84** with lithium tetrahydroaluminate afforded the aziridines **85**, the treatment of which with carbon disulfide leads to the thiazolidines **86**.[55] The condensation of the azalactone **88** with the ketone **87** affords the product **89** as a mixture of the (*Z*)- and (*E*)-isomers. The $TiCl_4$–pyridine system served as the catalyst in this reaction. Alkaline hydrolysis of compound **89** and subsequent reduction led to the synthesis of compound **90**, the hydrolysis of which with hydrochloric acid afforded the oxazole **91** (Scheme 16).[56]

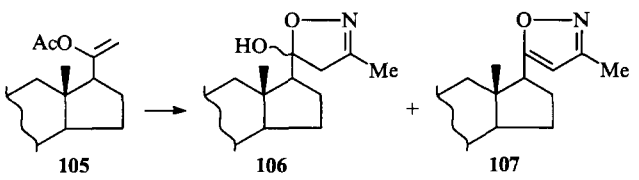
Scheme 16

The application of a series of new reagents opens the way to the synthesis of rare compounds and compounds which are difficult to synthesise. Alkylation of the ketone **87** with isopropenyllithium gives rise to the allyl alcohol **92**, which, as a result of the Claisen rearrangement in the presence of ethyl orthoacetate, is converted into the acids **93** and **94** after separation and hydrolysis. Kosor and Bersz[57] carried out the lactonisation stage with chlorophenyl selenide in the presence of triethylamine, since the use of sulfuric acid led merely to the decomposition products of the steroid molecule. However, the lactone **95** was obtained from the acid **93** instead of the expected selenolactone (Scheme 17).



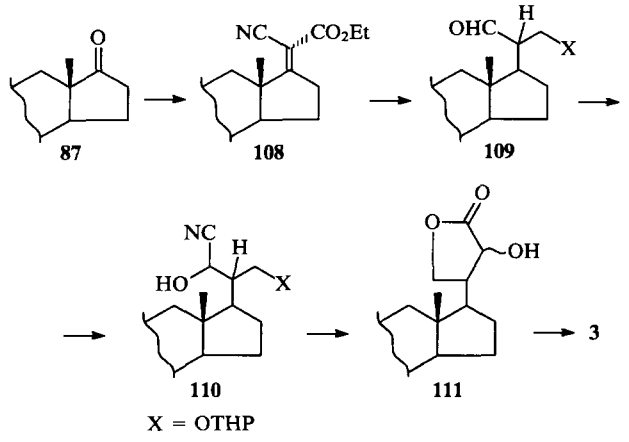
Scheme 17

A similar reaction occurs also with the acid **94**, which made it possible to obtain the isomeric lactone **96**. The dichloro-derivative **98** of the lactone **95** can be obtained stereoselectively[58] from the epoxyolefin **97** by the reaction of the latter with dichloroketene. The hydrogenation under acid conditions of the isoxazole **100**, obtained by the cycloaddition of the nitrile oxide to the acetylenic alcohol **99** led to high yields of the furanone **101**, which is otherwise difficult to obtain.[59]



The previously unknown 17-isoxazolinylsteroids **103** and **104** have also been obtained[60] by the 1,3-dipolar cycloaddition of the corresponding nitrile oxides to the steroid 20(22)-olefins **102**. The addition of the nitrile oxides is regioselective and leads to the corresponding pairs of epimers at C(20) in proportions of 20*R*:20*S* = (2.5–3):1 (Scheme 18).

Scheme 18

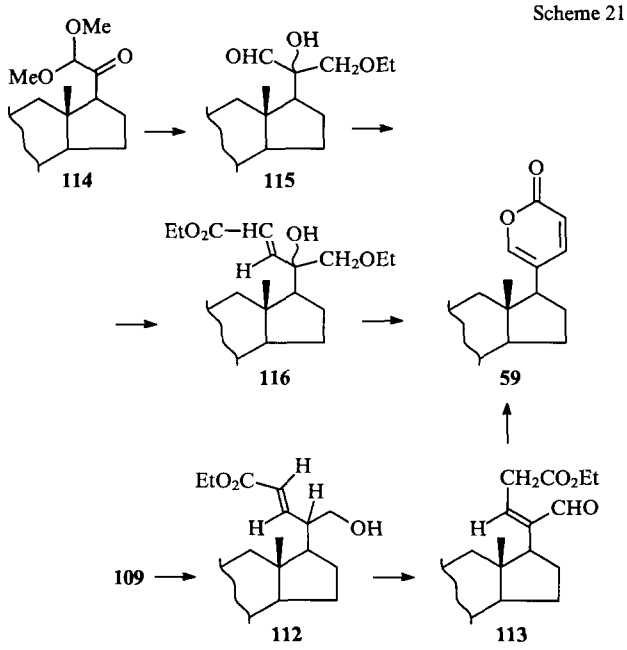


The use of the steroid enol ester **105** in the reaction with acetonitrile oxide leads to the formation of a mixture of a small amount of the isoxazoline **106** and its decomposition product—the isoxazole **107** (Scheme 19).[60]

Scheme 19

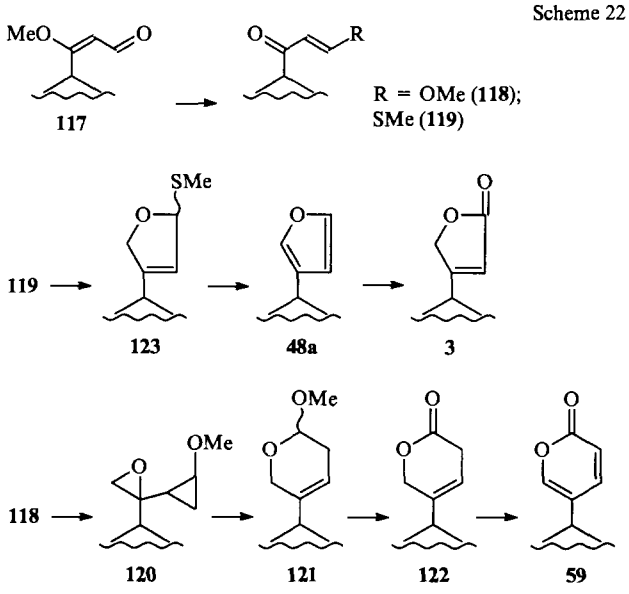
Other bifunctional compounds also serve, together with ketols, in the synthesis of cardiotonic steroids. Thus the product **108** of the condensation of the ketone **87** with cyanoacetic ester afforded the aldehyde **109** after the removal of the tetrahydropyranyl (THP) group (protecting the hydroxy-group) by treatment with $LiAlH_4$ in tetrahydrofuran (THF) and the reduction of the cyano-group with diisopropylaluminium hydride. This aldehyde is a common intermediate in the synthesis of the lactone ring in both cardenolides and bufadienolides. The γ-lactone was obtained from the cyanohydrin **110** by acid hydrolysis with simultaneous ring closure. The dehydration of the hydroxy-group in the resulting lactone **111** led to the required lactone **3** (Scheme 20).

Scheme 20



The δ-lactone **59** was formed by condensing the aldehyde **109** with the triethylphosphonoacetate ylide, the subsequent removal of the protective group, the oxidation of the alcohol **112** to the aldehyde **113** by pyridinium chlorochromate, and the cyclisation of the aldehyde to the lactone in the presence of toluene-*p*-sulfonic acid.[61,62] Engel and Dionne also used in an earlier study the aldehyde **113** in the synthesis of δ-pyrone **59**.[63]

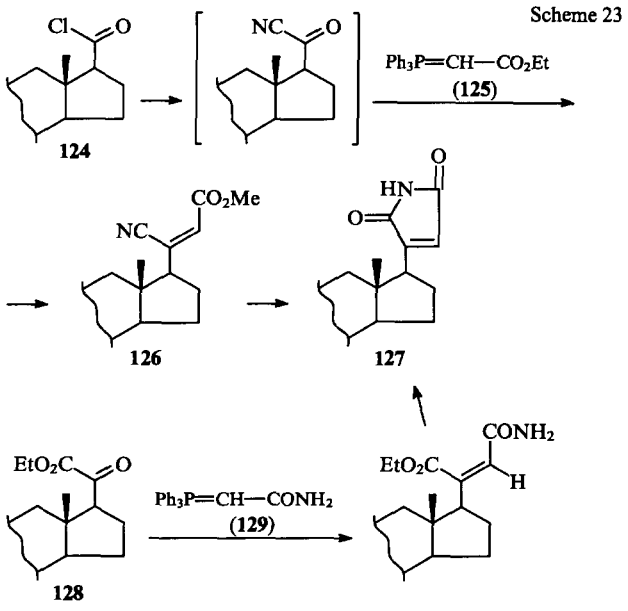
The δ-lactone **59** can be obtained from the acetal of the ketoaldehyde **114**. The aldehyde **115** was synthesised by the reaction of the above acetal with the Grignard reagent, obtained from ethoxymagnesiochloromethane, and subsequent hydrolysis. The product **116** of its condensation with the triethylphosphonoacetate ylide afforded the required bufadienolide **59** after hydrolysis and lactonisation with iodine (Scheme 21).[64]



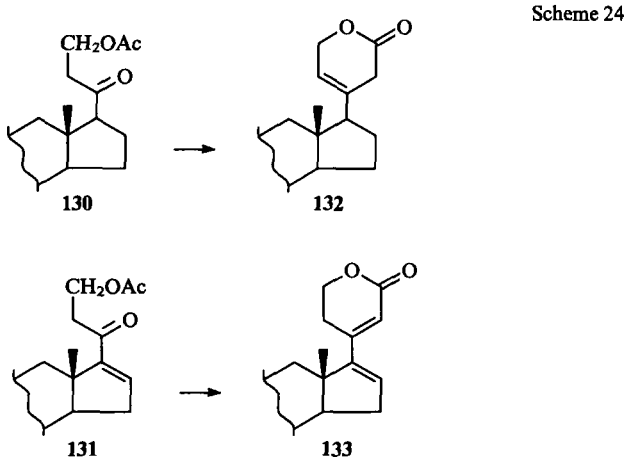
The enol ether **117** is a common intermediate (like compound **109**) in the synthesis of the γ- and δ-unsaturated lactones.[65,66] When it is heated in acidified methanol, compound **118** is obtained, while heating with methanethiol in benzene affords compound **119**. The reaction of the enol ether **118** with an excess of dimethylsulfonium methylide and subsequent treatment of the crude product with a methanol solution of HCl led to the dihydropyran **121**. After the hydrolysis of compound **121** and subsequent Jones oxidation, the lactone **122** was obtained. Its bromination and dehydrobromination by diazabicycloundecene led to the lactone **59**. The interaction of compound **119** with an equimolar amount of the methylide and subsequent desulfurisation led initially to the formation of the furan **48a** and then the lactone **3**. The formation of different compounds in the two fairly

Scheme 21

similar processes can be explained by the occurrence of different intermediates in these reactions. In the former case, the epoxide **120** is formed, its hydrolysis giving rise to the dihydropyran **121**, while in the latter case the intermediate is 2-methylthio-2,5-dihydrofuran **123** (Scheme 22).



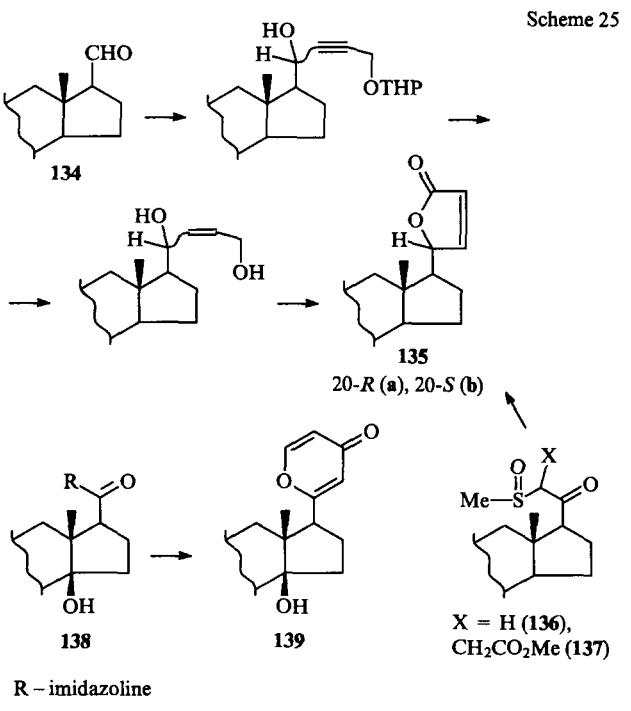
Scheme 22



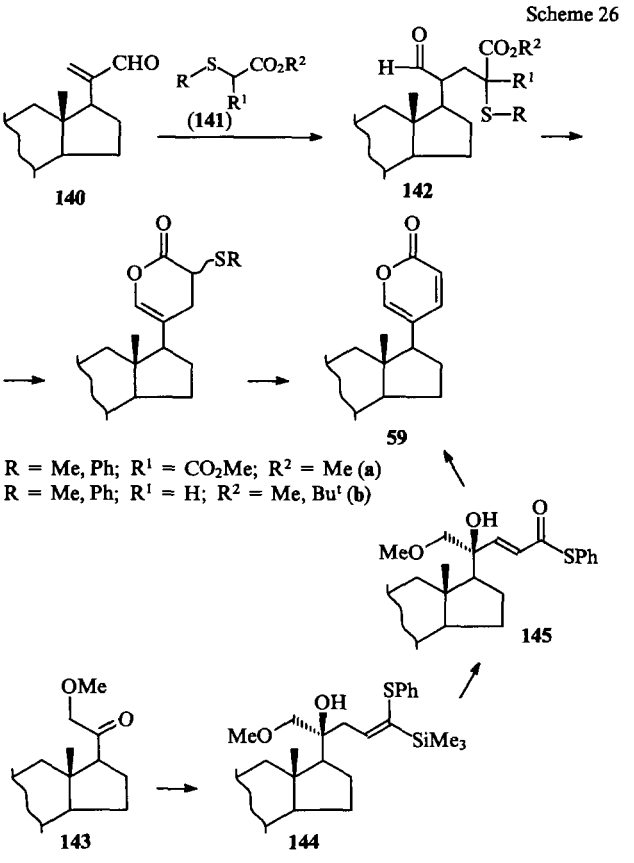
The cyanoacrylate **126**, obtained when the acid chloride **124** is treated with hydrogen cyanide in the presence of an excess of the ylide **125**, cyclises to the maleimide **127** on heating in a mixture of acetic acid, its anhydride, and sulfuric acid.[67] The maleimide **127** was synthesised in a higher yield from the ketoester **128** by condensing the latter with the ylide **129** and further cyclisation of the product (Scheme 23).[68]

An approach has been developed[69] to the synthesis of analogues of isobufadienolides from the ketoacetates **130** and **131**. Thus the lactone **132** has been obtained from the ketoacetate **130** under the conditions of the Reformatskii reaction with bromoacetic ester, while the ketoacetate **131** was converted under the same conditions into the conjugated lactone **133** (Scheme 24).

Scheme 23



Scheme 24



The isomeric lactones **135** have been obtained by alkylating the aldehyde **134** with acetylenes.[70] They had been synthesised previously[71] from bromoacetic ester and the ketosulfoxide **136** with subsequent reduction of compound **137** with $NaBH_4$. The addition of the potassium enolate derived from 4-methoxybut-3-en-2-one to the imidazoline derivative **138** led to the pyrone fragment of γ-isobufalin **139** (Scheme 25).[72]

The addition of sulfur-stabilised alkyl anions to carbonyl compounds proved to be effective for the synthesis of δ-unsaturated ketones.[73–76] Thus the Michael condensation of the aldehyde **140** with anions based on compounds **141** affords the 1,4-adducts **142**, the cyclisation and desulfurisation of which leads to the lactone fragment of bufalin **59**.[73–75] An interesting example of the formation of the δ-lactone from the ketoester **143** has been proposed.[76] The authors chose 1-phenylthio-1-trimethylsilyl-prop-2-ene as the equivalent of the homoenolate anion necessary for the introduction of three carbon atoms and capable of subsequent cyclisation to the pyrone ring. The addition of the propene to the ketoester **143** in the presence of butyllithium led to the formation of compound **144**. The oxidative desilylation reaction was achieved by treating the lithio-dianion of compound **144** with oxygen in solution in THF containing hexamethylphosphoramide. This resulted in the formation of the thioester **145** in 59% yield. Its cyclisation to the pyrone was achieved by treatment with hydrogen bromide in boiling acetonitrile (Scheme 26).[76]

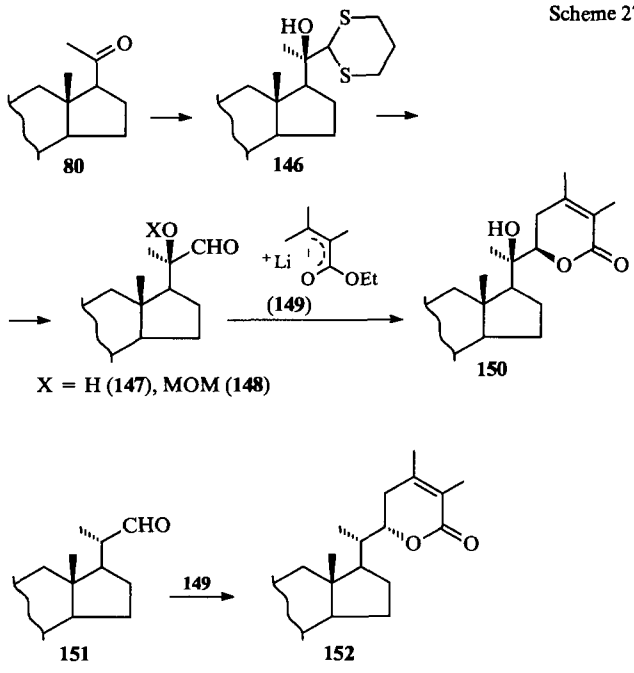
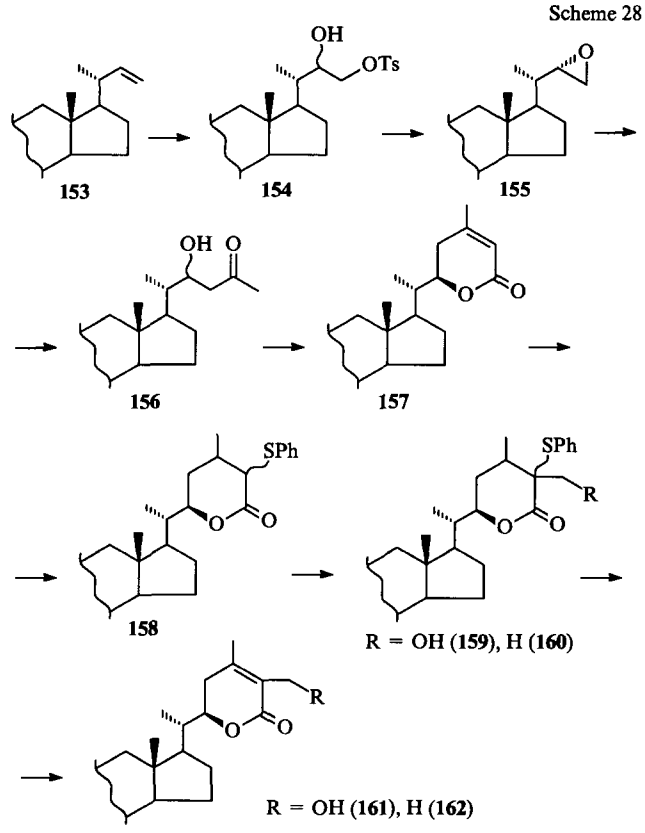
Scheme 26



III. Synthesis of steroids containing a heterocycle in the C(20) position

This section is devoted to the methods of synthesis of the side chains of withanolides and jaborosalactones, which are homologues of cardenolides, i.e. compounds having a heterocycle in the C(20) position in the steroid molecule.

There are two main approaches to the synthesis of the lactone fragment of withanolides and jaborosalactones — via the addition of stabilised lithio-enolates or lithiodithianes and via the addition of lithiofurans and transformation of the latter.

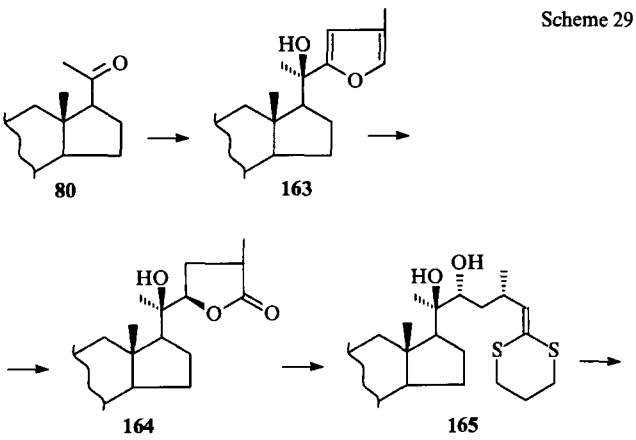


The aldehyde **147**, which is the starting material of the synthesis of the lactone fragment of the withanolide D, was synthesised by adding the anion of 1,3-dithiane to the ketone **80** with subsequent hydrolysis of the hydroxythioacetal **146**. After the protection of the hydroxy-group in the form of the methoxymethyl ester (MOM) **148** and the addition of the lithio-enolate **149**, formed from α,β-dimethylcrotonate and lithium diisopropylamide, the required lactone **150** was obtained.[77,78] It is of interest that the addition of the enolate **149** to the aldehyde **151** afforded the lactone **152** with the stereochemical configuration at C(22) opposite to that in 27-deoxywithaferin A, the attempts to invert the configuration proving unsuccessful (Scheme 27).[78]

Scheme 27

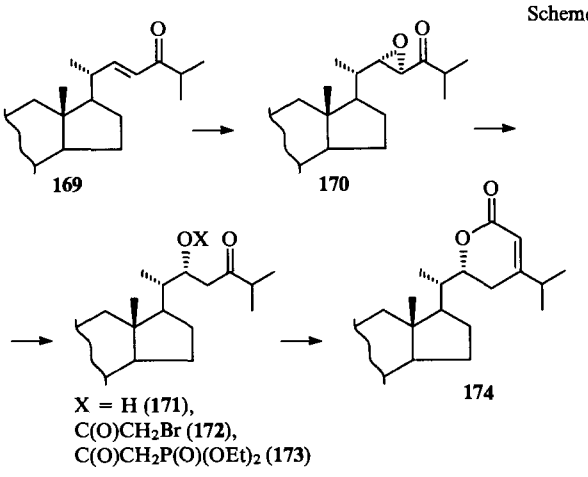
Since the addition of the enolate **149** to the aldehyde **151** does not ensure the required stereochemical configuration of the C(22) centre, another sequence of reactions, permitting the introduction of the hydroxy-group with the required configuration, was selected for the construction of the side chain in withaferin A, 27-deoxywithaferin A, and jaborosalactones. For this purpose, the olefin **153** was treated with OsO_4 and the reaction product was toluene-*p*-sulfonated, which led to a mixture of the isomeric toluene-*p*-sulfonates **154** in proportions of 5 : 1. The main isomer was converted quantitatively into the chiral epoxide **155**. The regiospecific alkylation of the epoxide with the 2-methyl-1,3 dithiane anion followed by the elimination of the thioketal ensured the necessary (22*R*)-configuration in the ketol **156**. Cyclisation to the lactone **157** was achieved by the McMorris method.[79] After the reduction of the double bond and treatment with diphenyldisulfide, the sulfide was obtained as a mixture of isomers with respect to C(24) (3 : 2). In order to obtain the side chain of jaborosalactone and withaferin A, the lithio-anion of the sulfide was treated[80,81] with monomeric formaldehyde, which afforded compound **159**, while for the synthesis of the side chain of 27-deoxywithaferin A the lithio-anion was treated with methyl iodide,[80–82] which afforded the methyl derivative **160**. Next, the sulfides were oxidised to the sulfoxides in both cases and after desulfurisation the required lactones **161** and **162** were obtained (Scheme 28).

Scheme 28



The synthesis of the side chain in withanolides by the addition of 2-lithio-4-methylfuran to the ketone **80** with formation of the furylsteroid **163** has been described.[83] After two-stage oxidation (with *m*-chloroperbenzoic acid and pyridinium chlorochromate) and hydrogenation over platinum dioxide, the lactone **164** was obtained. Its reduction with diisobutylaluminium hydride afforded a lactol, the treatment of which with 2-lithio-2-trimethylsilyldithiane resulted in the formation of the thioacetal **165**. The lactone **166**, obtained from the thioacetal after cyclisation in the presence of camphorsulfonic acid, was alkylated with methyl iodide in the presence of lithium isopropylcyclohexylamide. The lactone **167** was successfully converted into the sulfide, oxidised to the sulfoxide, and desulfurised. However, together with the required lactone **150**, the *exo*-product **168** was obtained in proportions of 1 : 4.2. The isomerisation of the *exo*-product to the *endo*-product was achieved on heating the lactone **168** in a sealed tube with rhodium trichloride in dry ethanol at 100 °C (Scheme 29).

The stereoselective epoxidation of the unsaturated ketones **169** with alkaline hydrogen peroxide proved to be an extremely useful reaction for the synthesis of 22,26-lactones.[79] Thus the ketol **171** was obtained by reducing the epoxide **170** with aluminium amalgam and was used as an intermediate in the synthesis of 23-deoxyantheridiol. The ketol **171** was converted into the bromoacetic ester **172** and the latter afforded the phosphonate **173** on heating with triethyl phosphite as a result of the Arbuzov reaction. The intermolecular Horner–Emmons condensation led to the required δ-lactone **174** (Scheme 30).



A compound with the side chain of withanolides was obtained from the ketone **175** by employing the sequence of reactions described above (Scheme 31).[84]

The isoxazoline **176** can serve as an intermediate in the formation of the side chain of 23-deoxyantheridiol.[85] Thus the 22-acetoxy-24-ketone **178**, formed after the acetylation of the β-ketol **177** (the product of the cleavage of the isoxazoline **176**) is converted by the Reformatskii reaction, followed by refluxing in acetic anhydride, into the δ-lactone **174** (Scheme 32).

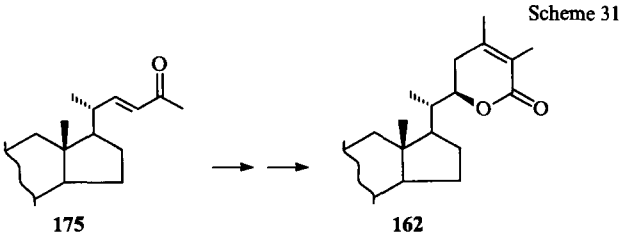
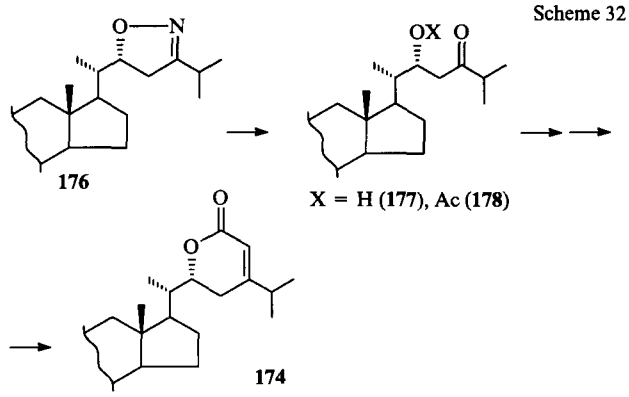


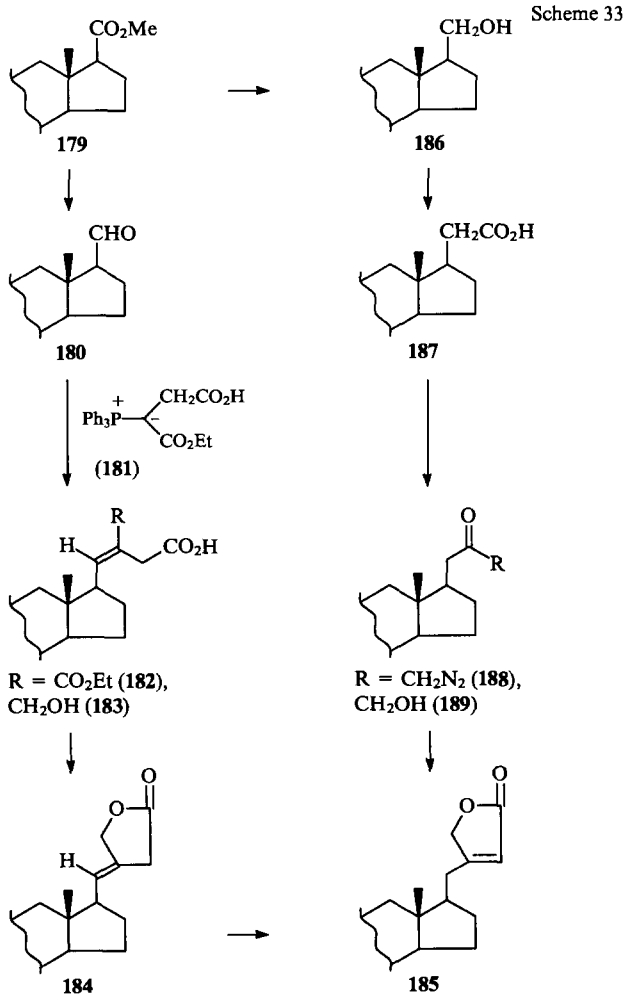
Scheme 30



X = H (171),
C(O)CH$_2$Br (172),
C(O)CH$_2$P(O)(OEt)$_2$ (173)

Scheme 31

The synthesis of homologues of cardiotonic steroids was based on the approaches described in the previous section. The key feature of their synthesis is the stage in which the chain is lengthened by a CH_2 group. Thus the aldehyde **180**, obtained by reducing the ester **179**, was used[86] to synthesise the cardenolide homologue **185**. The lactone fragment was introduced by means

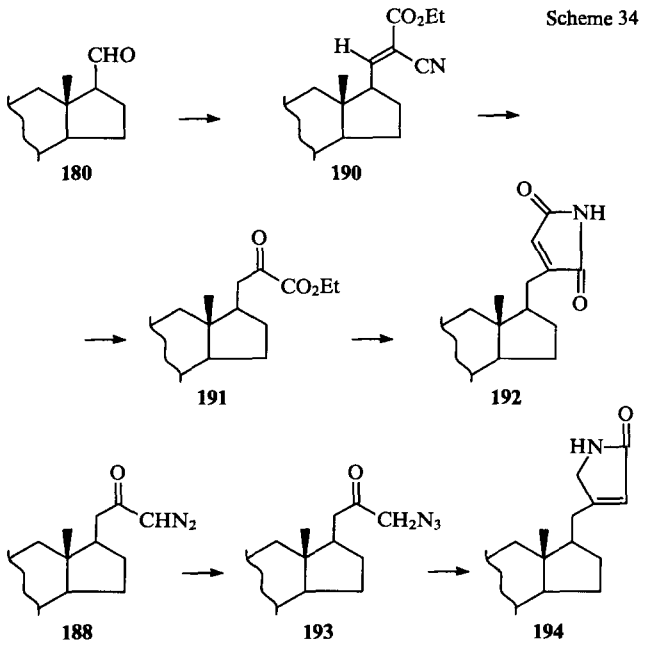


Scheme 32

X = H (177), Ac (178)

of the Witting reagent **181** obtained from triphenylphosphine and maleic anhydride. The product of the addition of this reagent to the aldehyde **180** — the half-ester **182** — was reduced with sodium diethylaluminium hydride to the alcohol **183**, which cyclised to the lactone **184** on heating in acetic anhydride. The shift of the double bond was achieved by treating the lactone **184** with alkali-activated alumina (Scheme 33).

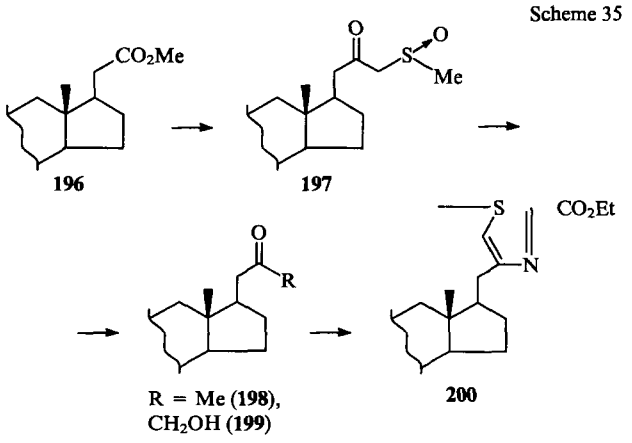
Scheme 33



R = CO_2Et (182),
CH_2OH (183)

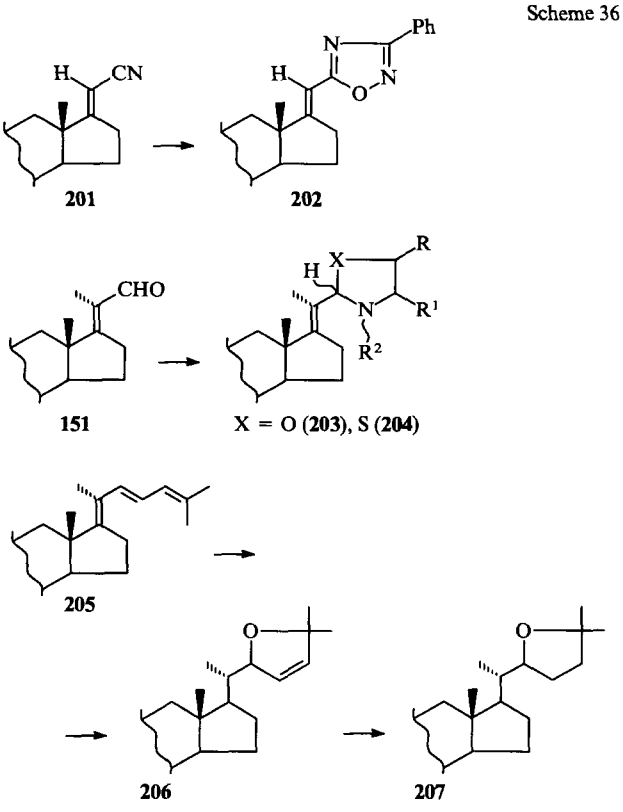
R = CH_2N_2 (188),
CH_2OH (189)

The unsaturated lactone **185** had been synthesised previously from the alcohol **186**, which was converted[87] via the toluene-*p*-sulfonate into a nitrile and, after hydrolysis, into the acid **187**. Treatment of the acid by the Arndt–Eistert method afforded the diazoketone **188**, which was converted into the hydroxyketone **189** and further into the lactone **185** using the method described by Fritsch et al.[11]



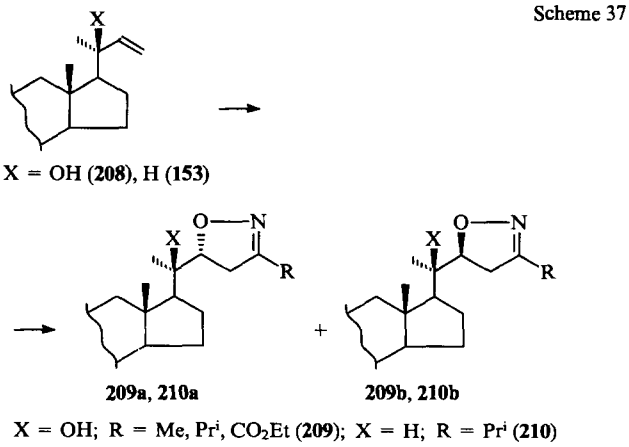
The approaches described have been applied in the synthesis of homologues of steroid compounds containing various heterocycles (maleimide, lactams, and thiazoles) in the side chain. Thus the ketoester **191** was obtained from the aldehyde **180** via the product of its condensation with the cyanoacetic ester **190**.[68] Compound **191** was transformed into the maleimide **192**. The lactam **194** was synthesised[88] from the diazoketone **188** by treatment with toluene-*p*-sulfonic acid, substitution of the toluene-*p*-sulfonate group by the azide group, and further transformation of the azide **193** (Scheme 34).[17,18]

Scheme 34



The methyl ester **196** served as the starting compound in the synthesis[89] of the thiazole **200**. It was converted into the ketone **198** by reducing with aluminium amalgam the ketosulfoxide **197** obtained from the ester **196** by treating the latter with dimsylsodium. Next the ketone **198** was oxidised via the silyl ether of the enol to the ketol **199**, which was converted in the usual way into an α-bromoketone. The addition of thioxamate to the latter by the Hantzch method afforded the thiazole **200** (Scheme 35).

Scheme 35

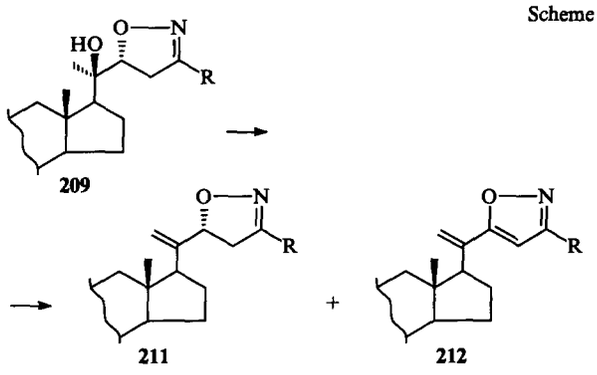


Apart from the approaches described above, steroids with a heterocycle in the C(20) position can be obtained by the dipolar cycloaddition of nitrile oxides, by the condensation of amino-alcohols, and by the hydroxymercuration of dienes. Thus the addition of benzonitrile oxide to the nitrile **201** led[90] to the formation of the oxadiazole **202**, while the condensation of amino-alcohols or aminothiols with the aldehyde **151** led to the formation of the oxazolidines **203** or the thiazolidines **204** respectively.[91] When an attempt was made to obtain the 22,25-dihydroxy-derivative from the diene **205** under hydroxymercuration conditions, the product **206** was isolated. Its reduction over $Pd/BaSO_4$ led to the formation[92] of the tetrahydrofuryl derivative **207** (Scheme 36).

