Attention has been drawn[1, 5, 43] to the difference between the contact angles θ_f and θ_0 and to the need to allow for this difference when using the expressions (146) and (147) in order to avoid crude errors in the calculation of the specific energy of interaction in the film at low contact angles and relatively large thicknesses of the liquid films.

We shall now establish how the equilibrium equations of films with a bulk meniscus can be obtained from the universal invariant (139) when the contact angle θ_0 is not formed. For example, the common black films, also known as α-films, between drops in which the capillary pressure $P_c = \Delta P = P_\beta - P_\alpha$ is smaller than the height Π_2 of the coagulation barrier in the disjoining pressure isotherm. The profile of these films (curve *1* of Fig. 19*a*) is characterised by a relatively large thickness H_f^c of the central plane-parallel part: as a rule the idealised profile $H^{id}(r)$ does not form a contact angle θ_0 under these conditions.

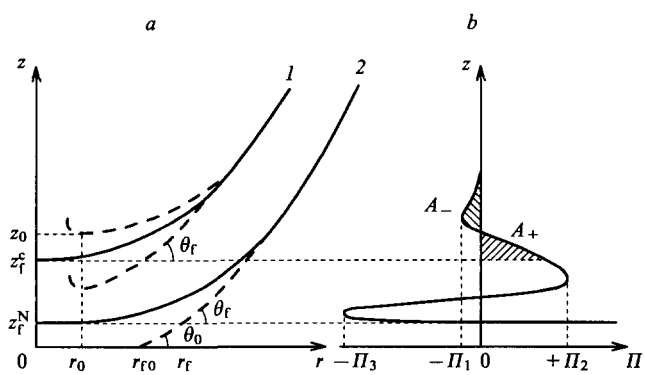

Figure 19. Creation of common and of Newtonian black films: (*a*) profiles of the common (*1*) and of the Newtonian black film (*2*); (*b*) profile of the disjoining pressure isotherm.

If $\Delta\Omega(H_f) < 0$, i.e. according to (145), the area of the cross-hatched negative region A^- (Fig. 19*b*) is greater than the area of the positive region A^+ (for example, for a high enough concentration of electrolyte in an aqueous dispersion medium, in which the coagulation barrier is low): the idealised profile $H^{id}(r)$ forms a contact angle θ_f and has a minimum $H_0 = 2z_0$, which is smaller than the film thickness $H_f^c = 2z_f^c$ (see Fig. 19*a*). On the other hand if $A^+ > A^-$ we have $\Delta\Omega(H_f) > 0$ and the idealised profile $H^{id}(r)$ lies above the real profile of the film $H(r)$, with $H_0 > H_f^c$.

Inserting into the right-hand side of the generalised invariant (139) the values $H^{id} = H_0$ and $\varphi^{id} = 0$, corresponding to a minimum on the $H^{id}(r)$ curve, we obtain the expression[18]

$$2\sigma_f + \Delta P H_f = 2\sigma_0 + \Delta P H_0 \,, \tag{148}$$

from which new relations are obtained:

$$\gamma = 2\sigma_0 + \Delta P H_0 \,, \tag{149}$$

$$\Delta\Omega(H_f) = \Delta P(H_0 - H_f) \,. \tag{150}$$

Thus, if $H_0 < H_f$ we have $\Sigma\Omega(H_f) < 0$. Eqn (150) for the case of $\Delta\Omega(H_f) > 0$ was obtained[45, 49, 50] for films with a cylindrical profile by applying the principle of detailed balancing developed by Deryagin for films.[51]

Newtonian black films, also known as β-films, are formed from the α-films when the height Π_2 of the coagulation barrier is lowered (for example, by increasing the concentration of electrolyte), or by increasing the capillary pressure P_c to a level higher than the coagulation barrier Π_2 (for example, by decreasing the radii of the liquid drops between which the liquid film is formed)[52] (see curve *2* of Fig. 19*a*).

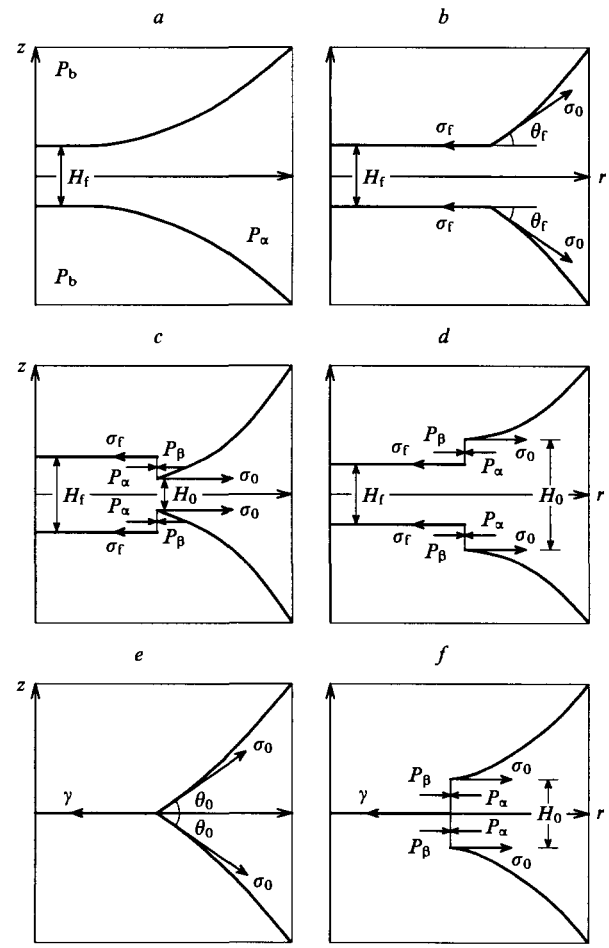

Figure 20. Equilibrium of a liquid film with a bulk meniscus (*a*) according to the thermodynamic model which stipulates two dividing surfaces (*b*–*d*) and according to the membrane model of the film (*e*, *f*).

The expressions (140), (144), (148), and (149) allow a clear mechanical interpretation of these effects (Fig. 20), which differs according to the thermodynamic model chosen to describe the thin liquid films.

If the model assumes two interacting dividing surfaces in the liquid film[53, 54] the equilibrium schemes illustrated in Fig. 20*b*–20*d* are usually adopted. Fig. 20*b* shows the equilibrium of the film with a meniscus, as in Eqn (140). When the contact angle θ_0 is not formed, and $H_0 < H_f$, Eqn (148) corresponds to the scheme shown in Fig. 20*c*. Under these conditions $\Delta\Omega(H_f) < 0$. If $\Delta\Omega(H_f) > 0$ we have $H_0 > H_f$, and the scheme shown in Fig. 20*d* corresponds to Eqn (148).

If the membrane model is chosen as a thermodynamic model of the film[55, 56] it is convenient to use the mechanical model shown in Fig. 20*e* [corresponding to Eqn (144)] for negative values of $\Delta\Omega(H_f)$, when the contact angle θ_0 is formed. On the other hand if the contact angle θ_0 is not formed we can use the mechanical model shown in Fig. 20*f*, corresponding to Eqn (149).

Under these conditions $\Delta\Omega(H_f)$ can take both negative and positive values.

The generalised invariant for circular liquid films can be obtained by integrating the fundamental equilibrium equation (130) over the thickness of the real profile [as was done for films with a cylindrical profile in the derivation of Eqn (138)], and combining the resulting expression with (101):

$$2\sigma(H)\cos\varphi(H)+\Delta PH(r)+\int_H^{H_1}\frac{\sigma(H)\sin\varphi(H)}{r}\,dH = 2\sigma_0\cos\varphi^{id}(H)+\Delta PH^{id}(r)+\int_{H^{id}}^{H_1}\frac{\sigma_0\sin\varphi^{id}(H)}{r}\,dH^{id}. \quad (151)$$

We shall show how accurate analytical expressions can be obtained from the generalised invariant (151) for circular films, allowing numerical estimates of the line tension.[1, 2, 5]

As was done for films with a cylindrical profile in the derivation of Eqns (140) and (146) we shall insert into the left-hand side of the invariant (151) the values $H = H_f$, $\varphi = 0$, and $\sigma = \sigma_f$, and into the right-hand side the values $H^{id} = H_f$ and $\varphi^{id} = \theta_f$, corresponding to the case of $\Delta\Omega(H_f) < 0$. The result is

$$2\sigma_f+\Delta PH_f+\int_{H_f}^{H_1}\frac{\sigma(H)\sin\varphi(H)}{r}\,dH = 2\sigma_0\cos\theta_f+\Delta PH_f+\int_{H_f}^{H_1}\frac{\sigma_0\sin\varphi^{id}(H)}{r}\,dH^{id},$$

which is usually written[41]

$$2\sigma_f+\frac{\tau}{r_f}=2\sigma_0\cos\theta_f, \quad (152)$$

or

$$\Delta\Omega(H_f)+\frac{\tau}{r_f}=2\sigma_0(\cos\theta_f-1), \quad (153)$$

where

$$\tau = r_f\left[\int_{H_f}^{\infty}\frac{\sigma(H)\sin\varphi(H)}{r}\,dH-\int_{H_f}^{\infty}\frac{\sigma_0\sin\varphi^{id}(H)}{r}\,dH^{id}\right]. \quad (154)$$

τ is the line tension in the film model based on the assumption of two dividing surfaces. Eqn (154) is the exact analytical expression[1, 18, 44] for the line tension τ, and differs substantially from the approximate expressions used by some workers.[36, 41] Detailed descriptions of the line tension theory and of results obtained in measurements of the line tension have already been published.[5, 6]

We shall now show how an expression for the line tension can be obtained in the membrane model of the film.[48, 57] To this end we shall insert into the right-hand side of the generalised invariant for a circular liquid film (151) the values $H^{id} = 0$ and $\varphi^{id} = \theta_0$ (postulating the formation of the contact angle θ_0). The result is

$$2\sigma_f+\frac{\varkappa}{r_{f0}}=2\sigma_0\cos\theta_0-\Delta PH_f, \quad (155)$$

or

$$\gamma+\frac{\varkappa}{r_{f0}}=2\sigma_0\cos\theta_0, \quad (156)$$

or

$$\Delta\Omega(H_f)+\frac{\varkappa}{r_{f0}}=2\sigma_0(\cos\theta_0-1)-\Delta PH_f, \quad (157)$$

where

$$\varkappa = r_{f0}\left[\int_{H_f}^{\infty}\frac{\sigma(H)\sin\varphi(H)}{r}\,dH-\int_0^{\infty}\frac{\sigma_0\sin\varphi^{id}(H)}{r}\,dH^{id}\right] \quad (158)$$

is the line tension in the membrane model of the liquid film.[6]

We note that the equilibrium equations for circular films (152) and (156) differ from the analogous equations for cylindrical films (140) and (144) by including the terms τ/r_f and $\varkappa/r_{f0}$ in the left-hand side: these can be interpreted as 'two-dimensional' capillary pressures, associated with an inflection in the contact line (or dividing line according to Gibbs), by analogy with the capillary pressure $2\sigma_0/R$ (in the case of a sphere of radius R) created by the bending of the dividing surface.

The equations (154) and (158) give the relationship between the two types of line tension in the various thermodynamic models of liquid films:[1, 6]

$$\frac{\varkappa}{r_{f0}}=\frac{\tau}{r_f}-\int_0^{H_f}\frac{\sigma_0\sin\varphi^{id}(H)}{r}\,dH^{id}.$$

Expressions for the equilibrium of circular films with a meniscus, analogous to (148)–(150) for cylindrical films, have also been given[1, 18] (see Fig. 19*a*):

$$2\sigma_f+\Delta PH_f+\int_{H_f}^{H_1}\frac{\sigma(H)\sin\varphi(H)}{r}\,dH = 2\sigma_0+\Delta PH_0+\int_{H_0}^{H_1}\frac{\sigma_0\sin\varphi^{id}(H)}{r}\,dH^{id}, \quad (159)$$

$$\gamma+\frac{\tau_B}{r_0}=2\sigma_0+\Delta PH_0, \quad (160)$$

$$\Delta\Omega(H_f)+\frac{\tau_B}{r_0}=\Delta P(H_0-H_f), \quad (161)$$

where

$$\tau_B = r_0\left[\int_{H_f}^{\infty}\frac{\sigma(H)\sin\varphi(H)}{r}\,dH-\int_{H_0}^{\infty}\frac{\sigma_0\sin\varphi^{id}(H)}{r}\,dH^{id}\right] \quad (162)$$

is the line tension.[1, 18, 44]

Profile of the lens-like thickening in equilibrium with a liquid film. In the transition region between the lens-like thickening and the plane-parallel liquid film (see Fig. 16) the first principal curvature changes sign from negative to positive, whereas the second principal curvature remains negative:

$$k_1=-\frac{d\sin\varphi(H)}{dr} \text{ and } k_2=-\frac{\sin\varphi(H)}{r}.$$

The average negative curvature of the surface in the transition region ($k = k_1 + k_2$) within the liquid lens decreases to zero in absolute value when r increases, then becomes positive, and finally decreases again to zero in the almost plane-parallel region of the liquid film surrounding the lens.

A characteristic feature of the lens–liquid system is its basic disequilibrium, due to the fact that the chemical potentials of the components μ_i within the lens exceed the corresponding values in the phase α. In particular, the hydrostatic pressure P_d within the lens is greater than the pressure P_α in the phase α, and therefore the material in the lens will tend to pass into the phase α by direct flow or as a result of bulk or surface diffusion. This tendency increases as the size of the lens decreases and as the pressure (i.e. the chemical potentials of the components) within the lens is increased.

If the rate of the hydrodynamic or diffusion processes is low the system can be treated as a quasi-equilibrium system. In a system of this type the energetics and the mechanical equilibrium can be described by the methods of equilibrium thermodynamics.

The main difficulty in the thermodynamic description of the lens–liquid film system is the lack of an unambiguous definition (in terms of the postulated presence of two dividing surfaces in the

film) of the reference system (in particular the Gibbs reference system) within the film itself, since a pressure gradient is formally present as a result of the obvious inequality $P_d > P_\alpha$. This gradient is increased by the flow of liquid from the lens.

Similar difficulties arise in the membrane approach to the description of the film, since the tension γ becomes a function of the coordinate r owing to the pressure gradient in the film in the direction of the r axis (see Fig. 16*c*).

A possible approach to the thermodynamic description of the transition region of the film at the boundary with the lens is described below.[18]

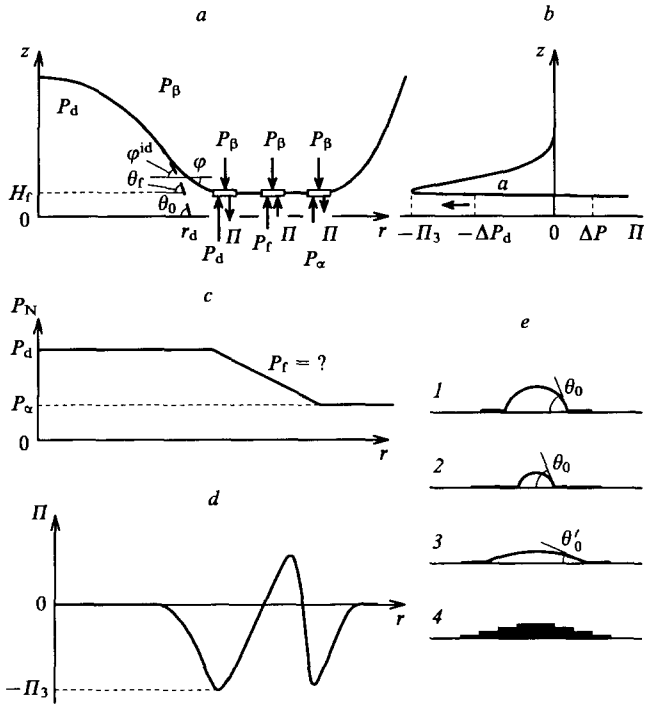

Figure 21. Equilibrium between the lens and the liquid film: (*a*) profile of the transition region between the liquid film and the lens; (*b*) profile of the disjoining pressure isotherm; (*c*) dependence of the normal component P_N of the reference pressure in the lens–liquid film system on the radius r; (*d*) distribution of the disjoining pressure in the lens–liquid film system; (*e*) evolution of the form of the liquid drop on a solid surface as a function of time.