Scheme 36

The synthesis of the new heterocyclic steroids **209** and **210** was achieved by the 1,3-dipolar cycloaddition of a series of nitrile oxides to the Δ^{22}-steroids **208** and **153** respectively.[85,93-97] The cycloaddition takes place stereoselectively[93] and in the case of allyl alcohols the epimer ratio 22*S*:22*R* reaches 6:1. The yield of the adducts depends on the nature of the substituents R in the nitrile oxide, diminishing when nitrile oxides with functional group substituents are used (Scheme 37).

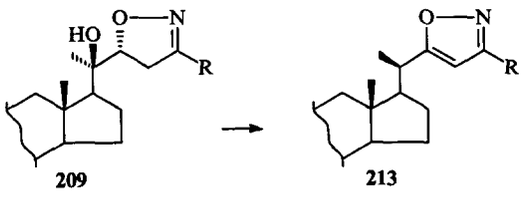
Scheme 37



X = OH; R = Me, Pr^i, CO_2Et (**209**); X = H; R = Pr^i (**210**)

The observation[98] of the dehydrogenation of the steroid isoxazolines **209**, which makes it possible to achieve their transition to the corresponding isoxazoles **212**, is interesting. In the study of the dehydration reaction on treatment with thionyl chloride in chloroform, the formation of the isoxazole **212** as a side product together with the main product—the olefin **211**—was

established. The replacement of chloroform by pyridine or DMF led to the preferential formation of compounds **212** (Scheme 38).

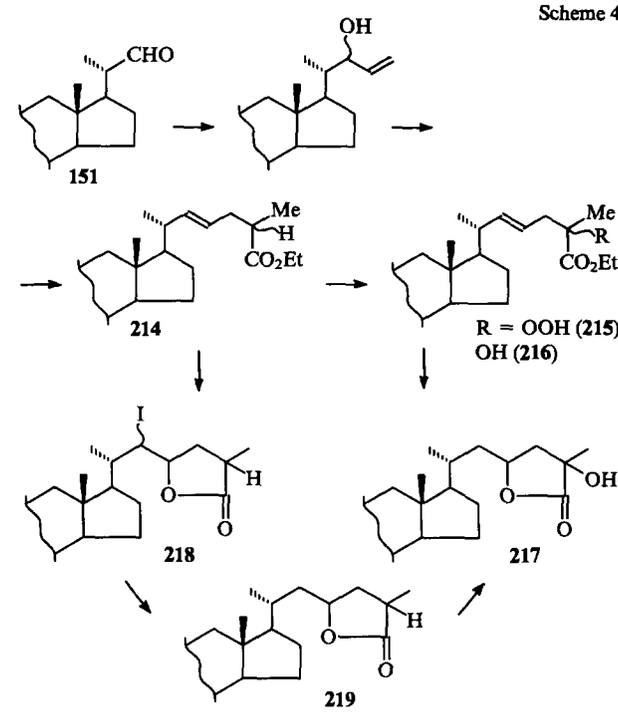


Scheme 38

R = Me, Pr^i, CO_2Et

A novel synthesis of 20-isosteroid isoxazoles has been proposed.[96] It consists in the transformation of the isoxazoline **209** into the isoxazole **213** with the simultaneous formation of a chiral centre at C(20). It was found that treatment of the isoxazoline **209** with trifluoroacetic acid in boiling nitromethane in the presence of lithium perchlorate affords only one C(20) isomer of compound **213** in a high yield (Scheme 39).

Scheme 39



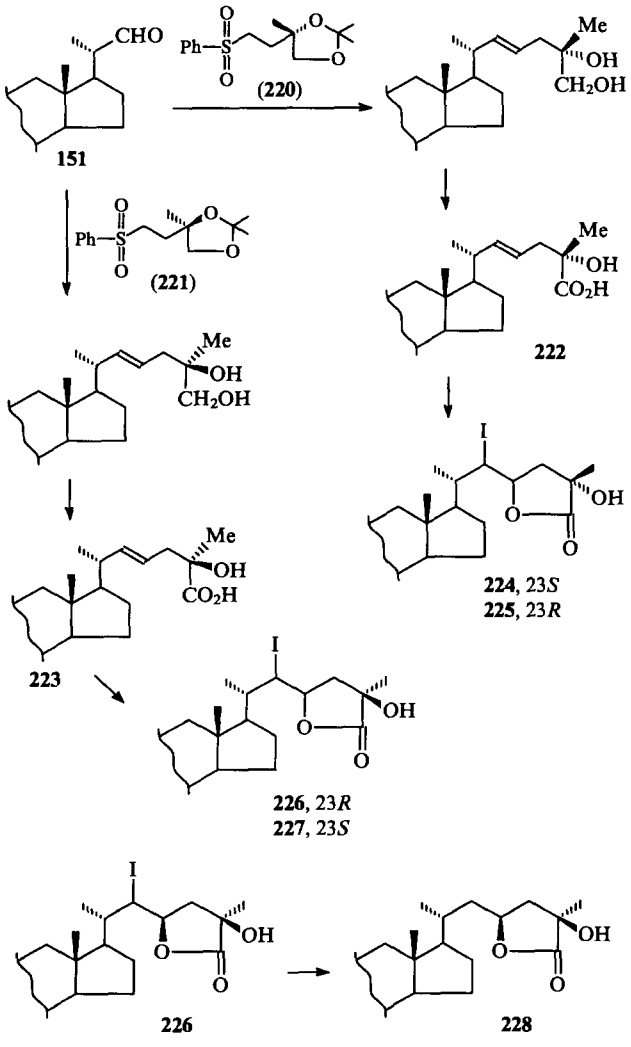
R = Me, Pr^i, CO_2Et

IV. Synthesis of steroids containing a heterocycle in the C(22) position

The approaches to the synthesis of the 25-hydroxycholecalciferol-26,23-lactone — the only known metabolite of vitamin D_3 having a lactone ring in the side chain — and several other compounds with the heterocycle in the C(22) position are considered in this section.

A new metabolite of vitamin D, having a 26,23-lactone ring, was isolated in 1979, but the stereochemical configuration of the C(23) and C(25) centres was not established. Synthetic chemists are therefore faced with the problem of not only obtaining this compound by chemical means but also of establishing the stereochemical configuration of the C(25) and C(23) centres. For this purpose, all four diastereoisomers were synthesised. One of the first syntheses of the side chain was achieved as follows. The aldehyde **151** was alkylated with vinylmagnesium bromide and the resulting mixture of isomers was used in the Claisen reaction with an excess of triethyl orthopropionate. This resulted in the formation of the ester **214**, which was converted into the enolate and oxidised at −78 °C with molecular oxygen. The hydroperoxide **215** formed in this reaction was reduced with triethyl phosphite, which afforded the α-hydroxyester **216**. After hydrolysis, the mixture of diastereoisomers was treated with iodine and potassium iodide under basic conditions, which led to the formation of a mixture of iodolactones. After their reduction with tributyltin hydride and separation, four diastereoisomers of compound **217** were obtained. However, the authors attributed[99] to the natural lactone the erroneous (23*R*,25*S*)-configuration (Scheme 40).

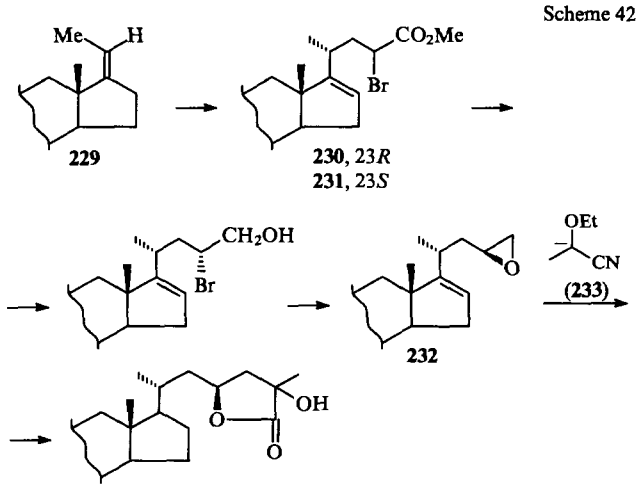
Scheme 40



This procedure largely repeats the earlier synthesis,[100] in which the 25-hydroxy-group was introduced, in contrast to the method described above, in the last stage (after the reduction of the iodolactone **218** and the oxidation of the lactone enolate **219** by the MoO_3–pyridine–hexamethylphosphoramide complex). The authors determined the configuration of only the C(23) centre as 23*R*.

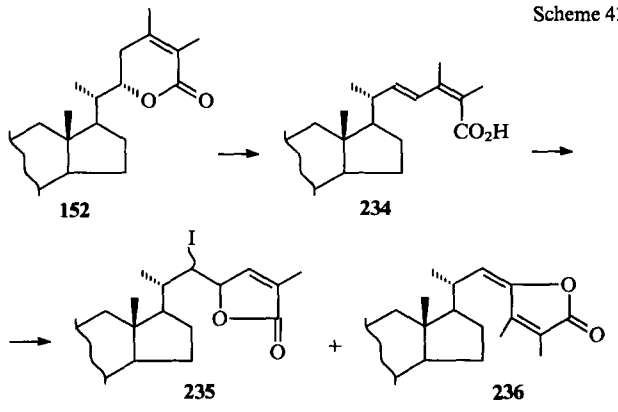
Several studies have been devoted to the determination of the structure of the above compound.[101–103] In order to avoid difficulties in the separation of the four diastereoisomers and to investigate in detail the iodolactonisation process, the stereoselective synthesis of the α-hydroxyacids **222** and **223** was carried out. The sulfones **220** and **221**, obtained respectively from (*S*)-(+)-citromalic acid (2-methylmalic acid)[101] and (*R*)-(−)-citromalic acid were used as the reagent with the required chirality.[102] The addition of these sulfones to the aldehyde **151** with subsequent desulfurisation, hydrolysis, and two-stage oxidation of the alcohol to the acid under mild conditions led to the hydroxyacids **222** and **223**. The iodolactonisation (iodine, MeCN) and reduction of the iodolactones led to the formation of two diastereoisomers of compounds **224**–**227** in each case (Scheme 41).

In their study of the iodolactonisation process[103] under various conditions, the authors observed that the selectivity of this reaction depends on stereochemical configurations at C(25) and the reaction conditions. The product **226** obtained by iodolactonisation under basic conditions afforded the lactone **228** in 56% yield relative to the acid **223** after reduction with tributyltin hydride. After the appropriate transformations of the cyclic component of this compound, its parameters proved to be identical with those of the natural metabolite. Thus the configuration of the C(23) and C(25) centres of the vitamin D metabolite was determined as 23*S*, 25*R*.



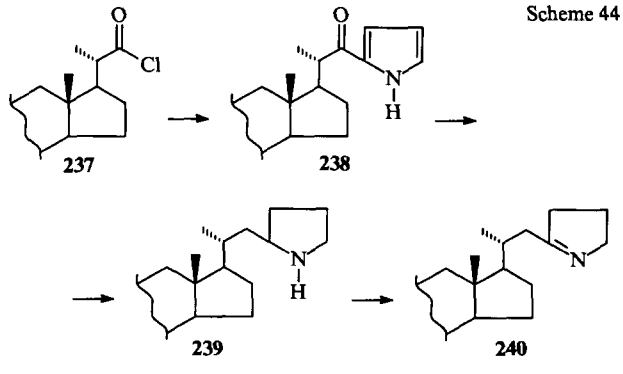
Yet another example of the synthesis of the side chain of the calciferol lactone, based on the introduction of chirality initially in the C(23) position, has been proposed.[104] Addition of α-bromo-acrylate to the olefin **229** in the presence of ethylaluminium dichloride afforded a mixture of bromo-derivatives in the proportions **230**:**231** = 13:87. The required diastereoisomer **230** was isolated from the mixture produced by reaction with lithium bromide in acetone. After four repetitions of this procedure, the bromo-derivative **230** was obtained from the

Scheme 41



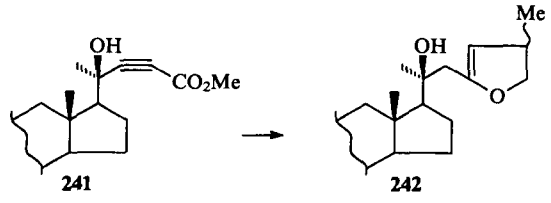
olefin in 63% yield. The ethoxycarbonyl group in compound **230** was reduced to the alcoholic group. The resulting bromohydrin afforded the epoxide **232** after treatment with a base. The missing three carbon atoms were introduced into the molecule by the addition of the anion **233** obtained from acetaldehyde cyanohydrin. After the hydrolysis of the intermediate, a 1 : 1 mixture of the lactones was isolated (Scheme 42).

Scheme 42



Steroids having a heterocyclic substituent in the C(22) position have not so far attracted much attention from organic chemists and syntheses of compounds of this kind are fairly rare. Thus the lactones **235** and **236**, which are structurally similar to calciferol lactone, have been isolated[78] after treating with iodine and selenium compounds the acid **234** obtained by hydrolysing compound **152** (Scheme 43).

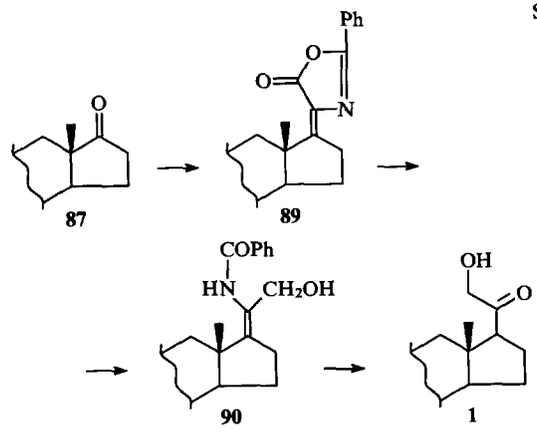
Scheme 43



Compound **240**, which is related to steroid alkaloids, was synthesised in accordance with Scheme 44.[105] The acid chloride **237** was treated with pyrrolylmagnesium bromide and the adduct **238** was hydrogenated over Raney nickel, which led to the reduction of the pyrrole ring and the removal of the carbonyl group. The resulting stereoisomeric mixture of the pyrrolidines **239** was converted by reaction with *N*-bromosuccinimide into *N*-chloroamines, which afforded the pyrroline **240** after alkaline treatment.

Scheme 44

The dihydrofuran derivative **242**, the structure of the side chain of which is similar (according to the authors) to that in shidasterone, was obtained by the reaction of methyl acetylenecarboxylate **241** with methylmagnesium iodide (Scheme 45).[106]

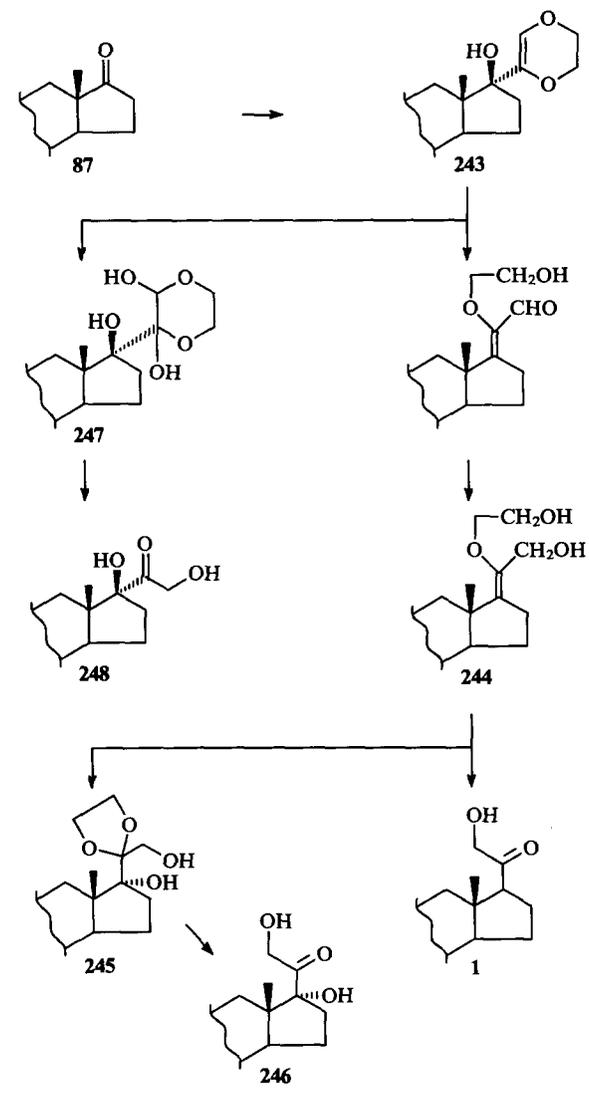


Scheme 45

V. Syntheses of the side chains of steroids including the transformation of heterocyclic structures

The synthetic possibilities of heterocycles for the construction of the side chains of steroids have not so far been employed in due measure. The only heterocycles which have found fairly extensive applications in the synthesis are probably furan derivatives. Nevertheless heterocyclic structures are attractive because of their fairly ready transformation into an open chain, which has stimulated interest in these compounds. This section deals with the syntheses of compounds with the side chains of the natural corticoids, ecdysones, brassinosteroids, vitamin D metabolites, etc. with participation of heterocyclic intermediates. The role of these intermediates is associated with the utilisation of the latent functionality of the heterocycle, which makes it possible to introduce the necessary substituents into definite positions, and also with the possibility of the stereocontrol of the products by virtue of the different accessibility of different sides of the heterocycle to the reagent. For example, the transformation of the heterocyclic derivatives **89** and **243**, obtained from the ketone **87**, makes it possible to form the side chain of corticosteroids.[51,56] Thus treatment of the product of alkaline hydrolysis with acetic acid and subsequent reduction of the heterocycle **89** via compound **90** lead to the formation of 21-hydroxyprogesterone **1** (Scheme 46).[56]

Scheme 46

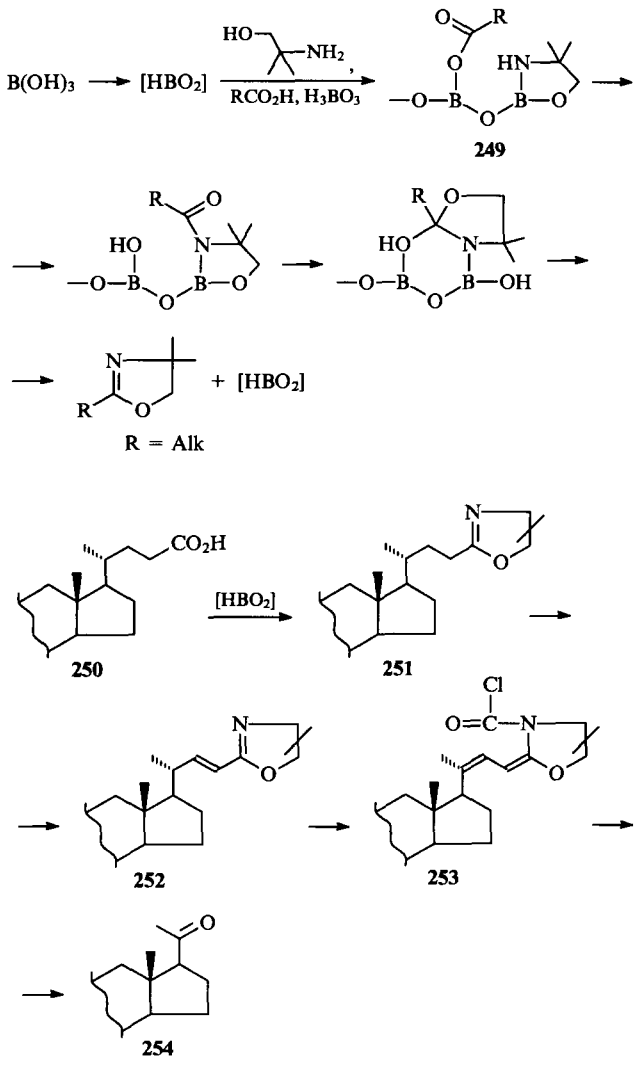


The cleavage of the heterocycle in compound **243** by various methods makes it possible to achieve the transition to a whole series of derivatives.[51] The acid-catalysed allyl rearrangement of compound **243** under very mild conditions (SiO_2, 5% oxalic acid) leads to the enol ether of an α-ketoaldehyde. Its reduction with $LiAlH_4$ and the subsequent hydrolysis of the ethyl ether afford the ketone **1**. Oxidation with *m*-chloroperbenzoic acid of the reduction product **244** led to the formation of the ketal **245** (via intramolecular cyclisation which followed the opening of the oxiran ring), the acid hydrolysis of which led to the ketodiol **246** with the natural orientation of the side chain. The authors also obtained the isomer of this compound with the 17α-configuration from the dioxene **243** (Scheme 47).

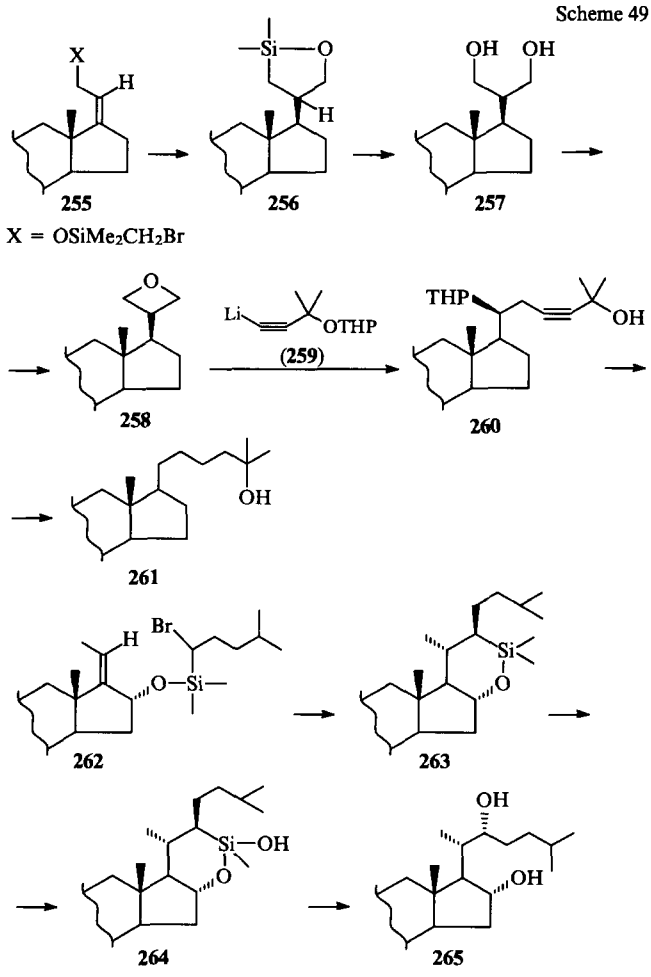
For this purpose, compound **243** was oxidised with *m*-chloroperbenzoic acid in methanol. The oxidation reaction occurred regioselectively at the electron-unsaturated C=C bond and led to the hemiacetals **247** in the form of a mixture of isomers with respect to C(20) and C(21). After their reduction with $NaBH_4$ and hydrolysis, the ketodiol **246** was obtained.

Barton and coworkers[107] developed a convenient and effective method for the conversion of cholic acids into pregnanes via oxazolines. The authors chose boric acid as the catalyst. Boric acid can react with cholic acid and the aminoalcohol, affording an intermediate of type **249** with an activated carbonyl group. Its subsequent reactions can lead to oxazolines. Using this method, the oxazoline **251** was obtained from the acid **250** in 95% yield.

Scheme 47



When it was heated with benzeneselenic acid in pyridine, the dehydrogenated compound **252** was obtained in a quantitative yield. In order to obtain the $\Delta^{20(22)}$-bond, the oxazoline **252** was acylated with phosgene at the nitrogen atom and the product **253** was ozonised, which led to the ketone **254** (Scheme 48).



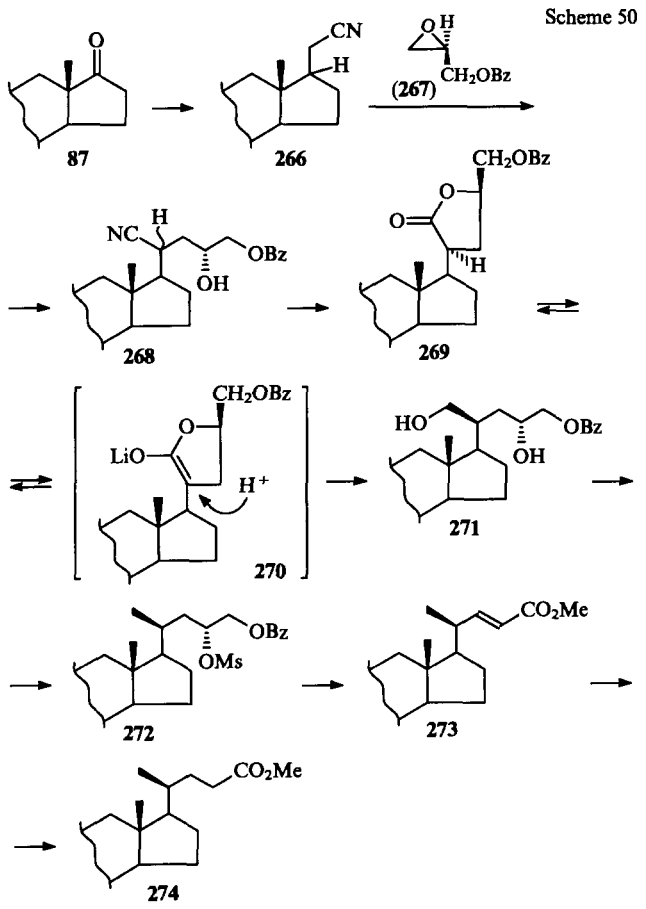
It has been observed recently[108,109] that the intramolecular cyclisation of α-silylsteroid groups to siloxanes proceeds with a high degree of selectivity, which makes it possible to employ the resulting siloxanes in the synthesis of the side chains. Thus the siloxanes **256** have been obtained[108] from the silyl ethers **255** by treatment with tributyltin hydride, while the siloxane **263** was obtained from the ether **262**.[109] Oxidation of the siloxanes **256** with hydrogen peroxide afforded the diol **257**. The latter was cyclised to the oxetan **258**, which was alkylated with lithium acetylide **259** in the presence of boron trifluoride etherate. This led to the isolation of the alcohol **260**. After removal of the 21-hydroxy-group via the methanesulfonate, hydrogenation of the triple bond, and hydrolysis, the tertiary alcohol **261** was obtained with the isosteroid (20*S*) side chain. The siloxane **263** proved to be resistant to the action of various oxidising agents, including concentrated (90%) hydrogen peroxide in DMF. Therefore, in order to open the heterocycle, the siloxane **263** was treated with KOH in dimethyl sulfoxide (DMSO), which led to a mixture of silanols **264**. The latter were readily oxidised with hydrogen peroxide to the diol **265** (Scheme 49).

Steroid γ-lactones have found applications as intermediates in the synthesis of the side chains of desmosterol[110] and (20*S*)-cholic acids.[111] The use of intermediates of this kind made it possible to

Scheme 48

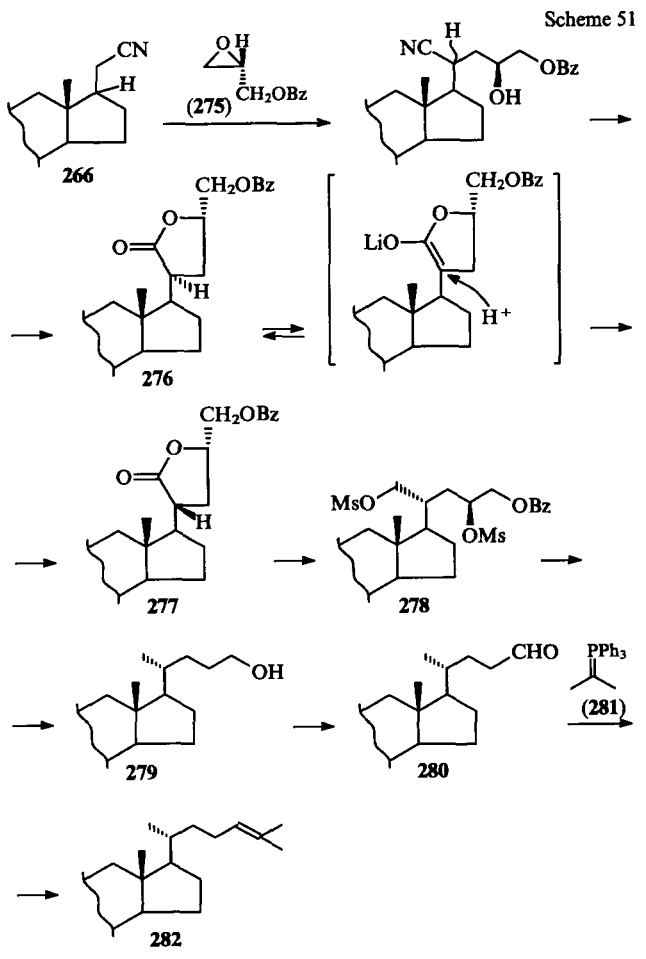
Scheme 49

form stereoselectively the 20*R* or 20*S* centre in the steroid molecule via the controlled protonation of the lactone enolate. The nitrile **266** was obtained in two stages from the ketone **87**. Its condensation with (*S*)-benzyl 2,3-epoxypropyl ether **267** in the presence of lithium hexamethyldisilazide afforded a mixture of the corresponding cyanoalcohols **268**, which could not be separated. After the hydrolysis of the cyanoalcohols (KOH, EtOH), a mixture of the lactone **269** and its C(20) epimer was obtained. The mixture was treated with lithium hexamethyldisilazide in THF at −78 °C and then with a saturated solution of Na_2SO_4 at the same temperature, which led to the selective protonation of the enolate intermediate **270** at C(20) from the less hindered side (opposite to the benzyl group) and to the exclusive formation of the (20*S*)-lactone **269**. The latter was reduced with $LiAlH_4$ to the diol **271**, which was converted into the dimethanesulfonate and reduced selectively with lithium triethylboron hydride to the methanesulfonate **272**. Dehydration, reductive debenzylation, oxidation, and hydrogenation led to the formation[111] of compounds **273** and **274**, which had been isolated previously from marine organisms (Scheme 50).



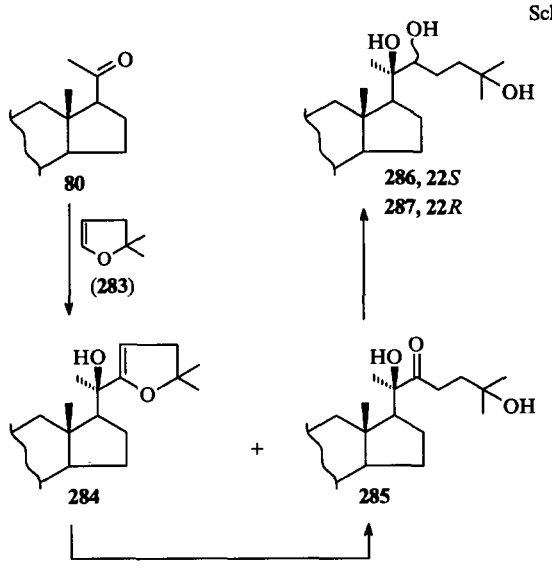
In the synthesis of desmosterol, the addition of the (*R*)-benzyl 2,3-epoxy propyl ether **275** to the nitrile **266** led, after cyclisation, to a 4 : 1 mixture of the lactone **276** and its C(20) epimer **277**. The protonation of this mixture under the conditions described above afforded exclusively the (20*R*)-lactone **277** (i.e. the minor component of the initial mixture). Like the lactone **269**, the lactone **277** was reduced and converted into the methanesulfonate **278** and the latter afforded the alcohol **279** as a result of reduction and debenzylation. The alcohol was oxidised to the aldehyde **280**, from which the product **282**, having the desmosterol side chain, was obtained on condensation with the ylide **281** (Scheme 51).[110]

The chemistry of furan derivatives has found an application also in the synthesis of side chains of ecdysones and brassinosteroids. The side chains of these compounds have from two (α-ecdysone) to four (brassinolide) chiral centres and several hydroxy-groups in different positions, which greatly complicates the synthesis of compounds of this kind. The use of heterocyclic intermediates in the synthesis in many respect helps in the solution of the problems of regio- and stereo-selectivity arising in this connection.



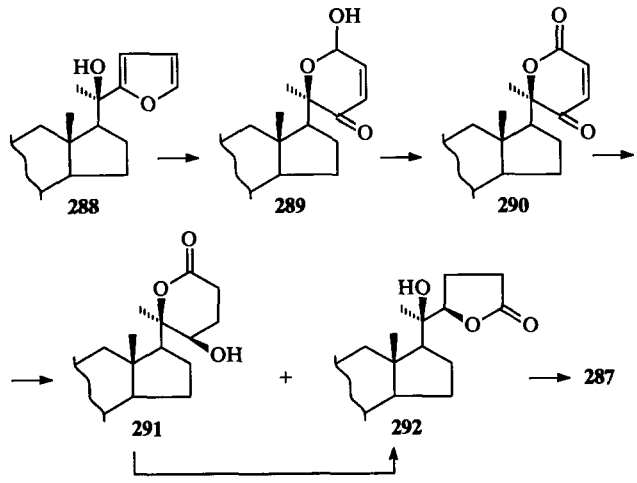
The dihydrofuran **283** was used to synthesise the side chain of 20-hydroxyecdysone.[112] The addition of its lithio-derivative to the ketone **80** led to a mixture of compounds **284** and **285** in 85% yield without any admixture of the (20*S*)-isomers. The dihydrofuran **284** was converted into compounds **285** by brief treatment with 0.1% HCl in THF. The reduction of the ketodiol **285** with Li selectride afforded, as expected, the (22*S*)-alcohol **286** (the ratio of the alcohol **286** to the isomer **287** was 16 : 1). Nevertheless, this product ratio as altered by protecting the hydroxygroup in the ketodiol **285** by forming the trimethylsilyl ether. The subsequent reduction with Li selectride at −78 °C and hydrolysis of the silyl ether led to the formation of the triol **287** in 58% yield (Scheme 52).

A more selective method was proposed by Kametani and coworkers.[113-115] After treatment of the furan **288** with *m*-chloroperbenzoic acid in sodium acetate and chloroform, the hemiacetal **289** was obtained and the oxidation of the latter with pyridinium chlorochromate afforded the lactone **290**. The stereoselective hydrogenation of the lactone **290** over PtO_2 proved to be the key stage. Hydrogen added from the less hindered side (opposite the bulky steroid skeleton) of the lactone afforded a mixture of the lactone **291** and its isomerisation



Scheme 50

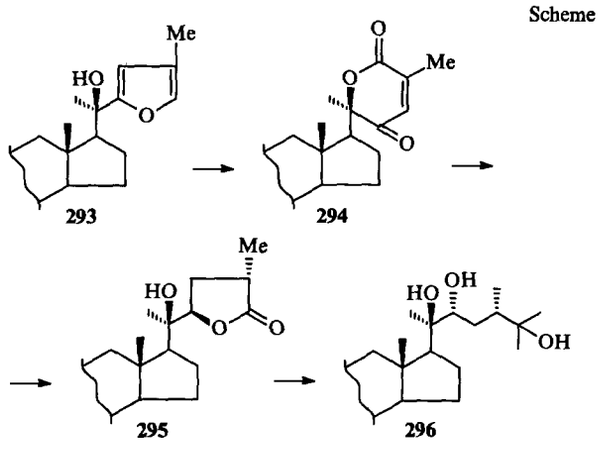
Scheme 51



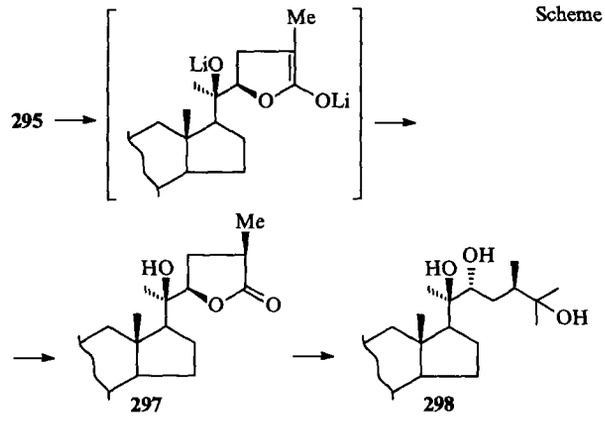
Scheme 52

product **292** (3 : 2) in an almost quantitative yield. The lactone **291** was converted by treatment with aqueous alkali into the thermodynamically more stable lactone **292**, which was alkylated with methyl magnesium bromide. Ultimately the (20*R*, 22*R*)-diol **287** was obtained in 88% yield. The stereoselective formation of the C(22) centre of ecdysones constitutes an appreciable advantage of the above investigation, because the reduction of 22-ketones by hydrides affords mainly the (22*S*)-hydroxy derivative (Scheme 53).[2]

Scheme 53



This approach was also applied to the synthesis of the side chain of makisterone A (three chiral centres in the side chain) and its 24-isomer.[115] The lactone **294** was obtained from the furan **293** and its stereoselective hydrogenation and recyclisation afforded the lactone **295** in a quantitative yield. The epimakisterone **296** was obtained by alkylating the latter with methylmagnesium bromide (Scheme 54).

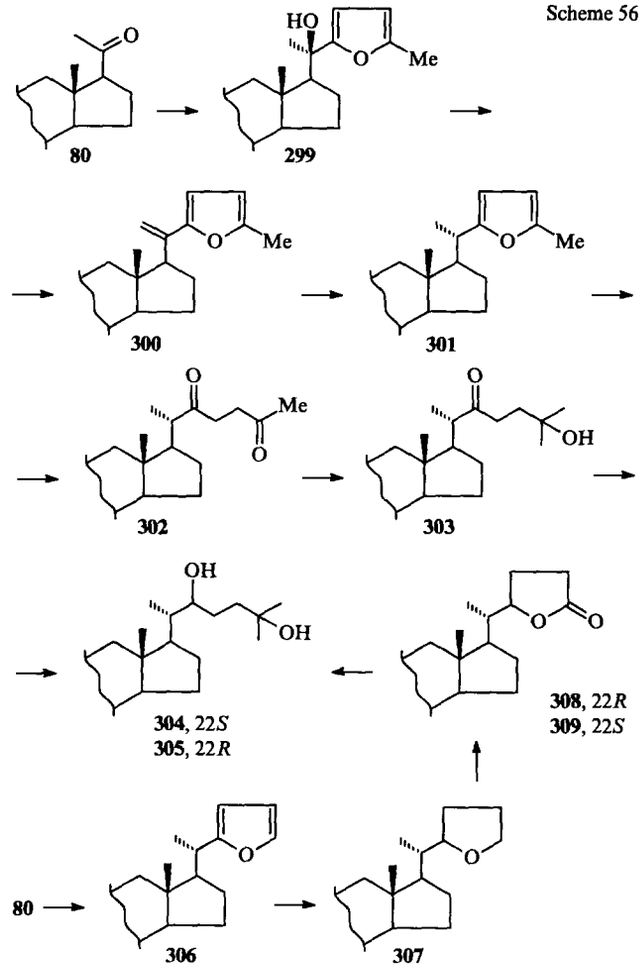


The side chain of makisterone was formed by inverting the C(24) centre in the lactone **295**, which is achieved by the kinetic protonation of γ-butyrolactone. For this purpose, the lactone **295** was enolised by treatment with lithium diisopropylamide and the enolate was treated at −78 °C with a Na_2SO_4 solution, which afforded the lactones **297** and **295** in proportions of 87 : 13 (Scheme 55).

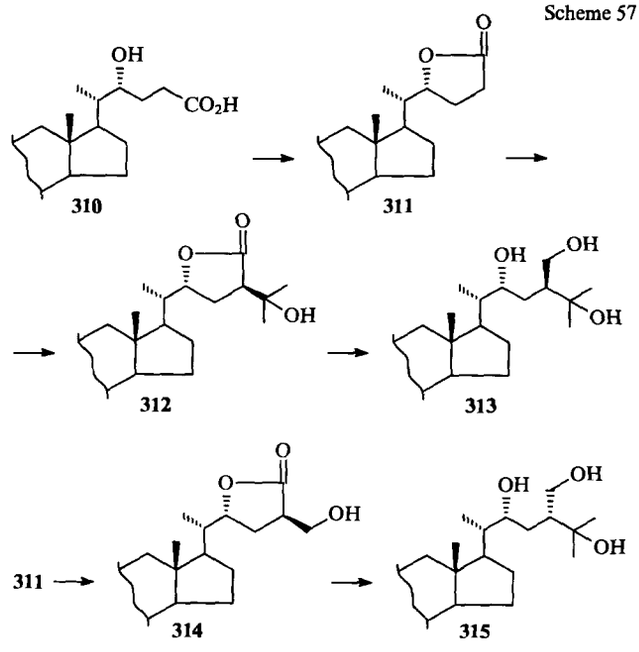
Synthesis using furans has been applied also to the formation of the side chain of α-ecdysone.[116–118] After the dehydration on silica gel of the product of the addition of compound **299** to the ketone **80**, namely 2-lithio-5-methylfuran, the furan derivative **300**

Scheme 54

Scheme 55



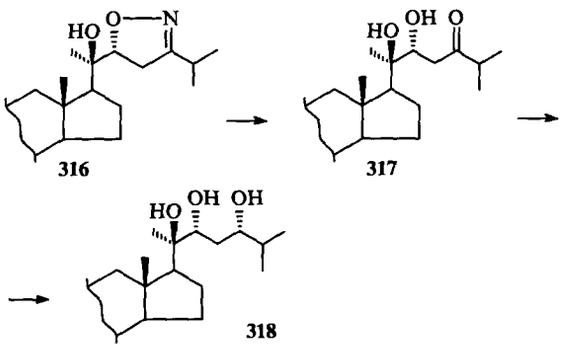
was obtained. The hydrogenation of its $\Delta^{20(21)}$-bond on Pd/C took place stereoselectively and afforded the product **301** without an admixture of the isomer. The furan ring in compound **301** was opened under acid conditions and the resulting diketone **302** was alkylated with methyllithium. The only product of this reaction was the ketol **303**, which was subjected to hydride reduction. As already pointed out, this process takes place with the preferential formation of the (22*S*)-isomer, which is uncharacteristic of the side chain of ecdysones. The best result was achieved using zinc tetrahydroborate in ether as the reductant.[116,117] The ratio of the (22*S*)- and (22*R*)-isomers was 2 : 1 (Scheme 56).



An increase in the yield of the (22*R*)-isomer was achieved by altering the strategy for establishing the chirality of C(22).[118] The furan **306**, obtained by the same mechanism as compounds **301**, was reduced over a rhodium-aluminium catalyst and the reduction product **307** was oxidised with ruthenium oxide. This resulted in the formation of a 1 : 1 mixture of the butenolides **308** and **309**. Grignard reaction with methylmagnesium bromide afforded the diols **304** and **305**.

An elegant method for the monitoring of the stereochemistry of the products formed via the steroid γ-lactones has been proposed[119] in order to establish the stereochemistry of depresosterol. The lactone **311**, obtained from the acid **310**, was enolised by treatment with lithium diisopropylamide and acetone was added, which led to the hydroxylactone **312**. This was converted, after reduction with $LiAlH_4$, into compound **313**, the latter proving to be the 24-stereoisomer of the natural steroid. Since the inversion of the C(24)-centre in the hydroxylactone **312** is impossible, the substituents were introduced at C(28) starting from the lactone **311**. The lactone enolate was treated with gaseous formaldehyde, which led to the hydroxylactone **314**, and the alkylation of the latter with methyllithium afforded the alcohol **315**, isomeric with respect to C(24), which is identical with the natural alcohol (Scheme 57).

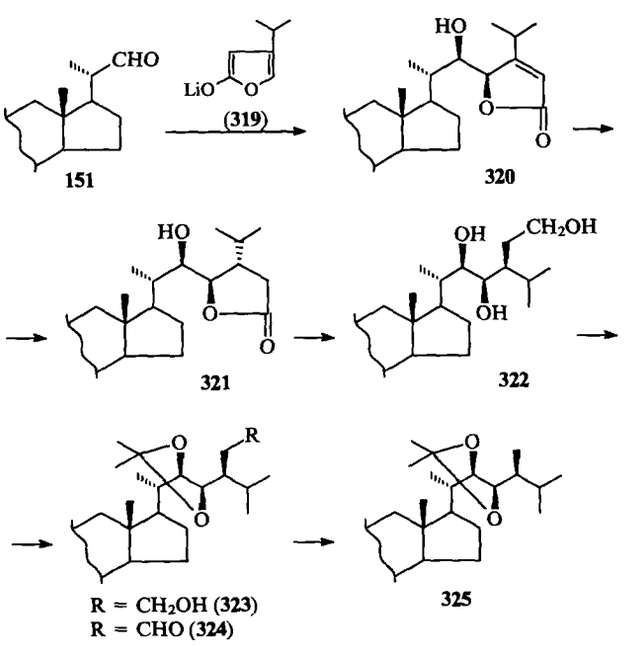
Scheme 56



Scheme 57

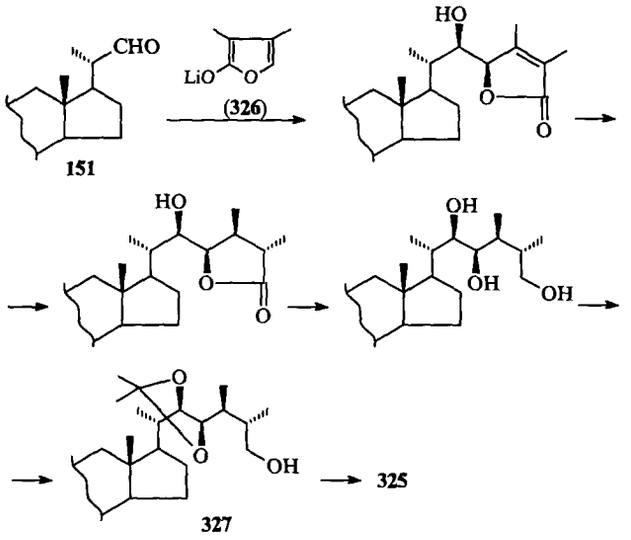
A procedure using the synthetic possibilities of isoxazolines has been proposed recently for the construction of the side chain in ecdysteroids. Thus the reductive cleavage of the isoxazoline **316** on Raney nickel in the presence of an inorganic acid results in the formation of the β-ketol **317**. The reduction of its carbonyl group with sodium tetrahydroborate in alcohol led to the formation of two alcohols isomeric with respect to C(24). The side chain of the

(24*S*)-epimer **318** corresponds to that of the side chain of the phytoecdysones ponasterone C and pterosterone (Scheme 58).[120,121]



Scheme 58

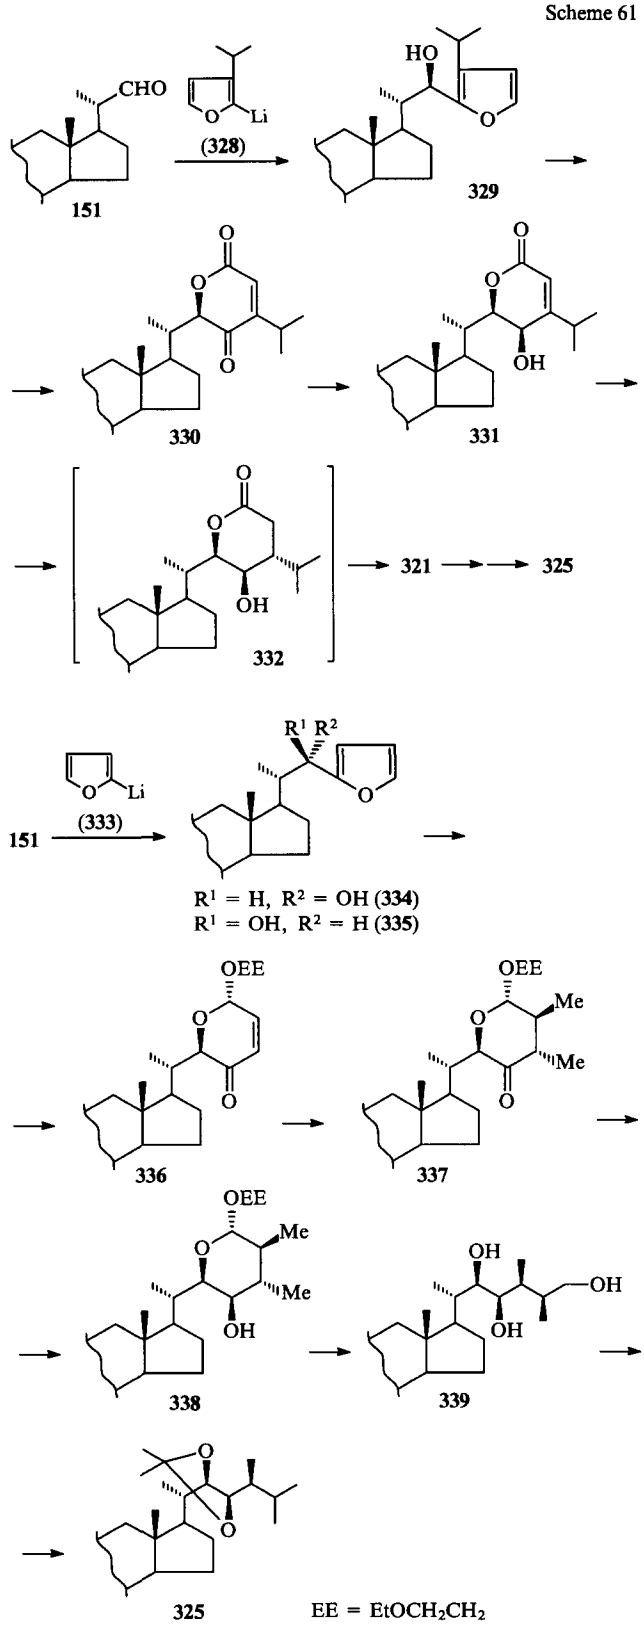
The isolation in 1979 of brassinolide—the first phytohormone having a steroid structure—initiated a multiplicity of studies devoted to its partial chemical synthesis. Heterocyclic intermediates have been used[95,122–127] for the selective formation of the side chain in this compound. As in the case of ecdysones, syntheses involving furan derivatives have come to be most widely used.



Having selected the aldehyde **151** as the starting material for the synthesis of side chains, it is necessary to form three chiral centres at C(22), C(23), and C(24). The use of furan derivatives[122–125] makes it possible to introduce the required functional groups in these positions, maintaining a high stereoselectivity. Thus the addition of the lithium enolate **319** at −78 °C to the aldehyde and treatment of the reaction mixture at this temperature (kinetic conditions) with dilute hydrochloric acid led to the formation of the butenolide **320** with the (22*R*, 23*R*)-configuration in 65% yield.[122] When the reaction mixture was treated at 0 °C, the main product was the (22*R*, 22*S*)-isomer, i.e. the thermodynamically more stable product is formed at a higher temperature (Scheme 59).

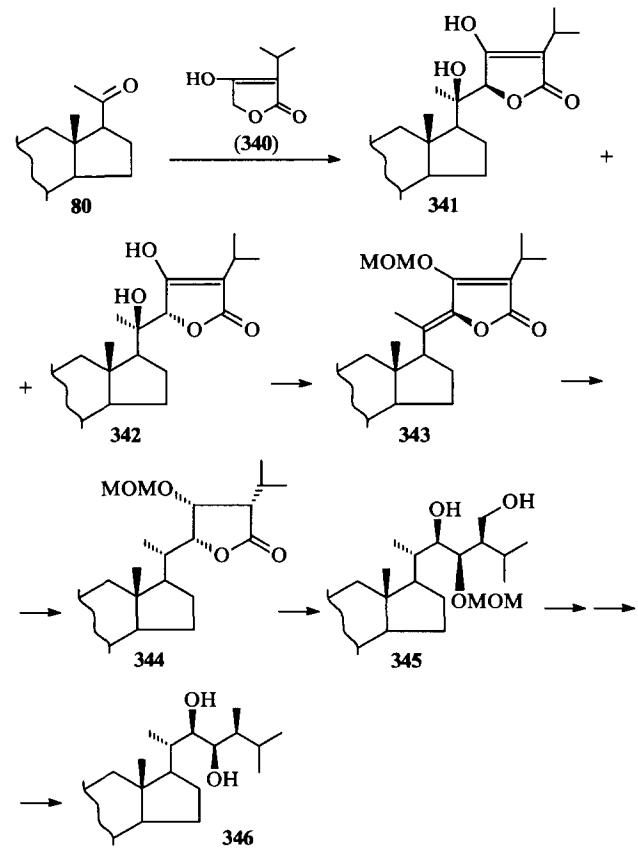
Scheme 59

Hydrogenation of the lactone **320** on platinum afforded a mixture of isomers with respect to C(24) in proportions of 78 : 22 in a quantitative yield. Since the constant for the spin–spin coupling of the protons of C(23) and C(24) in the main isomer **321** was smaller, the (24*S*)-configuration was attributed to the latter. After the reduction of the lactone **321** with $LiAlH_4$, the triol **322** was obtained and its refluxing with 2,2-dimethoxypropane in the presence of pyridinium toluene-*p*-sulfonate led to the formation of the acetonide **323** and the mixed acetal at C(29). The crude product was then refluxed in methanol, which afforded only the acetal **323** in 92% yield. The latter was oxidised with pyridinium chlorochromate and the resulting aldehyde **324** was decarbonylated with tris(triphenylphosphine)rhodium chloride. As a result of these transformations, the (24*S*)-methyl derivative **325** was obtained from the aldehyde **151** in an overall yield of 32%. A shorter synthesis of the side chain of brassinolide is possible when the lithium derivative **326** is used: a similar chain of transformations afforded the acetonide **327**, the treatment of which with methanesulfonyl chloride in pyridine and subsequent reduction of the methanesulfonate with $LiAlH_4$ lead to compound **325** (Scheme 60).[122]



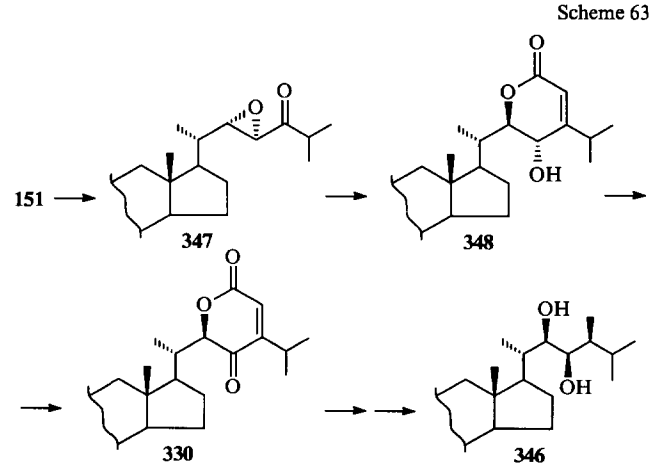
Scheme 60

The side chain of brassinolide was also formed by alkylating the aldehyde **151** with the lithiofurans **328** and **333**.[123,124] In the former cases, alkylation afforded 81% of the furylsteroid **329**, the successive oxidation of which the *m*-chloroperbenzoic acid and pyridinium chlorochromate led to the ketolactone **330**. The ketone functional group in compound **330** was reduced with sodium tetrahydroborate, which afforded exclusively the hydroxylactone **331**. Finally, its hydrogenation on PtO_2 and isomerisation (0.5 M NaOH) of the primary product **332** to the thermodynamically more stable γ-lactone led to the formation of 72% of the lactone **321** and 25% of its (24*R*)-isomer.[123] The addition of the furan **333** was less selective (**334** : **335** = 3 : 7), but the isomer **334** was converted into compound **335** by oxidising it with pyridinium chlorochromate and subsequently reducing the 22-ketone. As in the previous cases, the oxidation of the α-hydroxyfuran with *N*-bromosuccinimide led to a mixture of lactols, which were converted into ethoxyethyl ethers and separated. The ratio of the main product **336** to its 26-isomer was 3 : 1. Subsequently the ether **336** was subjected to coupled alkylation with lithium dimethylcuprate and methyl iodide. These reactions proceeded smoothly and it was assumed that the addition occurred on the opposite side of the plane of the ring in relation to the neighbouring group. The reduction of the carbonyl group of the dimethyl derivative **337** leads to the exclusive formation of the alcohol **338**. Hydrolysis of the ether group (10% HCl) and treatment with $LiAlH_4$ afforded the triol **339**, the subsequent transformations of which into compound **325** were described above (Scheme 61).[124]



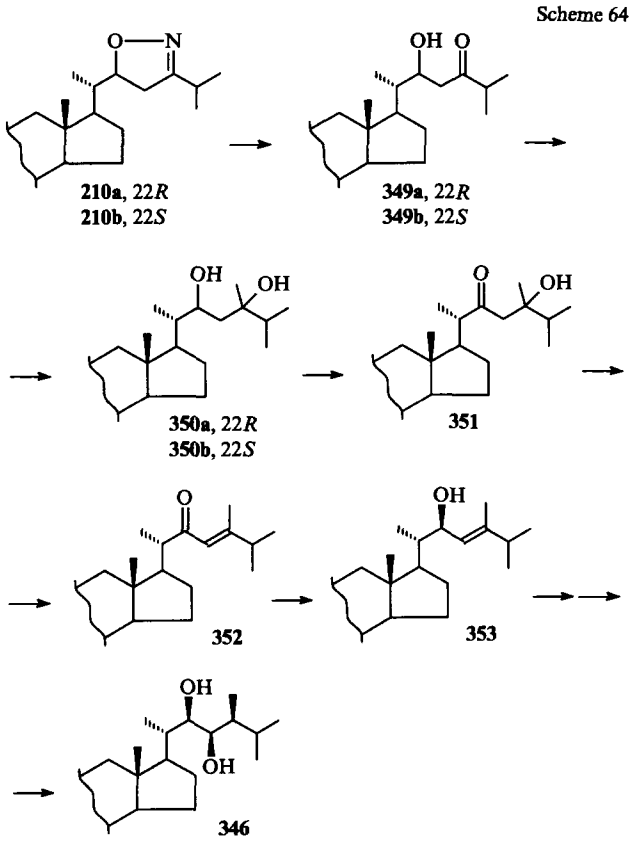
Kametani's group[125] were able to achieve the stereocontrolled formation of four chiral centres at once in the side chain of brassinolide. Alkylation of the ketone **80** with a fourfold excess

Scheme 61



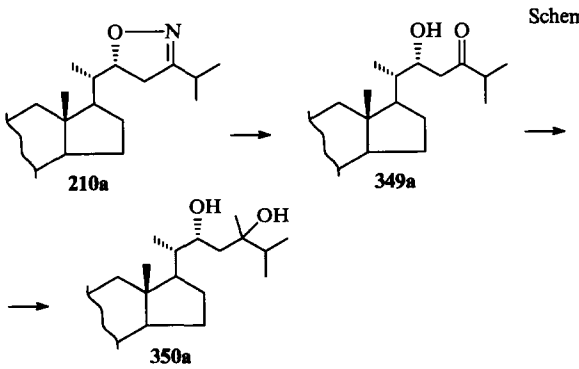
of the butenolide dianion **340** afforded a 9:91 mixture of the diastereoisomers **341** and **342** (84%), the enolic hydroxy-groups of which were protected by forming methoxymethyl ethers. The removal of the tertiary hydroxy-group of the MOM ether of the isomer **342** (via the formation of the trifluoroacetate) and hydrogenation over a rhodium catalyst of the (*Z*)-isomer **343** formed preferentially afforded the sole product **344** with the required stereochemical configuration of all four chiral centres in the side chain. After the reduction of the lactone **344** with $LiAlH_4$ to the alcohol **345**, the primary hydroxy-group of the latter was converted into the methanesulfonate and reduced, which led to the side chain of the brassinolide **346** (Scheme 62).

Scheme 62



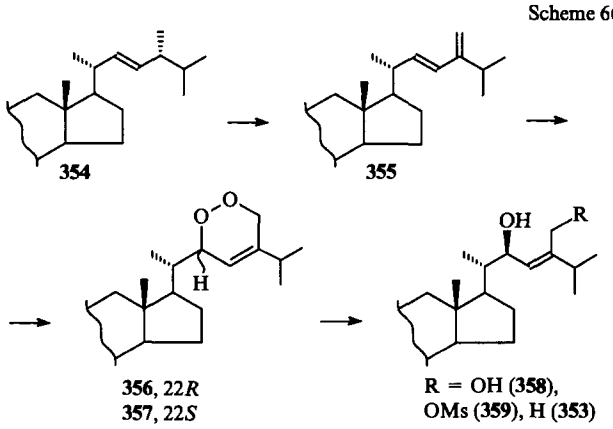
A somewhat different approach to increasing the length of the side chain of brassinolide, leading to common heterocyclic intermediates, has been developed by Chinese workers.[126] The aldehyde **151** was converted into the epoxyketone **347** by the method proposed in the synthesis of deoxyantheridiol.[79] The Wittig–Horner reaction of the epoxyketone with methoxycarbonylmethylphosphonate and subsequent lactonisation of the (*Z*)-isomer under acid conditions [occurring with inversion of the configuration at C(22)] ensured the formation of the hydroxylactone **348**. The oxidation of the hydroxy-group of this compound with pyridinium chlorochromate afforded the known intermediate **330**, the subsequent transformations of which lead to the side chain of brassinolide (Scheme 63).

Scheme 63



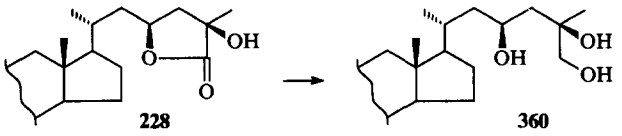
The growth of the side chain of brassinolide was achieved also by using isoxazoline intermediates.[95] Thus cleavage of the isoxazolines **210a, b** in the presence of acid on Raney nickel, the subsequent alkylation of the β-ketols **349** with methyllithium, oxidation of the resulting diols **350** by the Jones reagent, and finally dehydration of the tertiary alcohols **351** by thionyl chloride in pyridine led to the formation of the steroid 23-en-22-one **352**. Reduction of the eneketone **352** with diisobutylaluminium hydride leads[95] to the allyl alcohol **353** with a high stereoselectivity. The subsequent formation of the side chain of brassinolide can be readily achieved by Siddall's method (Scheme 64).[127]

Scheme 64



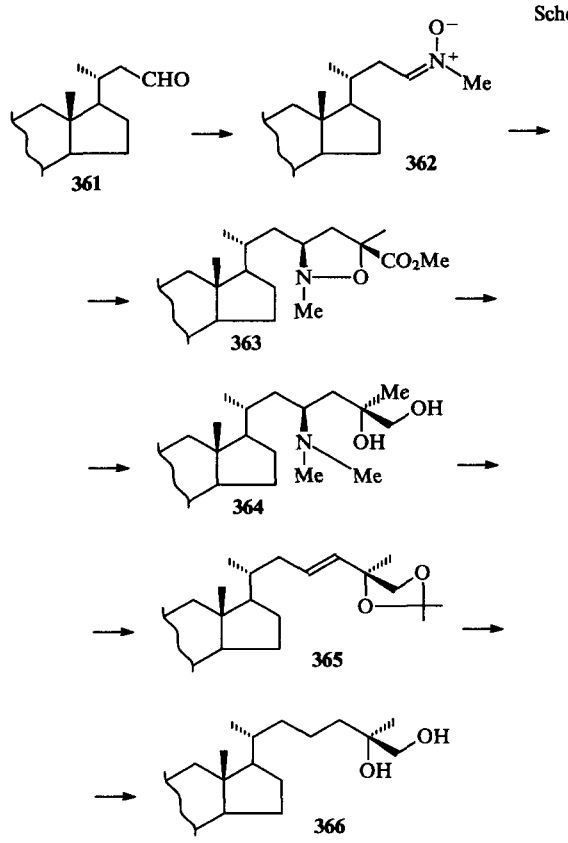
It is noteworthy that,using the (22*R*)-isoxazoline **210a**, it is possible to achieve, by means of a similar scheme, the formation of the side chain of the sapogenin isolated from the soft coral *Asterospicularia randalli* (Scheme 65).[128]

Scheme 65



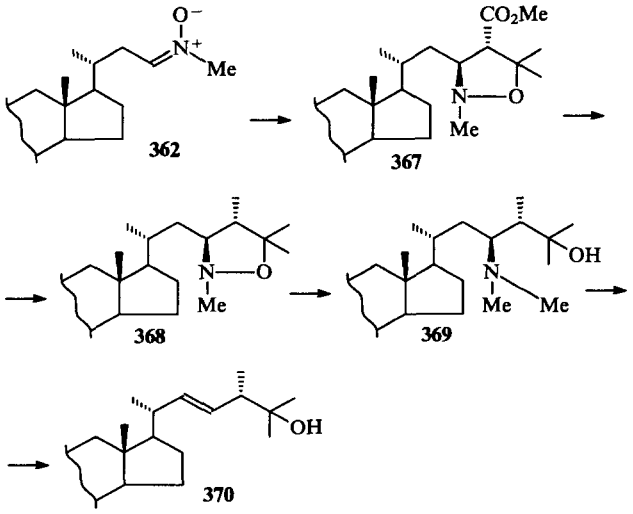
The use of heterocyclic derivatives[129] made it possible for the first time to transform the side chain ergosterol into the alcohol **353** (the intermediate in many syntheses of brassinolide and dolicholide[127]) without its cleavage. Thus the olefin **354** was converted via a bromination–dehydrobromination reaction into the diene **355**, the oxidation of which with molecular oxygen in pyridine under intense illumination in the presence of a sensitiser led to the chromatographically separatable mixture of the epidioxides **356** and **357** (in proportions of 7 : 3). The (22*R*)-isomer was reduced on the Lindlar catalyst to the diol **358**, the primary hydroxy-group of which was removed by reducing its methanesulfonate **359** with $LiAlH_4$. Analogous transformations of the epidioxide **357** led to the (22*S*)-isomer of the alcohol **353** (Scheme 66).

Scheme 66



Heterocyclic intermediates have been used in a number of studies[103,130] of the vitamin D_3 metabolites, undertaken to achieve stereocontrol in the formation of the side chain. In particular, in the synthesis 23,25,26-trihydroxy-vitamin D_3 **360**, the intermediate of this kind was the lactone **228** (calciferol-lactone), the reduction of which with $LiAlH_4$ afforded the required product (Scheme 67).

Scheme 67



Uskokovic and coworkers[131–133] developed a fairly effective stereoselective method of synthesis of vitamin D_3[131] and D_2[132,133] metabolites via the cycloaddition of steroid nitrones to olefins. The synthesis of the side chain of 1α-(25*S*),26-trihydroxy-cholecalciferol **362**, a new vitamin D_3 metabolite isolated in 1981, has been described.[131] The nitrone **366** was obtained from the aldehyde **361** and *N*-methylhydroxylamine in the form of one (*Z*)-isomer, the structure of which was determined by X-ray diffraction. The cycloaddition of methylacrylate to this compound afforded a mixture of four isoxazolidines diastereoisomeric with respect to C(23) and C(25). The existence of thermal equilibrium between them makes it possible to monitor the stereochemical configuration of the product. For this purpose, after the separation of the required (*S,S*)-isomer, the other three were heated at 140 °C in xylene in the presence of an excess of methyl methacrylate. This again led to four isomers. By several repetitions of the process, the required isomer **363** was obtained from compound **362** in 71% yield. The isoxazolidine **363** was then treated with methyl iodide and the product was reduced with $LiAlH_4$, which afforded 86% of the aminodiol **364**. The aminodiol was converted into the acetonide and the amino-group was eliminated by the Hofmann method. This resulted in the formation of the olefin **365**, the hydrogenation of which over palladium on charcoal and hydrolysis led to the diol **366** (Scheme 68).

Scheme 68

The same approach has been used[132, 133] for the synthesis of a vitamin D_2 metabolite — 1α,25-dihydroxyergocalciferol **370**. The addition of 3,3-dimethylacrylate to the nitrone **362** in boiling xylene led to the formation (in contrast to the previous case) of only two of the four possible diastereoisomers (*RR* and *SS*) in proportions of 1 : 1. The enrichment in the required (*SS*)-isomer **367** was carried out by a procedure similar to that described above. Next the carboxymethyl group in compound **367** was reduced to the hydroxy-group and the latter was removed via the toluene-*p*-sulfonate, affording the isoxazolidine **368**. Its alkylation at the nitrogen atom and subsequent cleavage of the ring led to the aminoalcohol **369**. Its deamination ensured the formation of the *trans*-Δ^{22}-steroid **370** (Scheme 69).

Abstract. The available information about the mechanisms of the interaction of pesticides having different chemical structures with the lipid bilayer in cell membranes is presented. It is shown that, depending on the degree of lipophilicity, the molecular dipole moment, and certain other characteristics of the pesticide compound, its interaction with the lipid bilayer generally takes place via one of the three main mechanisms involving the incorporation of the pesticide molecules in the hydrocarbon region within the bilayer, the adsorption of these molecules in the zone of the polar membrane phospholipids, or the incorporation of the amphiphilic pesticide compounds in both the non-polar and polar regions of the membrane. The bibliography includes 109 references.

I. Introduction

Various mechanisms of the action of pesticidal preparations on organisms are known at the present time. The principal site acted upon by pesticides is the cell membrane system. Pesticides can influence both the structure and the functions of membranes and are capable of damaging membrane systems directly (as a result of the physicochemical interaction with them) or indirectly (as a result of the physicochemical interaction with them) or indirectly (as a result of the blocking reactions involving the biosynthesis of specific membrane components).[1–5]

The direct interaction of pesticides with biological membranes is achieved as a result of the binding of the preparations to some type of component of the membranes, usually to the membrane proteins or lipids. The mechanisms of such interaction of pesticides with the lipid bilayer in cell membranes are considered in the present review.

The structural organisation and the principal functions of the lipid bilayer in cell membranes are fundamentally the same regardless of the purpose of the membranes. Therefore the nature of the direct interaction of pesticides with the lipid matrix of the membranes is as a rule independent of the particular membrane (plasma, chloroplast, mitochondrial, or some other membrane) with which the preparation interacts and is determined exclusively by the physicochemical properties as well as the overall types of organisation of lipids in the membranes.

Among the wide variety of the physicochemical properties of a pesticidal preparation, the nature of its interaction with the lipid bilayer is influenced decisively by its lipophilicity, which is usually characterised in terms of the partition coefficient of the pesticide between 1-octanol and water (K_{ow}). According to the value of K_{ow}, it is possible to differentiate three groups of pesticides — lipophilic, amphiphilic, and hydrophilic (Table 1).

The preparations of each group usually interact with the lipid bilayer via their own mechanism, which differs from the mechanisms of the interaction of the preparations of the other groups with the bilayer.

Table 1. The coefficients K_{ow} for certain pesticides.

Preparation	K_{ow}	Ref.

The nature of the interaction of the pesticide with the lipid matrix of the membranes depends not only on the lipophilicity of the preparation but also on its molecular properties, in particular on the molecular dipole moment, the size and shape of the molecule, and other steric factors.

II. Incorporation of pesticide molecules into the hydrocarbon region of bilayer lipid membranes

Most of the pesticide preparations are characterised by a high lipophilicity. Therefore the commonest way in which they interact with the lipids of cell membranes involves the incorporation of pesticide molecules into the hydrocarbon region of the lipid bilayer. It has been established that many organochlorine, organophosphorus, and pyrethroid insecticides, herbicides (derivatives of phenylureas), imidazole fungicides, and certain other compounds are incorporated into the non-polar region of the bilayer lipid membranes (BLM) (Table 2).

One of the most thoroughly investigated lipophilic pesticides is the organochlorine insecticide DDT [1,1,1-trichloro-2,2-bis-(*p*-chlorophenyl)ethane]. DDT is known to be capable of accumulating in living organisms for a long time. The principal objects in which insecticides accumulate are the lipid systems of the organism, in the first place the lipid-rich cell membranes.[42-44] This has been convincingly demonstrated by experiments both *in vivo* and *in vitro*. Studies on models of lipid systems have confirmed the hypothesis that DDT accumulates in the lipid matrix of cell membranes.[11, 15, 16, 45, 46]

Experimental determination of the localisation of DDT in biological membranes have shown that the preparation is present in the inner hydrophobic component of the lipid bilayer. Both DDT and its analogues DDE [1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene] and DDA [bis(*p*-chlorophenyl)acetic acid] give rise to distinct proton magnetic resonance (^{1}H NMR) spectra in CCl_4. They also have a distinct ^{1}H NMR spectrum in a suspension of lecithin liposomes in D_2O. On the other hand, in the absence of liposomes, the peak corresponding to the protons of the aromatic ring of chlorohydrocarbons in an aqueous medium was not observed.[17] The most distinct spectrum has been observed for DDA. The appearance in the presence of liposomes of signals in the high-resolution spectra, which strongly resemble the spectrum in CCl_4, shows that DDT and its analogues are incorporated into the lipid bilayer in such a way that the aromatic rings of their molecules are in a medium resembling CCl_4. Such a medium is evidently the liquid crystal phase within the bilayer. On the other hand, some inconsistency between the chemical shifts of the ring protons in CCl_4 and in a suspension of liposomes is evidence of the non-identity of the local micro-environment of the aromatic ring of the DDT molecules in the lipid and in the organic solvent.

Table 2. Examples of the incorporation of pesticidal compounds into various regions of the lipid bilayer.

Region of bilayer	Preparation	Ref.
Hydrocarbon region	DDT	15, 16, 11, 17
	Methoxychlor	16, 11
	Lindane	18, 19, 20, 11
	Parathion	21
	Malathion	22
	Diurone	23
	Permethrin	24
Region of polar groups	2,4-D (undissociated form)	25
	PCP (dissociated form)	26
	Triforine	27, 28
	Phytone	29
Polar and non-polar regions	Dodine	30-32
	Glyodin	33, 34
	Benzylalkylammonium chlorides	35, 36, 37, 38, 39, 40, 41

The incorporation of DDT into phosphatidylcholine liposomes containing carbazole-labelled phospholipids — β-[11-(9-carbazolyl)undecanoyl]-L-α-phosphatidylcholine and β-[3-(9-carbazolyl)propionyl]-L-α-phosphatidylcholine — as fluorescent probes led to the intense quenching of the fluorescence of the probes.[11] DDT and certain other chlorinated hydrocarbons are known to quench effectively the fluorescence of *N*-ethylcarbazole in homogeneous solutions.[20] Therefore the quenching, observed in liposomes, of the fluorescence of phosphatidylcholines containing a fluorescent carbazole fragment in the aliphatic acid chain must be interpreted as the result of the incorporation of the molecules of the quenching agent into the region of the hydrocarbon chains of the membrane lipids. Methoxychlor and DDE interact similarly with the lipid bilayer.[11, 47]

Yet another indication of the localisation of DDT in the hydrophobic part of the lipid bilayer is the decrease in the polarisation of the fluorescence of 12-(9-anthroyloxy)palimitic acid incorporated into lecithin liposomes in the presence of the insecticide, because in this case too the fluorophor is in the region of the hydrocarbon chains.[48]

There exist different views concerning the possible location of DDT within the hydrocarbon chains. For example, the displacement of DDT by cholesterol from the membranes of liposomes is regarded as an argument in support of the disposition of the extended DDT molecules alongside the planar cholesterol molecules.[15] Experiments with lecithin monolayers without cholesterol have shown that, for a 1 : 1 DDT : lecithin molar ratio, the minimum area occupied by the lecithin molecule in the monolayer increases from 50.8 Å (in the absence of the insecticide) to 56.3 Å, which is exactly equal to the minimum cross-sectional area of the DDT molecule.[49] This result permits the conclusion that DDT may form 1 : 1 complexes with lecithin as a result of the deposition of DDT molecules layer by layer on the surface of the lipid monolayer. One cannot rule out the possibility that the DDT molecules in the bilayer membrane can also be arranged in the vicinity of the ends of the aliphatic acid chains of the membrane lipids and occupy the space within the centre of the bilayer.