The real profile of the film $z(r)$, including the profile of the lens itself (Fig. 21*a*), can be described by the Gibbs–Duhem equation or by the system of equations

$$\frac{dz(r)}{dr} = -\tan\varphi(H) , \tag{163}$$

$$\sigma(H)\frac{d\sin\varphi(H)}{dr} + \sigma(H)\frac{\sin\varphi(H)}{r} + \Pi(H)\cos\varphi(H) + \Delta P_f(r) = 0 , \tag{164}$$

where $\Delta P_f(r) = P_f(r) - P_\beta$, and $P_f(r)$ is the reference pressure in the film region. The form of the function $P_f(r)$ is not previously known, though it is obvious that $P_f(r) = P_d$ for $r < r_d$ (r_d is the radius of the lens) and $P_f(r) = P_\alpha$ in the bulk of the phase α. The form of the function $P_f(r)$ is shown schematically in Fig. 21*c*. The question mark in the symbol $P_f = ?$ denotes the ambiguity in the choice of the form of this function in the film region.

In spite of this ambiguity we can assume that the film will be accurately plane-parallel because of the low compressibility of the liquid. We can therefore write the equilibrium equation (164) in the film region as

$$\Pi(H) + \Delta P_f(r) \simeq 0 . \tag{165}$$

This means that in the transition region of the lens, where $P_f \simeq P_d$ (see Fig. 21*c*), the disjoining pressure is negative, since

$$\Pi + P_d - P_\beta = 0 \quad \text{and} \quad P_d > P_\beta$$

(see Fig. 21*a*). We should note that a negative sign for the disjoining pressure denotes mutual attraction of the dividing surfaces in the film

As we move away from the transition region of the film along the r axis the disjoining pressure becomes positive (Fig. 21*d*) because of the decrease in the reference pressure P_f caused by the repulsion of the dividing surfaces in the film. In considering the changes in sign of the disjoining pressure it should not be forgotten that within the model of two dividing surfaces in the film the disjoining pressure is defined as the excess of the specific interaction force (between the surfaces) over the effect of the arbitrarily chosen reference pressure. Therefore both the magnitude and the sign of the disjoining pressure are arbitrary. For example, if P_d is chosen as the reference pressure the disjoining pressure within the film will be negative everywhere.

Let us assume that the choice of reference pressure shown in Fig. 21*c* is an optimum. Then the disjoining pressure Π changes sign once again and becomes negative when r is increased within the transition region between the film and the phase α (see Fig. 21*a*) for the choice of disjoining pressure isotherm shown in Fig. 21*b*: this effect is due to the capillary pressure forces (see Fig. 18*b*).

By using the procedure described above for applying the generalised invariant of the film profile to the lens–liquid film system we obtain[18]

$$2\sigma(H)\cos\varphi(H) + \int_H^{H_1}\Delta P_f(r)dH - \int_H^{H_1}\frac{\sigma(H)\sin\varphi(H)}{r}dH = 2\sigma_0\cos\varphi^{id}(H) + \Delta P_d[H_1 - H^{id}(r)] - \int_{H^{id}}^{H_1}\frac{\sigma_0\sin\varphi^{id}(H)}{r}dH^{id} , \tag{166}$$

where H_1 is the thickness of the profile in the region of the bulk phase of the lens.

Inserting into the left-hand side of the invariant (166) the parameters corresponding to the real profile of the film ($H = H_f$, $\varphi = 0$, and $\sigma = \sigma_f$) and into the right-hand side the parameters corresponding to the idealised profile ($H^{id} = 0$, $r = r_d$, and $\varphi^{id} = \theta_0$) gives the following equilibrium equation:

$$2\sigma_f + \int_{H_f}^{H_1}\Delta P_f(r)dH - \frac{\varkappa}{r_d} = 2\sigma_0\cos\theta_0 + \Delta P_d H_1 , \tag{167}$$

where $\varkappa$ is the line tension, defined by the expression

$$\varkappa = r_d\left[\int_{H_f}^{\infty}\frac{\sigma(H)\sin\varphi(H)}{r}dH - \int_0^{\infty}\frac{\sigma_0\sin\varphi^{id}(H)}{r}dH^{id}\right] . \tag{168}$$

On the other hand inserting into the right-hand side of (166) the parameters $H^{id} = H_f$, $r \simeq r_d$, and $\varphi^{id} = \theta_f$ gives

$$2\sigma_f + \int_{H_f}^{H_1}\Delta P_f(r)dH - \frac{\tau}{r_d} = 2\sigma_0\cos\theta_f + \Delta P_d(H_1 - H_f) , \tag{169}$$

where the line tension τ is given by the expression[18]

$$\tau = r_d\left[\int_{H_f}^{\infty}\frac{\sigma(H)\sin\varphi(H)}{r}dH - \int_{H_f}^{\infty}\frac{\sigma_0\sin\varphi^{id}(H)}{r}dH^{id}\right] . \tag{170}$$

The equilibrium equations (167) and (168) can be simplified if $dP_f(r)/dr \ll 1$. Under these conditions the reference pressure P_f in

the transition region of the film can be treated as constant and equal to P_d, which allows the equilibrium equation to be written in the form[18, 33]

$$2\sigma_f - \frac{\varkappa}{r_d} = 2\sigma_0 \cos\theta_0 + \Delta P_d H_f \tag{171}$$

or

$$2\sigma_f - \frac{\tau}{r_d} = 2\sigma_0 \cos\theta_f . \tag{172}$$

Replacing the film by a membrane of zero thickness and using the definition (143) for the tension γ of the film converts Eqn (171) into

$$\gamma - \frac{\varkappa}{r_d} = 2\sigma_0 \cos\theta_0 . \tag{173}$$

For the equilibrium of a fluid (liquid or gaseous) drop in contact with a solid substrate (see Fig. 16*b*) the relationships (171)–(173) become[6, 36, 58]

$$\sigma_f - \frac{\varkappa}{r_d} = \sigma_0 \cos\theta_0 + \Delta P_d H_f , \tag{174}$$

$$\sigma_f - \frac{\tau}{r_d} = \sigma_0 \cos\theta_f , \tag{175}$$

$$\gamma - \frac{\varkappa}{r_d} = \sigma_0 \cos\theta_0 . \tag{176}$$

Eqn (176) has been used[59, 60] to determine the line tension $\varkappa$ from the experimental dependence of the contact angle θ_0 on the drop radius r_d on a solid or a liquid support. In these measurements it is usually assumed[6] that the tension γ of the film stays constant when the size of the drop or lens is changed, and Eqn (176) is used in the form[59, 60]

$$\cos\theta_0 = \cos\theta_0(\infty) - \frac{\varkappa}{\sigma_0 r_d} , \tag{177}$$

where $\theta_0(\infty)$ is the constant value of the contact angle corresponding to the condition $r_d \to \infty$.

The line tension $\varkappa$ is treated as positive if the contact line (or dividing line, according to Gibbs) has an excess of positive free energy, i.e. if it tends to shorten itself.[6] In particular, reported[59, 60] positive values of the line tension $\varkappa$ correspond to an increase in the contact angle with decreasing drop size. In this connection it has been pointed out[6, 18] that the dependence of the contact angle θ_0 on the drop radius r_d could be associated with the changes in the film tension γ rather than with changes in the line tension. In this case Eqn (177) should be replaced by the more general relation

$$\cos\theta_0 = \cos\theta_0(\infty) - \frac{\varkappa}{\sigma_0 r_d} + \Delta\gamma(r_d) , \tag{178}$$

where $\Delta\gamma(r_d) = \gamma(r_d) - \gamma(\infty)$, and allowance should be made for the $\gamma(r_d)$ dependence, which is not previously known.

We note that according to the generalised theory of the line tension[2, 3, 5, 18] $\varkappa$ can take only negative values for systems characterised by finite values of the angle of contact. Numerical estimates of the line tension as a function of the physicochemical parameters (shape of the profile of the disjoining pressure isotherm, size of the contact angle, capillary pressure, film size) have been recently reviewed.[6]

We shall discuss the causes and the character of the changes in the film tension γ in the lens–film (or drop–solid support) system.[18] A possible evolution of the liquid drop–solid substrate system induced by decreasing the radius r of the drop is illustrated in Fig. 21*e*. The existence condition of the finite contact angle θ_0 is the inequality

$$\Pi_3 > \Delta P_d = P_\alpha - P_\beta , \tag{179}$$

where Π_3 is the depth of the short-range coagulation minimum in the disjoining pressure isotherm $\Pi(H)$ shown in Fig. 21*b*. The representative point *a* on the $\Pi(H)$ isotherm corresponds to the state *1* of the system in Fig. 21*e*. Decreasing the size of the drop (state *2*) raises the pressure P_d in the drop, and the representative point on the $\Pi(H)$ isotherm moves to the left in the direction of the arrow. Under these conditions the angle of contact θ_0 remains finite, but changes in size under the influence of the line tension, and also of the change in the film tension γ.

By postulating that the thickness of the liquid layer H_f is not affected by the displacement of the representative point *a* to the left we can treat the interfacial tension σ as constant [see Eqn (145)]: this leads to a decrease in the film tension $\gamma = 2\sigma_f - \Delta P_d H_f$ with decreasing radius r_d of the drop.

When the size of the drop is decreased to the critical radius r_d^*, for which the capillary pressure ($2\sigma_0/R = 2\sigma_0 \sin\theta_0/r_d^*$) reaches the value Π_3, i.e.

$$r_d^* = \frac{2\sigma_0 \sin\theta_0}{\Pi_3} , \tag{180}$$

the finite contact angle θ_0 can no longer exist, and the drop discontinuously changes to the new state *3* (Fig. 21*e*) with a smaller contact angle θ_0' [if the $\Pi(H)$ isotherm has a long-range coagulation minimum Π_1, see Fig. 19*b*]. Under these conditions the new state is stable if the drop radius is greater than the critical value, defined by the relation (180), with Π_3 replaced by the new value Π_1.

If the Π_1 minimum does not exist, or the drop is smaller than the critical size, we observe spreading of the drop over the liquid layer, sometimes accompanied by the formation of several layers of molecular dimension[61–63] (state *4* in Fig. 21*e*).

This discussion of the equilibrium in the lens–liquid film system would not be complete without a mention of the possibility of spontaneous formation of lens-like thickening within initially plane-parallel films, accompanied by the thinning down of these initial formations. This effect can occur as a result of a local decrease in the interfacial tension σ_0: for example, during the mass transfer of SAS through a phase separation surface from the film to the boundary phase.[64]

The spontaneous thinning of plane-parallel liquid films stabilised by SAS at concentrations higher than the CMC often takes place by the stratification mechanism, i.e. a gradual layer-by-layer thinning to give increasingly thin layers.[65–67] The mechanism of this phenomenon is not clear.[67]

4. Interaction of interfacial surfaces in microscopic films

The microscopic liquid films (MLF) formed in the region of the contacts between emulsion drops and foam bubbles have an extremely small (almost zero) plane-parallel region, i.e. they consist almost entirely of a transition region, characterised by its profile $H(r)$ (Fig. 22*a*). This feature greatly complicates their thermodynamic description, since in order to determine the parameters of the interaction between fluid particles in a liquid medium we require information on the profile of the film, including the transition region.

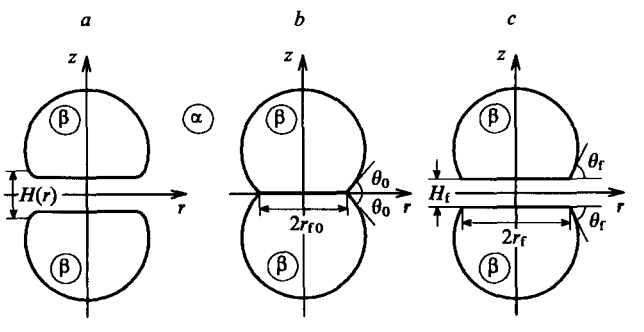

Figure 22. Representation of a microscopic liquid film (*a*) by the membrane model (*b*) and by a model which assumes two dividing surfaces in the film (*c*).

In particular this information is needed to calculate the grand thermodynamic potential Ω of the system which includes the volumes of the phases α and β, and also of the liquid film (for constant T and μ_i[5, 6, 14, 18]):

$$\Omega = -P_\alpha V_\alpha - P_\beta V_\beta + \int \sigma \, dA \,, \tag{181}$$

where the integration is carried out over the interfacial surface (the Gibbs dividing surface) allowing for the dependence of the interfacial tension σ on the position of the surface.

To simplify their thermodynamic description these systems are replaced by their analogues (reference or comparison systems), in which, for example, a circular membrane of zero thickness[55, 56] is used instead of the real microscopic liquid film (the membrane approach, Fig. 22*b*), or alternatively a circular plane-parallel film[12, 13] of thickness H_f (the approach based on the assumption of two dividing surfaces in the film, Fig. 22*c*). In this case the thermodynamic excess quantities are referred to the dividing (contact) lines. This creates the concept of linear thermodynamic excesses: for example, a line tension, representing the excess of the grand thermodynamic potential referred to unit length of the contact line.

In the membrane approach the expression for the grand thermodynamic potential of the idealised system is[5, 6, 14, 18]

$$\Omega^{id} = -P_\alpha V_\alpha^{id} - P_\beta V_\beta^{id} + \sigma_0 A^{id} + \pi r_0^2 \gamma + 2\pi r_{f0}^2 \varkappa \,, \tag{182}$$

where $\varkappa$ is the line tension of the film (or membrane) and the superscript id denotes quantities referred to the idealised system shown in Fig. 22*b* (in particular, A^{id} is the combined area of the two drops having a total volume V^{id} diminished by the two membrane areas πr_{f0}^2). The interfacial tension of this surface is arbitrarily taken to be equal to σ_0, even in the transition region, since it is assumed that no interaction exists between the drop surfaces (in keeping with stipulations of the method). By starting from the condition of energy equivalence of the real and the idealised system, i.e. $\Omega = \Omega^{id}$, we can define the line tension $\varkappa$ and calculate it. This approach has been fully discussed.[5, 6, 18]

When describing the interaction between drops in terms of the model of two dividing surfaces in the film the grand thermodynamic potential of the idealised system Ω^{id} is expressed[5, 6, 18] as (Fig. 22*c*)

$$\Omega^{id} = -P_\alpha V_\alpha^{id} - P_\beta V_\beta^{id} + \sigma_0 A^{id} + 2\pi r_f^2 \sigma_f + 2\pi r_f \tau \,, \tag{183}$$

where τ is the line tension, and the values V_α^{id}, V_β^{id}, and A^{id} differ from the corresponding quantities in Eqn (182), which relates to the membrane model of the film. Calculations of τ allowing for the condition $\Omega = \Omega^{id}$ have been reported.[5, 6, 18]

If the contact angles θ_0 and θ_f are not formed we can use idealised models (see Fig. 20*e*), relating to the membrane model and to the postulate of two dividing surfaces in the film respectively. The expressions for the grand thermodynamic potential corresponding to these models are

$$\Omega^{id} = -P_\alpha V_\alpha^{id} - P_\beta V_\beta^{id} + \sigma_0 A^{id} + \pi r_0^2 \gamma + 2\pi r_0 \varkappa_B \,, \tag{184}$$

$$\Omega^{id} = -P_\alpha V_\alpha^{id} - P_\beta V_\beta^{id} + \sigma_0 A^{id} + 2\pi r_0^2 \sigma_f + 2\pi r_0 \tau_B \,. \tag{185}$$

Calculations of the line tension τ_B have been reported.[5, 6]

5. Contact interactions in emulsions and foams

Theories of the adhesion of solid particles. The relationship between the adhesion force acting on solid (rigid) particles in liquid media and the parameters which characterise the interaction between phases in microscopic liquid films was established by Bradley[68] and Deryagin[69] during their development of the thermodynamic theory of solid particles. Their expression

$$f_a^* = \pi R \Delta F_a = \pi R \Delta \Omega(H_f) \,, \tag{186}$$

relates the force of adhesion f_a^* of solid non-deformable particles of radius R with the specific free energy of adhesion ΔF_a [equal to the specific grand thermodynamic potential of the interaction $\Delta\Omega(H_f)$ in a liquid film of thickness H_f for constant T and μ_i. In calculations of $\Delta\Omega(H_f)$ by formula (145) H_f is taken to be $\sim 0.2-0.5$ nm (see Refs 70 and 71), which corresponds to the short-range coagulation minimum on the $\Pi(H)$ isotherm.]