Finally, experiments designed to investigate the interaction of DDT with lecithin in CCl_4 by ^{1}H NMR spectroscopy have shown that lecithin causes an appreciable shift and broadening of the signal corresponding to the proton of the diphenylmethyl group of DDT and the latter in its turn appreciably alters the positions of the proton resonances of the choline group of lecithin.[50] These data are interpreted as an indication of the binding of the proton of the diphenylmethyl group of DDT (the acidity of which is due to the presence in the insecticide molecule of five chlorine atoms) to the electronegative oxygen atom of the phosphate group of lecithin. The formation of similar complexes with lecithin has been observed also in the study of analogues of DDT such as methoxychlor, 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane, and DDA.[51]

The possibility of the formation of complexes of this kind by DDT owing to the presence of the highly polar H-C-C-Cl group has been confirmed in experiments with a series of inorganic compounds,[52, 53] but the significance of these structures in biochemical processes remains controversial. Apparently, the formation of complexes in organic solvents is consistent with the ability of the DDT molecules to assume an arrangement in membranes such that the proton of the diphenylmethyl group is close to the phosphate group of the lecithin molecule, while the benzene rings of the insecticide molecule are 'immersed' in the hydrocarbon region of the bilayer. Such location of the insecticide molecules near the polar groups of the lipid molecules, while most of the insecticide molecule is still in the region of hydrocarbon chains, appears extremely likely for the more polar compounds of the DDT series, for example for dicofol.[54, 55]

A similar mechanism of the interaction with lecithin based on ^{1}H NMR data has been proposed also for the vinyl organophosphorus insecticides dichlorofos and azodrin.[56] It has been suggested tentatively that the insecticide–dipalmitoyllecithin complex is formed as a result of the interaction of the acid proton of the vinyl group of the insecticide molecule with the oxygen anion of the phospholipid molecule. However, as in the case of DDT, the toxicological importance of this interaction is not clear.

However, evidently the ability to form hydrophobic complexes with lecithin is characteristic also of imidazole antibiotics — miconazole and chlotrimazole, which are effective fungicides.[57] When unsaturated lecithins are added to a suspension of the fungi *Candida albicans*, which are sensitive to imidazole preparations, the fungicidal effect of both antibiotics virtually disappears. Saturated lecithins do not exhibit a similar protective action. Furthermore, it has been reported that these imidazole fungicides interact preferentially with liposomes consisting of unsaturated phospholipids.[58] These data as well as analysis of the UV spectra of the fungicides in the presence of lecithin indicate the possibility of the formation of miconazole and chlotrimazole complexes with unsaturated lecithin. The inter-action, responsible for the formation of complexes of this type probably leads to the incorporation of the molecules of the above antibiotics into the hydrophobic component of the lipid bilayer of the fungal membranes with a high content of unsaturated phospholipids.[57, 59]

The conclusion that molecules of imidazole fungicides are incorporated into the hydrocarbon component of the membrane has been confirmed by the results of conformational analysis.[60] It was observed that the molecules of the two dichlorophenyl groups of miconazole and the piperazine fragment of the molecule of kitaconazole are localised in the hydrophobic component of the lipid bilayer. On the other hand, part of the fungicide molecule (the imidazole ring of miconazole and the dichlorophenyl group of kitaconazole) are located in the region of the polar groups of the phospholipid molecules, which makes the pattern in the interaction of imidazoles with the lipid bilayer similar to the mechanism of incorporation of fungicidal surfactants into the lipid component of the membranes. The interaction of miconazole with the polar region of the cell membranes has been confirmed by the dependence of the effectiveness of its action on the permeability of lecithin liposomes and their surface charge[58] and also by the protective effect of magnesium ions when the plasma membranes of the fungi *Candida albicans* are damaged by high concentrations of miconazole. It may be that the protective effect is a consequence of the competition between Mg^{2+} and miconazole for common binding sites on the membrane.[61]

Various isomers of hexachlorocyclohexane (HCCH), namely the α-, β-, γ-, (lindane), and δ-isomers, are readily incorporated into the hydrocarbon component of cell membranes. They all effectively quench the fluorescence of carbazole-labelled phospholipids incorporated into the aliphatic acid chain liposomes.[11, 19, 20] Fluorescence data make it possible to estimate the diffusion coefficient of the quenching agent in the membranes of the liposomes, which, for example, in the case of lindane, is on average 10^{-6} cm^2 s^{-1}.[19] Comparison of this coefficient with the diffusion coefficients of other molecules in the hydrophobic part of the membranes (about 5×10^{-8} cm^2 s^{-1} for phospholipids, 10^{-7} cm^2 s^{-1} for pyrene, and 8×10^{-6} cm^2 s^{-1} for oxygen) confirms that lindane is localised in the hydrocarbon part of the lipid bilayer. The diffusion coefficient of the insecticide corresponds to an intermediate molecular size (between the molecular sizes of pyrene and oxygen). Experiments designed to investigate the incorporation of ^{14}C-labelled lindane into the lecithin liposomes have shown that the insecticide molecule is located within the lipid bilayer between the hydrocarbon chains of the phospholipids.[62]

Diurone, a well known inhibitor of the photosynthetic electron transport, is also localised in the hydrophobic component of the membranes of phospholipid liposomes.[23]

The study of the ^{1}H NMR spectra made it possible to determine the disposition of the phosphonothioate insecticide derived from bis(5-chloro-2-hydroxyphenyl)methane (GA-41).[63] The decrease in the spin–lattice relaxation time of the protons of the methyl group linked to the phosphorus atom of the insecticide molecule when the insecticide is transferred from an aqueous solution to a suspension of lecithin liposomes indicates the incorporation of GA-41 into the lipid bilayer. The absence of an effect by the insecticide on the spin–lattice relaxation time of the protons of the choline group of lecithin permits the conclusion that GA-41 is located in the region of the hydrocarbon chains of the membrane lipids. Certain insecticides (permethrin, cypermethrin, fenpropathrin, and fluvalinate) decrease the fluorescence and the lifetime of the excited state of 1,6-diphenylhexatriene incorporated into the liposomes comprising dipalmitoylphosphatidylcholine.[24] The 1,6-diphenylhexatriene molecule has an extended shape and is in all probability located within the bilayer parallel to the hydrocarbon chains of the lipids. The reason for the observed effects is evidently the disturbance of the packing of the membrane lipids in the presence of pyrethroids and also the quenching of the fluorescence of the probe as a result of the collisions with the insecticide molecules. One can therefore postulate that pyrethroids are localised in the hydrocarbon part of the membranes next to the molecules of 1,6-diphenylhexatriene. The molecules of certain herbicidal inhibitors — uncoupling agents, which also affect the anisotropy of the fluorescence of 1,6-diphenylhexatriene are probably also at least partly located in the same region of the membranes.[3, 64, 65]

Apart from the results of experiments specially carried out in order to elucidate the positions of the pesticide molecules in the lipid bilayer, there exist a series of experimental data indicating indirectly the incorporation of pesticides into the hydrophobic region of cell membranes. Thus the pronounced dependence of the partition coefficient of the pesticide between the membrane medium and water (K_{mw}) on the fluidity of the membranes, observed for parathion and malathion as well as DDT and various isomers of HCCH, indicates the incorporation of the preparations into the inner hydrophobic component of the cell membranes.[16, 18, 21, 22, 62]

The decrease in K_{mw} with decrease in the fluidity of the membrane lipids, observed in experiments with organophosphorus and organochlorine pesticides, is in all probability a reflection of the more general dependence of the degree of incorporation of lipophilic pesticidal preparations into the lipid bilayer on its fluidity. This is expressed, in particular, by the dependence of K_{mw} on parameters influencing the fluidity of membranes such as temperature, length and degree of unsaturation of aliphatic acid chains of the membrane phospholipids, and the concentration of cholesterol in the membrane. Table 3 presents typical values of K_{mw} for certain lipophilic pesticides.

A change in temperature has different effects on the incorporation of pesticides into membranes made up of phospholipids in the liquid crystal and gel states. In the liposomes comprising egg lecithin, which has largely unsaturated aliphatic acid chains and undergoes a phase transition in the range from −15 to −5 °C,[66, 67] an increase in temperature from 10 to 40 °C leads to a monotonic decrease in the partition coefficient of the ^{14}C-labelled DDT,[15] lindane,[62] parathion,[21] and malathion[22] between the membrane medium and water. Experiments involving the use of fluorescent probes have shown that, with increase in temperature in the same range, there is a significant decrease also in the partition coefficient of lindane[18,20] and one of its analogues (the α-isomer of HCCH[18]) between dioleoyl-phosphatidylcholine liposomes and water (the gel–liquid crystal phase transition temperature for dioleoylphosphatidylcholine is −22 °C).[68] A similar decrease in K_{mw} on

Table 3. The coefficients K_{mw} for certain lipophilic compounds and their analogues.

Preparation	Membrane lipid[a]	T/ °C	K_{mw}	Ref.

	DPPC	41	244	22

[a] The following abbreviations have been adopted: EL = egg lecithin, DPPC = dipalmitoylphosphatidylcholine, PM = plasma membranes of the mouse liver mitochondria.

raising the temperature has been observed for phospholipids with saturated aliphatic acid chains but only above their phase transition temperatures, where these lipids also exist in the liquid crystal state. Thus the incorporation of all the pesticides mentioned into dimyristoyl-, dipalmitoyl-, and distearoyl-phosphatidylcholine liposomes diminishes on raising the temperature in the region above the phase transition temperatures of the lipids.[15,21,22,62]

On the other hand, the incorporation of pesticidal preparations into the hydrocarbon component of membranes comprising phospholipids in the 'solid' state increases appreciably on raising the temperature. This effect has been observed in dimyristoyl-, dipalmitoyl-, and distearoyl-phosphatidylcholine liposomes for DDT, lindane, parathion, and malathion.[15, 18, 21, 22, 62]

The temperature variation of K_{mw} at temperatures both above and below the phase transition temperatures of the membrane lipids shows that the maximum value of K_{mw} should be observed directly in the phase transition. Experiments with synthetic phospholipid bilayers have clearly confirmed this conclusion.[15, 18, 21, 22, 62] The attainment of the maximum value of K_{mw} at the phase transition temperature of the membrane lipid is evidently associated with the fact that the incorporation of pesticides into the lipid bilayer takes place most effectively at the interface between the two phases coexisting in the membrane during the phase transition.

Comparison of the values of K_{mw} at temperatures equidistant from the phase transition temperature shows that pesticidal preparations are usually incorporated more readily into the more 'liquid' membranes. In other words, an increase in the fluidity of the membranes usually promotes the incorporation of pesticides into them. This effect has been clearly noted in experiments designed to investigate the incorporation of parathion, malathion, and lindane into dipalmitoyl- and distearoyl-phosphatidylcholine liposomes[21,22,62] and of DDT, 2-(2,4-dichlorophenyl)-1-chloro-2-(4-chlorophenyl)ethylene (DDE), and methoxychlor into dimyristoyl- and dipalmitoyl-phosphatidylcholine liposomes.[16] The preferential incorporation of pesticide molecules into bilayers with a higher fluidity makes it possible to explain the positive value of K_{mw} at temperatures below the phase transition temperature of the membrane lipid by the fact that, on raising the temperature in this region, there is an increase in the number of liquid crystal domains in the 'solid' phase, which promotes an enhanced incorporation of pesticides into the bilayer. On the other hand, the incorporation of certain insecticides into dimyristoyl-phosphatidylcholine liposomes takes place more effectively in the gel state of the membrane lipid. This serves as yet another confirmation of the fact that the incorporation of pesticides into lipid membranes is determined not only by the fluidity of the latter but also by other factors, in particular by the geometry of the molecules of the phospholipids and pesticides.

The facilitation of the incorporation of pesticides into membranes with increase in the fluidity of the membrane lipids is manifested also by the fact that, for example, DDA is hardly incorporated, according to ^{1}H NMR data, into dimerystoyl-lecithin liposomes below the phase transition temperature of this lipid,[17] while experiments with mouse liver mitochondria have shown that the inhibition, observed in the presence of DDT, of the valinomycin-induced absorption of potassium by the mitochondria is independent of temperature in the range up to 20 °C, but increases sharply on further heating of the suspension.[69] Furthermore, the insecticide increases the release of endogenic potassium from the mitochondria, although the effect is observed only at temperatures above 10 °C (the temperature corresponding to the phase transition of the mitochondrial lipids) and increases on raising the temperature.

Evidently this effect of DDT on the transport of potassium through the mitochondrial membranes is due to its incorporation into the membranes, which occurs much more effectively when the membranes are in the liquid crystal state. Finally, comparison of the ^{1}H NMR spectra of DDE obtained in D_2O in the presence of dipalmitoyl-lecithin at different temperatures permits the conclusion that DDE is also incorporated preferentially into the more 'liquid' part of the bilayer.[70]

Since the fluidity of the lipid membranes depends in many respects on the length of the hydrocarbon chains of the membrane lipids, it is natural to expect that the incorporation of pesticides into the lipid bilayer will also depend on this length. Indeed, experiments have shown that an increase in the length of the aliphatic chains of phosphatidylcholines in the range corresponding to 14–18 carbon atoms as a rule diminishes significantly the partition coefficients of insecticides between liposomes and an aqueous solution.[15,19,21,22,62] For example, in the case of DDT an increase in the length of the hydrocarbon chain by one methylene group is accompanied by a decrease in K_{mw} approximately by 50%.[15] The dependence of K_{mw} on the length of the hydrocarbon chain of phosphatidylcholines proves to be linear under these conditions.[15,22] As a result of such significant hindrance of the incorporation of pesticides into the membranes with increase in the length of the aliphatic acid chains of the membrane lipids, in mixtures of phospholipids having chains of different lengths the preparations may be distributed preferentially in the membrane domains consisting of lipids with shorter chains, as happens, for example, in the interaction of parathion with liposomes comprising a mixture of dimyristoyl- and distearoyl-phosphatidylcholines.[21]

The incorporation of pesticides into the hydrocarbon region in lipid membranes is greatly facilitated by the increase in the degree of unsaturation of the membrane phospholipids. Thus at 20 °C the transition from dipalmitoyllecithin to dioleoyllecithin liposomes increases K_{mw} for lindane by a factor of 2.7,[18] while K_{mw} for DDT increases by a factor of 6.3.[16] With increase in temperature, the promoting influence of the degree of unsaturation of the lipids on the incorporation of pesticides into the bilayer increases still further.[11] Furthermore, an increase in the degree of unsaturation of the membrane phospholipids of human erythrocytes, for example, by their preincubation with dioleoylphosphatidylcholine liposomes, greatly intensifies (by 60% after incubation for 4 h) the outflow of potassium from the erythrocytes induced by DDT.[71] This result can also serve as confirmation of the more effective incorporation of pesticides into membranes with an increased fluidity. Finally, the marked dependence of the fluidity of cell membranes on their cholesterol content is also reflected in the characteristic features of the incorporation of pesticides into the hydrocarbon component of the membrane. The increase in the cholesterol content from 0 to 50 mol% leads to almost complete elimination from the membranes of lecithin liposomes of lindane,[62] parathion,[21] and malathion[22] and appreciably reduces the content of DDT.[15]

The inclusion of cholesterol (20 mol%) in dipalmitoylphosphatidylcholine liposomes diminishes the partition coefficients of lindane in the membrane/water system from 3800 to 800.[59] Furthermore, the decrease in the cholesterol content in the erythrocyte membranes in the presence of DDT[71] is in all probability a consequence of the increased concentration of the insecticide in the membranes. Evidently, the cause of all the observed effects is that cholesterol displaces the insecticides from the membrane by occupying their place in the region of the aliphatic acid chains of the membrane lipids.

In the experiments designed to investigate the incorporation of pesticides into biological membranes, it has been observed that all the preparations investigated (parathion, lindane, malathion, DDT) are incorporated into cell membranes (and, incidentally, also into the liposomes comprising the total lipids of these membranes) much less effectively than into the membranes of the liposomes made up of the individual lipids.[15,21,22,62]

For all the preparations investigated, K_{mw} diminishes with increase in the content of cholesterol in membranes of different types (of the sarcoplasmic reticulum, mitochondria, microsomes, myelin, and erythrocytes). This confirms yet again the appreciable role of the fluidity of the lipid bilayer in the incorporation of pesticides into the membranes, but in this case this applies to biomembranes. However, when the dependence of K_{mw} on the cholesterol content in membranes is extrapolated, the total displacement of lindane, parathion, and malathion from the biomembranes occurs no longer for 50 mol% of cholesterol but at much higher concentrations of the latter. This result may indicate a definite role of the membrane proteins in the incorporation of insecticides into cell membranes, which consists in the facilitation of the entry of the molecules of the preparations into the membranes tentatively as a result of the formation of defects at the lipid/protein interfaces. On the other hand, the results of the determination of K_{mw} for certain organochlorine insecticides in various biological membranes with the aid of carbazole-labelled probes do not indicate any significant role of the membrane proteins in the incorporation of insecticides into the membranes,[47] so that the question of the influence of the proteins on this process still remains open.

III. Adsorption of pesticide molecules in the region of polar groups

The adsorption of pesticide molecules in the region of the polar groups of the membrane phospholipids is characteristic of the interaction of hydrophilic preparations and lipophilic compounds with the lipid bilayer.The molecules of hydrophilic substances are then distributed in the bilayer in a way designed to ensure the retention of the possibility of the interaction with the aqueous medium, while lipophilic molecules, which have a high dipole moment, are immersed in the lipid matrix somewhat deeper and much closer to the hydrocarbon chains of the phospholipids.

On the basis of a wide variety of experimental data, one may assume that individual phenoxyacetic and phenolic preparations as well as certain pesticides with different chemical structures are adsorbed in the region of the polar groups of membrane lipids (Table 2).

The commonest phenoxyacetic acid herbicide, namely 2,4-dichlorophenoxyacetic acid (the 2,4-D preparation) is effectively incorporated into the membranes only in the undissociated form, which is extremely lipophilic (Table 1). Experiments with lecithin BLM have shown that the undissociated form of the herbicide increases the rate of transport of lipophilic cations through the membrane and inhibits the transport of lipophilic anions, acting as a typical dipolar modifying agent.[25] Evidently the cause of the observed effect is that 2,4-D makes the potential within the bilayer more negative. In all probability, the herbicide molecules are adsorbed in the region of polar groups (closer to the hydrocarbon part of the membranes) in such a way that the vectors of their dipole moments are directed towards the aqueous medium, altering thereby the dipolar potential of the bilayer. The acid anions are probably adsorbed on the membrane surface itself.[72]

Such disposition of the 2,4-D molecules in the membranes is probably due to their interaction with the ammonium and/or phosphate groups of the polar part of the lecithin molecule. Evidence in support of such interaction comes from the sharp increase in the diffusion transport of 2,4-D from one aqueous phase to another via pentanol[73] and model lipid membranes formed on a millipore filter[74] in the presence of lecithin and also from the increase in the adsorption of 2,4-D by the parenchyma of the potato tubers under the influence of this lipid.[75] The influence of lecithin on the transport of the herbicide through lipid membranes increases with decrease in the pH of the medium, which may indicate a more effective interaction of the phospholipids with the undissociated form of 2,4-D.[74] Furthermore, the addition of lecithin to carbon tetrachloride in contact with an aqueous phase greatly diminishes the amount of 2,4-D present in the aqueous phase, which indicates a strong interaction of the latter with lecithin.[76,77] Tentatively, this interaction takes place via the formation of a hydrogen bond between the herbicide and the phosphate group of lecithin or, in the case of the dissociated form of 2,4-D, of an ionic bond with the ammonium group of the choline residue. Evidently, the carboxy-group of the 2,4-D molecule is located in the membrane close to the choline group of the lecithin molecule, while the benzene ring is immersed somewhat deeper in the bilayer.[74]

It may be that a similar mechanism of the binding to lecithin molecules operates in the incorporation of benzoic acid molecules into cell membranes, in particular those of 2,3,6-trichlorobenzoic acid when they are absorbed from solution by segments of the oat mesocotyls.[78] The carboxy-group of the acid molecule can interact with the nitrogen atom of the choline group of the phospholipid. One cannot rule out the possibility that these processes constitute the basis of the adsorption of 2-methyl-4-chloro-phenoxyacetic acid (the 2M-4C preparation) on plasma membranes observed in experiments with the leaves of various plants.[79]

Triforine and dinitro-*o*-cresol can be located, in all probability, like other lipophilic pesticidal compounds, in the region of the polar groups of the membrane phospholipids. Like 2,4-D, the systemic fungicide triforine increases the rate of transport through the lecithin BLM of lipophilic caitons, in the given instance the valinomycin-K^+ complexes, and diminishes the permeability of the membranes in the presence of the lipophilic tetraphenylborate anions.[80] Furthermore, the fungicide imparts to the BLM, formed in solution in KCl at physiological pH, a weak cationic selectivity.[28] The nature of the dependence of the cationic-anionic selectivity of the membranes on the pH permits the conclusion that, being a lipophilic compound, triforine is incorporated into the lipid matrix of the membranes and lowers the positive potential of the inner component, but is located in the vicinity of the polar groups of the lecithin molecules and not in the hydrocarbon region. Apparently the mechanism of the incorporation of triforine into the lipid membranes is in many respects similar to the mechanism of the inclusion of the undissociated form of 2,4-D in the lipid bilayer. Furthermore, measurements of the fluorescence of 1-anilino-naphthalene-8-sulphonate incorporated into erythrocyte membranes have shown that 2-methyl-4,6-dinitrophenol (the herbicide DNOC) is located in the polar component of the lipid bilayer.[81]

On the other hand, the herbicide dinoseb, a structural analogue of DNOC, partially penetrates into the hydrophobic region of the membrane by virtue of the intensified interaction with the hydrocarbon chains of the lipids resulting from the appearance of the alkyl side chain in the dinitrophenol molecule.[81] Evidently, when the dinitrophenol preparations are incorporated into the bilayer, their benzene ring is located between the polar groups of the phospholipid molecules, the hydroxy-group being apparently oriented in the direction of the

aqueous phase, while the alkyl chain, if present in the herbicide molecule, is directed towards the hydrocarbon component of the bilayer parallel to the aliphatic acid chains of the lipid molecules.[82] The results of ^{31}P and ^{13}C NMR studies permit the conclusion that the molecules of certain acylanilide (propanil, karsil) and phenylcarbamate (propham chlorpropham) herbicides, which also contain a benzene ring and a hydrocarbon side chain, are incorporated similarly into the lipid bilayer.[89]

Certain hydrophilic pesticidal preparations are likewise adsorbed in the region of the polar groups. Thus, when the readily water-soluble fungicide phytone is introduced into an aqueous solution on one side of a bilayer lipid membrane comprising brain phospholipids, it induces the appearance of a transmembrane potential difference on the membrane.[29] Since phytone is the complex between $CuCl_2$ and ε-caprolactam $[Cu(CLM)_2]^{2+}$ $[CuCl(CLM)_2]_2$ (CLM = caprolactam), a single crystal of which has an ionic structure, the generation of potentials on the membrane is evidently associated with the adsorption of the charged form of the fungicide on it. By virtue of the hydrophilicity of the preparation, it is probably adsorbed at the lipid/water interface.

Finally, according to the measurements of the electrophoretic mobility of lecithin liposomes, the ionised form of pentachlorophenol (PCP) may be adsorbed in the layer of lipid membranes adjoining the aqueous medium.[25,26] Apparently, the adsorbed PCP anion is capable of forming a hydrogen bond with a water molecule. On the other hand, the undissociated form of PCP is located in the hydrocarbon region of the membranes. The adsorption of the neutral and ionised forms of PCP in egg lecithin liposomes constitutes competitive processes. The adsorption centre consists of six lecithin molecules.[84] The undissociated form of the preparation is bound to the liposomes more effectively than the dissociated form (the corresponding association constants are 55000 litre mol^{-1} for the dissociated form and 279 litre mol^{-1} for the undissociated form).[85] It is of interest that the binding to the membrane alters the pK_a of PCP, increasing it from 4.75 in a homogeneous solution to 5.97 on a phosphatidylcholine membrane formed in 0.1 M KCl.[26]

The different nature of the interaction of the dissociated and undissociated forms of pesticides such as 2,4-D and PCP with the lipid membranes suggests a dependence of the effectiveness of their incorporation into the membranes on the pH of the medium. Indeed, the results of numerous studies have demonstrated an increase in the incorporation of 2,4-D and some of its analogues into various membrane systems with increase in the acidity of the solution employed.[13,74,86] This leads to an increase in the degree of adsorption of the herbicide,[73,75,87-90] the intensification of its influence on various processes associated with the membranes,[74,82,89-96] and an increase in its toxicity.[97] Thus 2,4-D and 2,4,5-triphenylacetic acid (the 2,4,5-T preparation) are adsorbed much more effectively by lecithin liposomes in a medium at pH 3 than in more alkaline solutions (pH 5.5 or 9.8).[86] On reduction of the pH from 6.5 to 4.5, the maximum concentration of the absorbed 2,4-D in the protoplasts isolated from the roots of the rye plant increases from 4.02 to 32.13 μM.[87] These data confirm yet again that 2,4-D is incorporated into the membranes mainly in the undissociated form. Indeed, it has been found, for example, that the permeability of the cell membranes of the roots of the barley plant to the dissociated form of the herbicide is smaller by a factor of 5.5×10^4 than to the undissociated form.[13]

A similar increase in incorporation into the cell membranes and the associated increase in the degree of absorption and toxicity with decrease in the pH has been observed for PCP,[98,99] and dinoseb.[12] On the other hand, the biological activity and the incorporation into the membranes of basic preparations, the molecules of which are protonated with decrease in pH, are appreciably reduced in acid solutions. The imidazole fungicide imasalil ($pK_a = 6.53$), the antifungal activity of which falls sharply as the pH is reduced from 0.7 to 5.2,[59] as well as the formamidine acaricide chlordimeform (its uncoupling activity increases with increase in the pH)[100] may serve as examples. The preferential incorporation into the lipid bilayer of the unionised compounds has been confirmed, in particular, by the appreciable weakening of the effect of chlorphenprop-methyl on the leakage of aminoacids from the tissues of *Avena fatua* when it is hydrolysed to chlorphenprop — the corresponding acid with the carboxy-group charged at physiological pH.[101]

The effectiveness of the adsorption of pesticidal preparations by cell membranes is also influenced by the molecular structure of the pesticides. This influence is clearly demonstrated, for example, by phenoxyacetic acids — when the latter are chlorinated, the effectiveness of their permeation into bean leaves increases.[102] As already mentioned, this is caused by the increase in the lipophilicity of compounds of the given series on chlorination.

The fluidity of the lipid bilayer also exerts a definite influence on the adsorption of pesticides in the polar component of the membrane. Thus, with increase in the cholesterol content in lecithin liposomes, the amount of uncharged 2,4-D in 2,4,5-T molecules bound to the membranes diminishes,[86] while the degree of adsorption of PCP on egg lecithin liposomes increases in the phase transition of the lipid from a gel to a liquid crystal.[84]

IV. Interaction of amphiphilic pesticidal compounds with the lipid bilayer

In the interaction of amphiphilic pesticidal compounds with the lipid bilayer, the polar component of the pesticide molecule is located in the region of the polar groups of the membrane lipids, while the non-polar component is incorporated into the hydrocarbon part of the membranes. This mechanism is characteristic of the interaction of various ionogenic surfactants with lipid membranes. Some of these substances (dodine, glyodin, quaternary ammonium salts) are effective fungicides (Table 2).

The cationic fungicides dodine and glyodin, which have long hydrocarbon chains and small polar components (the latter comprise the guanidine and imidazole basic groups in dodine and glyodine respectively), are readily incorporated into the cell membranes of different fungi. The fungicides then interact with the negatively charged sections of the membrane surfaces, neutralising their surface charge.[33] Thus dodine rapidly diminishes to zero the negative charge on the surfaces of intact conidia, cell walls, and protoplasts in the spores of *Neurospora crassa*. In the case of the protoplasts, this takes place at a fungicide concentration in solution of only 0.35 μM.[32] In other words, the process involving the incorporation of dodine into the cell membranes is extremely rapid and effective.[38] A further increase in the fungicide concentration in solution renders the surface charge on the membranes positive. Apparently dodine is bound to the membranes as a result of electrostatic interaction with the basic charge-generating components on the surfaces of fungal spores — the phosphate groups of the polar fragment of membrane lipids and the carboxy-groups of the aminoacid residues of the membrane proteins.

This hypothesis is consistent also with the decrease in the binding of the fungicide in the presence of divalent metal ions (apparently owing to competition for common binding sections) and also with suppression of the dissociation of the carboxy- and phosphate groups present on the surface of the membrane.[31] The van der Waals interaction of the fungicide hydrocarbon chains and the membrane phospholipids also plays a significant role in the retention of the dodine molecules in the lipid bilayer because these chains are evidently arranged parallel to one another in the bilayer.

Glyodin apparently also interacts in the same way with the cell membranes of microorganisms.[34] In the general case, the electrostatic interaction of virtually all the amphiphilic pesticidal compounds with the ionogenic groups of the membrane lipids and the van der Waals interaction with their non-polar components determine the detergent nature of the binding to the lipid bilayer.

A similar mechanism of the interaction with biomembranes has been proposed also for the morpholine fungicide tridemorph, which has a long alkyl chain.[103] The induction by the fungicide of the outflow of the electrolyte from the zoospores of *Plasmopora halstedii* and the *Corynebacterium* bacteria only a few minutes after treatment also supports this mechanism.[104,105] On the other hand, experiments on the determination of the electrophoretic mobility of the protoplasts of the micelia of *Neurospora crassa* and *Botrytis fabae* as well as the spores of *N. crassa* in the presence of this fungicide have not revealed any kind of influence on tridemorph on their surface charge.[106] In all probability, these results show that the long-chain molecules of tridemorph are incorporated into the lipid bilayer of the cell membranes in the same way as those of dodine and disturb the integrity of the bilayer but do not necessarily influence the surface charge of the membranes.

It may be that cationic imidazole fungicides — clotrimazole, miconazole, and econazole — are also capable of interacting with the lipid bilayer via the mechanism of the interaction of the amphiphilic detergents. These cationic fungicides are, on the one hand, lipophilic preparations, but they contain at the same time an imide nitrogen atom, which readily combines with a proton on acidification of the medium. This hypothesis is based on the increase in the effectiveness of the interaction of the above fungicides with lecithin liposomes when a negative charge is imparted to the surface of the latter (by incorporating diacetyl phosphate into their membranes) and also on the decrease in the effectiveness of the interaction when a positive charge is induced in the liposomes (with the aid of stearylamine).[58]

Quaternary ammonium salts with fungicidal activity constitute a large group of amphiphilic pesticides which interact effectively with the lipid bilayer. The disruptive effect of these cationic surfactants on the membranes, exerted via the usual detergent mechanism, has been known for a fairly long time,[107] but a systematic study of its characteristic features has been carried out comparatively recently. The detergent mechanism of the incorporation of the fungicidal ammonium salts into the lipid matrix of the membranes has been established in experiments with various compounds — benzylalkylammonium chlorides[108] and bromides[32] and nitro-vinylalkylammonium,[36,38,40] alkoxymethylenemorpholinium,[35] and nitrovinylbenzylmorpholinium[38,39] chlorides.

The experiments showed that the effectiveness of the incorporation of these preparations into the lipid bilayer depends significantly on the characteristics of the polar and non-polar fragments of their molecules. Thus, among the three benzylalkylammonium fungicides investigated, the preparation containing in the polar component of the molecule two electronegative groups at once — nitrovinyl and benzyl — exerts the greatest influence on the haemolysis of erythrocytes and the conductivity of bilayer lipid membranes.[39,40] The removal of one of these groups (nitrovinyl) from the molecule leads to some weakening of the effect of the fungicide on the membrane; an even greater effect is shown by the removal of both the electronegative fragments. Evidently the increased electronegativity of the polar component of the fungicide molecule intensifies its electrostatic interaction with the positively charged choline group in the polar component of the membrane lipids and ensures thereby a deeper penetration not only by the polar component but also by the entire molecule of the preparation into the lipid bilayer. The more effective incorporation of the hydrocarbon chain of the fungicide into the membrane inevitably leads in its turn to an increase in the degree of disorder in the internal part of the bilayer and hence to a stronger effect on the barrier properties of the membranes.

A similar dependence of the degree of incorporation into the lipid bilayer on the electronegativity of the polar component of the molecule has been observed also in the series of benzylalkylmorpholinium chlorides.[39] On the other hand, when the ammonium residue in the fungicide molecule is replaced by the morpholinium residue, the fungicidal activity of the preparations diminishes somewhat, which may be associated with the increase in the size of the polar part of the molecule.[38,39] It may be that the unduly large size of the polar components of the molecules of the quaternary ammonium salts weakens their interaction with the polar groups of the phospholipid molecules, which leads to a less deep incorporation of the fungicide molecules into the bilayer and hence to a weaker perturbation of the latter.

Furthermore, when quaternary ammonium salts are incorporated into the cell membranes, the membrane characteristics such as the surface charge of the lipid bilayer and the effectiveness of the interaction of the molecules of the membrane phospho-lipids with one another change in all probability.[36-39] These data also show that the positively charged polar part of the fungicide molecule is located at the membrane/water interaface, disturbing thereby the interaction of the polar groups of the membrane lipids.

Finally, the degree of interaction of benzylalkylammonium fungicides with the lipid matrix of cell membranes depends on the length of the hydrocarbon chain of the molecule of the preparation. In the series of alkoxymethylenetrimethylammonium chlorides, there is an optimum chain length, which influences the transport of Ca^{2+} and SO_4^{2-} through the liposome membranes. This length corresponds to 12-16 carbon atoms.[37] Approximately the same optimum length of the hydrocarbon chain (10-14 carbon atoms) is observed in the series of alkoxymethylenetrimethylammonium chlorides and also among alkylguanidine acetates — dodine analogues.[35] Evidently, the existence of an optimum hydrocarbon chain length is associated with the fact that compounds with chains much longer than those of the membrane phospholipids form fewer structural defects in the lipid bilayer than preparations with the optimum chain length. On the other hand, in the case of compounds with a much shorter chain length the hydrophobic interaction of the chain with the hydrocarbon tails of the membrane lipids may be too weak to affect the packing of the membranes.[37]

In conclusion, it is essential to note that, apart from amphiphilic pesticides, preparations such as metribuzin and D$_5$[*N*-butyl-*N*-(3,4-dichlorophenyl)-*N*-methylurea] — an analogue of the herbicide neburon — evidently possess the ability to form transbilayer structures. They apparently produce ionic channels in the lipid bilayer, resembling the dimeric channels of gramicidin A.[109]

Thus, depending on the degree of lipophilicity, the molecular dipole moment, and other characteirstics of the pesticide, its interaction with the lipid bilayer of cell membranes as a rule takes place via one of the three mechanisms described above. The type of the biological activity of the pesticide hardly affects the overall pattern of its interaction with the membrane lipids. Furthermore, it is usually impossible to observe correlations between the biological activity of the preparations and the effectiveness of their interaction with the lipid bilayer. These factors suggest that the membranotoxic activity of pesticides does not usually operate at the level of membrane lipids. On the other hand, the incorporation of pesticides into the lipid matrix of the membranes can frequently make a significant contribution to the usual toxicity of the pesticides as a result of the infringement of the barrier properties of the bilayer (for example, in the case of pesticide-protonophores) or of the allosteric effect on the operation of the membrane proteins when the properties of their lipid microenvironment are altered (for example, in the case of DDT and pyrethroids).

V. Conclusion

The studies carried out in recent years have made it possible to establish the mechanisms of the toxic activity of many organochlorine, organophosphorus, and carbamate insecticides, phenylurea, triazine, and phenolic herbicides, fungicidal azoles, pyrethroid compounds with insecticidal activity, and also a whole series of other pesticidal preparations.

The knowledge of the mechanisms of the action of pesticides makes it possible to increase appreciably their effectiveness, to modify specifically their structure and properties, and to synthesise new highly effective preparations. The increase in the effectiveness of pesticides resulting from the determination of the biochemical mechanisms of their action is achieved by improving the existing technologies for the treatment of harmful organisms. The specific synthesis of new pesticides is carried out taking into account the characteristic features of the interaction of the pesticide molecules with their molecular targets in sensitive organisms. Furthermore, the data obtained in the study of the mechanisms of the action of pesticides can be used to develop compounds with antidotal properties and compounds which diminish the toxicity of pesticides to warm-blooded organisms. Finally, studies of this kind are frequently of fundamental importance. The best known illustration of this is the determination of the mechanism of the action of the herbicide diurone, which has promoted the development of research into photosynthetic electron transport.

Various mechanisms of the toxic action of pesticides on the organisms sensitive to them are now known. However, in all cases the principal site where pesticides act is the system of cell membranes. Pesticides are capable of influencing both the structure and the functions of the membranes and can damage the membrane systems either directly or indirectly. The direct interaction of pesticides with biological membranes takes place via the binding of the preparations to certain components of the membranes, usually to the membrane proteins or lipids. An indirect effect of pesticides on membranes occurs when the biosynthesis of the proteins, lipids, or pigments of the cell membranes is affected and leads initially to changes in the protein-lipid or pigment composition of the membranes and then, as a consequence, to the breakdown of their structure and functioning.

Abstract. We describe the gradient barochromatography method, in which the eluent plays an active as well as a transport role, and thus offers an increased resolving power. The effect of the nonideality of the mobile gas phase, determined by its nature and pressure, on the retention and spreading of the chromatographic bands is examined, together with the prospects of controlling the selectivity of the column and the degree of separation of the sorbates. Special attention is paid to the role of the pressure gradients and of the velocity of the gas, including discontinuous changes in work with composite columns. The prospects of the practical application of gradient barochromatography to the identification of the components of complex mixtures and to the control of the chemical composition of various types of sample are examined. The bibliography includes 81 references.

I. Introduction

The nature and the working conditions of the mobile phase play only a secondary role among the many variables which control the selectivity, the effectiveness, and the sorption capacity in gas chromatography. This is because many workers treat the carrier gas merely as a transporting agent, whose influence on the completeness of the separation of sorbates is confined to a relationship between the flow rate of the carrier and the spreading of the bands. However, by assigning active functions as well as transport functions to the gaseous eluent we can obtain some quite unexpected advantages. Furthermore this is a way of building a kind of bridge between gas and liquid chromatography. Supercritical fluid chromatography is one of the best examples of an intermediate variant of chromatography.[1–3]

The active functions of the eluent are determined by the following properties: the dissolving power of the eluent with respect to the sorbates, which depends on its nature and on its pressure; the solubility of the stationary liquid phase in the eluent, which determines the nonideality of the latter; the solubility of the eluent in the stationary liquid (or its condensation, in cases of low mutual solubility) and the formation of a binary stationary phase; the adsorption of the eluent on the gas–liquid and liquid–solid interfaces of the carrier, and the consequent change in the overall sorption characteristics for the sorbates to be analysed (in the partition chromatography regime); the adsorption of the eluent on the gas–liquid interface (in the adsorption chromatography regime) and in the gas–solid carrier interface (in the partition chromatography regime for incomplete coverage of the carrier surface with a layer of stationary liquid phase); the disequilibrium of the sorption process, which increases at high flow rates of the eluent (especially when the viscosity of the stationary liquid is high) with a corresponding change in the retention of the sorbates to be analysed.