Eqn (186) can be used to calculate the influence of physicochemical factors (pH and ionic strength of the solution, surface charge, etc.) on the force of adhesion between the particles, since the effect of these factors on $\Delta\Omega(H_f)$ can be established on the basis of the Deryagin–Landau–Verwey–Overbeek theory[72, 73] or of the modern theories of the steric stabilisation of dispersions.[74–76]

The effect of the deformability of solid particles on the force of adhesion between them is allowed for in the Johnson–Kendall–Roberts theory,[77] according to which (in our symbols)

$$f_a^* = 0.75\pi R \Delta\Omega(H_f) \,. \tag{187}$$

The Muller–Yushchenko–Deryagin theory[78] led to the expression

$$f_a^* = \nu \pi R \Delta\Omega(H_f) \,, \tag{188}$$

in which the parameter ν takes values in the range $0.75-1$, depending on the size of the particles, their elastic properties, the thickness of the film, and the Hamaker constant (which characterises the energy of the molecular attraction between the surfaces).

The theory of adhesion of fluid particles was constructed and applied,[4, 18] and then further developed.[5, 6, 79] The proposed equation

$$f_a^* = \nu_a \pi R \Delta\Omega(H_f) \tag{189}$$

has the same form as the relationship of the previous theory, but the parameter ν_a, which lies in the range $0.5 \leqslant \nu_a \leqslant 1.0$, is more easily accessible for numerical calculations. For example, for the disjoining pressure $\Pi(H)$ isotherm, characterised by a single coagulation minimum (Fig. 23), the parameter ν_a is expressed as follows:[5]

$$\nu_a \approx \frac{1 + 0.5\alpha_a}{1 + \alpha_a} \tag{190}$$

where

$$\alpha_a = \frac{|\Delta\Omega(H_f)|}{\Delta_3 \sigma_0 k_0} = \frac{\Pi_3}{\sigma_0 k_0} = \frac{\Pi_3}{P_c} \,, \tag{191}$$

Δ_3 is the effective width of the short-range coagulation minimum, and P_c is the capillary pressure. If the particles are in the long-range coagulation minimum we must replace Π_3 by Π_1 according to Eqn (191) (see Fig. 20*b*).

The parameter α_a is characterised by the deformability of the particles: the lower the deformability, the greater is the similarity in properties between the fluid particles and the rigid solid particles during extension. For example, for $\Pi_3 \ll P_c$ we have $\alpha_a \simeq 0$, and therefore $\nu_a \simeq 1$, which corresponds to the Bradley–Deryagin adhesion theory. If $\Pi_3 \gg P_c$ we have $\alpha_a \gg 1$, and $\nu_a \approx 0.5$, and (189) becomes

$$f_a^* = 0.5\pi R \Delta\Omega(H_f) \,.$$

The dependence of the radius of the liquid film r_f between particles on the external force f_e has been obtained[4] by numerical modelling of the contact interactions between two identical liquid particles. This involved numerically solving the system of differential equations (97), (117), (129), (130), and (137) for fixed values of σ_0 and P_c, and also of the parameters which characterise the shape of the disjoining pressure isotherm $\Pi(H)$, but with a variable external force f_e [compressing ($f_e = f_p > 0$) or extending the particle ($f_e = f_a < 0$)]. The results of one series of

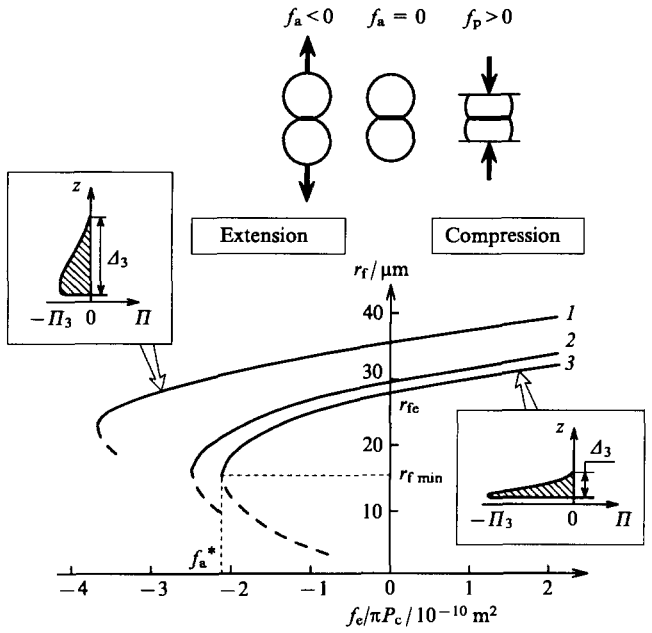

Figure 23. Dependence of the film radius on the reduced external force applied to a fluid particle of radius 1 mm ($\sigma_0 = 30$ mJ m^{-2}; $\Delta\Omega(H_f) = -60 \times 10^{-17}$ J m^{-2}) for different effective values of the parameter Δ_3, nm: (*1*) 10, (*2*) 10^2, (*3*) 10^3; $r_{f\,min}$ is the minimum stable radius of the film at the moment of detachment of the particle; r_{fe} is the equilibrium radius of the liquid film for $f_e = 0$.

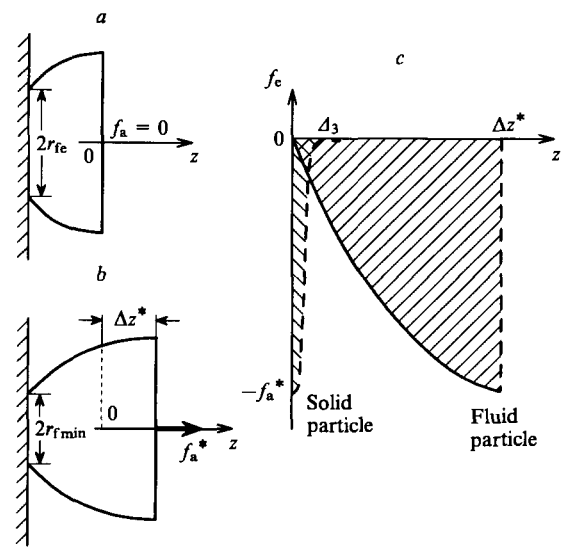

Figure 24. Illustration of the calculation of the work of removal of a fluid particle. Shape of the particle for $f_e = 0$ (*a*) and at the instant of removal f_a^* (*b*); dependence of the external force f_e on the displacement z for the removal of a solid or a liquid particle (*c*).

measurements of this type are shown in Fig. 23 as an illustration of the proposed method.[2, 4]

We should specially note that the shape of the $\Pi(H)$ isotherm (the width of the coagulation minimum Δ_3) for a given value of the free energy of interaction $\Delta\Omega(H_f)$ is strongly dependent on the force of adhesion f_a^* in the case of fluid particles, but in solid particles the dependence is negligibly small.

Work of separation of fluid particles. The strongest dependence on the shape of the disjoining pressure isotherm is seen in the work of separation of fluid particles W_a^f, which can exceed the work of separation of rigid solid particles W_a^s by more than a factor of 10^3 for equal values of $\Delta\Omega(H_f)$ and other parameters. The work W_a^f can be calculated by the relation (Fig. 24*c*)

$$W_a^f = \int_0^\infty f_e(H)\,dz \approx \tfrac{1}{2} f_a^* \Delta z^* , \tag{192}$$

where Δz^* is the displacement of the detachment force caused by the moment of the force which breaks the adhesion contact between the particles. The corresponding work W_a^s is

$$W_a^s = \int_0^\infty f_e(H)dz \approx \tfrac{1}{2} f_a^* \Delta_3 . \tag{193}$$

Obviously, the more deformable the particle, i.e. the greater the parameter α_a, the more markedly does the displacement Δz^* (Fig. 24*b*) exceed the radius of action of the molecular forces of attraction Δ_3, and the greater is W_a^f in comparison with W_a^s for a practically constant adhesive force f_a^*. In particular it has been shown[4, 5, 79] that

$$W_a^f \approx W_a^s\left(1 + \frac{\alpha_a}{2}\right) . \tag{194}$$

Eqn (194) provided the basis for the derivation of the criterion of the aggregation stability (stability towards coagulation) of emulsions,[5, 18] which for a disjoining pressure with one coagulation minimum takes the form

$$\nu_a \frac{R\Delta\Omega^2(H_f)}{\Pi_3}\left(1 + \frac{\alpha_a}{2}\right) \leqslant B , \tag{195}$$

where B is a parameter of the order of $10k_BT$, and k_B is Boltzmann's constant. If the emulsion is stable towards coalescence the relationship (195) is also the thermodynamic criterion for the spontaneous dispersing of the precipitate from such an emulsion.

In the cases of $\alpha_a = \Pi_3/P_c \to 0$ the liquid drops in the emulsion can be treated as completely rigid, and (195) is converted into the thermodynamic criterion of the aggregation stability of sols,[80, 81] i.e. (in our symbolism)

$$\frac{R\Delta\Omega^2(H_f)}{\Pi_3} \leqslant B . \tag{196}$$

For emulsions with a low value of the interfacial tension σ_0 and $\alpha_a \gg 1$ we obtain from (195) the corresponding criterion for the stability to aggregation and spontaneous dispersion of these emulsions:[5, 79]

$$\frac{R^2\Delta\Omega^2(H_f)}{\sigma_0} \leqslant B . \tag{197}$$

The expression (197) shows that if the isotherm $\Pi(H)$ has one coagulation minimum the coagulation tendency increases as σ_0 decreases, and that the tendency towards spontaneous dispersion of the precipitate from these emulsions decreases. The criterion (197) differs from the Lee and Tadros criterion for spontaneous emulsification,[82] given (in our symbols) by

$$\pi R^2\sigma_0 \leqslant B , \tag{198}$$

which describes the spontaneous formation of emulsions from macroscopic phases and predicts an increased propensity towards emulsification for lower values of σ_0.

Effect of the coagulation barrier on the adhesion of fluid particles. If the disjoining pressure isotherm $\Pi(H)$ has a coagulation barrier of height Π_2 (see Fig. 20*b*) the barrier can be surmounted in a fluid particle by applying the critical compressive force f_p^* (for a zero or negligibly small long-range coagulation minimum Π_1):[3, 5, 79, 83]

$$f_p^* = \nu_p \pi R\Delta\Omega(H_f^c) , \tag{199}$$

where $\Delta\Omega(H_f^c)$ is the specific free energy of the interaction for a thickness corresponding to the transition from a common black film to a Newtonian Black film or to coalescence, and $\nu_p = \Pi_2/P_c$ is a parameter which characterises the deformability of the particle in compression:

$$\nu_p \simeq \frac{1}{1-\alpha_p} \quad \text{for } P_c > \Pi_2 , \tag{200}$$

$$\nu_p = +\infty \quad \text{for } P_c \leqslant \Pi_2 .$$

Obviously, if the interfacial tension σ_0 is so low that the capillary tension P_c is smaller than Π_2 the coagulation barrier prevents the transition from α to β films (see Fig. 20*a*). At constant σ_0 the critical force f_p^* increases with the radius R of the particle. When $P_c > \Pi_2$ β-films are formed, and their adhesion force f_a^* is proportional to $\Delta\Omega(H_f^N)$ (see Fig. 20*a*). On the other hand if $P_c < \Pi_2$ α-films are formed, whose adhesion force f_a^* is proportional to $\Delta\Omega(H_f^c)$, i.e. it is $\sim 10^2 - 10^3$ times smaller than for β-films. During phase transitions (for example, during the melting of solid particles) we can expect a large decrease in the force of adhesion if the condition $P_c < \Pi_2$ applies to the liquid particles (assuming that compression of the solid particles invariably produces β-films).

These features of the contact interactions of liquid particles of emulsions and of the same particles with solid supports play an important role in technological processes (microencapsulation, filtration of emulsions, etc.), and also in biological processes.[27, 84–87]

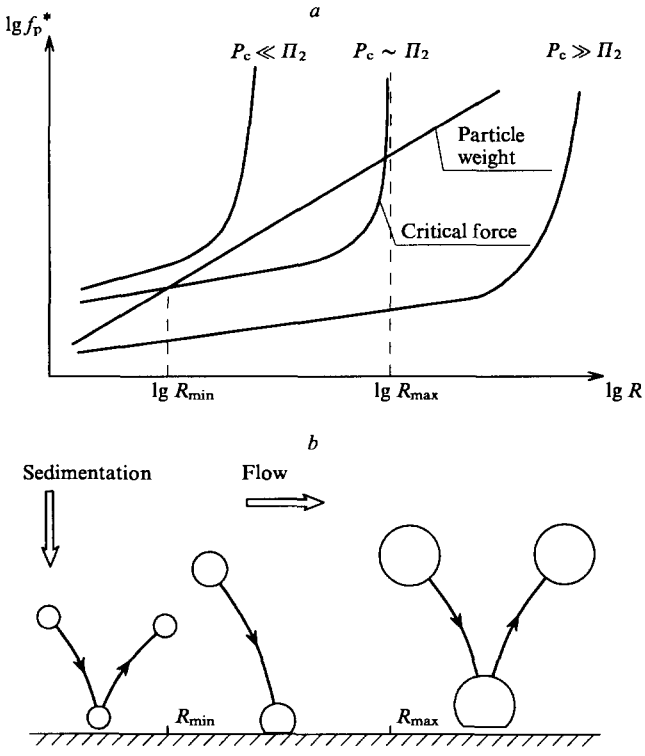

Figure 25. Effect of the radius of a liquid particle on its adhesion to a solid surface (idealised): (*a*) the dependence of the weight of a liquid particle and of the critical breaking force of the α-film for different relative values of the capillary pressure and of the height of the coagulation barrier in the disjoining pressure isotherm; (*b*) schematic illustration of the selective hetero-coagulation of the emulsion drops on the solid surface during sedimentation and flow.

The results of the theory of adhesion of solid particles are illustrated in Fig. 25*a*, which shows the dependence of the critical force f_p^* on the radius R, calculated by Eqn (199) for different heights of the coagulation barrier Π_2 in the disjoining pressure isotherm. For comparison we also show the dependence on R of the gravity force on the particles in the liquid.[3] In the case of the flow of a polydispersed emulsion with sedimentation of the liquid drops the drops accumulating at the bottom will experience the Stokes frictional force, and their weight will reflect the resultant of the force of gravity and of the repulsive force (Fig. 25*b*).

In the general case the plots of the critical force and of the weight against the radius of the particles intersect at two points, corresponding to R_{min} and R_{max}. In the region of $R < R_{min}$ the weight of the particle is insufficient to overcome the coagulation barrier Π_2, and the particles form α-films with a solid surface. They can be extracted by the flow because the force f_a^* is very small.

Similar effects are observed when $R > R_{max}$, i.e. for $P_c < \Pi_2$.

On the other hand if the condition $R_{min} < R < R_{max}$ applies the weight of the particles is insufficient to overcome the coagulation barrier and the drops form thin β-films with the surface. Under these conditions the force of adhesion may be sufficient to hold the drops on the surface during the flow of liquid. Thus we may achieve the selective heterocoagulation of fluid particles on a solid surface: only particles of a size within a fairly narrow range of radii become adsorbed.[3] The radius range corresponding to heterocoagulation can be varied by varying the physicochemical parameters of the system. For example, raising the coagulation barrier (by decreasing the concentration of electrolyte in solution) can make the $f_p^*(R)$ curve lie above the graph of the force of gravity experienced by the particles (Fig. 25*a*), and β-films will not be formed, whatever the radius of the particles. If the concentration of electrolyte is increased, i.e. if the coagulation barrier is lowered, the $f_p^*(R)$ curve will lie below the plot of the particle weight in a range of radii, and only β-films will be formed.

The radii R_{min} and R_{max} have been established experimentally[88] for a system in which gas bubbles are in contact with the phase boundary in gas–aqueous SAS solutions. The experimental values of R_{min} and R_{max} have been used[3] to calculate the parameters which characterise the coagulation barrier (Π_2 and Δ_2) of the disjoining pressure isotherm.

The work W_p^s needed to overcome the coagulation barrier at the contact of solid particles can be written as[18, 83]

$$W_p^s \simeq \pi R \frac{\Delta\Omega^2(H_f^s)}{\Pi_2}(1+\beta) , \tag{201}$$

where $\beta = \Pi_2/\Pi_3$. Under these conditions the corresponding work for liquid particles is[5, 18, 83]

$$W_p^f \simeq W_p^s \frac{1+\alpha_p}{1-\alpha_p} \quad \text{for } P_c > \Pi_2 . \tag{202}$$

The value of this work tends towards infinity for $P_c \leqslant \Pi_2$.

If the solid particle can overcome the coagulation barrier by expending an amount of work W_p^s it can be extracted (i.e. it can overcome the coagulation barrier in the reverse direction) by performing an amount of work[79]

$$W_a^s \simeq \pi R \frac{\Delta\Omega^2(H_f^N)}{\Pi_1} , \tag{203}$$

where

$$\Delta\Omega(H_f^N) \simeq \Pi_3 A_3(\alpha - 1) \quad \text{and} \quad \alpha = \frac{\Pi_2 A_2}{\Pi_3 A_3} .$$

The expression for the corresponding work in the case of a liquid particle is

$$W_a^f \simeq W_a^s(1 + \alpha_p + \alpha_a) , \tag{204}$$

where $\alpha_p = \Pi_2/P_c$ and $\alpha_a = \Pi_3/P_c$.