When working with nonideal eluents in highly efficient columns we can exploit various factors which have little effect on the separation in the case of ordinary packed columns (i.e. which do not significantly alter the shape of the chromatogram).

At present the range of pressure used in gas chromatography extends from tens of millimetre mercury to thousands of atmospheres, in regimes varying from almost isobaric (in the case of low pressure drops) to gradient regimes, in which the pressure is programmed both over the length of the column and in time. In this respect the active (or pseudoactive) function of the gaseous eluent can also take the form of a change in the selectivity of the composite column, which is controlled by the ratio of the pressures in the sections packed with different sorbents.

The theoretical and the applied aspects of chromatography with nonideal eluents have been examined in various monographs and review articles.[2–5] The present review is aimed at recent work on the specific features of barochromatography.

II. Classification of gas-chromatographic methods

The following classification of gas-chromatographic methods[2] can be proposed in order to allow for the effect of the nature and pressure of the carrier gas on the chromatographic process.

1. Vacuum chromatography using conventional carrier gases or the vapours of low-boiling liquids under reduced pressure.[6–9]

2. The traditional gas chromatography, using carrier gases at ordinary pressures (near-atmospheric at the column outlet, and

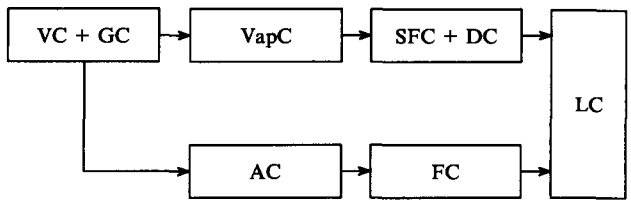

Figure 1. Variants of column molecular chromatography, classified according to the phase states of the mobile phase.
GC, traditional gas chromatography; VC, vacuum chromatography; VapC, vapour chromatography; DC, density chromatography; SFC, supercritical fluid chromatography; AC, aerosol chromatography; FC, foam chromatography; LC, liquid chromatography.

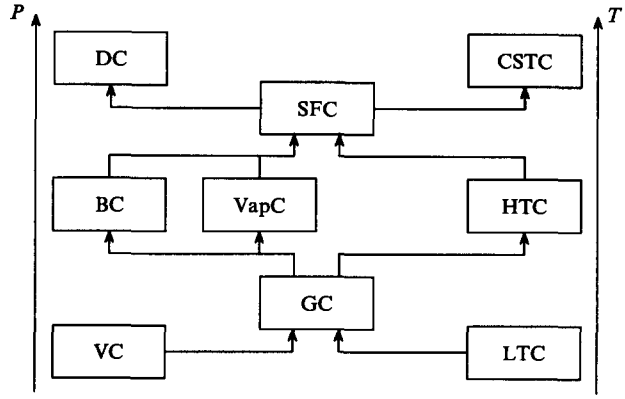

Figure 2. Chromatography methods and their intermediate variants, classified according to pressure and temperature levels (symbols as in Fig. 1); LTC, low-temperature chromatography; HTC, high-temperature chromatography; STC, super-high temperature chromatography; BC, barochromatography.

under an overpressure sufficient to give the required flow rate at the inlet).

3. Barochromatography, in which permanent-gas carriers at high pressures are used to embody some of the active functions listed above: of course, a pressure gradient along the column axis is unavoidable (unlike a temperature gradient) except in diffusion chromatography.[10]

3.1. Gradient barochromatography.

3.1.1. Gradient barochromatography with pressure and flow rate of the carrier gas programmed in time.

3.1.2. Gradient barochromatography with strong pressure gradients (pressure programmed along the column).

3.1.3. Gradient barochromatography with pressure programmed in time and strong pressure gradients.

3.2. Barochromatography with weak pressure gradients..

4. Vapour chromatography, in a flow of the vapour of low-boiling liquids (pure, or mixed with a gas) at ordinary or elevated (up to critical) pressures[11,12] including the addition of a ligand to the carrier gas in order to analyse chelates.[13] Vacancy chromatography, differential chromatography, and other forms of carrier-free chromatography can also be classified with this variant.[23,25,26]

5. Supercritical fluid chromatography, carried out in a flow of substances at a temperature and pressure just above their critical values.[3,4]

6. High-density chromatography, carried out in a flow of gases under pressures much higher than their critical values (up to thousands of atmospheres). Under these conditions the density and the solvent power can approach values typical of liquid solvents.[14]

Of course, this classification cannot claim to be complete, because it omits a number of possible methods, some of which have already been realised. The latter include, in particular, the programming of the parameters[15,16] and the establishment of conditions which favour turbulent flow,[17,18] whereas methods not yet realised include the use of heterogeneous eluents such as aerosols and foams†, and also the use of high vacua.

In the scheme shown in Fig. 1 the intermediate chromatographic methods are listed sequentially in the order of a change of the phase state of the eluent from gas to liquid. The upper branch of the diagram refers to homogeneous mobile phases, the lower branch to heterogeneous.

In order to establish a clear picture of the effect of the nature and of the operating conditions of the mobile phase on the chromatographic process it is useful to compare the above classification with the classification of the methods in which a temperature distribution is postulated. The same system of numbering is used for the variants (except variant 4).

†This method should not be confused with the well-known variant of foam chromatography in which the retention is determined by the formation of a foam between the sorbent and the stationary phase.[19]

1. Low-temperature chromatography, including cryogenic.[20-22]

2. Gas chromatography at ordinary temperatures (up to 200–250 °C).

3. Isothermal and gradient chromatography at elevated temperatures (up to 500–600 °C).

3.1. Programmed temperature chromatography.

3.1.1. Chromatography with time-programmed temperature.

3.1.2. Chromatography with time-programmed temperature and a constant temperature gradient along the column axis.

3.1.3. Chromathermography[23] and other variants of temperature programming in time and space. A variant[24] which stipulates the programmed transfer of the column from one part of the thermostat to another part (set for a different temperature) can also be classified in this section.

3.2. Isothermal chromatography.

5. Supercritical fluid chromatography.

6. 'Ultra-high temperature' chromatography (up to 1200–1350 °C).[27] Pyrolytic gas chromatography can be arbitrarily included in this section, since it features a large (though formal) increase in the mobility of the sorbate.[28]

The change from one methodology to another in terms of temperature and pressure is shown schematically in Fig. 2. In both cases an increase in the stated parameter tends to lower the sorption capacity of the stationary phase and hence to increase the mobility of the sorbates‡.

III. Effect of the nature of the mobile phase on the retention of sorbates under the conditions of barochromatography

Barochromatography covers the range from ordinary pressures to several tens of atmospheres when traditional carrier gases are used. Therefore in order to calculate the retention values we can use virial equations of state including the second and the third virial coefficients.[2] Obviously in most cases the solvent power of the eluent towards the sorbate and its dissolution in the stationary liquid are relatively small. However, they are usable for analytical purposes and for physicochemical measurements.

The first unambiguous example of the influence of the nature of the carrier gas on the retention was provided by the

‡Departures from this tendency in the right-hand loop of the scheme are due to phase transitions in the stationary phase (e.g., melting in the LC–GC stage). Little is known about the special problems of working with high vacua.

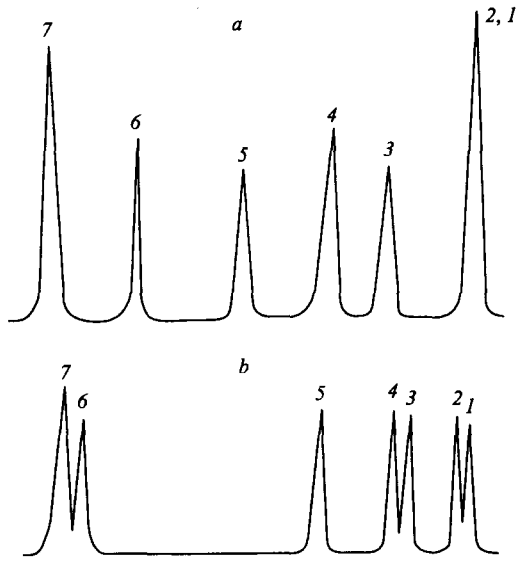

Figure 3. Chromatograms of a mixture of hydrocarbons obtained on a capillary column (270 m × 0.15 mm) with squalane and nitrogen (*a*) or hydrogen (*b*) as the carrier gas:[29] *1*, methylcyclopentane; *2*, 2,2-dimethylpentane; *3*, 2,4-dimethylpentane; *4*, benzene; *5*, 2,2,3-trimethylbutane; *6*, 3,3-dimethylpentane; *7*, cyclohexane.

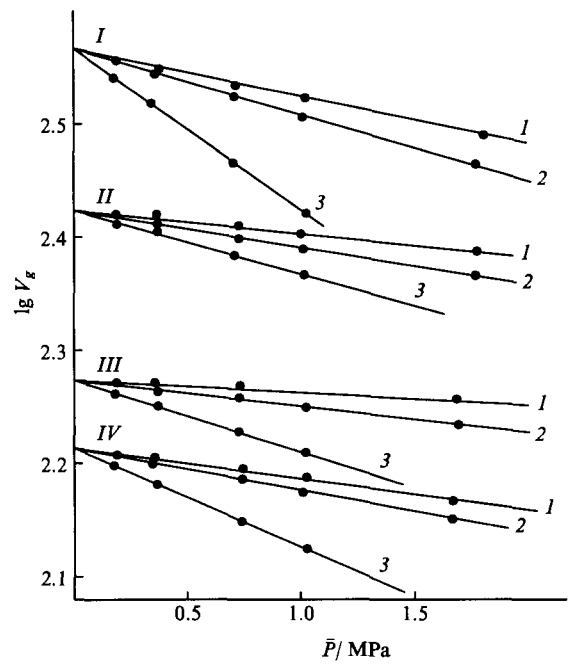

Figure 4. Plots of the logarithm of the absolute specific retention volume against the average pressure in the column at 80 °C in a nitrogen (*1*), argon (*2*), or carbon dioxide medium (*3*) for butyl acetate (*I*), toluene (*II*), n-octane (*III*), and dioxan (*IV*).[34]

chromatograms for hydrocarbons obtained on a capillary column 270 m long with a squalane stationary phase and using nitrogen and hydrogen as the carrier gases at an inlet pressure of 10.7 atm.[29] As can be seen from Fig. 3, replacing one carrier gas by the other affects both the retention and the selectivity of the separation of these sorbates. This effect is due to the well known relationship between the separation coefficient of the sorbate Γ and the second virial coefficient B_{12} in the gas-state equation for the mixture of sorbate and carrier gas:[30]

$$\Gamma = \Gamma_{(P\to 0)}\exp(\beta P)\,, \qquad (1)$$

where $\Gamma_{(P\to 0)}$ corresponds to zero pressure, $\beta = (2B_{12} - V_1^{\infty})/RT$ [V_1^{∞} is the partial molar volume of the sorbate at infinite dilution in the stationary liquid], and P is the pressure in the column.

At moderately high pressures, which satisfy the condition $\beta P \ll 1$, we can use the expression[31]

$$\Gamma = \Gamma_{(P\to 0)}(1 + \beta P)\,. \qquad (2)$$

Over a wider range of pressure we must include the third (mixed) virial coefficient C_{122} (See Ref. 32):

$$\ln\Gamma = \ln\Gamma_{(P\to 0)} + \beta P + \xi P^2\,, \qquad (3)$$

where

$$\xi = \frac{3C_{122} - 4B_{12}B_{22}}{2(RT)^2}\,. \qquad (4)$$

(B_{22} is the second virial coefficient in the equation of state of the carrier gas). A more complex equation was obtained when allowing for the solubility of the carrier gas in the stationary liquid.[33]

The effect of the nature of the carrier gas and of the pressure in the column on the retention of the sorbates is clearly shown by the plots in Fig. 4. Clearly, the commonly used carrier gases can be conveniently classified into three groups. The first includes hydrogen and helium, which are characterised by relatively small values of the second virial coefficient in the equation of state for the gas, and therefore in these gases the change in retention of the sorbates at higher pressures is very slight. In the case of nitrogen and argon (the second group) these changes become significant, and lastly to the third group we must assign carbon dioxide and some Freons, which produce an even larger shift in the phase equilibria of the sorbates. Furthermore the critical state of these eluents is reached at pressures as low as 30 atm.

A study of the dependence of the retention indices of the hydrocarbons in gasoline on the mean pressure of helium, argon, and carbon dioxide at pressures between atmospheric and 18 atm (using a capillary column 120 m long with octadec-1-ene) has been reported.[35] The results are consistent with the above argument (Fig. 5, see over). It was also established that the analysis time decreases when argon is replaced by carbon dioxide and the pressure is increased. The changes in the retention indices of aromatic hydrocarbons with increasing pressure in nitrogen and carbon dioxide have been discussed[36,37] by analogy with the corresponding changes in the retention index caused by an increase in temperature.

It has been pointed out[35] that carbon dioxide is sorbed by the wall of a copper capillary and blocks the active centres on the liquid–solid interface. This effect produces narrower and more symmetrical peaks for the aromatic hydrocarbons on the chromatograms: in a stream of CO_2 the height of the benzene peak is almost double that of the same peak in a stream of argon.

Of course, in gas adsorption chromatography the nature of the eluent produces even more marked effects, as shown by the possibility of separating gases by adsorption methods.[38,39]

Data on the role of the solubility of the eluent in the stationary phase and of the stationary phase in the eluent have been reviewed.[2] The most striking effects are seen in vapour chromatography. However, the effects can be substantial also when traditional carrier gases are used. For example, increasing the pressure of carbon dioxide in a column with a liquid-crystalline stationary phase suppresses the characteristic meta-para selectivity of the mesophase because of the disordering of the structure caused by the dissolution of the carbon dioxide.[40]

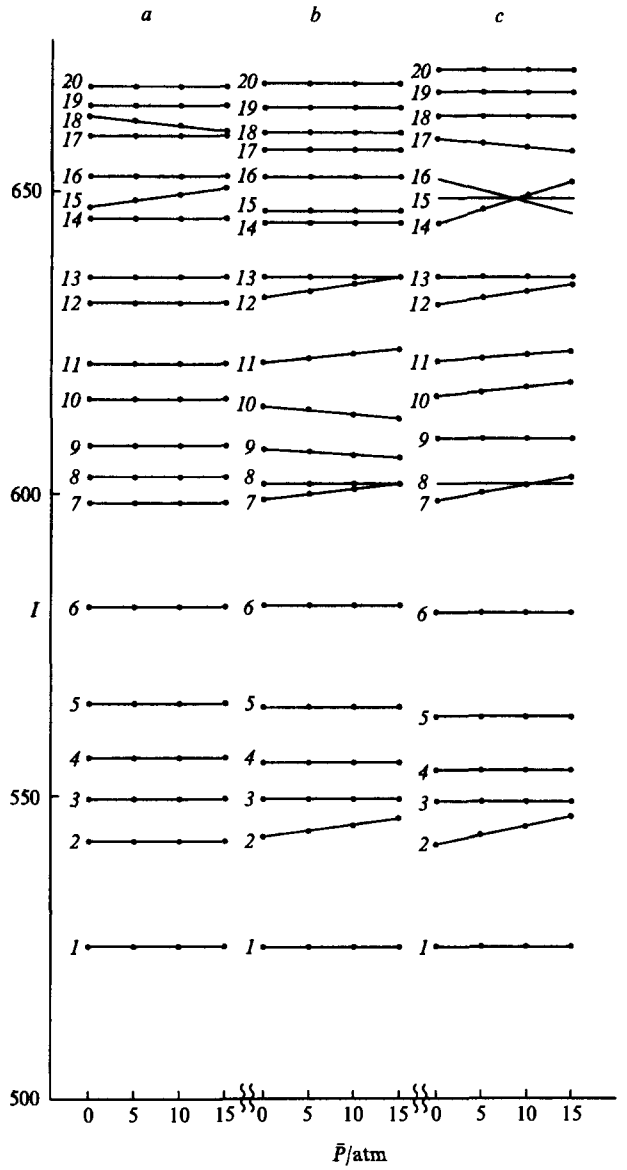

Figure 5. Dependence of the retention index of hydrocarbons at 25 °C on the average pressure in a column with octadec-1-ene with helium (*a*), argon (*b*), or carbon dioxide (*c*) as the carrier gas.[35] *1*, 2,2-dimethylbutane; *2*, cyclopentane; *3*, 2,3-dimethylbutane; *4*, 2-methylpentane; *5*, 3-methylpentane; *6*, n-hexane; *7*, methylcyclopentane; *8*, 2,2-dimethylpentane; *9*, 2,4-dimethylpentane; *10*, 2,2,3-trimethylbutane; *11*, benzene; *12*, cyclohexane; *13*, 3,3-dimethylpentane; *14*, 1,1-dimethylcyclopentane; *15*, 2-methylhexane; *16*, 2,3-dimethylpentane; *17*, 3-methylhexane; *18*, *cis*-1,3-dimethylcyclopentane; *19*, *trans*-1,3-dimethylcyclopentane; *20*, *trans*-1,2-dimethylcyclopentane.

IV. Contribution from pressure gradients to the retention and spreading of the bands

When discussing the role of the nonideality of the carrier gas and of its solubility (or adsorption) in the stationary liquid in the barochromatography regime it should not be forgotten that the contribution of these factors to the retention of sorbates in the presence of substantial pressure gradients can vary along the length of the column.

Since the specific retention volume V_g^T for a column temperature T is related to the distribution coefficient Γ (in gas – liquid chromatography) by the simple expression

$$V_g^T = \frac{\Gamma}{\rho_1} \tag{5}$$

(where ρ_1 is the density of the stationary liquid at the temperature T) we can use the expressions (1) – (4) given above to calculate the retentions.

According to van Swaay[41]

$$\ln V_g^T = \ln V_{g(P\to 0)}^T + \frac{\beta P_0}{J_3^2} . \tag{6}$$

Here $V_{g(P\to 0)}^T$ is related to the coefficient $\Gamma_{(P\to 0)}$, and J_3^2 is the pressure gradient factor,[42] equal to

$$J_3^2 = \frac{3(P_1/P_0)^2 - 1}{2(P_1/P_0)^3 - 1},$$

where P_1 and P_0 are the pressure at the inlet and at the outlet of the column respectively. The mean pressure over the length of the column is $\bar{P} = P_0/J_3^2$.

According to Everett,[30]

$$V_g^T = V_{g(P\to 0)}^T \left(1 + \frac{\beta P_0}{J_4^3}\right), \tag{7}$$

where the pressure $\bar{P} = P_0/J_4^3$ is averaged over the residence time of the sorbate in the column.

In general the pressure gradient factor can be expressed as

$$J_n^m = \frac{n}{m} \frac{(P_1/P_0)^m - 1}{(P_1/P_0)^n - 1} .$$

Equations of the following type are often used in published papers:[43,44]

$$\ln V_g^T = \ln V_{g(P\to 0)}^T + \beta P_0 J_3^4 \left[1 - aP_0(J_4^5 - J_3^4)\right], \tag{8}$$

where $a = cB_{22}/RT$ (and c is a constant).

Allowing for the dissolution of carrier gas in the stationary liquid Eqn. (6) becomes[37,45]

$$\ln V_g^T = \ln V_{g(P\to 0)}^T + \left[\beta + \lambda\left(1 - \frac{\delta \ln \gamma^\infty}{\delta X}\right)\right] \frac{P_0}{J_3^2}, \tag{9}$$

where λ is the molar solubility of the carrier gas in the stationary liquid, and $(\delta \ln \gamma^\infty)/\delta X$ is the change in activity coefficient of the sorbate as a function of its mole fraction in the stationary phase.

It follows that the slope of the straight lines in Fig. 4 is determined not by the virial coefficient B_{12} (which determines the factor β) but by its effective value[37]

$$B_{ef} = B_{12} + 0.5\lambda\left(1 - \frac{\delta \ln \gamma^\infty}{\delta X}\right) RT . \tag{10}$$

The effect of pressure and of the pressure gradients on the blurring of the bands has already been discussed in depth.[46] It was shown that the effectiveness of the column increases with pressure for the optimum flow rate of the carrier gas (the flow rate corresponding to the minimum on the curve, which defines the dependence of the height equivalent to a theoretical plate on the velocity of the gas). The latter decreases as the pressure increases. Theoretically, pressure gradients cannot lower the number of plates by more than 1/9, since

$$n^0 \geqslant n \geqslant \left(\frac{\varkappa}{J_3^2}\right)^2 n^0 , \tag{11}$$

where n^0 is the number of theoretical plates for the minimum gradient and

$$\varkappa = \sqrt{\frac{2}{(P_1/P_0)^2 + 1}}.$$

These conclusions are valid for a laminar flow of the eluent, to which Darcy's law applies. Changing to a turbulent regime by choosing an appropriate Reynolds number equalises the velocities over the cross-section and lowers the mass transport between the phases, increasing the effectiveness and the operating speed of the column.[17,18,47] Turbulence is produced not only by increasing the velocity of the mobile phase (i.e. by increasing the pressure at the column inlet) but also by increasing its density, since the Reynolds number is $d\alpha\rho/\eta$, where d is the diameter of the tube and α, ρ, and η are the linear velocity, the density, and the dynamic viscosity of the eluent respectively.

However, we should note that in addition to causing turbulence (which increases the effectiveness of the column) an increase in flow rate can disturb the thermodynamic equilibrium of the sorbate in the sorbent – carrier gas system. The equilibrium is usually shifted in the direction of a decrease in the distribution coefficient, and also it induces additional spreading of the bands.

Thus, it has been shown[48] that in a column with apiezon L (30% on hexasorb) an increase in the linear velocity of the carrier gas to 19.4 cm s^{-1} produces a relative change of 5% in the retention values. The problems resulting from the failure of the sorbate molecules to diffuse through the whole layer of liquid phase at high flow rates are even more serious when the viscosity is high. In a study[49] of polymers with a high molecular weight non-equilibrium was observed even at ordinary velocities of the carrier gas: this suggested a method of determining the retentions by extrapolating the experimental data to zero flow rate.

Kirsh et al.[50] have proposed the use of the equilibrium displacement effect to control the selectivity of chromatographic columns containing multilayer stationary phases. An experiment with columns 1.2 m long and an internal diameter of 3 mm with layers of apiezon L and 1,2,3,4,5,6-hexakis(β-cyanoethoxy)-hexane successively deposited on chromaton (from different solvents) showed that an increase from 5–8 to 500–550 cm^3 min^{-1} in the volume flow rate (at 60 °C) can lower the specific retention volumes of the sorbates by tens of per cent, the magnitude of the effect depending on the order in which the layers are deposited. The Kovats retention index can decrease by 4–13 units.

V. Chromatography with programmed pressure and flow rate of the carrier gas

Programmed flow rate of the carrier gas has been applied since 1959, usually by controlling the pressure at the column inlet.[51] It has been pointed out[16] that the use of this variant creates an alternative to temperature programming, since it makes possible the separation of mixtures of components boiling at very different temperatures as well as compressing the chromatographic bands, with a marked increase in sensitivity§. Also, since the analysis is carried out at relatively low temperatures, thermally unstable compounds can be separated, using more volatile and less thermally stable stationary phases if necessary. Both linear[52,53] and exponential[54,55] pressure programmes have been used, with or without a corresponding temperature programming. The relative advantages of packed and of capillary columns in pressure-programmed chromatography have been compared.[56,57]

There is no reference to the relationship between retention and changes in the nonideality of the eluent in papers on pressure-programmed measurements published so far, though it is evident from the above discussion that such a relationship exists.

§The height of the peak observed with a flow-type detector (for example, a flame ionisation detector) increases with the flow rate: this produces a convergence of the lower detection limits of light and of heavy sorbates.

VI. Retention of sorbates and the effectiveness of composite columns. Role of pressure gradients

Composite columns are widely used to achieve an intermediate separation of multicomponent mixtures. The selectivity is controlled by varying the ratio of the section lengths (or, more strictly speaking, the ratio of the amounts of individual sorbents). The classification of the binary sorbents and the fundamental relationships between the retention and the composition of the columns in each of the variants are discussed, in particular in our recent monograph.[46]

For low pressure gradients the retention volume on a composite column is determined by the sum of the retention volumes in the individual sections. For example, the specific retention volume in a two-section column is

$$V_g^T = \frac{g_1}{g} V_{g_1}^T + \frac{g_2}{g} V_{g_2}^T, \qquad (12)$$

where the subscripts 1 and 2 refer to the first and the second section respectively, and g is the total mass of the two stationary phases ($g = g_1 + g_2$).

However, in the presence of large pressure gradients we observe departures from this expression, which can be attributed to the difference in average pressure between the sections, and therefore to differences in the velocity of the carrier gas. The possibility of controlling the retention and the other chromatographic characteristics is determined mainly by the increased flow rate associated with the decrease in pressure along the column, so that the volume of substance entering the second section is greater than the volume corresponding to the average pressure in the first section. We can allow for this factor by using the expression

$$V_g^T = \frac{g_1}{g} V_{g_1}^T \frac{P_{0_1}}{P_0} \frac{J_3^2}{J_{3_{(1)}}^2} + \frac{g_2}{g} V_{g_2}^T \frac{J_3^2}{J_{3_{(2)}}^2} \cdot$$

$$= \frac{g_1}{g} V_{g_1}^T \frac{\bar{P}_1}{\bar{P}} + \frac{g_2}{g} V_{g_2}^T \frac{\bar{P}_2}{\bar{P}}, \qquad (13)$$

where $P_{0_{(1)}}$ is the pressure at the inlet of the first section; the pressure gradient factors J_3^2, $J_{3_{(1)}}^2$ and $J_{3_{(2)}}^2$ (and also the average pressures $\bar{P}$, $\bar{P}_1$, and $\bar{P}_2$) refer to the whole composite column and to its separate sections respectively.

Expressions for the effective values of the separation coefficients and for other quantities which characterise the retention (the coefficient Γ, associated with the volume composition, the molar retention volume, the molar composition, etc.) can be obtained in a similar way. The equation for the retention volume for unit length of the column V_L is

$$V_L = \frac{\bar{L}_1}{\bar{L}} V_{L_1} + \frac{\bar{L}_2}{\bar{L}} V_{L_2}, \qquad (14)$$

where the effective length $\bar{L}$ is equal to the product of the length of the column and of the average pressure (for each of the sections as well as for the whole column).

The linear retention index is calculated by the equation[46]

$$J = \frac{t_{R_i} - t_{R_z}}{t_{R_{(z+1)}} - t_{R_z}} + z,$$

where t_{R_i}, t_{R_z}, $t_{R_{(z+1)}}$ are the retention times of the experimental sorbate and of n-paraffins containing z and $z + 1$ carbon atoms. For a composite column

$$J = \frac{J_1 + mJ_2}{1 + m}, \qquad (15)$$

where $m = (\bar{L}_2/\bar{L}_1)(\Delta V_{L_2}/\Delta V_{L_1})$; ΔV_{L_1} and ΔV_{L_2} are the differences between the retention volumes of the standard n-paraffins (contains z and $z + 1$ carbon atoms) in the first and the second section.

From Eqn. (14) it follows, in particular, that inverting the order of the two sections in a given composite column affects the ratio of the average pressures in the sections, thus affecting also the total retention. This effect was first observed experimentally during the separation of a mixture of C_2-C_5 hydrocarbons using a composite column with mineral oil and β,β′-dicyanodiethyl ether.[23,58]

We have described[59] a method of determining propadiene and methylacetylene impurities in the propane–propene fraction in a composite column 7.1 m long consisting of two sections, one containing 20% n-heptadecane and the other 20% di-isodecyl phthalate on a diatomite carrier (2.4 and 4.7 m respectively). As can be seen from Fig. 6*a*, with the sections in the above sequence the impurities are detected as a single peak, which is convenient for operational production control. With the opposite arrangement of the sections (Fig. 6*b*) propadiene and methylacetylene give separate peaks, which allows a more detailed analysis of the chromatogram.

A 13-component mixture of naphthalene and its methyl and dimethyl derivatives was separated on a composite column with liquid-crystalline *p,p′*-azoxyphenetole and poly(ethylene glycol)-2000 on chromosorb.[60] The optimum value of $\bar{L}_2/\bar{L}$, which allows the separation of 12 peaks with a given effectiveness (broken line *A*), corresponds to the real column, consisting of a 4 m long poly(ethylene glycol)-2000 section and a 3 m long azoxyphenetole section (Fig. 7). In this case only the 2,6 and the 2,7 pair of dimethylnaphthalenes remains unresolved. Arranging the sections in the opposite order increases $\bar{L}_2/\bar{L}$ (broken line B) and allows even these isomers to be separated.

A study[61] of the spreading of sorbate bands in composite columns has shown that whereas at low pressure gradients the width ω of the peak (in units of the volume of carrier gas) is given by the formula

$$\omega^2 = \omega_1^2 + \omega_2^2 , \tag{16}$$

with large gradients the following expression should be used for the corrected peak width $\omega^0 = \omega J_3^2$:

$$(\omega^0)^2 = (\omega_1^0)^2\left(\frac{P_{0_{(1)}}}{P_0}\right)^2\left(\frac{J_3^2}{J_{3_{(1)}}^2}\right)^2 + (\omega_2^0)^2\left(\frac{J_3^2}{J_{3_{(2)}}^2}\right)^2 . \tag{17}$$

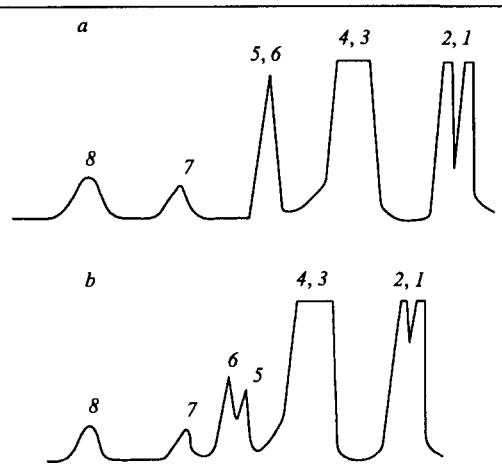

Figure 6. Chromatograms of a propane–propene fraction on a composite two-section column for different relative positions of the sections (see text).[59] *1*, ethylene; *2*, ethane; *3*, propene; *4*, propane; *5*, propadiene; *6*, methylacetylene; *7*, isobutane; *8*, n-butane.

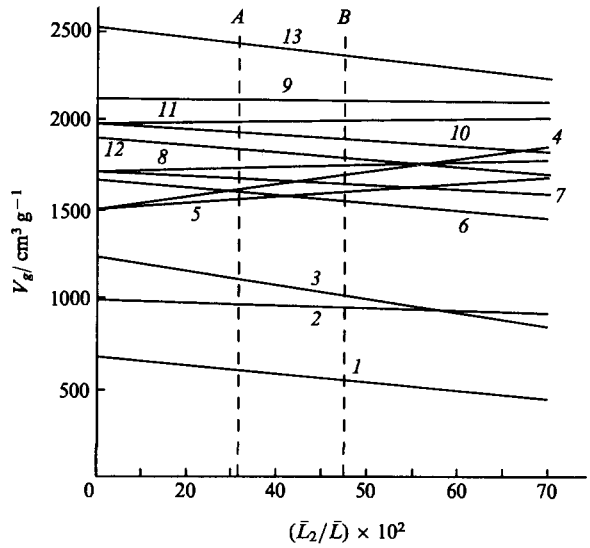

Figure 7. Plots of the retention volumes of alkylnaphthalenes against the ratio of the effective section lengths with *p,p′*-azoxyphenetole and poly(ethyleneglycol)-2000.[60] *1*, naphthalene; *2*, β-methylnaphthalene; *3*, α-methylnaphthalene; *4*, 2,6-dimethylnaphthalene; *5*, 2,7-dimethylnaphthalene; *6*, 1,7-dimethylnaphthalene; *7*, 1,3-dimethylnaphthalene; *8*, 1,6-dimethylnaphthalene; *9*, 1,2-dimethylnaphthalene; *10*, 1,5-dimethylnaphthalene; *11*, 2,3-dimethylnaphthalene; *12*, 1,4-dimethylnaphthalene; *13*, 1,8-dimethylnaphthalene.

Corresponding expressions have been obtained for the number of theoretical plates and for the degree of separation.[61]

VII. Chromatography with discontinuous changes in the pressure and/or flow rate of the carrier gas between the sections of a composite column

As was said above the retention of the sorbates (and therefore also the selectivity of the column) can be controlled by varying the ratio of the average pressures in the sections of a composite column, since this procedure varies the relative values of the volume flow rates in the sections and of the effective section lengths.

An analysis scheme[63] based on a system developed for multistage programmes includes introducing an additional flow between the sections (or extracting part of the flow emerging from the first section). By regulating the pressure of this additional flow we can control the pressure drop between the sections and thus determine the ratio of the average pressures and rates in the sections for constant inlet (P_1) and outlet pressures (P_0). A suitable assembly is shown diagrammatically in Fig. 8.

Deans and Scott[62] have shown that the relative retention of the sorbates A and B on a composite column, equal to the ratio of the reduced retention times

$$r = \frac{t'_{R(A)}}{t'_{R(B)}} \tag{18}$$

(where $t'_R = t_R - t_0 = t_0\Gamma/\beta'$, t_R is the retention time of the sorbate, t is the retention time of the non-sorbed gas, and $\beta' = \kappa/\kappa_1$ is the ratio of the volume fractions of the column occupied by the gas and the liquid phase respectively), can be expressed in terms of the ratio of the t_0 values for the two sections:

$$r = \left[\frac{\Gamma_{A_{(1)}}}{\beta'_1} + \frac{t_{0_{(2)}}}{t_{0_{(1)}}}\frac{\Gamma_{A_{(2)}}}{\beta'_2}\right] \Big/ \left[\frac{\Gamma_{B_{(1)}}}{\beta'_1} + \frac{t_{0_{(2)}}}{t_{0_{(1)}}}\frac{\Gamma_{B_{(2)}}}{\beta'_2}\right] . \tag{19}$$

The change in the pressure drop between the section produced by the insertion (or extraction) of an additional flow alters the velocities in the sections and thus affects the ratio $t_{0_{(1)}}/t_{0_{(2)}}$.

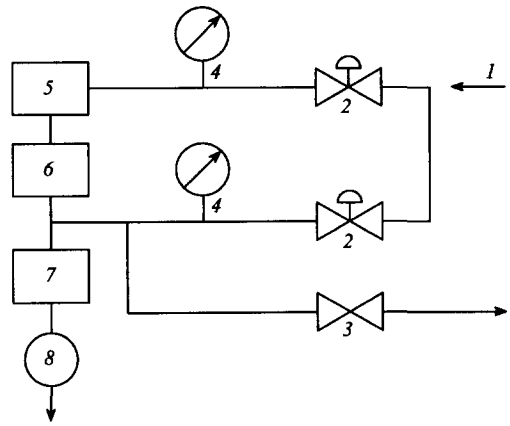

Figure 8. Two-section column with control of the flow and of the pressure drop between the sections.[68] *1*, gas flow; *2*, pressure regulator; *3*, needle valve; *4*, manometer; *5*, sample injection system; *6*, and *7*, sections of the composite column; *8*, detector.

Commercial equipment for assembling a similar scheme can be obtained from the German firms Gerstel and Siemens.

A group of papers[64,65] published in 1985 described a systematic study, with the scheme shown in Fig. 8, of the practical application of this method of analysis, called the multi-chromatographic method. In later work the technique was combined with liquid (column) chromatography and thin-layer chromatography. The method was used for 'tuning' the selectivity of capillary columns.[66,67]

Another suggested variant of barochromatography with composite columns uses an intermediate controllable throttle (Fig. 9) which allows the contribution of each section to the total retention to be varied precisely and between wide limits. Obviously, for a large enough ratio of the pressures in the sections the second section can be effectively 'switched off' (or the first, if the sections are connected in the opposite order). Thus by filling the sections with a suitable mixture of polar and of nonpolar sorbents the control range can be made to approach Rohrschneider's range of chromatographic polarities.[70]

Fig. 10 (see over) shows a series of chromatograms of a mixture of hydrocarbons and oxygen compounds recorded in a baro-chromatographic apparatus with different pressures in the sections, using poly(ethylene glycol adipate) and 1,2,3,4,5,6-hexakis-(β-cyanoethoxy)hexane on zeolite at 85°C in a stream of carbon dioxide.[68] Obviously the system offers adequate control over the selectivity of the separation: even the order in which the peaks appear in the chromatogram can be controlled.

The total effective sorption capacity is also controllable. Table 1 shows the absolute specific retention volumes $[V_g = V_g^T(273.15/T)]$ on a composite column which included sections with 1,2,3,4,5,6-tetrakis-(β-cyanoethoxy)hexane and almost com-pletely nonpolar silicon grease on chromosorb W at

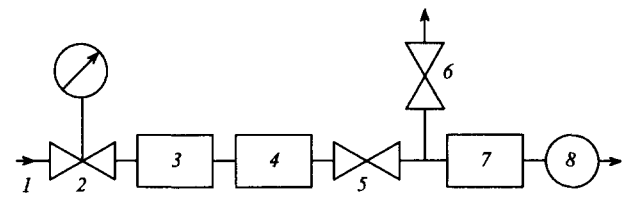

Figure 9. Barochromatography apparatus.[68,69] *1*, gas flow; *2*, pressure regulator; *3*, sample injection system; *4*, and *7*, column sections; *5*, intermediate throttle; *6*, vent to atmosphere; *8*, detector. In studies of the regime the pressure was measured also before and after the throttle *5* and after the section *7*.

353.15 K.[69] Of course in this case, since carbon dioxide was used as the eluent, the sorption capacity and the selectivity at high pressures are also affected by the nonideality of the mobile phase.

We have also examined[71] the possibility of using a universal equation for the *a priori* calculation of the retention of sorbates by binary sorbents[72] in a barochromatographic system. The equation takes the form

$$y = y_1 + \frac{X_{ef_2}}{1 - b(1 - X_{ef_2})}(y_2 - y_1)\,, \tag{20}$$

where y_1 and y_2 are the retentions of the sorbate by the binary and by the individual sorbents respectively, X_{ef_2} is the fraction of sorbent 2 in the total amount of binary sorbent (or the ratio of the length of section 2 or of its internal volume to the total length or volume of the composite column), and b is a coefficient which characterises the given system. It was shown, in particular, that whether or not the system included an intermediate throttle the average pressure in the composite column was

$$\bar{P} = \frac{L_1}{L}\frac{P_{0_{(1)}}}{J^2_{3_{(1)}}} + \frac{L_2}{L}\frac{P_{0_{(1)}}}{J^2_{3_{(2)}}}\,. \tag{21}$$

Since $\bar{P} = P_0/(J_3^2)_{ef}$, where $(J_3^2)_{ef}$ is the effective pressure gradient factor along the column, we have

$$\frac{1}{(J_3^2)_{ef}} = \frac{L_1}{L}\frac{P_{0_{(1)}}}{P_0}\frac{1}{J^2_{3_{(1)}}} + \frac{L_2}{L}\frac{1}{J^2_{3_{(2)}}}\,. \tag{22}$$

In general, if the intermediate throttle is used in conjunction with an additional gas flow (or with the partial extraction of the flow from the system) the equation for the relative retention becomes

$$r = \frac{(\Gamma_{A_{(1)}}/\beta'_1)\varkappa_{(1)} + K_V K_\alpha(\Gamma_{A_{(2)}}/\beta'_2)\varkappa_{(2)}}{(\Gamma_{B_{(1)}}/\beta'_1)\varkappa_{(1)} + K_V K_\alpha(\Gamma_{B_{(2)}}/\beta'_2)\varkappa_{(2)}} = \frac{\Gamma_{A_{(1)}}\varkappa_{l_{(1)}} + K_V K_\alpha \Gamma_{A_{(2)}}\varkappa_{l_{(2)}}}{\Gamma_{B_{(1)}}\varkappa_{l_{(1)}} + K_V K_\alpha \Gamma_{B_{(2)}}\varkappa_{l_{(2)}}}\,. \tag{23}$$

Table 1. Absolute specific retention volumes of the sorbates for different average pressures (in atm) in the sections.[69]

Sorbate	$\bar{P}_1 = 1.74$ $\bar{P}_2 = 1.36$	$\bar{P}_1 = 3.86$ $\bar{P}_2 = 1.66$	$\bar{P}_1 = 6.99$ $\bar{P}_2 = 1.65$	$\bar{P}_1 = 10.16$ $\bar{P}_2 = 1.68$	$\bar{P}_1 = 12.96$ $\bar{P}_2 = 1.68$	$\bar{P}_1 = 19.89$ $\bar{P}_2 = 2.18$
n-Hexane	13.3	11.6	6.9	5.6	5.0	4.5
Cyclohexane	24.1	19.9	12.2	10.3	9.3	8.6
Ethanol	24.7	29.8	29.0	29.7	29.2	29.6
Iso-octane	28.0	22.8	13.2	10.8	9.7	8.8
Ethyl methyl ketone	33.0	33.2	31.9	32.2	31.0	30.3
n-Heptane	29.7	23.8	14.0	11.5	10.3	9.6
Benzene	33.3	30.6	25.4	24.4	23.7	23.5
n-Octane	63.2	48.7	28.0	24.2	22.5	19.6
n-Nonane	–	–	–	51.0	47.2	42.9

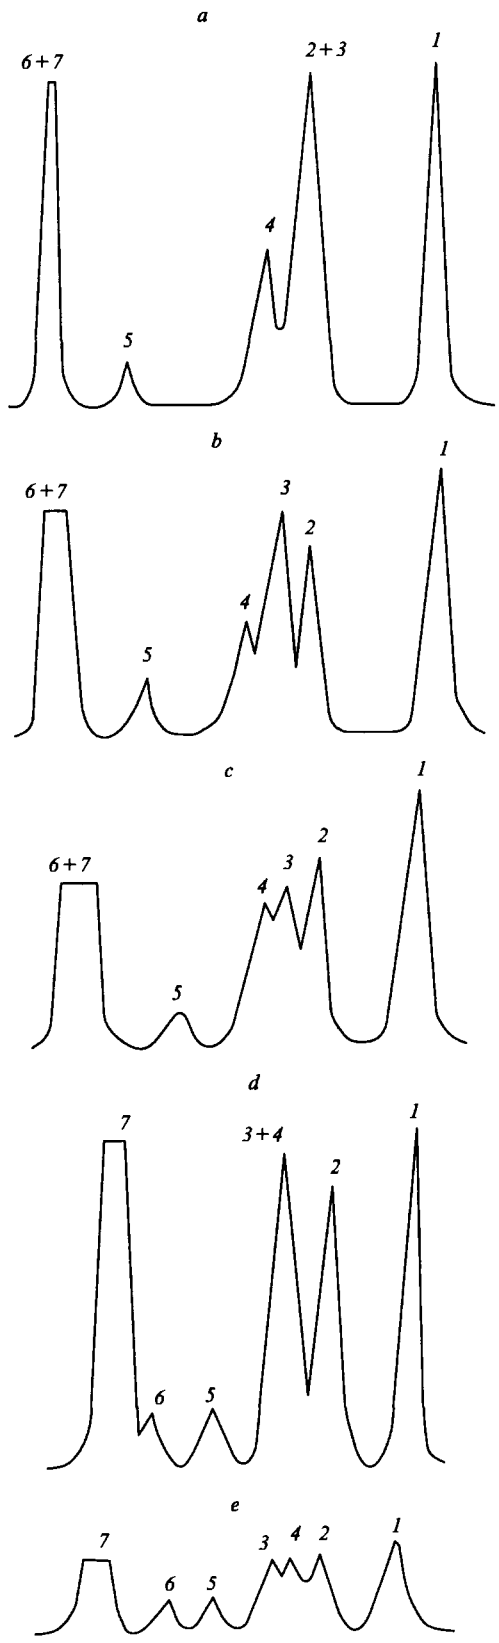

Figure 10. Chromatograms of a mixture of organic compounds obtained at different pressures in a barochromatographic column.[68] *1*, n-octane; *2*, propionaldehyde; *3*, n-nonane; *4*, acetone; *5*, butyraldehyde; *6*, ethyl methyl ketone; *7*, benzene. Average pressures in the first and the second section/atm:

	a	*b*	*c*	*d*	*e*
$\bar{P}_1$	2.24	3.79	6.67	9.69	19.72
$\bar{P}_2$	1.37	1.47	1.44	1.38	1.73

Here $K_V = [V_{\alpha_0} \pm (PV_\alpha)_{exc}]/V_{\alpha_0}$ is a coefficient which allows for the additional flow (the minus sign corresponds to the injection of an additional flow into the system, the plus sign to the extraction of part of the flow from the system). If the flow is injected (or extracted) at a point downstream from the intermediate throttle the pressure and the flow are P_2 and V_{α_2}; V_{α_0} is the flow of gas emerging from the second section (normalised to a pressure of 1 atm). If the fraction of the volume occupied by the phase $\varkappa_1$ is the same in both sections we can write

$$r = \frac{\Gamma_{A_{(1)}} + K_V K_\alpha \Gamma_{A_{(2)}}}{\Gamma_{B_{(1)}} + K_V K_\alpha G_{B_{(2)}}} . \qquad (24)$$

With sections of the same size $K_V = \bar{P}_2/\bar{P}_1$. In the absence of an additional flow (or extraction) we have $K_\alpha = 1$.

The above expressions do not allow for the nonideality of the gas or for the effect of pressure on its solvent power for the sorbate. A correction for the former effect can be inserted into K_α and K_V (by using the equation $PV = ZRT$), and a correction for the latter effect can be inserted into Γ [see Eqn. (1)].

VIII. Modifications of the gradient barochromatography method

The examples of the methods of controlling chromatographic processes discussed above can be used in practice to identify the optimum conditions of analysis of multicomponent mixtures while using the smallest possible number of stationary phases.[73] Since the use of composite columns with a controlled ratio of effective section lengths allows us to evaluate the chromatographic properties of sorbents of moderately high selectivity the presence of several sections with 6–10 sorbents undergoing different intermolecular interactions with the sorbates should enable us to solve a wide range of analytical problems by gas chromatography.

Furthermore in the chromatographic identification of substances from multiple retention spectra[74] an unambiguous correspondence between peaks obtained in columns with sorbents of different nature can be established by a series of measurements on columns with a gradually varying selectivity.[74–76] The barochromatographic method is a convenient way of obtaining the required series of chromatograms (see Fig. 10).

In a proposed variant of the design of the column, three sections are connected in a triangular arrangement. They contain sorbents of different types, and controllable flow resistances are mounted between the sections. The location of the points of insertion (or extraction) of the gas into or out of the system and the point at which the gas flow is led from the sections to the detector can be varied to produce the required sequence of sections.

Multielement spectra can be obtained in a cruciform barochromatographic column[77] (a modification of a column already described),[78] which includes sections with different sorbents, intermediate throttles, and detectors.

The range of possible applications of composite columns can be extended by the following methods: by operating both sections under vacuum conditions, which combine large values of $\bar{P}_1/\bar{P}_2$ with adequate resolution; by operating the first section under near-atmospheric pressure and the second in a vacuum,[79,80] which offers (as before) a wider range of selectivity control and a saving in eluent without introducing experimental complications or allowing nonideality to appear in the carrier gas; by assembling combined variants of chromatography,[81] in particular by operating the first section in the supercritical fluid chromatography regime and the second in the barochromatography or traditional gas chromatography regime; by programming the pressure in the course of the analysis in one or both of the sections (for example, by varying the pressure at the inlet to the first section, by varying the throttle setting, by varying the pressure of the gas flow inserted between the sections or by varying the flow of

gas vented to the atmosphere); by combining the partition and the adsorption regime; by programming the temperature in one or both sections; by using sections of different diameter, including narrow packed columns and capillary columns; by inserting samples and standards at intermediate points (between the sections); by using several parallel sections; by extracting from the system some components or fractions separated in the first section; by combining barochromatography with other multistage schemes (reverse, semireverse, parallel exhaust, etc.).

V. Conclusions	726

Abstract. Publications on the thermodynamics of free and of interacting curved interfaces in liquid films are reviewed. The approaches of Gibbs, Boruvka–Neumann, and others to the determination of the surface tension of free curved surfaces are compared. The dependences of differently defined interfacial tensions on the radius of curvature of the interface are obtained. The fundamental equilibrium equations for systems containing curved surfaces, including the transition region of the liquid film, are proposed. A generalised invariant of the profile of the liquid film is obtained, and used to derive all the known equilibrium equations for a liquid film with a bulk meniscus, including the equation for a liquid drop on a solid surface and precise analytical expressions describing the line tension for different thermodynamic models of the liquid film. The theory of the adhesion of fluid particles, which relates the adhesion force and the potential energy of the interaction between deformable particles to the parameters of the disjoining pressure isotherm, is discussed. The bibliography includes 88 references.

I. Introduction

Emulsion and foam films are formed at the contact between two liquid drops or gas bubbles (Fig. 1, phase β) in a liquid dispersion medium (Fig. 1, phase α).

The plane-parallel part of a liquid emulsion or foam film at the centre of the contact region is characterised by the equilibrium condition

$$\Pi = P_\beta - P_\alpha , \qquad (1)$$

where P_β and P_α are the hydrostatic pressures in the phases β and α respectively, and Π is the disjoining pressure in the film.

In the bulk meniscus region of the liquid film the interaction between the interfaces vanishes (i.e. $\Pi = 0$). Therefore the curvature of these surfaces is constant, and is determined exclusively by the difference between the hydrostatic pressures $P_\beta - P_\alpha$.

The profile of the liquid film $H(r)$ in the region of the meniscus [or the profile of the free curved surface $z(r)$] contains information on the contact force (compressive, f_p, or repulsive, f_a) applied to the fluid particles,[1–3] and on the integral characteristic of the surface forces [a large thermodynamic potential $\Delta\Omega(H_f)$]. Furthermore the experimental dependence of the contact angle θ_f on the radius of the film r_f contains information on the line tension in the liquid film, i.e. on the form of the profile of the disjoining pressure isotherm $\Pi(H)$ in the transition region.[4–6].

Unlike the region of the bulk meniscus the curvature of the interfaces in the transition region of a liquid film is not constant but shows a complicated dependence on the local thickness H of the film profile. Therefore the profile of the meniscus in the transition region of a liquid film contains information on the $\Pi(H)$ isotherm,[2, 3] which can be obtained from experimental plots of the contact angle against the thickness of the film in the transition region [$\phi(H)$]. Unfortunately the length of the transition region of the film is small, and therefore the disjoining pressure isotherm $\Pi(H)$ cannot be determined to within an acceptable precision from the $H(r)$ profile in this region, measured for example by the so-called topographic method.[7] In the region of the bulk meniscus this profile can be determined very accurately for small contact angles, and it is effectively the only meaningful source of information on surface forces.

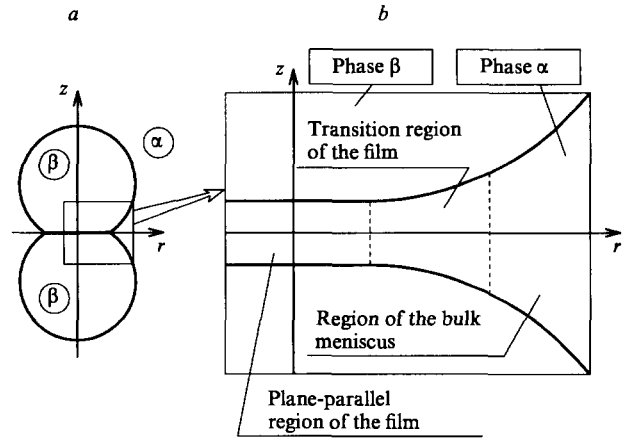

Figure 1. Thermodynamics of liquid films: (*a*) symmetrical microscopic liquid film (emulsion or foam) produced between two identical fluid particles (liquid or gaseous) of phase β in the liquid phase α; (*b*) central plane-parallel region, transition region, and region of the bulk meniscus (containing two non-interacting curved interfaces in the symmetrical liquid film).

The thermodynamics of free curved surfaces in liquid films were established by Gibbs,[8] and further developed by Buff,[9] Ono and Kondo,[10] Rusanov,[11-13] Rowlinson and Widom,[14] Ivanov and Kralchevsky,[15] Markin et al.,[16, 17] Babak,[5, 18] and others.[19-21]

The next step forward in the development of the thermodynamics of free curved surfaces was its extension to the transition region of emulsion and foam films of variable thickness, in which a disjoining pressure is generated and which smoothly change into a plane-parallel film on one side and into a system of two free (non-interacting) curved interfaces in the region of the bulk meniscus.[1, 5, 18, 22] Clearly, the best thermodynamic model for this generalisation is the liquid film model, based on the assumption of two interfaces (in the Gibbs sense) defining a layer of finite thickness of a liquid reference phase (the Gibbs comparison phase). The thermodynamics of plane-parallel liquid films based on this model were developed by Rusanov,[11-13] and those of free curved interfaces in the region of the bulk meniscus by Gibbs.[8] However, neither of these models allows for the presence of a transition region characterised by a surface tension gradient.[1, 5, 18] As a result, the thermodynamics of plane-parallel liquid films and those of free curved surfaces are not mutually consistent.

The two approaches can be reconciled in terms of the thermodynamics of the transition region of the liquid film,[1, 5, 18] which naturally reduce to the thermodynamics of plane-parallel liquid films and to the thermodynamics of free curved interfaces in the appropriate regions of the system.

The aim of the present review is to discuss recent work on the thermodynamics of free and of interacting curved interfaces in emulsion and in foam films.

II. Thermodynamic description of free curved interfaces

The study of curved interfaces reveals a number of problems associated with the development of the thermodynamics of the transition region in thin liquid films.

First, the fundamental equation of the system containing a curved interface is no longer invariant with respect to the method of localisation of the curved interface. This is formally shown by the appearance in the fundamental equation of terms relating to the work of bending and twisting of the interface (whose magnitude depends on the mode of localisation of the interface).

Second, we find a problem in determining the interfacial tension, whose magnitude depends both on the position of the interface and on the method of selecting the reference system used to define the interfacial tension. The different possible choices of a reference system to determine the interfacial tension led to a discussion of the validity of the generalised Laplace equation.[15, 16, 19-21] We note that correct allowance for the bending and twisting moments in the generalised Laplace equation is essential also in the case of liquid particles with low and ultra-low interfacial tension, such as micelles, vesicles, and drops of a coacervate phase.

1. Cylindrical free interfaces

We shall begin our discussion of the thermodynamics of curved interfaces with the simplest case of cylindrical surfaces, i.e. surfaces having only one principal radius of curvature, thus avoiding mathematical difficulties due to the need to allow for the second radius of curvature without loss of generality.

Systems containing a free cylindrical interface. Let us consider a multicomponent system including two macroscopic phases α and β separated by a free cylindrical interface (Fig. 2). To simplify the discussion we shall ignore gravity, and we shall assume that the hydrostatic pressures P_α and P_β in the two phases are known. All the parts of the system in equilibrium have the same temperature T and the same chemical potential μ_i of the i-th component [$i = 1, 2, \ldots, N$; N is the number of components, of which the total number of moles (N_i) in the system is controlled by the material source ν_i].

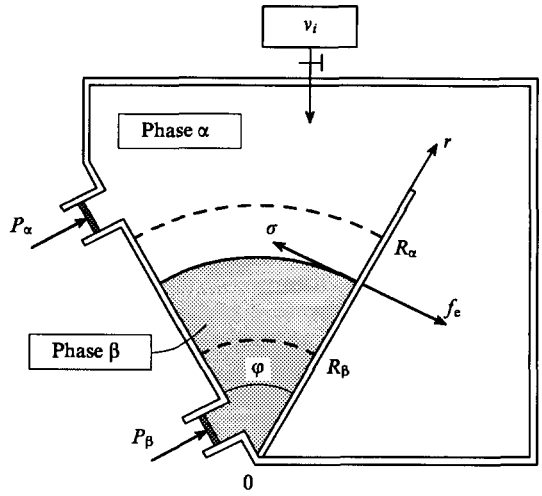

Figure 2. Thermodynamic system including a fluid (liquid or gaseous) phase β and a liquid phase α separated by a curved free cylindrical interface.

We shall also assume that the above system is in thermodynamic equilibrium with an open subsystem bounded on the right by a mobile side-wall (Fig. 2) forming a dihedral angle φ with the fixed left-hand wall, and by two arbitrarily located dividing surfaces having radii R_α and R_β (enclosing the interface) and two flat end faces forming a layer of thickness l_z. The moment of the external force f_e balances the moments of the interfacial tension σ and of the pressure force P_α and P_b acting on the system.

Hydrostatic description of the curved interface. The capillary properties of curved interfaces have been widely discussed in the framework of local thermodynamics.[9, 10-12, 16, 23, 24]

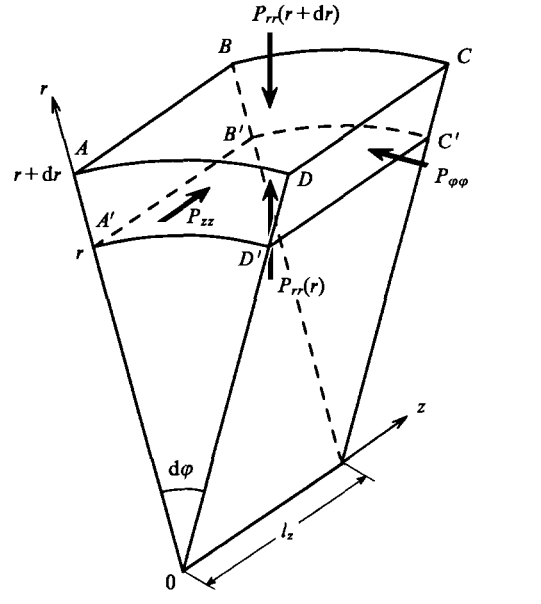

Figure 3. Element of volume of the thermodynamic system containing a cylindrical interface.

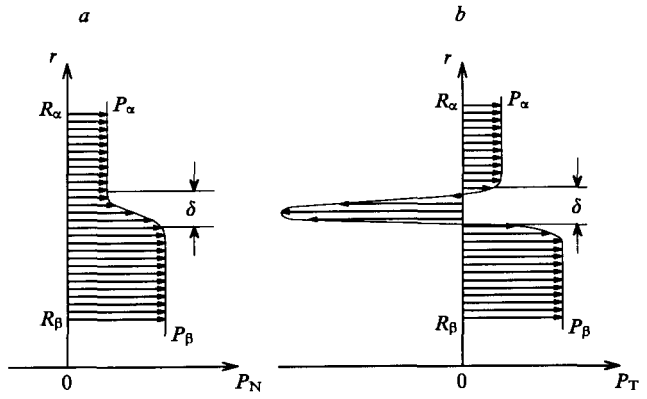

Figure 4. Distribution of the normal P_N (*a*) and of the tangential P_T component (*b*) of the hydrostatic pressure tensor in the transition region of a curved interface.

We shall use the following symbols for the non-zero components of the hydrostatic pressure $\hat{P}$ in cylindrical coordinates (Fig. 3):

$$P_N(r) = P_{rr}\,, \quad P_T(r) = P_{zz} = P_{\varphi\varphi}\,.$$

An idealised plot of the dependence of these components on the radius r is shown in Fig. 4. Unlike the planar interface[22] the normal component of the pressure tensor $P_N(r)$ (see Fig. 4*a*) varies sharply in a narrow region of the interfacial transition layer of thickness δ (see Fig. 4*b*). In the region of the bulk phases α and β the two components are equal to P_α and P_β respectively.

In cylindrical coordinates the hydrostatic equilibrium condition

$$\mathrm{div}\hat{P} = 0$$

becomes

$$\frac{dP_N}{dr} + \frac{P_N}{r} = \frac{P_T}{r} \tag{2}$$

and can be obtained from the mechanical equilibrium condition of the element of volume $ABCDA'B'C'D'$ (see Fig. 3) which experiences the pressure components $P_N = P_{rr}$ and $P_T = P_{\varphi\varphi} = P_{zz}$. Equating to zero the projection of the resulting force in the r direction and noting that

$$P_N(r + dr) = P_N(r) + \frac{dP_N}{dr}dr\,,$$

we find

$$-\left[P_{rr} + \frac{dP_{rr}}{dr}dr\right] l_z(r + dr)d\varphi + P_{rr}(r) l_z r\,d\varphi + P_{\varphi\varphi} l_z\,dr\,d\varphi = 0\,,$$

whence we obtain Eqn (2), which can also be rewritten

$$\frac{d(rP_N)}{dr} = P_T\,, \tag{3}$$

or

$$\frac{d(r^2P_N)}{dr} = r(P_N + P_T)\,.$$

The mechanical equilibrium condition (2) is sometimes used in the form[25]

$$\frac{dP_N}{dr} = (P_T - P_N)k_1(r)\,, \tag{4}$$

where $k_1(r) = 1/r$ is the curvature of the interface.

The integral form of the equilibrium Eqn (4) is

$$P_\alpha - P_\beta = \int_{R_\beta}^{R_\alpha} [P_T(r) - P_N(r)]k_1(r)\,dr\,, \tag{5}$$

with integration limits R_α and R_β in the region of the macroscopic phases where the difference $(P_T - P_N)$ is zero, since the pressures P_T and P_N are P_α and P_β in the phases α and β respectively. Eqn (5) can also be obtained by integrating Eqn (3):

$$P_\alpha R_\alpha - P_\beta R_\beta = \int_{R_\beta}^{R_\alpha} P_T(r)\,dr\,. \tag{6}$$

Interfacial tension. Using the method of Gibbs excesses[8] we shall replace the real open subsystem containing a cylindrical interface (Fig. 5*a*) by an idealised system (Fig. 5*b*) including two reference phases α and β and an interface (according to Gibbs) having an arbitrary radius R.

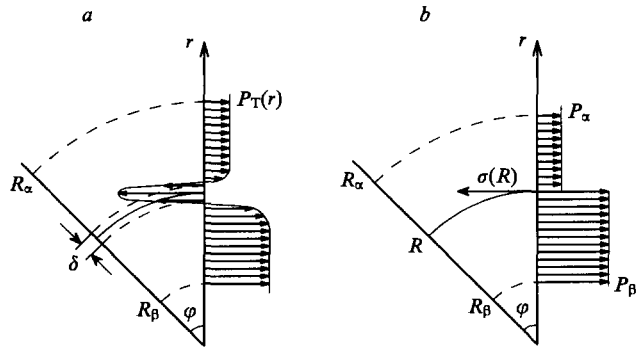

Figure 5. Definition of the interfacial tension of a cylindrical interface: (*a*) distribution of the pressure component $P_T(r)$ near the interface; (*b*) result of replacing the interface by a Gibbs cylindrical dividing surface.

The mechanical moment M applied by the real system to the right-hand (mobile) wall is

$$M = \int_{R_\beta}^{R_\alpha} P_T(r) r\,dr\,. \tag{7}$$

The mechanical moment is referred to unit length l_z of the cylindrical layer of the system (see Fig. 3).

The idealised system acts on a unit length of the mobile wall with a mechanical moment M^{id} equal to

$$M^{id} = \int_{R_\beta}^{R} P_\beta r\,dr + \int_{R}^{R_\alpha} P_\alpha r\,dr - \sigma(R)R\,, \tag{8}$$

where $\sigma(R)$ is the interfacial tension of the cylindrical surface of radius R. From the condition of mechanical equivalence between the idealised and the real system, i.e. for $M^{id} = M$, we obtain the following expression for the interfacial tension

$$\sigma(R) = \int_{R_\beta}^{R} [P_\beta - P_T(r)]\frac{r}{R}dr + \int_{R}^{R_\alpha} [P_\alpha - P_T(r)]\frac{r}{R}dr\,. \tag{9}$$

According to Kondo[26] the function $\sigma(R)$ has a single minimum σ_t at a radius R_t of the cylindrical surface, which Gibbs called the tension surface.[8]

The fundamental equation of the system containing a cylindrical interface. We shall derive the fundamental equation of a system containing a curved interface by considering the element of volume $ABCDA'B'C'D'$ shown in Fig. 3, of thickness $AA' = h$

and having a base area $A(r) = rl_z\,d\varphi$. The work done by the external forces in deforming this volume (at constant T and μ_i) is

$$\delta W = -P_N(r)A(r)\delta r - P_T(r)h\,\delta A(r)$$
$$= -P_N(r)\delta V + [P_N(r) - P_T(r)]h\,\delta A(r)\,, \qquad (10)$$

where $\delta V = A(r)\delta r + h\,\delta A(r)$ is the variation of the volume. Integrating (10) over the whole volume of the open subsystem gives

$$\Omega = \left\{-\int_{R_\beta}^{R_\alpha} P_N(r)r\,dr + \int_{R_\beta}^{R_\alpha}[P_N(r) - P_T(r)]r\,dr\right\}\varphi$$
$$= \left[\int_{R_\beta}^{R_\alpha} P_T(r)r\,dr\right]\varphi\,. \qquad (11)$$

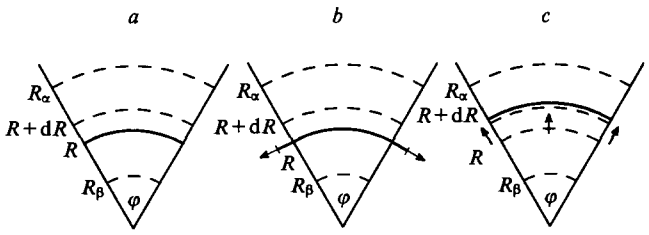

Figure 6. Derivation of the fundamental equation of a system containing a curved cylindrical surface of radius R. The deformation of the dividing surface produced by a change in the radius of curvature from R to $R + dR$ (*a*) includes the work of simple extension of the surface for constant R (*b*) and the work of simple bending of the surface for constant area (*c*).

Let us now consider an element of volume of the idealised system (Fig. 6) including a cylindrical interface of radius R, and let us calculate the work δW performed by the external forces in deforming this surface. It can be arbitrarily divided into four parts: the work of deformation of the phase α ($-P_\alpha\delta V_\alpha$, Fig. 6*a*), the work of deformation of the phase β ($-P_\beta\delta V_\beta$, Fig. 6*a*), the work of simple expansion of the interface with a constant radius of curvature $R[\sigma(R)\delta A(R)$, Fig. 6*b*], the work of simple bending of the interface with a constant area and a change in curvature of δk_1 ($C_1\delta k_1$, Fig. 6*c*).†

Thus the work of the external forces during the deformation of an element of volume of the idealised system (which includes the interface) can be written

$$\delta W = -P_\beta\,\delta V_\beta - P_\alpha\,\delta V_\alpha + \sigma(R)\delta A(R) + c_1A(R)\delta k_1\,. \qquad (12)$$

The fundamental equation for this system in the general case is

$$d\Omega^{id} = -S\,dT - \sum_i N_i\,d\mu_i - P_\beta dV_\beta - P_\alpha dV_\alpha$$
$$+\sigma(R)dA(R) + c_1A(R)dk_1\,, \qquad (13)$$

where S is the entropy of the open system.

By integrating this equation over the extensive parameters we obtain an expression for the grand thermodynamic potential of the idealised system:

$$\Omega^{id} = -P_\beta V_\beta - P_\alpha V_\alpha + \sigma(R)A(R)\,, \qquad (14)$$

† In the Gibbs terminology[8] the coefficient C_1 has the dimensions of J m^{-1}. Other workers refer this coefficient to unit surface area and express it as $C_1 = c_1A(R)$. In the case of a cylindrical surface the physical significance of the coefficient c_1 is that of a bending moment referred to unit width of the cylindrical surface.

which is easily converted into a form convenient for a comparison with Eqn (11):

$$\Omega^{id} = \left[-\int_{R_\beta}^{R} P_\beta r\,dr - \int_{R}^{R_\alpha} P_\alpha r\,dr + \sigma(R)R\right]\varphi\,. \qquad (15)$$

From the condition of energy equivalence of the real and the idealised system, $\Omega = \Omega^{id}$, we can obtain the expression (9) for the interfacial tension $\sigma(R)$.

Fundamental equation of a cylindrical separating surface. The separating surface method is based on the presentation of the extensive parameters Ω, S, V, N_i as sums of bulk parts, relating to the reference phases α and β, and excesses, relating to the separating surface. In this convention the fundamental equation (13) of the system can be written as follows for the reference phases:

$$d\Omega = d\Omega_\alpha + d\Omega_\beta + d\Omega_s\,, \qquad (16)$$

where

$$d\Omega_\alpha = -S_\alpha dT - \sum_i N_{i\alpha}d\mu_i - P_\alpha dV_\alpha\,, \qquad (17)$$

and

$$d\Omega_\beta = -S_\beta dT - \sum_i N_{i\beta}d\mu_i - P_\beta dV_\beta\,, \qquad (18)$$

where

$$d\Omega_s = -S_s dT - \sum_i N_{is}d\mu_i + \sigma(R)dA(R) + c_1A(R)dk_1 \qquad (19)$$

is the fundamental equation of the free curved (cylindrical) separating surface.

Eqn (19) differs from the corresponding equation for a planar separating surface[22] by the term $c_1A(R)dk_1$, equal to the work done by the external forces during the simple bending of the separating surface, and also by the dependence of the interfacial tension $\sigma(R)$ on the localisation of the curved separating surface. We note that the fundamental equation of the planar interface contains the interfacial tension σ_0, which is invariantly related to the position of the separating surface.[22]

The Gibbs–Duhem equation for a cylindrical separating surfaces. Integrating Eqn (19) over the parameter $A(R)$ for constant T, μ_i, and k_i gives

$$\Omega_s = \sigma(R)A(R)\,. \qquad (20)$$

By differentiating Eqn (20) and combining it with (18) we obtain the Gibbs–Duhem equation for this surface,

$$A(R)d\sigma(R) = -S_s dT - \sum_i N_{is}d\mu_i + c_1A(R)dk_1\,,$$

which can be written

$$d\sigma(R) = -s_s dT - \sum_i \Gamma_i\,d\mu_i + c_1dk_1\,, \qquad (21)$$

where $s_s = S_s/A(R)$ and $\Gamma_i = N_{is}/A(R)$ are the entropy excess and the excess in the number of moles of the ith component respectively referred to unit area of the separating surface.

Unlike the Gibbs–Duhem equation for a flat interface Eqn (21) is not invariant with respect to the position of the curved separating surface.[22]

Eqn (21) defines the relationship between the excesses of the thermodynamic quantities, but it contains no information on the condition of the equilibrium between this separating surface and the bulk reference phases α and β. This equilibrium condition can

be obtained only from the fundamental equation for the whole system containing the curved interface.

Fundamental equilibrium equation of a system containing a cylindrical interface. This equation can be obtained by minimising the grand thermodynamic potential of the system (13). The minimisation can be carried out by two methods: the imaginary displacement of the separating surface, i.e. a change in the radius R of this surface for a fixed physical state of the system, determined by the parameters T, μ_i, P_α, and P_β (Kondo's method[26]), or a real deformation of the separating surface with changes in the physical parameters P_β and P_α but constant T and μ_i (the method of Gibbs[8]).

Both methods lead to the same final equilibrium equation for a system containing a cylindrical interface.

By using Kondo's method,[26] i.e. by varying the grand thermodynamic potential of the system Ω^{id} in Eqn (14) over the radius R of the separating surface and equating the variation $\sigma\Omega^{id}$ to zero, we obtain

$$-P_\beta\left\{\frac{\partial V_\beta}{\partial R}\right\}\delta R - P_\alpha\left\{\frac{\partial V_\alpha}{\partial R}\right\}\delta R + \sigma R\left\{\frac{\partial A(R)}{\partial R}\right\}\delta R + A(R)\left\{\frac{\partial\sigma(R)}{\partial R}\right\}\delta R = 0\,,$$

where the braces denote a virtual differentiation. Allowing for the self-evident geometric relations

$$\frac{\partial V_\beta}{\partial R} = A(R)\,;\quad \frac{\partial V_\alpha}{\partial R} = -A(R)\,;\quad \frac{\partial A(R)}{\partial R} = \frac{A(R)}{R}\,; \tag{22}$$

we can convert the resulting equation into the fundamental equilibrium condition for a system containing a cylindrical separating surface:

$$\frac{\sigma(R)}{R} + \left\{\frac{\delta\sigma(R)}{\partial R}\right\} = P_\beta - P_\alpha\,. \tag{23}$$

For the tension surface, where $\partial\sigma(R)/\partial R = 0$, $R = R_t$, and $\sigma(R_t) = \sigma_t$ (the subscript t denoting quantities referred to the tension surface) we obtain from (23) the Laplace equation for a cylindrical tension surface:

$$\frac{\sigma_t}{R_t} = P_\beta - P_\alpha\,. \tag{24}$$

By minimising Eqn (13) with respect to δR (for a real deformation of the interface) with constant T and μ_i we arrive at

$$-P_\beta\frac{\partial V_\beta}{\partial R}\delta R - P_\alpha\frac{\partial V_\alpha}{\partial R}\delta R + \sigma R\frac{\partial A(R)}{\partial R}\delta R + c_1 A(R)\frac{\partial k_1}{\partial R}\delta R = 0\,.$$

Using the geometric relations (22) we can convert this equation into the fundamental equilibrium equation for a system containing a cylindrical separating surface:

$$\frac{\sigma(R)}{R} + c_1\frac{\partial k_1}{\partial R} = P_\beta - P_\alpha\,. \tag{25}$$

According to Gibbs[8] a separating surface having a zero bending moment is called a tension surface. On such a surface $c_1 = 0$, and Eqn (25) yields the Laplace equation (24).

Since according to the Gibbs–Duhem equation (21) we can write

$$c_1 = \left.\frac{\partial\sigma(R)}{\partial k_1}\right|_{T,\,\mu_i}\,, \tag{26}$$

Eqn (25) can be expressed as

$$\frac{\sigma(R)}{R} + \frac{\partial\sigma(R)}{\partial R} = P_\beta - P_\alpha\,. \tag{27}$$

Unlike Eqn (23) this equation contains the real derivative $\partial\sigma(R)/\partial R$.

By using the obvious relationship

$$\frac{\partial k_1}{\partial R} = -\frac{1}{R^2} = -k_1^2$$

we can convert (25) into

$$k_1\sigma(R) - c_1k_1^2 = P_\beta - P_\alpha\,, \tag{28}$$

which is known as the Gibbs–Kelvin equation for a system containing a cylindrical separating surface.[9, 25] For a tension surface ($c_1 = 0$) the Gibbs–Kelvin equation is converted into the simpler Laplace equation

$$k_1\sigma_t = P_\beta - P_\alpha\,. \tag{29}$$

We note that Boruvka and Neumann[19] have doubted the validity of Eqn (28). They suggest that in the case of cylindrical surfaces the Laplace equation (29) is satisfied for any position of the separating surface.

The problem of determining the interfacial tension of curved surfaces. During the last decade the work of Boruvka and Neumann[19] has been widely quoted and discussed in relation to proposed generalisations of the Laplace equation to include non-spherical surfaces.[15, 16, 20, 21] Let us examine the main topics of these discussions.

By using their fundamental equation for a system containing a non-spherical interface with two different principal radii of curvature Boruvka and Neumann[19] obtained a fundamental equilibrium equation for the system (of the Laplace equation type), which in the case of a cylindrical separating surface in any position (i.e. of a surface having only one principal radius of curvature) takes the form

$$k_1\sigma_{BN} = P_\beta - P_\alpha\,. \tag{30}$$

They called σ_{BN} the interfacial tension,[19] and did not consider the possibility of inconsistency between the definitions of interfacial tension given by Eqns (30) and (28). [We shall arbitrarily call the interfacial tension in formula (28) the Gibbs interfacial tension σ_G.] Eqn (28) in the form

$$k_1\sigma_G - c_1k_1^2 = P_\beta - P_\alpha \tag{31}$$

was criticised by Boruvka and Neumann, who believed it to be incorrect. The resulting controversy[20, 21] was widened by Markin et al.,[16] who pointed out that the interfacial tensions σ_G and σ_{BN} in the expressions (30) and (31) are defined in different ways, and therefore the two formulae for the generalised Laplace equation of non-spherical surfaces are both correct if allowance is made for the difference between σ_G and σ_{BN}. These workers[16] obtained expressions for σ_G and σ_{BN} within the scope of local thermodynamics and established a relationship between these quantities. For a cylindrical separating surface this relationship is

$$\sigma_G = \sigma_{BN} + c_1k_1\,. \tag{32}$$

We shall examine the physical meaning of the definitions of σ_G and σ_{BN} by considering a cylindrical separating surface.