In conclusion we quote expressions for the aggregation stability criterion of the emulsion in the case of irreversible coagulation of the particles (for the condition $W_a^f \gg k_B T$),[83]

$$W_p^s \frac{1+\alpha_p}{1-\alpha_p} > B , \tag{205}$$

and for the spontaneous dispersion of the precipitates from the emulsion[83]

$$W_a^s(1 + \alpha_p + \alpha_a) < B . \quad (206)$$

The writer has discussed[18, 79, 83-87] the effect of σ_0 on the stability of emulsions and their propensity for spontaneous dispersion by allowing for the criteria (195), (196), (197), (205), and (206). In particular it was shown that whereas in a disjoining pressure isotherm without a coagulation barrier a decrease in the interfacial tension lowers the aggregation stability of the emulsion, in the presence of a coagulation barrier of sufficient height the effect of the surface tension on the stability of the emulsion is exactly the opposite. Therefore when examining the stability of emulsions and comparing the results of different studies of its dependence on σ_0 it is essential to allow for differences in the concentration of electrolytes and for other factors which influence the height of the coagulation barrier.

V. Conclusions

This review of studies of the thermodynamics of curved free interfacial surfaces in the region of the bulk meniscus of liquid films has identified different approaches to the determination of the interfacial tension of these surfaces.[8, 19, 21] We have shown that alternative methods of determining the interfacial tension of curved surfaces are possible, and that they lead to fundamental (Gibbs–Kelvin) equilibrium equations more convenient for practical applications in the case of objects of submicroscopic dimensions.

The thermodynamics of interacting curved interfaces (i.e. the thermodynamics of the transition region of a liquid film)[1-6, 18] are a self-consistent and closed system of concepts and of equations relating the disjoining pressure to other thermochemical parameters and functions. They reconcile the thermodynamics of free curved interfaces with those of the interacting interfaces in plane-parallel liquid films, and they reduce to the latter in the appropriate ranges.

The invariants obtained for the profiles of liquid films can be used to find all the known equations for the equilibrium of liquid films with a bulk meniscus, both in the membrane approach and in the approach based on the assumption of two dividing surfaces in the liquid film. These invariants can also be used to derive precise analytical expressions for the line tension.[3, 5, 6]

The theory of the adhesion of liquid particles developed by the writer[1, 4, 18] establishes the relationship between the adhesion forces and the parameters which characterise the disjoining pressure isotherm in the liquid film. The relationship between the force of adhesion and the specific free energy of adhesion obtained by this theory differs from the corresponding expression of the Johnson–Kendall–Roberts theory,[77] which is usually adopted to describe the adhesion of elastic solid particles and includes the Bradley–Deryagin theory[68, 69] as a limiting case (relating to liquid particles with a very large capillary pressure).

Our criterion[18, 79, 83] for the aggregation stability of emulsions can be used to explain the effect of the interfacial tension and of the shape of the disjoining pressure isotherm on the stability of emulsions towards coagulation. In particular we have shown that a decrease in σ_0 can both increase and decrease the aggregation stability of emulsions, depending on whether or not the $\Pi(H)$ isotherm includes a coagulation barrier. This large difference in the behaviour of emulsions as compared with sols under identical physicochemical conditions is attributed to the fact that in the interaction between liquid drops in emulsions the work associated with the deformation of the particle surfaces can exceed by a factor of $\sim 10^3$ the work of the disjoining pressure forces.[1, 4]

Abstract. Modern ideas concerning electrical transport in electrolyte solutions and capillary isotachophoresis—one of the microanalytical methods based on the different mobilities of ions in electrolyte solutions—are briefly considered. The isotachophoretic methods are classified in terms of the positions of the solutions and the directions of motion of the boundaries. The application of the coulophoretic method to the analysis of solutions, the measurement of the amount of electricity passed through the system, and the measurement of the internal cross-section of the capillaries are described. A description is also given of the electromigration method for crystallisation in capillaries and the isotachophoretic method for the determination of the electrical transport of the solvent in electrolyte solutions. The bibliography includes 96 references.

I. Introduction

The phenomena associated with the motion of ions in electrolyte solutions were discovered in the middle of the XIXth century. It was then observed that species migrate in an electrolyte solution when a constant electric field is applied to the latter,[1–3] the cations and anions of the same electrolyte moving at different rates in the electric field in the solution.[4] The concepts of the mobility and transport numbers of ions in solution were therefore introduced. The formation of a boundary between two electrolyte solutions with a common ion was later observed in a constant electric field.[5] The boundary between solutions having a common anion migrates to the cathode while that between solutions having a common cation migrates to the anode. Kohlrausch and Whethem formulated the stability conditions in their classical studies.[6,7] They showed that a boundary between solutions which are stable in time may be formed only when the mobility of the non-common ion of the electrolyte, present ahead of the boundary in the direction of its motion under the influence of the electric field, is greater than the mobility of the non-common ion of the electrolyte to the rear of the boundary. Kohlrausch also established that the concentration of the solution to the rear of the boundary in the steady state is constant under the given conditions and is determined by the concentration of the solution ahead of the boundary. He derived theoretically the so-called regulating function, one of the forms of which was later given his name:

$$\frac{c_1 z_1}{c_2 z_2} = \frac{u_{c1}}{u_{c1} + u_{a2}} \frac{u_{c2} + u_{a2}}{u_{c2}} = \frac{t_{c1}}{t_{c2}} . \qquad (1)$$

Here c_1 and c_2 are the concentrations of two solutions with a common anion separated by a steady-state boundary, the subscripts 1 and 2 denote that the given quantity refers respectively to the front and rear solutions, u_c and u_a are the mobilities, i.e. the velocities in a unit electric field, of the cations and anions respectively, z_1 and z_2 are the charges on the cations, and t_c are the transport numbers of the cations. The Kohlrausch function (1) was formulated for a boundary between two solutions with different cations and a common anion.

The electrode solution (catholyte or anolyte) ahead of the boundary is called the leading solution (leader), while that to the rear of the boundary is called the terminating solution (terminator). The concentration of the terminating solution changes during the adaptation process (the attainment of the stationary state) in such a way that after a certain time, determined by the strength of the electric field and the difference between the mobilities ($u_{c1} - u_{c2}$), it becomes comparable to the quantity required by the regulating function. The adaptation constitutes an important property of such boundaries.

The formation of boundaries between two solutions is used to determine the transport numbers and mobilities of ions. The widths of the boundaries have been estimated theoretically.[8–10] Towards the end of the 1920s, the first attempts were made to use ionic boundaries for the separation of certain chemical elements.[11] Considerable interest in electromigration methods arose again in the 1960s in connection with the use of capillaries and the development of instrumental methods for the detection of boundaries in them. Such is a brief history of the development of *isotachophoresis*—the term applied to this phenomenon at the present time. This term implies the motion of non-common ions

on either side of the boundary at the same rate (equal velocity motion).[12]

It is noteworthy that the study of the phenomenon of isotachophoresis involved mainly dilute solutions and certain fundamental problems of electrical transport in electrolyte solutions were not considered. Up to the 1960s, simplified ideas concerning the motion of species in electrolyte solutions predominated. It was assumed that, at least in strong electrolyte solutions, ions are rigidly bound to the nearest water molecules and migrate together with the latter under the influence of the field.[13] This led to the erroneous view that the water in the electrolyte solution is present in two states—'free' and 'bound'. The so-called free water was chosen as the reference system in the measurement of the mobilities and the corresponding transport numbers of ions. Hence appeared the widely used concepts of 'apparent' and 'true' transport numbers corresponding to the 'apparent' and 'true' mobilities, etc. The incorrect ideas about the kinetic phenomena in electrolyte solutions led to a whole series of errors, which entered into a familiar monograph on kinetic phenomena in electrolyte solutions[14] and electrochemical manuals.[15]

II. Modern ideas about electrical transport in electrolyte solutions

The initial concept in electrical transport phenomena is that of ionic mobility. The latter is considered, in particular, because it is assumed that the electrolyte under consideration dissociates in aqueous solution only into ions of known composition. According to modern ideas, this claim is valid only for a small number of strong electrolytes in an aqueous solution in the range of low and moderate concentrations. As regards the majority of ionogenic substances, one cannot assume that all the ions into which they dissociate in aqueous solutions are known over a wide range of concentrations. Therefore in the general case one introduces the concept of the mobility of an ionic component. This is the average mobility of all the ionic forms, which includes the ionic component under consideration.[16] For example, in a cadmium chloride solution, the ionic component (cadmium) forms part of the cations Cd^{2+} and $CdCl^{+}$ and the anions $CdCl_3^-$ and $CdCl_4^{2-}$, but at moderate concentrations it migrates to the cathode in an electric field. The experimentally measured quantity is in fact the transport number of the ionic component. It is equal to the number of equivalents of this component transported in the direction of the cathode (or anode) when one Farad (0.96×10^5 C) passes through the solution. Clearly, when the ion is identified with the ionic component, significant errors may arise in the interpretation of the experimental results for electrical transport.[16] Unfortunately, the necessary difference is not drawn between the ion and the ionic component in many monographs and textbooks.

The concept of mobility presupposes the existence of a reference system in the measurement of the rate of motion of the ionic component in a specified electric field. The reference systems may be various including stationary and mobile ones. The laboratory system linked to the measuring instrument is stationary. Mobile systems may be linked to any species migrating in the solution under the influence of the field, for example to solvent species. The reference system can move at a rate averaged over all the moving species constituting the solution (mass-average, molar-average, etc. rate).[17] Another characteristic of electrical transport is the transport numbers expressed in terms of the mobilities of the ionic components (J). According to IUPAC rules,[18] they should be referred to the ionic components and determined in the coordinate system in which the mobilities included in them have been measured. It is noteworthy that the majority of Russian textbooks on electrochemistry did not require, until very recently, the introduction of a reference system in the determination of mobilities and transport numbers (two textbooks are exceptions[19,20]). These problems have been considered in detail by the present authors.[21]

The question which transport numbers (and in what coordinate systems) are measured by the corresponding experimental methods is fundamental.

We shall begin its consideration with the isotopic boundary method,[22] since it made it possible to demonstrate experimentally the difference between the reference systems in the measurement of mobilities and transport numbers. The essential feature of the method is as follows. Conditions preventing the convective mixing of the solutions are established in the electrolytic cell. A boundary is formed in the cell between two solutions with the same electrolyte concentration but different concentrations of an isotope of one of the elements of the electrolyte and the solvent. The position of the isotopic boundary of the electrolyte and the solvent is fixed relative to the measuring tube. A definite amount of electricity is passed through the cell, after which a number of samples are taken and the isotopic concentrations of the ionic component and the solvent are measured in them. The positions of the isotopic boundaries of the solvent and the ionic component are found from these data after passing a current or, in other words, the migration of the ionic component in the solvent as a result of the passage of a definite amount of electricity is determined.

The isotopic boundary method can be applied using a specially developed apparatus.[23] In order to eliminate convective mixing, the working compartment is filled with finely dispersed quartz sand with a grain size of 20–40 μm. The introduction of a bypass tube with a tap precludes the possibility of hydrodynamic flow (and hence a displacement of the boundaries) by a process other than electromigration. The extent of electroosmotic flow (V_{osm}) and the displacement of the boundaries caused by it are calculated from preliminary measurements of the flow potential ΔV for a pressure drop ΔP from the thermodynamic relation

$$\frac{V_{osm}}{I} = \frac{\Delta V}{\Delta P},$$

where I is the electric current passed during the period of the experiment.

Special measures are taken in order to obtain results stable in relation to the flow potential. The isotopic solvent (water) boundary is established by adding deuterium-enriched water to the second solution. The concentration of deuterium does not then exceed several atomic per cent, which makes it possible to refer the measured characteristics of the electrical transport to aqueous solutions with the usual isotopic composition. The deuterium content in the water is determined by the highly sensitive temperature-flotation method from the temperature of the indifferent equilibrium of a quartz microfloat.[24] The isotopic analysis of the added components is carried out mass spectrometrically. The water and lithium isotopic boundaries in the lithium chloride solution under conditions where a 50 mA current is passed through the system for 5 h migrate in the tube towards the cathode without change in their initial form. The water isotopic boundary lags behind the lithium isotopic boundary. It should be noted specially that the migration of the boundary due to the electroosmotic flow of the entire solution is similar in terms of magnitude to the electromigration displacement even at the fairly high solution concentration of 2 M. Failure to take into account electroosmosis was apparently the principal cause of the considerable scatter in the experimental results in previous studies of electromigration in solutions.[25]

Thus it has been confirmed experimentally that water in the lithium chloride test solution migrates towards the cathode when the current is passed and the difference between the laboratory coordinate system and the 'solvent as a whole' system in the measurement of the mobilities and transport numbers was clearly demonstrated. This result agrees qualitatively with the idea that the frequency of exchange of the water molecules close to the surface of the strong electrolyte ion and the remaining water is close to the exchange frequency of the water molecules in water.[26] One may conclude that at the same time there are no grounds for

subdividing the solvent molecules into those which are bound and not bound to the electrolyte ion and for the selection of the free solvent as the reference system in measurements of mobilities and transport numbers. Naturally, all the above effects are manifested appreciably only at moderate and high concentrations of electrolyte solutions. When the solution concentration tends to zero, the differences between the reference systems disappear.

We shall consider, from the standpoint of modern ideas, the coordinate systems in which mobilities and transport numbers are measured by classical methods.

The *Hittorf method*–the first known method for the measurement of transport numbers—consists of the following steps. The change in the number of equivalents of the ionogenic substance is measured (the transport numbers of the ionic components are determined for this purpose) in the electrode compartment of the electrolytic cell after passing a definite amount of electricity. For this purpose, the cell is fitted with a tap, which makes it possible to remove part of the solution from the electrode compartment after electrolysis and to determine the concentration of the test substance in it. On the basis of the erroneous ideas concerning the water bound to ions, most workers assumed that the Hittorf method yields apparent transport numbers. This was explained by the presence of an unaccounted for amount of water transported into the electrode compartment, where the difference between the concentrations before and after electrolysis is determined.[13,15] However, the Hittorf method has one experimental feature which has not been noted by many investigators. The point is that the amount of solution in the section separated for analysis changes during electrolysis. Therefore one determines in this section not only the amount of the test substance but also that of the solvent. Since the volume of the corresponding section of the apparatus is known, the amount of the solvent in it before the start of the electrolysis is likewise known. The most important element of the calculation by the Hittorf method is the adjustment of the amount of the test substance after electrolysis to the amount of water which was present in the separated volume before the passage of current. Without such adjustment, the error in the interpretation of the results is negligible only for dilute solutions. It has been shown[27] that this computational procedure makes it possible to obtain transport numbers in a coordinate system linked to the solvent as a whole without determining the rate of migration of the solvent itself. The above study was carried out in a general form without resorting to any model ideas about electrical transport in electrolyte solutions.

There exist methods for the determination of transport numbers from measurements of the e.m.f.'s of concentration and galvanic cells in an external gravitational field. The accuracy of the determination of transport numbers by these methods is appreciably lower than that of the determination by other classical methods.[28]

The *isotachophoretic method* is based on the direct measurement of the rate of motion of ionic components (in the simplest case ions). In the past, this method was known under different names: ion migration, analysis based on ionic mobilities, and the moving boundary method. In its application, a steady-state boundary is created between two electrolyte solutions with a common ion. The theory of the method has been described most fully by Milios and Newman.[29] On the basis of the general postulates of the thermodynamics of irreversible processes, the authors showed that the isotachophoretic method makes it possible to obtain transport numbers rigorously in a 'solvent as a whole' coordinate system. A cell in the closed compartment around one of the electrodes, at which the electrode process is known exactly, is used for this purpose. This permits the calculation of all the changes in the volumes of the substances segregating and dissolving. A correction is also introduced for the volume change during diffusional mixing at the boundary between the saturated solution at the electrode and the working solution in the main volume. The hydrodynamic processes in the region of the isotachophoretic boundary have been considered in a theoretical study.[30] A general expression was obtained for the fluxes of all the components of the solutions on either side of the boundary:

$$\rho_i(v_i - w) = \text{const},$$

where ρ_i is the concentration of the ith component (g cm^{-3}) and v_i and w are respectively the velocities of the component and the boundary in the laboratory coordinate system (cm s^{-1}). This equation was quoted without derivation by Milios and Newman.[29] We recall that the ith component can be characterised by the subscript 1 or 2 depending on whether the given species belongs to the leading or terminating solutions respectively. For the solvent (water), we have

$$\rho_{01} = \rho_{01}(v_{01} - w) = \rho_{02}(v_{02} - w).$$

Hence it follows directly that, when a direct electric current is passed through the leading and terminating electrolyte solutions, component transfer of the solvent by electromigration should take place since the water concentrations in the two solutions are in general not equal ($\rho_{01} \neq \rho_{02}$). The occurrence of water transfer by electromigration in each of the solutions 1 and 2 considered separately for the electric fields which exist in them when they form an isotachophoretic boundary also follows from this relation. The attempts to measure the electromigration transport of the solvent were made a fairly long time ago, but the scatter of the experimental data was so great[25] that these studies can be regarded only as evidence for the occurrence of the effect itself. The modern method for the measurement of the electromigration transport of the solvent in electrolyte solutions, based on the isotachophoretic regulating function, will be considered below adducing some results obtained by the isotopic boundary method.

One of the versions of the isotachophoretic method is the *method involving the joint observation* of the motion of the ions and the solution.[31] It does not require the exact knowledge of the electrochemical process at the electrode and therefore expands the possibilities of the usual isotachophoretic method. Under certain conditions, the joint observation method also permits the determination of the transport number relative to the solvent.[32] This is confirmed by the agreement between the results of the measurements of the transport numbers by this method and by the Hittorf method.[28]

The regulating function (1) constitutes the basis of all the ideas about isotachophoresis. In principle, the boundary between two electrolyte solutions with a common ion can be created at any concentrations of these solutions, but, when a direct electric current is passed through this boundary, it will be stable as a function of time only when the concentrations of the solutions satisfy the regulating function. Otherwise the concentration of the terminating solution will vary continuously and spontaneously until it reaches the value determined by the regulating function. The regulating function can be written in the following forms:[33]

$$\frac{c_1 z_1}{c_2 z_2} = \frac{t_1}{t_2} \qquad \text{(Kohlrausch form)}, \qquad (2)$$

$$\frac{c_1^0 z_1}{c_2^0 z_2} = \frac{t_1^0}{t_2^0} \qquad \text{(Hartley form)}, \qquad (3)$$

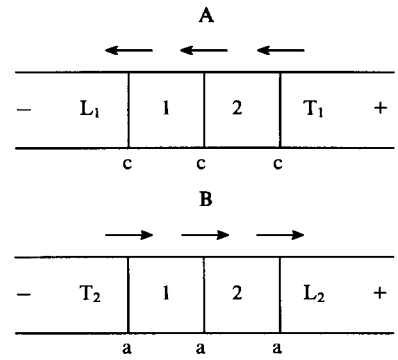
where c_1 and c_2 are the molar concentrations of the solutions and c_1^0 and c_2^0 are the corresponding molal concentrations (mol/kg of water).

The transport numbers in Eqns (2) and (3) differ fundamentally from one another, since they are measured in different coordinate systems: in the first case, measurements are made in the laboratory coordinate system in the absence of the flow of the solutions as a single whole, i.e. in a coordinate system common to both solutions, while in the second case measurements are made relative to the solvent of each solution, i.e. in coordinate systems which are different for the two solutions, since the flow rates of the solvent in the leading and terminating solutions are different.

The discrepancy between the right-hand sides of Eqns (1) and (2) and the identity of the left-hand sides should be noted. The point is that in Kohlrausch's time it was assumed that the Hittorf method (the only one known at the time) yields transport numbers in the laboratory coordinate system which are suitable for the regulating function. It is now clear that only a small error was then introduced, since the experiments were carried out with fairly dilute solutions. The expression relating both forms of the regulating function was obtained for the first time by Gorshkov:[33]

$$\frac{t_1^0}{t_2^0} = \frac{\rho_{02} t_1}{\rho_{01} t_2} \quad (4)$$

We may note that the differences between the two forms of the regulating function vanish, like the differences between the reference systems for the measurement of transport numbers, when the concentrations of the solutions tend to zero. Eqns (2) – (4) have been used in the development of a method for the determination of the electromigration transport of the solvent (water) in electrolyte solutions over a wide concentration range.

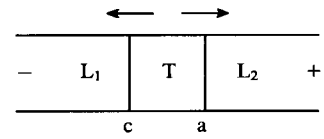


III. Modifications of the isotachophoretic method

Hitherto, in speaking of isotachophoresis, we considered only two solutions with a common ion. These solutions, placed in a electrolytic cell where their mixing is hindered, form after a time a moving steady-state isotachophoretic boundary when a current is passed. It is found that, when certain conditions are maintained in the electrolytic cell, several and not one boundary may exist. Depending on the type of these boundaries, on the direction of their motion in the electrolytic field, and on the disposition of the solutions in the column (electrolytic cell), it is possible to distinguish different varieties of isotachophoresis.[34]

1. Classical isotachophoresis

Classical isotachophoresis can be naturally subdivided into cationic and anionic. In the cationic version, the two electrolytes have a common anion and the boundary between the solutions with different cations accordingly migrates to the cathode. In anionic isotachophoresis, the electrolytes have a common cation and the boundary moves towards the anode in the electric field. The steady-state concentrations of the leading and terminating solutions are described by the regulating function. However, the terminating solution in the above pair can itself be the leading solution for a third solution if the mobility of the non-common ionic component of this third solution is lower than the mobility of the non-common ionic component of the given terminating solution. For the third solution, the former terminating solution becomes the leading solution. The concentration of the third solution is also determined by the regulating function, which includes the transport numbers of the non-common ionic components of the second and third solutions. Thus in cationic isotachophoresis it is possible to obtain a whole series of zones in the electrolytic cell, the boundaries between which correspond to the steady state. When the regulating function holds, they move to the cathode at the same rate. Similarly in anionic isotachophoresis it is likewise possible to obtain a series of zones of pure solutions, but this time with a common cation, which move at their constant rate towards the anode in the electric field. The disposition of the solutions in the direction of the movement of the boundaries in cationic (A) and anionic (B) isotachophoresis is illustrated in Scheme 1, which represents an electrolytic cell with solutions. The plus and minus signs in the scheme indicate the polarity of the applied potential, the numerals 1 and 2 denote the zones of the pure solutions, and L and T denote the leading and terminating solutions. The vertical lines indicate the boundaries of the solutions and the arrows show the direction of motion of the boundaries. The letters 'c' and 'a' denote the cationic and anionic boundaries.

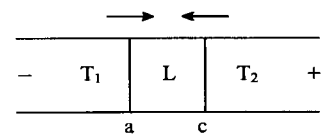


Scheme 1

2. Electrosynthesis at the ionic boundaries

The possibilities of isotachophoresis are greatly expanded when cationic and anionic boundaries are used simultaneously in the electrolytic cell. Electrosynthesis is the term given to the simultaneous formation and movement under the influence of the electric field of two diverging (cationic and anionic) isotachophoretic boundaries. The disposition of the solutions and the direction of the motion of the boundaries under the influence of the electric field are presented in Scheme 2.

Scheme 2



It is striking that one less electrically conducting solution can be synthesised from two more conducting solutions. During electrosynthesis, a third solution is formed from the leading solutions L_1 and L_2. It has a common cation with one leading solution and a common anion with the other. The amount of terminating solution synthesised increases continuously. The phenomenon of electrosynthesis frequently occurs in analytical capillary isotachophoresis and coulophoresis (see below). Electrosynthesis was first predicted by Kohlrausch.[6] Electrosynthesis at the ionic boundaries has nothing in common with the familiar synthesis of substances at electrodes. It makes it possible to obtain various electrolytic solutions — both inorganic and organic. Unfortunately, the method has not received a technological formulation and is not used in preparative let alone industrial practice.

3. Coulometric titration at ionic boundaries (coulophoretic method, coulophoresis)

In contrast to electrosynthesis, in coulophoresis the cationic and anionic isotachophoretic boundaries move towards one another under the influence of the electric field, as shown in Scheme 3.

Scheme 3

In this case, the leading solution is located between two terminating solutions and has a common cation with one of the terminating solutions and a common anion with the other. During electrolysis, the amount of the leading solution continuously diminishes up to its complete disappearance.

The coulophoretic method was proposed in 1974 as a new microanalytical method in capillaries based on the Faraday law.[35,36] The modifications of isotachophoresis (other than electrosynthesis) are considered below in the version performed

in capillaries, i.e. in the form of capillary isotachophoresis which is most widely used in practice.

IV. Classical capillary isotachophoresis

In order to carry out isotachophoretic processes, it is essential to ensure conditions under which convective stirring of the solutions in the column would be eliminated and instrumental methods for the detection of the boundaries must be available. The boundaries between coloured and colourless solutions can be detected visually at certain concentrations, but the region of applicability of isotachophoresis is then negligible. The conditions under which convective mixing is excluded in the electrolytic column have been examined.[37] The structure of the boundary between two solutions is influenced by the heat change. Heat is evolved in the column uniformly throughout its volume and is removed via the surface, as a result of which a temperature drop between the centre and the surface arises in the column cross-section. Since the mobility of ions depends on temperature, a convective mixing stream is superimposed on the rate of their translational motion. A second factor inducing the spreading of the boundary is the hydrodynamic and electroosmotic flow of the solutions in the column. All these factors can be described as purely diffusional mixing by introducing a quantity equivalent to the diffusion coefficient (D_{eq}). There exists an expression which makes it possible to estimate this quantity in columns with a circular cross-section.[37] Even for an electric field strength of 20–50 V cm^{-1}, the quantity D_{eq} differs little from the molecular diffusion coefficient provided that the column consists of a cylindrical capillary with an internal diameter of 0.2–0.5 mm. Even under the conditions of a hydrodynamic countercurrent the width of the majority of boundaries is then about 0.2 mm and the temperature drop between the centre and the periphery is about 1 °C. The countercurrent represents the hydrodynamic flow of both solutions against the motion of the boundary. If the velocity of the countercurrent is equal to the rate of mixing of the boundary in the electric field, then the boundary is stationary relative to the walls of the separating column.

The use of capillary columns makes it possible to eliminate the need for the maintenance of gravitional stability of the boundary. This means that in an electrolytic cell the boundary remains stable regardless of whether the denser solution is below it or above it. When columns with a large diameter are used, the mixing of the solutions due to the hydrodynamic flow, the operation of gravitational forces, and heating as a result of the evolution of heat are excluded by filling the column with an agar gel or finely disperse particles (sand, glass wool). The use of a gel is possible only in some cases, since it does not set at high concentrations of the solutions, decomposes in solutions of acids and alkalis, is sensitive to heating, and does not allow the use of a hydrodynamic countercurrent.

The choice of the geometrical parameters of the column and its operating conditions (the electric current, temperature, and the countercurrent) is made taking into account the proposed method for the detection of ionic boundaries. The optimum procedures for the detection of the boundaries are those which employ the common properties of the solutions. They include the thermometric method, the observation of the diffraction pattern when the capillary is illuminated with a narrow light beam, the measurement of the electrical conductivity of the solutions, and the measurement of the electric field in the solutions. These and other specific methods for the detection of boundaries in isotachophoresis have been briefly reviewed.[38] Yet another universal method for the detection of boundaries, based on detection with the aid of a thermoviewer of the IR radiation emitted from the surface of the column, was proposed in the same communication. For capillary columns with an internal diameter of 0.1–0.8 mm, it is most convenient to employ, depending on the tasks to be performed, the thermometric method and the methods involving the measurement of the electrical conductivity and the electric field, on the one hand, and the methods involving the observation of the diffraction pattern and the thermovisual observation, on the other. Such combination of a capillary electrolytic cell with instrumental methods for the detection of boundaries between the electrolyte solutions in them actually constitutes *capillary isotachophoresis*. It was proposed in 1962 in our country.[39,40] Studies on capillary isotachophoresis were subsequently published also abroad.[41]

Capillary isotachophoresis makes it possible to solve all analytical problems using microamounts of test substances and microvolumes of the solutions. At the present time, there are two versions of the instrumental formulation of the capillary isotachophoretic method. The first version, mainly developed abroad, presupposes the use of capillaries with an internal diameter up to 0.8 mm and the detection of the boundaries by means of a point detector on the basis of the temperature, the electrical conductivity, and the electric field strength frequently combined with additional detection based on the absorption of UV light. Such a detector makes it possible to determine the positions of all the boundaries only consecutively. One usually detects under these conditions boundaries moving past a stationary detector, although sometimes the detector is also moved (for example, a thermometric detector) relative to the capillary. In the second version, use is made of long detectors capable of detecting all the boundaries simultaneously. Such detectors are based on the observation of a diffraction pattern from a slit with sharp edges obtained when the capillary is illuminated with a narrow light beam. The capillary then acts as a cylindrical lens and the zones of solutions with various refractive indices appear on the screen as rectangles of different widths within which there are interference bands approaching one another towards the centre† (Fig. 1). The sensitivity of the method ensures the detection of boundaries for a difference between the refractive indices of the solutions forming them of 0.001–0.002.[42] A long detector based on measurements of the electrical conductivity of the solutions,[43] which consists of a horizontal section of a 9 cm long column with a rectangular cross-section (1 × 0.4 mm) on which 256 electrodes have been deposited at distances of 340 μm, has been described. A long detector in which the absorption of UV light is employed has also been proposed.[44] The detector in which the boundaries are detected with the aid of a thermoviewer also belongs to the class of long detectors.[38]

We shall now compare qualitatively the types of long detectors described. The diffraction detector makes it possible to detect relatively readily all the boundaries in a cylindrical transparent capillary over a section of any reasonable length. There are instruments in which the length of such a section reaches 240 mm.[45] This method of detection does not alter the natural width of the boundary. The detector has been used[43] in a column with a large cross-sectional area where the width of the boundary

Figure 1. was therefore about 3 mm. The diffraction method is best used for highly concentrated solutions, although in the case of high-molecular-mass compounds the sensitivity indicated above (a difference between the refractive indices of 0.001–0.002) is attained at a concentration of about 0.01 M. A long thermal conductivity detector operates best in dilute solutions. Thus solutions with a concentration of about 0.01 M have been used.[43] The thermovisual method naturally has a higher sensitivity in the region of more dilute solutions. Industrial instruments in which this type of detection is employed have not so far been developed.

Evidently universal long detectors, effective over a wide concentration range (approximately from 0.001 M to saturated solutions) are most promising. Such detectors significantly facilitate the experiment, since they make it possible to observe the very process in which mixtures are separated into zones of pure solutions and one can make sure directly that it has reached completion when the lengths of the zones cease to change with time. The latter cannot be achieved when the zones move past a point detector and the completion of the separation process must be inferred in this case solely from indirect data.

Capillary isotachophoresis using the above methods for the detection of zone boundaries is a modern ultramicromethod for the qualitative and quantitative analysis of ionogenic substances in electrolyte solutions. The instruments used in capillary isotachophoresis in our country include the following: the single-channel AIP-1 apparatus,[37] the six-channel AIP-2 apparatus,[46] the four-channel IS-5501 apparatus,[45] and the single-channel ITFK-2-001 apparatus.[47] The electrolytic column and the optical part of the single-channel IS-5501 apparatus are illustrated schematically in Fig. 2.

1. Qualitative analysis

A method for qualitative analysis with the aid of capillary isotachophoresis, called the method of additives to standard mixtures, has been proposed recently.[48] Its essential feature is as follows. A preliminary study is carried out initially where the order in which the ionic components move to the electrode is investigated. For this purpose, one selects a series of compounds soluble in water (or another ionogenic solvent) with a common anion and another series with a common cation. The solutions are separated into zones with a single common anion by means of cationic capillary isotachophoresis and the sequence in which the zones move to the cathode is studied. This procedure includes the addition to the initial pure solution of a second solution with a common cation, the separation of the mixture into zones, the attainment of a steady state, and photography of the diffraction pattern. After this, the mixture is again separated changing the content of one of the components.

By comparing the photographs obtained, one can establish readily the order in which the two zones with a common anion follow one another. Next, a third pure solution is added with the same common anion, the mixture is again separated into zones and so on. It is thus possible to establish the order in which any number of zones with a common anion follow one another. For example, in solutions of formates the ammonium zone is followed by the sodium, barium, calcium, lithium, magnesium, cobalt, zinc, cadmium, and acetic acid zones.[49] At the same time conditions are selected under which the order in which the above zones follow one another is retained, i.e. the current, the concentration of the leading solution, and the concentration and pH of the terminating solution are selected.