From the fundamental Eqn (19) we obtain an expression for σ_G which is identically equal to $\sigma(R)$ for a cylindrical surface:

$$\sigma_G = \left.\frac{\partial\Omega_s}{\partial A}\right|_{T,\,\mu_i,\,k_1}\,. \tag{33}$$

A special feature of this definition is that the interfacial tension σ_G is interpreted as the increment of the specific excess of the grand thermodynamic potential resulting from an increase in the area $A(R)$ of a curved (rather than a planar) separating surface

having a constant curvature $k_1 = 1/R$. This means that σ_G includes both the intrinsic work of formation of a new separating surface and the work done in bending it. In fact, the interfacial tension σ_G is defined in terms of a reference system which includes the two phases β and α (with different hydrostatic pressures P_β and P_α: $P_\beta > P_\alpha$, see Fig. 2) and the curved separating surface.

Boruvka and Neumann used as a standard a hypothetical state of the system in which the interfacial surface has a zero curvature but the pressures in the phases α and β are different. In spite of the fact that this state of the system is not realisable in practice it allows an unambiguous definition of the interfacial tension, which we shall arbitrarily denote σ_{BN}:

$$\sigma_{BN} = \int_{R_\beta}^{R} [P_\beta - P_T(r)]dr + \int_{R}^{R_\alpha} [P_\alpha - P_T(r)]dr \,. \tag{34}$$

We note that an expression for σ_G [Eqn (9)] was obtained by using the principle of mechanical equivalence of the real and the idealised system, i.e. by equating the moments of the forces M and M^{id}, and that the expression for σ_{BN} follows formally from the condition of equality of the forces f and f^{id} which act on the side surface separating the real from the idealised system:

$$f = \int_{R_\beta}^{R_\alpha} P_T(r)dr \,;\; f^{id} = \int_{R_\beta}^{R} P_\beta dr + \int_{R}^{R_\alpha} P_\alpha dr - \sigma_{BN} \,. \tag{35}$$

According to the fundamental Eqn (19) the work done by external forces in increasing the area $A(R)$ of a cylindrical separating surface of radius R (with constant T, μ_i, and k_1) is $\sigma_G dA(R)$, as shown in Fig. 7*a*. According to Boruvka and Neumann[19] σ_{BN} is defined as the work which must be expended to create a unit area of planar interface by the deformation of the system illustrated in Fig. 7*b* (with constant T, μ_i, P_α, and P_β).

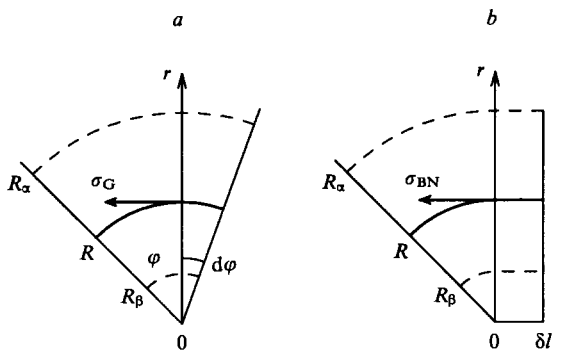

Figure 7. Illustration of the difference between the Gibbs (*a*) and the Boruvka–Neumann (*b*) definition of the interfacial tension.

The following expression has been proposed[19] for the fundamental equation in the case of the cylindrical separating surface:

$$d\Omega_s = -S_s dT - \sum_i N_{is} d\mu_i + \sigma_{BN} dA + c_1 d\tilde{K}_1 \,, \tag{36}$$

where

$$\tilde{K}_1 = \int_A k_1 dA \tag{37}$$

is the extensive parameter of the curvature, corresponding to the work needed to bend the separating surface.

It was also suggested[19, 21] that the free energy Ω_S is a uniform first-order function of the parameter $\tilde{K}_1$. Rowlinson rejected this suggestion,[20] and doubted the validity of the fundamental equation for the separating surface in the form of Eqn (36). The formal thermodynamic definition of σ_N follows from Eqn (36):

$$\sigma_{BN} = \left.\frac{\partial \Omega_s}{\partial A}\right|_{T, \mu_i, \tilde{K}_1} \,. \tag{38}$$

Since in the case of a cylindrical surface the right-hand side of Eqn (37) can be expressed as $k_1 A(R)$ we can apply Euler's theorem of uniform functions to Eqn (36) and write

$$\Omega_s = \sigma_{BN} A + c_1 \tilde{K}_1 \,. \tag{39}$$

By comparing (39) with the expression (20) previously obtained we obtain a relationship between σ_G and σ_{BN} [Eqn (32)]. Thus σ_{BN} is equal to the specific excess free energy at constant T and μ_i referred to unit area of a flat dividing surface, and σ_G includes also the excess free energy associated with the deformation (change in curvature) of the dividing surface.[16]

Dependence of the interfacial tensions on the radius of the dividing surface. The interfacial tensions σ_G and σ_{BN} depend on the method of localisation of the curved surfaces, i.e. on the subjective choice of a radius of curvature R for these surfaces. Analytical expressions for the functions $\sigma_G(R)$ and $\sigma_{BN}(R)$ in the case of cylindrical dividing surfaces can be obtained by using in the calculation an idealised function $P_T^0(r)$ in the form of a rectangular well with parameters Π_0 and Δ (Fig. 8*a*). The superscript '0' shows that the function $P_T^0(r)$ corresponds to a standard state, i.e. a flat dividing surface and pressures $P_\alpha = P_\beta$. Increasing the pressure P_β gives the function $P_T^0(r)$ a new form (Fig. 8*b*).

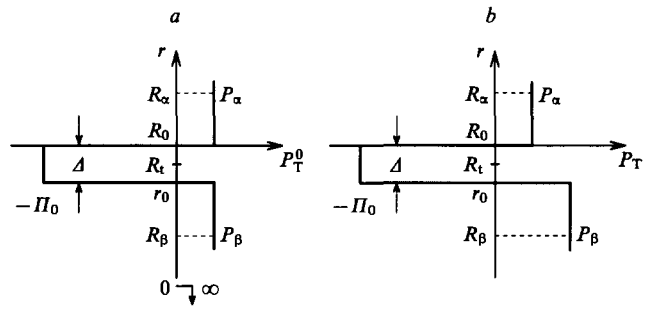

Figure 8. Representation of the function $P_T(r)$ as a rectangular well for a flat (*a*) and a curved interface (*b*).

One of the problems met when studying the bending of the interfacial surface is the ambiguous dependence of the parameters of the function $P_T(r)$ on the pressure P_β. In particular, it is not clear whether an increase in the pressure P_β affects the depth of the minimum (Π_0) in the $P_T(r)$ curve or the width Δ of the rectangular well, and we cannot describe the lower branch of the $P_T(r)$ curve (on the side of the phase β) analytically even when an analytical form of this curve is known for the $P_T^0(r)$ function when $P_\alpha = P_\beta$.

The interfacial tension σ_G and σ_{BN} can be calculated numerically when a complete and unambiguous description of the function $P_T(r)$ is available for any pressure P_β [i.e. when the function $P_T(r)$ is determined as a functional]. In the calculations shown below it is assumed that the parameters Π_0 and Δ of the function $P_T(r)$ are unaffected by an increase in the pressure P_β.

In particular, if the physical radius of the drop (in this case, a 'cylindrical' drop) is known, i.e. if we know the distance from the axis of curvature to some characteristic point of the $P_T(r)$ curve (which could be the radius r_0 or R_0 in the case of the rectangular well shown in Fig. 8*b*), we can use the hydrostatic equilibrium condition ($\operatorname{div} \hat{P} = 0$) to determine unambiguously the function

$P_N(r)$, and if the pressure P_α in the phase α is known the previously unknown pressure P_β in the phase β can be obtained from Eqn (6). Then, once P_β is known, the formulae (9) and (34) can be used to find the interfacial tensions σ_G and σ_{BN} for any radius R of the dividing surface.

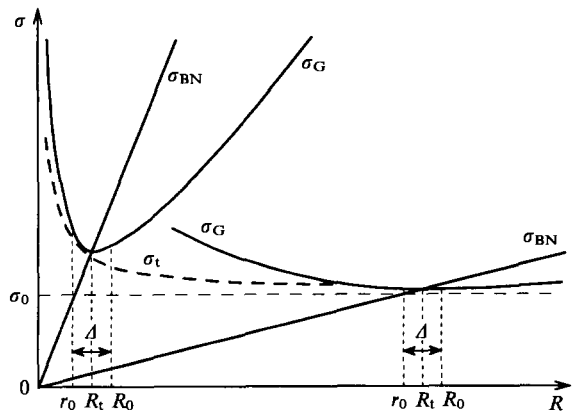

Figure 9. Dependence of the Gibbs and the Boruvka–Neumann interfacial tension on the radius of the cylindrical dividing surface for different values of the radius of the interfacial surface (see Fig. 7): σ_0 is the interfacial tension of the flat surface; R_t is the radius of curvature of the tension surface; $\sigma_t(r_0)$ is the interfacial tension of the Gibbs tension surface.

In Fig. 9 we show the dependence of σ_G and σ_{BN} on the radius of curvature R of the cylindrical dividing surface, calculated for the idealised form of the function $P_T^0(r)$ as a rectangular well with parameters Π_0 and Δ.

The $\sigma_G(R)$ functions calculated by Eqn (9) have a minimum (σ_t) at $R = R_t$ (the radius of the tension surface):

$$\frac{\sigma_G(R)}{R} + \frac{1}{2}\frac{\sigma_0}{r_0}\left(1 - \frac{R_t^2}{R^2}\right) = P_\beta - P_\alpha , \tag{40}$$

where

$$R_t = r_0(1+\alpha)^{1/2} , \tag{41}$$

$$\sigma_t = \sigma_0(1+\alpha)^{1/2} , \tag{42}$$

$$\sigma_0 = \int_{R_\beta}^{R_\alpha} [P_\alpha - P_T^0(r)]\mathrm{d}r = (\Pi_0 + P_\alpha)\Delta , \tag{43}$$

$$\alpha = \frac{\Delta}{r_0} .$$

We note an interesting property of the $\sigma_G(R)$ function. When the physical radius r_0 of the interface is decreased the radius of the tension surface R_t remains within the limits of the transitional interface layer, i.e. the system satisfies the condition

$$r_0 < R_t < R_0 = r_0 + \Delta ,$$

according to which the difference $\delta_t = R_t - r_0$ decreases from $\delta_t = \Delta/2$ for $r_0 \gg \Delta$ to zero for $r_0 \to 0$. Thus we may assume that the tension surface is almost indistinguishable from the Gibbs 'detachment surface', corresponding to a maximum density gradient in the inner phase. The interfacial tension σ_t increases as the radius r_0 decreases [see Eqn (42) and Fig. 9]. Eqn (40) is a generalised form of the Laplace equation, which in the case of the tension surface takes the simple form

$$\frac{\sigma_t}{R_t} = P_\beta - P_\alpha .$$

The interfacial tension σ_{BN} obtained from Eqn (34) is

$$\sigma_{BN} = \sigma_0 \frac{R}{r_0} . \tag{44}$$

The plots of the function $\sigma_{BN}(R)$ intersect those of $\sigma_G(R)$ at their minima (see Fig. 9). Under these conditions

$$\sigma_{BN}(R) = \sigma_t = \frac{\sigma_0 R_t}{r_0} .$$

Thus we may conclude that the Gibbs (σ_G) and the Boruvka–Neumann (σ_{BN}) interfacial tensions are indistinguishable for a tension surface of radius R_t.

With respect to this special property of the $\sigma_G(R)$ and $\sigma_{BN}(R)$ functions we note that some workers[10, 11, 14, 15] have calculated the radius of curvature R_t of the tension surface from the condition of simultaneous fulfilment of the equalities

$$f = f^{id} \quad \text{and} \quad M = M^{id} ,$$

but (as shown above) the condition $M = M^{id}$ leads to the Gibbs definition of the interfacial tension (σ_G) whereas the condition $f = f^{id}$ leads to the Boruvka–Neumann definition (σ_{BN}). Thus in that work the radius of curvature of the tension surface is obtained from the equality condition $\sigma_G(R_t) = \sigma_{BN}(R_t) = \sigma_t$.

For a cylindrical interfacial surface the generalised Laplace equation[19] is

$$\frac{\sigma_{BN}(R)}{R} = P_\beta - P_\alpha$$

for any radius of curvature R of the dividing surface (not only for the tension surface radius R_t) as function of $\sigma_G(R)$. The relationship between σ_G and σ_{BN} is obtained from Eqns (40) and (44):

$$\sigma_G = \frac{1}{2}\sigma_{BN}\left(1 + \frac{R_t^2}{R^2}\right) . \tag{45}$$

The choice of a standard state of the system in the determination of the interfacial tension. The difference between σ_G and σ_{BN} is significant (for all radii R of the dividing surface within the region $r_0 \leqslant R \leqslant r_0 + \Delta$) only when $r_0 \approx \Delta$ (a value typical of micelles and of nuclei of a new phase). A correct choice of the optimum reference system and of its standard state is very important for the thermodynamic description of these objects. The choice affects both the determination of the interfacial tension and the construction of the fundamental equation of the system and of the fundamental equilibrium equation in the most suitable form.

For example, in the Gibbs approach to the determination of σ_G [Eqn (9)] the fundamental equation for a cylindrical dividing surface (19) takes its simplest form for the tension surface of radius R_t:

$$\mathrm{d}\Omega_s = -S_s\mathrm{d}T - \sum_i N_{is}\mathrm{d}\mu_i + \sigma_t\,\mathrm{d}A_t ,$$

where $A_t = A(R_t)$ is the area of the tension surface, so that the excess in the grand thermodynamic potential is

$$\Omega_s = \sigma_t A_t ,$$

and the equilibrium equation of the system containing a cylindrical interfacial surface is the Laplace equation (24).

However, the interfacial tension σ_t and the radius of the tension surface are themselves dependent on the physical radius r_0 of the interfacial surface [see Fig. 9 and Eqns (41) and (42)], which complicates practical calculations of capillary effects.

Another method of determining the interfacial tension for a cylindrical surface relies on choosing as the standard state a state of the reference system for which $P_\beta^0 = P_\alpha^0$ and the interface is flat. The $P_T^0(r)$ function which corresponds to this interfacial surface is assumed to be known.

The deformation of a system containing a cylindrical interfacial surface can be arbitrarily divided into three stages: (1) the conversion of the curved surface into a flat surface by an imaginary change in the physical state of the system, i.e. by lowering the pressure from P_β to P_α^0; (2) stretching the flat interface to a new (larger) area; (3) bending the new surface to a new radius of curvature. Finally, by summing the amounts of work done in the three stages we obtain the fundamental equation for the excess in the grand thermodynamic potential (at constant T and μ_i) in the form

$$d\Omega_s = \sigma_0 dA_0 + dW_b(r_0) , \tag{46}$$

in which the dividing surface has a radius r_0, and the term $dW_b(r_0)$ is the work of bending the interface for an infinitesimally small change in curvature (the subscript b denotes a characteristic of the bending).

When the function $P_T^0(r)$ is modelled by a rectangular well (see Fig. 8) the work of bending $dW_b(r_0)$ for the cylindrical surface is zero. This follows from the fact that the interfacial tension σ_G calculated by Eqn (9) is independent of the pressure P_β and equal to σ_0. In this case Eqn (46) becomes

$$d\Omega_s = \sigma_0 dA_0 , \tag{47}$$

and the corresponding fundamental equation for the equilibrium of a system containing a cylindrical interface,

$$\frac{\sigma_0}{r_0} = P_\beta - P_\alpha^0 , \tag{48}$$

reduces to the Laplace equation (24), except that the pressure P_β is treated as arbitrary (not standard) and the interfacial tension σ_0 refers to a flat dividing surface with $P_\beta^0 = P_\alpha^0$.

We should stress the following advantages of the proposed thermodynamic description of a system containing a cylindrical interfacial surface which postulates a $P_T^0(r)$ function in the form of a rectangular well: (1) the dividing surface is identified with a physical surface of radius r_0 rather than with a tension surface of radius $R_t = r_0(1 + \Delta/r_0)^{\frac{1}{2}}$ (which depends on the radius of curvature r_0); (2) the interfacial tension σ_0 stays constant when the interface is bent, unlike the interfacial tension $\sigma_t = \sigma_0(1 + \Delta/r_0)^{\frac{1}{2}}$, which depends also on the radius of curvature r_0; (3) the Laplace equation is in its simplest form, and therefore makes the method very attractive for the thermodynamic description of systems in which the interfacial surface has a small radius of curvature.

When $P_T^0(r)$ is a function of arbitrary form the work of bending the dividing surface in (46) can be expressed as

$$dW_b(r_0) = c_1^0 A_0 dr_0 , \tag{49}$$

where

$$c_1^0 = \frac{1}{A_0}\frac{\partial \Omega_s}{\partial r_0}\bigg|_{T, \mu_i, A_0} .$$

The parameter r_0 must be chosen so as to make the interfacial tension $\sigma(R)$ equal to σ_0. We shall arbitrarily call this dividing surface a standard dividing surface.

2. Spherical free interfaces

Spherical free interfaces are characterised by two identical principal radii of curvature: $R_1 = R_2 = R$ (Fig. 10).

The work done by the tangential pressure $P_T(r)$ during changes in volume of a system containing a surface of this type (as a result of infinitesimally small changes $d\varphi_1$ and $d\varphi_2$ in the angles φ_1 and φ_2 at constant T and μ_i) can be expressed as

$$dW = \int_{R_\beta}^{R_\alpha} P_T(r) r\, d\varphi_1 r\, d\varphi_2 dr . \tag{50}$$

Replacing this real system by an idealised model formed by two reference phases α and β with a spherical dividing surface of

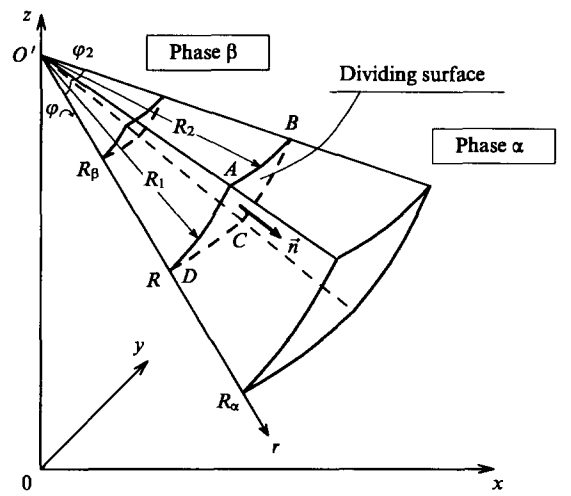

Figure 10. Element of volume of a system containing a spherical interface.

radius R gives an expression for the work dW^{id} in the form [see Eqn (15)]

$$dW^{id} = \left\{\int_{R_\beta}^{R} P_\beta r^2 dr + \int_{R}^{R_\alpha} P_\alpha r^2 dr - \sigma(R)R^2\right\} d\varphi_1 d\varphi_2 . \tag{51}$$

It follows from the condition of mechanical equivalence of the real system and of its idealised model.[11, 26] that

$$\sigma(R) = -\int_{R_\beta}^{R} [P_T(r) - P_\beta]\frac{r^2}{R^2} dr - \int_{R}^{R_\alpha} [P_T(r) - P_\alpha]\frac{r^2}{R^2} dr . \tag{52}$$

The fundamental equation of a system containing a spherical free interface is given as

$$d\Omega = -S dT - \sum_i N_i d\mu_i - P_\beta dV_\beta - P_\alpha dV_\alpha + \sigma(R) dA(R) + cA(R) dk , \tag{53}$$

where c is a coefficient for the differential of the average curvature k:

$$k = k_1 + k_2 = \frac{1}{R_1} + \frac{1}{R_2} = \frac{2}{R} . \tag{54}$$

Eqn (53) is the analogue of the fundamental equation for a cylindrical surface (13), but the coefficients c and c_1, and also the interfacial tensions, are differently defined in the two equations.

As in the case of the cylindrical surface we can obtain a fundamental equation for a spherical free dividing surface,

$$d\Omega_s = -S_s dT - \sum_i N_i d\mu_i + \sigma(R) dA(R) + cA(R) dk , \tag{55}$$

and the Gibbs–Duhem equation for this surface

$$d\sigma(R) = -s_s dT - \sum_i \Gamma_i d\mu_i + c\, dk . \tag{56}$$

By minimising the free energy in Eqn (53) through variations of the radius of curvature of the dividing surface we obtain the fundamental equilibrium equation of a system containing a spherical interface:

$$\frac{2\sigma(R)}{R} + c\frac{\partial k}{\partial R} = P_\beta - P_\alpha , \tag{57}$$

which reduces (allowing for the self-evident geometric relation $\partial k/\partial R = -k^2/2$) to an equation of the Gibbs–Kelvin type for a spherical surface,

$$k\sigma(R) - \tfrac{1}{2}ck^2 = P_\beta - P_\alpha . \tag{58}$$

For $c = 0$ (the condition for which the Gibbs tension surface is defined[8]) we obtain form (58) the familiar Laplace equation for a spherical surface

$$\frac{2\sigma_t}{R_t} = P_\beta - P_\alpha \,. \tag{59}$$

For the tension surface the fundamental equation of a system containing a spherical interface becomes[11]

$$d\Omega = -S\,dT - \sum_i N_i\,d\mu_i - P_\beta dV_\beta - P_\alpha dV_\alpha + \sigma_t dA_t \,. \tag{60}$$

Eqn (52) is the definition of the interfacial tension which may be called the Gibbs interfacial tension.[16] It is obtained from the condition of equality of the mechanical moments of the pressure forces $M = M^{id}$ acting in a plane drawn within an element of spherical volume (Fig. 10) of the real and of the idealised system respectively.

In the case of a spherical surface the Boruvka–Neumann interfacial tension,[19] defined by Eqn (34), does not follow from the condition of equality of the forces f and f^{id} acting on the side surface which limits the element of volume (see Fig. 10) of the real and the idealised system respectively, as it does in the case of a cylindrical interface.

On the other hand we obtain from the condition $f = f^{id}$ a new definition of the interfacial tension, denoted by the symbol σ_f:

$$\sigma_f(R) = \int_{R_\beta}^{R} [P_\beta - P_T(r)]\frac{r}{R}dr + \int_{R}^{R_\alpha} [P_\alpha - P_T(r)]\frac{r}{R}dr \,. \tag{61}$$

This parameter differs from the Gibbs and the Boruvka–Neumann interfacial tensions for spherical surfaces [Eqns (52) and (34), respectively], though its form is consistent with the expression (33) for σ_G in the case of a cylindrical surface.

Thus in the case of spherical dividing surfaces the interfacial tension can be defined in three ways: as σ_G, σ_f, or σ_{BN}. These quantities are different functions of the radius R of the spherical dividing surface. Some workers[10, 14, 19, 21] ignore this difference, or at least they fail to allow for it adequately: this accounts for the different version of the Gibbs–Kelvin equation which had been proposed.

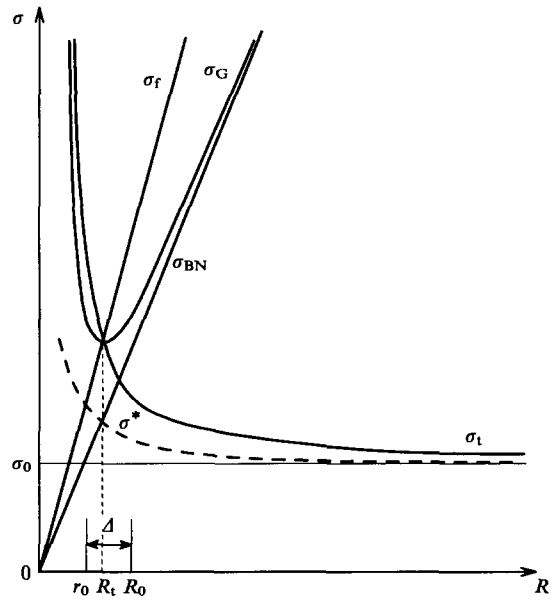

Figure 11. Dependence of the Gibbs and the Boruvka–Neumann interfacial tension and of σ_f [defined by Eqn (61)] on the radius of the spherical interface for $r_0 = \Delta$ (see Fig. 7): σ_0 is the interfacial tension of the flat surface; σ_t is the interfacial tension of the tension surface as a function of the radius of curvature r_0; σ^* is the interfacial tension defined by Eqn (37); R_t is the radius of curvature of the tension surface.

The dependences $\sigma_G(R)$, $\sigma_f(R)$, and $\sigma_{BN}(R)$, illustrated in Fig. 11, should be compared with Fig. 9, which shows similar plots of the functions $\sigma_G(R)$ and $\sigma_{BN}(R)$ for a cylindrical dividing surface.

The following relationships which follow from the condition of mechanical equilibrium $\operatorname{div}\hat{P} = 0$ for a spherical surface[10, 15] have also been used to calculate the hydrostatic pressure P_β and the interfacial tensions:

$$\frac{d(r^2 P_N)}{d(r^2)} = P_T \,, \tag{62}$$

$$\frac{dP_N}{dr} = \frac{2}{R}(P_T - P_N) \,, \tag{63}$$

$$\frac{d(r^3 P_N)}{dr} = r^2(P_N + 2P_T) \,. \tag{64}$$

Eqn (63) can also be written[25] as

$$\frac{dP_N}{dr} = k(r)(P_T - P_N) \,, \tag{65}$$

where $k(r) = 2/r$ is the curvature of a spherical dividing surface of radius r. In an integral form Eqn (65) becomes

$$P_\beta - P_\alpha = \int_{R_\beta}^{R_\alpha} [P_N(r) - P_T(r)]k(r)dr \,.$$

Integration of (62) leads to the equation[15]

$$\tfrac{1}{2}(P_\alpha R_\alpha^2 - P_\beta R_\beta^2) = \int_{R_\beta}^{R_\alpha} P_T(r) r\,dr \,.$$

We note that the plots of the functions $\sigma_G(R)$ and $\sigma_f(R)$ intersect at one point, corresponding to the values R_t and σ_t. As reported,[10, 11] the spherical tension surface is defined as the dividing surface which satisfies the condition

$$\sigma_G(R_t) = \sigma_f(R_t) \,, \tag{66}$$

where $\sigma_G(R)$ and $\sigma_f(R)$ are described by Eqns (52) and (61) respectively. Thus the values of R_t and σ_t given by the plots in Fig. 11 are respectively the radius and the interfacial tension of the tension surface. Fig. 11 also shows the $\sigma_t(R_t)$ dependence.

We also note that, in contrast to the cylindrical surface, in a spherical dividing surface the graphs of $\sigma_G(R)$ and $\sigma_{BN}(R)$ do not intersect anywhere.

As was pointed out above, in submicroscopic liquid drops (micelles, vesicles, coacervate drops), characterised by ultra-low interfacial tensions, a very important role is played by the form of the fundamental equation and of the generalised Laplace (or Gibbs–Kelvin) equation. Analytical equilibrium equations of the Gibbs–Kelvin type, obtained for the idealised profile of the $P_T(r)$ component of the hydrostatic pressure tensor shown in Fig. 8*a*, are given below for comparison.

The generalised Laplace equation for the tension surface is

$$\frac{2\sigma_t}{R_t} = P_\beta - P_\alpha \,. \tag{67}$$

Here

$$\sigma_t = \sigma_0\left[(1+\alpha)\left(1+\frac{\alpha}{2}\right)\right]^{2/3} \,,$$

$$R_t = r_0\left[\frac{(1+\alpha)^2}{1+\alpha/2}\right]^{1/3} \,, \tag{68}$$

where $\alpha = \Delta/r_0$, Δ is the width of the transition region, and σ_0 is the interfacial tension of the flat interfacial surface,

$$\sigma_0 = \int_{R_\beta}^{R_\alpha} [P_\alpha - P_T^0(r)]dr \,, \tag{69}$$

where the standard $P_T^0(r)$ function is a rectangular well (Fig. 8*a*), i.e. it corresponds to the condition $P_\alpha = P_\beta$.

For the Boruvka–Neumann interfacial tension[19, 21] the generalised Laplace equation is

$$\frac{2\sigma_{BN}}{R}\left(1+\frac{\alpha}{2}\right) = P_\beta - P_\alpha , \tag{70}$$

where

$$\sigma_{BN} = \sigma_0 \frac{R}{r_0} . \tag{71}$$

For the interfacial tension σ_0 defined by Eqn (69) we have

$$\frac{2\sigma_0}{r_0}\left(1+\frac{\alpha}{2}\right) = P_\beta - P_\alpha . \tag{72}$$

Lastly, for the interfacial tension σ^*, defined by the expression

$$\sigma^* = \int_{R_\beta}^{R_\alpha} [P_\alpha - P_T^0(r)]\frac{r}{r_0}dr = \sigma_0\left(1+\frac{\alpha}{\Delta}\right) , \tag{73}$$

the generalised Laplace equation takes the very simple form

$$\frac{2\sigma^*}{r_0} = P_\beta - P_\alpha . \tag{74}$$

By comparing the generalised Laplace equations for different definitions of the interfacial tension and different radii of the spherical separation surfaces we may conclude that the simplest thermodynamic description of these surfaces is offered by using the interfacial tension σ_0, defined for flat interfaces, and the physical radius of curvature of the surface r_0 [see Eqn (72)]. On the other hand, the advantage of using the interfacial tension σ^* [defined by Eqn (73)] and the radius r_0 [see Eqn (74)] is not clear. In practical calculations of the Gibbs interfacial tension (including calculations of the tension surface) and of the Boruvka–Neumann interfacial tension slight deviations of the radius of the dividing surface from the chosen value (for example, from the value R_t) produce changes in the functions $\sigma_G(R)$ and $\sigma_{BN}(R)$, i.e. they complicate the form of the Laplace equation. However, we should stress that all these remarks are of practical significance only for the interfacial surfaces of submicroscopic objects, having radii commensurate with the transition region of the interfacial surface. For higher values of the radius r_0, i.e. $\alpha \to 0$, all the interfacial tensions are effectively equal.

3. Non-spherical free interfaces with two principal radii of curvature

By analogy with the cylindrical and the spherical interfacial surfaces we shall write the fundamental equation for systems containing a non-spherical free interface with two principal radii of curvature R_1 and R_2 in the form

$$d\Omega = -S\,dT - \sum_i N_i\,d\mu_i - P_\alpha dV_\alpha - P_\beta dV_\beta + \sigma_G dA + c_1 A dk_1 + c_2 A dk_2 , \tag{75}$$

in which $k_1 = 1/R_1$ and $k_2 = 1/R_2$ are the principal values of the surface curvature, c_1 and c_2 are the coefficients of the curvature differentials, and R_1 and R_2 are the radii (i.e the distances along the z axis from the points O_1 and O_2 to the dividing surface, see Fig. 12). Integrating Eqn (75) with respect to the extensive parameters V_α, V_β, and A with constant intensive parameters T, μ_i, k_1, and k_2 yields an expression for the grand thermodynamic potential of the system:

$$\Omega = -P_\alpha V_\alpha - P_\beta V_\beta + \sigma_G A , \tag{76}$$

where A is the area of interfacial surface generated by stretching with constant values of k_1 and k_2, and σ_G has the meaning of a Gibbs interfacial tension.

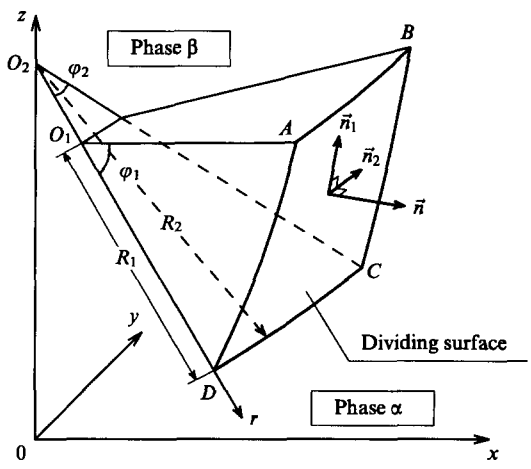

Figure 12. Element of volume of a system containing a non-spherical interface with two different principal radii.

By minimising the grand thermodynamic potential while varying the displacement of the separation surface in the direction of the normal $\vec{n}$ by δR and allowing for the obvious geometric relations

$$\frac{\partial V_\beta}{\partial R} = A ; \quad \frac{\partial V_\alpha}{\partial R} = -A ; \quad \frac{\partial A}{\partial R} = kA ;$$

$$k = k_1 + k_2 ; \quad c_1\frac{\partial k_1}{\partial R} + c_2\frac{\partial k_2}{\partial R} = \frac{\partial \sigma_G}{\partial R} ;$$

we obtain

$$k\sigma_G + \frac{\partial \sigma_G}{\partial R} = P_\beta - P_\alpha . \tag{77}$$

Eqn (77) is the fundamental equilibrium equation for a system containing a non-spherical separation surface.

The fundamental equation of the non-spherical separation surface itself is[8]

$$d\Omega_s = -S_s dT - \sum_i N_{is} d\mu_i + \sigma_G dA + c_1 A dk_1 + c_2 A dk_2 , \tag{78}$$

which should be compared with the equations (19) and (55) for cylindrical and for spherical surfaces respectively.

By applying Euler's theorem of homogeneous functions we find that, by analogy with (21) and (56), the Gibbs–Duhem equation for a non-spherical separation surface is

$$d\sigma_G = -s_s dT - \sum_i \Gamma_i\,d\mu_i + c_1 dk_1 + c_2 dk_2 . \tag{79}$$

We shall now briefly review various approaches to the description of non-spherical free interfaces.

The concepts of average curvature (H) and of differential curvature (D) were first proposed by Gibbs,[8] who defined them as

$$H = \tfrac{1}{2}(k_1 + k_2) \quad \text{and} \quad D = \tfrac{1}{2}(k_1 - k_2) . \tag{80}$$

In these symbols the fundamental equation of the system is

$$d\Omega = -S\,dT - \sum_i N_i\,d\mu_i - P_\alpha dV_\alpha - P_\beta dV_\beta + \sigma_G dA + AB\,dH + A\theta\,dD , \tag{81}$$

where B and θ are the specific bending and torsion moment respectively (referred to unit area of the separation surface):

$$B = c_1 + c_2 , \quad \text{and} \quad \theta = c_1 - c_2 . \tag{82}$$

In his derivation of the fundamental equilibrium equation of the system Gibbs[8] ignored the torsion moment θ (a second-order quantity as compared with the bending moment B: in the case of spherical surfaces the condition $\theta = 0$ applies exactly). By applying also the condition $B = 0$ to the tension surface Gibbs obtained the Laplace equation from the fundamental equation of the system (81) (by minimising the grand thermodynamic potential):

$$k_t\sigma_t = P_\beta - P_\alpha , \tag{83}$$

where

$$k_t = k_{1t} + k_{2t} , \tag{84}$$

and k_{1t} and k_{2t} are the principal curvatures of the tension interface.

Later work on the thermodynamics of non-spherical free interfaces dealt with the effect of the torsion moment θ on the generalised Laplace equation,[15, 16, 19, 21, 25]

Applying the minimisation procedure to Eqn (81) while allowing for the moment θ gives the following fundamental equilibrium equation:[25]

$$2H\sigma_G - B(H^2 + D^2) - 2\theta HD = P_\beta - P_\alpha . \tag{85}$$

Eqn (85) known as the Gibbs–Kelvin equation for non-spherical surfaces.[25] By comparing it with (77) we obtain

$$\frac{\partial\sigma_G}{\partial R} = -B(H^2 + D^2) - 2\theta BD . \tag{86}$$

The condition

$$\frac{\partial\sigma_G}{\partial R} = 0 , \tag{87}$$

corresponding to a minimum in the interfacial tension, takes the form

$$B(H^2 + D^2) + 2\theta BD = 0 . \tag{88}$$

The interface which satisfies the condition (88) is called the surface of minimum tension, in contrast to the Gibbs tension surface, obtained for the condition $B = 0$. Thus Gibbs ignored the term $2\theta HD$ in his definition of the tension surface. Obviously, the spherical surfaces of tension and of minimum tension coincide when $\theta = 0$.

Some workers[16, 19, 21] have suggested replacing H and D by the principal (first) curvature J and the Gaussian (second) curvature K of the surface:

$$J = k_1 + k_2 , \quad \text{and} \quad K = k_1k_2 . \tag{89}$$

In this case the fundamental equation of the system for a nonspherical surface becomes

$$d\Omega = -S\,dT - \sum_i N_i\,d\mu_i - P_\alpha dV_\alpha - P_\beta dV_\beta + \sigma_G dA + AC_1 dJ + AC_2 dK , \tag{90}$$

and the fundamental equilibrium equation of the system is[16]

$$J\sigma_G - C_1(J^2 - 2K) - C_2JK = P_\beta - P_\alpha , \tag{91}$$

where

$$C_1 = \frac{c_1k_1 - c_2k_2}{k_1 - k_2} ; \quad C_2 = \frac{c_1 - c_2}{k_1 - k_2} \tag{92}$$

[the coefficients c_1 and c_2 occur in Eqn (79)].

The condition which defines the interface of minimum tension (88) can be written[16]

$$C_1(J^2 - 2K) + C_2JK = 0 . \tag{93}$$

The Laplace equation is obtained by inserting the condition (93) into (91):

$$k_0\sigma_G^0 = P_\beta - P_\alpha , \tag{94}$$

where $k_0 = J_0 = k_{10} + k_{20}$, k_{10} and k_{20} are the principal curvatures of the minimum tension surface, and σ_G^0 is the minimum tension of the nonspherical surface.

III. Equilibrium of interfaces in the bulk meniscus region of a liquid film

If the separation surfaces in a liquid film are assumed to be surfaces of minimum tension, and allowance is made for the close similarity of σ_G^0 with σ_t for the tension surface with σ_0 for plane-parallel surfaces (when the radius of curvature is much greater than the thickness of the transitional interfacial layer, i.e. in practical terms for $r_0 > 10$ nm) the equilibrium equation (85) becomes

$$k_0\sigma_0 = P_\beta - P_\alpha = \Delta P , \tag{95}$$

where $k_0 = k_1 + k_2$, and k_1 and k_2 are the first and the second principal curvatures of the surface.

1. Invariants of the profile of a liquid film

Since the profile of liquid films is determined experimentally by the topographic method[7] (from interference pictures of the film in reflected monochromatic light) it is convenient to use Eqn (95) in $z(r)$ coordinates (Fig. 13). This gives invariants of the profile of liquid films related to differences in geometry.