The order in which the zones follow one another in solutions with other common anions and common cations are studied similarly. Examples of the separation of multicomponent solutions containing the cationic and anionic components of inorganic, organic, and amphoteric compounds have been published.[50–54] We may note that mixtures containing lanthanide ions and amino-acids, which are difficult to separate by the usual methods, were separated in the above investigations. The number of components in the mixtures separated sometimes reached 20. As already stated, the detection of the zone boundaries from the diffraction pattern is possible when the difference between the refractive indices of the solutions in the zones is not less than 0.001. For low-molecular-mass compounds, this difference is maintained when a solution with a concentration of about 0.5 M is used as the leading solution. For high-molecular-mass compounds, the lower limit of the concentration of the leading solution may be reduced by one or sometimes even two orders of magnitude.

The qualitative analysis of the mixture consists of the following steps. A standard solution with a known set of ionic components at approximately identical concentrations is separated under the chosen conditions with the aid of capillary isotachophoresis into zones of pure solutions. The zones obtained are then photographed. After this, part of the leading or terminating solution is removed from the capillary and the same volume of the test solution is introduced. An electric current is again passed through the column. Separation is carried out until the attainment of a steady state and the zones are photographed. The components of the test solution are then incorporated into the corresponding zones and increase their length [adaptation (Translator)]. The increase in the length of any one zone compared with the initial zone indicates the presence of the corresponding component in the test specimen.

The sensitivity of the qualitative analytical method described is determined by the width of the boundaries between the zones. The width is about 0.2 mm. The length of the zone for a specified amount of the substance in it is determined by the concentration and cross-sectional area of the column. If the initial length of the column of the test mixture placed in the capillary is 50 cm for a concentration of the leading solution of 0.5 M, then, in order that the length of the zone after adaptation should reach 0.2 mm (the width of the boundary), the concentration of the component in the solution should be not less than 10^{-4} M. There is in principle no upper limit to the concentration.

The analysis is carried out most readily when the concentrations of the components in the test solution differ by not more than two orders of magnitude for a length of the column

of solution of about 10 cm. In other cases, certain special procedures must be carried out in a preliminary step, which makes it possible to remove from the capillary the excess of the component present in an overwhelming amount. We may note that the qualitative analytical method considered requires the application of a universal long detector which detects simultaneously all the boundaries, for example a diffraction detector or a thermoviewer.

2. Quantitative analysis

Quantitative analysis with the aid of capillary isotachophoresis is based [40] on the regulating function. This is why so much attention was devoted above to the examination of its different forms. The quantitative analytical method may be absolute if the transport numbers of the ionic components of the leading and terminating solutions are known beforehand with the necessary accuracy (or, which is equivalent to the above, the concentration of the terminating electrolyte incorporated in the leading solution) over a wide range of concentrations of the solutions. Unfortunately, there are very few experimental data of this kind [28, 55–57] and the method is therefore used as a relative procedure requiring comparison with a standard. For this purpose, the length of the zone of the component to be determined (or the rate of movement of the zone past the detector, which is proportional to the above quantity) is measured in the standard and text mixtures under identical conditions. The methods for the quantitative analysis of dilute and concentrated solutions have been described in detail in numerous original communications and monographs [58–69] and we shall not be concerned with them here. We may note only that industrial products from different industries, natural waters and brines, aminoacids, as well as certain natural products were analysed.

Interesting features of the isotachophoretic separation of a two-component mixture have been noted.[70] It was found that the separation after adaptation is not accompanied by a change in the total volume of the solution. Therefore, by measuring during the separation process the lengths of the zones of the pure electrolyte solutions and the unseparated mixture, it is possible to determine, without waiting for the end of the separation process, the time required for the total separation and the contents of the components.

Thus the suitability of capillary isotachophoresis for both qualitative and quantitative analysis makes it an independent instrument in the laboratory identification and determination of ionogenic substances in electrolyte solutions.

3. Preparative possibilities of capillary isotachophoresis

A characteristic feature of capillary isotachophoresis is the use of ultrasmall amounts of substances and a virtually 100% separation of mixtures into pure solution zones, which leads to the possibility of its application as a preparative method. This concerns the isolation of a solution of the required substance from a mixture of electrolyte solutions and its separation in space for use in the solution of specific problems where pure substances in small amounts are required. Capillary isotachophoresis has been used, for example, for the separation of lithium salts from sodium salts.[71] The pure lithium chloride solution zone was cut off together with part of the capillary for subsequent isotopic analysis with the aid of a mass spectrometer.

The preparative possibilities of the method include also the concentration and dilution of solutions by adaptation with respect to the regulating function. A special case of such concentration is crystallisation with the aid of isotachophoresis.

Capillary isotachophoresis makes it possible to enrich a mixture of components present at low concentrations. The enrichment takes place as a result of the prolonged withdrawal of an element from a large volume into the capillary column. This preparative procedure has been used to determine small amounts of potassium chloride in an aqueous lithium chloride solution.[72]

The transfer of an ionic substance from one solvent to another can also be regarded as a preparative application of capillary isotachophoresis.[73] This procedure is based on the ability of the isotachophoretic boundary to transmit only the common ion and the solvent.

Thus capillary isotachophoresis may be used for preparative purposes. However, the use of large diameter columns will apparently become most promising in preparative isotachophoresis.

V. The coulophoretic method

1. Theoretical principles

Isotachophoresis was classified above in terms of the positions of the leading and terminating solutions in the column. One of its varieties is the coulophoretic method (coulometric analysis of the electrolyte solutions using ionic boundaries). A characteristic feature of the method is the presence in the electrolytic cell of cationic and anionic isotachophoretic boundaries moving towards one another (see Scheme 3). The formula for the rate of movement of a steady-state boundary between two solutions with a common anionic component is used in the theory of isotachophoresis.[29, 74, 75] It can include the characteristics of both the leading and terminating solutions. Thus the rate of movement of the cationic boundary v_c of the leading solution L_1 is

$$v_c = \frac{It_c}{zc_qS}.$$

where (in addition to the previous notation) I is the electric current (A), S the internal cross-sectional area of the electrolytic cell (dm^2), and c_q the concentration of the charges of the same sign per unit volume of the leading solution (C litre^{-1}). We recall that t_c is the transport number of the non-common cationic component in the laboratory coordinate system. A similar relation describes also the rate of movement of the second, anionic boundary between the above leading solution and the second terminating solution T_2:

$$v_a = \frac{It_a}{zc_qS}.$$

It includes the transport number of the anionic component of the leading solution in the same laboratory coordinate system. We transform the linear rates of movement of the boundaries into volume rates (v_cS and v_aS) and add together the last two expressions:

$$S(v_c + v_a) = \frac{I(t_c + t_a)}{zc_q},$$

where $S(v_c + v_a)$ is the volume traversed by the two (cationic and anionic) boundaries per unit time. We introduce yet another quantity – the time from the start of electrolysis until the instant t when the boundaries meet, and multiply both sides of the last equation by this time. Since $S(v_c + v_a)t = V$ is the volume of the leading solution before the start of electrolysis (as already mentioned, during the passage of current this volume continuously diminishes and becomes zero at the instant when the boundaries meet) and $t_c + t_a = 1$, it follows that

$$Vc_qz = VFcz = It, \qquad (5)$$

where F is the Faraday constant.

Eqn (5) constitutes the basis of the coulometric analysis of solutions using ionic boundaries. We shall consider it in greater detail. It relates the concentration of the leading solution investigated to the amount of electricity passed through the system and to the volume of the solution taken for analysis. Eqn (5) can be used to determine one of the three quantities mentioned above when the other two are known. The greatest interest attaches to the determination of the concentration of the solution from the amount of electricity passed through it and the volume traversed by the two boundaries. We have called this procedure the coulophoretic method of analysis of the solution or

coulometric analysis using ionic isotachophoretic boundaries. This analytical method will be examined in greater detail below. The second possibility presented by Eqn (5) consists in the determination of the amount of electricity passed in the circuit from the concentration of the solution and its volume. Such determination constitutes the basis of the new method, proposed by the authors, for the measurement of the amount of electricity by observing the motion of boundaries (see below). The determination of the volume traversed by the boundaries when the concentration of the solution and the amount of electricity passed through it are known constitutes the basis of the method for the determination of the internal cross-sectional area of the capillary and for the monitoring its constancy along the length.

The following characteristic features of the coulophoretic method may be noted. It is based on the Faraday law. However, the method differs fundamentally from the method of analysis of substances from their amounts produced at the electrode and the coulometric titration method, which is also associated with the reaction at the electrode. In the coulophoretic method, one compares the direct motion of the ions with the amount of electricity passed through the system, while the boundaries between the leading test solution and the two terminating solutions are actually set up in order to be able to follow the motion of the ions. Each boundary operates in a certain sense as an electrode with a 100% current yield;[76] only the common ionic component and the solvent pass through it. The rate of movement of the non-common ionic component constitutes the rate of movement of the boundary itself. The coulophoretic method is independent of the nature of the electrodes employed, the nature of the electrode reactions, and their current yield. This constitutes the fundamental difference between the electrodeposition and coulometric titration methods.

2. Analysis of electrolyte solutions

The theoretical aspects of the coulophoretic method were examined above. We shall now proceed to the description of its analytical application. The method may be used to solve three different problems: the determination of the concentration of the pure electrolyte solution; the analysis of a mixture of electrolyte solutions after its preliminary separation by capillary isotachophoresis into zones of pure solutions; the analysis of a two-component mixture without its complete separation into pure solutions.

Analysis of the pure solution. In order to determine the concentration of the test solution in conformity with Eqn (5), one should know the volume of the solution taken for analysis. For this purpose, a mercury column 20 – 30 cm long is introduced into a π-shaped capillary filament and narrow markers, 0.1 mm wide, are deposited on its ends with coloured sealing wax. The terminating electrolyte solutions are selected for the electrolyte test solution in accordance with the rules of isotachophoresis — one solution in terms of the cations and the other in terms of the anions; their chosen concentrations are close to that of the test solution. The exact concentration is unimportant, since the concentrations of the terminating solutions in the region of the boundaries automatically adapt to the concentration of the test solution in conformity with the regulating function when a current is passed. It is desirable that the concentrations of the terminating solutions should be below the equilibrium values, whereupon their adaptation is faster. In practice all these concentrations should not differ from the equilibrium concentrations by a factor greater than 10.

The capillary is filled with solutions with the aid of a water pump in the following way. Initially the entire capillary is filled with distilled water and then a tiny bubble (about 1 mm long) is formed at its end and beyond it one of the terminating solutions is introduced — up to the first marker. The bubble serves as an indicator of the movement of the solutions. The end of the capillary is then lowered into the test solution and the latter is introduced into the capillary until the indicator bubble moves to the second marker. Next, the end of the capillary is lowered into the second terminating solution and is filled until the bubble emerges from the capillary. As a result, the test solution is present in the middle part of the capillary between the markers and the terminating solutions are on either side of it. The ends of the capillary are lowered into approximately 5 cm^3 electrolytic vessels filled respectively with the solutions present at the two ends of the capillary. At the same time, the passage through the cell of a stabilised direct current is begun and a stopwatch, reckoning the time from the start of electrolysis to the instant when the boundaries meet, is started.

The cationic and anionic boundaries, moving towards one another, are formed between the test solution and the terminating solutions. The boundaries are observed with the aid of, for example, diffraction. At the instant when the boundaries meet, the stopwatch is arrested and the time from the start of electrolysis to the instant of the disappearance of the test solution is determined. The concentration of the test solution is calculated by Eqn (5). A universal long detector, for example a thermoviewer, is also suitable for the detection of the boundaries between the solutions. In certain cases the instant when the boundaries meet can be simply recorded visually.

The coulophoretic method has been used to determine the concentrations of solutions of various electrolytes: acids, alkalis, simple salts, and complexes with a low instability constant. The concentrations of an acid and alkali can be determined by this method with the aid of only one terminating solution, forming both the cationic and anionic boundaries, and salts can also be determined with the aid of another salt.[36]

Analysis of mixtures of electrolyte solutions. Mixtures are analysed after their preliminary separation into zones of pure solutions by isotachophoresis. The analytical method is as follows: as in the previous case, the volume of the marked section of the capillary is determined with the aid of mercury. Next, using the rules of isotachophoresis, the leading and terminating solutions are selected. The capillary column is filled with solutions in such a way that the test mixture is located in the capillary between the leading and terminating solutions. After this, the mixture is separated into pure solutions under the conditions of a hydrodynamic countercurrent. The separation is terminated when the number of zones becomes equal to the number of components to be determined and the lengths of the zones no longer vary with time. The leading solution is then replaced by a new solution (the second terminating solution prepared beforehand) in order to form a boundary moving through the solutions in opposition to the zones.

If the initial mixture was separated in terms of the cations, then the leading solution is the catholyte and is replaced by another solution, which serves as the terminating solution for the common anion of all the zones. Conversely, if the separation was carried out in terms of the anions, the leading solution is the anolyte and is replaced by another solution — the terminating solution for the common cation of the zones. In order to replace the leading solution by the second terminating solution, an electric current is switched on, the electrode vessel with the leading solution is lowered and is replaced by an electrode vessel with the new terminating solution prepared beforehand. This procedure should be carried out as fast as possible (about 3 s) in order to avoid the leakage of the solution, mixing, etc. After this, the current is switched on again and a boundary, moving through the leading solution in opposition to the zones, is formed at the end face of the capillary.

When this boundary meets the boundary of the first zone, the first stop-watch is started and the time up to the meeting of the given boundary with the boundary of the second zone is measured. At this instant, the first stopwatch is arrested and the second is started. The time reckoned by the first stopwatch is the initial quantity for the determination of the concentration of the

solution in the first zone. The time for the traversal of the second zone by the boundary is measured similarly, the stopwatch being stopped when this additional boundary encounters the beginning of the third zone. The first stopwatch, used for the preliminary reckoning of the time taken by the additional boundary to traverse the first zone, is started simultaneously. Thus one determines the time taken to traverse all the zones and hence also the concentrations of the solutions in these zones.[77] If a solid is analysed and all the components are determined by the coulophoretic method, it is not necessary to know the volume of the solution taken up into the capillary.

Analysis under conditions of incomplete separation of the mixture. In practice, one may encounter situations where a two-component mixture cannot be separated into zones of pure solutions by isotachophoresis. This happens, for example, if the mixture analysed includes a leading solution for which it is impossible to select a second leading solution with a greater mobility of the non-common ionic component. However it is found that the concentrations of the components of such a mixture can also be determined coulometrically by means of ionic boundaries, but this requires the use of standard specimens and a partial preliminary separation of the mixture analysed.[78]

We shall now estimate the error of the above coulophoretic method for the determination of the concentrations of solutions. It includes the contribution by the error of the determination of the volume of the capillary between the markers, the error of the measurement of the volume of the solution filling the capillary, the error of the determination of the time of traversal of the test solution by the boundaries, the error of the measurement of the current, and the errors of the stopwatches. The main contribution to the error of the method comes from that in the measurement of the volume of the section of the capillary between the markers ($\sim 0.5\%$) and also the error of the measurement of the volume of the solution taken up into the capillary (also $\sim 0.5\%$). The relative error of the measurement of the time of traversal of the zone by the additional boundary is equal to the ratio of the width of the boundary to the initial length of the zone. For a zone approximately 10 cm long and a width of the boundary of 0.2 mm, the error reaches 0.2%. Thus the overall error of the coulophoretic method for a zone length of 10 cm is not more than 1%.

The sensitivity of the method is determined by the potential of the chosen procedure for the detection of the boundaries. Thus when the diffraction pattern is used, the concentrations of the solutions should be not less than 0.1 M and for lower concentrations preliminary enrichment is necessary.

The following chemical compounds have been analysed hitherto by the coulophoretic method: HCl, KCl, NaCl, LiCl, NH_4Cl, $BaCl_2$, $CaCl_2$, $MgCl_2$, $CoCl_2$, $SmCl_3$, $NaNO_3$, NH_4NO_3, Na_2SO_4, $(NH_4)_2SO_4$, $(NH_4)_2HPO_4$, KCNS, $K_3Fe(CN)_6$, $K_4Fe(CN)_6$. Many of these were part of the composition of industrial products (fluxes, alloys, brines, melts, electrolytes), natural waters, and minerals.[36, 77, 79]

We may note the characteristic features of the coulometric analysis of solutions with the aid of ionic boundaries. The method is suitable for any ionogenic solutions of inorganic and organic substances and permits the analytical determination of the cationic and anionic components of electrolyte solutions. It is an ultramicromethod, which is fairly accurate, sensitive, and rapid. The method is absolute and does not require the use of standard specimens (with the exception of cases where a mixture with incomplete separation or with incomplete dissociation of ionogenic substances is analysed). In the analysis of a multi-component mixture where all the components are determined by the coulophoretic method, there is no necessity to know the weight of the initial mixture.[77] In practice, this method can be applied fairly simply: one can use commercial apparatus for capillary isotachophoresis with the detection of boundaries from the diffraction pattern; the capillary columns can be prepared under laboratory conditions; the capillaries need not necessarily have a constant internal cross section along the length; repeated use of the same capillary column is possible. Finally, a characteristic feature of all isotachophoretic methods, due to the adaptation of the terminating solution concentration, is the possibility of using terminating solutions at concentrations which have been determined only approximately.

The coulophoretic method has certain unique possibilities. It permits the analysis of a given solution with the aid of any terminating solution from the enormous set of those which are possible and conversely one can analyse many solutions using only one terminating electrolyte solution.[80] Terminating solutions containing mixed solvents can also be employed. Inert additives to a terminating solution do not affect the analyses. The coulophoretic method is perhaps the only one which makes it possible to determine the concentration of pure acids, alkalis, and salts with the aid of a solution of only one salt.[80] The method also permits the transfer of the ionogenic substance from one solvent to another simultaneously via two boundaries.[73]

However, the method described, which has important advantages, has not unfortunately found a sufficiently wide application consistent with its possibilities. This is probably associated with the rare use of the method of detection of the boundaries from the diffraction pattern.

3. Determination of the amount of electricity

The amount of electricity passed through the circuit is one of the fundamental quantities used in electrochemical studies. Therefore the new method for its measurement, proposed by Ansorg,[81] merits attention. The method is based on a familiar phenomenon — the transport of electricity by ions in the bulk of the electrolyte solution. The motion of the ions is followed by creating isotachophoretic boundaries between the solutions which can be readily detected experimentally. We recall that Eqn (5) relates the amount of electricity passed through the system to the number of charges of the same sign per unit volume of the solution and to the volume traversed by both boundaries (cationic and anionic) when a given amount of electricity is passed through the capillary.

The method of measurement of the amount of electricity depends on the electrolyte selected.

1. Suppose that a strong electrolyte solution, for which c_q is known and the degree of dissociation is unity, has been chosen. Then $c_q = czF$, where c is the molar concentration of the solution. In this case, the method of determining the amount of electricity passed through the circuit by Eqn (5) is absolute.

2. Suppose that an electrolyte solution for which c_q is not known beforehand, has been adopted. Then the proposed method is relative and requires preliminary calibration, i.e. the determination of c_q in the chosen solution at the concentration adopted by measuring, using some other procedure, the amount of electricity Q and the pathway traversed by both boundaries (cationic and anionic) ($l_c + l_a$) during the measurement. Clearly, such calibration constitutes simultaneously an independent method of determining the degree of dissociation of the electrolyte under the chosen conditions. These data could be of interest for the study of electrolyte solutions, particularly in the light of the attempts undertaken recently to consider certain strong electrolytes in solution as incompletely dissociated.[82]

The experimental formulation of the method for the measurement of the amount of electricity considered is in the main the same as that of the coulophoretic method for the determination of the concentration of a one-component solution, which was described above. The difference consists in the fact that in the given instance it is essential to have a capillary column with a constant cross-sectional area along its length. This makes it possible to determine the amount of electricity passed through the circuit during any time interval. The quantity measured directly as $l_c + l_a$. The maximum amount of electricity measured in an individual experiment is determined by the length

of the zone of the leading solution taken up into the capillary. The dependence of the amount of electricity passed on the path traversed by the cationic and anionic boundaries is linear, as can be seen from Eqn (5), which must be included among the advantages of the method. The range in which the amount of electricity can be measured depends on the concentration of the chosen solution, the cross-sectional area of the capillary, and the length of the column of the solution placed in the capillary. It can be readily varied. The optimum range is 0.15–3 C, the absolute sensitivity is 4 μC, and the accuracy of the determination for a column length of 200 mm is 0.1%. We may note that the method considered requires the use of high-voltage sources (1–10 kV).

4. Determination of the internal cross-sectional area of the capillary and the monitoring of its constancy along the length

Capillaries have been used widely in recent times in physicochemical practice—in capillary isotachophoresis, in high-pressure capillary chromatography, in ionic chromatography, and in capillary electrophoresis.[37,83–85] It is frequently necessary to measure the internal cross-sectional areas of transparent glass or quartz capillaries and to monitor their constancy along the length. The mercury method has been used traditionally for this purpose, but it suffers from evident disadvantages: it is laborious, it is difficult to automate, and it requires definite safety measures. The coulophoretic analytical method examined above can serve as a basis also for a novel method of measurement of the internal cross-sectional areas of transparent capillaries and for the monitoring of their constancy along the length.[86] In the horizontal part of the capillary the cross-sectional area of which is to be determined, one selects a column of the leading solution of a definite length between the two terminating solutions. By passing a stabilised direct current, one of the boundaries is made stationary relative to the walls of the capillary by means of a countercurrent. One then measures the distance Δl over which the secondary boundary moves during a time Δt. The average cross-sectional area of the capillary along the section Δl is found from the formula

$$S_{av} = \frac{I\Delta t}{Fcz\Delta l},$$

where z is the charge of the non-common ion of the leading solution forming the moving boundary. If the quantity $I\Delta t/F$, i.e. the amount of electricity passed through the column, is plotted against $cz\Delta l$, then the slope of the curve at a given point yields the internal cross-sectional area of the column at this point. The linearity of the relation indicates the constancy of the internal cross-sectional area of the capillary along its length. It has been suggested that a fully dissociated strong electrolyte solution be used as the leading solution. The accuracy of the determination of the internal cross-sectional area by this method for a width of the boundary of 0.2 mm is 2% along a section 1 cm long.

The method is suitable also for the determination of the free cross-sectional area of a column consisting of a transparent tube up to 10 mm in diameter with a filler (particle size 20–50 μm). The leading solution should then be coloured and the terminating solutions should be colourless or conversely. The positions of the boundaries at different times can be observed visually in this instance. Owing to the considerable width of the boundary, the accuracy of the determination of the free cross-sectional area of the tube with the filler is about 5% along a section 10 cm long.

The electrochemical procedure considered permits the measurement and the monitoring of the constancy of the internal cross-sectional areas of transparent capillaries with diameters of 0.05 to 0.8 mm without breaking them. This range is determined by the possibility of observing steady-state isotachophoretic boundaries in capillaries regardless of the ratio of the densities of the solutions employed. The method also permits the determination of free cross-sectional areas of columns with a diameter up to 10 mm and containing a finely dispersed filler.

VI. Steady-state concentration boundaries in isotachophoresis

The concentration boundaries are special types of boundaries in isotachophoresis. As a result of the passage of a direct current through the cell containing two electrolyte solutions with different concentrations of the same substance, it is possible to achieve a distribution of the concentrations of this substance in the intervening region which is stable as a function of time. The boundary between the solutions migrates to one of the electrodes at a constant rate. The conditions for the attainment of a steady distribution of concentrations or, in other words, the formation of a steady-state concentration boundary have been formulated by Stefanovskii:[87] (1) a stable boundary can exist only in solutions of electrolytes characterised by a non-linear dependence of the transport numbers of the ionic components on the concentration; (2) if the boundary is formed in such a way that $\partial c/\partial x > 0$ (the direction of the x axis coincides with the direction of motion of the cationic component in the electric field), then it will be stable for solutions of electrolytes where $\partial^2 t/\partial c^2 < 0$; (3) if the boundary is formed in such a way that $\partial c/\partial x < 0$, then it will be stable provided that $\partial^2 t/\partial c^2 > 0$ (here t is the transport number and c the concentration of the electrolyte solution). It has been shown in a study[88] where this process was examined most rigorously that the above conditions for the stability of concentration boundaries are valid only when the quantities t are understood as the transport numbers of non-common ionic components in the laboratory coordinate system and not relative to the solvent, as was implied in Stefanovskii's study.[87]

The criteria of the stability of concentration boundaries formulated above have been used to test the validity of the relations obtained by different workers between the transport numbers and the concentration of the electrolyte solution and for the prediction of the form of such relations if they have not yet been derived. For this purpose, the capillary column was filled with two solutions at different concentrations and a direct current was passed through it under the conditions of a hydrodynamic countercurrent. The migration of the concentration boundary was followed from the diffraction pattern. If the concentration boundary corresponding to the chosen direction of the current became stable after a time, the experiment was terminated. If the boundary remained unstable, the experiment was repeated having reversed the electric current. The direction of the current for which the concentration boundary is stable with time was found in this way.

The nature of the required relation was established from the results obtained, on the basis of conditions (1)–(3), i.e. it was found if this relation is convex or concave relative to the concentration axis in the chosen range. The instability of the boundary for any direction of the current implied that the concentration dependence of the transport number is linear in the selected range. The nature of the dependences of the transport numbers of the cationic and anionic components on the concentration in aqueous HCl, H_2SO_4, LiCl, NaCl, KCl, NH_4Cl, $BaCl_2$, $CuCl_2$, $NiCl_2$, Li_2SO_4, $LiNO_3$, $NaNO_3$, NaAc, KAc, $K_2Cr_2O_7$, $Na_2Cr_2O_7$, LiOH, NaOH, and KOH solutions was established by the method described.[89,90] The validity of the determination of the form of the relations (convex, concave) was confirmed by classical methods. At the same time, the conclusions concerning the form of the relations found by the method based on incorrect theoretical ideas concerning the motion of ions in electrolyte solutions were partly disproved. Certain concentration ranges were found in solutions of potassium and ammonium chlorides in which concentration boundaries are not formed whatever the direction of the current, which indicates a linear concentration dependence of the transport numbers.

Thus the apparatus for capillary isotachophoresis with detection of the boundaries from the diffraction pattern without any partitions can be used in experiments with concentration boundaries. Specially complex concentration boundaries,

considered, for example, by Stefanovskii,[91] require a comprehensive and systematic study.

VII. Electrocrystallisation with the aid of isotachophoresis

One of the most important features of isotachophoresis, namely the possibility of adaptation, i.e. a change in the concentrations of all the solutions following the leading solution when they differ from the steady-state concentrations, was examined in detail above. It was found that this feature can be used as a basis of a new electrochemical method for the crystallisation of ionogenic substances in a capillary.[92] The essential feature of the method is as follows. The transport numbers of any one ionic component of a saturated solution at room temperature are found directly from the literature or by extrapolating literature data. The leading solution having an ion in common with the solution to be crystallised, in which the mobility of the non-common ionic component is greater than that of the non-common ionic component of the solution crystallised, is selected on the basis of the accumulated data. The concentration of the leading solution, which as a result of adaptation determines the concentration of the saturated solution and the solution to be crystallised which follows it, is found from the regulating function (3). Next, the concentration of the leading solution calculated in this way is increased by 20% – 30% depending on the nature and properties of the solution to be crystallised. This is necessary for a number of reasons, including the possible inaccuracy of reference data, the tendency of the solution to be crystallised to become supersaturated in view of the small number of crystallisation centres, and the presence of a long latent period in which the onset of crystallisation is delayed when the degree of supersaturation is low. The crystallisation is carried out in a capillary employing the usual device for capillary isotachophoresis. The adaptation of the solution to be crystallised is followed from the diffraction pattern. The passage of current leads to the precipitation of crystals, which is manifested by a darkening of the diffraction pattern. The crystallisation of an aqueous potassium chloride solution with an initial concentration of 1 M using a hydrochloric acid solution at a concentration of 10 M as the leading solution and a cobalt chloride solution at a concentration of 1.5 M as the terminating solution has been described.[92] As a result of the passage of a direct current of 3 mA for 3 h, fine (approximately 0.1 mm) crystals were formed in the potassium chloride zone. As the potassium chloride solution zone migrated to the cathode under the influence of the electric field, the crystals migrated in the same direction.

The method considered makes it possible to carry out crystallisation under mild conditions, varying smoothly the degree of supersaturation. This variation can be made even smoother by altering the concentration of the leading solution during the experiment. The method is universal and permits the crystallisation of any inorganic, organic, and bioorganic ionogenic substances. One may add to this the advantages of the capillary isotachophoresis itself, the possibility of the preliminary purification of the solution itself and of the crystallisation of several zones simultaneously, as well as the possibility of using microgramme amounts of the substances and microlitre volumes of the solutions.

All the foregoing considerations make the proposed method promising, particularly in the study of the crystallisation process itself and for the practical preparation of small amounts of crystals of especially rare and expensive ionogenic substances.

VIII. The isotachophoretic method for the determination of the electromigration transport of the solvent in electrolyte solutions

The two forms of the regulating function and Eqns (2) – (4) relating them have been used to develop a relative method for the measurement of the electromigration transport of the solvent in electrolyte solutions.[93,94]

Electromigration transport of the solvent, constituting the migration of the solvent as component (not hydrodynamic) migration to the cathode or anode associated with its interaction with the ions, may occur in electrolyte solutions. This process, which takes place when a direct current passes through electrolyte solutions, has been the object of study since the 1930s, but hitherto the scatter of the experimental results has been considerable. This made it necessary to consider these data as only qualitative, indicating merely the occurrence of the effect itself.

The proposed method makes it apparently possible to solve this problem. One selects an electrolyte which forms aqueous solutions over a wide concentration range. It is necessary that the transport numbers of the cationic (or ionic) components of these solutions relative to the solvent are known. Suppose that the concentration of this solution is c_1 and the transport number relative to the solvent at the given concentration is $t_1^0(c_1)$. Next, one selects another, test electrolyte in solutions of which it is necessary to determine the electromigration mobility of the solvent (water). We shall assume for the sake of specificity that the transport numbers of the cationic component are smaller in the electrolyte solution investigated, which is the terminating solution, and that a steady-state isotachophoretic boundary may be formed between this solution and the first solution. For solutions of the test electrolyte, the transport numbers $t_2^0(c)$ of the cationic components relative to the solvent must also be known over a certain concentration range or must be specially measured. The relation

$$\frac{t_2^0}{c_2^0 z_2} = f(\lg c) \,. \tag{6}$$

is derived from these data.

According to the regulating function (2), a steady-state isotachophoretic boundary arises between the first and second solutions with concentrations (mol/kg of water) c_1^0 and c_2^0 respectively. Therefore, having calculated the quantity $t_1^0/c_1^0 z_1$ for the chosen concentration c_1 of the leading solution, the concentration c_2 of the terminating solution, forming with the former a steady-state isotachophoretic boundary, is found from the plot of Eqn (6). Next, the transport number $t_2^0(c_2)$ of the cationic component relative to the solvent is found for this concentration from reference data. After this, the quantity

$$t_2(c_2) = t_1(c_1)\frac{t_2^0(c_2)\rho_2^0}{t_1^0(c_1)\rho_1^0} \,, \tag{7}$$

i.e. the transport number of the same cationic component of the test solution at the concentration c_2 but this time in the laboratory coordinate system for a stationary solution, is found from Eqn (4). The electromigration mobility of water u_0 (the rate in a unit electric field) is calculated from these data:

$$u_0 = \frac{10^3 K}{czF}(t_2 - t_2^0) \,,$$

where K is the specific conductance of the test solution at the concentration c_2.

Eqn (7) includes one unknown quantity — $t_1(c_1)$, i.e. the transport number of the cationic component in the first (leading) solution at the concentration c_1 in the laboratory coordinate system, which must be measured independently.

A procedure for the determination of the electromigration mobility of the solvent in the chosen solution at a concentration c_2 was described above. The second, third, fourth, etc. concentrations of the initial solution are selected similarly and the corresponding second, third, fourth, etc. concentrations of the test solution are obtained, i.e. the concentration dependence is found. For each concentration of the two solutions, the transport numbers of the cationic components relative to the solvent must

be known. The transport numbers in the first solution at the chosen concentrations in the laboratory coordinate systems are unknown, which implies that their concentration dependence over a certain range or, what amounts to the same thing, the quantitative characteristic of the electromigration transport of water at the same concentrations, is unknown. A similar computational procedure can be applied to all electrolyte solutions where it is necessary to determine the electromigration transport of water. Using initial aqueous potassium chloride solutions at concentrations of 1 and 3 M, the absence of electromigration transport of water was noted by the isotopic boundary method. This means that $t_1(c_1)/t_1^0(c_1) = 1$ in Eqn (7).