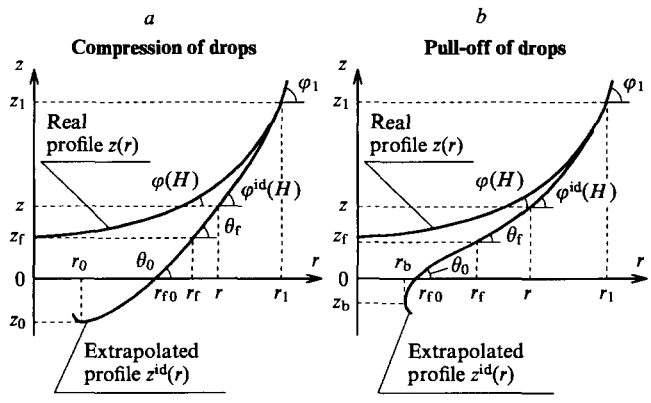

Figure 13. Form of the extrapolated profile of the surface of the liquid film between two liquid drops during compression by an external force (*a*) and pull-off (*b*).

It should be noted that because of the experimental difficulties in determining the real profile of a liquid film in the transition region a hypothetical profile (obtained by extrapolating the profile of the surface with a constant average curvature k_0 in the region of the bulk meniscus to the transition region) is often used in the thermodynamic description instead of the real profile, on the assumption that disjoining pressures are negligible (Fig. 13). This extrapolated (idealised) profile $z^{id}(r)$ differs from the real profile $z(r)$ in the transition region of the film, and coincides with the real profile in the region of the bulk meniscus.

The idealised profile can intersect the plane $z_f = H_f/2$ (where H_f is the thickness of the plane-parallel region of the film, and the subscript f denotes a quantity characteristic of the film) at a contact angle θ_f, or the plane $z = 0$ at a constant angle θ_0, whose values are used to calculate the specific free energy of the interaction in the flat part of the film.

For cylindrical interfaces, which have only one principal radius of curvature, Eqn (95) becomes

$$\sigma_0\frac{d\sin\varphi^{id}(r)}{dr} - \Delta P = 0 , \tag{96}$$

where $\varphi^{id}(r)$ is the local angle, formed by the surface of the idealised profile with the r axis. The equation

$$\frac{dz^{id}(r)}{dr} = \tan\varphi^{id}(r) \tag{97}$$

in conjunction with Eqn (96) forms a system which fully defines the profile of the film $H^{id}(r) = 2z^{id}(r)$ if the following boundary conditions are given: $\varphi^{id}(r) = \varphi_1$ and $z^{id}(r) = z_1$ for $r = r_1$, where r_1 is the radius of the film determined experimentally in the region of the bulk meniscus.

Integrating (96) over the idealised profile z^{id} from $z^{id}(r)$ to z_1 gives

$$\int_{z^{id}}^{z_1} \sigma_0 \frac{d\sin\varphi^{id}(r)}{dr} dz^{id} - \Delta P(z_1 - z^{id}) = 0 . \tag{98}$$

Since $[d\sin\varphi^{id}(r)/dr]dz^{id} = -\cos\varphi^{id}$ we obtain from (98) an invariant which is independent of the film thickness:

$$2\sigma_0\cos\varphi^{id}(r) + \Delta P H^{id}(r) = 2\sigma_0\cos\varphi_1 + \Delta P H_1 = \text{const} . \tag{99}$$

In the case of nonspherical interfaces characterised by two different radii of curvature the Laplace equation (95) becomes

$$\sigma_0 \frac{d\sin\varphi^{id}(r)}{dr} + \sigma_0 \frac{\sin\varphi^{id}(r)}{r} - \Delta P = 0 . \tag{100}$$

Integrating (100) as was done for the cylindrical surface gives an invariant independent of the local thickness of the idealised film profile $H^{id}(r)$:

$$2\sigma_0\cos\varphi^{id}(r) + \Delta P H^{id}(r) + 2\sigma_0 \int_{z^{id}}^{z_1} \frac{\sin\varphi^{id}(r)}{r} dz^{id}$$

$$= 2\sigma_0\cos\varphi_1 + \Delta P H_1 = \text{const} . \tag{101}$$

If the interfacial surface in the liquid film is spherical, i.e. if $k_1 = k_2$, the integral in Eqn (101) reduces to $\Delta P[H_1 - H(r)]/2$, and the invariant of the surface profile of the film takes the form

$$2\sigma\cos\varphi^{id}(r) + \tfrac{1}{2}\Delta P H^{id}(r)$$

$$= 2\sigma_0\cos\varphi_1 + \tfrac{1}{2}\Delta P H_1 = \text{const} . \tag{102}$$

2. Analytical expression for the idealised profile of the liquid film

Let us consider two fluid (liquid or gaseous) particles of the phase β forming a symmetrical liquid film in the phase α. To simplify the discussion we shall ignore the effect of gravity, and assume that the film is stable towards rupture and is not spontaneously thinned.

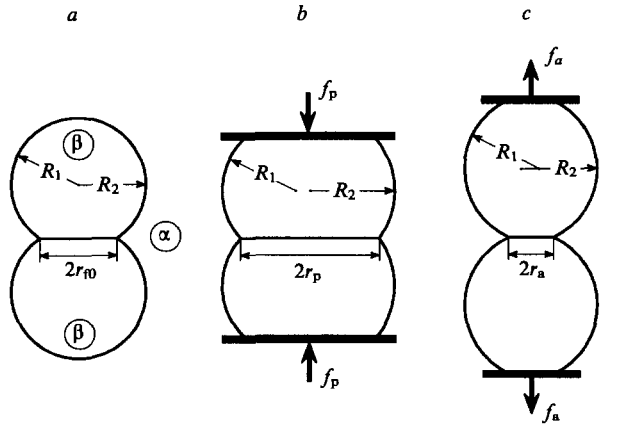

Figure 14. Shape of contacting drops in the absence of an external force (*a*), under compression (*b*), and during pull-off (*c*).

If the fluid particles do not experience an external force f_e (compressive, $f_p > 0$, or stretching, $f_a < 0$) the particles are spherical (Fig. 14*a*), and $k_1 = k_2 = k_0 = 2/R$, where R is the radius of the particles. In this case the profile of the surface of the particles, or the idealised profile of the film surface $z^{id}(r)$ [see Eqn (97)], is described by the equation

$$z^{id}(r) = z_1 - \int_{z^{id}}^{z_1} \tan\varphi^{id}(r) dr$$

$$= z_1 + R[\cos\varphi_1 - \cos\varphi^{id}(r)] . \tag{103}$$

If the particles are compressed by an external force f_p (Fig. 14*b*) the radius of the film increases to r_p, and the surface of the drops is no longer spherical, the radius R_2 increasing and R_1 decreasing. When a tensile force f_a is applied to the drops (Fig. 14*c*) R_2 decreases and R_1 increases.

By re-writing Eqn (100) as

$$\sigma_0 \frac{1}{r}\frac{d}{dr}[r\sin\varphi^{id}(r)] = \Delta P \tag{104}$$

and integrating it from r to r_1 we obtain the equation[1, 4]

$$\sin\varphi^{id}(r) = \frac{k_0}{2}r + \frac{B}{r} , \tag{105}$$

in which

$$k_0 = \frac{\Delta P}{\sigma_0} ,$$

$$B = r_1\sin\varphi_1 - \frac{k_0}{2}r_1^2 . \tag{106}$$

The physical significance of the parameter B can be understood by the following considerations. If the reference radius r_1 is taken to be R_2 (see Fig. 14*a*) we have $\varphi_1 = \pi/2$, and we arrive at the expression

$$B = \frac{k_{20} - k_{10}}{2k_{20}^2} = \frac{1}{k_{20}}\left(1 - \frac{k_0}{2k_{20}}\right) , \tag{107}$$

where k_{10} and k_{20} are the principal values of the curvature of the particle surfaces, corresponding to the 'equator', for which $\varphi_1 = \pi/2$. Obviously, the parameter B can be positive or negative, depending on the sign of the difference $(k_{20} - k_{10})$.

We shall now obtain expressions for the contact forces acting on fluid drops for the cases of mutual compression or pull-off.

In the case of a compressive force $f_e = f_p > 0$ the $z^{id}(r)$ profile has a maximum (see Fig. 13*a*) since, when $\varphi^{id}(r_0) = 0$, Eqn (105) has a real solution (allowing for the fact that $B < 0$):

$$r_0 = \sqrt{-\frac{2B}{k_0}} , \tag{108}$$

where k_0 is the average curvature.

From the condition of mechanical equilibrium of the drop we obtain the expression

$$f_p = \pi r_0^2 \Delta P = \pi r_0^2 \sigma_0 k_0 , \tag{109}$$

and in conjunction with (108) this gives

$$f_p = -2\pi\sigma_0 B . \tag{110}$$

The parameter B can be determined experimentally from the interference picture of the film.[27-29] The compressive force can also be determined[4] from Eqn (110). A mechanical interpretation of Eqn (109) is proposed in Fig. 15*a*. Evidently, the outer compressive force f_p is balanced by a pressure force of $\pi r_0^2\sigma_0 k_0$.

If a pull-off force $f_e = f_a < 0$ is applied to the drops (see Fig. 14*c*) it follows from (107) that $B > 0$, and Eqn (105) does not have a real solution for $\varphi^{id}(r) = 0$ [i.e. the profile $z^{id}(r)$ has no minimum].

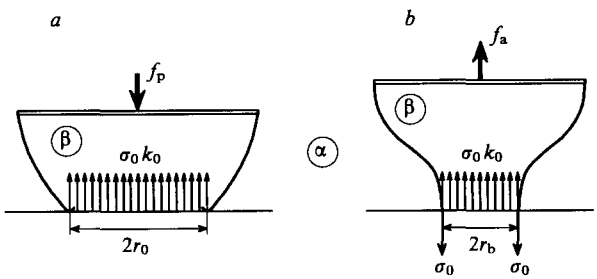

Figure 15. Equilibrium of a liquid drop under the influence of compression (*a*) and extension forces (*b*).

On the other hand for $\varphi^{id}(r) = \pi/2$, Eqn (105), written as

$$1 = \frac{k_0}{2} r + \frac{B}{r} , \tag{111}$$

has two real roots:

$$r_{(1)} = r_b = \frac{1 - \sqrt{1 - 2k_0 B}}{k_0} = \frac{1}{k_0}\left(1 - \frac{k_{10}}{k_{20}}\right) , \tag{112}$$

(see Fig. 13*b* for r_b), and

$$r_{(2)} = \frac{1}{k_{20}} = R_{20} . \tag{113}$$

The geometrical significance of the second root $r_{(2)} = R_{20}$ is illustrated in Fig. 13*b*. A positive value of the first root $r_{(1)} = r_b$ denotes the appearance of a 'neck' in the profile of the drop. Obviously, for $z^{id} = z_b$ (see Fig. 13*b*) the curvature $k_{20} = 1/r_b$ is positive, and $k_{10} = k_0 - k_{20}$ is negative for a positive average curvature k_0.

The relationship between r_b and f_a can be obtained by the following argument (Fig. 15*b*). Since the drop is assumed to be in equilibrium the resultant of all the forces acting on it must vanish. These forces are: the external pull-off force f_a; the interfacial tension force acting on the perimeter of the neck and equal to $-2\pi r_b \sigma_0$; and the hydrostatic pressure force, equal to $\pi r_b^2 \Delta P = \pi r_b^2 \sigma_0 k_0$. Equating their sum to zero gives

$$f_a - 2\pi r_b \sigma_0 + \pi r_b^2 \sigma_0 k_0 = 0 , \tag{114}$$

which becomes, when combined with (111),

$$f_a = 2\pi\sigma_0 \left[r_b - \tfrac{1}{2} k_0 r_b^2\right] = -2\pi\sigma_0 B . \tag{115}$$

Thus in the case of pull-off of the drops the parameter B is proportional to the applied negative force f_a.

Furthermore by using the sign convention for the force f_e, according to which $f_e = f_p > 0$ and $f_e = f_a < 0$, Eqn (110) and (115) can be re-written[4]

$$f_e = -2\pi\sigma_0 B , \tag{116}$$

while Eqn (105) becomes[4]

$$\sin\varphi^{id}(r) = \frac{k_0}{2} r - \frac{f_e}{2\pi\sigma_0} \frac{1}{r} . \tag{117}$$

Thus we may conclude that the extrapolated profile of the liquid film contains information on the external force f_e acting on the drop and on its sign: if $B > 0$ the drop is experiencing a pull-off force, whereas if $B < 0$ the applied force is compressive.

3. Various approximations to the idealised profile of the liquid film

The idealised profile of a curved liquid film (the profile of the film in the region of the bulk meniscus) contains information on the specific free energy of the interaction in the plane-parallel region of the film. Therefore measurements of the profile of these films are one of the main experimental methods of studying the energetics of thin liquid films.

Since the analytical expression for the function $z^{id}(r)$ usually contains elliptical integrals of the second kind various simplifications of the idealised profile have been suggested for practical use.[7, 28, 29] The approximating functions proposed by Kolarov et al.[7, 28] are among the most widely used:

$$z^{id}(r) = ar^2 + b , \tag{118}$$

$$z^{id}(r) = ar^2 + b' \ln r + c , \tag{119}$$

where a, b, b', and c are empirical coefficients, determined by measuring the profile of the film in the region of the bulk meniscus. The contact angles θ_f and θ_0 and the radii r_f and r_{f0} of the curved films (see Fig. 13) are found by extrapolating the approximating functions to the transition region of the film.

We should stress that the approximating functions (118) and (119) are obtained from the strict solution of the system of differential equations (97) and (117) for the following approximations: $\tan\varphi^{id} \simeq \sin\varphi^{id}$ and $f_e = 0$ for Eqn (118) and $\tan\varphi^{id} \simeq \sin\varphi^{id}$ for Eqn (119). For large enough values of the contact angle both these approximating functions are almost identical to the exact function. However, for the contact angles formed by the common black films or by the Newtonian black films, usually in the ranges $\lesssim 1°$ and $1° - 5°$ respectively, replacing the exact functions by the approximating functions can result in erroneous calculations of the contact angles.

In particular, an estimate of the precision of the approximated profile obtained by the functions (118) and (119) for a liquid film having an angle of contact of $\sim 1°$ has been reported.[30] It was shown that the function (119) satisfactorily describes the profile of these films. On the other hand, use of the parabola (118) introduces serious errors in the determination of the contact angles. It was also found[31] that the function (119) is convenient for describing the profiles of films which do not form contact angles θ_0 and θ_f (in the latter case the specific free energy of the interaction in the film is positive). On the other hand the use of the parabola to describe the profile of these films results in the formation of contact angles, i.e. it leads to the erroneous conclusion that the specific free energy is negative in these films.

4. Lens-like thickening in equilibrium with a thin liquid film

A lens-like thickening (or dimple) at the centre of a round liquid film is formed when two fluid drops (liquid or gaseous) are rapidly brought into contact in a liquid medium (Fig. 16*a*) or in the contact region between a drop and a solid surface (Fig. 16*b*).

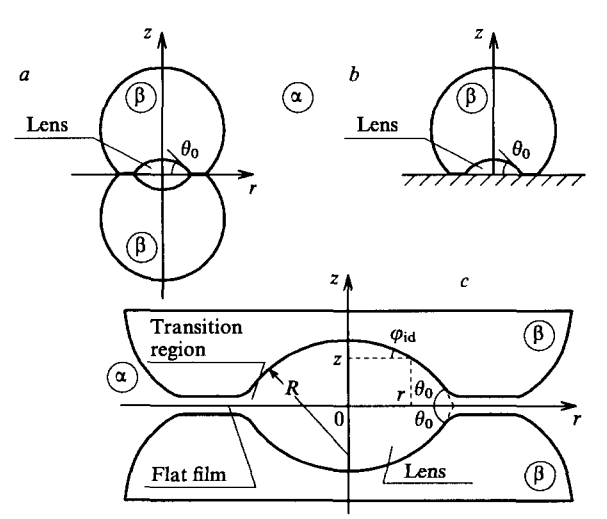

Figure 16. Lens-like thickening produced in the contact region between two fluid drops of phase β in the liquid phase α (*a*) and in the contact region between a fluid drop and a solid surface (*b*); geometric parameters of the liquid lens in equilibrium with the liquid film (*c*).

We shall obtain the equation for the profile of these lenses in the coordinates defined in Fig. 16c.

Since the first and the second principal curvature of the lens profile are given by the expressions

$$k_1 = -\frac{\mathrm{d}\sin\varphi^{\mathrm{id}}(r)}{\mathrm{d}r}\ ;\ k_2 = -\frac{\sin\varphi^{\mathrm{id}}(r)}{r}\ ,$$

the fundamental equilibrium equation (100) is[18]

$$\sigma_0\frac{\mathrm{d}\sin\varphi^{\mathrm{id}}(r)}{\mathrm{d}r} + \sigma_0\frac{\sin\varphi^{\mathrm{id}}(r)}{r} + \Delta P_\alpha = 0\ , \tag{120}$$

where $\Delta P = P_\alpha - P_\beta$ is the difference between the hydrostatic pressures in the lens and in the external medium (phase β).

Eqn (97) becomes

$$\frac{\mathrm{d}z^{\mathrm{id}}(r)}{\mathrm{d}r} = -\tan\varphi^{\mathrm{id}}(r)\ , \tag{121}$$

since $z^{\mathrm{id}}(r)$ decreases when r increases.

By integrating (120) with respect to r from zero to an arbitrary value of r corresponding to the bulk region of the meniscus (or to some point on the idealised profile coinciding with the real profile in the region of the bulk meniscus) we obtain

$$\sin\varphi^{\mathrm{id}}(r) = \tfrac{1}{2}k_0 r\ . \tag{122}$$

This expression is the equation for a region of radius $R = \frac{1}{2}k_0$, where $k_0 = \Delta P_{\mathrm{d}}/\sigma_0$. Extrapolating this profile to its intersection with the r axis gives the contact angle θ_0, which is used to calculate the specific free energy of the interaction in the plane-parallel region of the film.

This method of measuring the contact angle θ_0 is known as the floating lens method.[32] It has been used to measure the specific free energy of the interaction[33] in Newtonian black films of hydrocarbons (bilayer lipid membranes), within which microscopic lenses of liquid hydrocarbons had been formed.

We note that Eqns (120) and (121) are convenient for describing the profile of a liquid drop in contact with a flat solid surface under conditions of zero gravity, when the perturbing effect of the gravity forces on the profile of the drop can be neglected.

5. Vertical liquid films in a gravitational field

The effect of gravity on the form of the profile of liquid films will be examined by considering a vertical liquid film produced by drawing a flat plate (for example, a Wilhelmi plate) out of a liquid phase α into a fluid (liquid or gaseous) phase β (Fig. 17).[34]

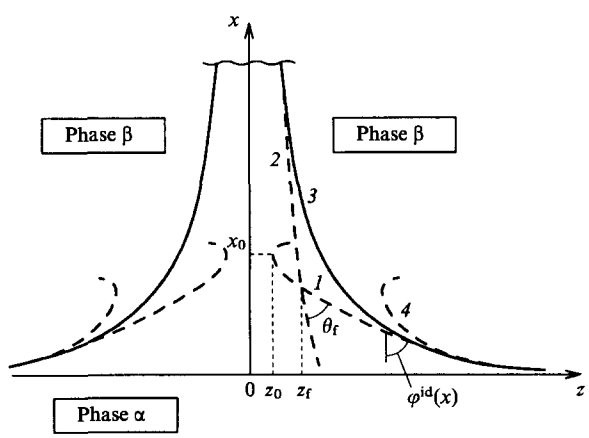

Figure 17. Vertical film in a gravitational force field: *1* and *4*, extrapolated profile of the cylindrical surface; *2*, extrapolated profile of the vertical film; *3*, real surfaces.

In this case the profile of the film in the region of the bulk meniscus is described by the system of equations

$$\sigma_0\frac{\mathrm{d}\sin\varphi^{\mathrm{id}}(x)}{\mathrm{d}x} = \Delta P\ ;\quad \frac{\mathrm{d}z^{\mathrm{id}}(x)}{\mathrm{d}x} = \tan\varphi^{\mathrm{id}}(x) \tag{123}$$

with the boundary conditions $x = 0$ and $\varphi^{\mathrm{id}}(x) = \pi/2$ for $z \to \infty$. Within the liquid film the difference in hydrostatic pressures is

$$\Delta P = P_\beta - P_\alpha = -\Delta\rho g x\ ,$$

i.e. ΔP is now no longer a constant, and Eqn (123), allowing for the chosen direction of the x axis and for the definition of the angle $\varphi^{\mathrm{id}}(x)$, takes the form

$$\frac{\mathrm{d}\sin\varphi^{\mathrm{id}}(x)}{\mathrm{d}x} = -\frac{\Delta\rho g x}{\sigma_0}\ , \tag{124}$$

where $\Delta\rho = \rho_\alpha - \rho_\beta$, and ρ_α and ρ_β are the densities of the phases α and β respectively. Since $\varphi^{\mathrm{id}}(0) = \pi/2$ for $x = 0$, the solution of (124) is

$$\sin\varphi^{\mathrm{id}}(x) = 1 - \frac{x^2}{a^2}\ , \tag{125}$$

where $a = \sqrt{2\sigma_0/\Delta\rho g}$ is the capillarity constant.

The idealised profile of the vertical liquid film in a field of gravity forces can be found by solving Eqn (123) with the boundary conditions $\varphi^{\mathrm{id}}(x) = 0$ and $z^{\mathrm{id}}(x) = z_0$ for $x = x_0$, where $x_0 = a$ [for which the idealised profile $z^{\mathrm{id}}(x)$ has a minimum].

Depending on the sign of the specific free energy of the interaction in the flat part of the film the idealised profile can pass either within the liquid film or outside it, i.e. in the phase β. The method of determining angles of contact in these films has already been discussed in depth.[18, 34]

IV. Thermodynamic description of interacting interfaces in the transition region of a liquid film

The main difficulty in constructing the thermodynamics of interacting interfaces in the transition region of liquid films is the absence of generally accepted views on the disjoining pressure. If the shear components of the generalised pressure tensor $\boldsymbol{P}$ are assumed to be zero in the plane-parallel region of the liquid film, and the tension γ is defined by the expression[22]

$$\gamma = \int_{-\infty}^{+\infty}[P_\beta - P_{\mathrm{T}}(z)]\mathrm{d}z\ , \tag{126}$$

in the transition region (and in particular in the symmetry plane for $z = 0$) the component P_{T} of the pressure tensor varies as a function of the coordinate r from a negative value at the centre of the circular thin liquid film (i.e. at $r = 0$) to a positive value for $r \to \infty$ (i.e. in the region of the bulk meniscus of the film). It is no longer convenient to use the tension γ to construct the fundamental thermodynamic equation of the system in the transition region of the film: firstly, because γ is now a function of the coordinate r, and secondly because shear components of the pressure tensor are now present in the transition region [due to the gradient $P_{\mathrm{T}}(z, r)$], and the relationship (126) ceases to be valid.

Thus we need to develop other approaches to the thermodynamics of the transition region in liquid films.

1. Various definitions of the disjoining pressure

An analysis of recent publications on this topic reveals two points of view on the physical nature of the disjoining pressure and on the mechanism of its action in the transition region of thin liquid films.

The disjoining pressure as a bulk force. According to this model[35–37] the disjoining pressure should be treated as a manifestation of 'forces of the second kind',[38] arising in the region of mutual overlapping of the 'surface forces of the first kind',

i.e. of the two phase separation surfaces (after Gibbs[8]). The disjoining pressure Π, defined by the expression[38]

$$\Pi = P_N - P_\alpha = P_\beta - P_\alpha , \quad (127)$$

is represented as a bulk pressure having tensor properties and existing independently of the separation surfaces of the film. According to this model the action of the disjoining pressure is normal to these surfaces in both the plane-parallel and the transition region of the film[37] (Fig. 18*a*). As a consequence of this model the separation surfaces in the film are treated as non-interacting, and therefore the interfacial tension is assumed to be constant over the whole of the transition region and equal to the interfacial tension σ_0 at the boundary of the bulk phases.[36, 37] The curved separation surfaces, characterised by a constant interfacial tension σ_0, are called 'surfaces of tension' by Eriksson and Toshev:[37] the fundamental equilibrium equation in the transition region of the film becomes[35, 37]

$$\sigma_0 k(H) + \Pi(H) - \Delta P = 0 , \quad (128)$$

where $\Pi(H)$ is the local value of the disjoining pressure (a function of the film thickness H); $\Delta P = P_\beta - P_\alpha$ is the difference between the hydrostatic pressures in the phases β and α; $k(H)$ is the local value of the curvature of the film surface in the transition region.

In the region of the bulk meniscus (Fig. 18*a*) $\Pi = 0$, and from Eqn (128) we obtain the Laplace equilibrium equation $\sigma_0 k_0 = \Delta P$, where k_0 is the constant average curvature of the free curved surface. Eriksson and Toshev[35, 39] define a reference pressure of the Gibbs type at the centre of the circular film, equal to the hydrostatic pressure in the phase β. This assumption formally leads to the creation of a hydrostatic pressure gradient in the transition region, since in the transition region of the bulk meniscus the hydrostatic pressure is P_α. Therefore Eriksson and Toshev[37] introduced into the model an additional force to balance the pressure gradient in the transition region. This expedient produced unnecessary complications in the thermodynamic description of this region of the film, including a number of inconsistencies. For example, the constancy of the interfacial tension σ_0, which follows from the assumption that the action of the disjoining pressure is in a direction normal to the dividing surfaces, is formally incompatible with the Gibbs–Duhem equation,[22] widely used (by Eriksson and Toshev,[37, 39, 40] among others, to describe plane-parallel films):

$$\Pi(H) = -2\frac{\partial\sigma}{\partial H}\bigg|_{T,\mu_i,A} . \quad (129)$$

This contradiction has been pointed out previously.[15]

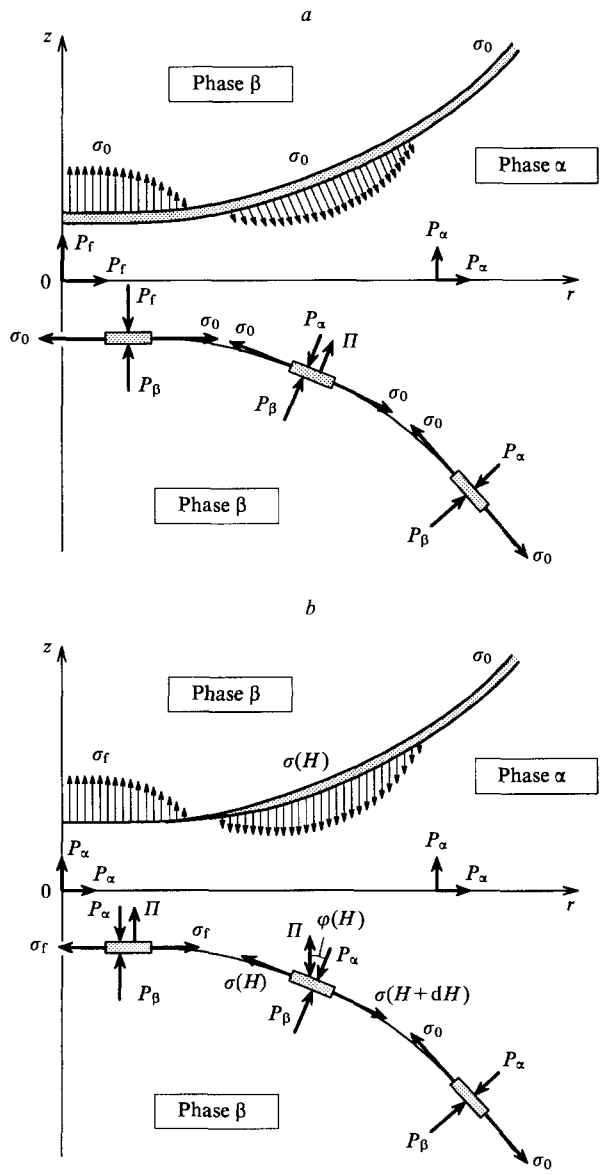

Figure 18. Representation of the disjoining pressure in a liquid film as a pressure tensor (*a*) and as a tensor of the specific interaction force between the dividing surfaces in the film (*b*).

The disjoining pressure as a specific interaction force between the dividing surfaces in the film has been discussed by the present writer[1–4] and by De Feijter et al.[41–43] The phase α and the pressure P_α are chosen as the reference phase and the reference pressure (in the Gibbs sense), and therefore no pressure gradient appears in the transition region in this model (Fig. 18*b*). An important assumption in this case is that the radial component of the disjoining pressure is zero: this leads to the following fundamental equilibrium equation for the film in the transition region:[1, 31, 44]

$$\sigma(H)k(H) + \Pi(H)\cos\varphi(H) - \Delta P = 0 , \quad (130)$$

where $\sigma(H)$ is the local value of the interfacial tension in the transition region; $\varphi(H)$ is the local contact angle of the real profile of the film surface.

Eqn (130) can be interpreted as the mechanical equilibrium condition of the dividing surface in a direction normal to this surface under conditions of an interfacial tension gradient $\sigma(H)$ in the transition region of the film. Diagrams illustrating the mechanical equilibrium of a dividing surface for a plane-parallel film in the transition region and in the region of the bulk meniscus are shown in Fig. 18*b*: here $\sigma_f = \sigma(H_f)$ is the interfacial tension in a plane-parallel film of thickness H_f. Thus the forces acting at right angles to the film surface in the transition region include the capillary pressure $\sigma(H)k(H)$, the hydrostatic pressures P_α and P_β, and also the projection of the disjoining pressure $\Pi(H)\cos\varphi(H)$, whose sum vanishes at equilibrium [see Eqn (130)].

Evidently, the equilibrium equation (130) reduces to the Eqns (127) and (95), which describe the equilibrium of the film in the plane-parallel region and in the region of the bulk meniscus respectively.

The fundamental equation (130) describes the equilibrium of the film surface in the transition region in a direction tangential to this surface, and allows it to be interpreted mechanically. The gradient of the interfacial tension $d\sigma(H) = \sigma(H + dH) - \sigma(H)$ in a direction tangential to the surface of the film is thus balanced by the force $-\Pi(H)\sin\varphi(H) \times dl$, which can be written

$$d\sigma(H) = \sigma(H + dH) - \sigma(H) = -\Pi(H)\sin\varphi(H) \times dl .$$

This equation is consistent with the Gibbs-Duhem equation (129), since the length of the element of surface dl under consideration is expressed in terms of dH and $\varphi(H)$ by the relation $dH = 2\sin\varphi(H) \times dl$.

2. The fundamental equation of a liquid film in the transition region

The writer has shown[22] that the fundamental equation of a system containing a plane-parallel film can be written in the form

$$d\Omega = -SdT - \sum_i N_i d\mu_i - \Delta P dV_\beta - \Pi(H) A dH + 2\sigma(H) dA . \quad (131)$$

We note that the layout of this equation does not require a subjective choice of the position of the dividing surfaces in the film, i.e. it is independent of H, even though $\sigma(H)$ and also V_α and V_β depend on the localisation of the dividing surfaces.

The fundamental equation of the system, including two curved non-interacting dividing surfaces of minimum tension in the region of the bulk meniscus, can be written in terms of the equation (90) and the condition (93) in the form[5]

$$d\Omega = -SdT - \sum_i N_i d\mu_i - \Delta P dV_\beta + 2\sigma_0 dA , \quad (132)$$

where $\sigma_0 \equiv \sigma_G^0$ [see Eqn (94) and discussion].

Eqn (131) has been used[1-5, 18, 44] as the fundamental equation for the transition region of a liquid film, the position of the dividing surfaces being chosen so as to satisfy the condition (94) over the whole of the transition region. In this case Eqn (131) is converted into Eqn (132) in the region of the bulk meniscus. Since the position of the dividing surfaces in the transition region is unambiguously fixed, the fundamental equation in the plane-parallel region of the film should be written[5]

$$d\Omega = -SdT - \sum_i N_i d\mu_i - \Delta P dV_\beta - \Pi(H_f) A dH + 2\sigma_f dA , \quad (133)$$

where $\sigma_f \equiv \sigma(H_f)$, since the minimum tension surfaces have now been chosen as the dividing surfaces in the plane-parallel film.

Minimising the functional (131) at constant T and μ_i in a direction normal ($\vec{n}$) to the surface of the film in the transition region leads to the expression

$$\delta\Omega = -\Delta P \frac{\partial V_\beta}{\partial \vec{n}_\beta}\delta\vec{n} - \Pi(H) A \frac{\partial H}{\partial \vec{n}}\delta\vec{n} + 2\sigma(H)\frac{\partial A}{\partial \vec{n}}\delta\vec{n} ,$$

which is converted, allowing for the self-evident geometric relations

$$\frac{A\partial H}{\partial \vec{n}} = -\cos\varphi(H)\left(\frac{\partial V_\beta}{\partial \vec{n}}\right) ; \quad \frac{2\partial A}{\partial \vec{n}} = k(H)\left(\frac{\partial V_\beta}{\partial \vec{n}}\right) ,$$

into the fundamental equilibrium equation for the surface of the film in the direction of the normal [Eqn (130)].[1, 5, 18, 44] Under these conditions the Gibbs–Duhem equation (129) defines the equilibrium of an element of surface in a direction tangential to the surface.

The fundamental equation for interacting curved dividing surfaces of minimum tension in the transition region of the film can be obtained from Eqn (131) by subtracting from it the 'bulk' part, corresponding to the macroscopic phases α and β:[5, 18]

$$d\tilde{\Omega}_s = -\tilde{S}_s dT - \sum_i \tilde{N}_{is} d\mu_i - \Pi(H) A dH + 2\sigma(H) dA , \quad (134)$$

where the tilde sign denotes Gibbs excesses of the corresponding quantity.

In the region of the bulk meniscus Eqn (134) becomes

$$d\tilde{\Omega}_s = -\tilde{S}_s dT - \sum_i \tilde{N}_{is} d\mu_i + 2\sigma_0 dA , \quad (135)$$

and the fundamental equation for interacting surfaces of minimum tension in a plane-parallel is

$$d\tilde{\Omega}_s = -\tilde{S}_s dT - \sum_i \tilde{N}_{is} d\mu_i - \Pi(H_f) A dH + 2\sigma_f(H) dA . \quad (136)$$

3. Shape of the profile of a liquid film in the transition region

The shape of the real profile $H(r) = 2z(r)$ of a symmetrical circular liquid film (see Fig. 1) is uniquely described by the system of Eqns (129) and (130), together with

$$\frac{dH(r)}{dr} = 2\tan\varphi(H) . \quad (137)$$

In the region of the bulk meniscus the real profile $H(r)$ coincides with the ideal profile $H^{id}(r) = 2z^{id}(r)$, which can be determined experimentally with adequate precision.[7] The position of the point (r_1, z_1) can be used as a boundary condition: it is the same for the real and the idealised profile in the region of the bulk meniscus, in which the two profiles have the same angle of contact φ_1 (see Fig. 13).

In cylindrical films, having only one principal radius of curvature, integration of the fundamental equilibrium equation of the film (130) over the thickness of the real profile from a value H in the transition region to a value H_1 in the region of the bulk meniscus yields an invariant, independent of the thickness of the profile:[1, 5, 6, 18]

$$2\sigma(H)\cos\varphi(H) + \Delta P H(r) = 2\sigma_0\cos\varphi_1 + \Delta P H_1 = \text{const} . \quad (138)$$

The invariant (138) is the analogue of (99), obtained for noninteracting cylindrical surfaces. Since the right-hand sides of the two invariants are equal the left-hand sides must also be equal. This produces a new generalised invariant:[1, 5]

$$2\sigma(H)\cos\varphi(H) + \Delta P H(r) = 2\sigma_0\cos\varphi^{id}(H) + \Delta P H^{id}(r) , \quad (139)$$

which establishes a mutual relationship between the parameters which characterise the real $[H(r)]$ and the idealised film profile $[H^{id}(r)]$.

From the generalised invariant (139) we obtain well known expressions, widely used in the thermodynamics of thin liquid films, which are usually based on mechanical models of the liquid films, for example[46, 47]

$$\sigma_f = \sigma_0\cos\theta_f , \quad (140)$$

or (see Sheludko et al.[48] and Fig. 13)

$$\sigma_f = \sigma_0\cos\theta_0 - \tfrac{1}{2}\Delta P H_f . \quad (141)$$

We shall illustrate these assertions with a number of examples.[1, 5, 6, 18]

Let us insert into the left-hand side of the generalised invariant (139) values corresponding to the real profile $H(r)$: $H = H_f$, $\varphi(H_f) = 0$, and $\sigma(H_f) = \sigma_f$. Into the right-hand side we insert the corresponding values for the idealised profile $H^{id}(r)$: $H^{id} = H_f$, and $\varphi^{id}(H_f) = \theta_f$. The result is

$$2\sigma_f + \Delta P H_f = 2\sigma_0\cos\theta_f + \Delta P H_f ,$$

from which we obtain Eqn (140).

On the other hand if the values $H_{id} = 0$ and $\varphi^{id}(0) = \theta_0$ are inserted into the right-hand side of the generalised invariant (139) they produce the equation

$$2\sigma_f + \Delta P H_f = 2\sigma_0\cos\theta_0 , \quad (142)$$

from which (141) is obtained. Since γ is related to the interfacial tension σ_f in a film of thickness H_f by the expression[22]

$$\gamma = 2\sigma_f + \Delta P H_f , \quad (143)$$

Eqn (142) leads to the well known relation[48]

$$\gamma = 2\sigma_0\cos\theta_0 . \quad (144)$$

By using the relationship [which follows from the Gibbs–Duhem equation (129)] between the specific free energy of

interaction (grand thermodynamic potential) in a plane-parallel film and the interfacial tension[34, 41, 45]

$$2\sigma_f - 2\sigma_0 = \Delta\Omega(H_f) = \int_{H_f}^{\infty} \Pi(H)\mathrm{d}H \,, \tag{145}$$

we obtain from Eqns (140) and (142) the familiar relations[46, 47]

$$\Delta\Omega(H_f) = 2\sigma_0(\cos\theta_f - 1) \tag{146}$$

or[48]

$$\Delta\Omega(H_f) = 2\sigma_0(\cos\theta_0 - 1) - \Delta P H_f \,. \tag{147}$$