The proposed method permits the calculation of the electromigration mobility of water in solutions of any electrolytes over a wide concentration range. The transport numbers relative to the solvent and the fact that there is no transport of the solvent in potassium chloride solutions at all concentrations are used in the calculations. The characteristics of the electromigration transport of water in solutions of a number of alkali metal halides and alkaline earth metal, zinc, cobalt, copper, and cadmium chlorides as well as a series of water-containing substances such as hydrochloric acid, ammonium chloride, and potassium hydroxide over a wide concentration range have been published.[94] The internal consistency of the method considered was confirmed by the results of measurements by the isotopic boundary method of the characteristics of the electrical transport of water in aqueous lithium chloride solutions at concentrations of 1 and 2 M and in rubidium chloride solutions at concentrations of 1 and 3 M and by comparing the results of these measurements with calculated data.

The characteristic features of the above method for the determination of the electromigration mobility of the solvent (water) are as follows.

1. The regulating function of isotachophoresis, constituting the basis of the method, is itself based on the law of conservation of matter and is therefore applicable without limitations as regards the types and concentrations of the solutions.

2. In proving the validity of the method, no model ideas and no mechanisms of the motion of the species in solutions were resorted to.

3. The method can be applied equally successfully to the determination of the electromigration mobility of any non-aqueous solvent.

4. Using a small number of experimental data, the method can be used to obtain the characteristics of the electrochemical transport of the solvent in all aqueous solutions of electrolytes for which the transport numbers relative to the solvent have been measured by the usual experimental methods.

IX. Conclusion

Progress in the development of new aspects of capillary isotachophoresis is linked directly to the establishment of modern ideas concerning the kinetic phenomena in electrolyte solutions and processes occurring near the isotachophoretic boundary. The aspects considered include those which are of purely theoretical importance as well as applied aspects. Thus the method for the determination of the electromigration transport of the solvent is important for the establishment of the physical picture of the passage of electric current through electrolyte solutions. Analytical capillary isotachophoresis has already become fairly common and in the present instance has been supplemented only by qualitative analysis. The coulophoretic analytical method constitutes a separate analytical electrochemical field. Methods for the measurement of the amount of electricity passed through the system, for the determination of the internal cross-sectional area of the capillary, for the monitoring of the constancy of the cross-sectional area of the capillary along its length, and for the determination of the free cross-sectional area of a tube with a filler have been developed on its basis. A property fundamental for isotachophoresis — the adaptation of the concentrations of all the solutions following the leading solution — has been used as the basis of a novel method for the electrocrystallisation of an ionogenic substance on passage of an electric current. In contrast to electrocrystallisation which occurs when a substance is segregated at electrodes, in this case crystallisation takes place in solution when opposed fluxes of cations and anions meet. The electrosynthesis of electrolyte solutions with the aid of ionic boundaries, which is one of the modifications of isotachophoresis for which this principle had already been nidicated by Kohlrausch, has expanded significantly the possibilities of capillary isotachophoresis as a preparative method.

All the modifications of isotachophoresis examined are characterised by a high resolving capacity, adequate sensitivity and accuracy, applicability over a wide concentration range (from dilute to saturated solutions), and satisfactory time parameters. The methods described make it possible to use microgramme amounts of test substances and microlitre volumes of the solutions and to work with aqueous and non-aqueous electrolyte solutions.

All the features listed above are possible exclusively owing to the availability of the universal diffraction method for the detection of electrolyte boundaries in capillaries. The ecological purity of all the processes examined, to which much attention has been devoted recently, is especially attractive.[95] The foregoing permits the assumption that capillary isotachophoresis and its modifications constitute a promising set of analytical and preparative methods.[96]

Niobic acid — a new heterogeneous catalyst for processes in petrochemical and organic syntheses

F A Chernyshkova

Contents

I. Introduction	743
II. The structure and properties of the surface of niobic acid	744
III. The use of niobic acid as a catalyst	745
IV. The use of niobium oxide as a carrier and promoting agent	748
V. Other niobium compounds used in catalysis	748

Abstract. Questions associated with the application of niobium compounds in catalysis are considered. Niobic acid $Nb_2O_5 \cdot nH_2O$ contains an appreciable amount of water, but its surface exhibits a high acidity — equivalent to the acidity of 70% sulfuric acid. This unusual solid acid manifests not only a high activity and sensitivity but also an appreciable stability as a catalyst in reactions in which water is present or is evolved (condensation, hydration, dehydration, and esterification). It may be used also as a catalyst in other reactions. The structure and properties of the surface of niobic acid are examined. The bibliography includes 54 references.

I. Introduction

Technologies which permit industrial production satisfying world standards, giving rise to a high output without contamination of the environment, have acquired prime importance at the present time. In this connection, the use of niobic acid, the term usually applied to hydrated niobium pentoxide $Nb_2O_5 \cdot nH_2O$, as a solid acid catalyst for a number of processes can undoubtedly be of practical interest. The most important property of niobic acid is that, after heat treatment at 100 – 300 °C, its surface acquires a high acidity, although an appreciable amount of water is present on it.[1] The activity of niobic acid is manifested already at a low temperature (100 – 120 °C) even in the presence of water vapour. The oxides of other metals do not possess similar properties: it is known that their acidity is lost or diminishes as a consequence of the adsorption of water. The use of niobic acid as a catalyst in reactions with participation or elimination of water — esterification, hydration, dehydration, Prins reaction, hydrolysis, and others — is especially effective. In these reactions, niobic acid exhibits a high activity, selectivity, and stability.[1 – 3] Even in the presence of components with a reducing capacity, the acidity of niobic acid does not diminish, since the oxide Nb_2O_5 is stable.

Until recently, niobium catalysts have not attracted special attention despite the fact that catalysts based on molybdenum and vanadium — elements adjoining niobium in the Periodic System — have been widely used in industry. However, during approximately the last five years, the attitude to niobium-based catalysts and especially to niobic acid changed significantly.[1 – 3] Niobic acid has begun to be used in Japan as an industrial catalyst of condensation, dehydration, hydration, and esterification reactions.[2]

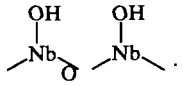
H_2SO_4, H_3PO_4, HF, and sulfonic acid cation-exchange resins are frequently used in industrial processes as acid catalysts. A number of problems associated with the corrosion of equipment, the inadequate selectivity of the processes, the presence of a large amount of waste, and the need to utilise the spent catalysts and their toxicity then arise. The employment of niobic acid could help in many instances to solve these problems. Not only hydrated niobium oxide (niobic acid) but all composite systems based on niobium oxide are of interest for catalysis. There are prospects for their employment as both catalysts and carriers.

The world niobium resources (excluding the Union of Independent States) amount to 28 000 tonnes, which exceeds somewhat the resources of elements such as molybdenum, tungsten, and cobalt.[5] According to data concerning the state of the world market in niobium and its consumption,[6] the production of niobium in 1987 was 14 900 tonnes, of which 85% was produced by the CBMM Company (Brazil). According to these data, 87% of niobium is consumed as an additive to steel, 10% in the preparation of nickel – niobium alloys, and the rest in the manufacture of optical glasses, dielectric materials, and superconductors. According to a forecast,[5] the world production of niobium will increase by 8% – 10% annually.

Niobium is also extracted in our country.[5] An appreciable amount of niobium is present in the waste from tungsten ore in the processing plants (niobium is known to accompany tungsten). A low-waste technology has been proposed for the extraction of a niobium and tantalum concentrate from such waste.[7] Instances of occupational poisoning by niobium have not been described.[8]

The principal results achieved as a result of the use of niobic acid and other niobium-based materials in catalysis have been described in reviews [1 – 3] and in the proceedings of an international symposium on catalysis by niobium materials.[4]

The aim of the present review is to survey the latest advances in catalysis by niobic acid and other niobium-based compounds and also to draw the attention of investigators to this new problem, which is promising from the practical standpoint.



Data published during the last five years are mainly considered. References to earlier studies may be found in the papers of Tanabe[1,3] and Okazaki[2].

II. The structure and properties of the surface of niobic acid

Hydrated niobium pentoxide $Nb_2O_5 \cdot nH_2O$ is a white polymeric amorphous material. Its composition is variable owing to the inconstancy of its water content,[9] which varies depending on the method of preparation and drying. The nature and structure of niobic acid and of the products of its thermal decomposition have been examined in a number of publications.[9-11] It was established[9] that hydrated niobium pentoxide consists of the niobic isopolyacid having the composition $H_8Nb_6O_{19}$. On heating, the hydrated isopolyacid splits off water, forming stoichiometric hydrates, while above 1200 °C it also loses a certain amount of oxygen with formation of oxygen-deficient non-stoichiometric niobium oxides:[10]

$$H_8Nb_6O_{19} \cdot 18H_2O \longrightarrow H_8Nb_6O_{19} \cdot 12H_2O \longrightarrow$$
$$\longrightarrow H_8Nb_6O_{19} \cdot 6H_2O \longrightarrow H_8Nb_6O_{19} \cdot 3H_2O \longrightarrow$$
$$\longrightarrow H_8Nb_6O_{19} \longrightarrow [H_2Nb_6O_{16}]_n \xrightarrow{1200\ ^\circ C}$$
$$\longrightarrow [Nb_6O_{15}]_n \longrightarrow [NbO_{2.5-2.33}]_m .$$

The amorphous modification, called γ-niobic isopolyacid, exists up to 435 °C. On further heating, it passes to the low-temperature crystalline state and at 830 °C to the high-temperature crystalline state (α-Nb_2O_5). The steric structure of $H_8Nb_6O_{19}$, which will henceforth be referred to as niobic acid by tradition, is illustrated in Fig. 1. In this structure, the eight protons are located over the triangular faces of the octahedron formed by the six niobium atoms. Among the oxygen atoms, 12 bridging atoms, 6 terminal atoms, and one central atom are distinguished. Each hydrogen atom is coordinated to three bridging oxygen atoms, three terminal oxygen atoms, and one central oxygen atom. The protons in niobic acid form part of the composition of the hydroxy-groups linked to the niobium atoms:

The H...H distance is fairly long—more than 4 Å. Conductimetric and IR spectroscopic studies suggested the possibility of the migration of protons in the niobic acid matrix.[9] Water molecules are linked to $H_8Nb_6O_{19}$ by a hydrogen bond via the peripheral oxygen atoms.[10] Only 1.2% of the protons in $H_8Nb_6O_{19}$ can be substituted by sodium ions in a slow exchange process.[9]

When $Nb_2O_5 \cdot nH_2O$ is heated, the derivatogram shows[12] two endothermic peaks at 90 and 190 °C. The weight loss at these temperatures is associated with the dehydration of the gel-like niobic acid and its transition to the amorphous state. The surface of niobic acid then acquires strong acidic properties ($H_0 \leqslant -5.6$), corresponding to the acidity of 70% sulfuric acid. Strong acid centres arise even after mild heat treatment of niobic acid at 100 °C and the residual water can then cover the entire surface of the catalyst. The acidity of metal oxides is usually lost or reduced as a result of the adsorption of water. For example, strong acid centres appear on the surfaces of the $SiO_2-Al_2O_3$ and SiO_2-TiO_2 systems only after heat treatment at about 500 °C simultaneously with the removal of water from the surface. The dehydration of $Nb_2O_5 \cdot nH_2O$ terminates at 300 °C. Further heating from 300 to 700 °C is not accompanied by a change in the weight of the specimen. After heat treatment at 500 °C, niobic acid becomes almost inactive and does not exhibit any acid properties.[1,12] This occurs as a consequence of the phase transition of the amorphous $Nb_2O_5 \cdot nH_2O$ to a crystalline phase.[1]

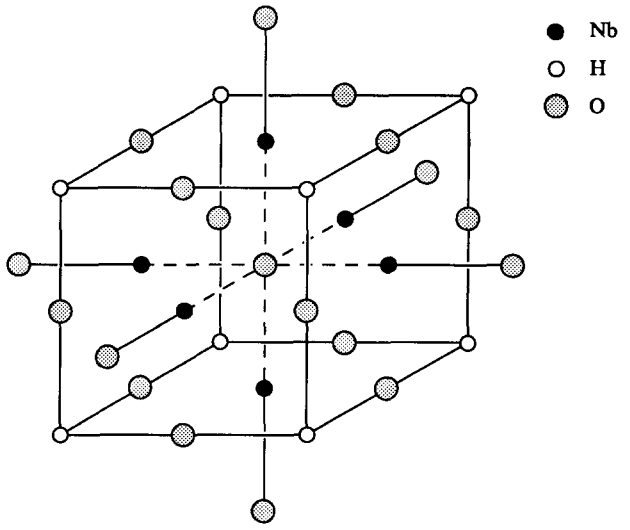


Figure 1. The structure of $H_8Nb_6O_{19}$.

According to Tanabe,[1] the specific surface of niobic acid is respectively 164, 126, and 42 $m^2\ g^{-1}$ after evacuation at 100, 300, and 500 °C. The number of OH groups on the surface of niobic acid depends on the heat treatment temperature:[1,12]

T/°C	120	200	300	400
[OH]/mmol g^{-1}	1.0	0.8	0.7	0.55

The acid properties of niobic acid, investigated by titration with *n*-butylamine in the presence of Hammett indicators, can be inferred from Fig. 2. The greatest number of strong acid centres ($H_0 = -5.6$) are present in niobic acid after its heat treatment at 120–300 °C.

Analysis of the IR spectra of pyridine adsorbed on niobic acid shows that the intensity of the absorption band (a. b.) corresponding to the Brønsted acid is a maximum when the temperature of the preliminary heat treatment of the specimen is 100 °C (Fig. 3*a*). It diminishes with increase in the heat treatment temperature.[12] On the other hand, the

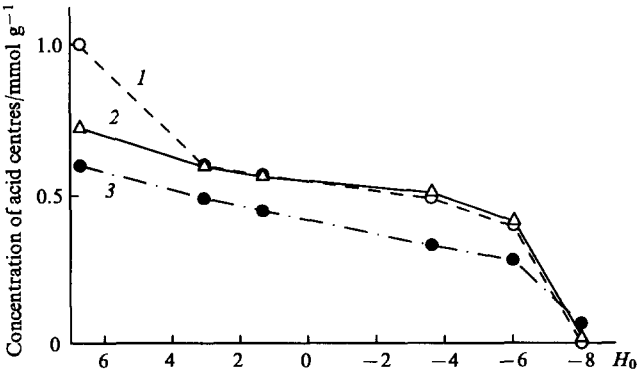

Figure 2. Distribution of the acid centres of niobic acid with respect to their strength as a function of the heat treatment temperature (°C): *1*, 120; *2*, 200; *3*, 300.[1]

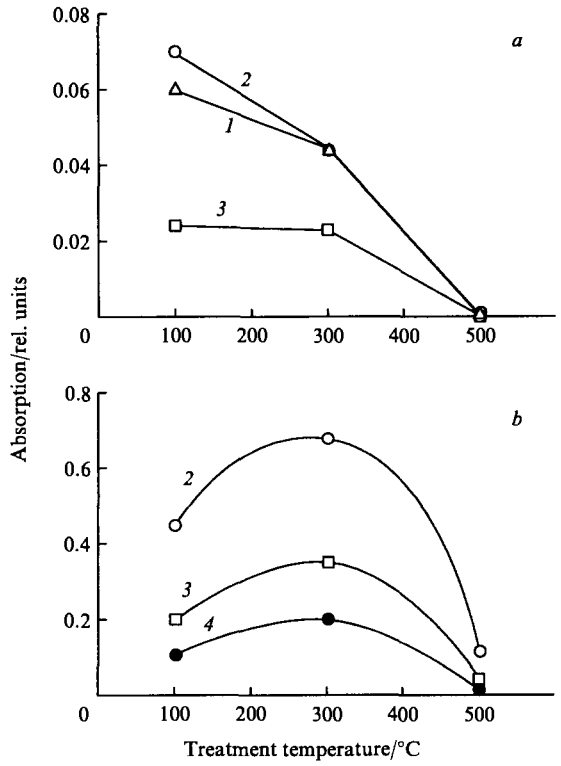

Figure 3. Variation of the Brønsted (*a*) and Lewis (*b*) acidities of niobic acid with the temperature of the preliminary treatment with the specimen evacuated after the adsorption of pyridine. Treatment temperature (°C): *1*, room temperature; *2*, 100; *3*, 200; *4*, 300.

intensity of the spectral band corresponding to the Lewis acid reaches a maximum at a preliminary heat treatment temperature of 300 °C (Fig. 3*b*).

The study of the IR spectra of adsorbed CO_2 showed that niobic acid has only weak basic properties.[12]

The data presented in Table 1 make it possible to compare the properties of the surfaces of different oxides.[2]

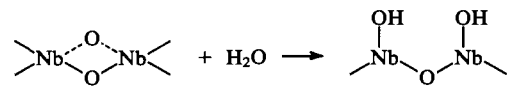

Table 1. The properties of the surfaces of different oxides treated with steam at 300 °C for 3 h.

Oxide	Specific surface/$m^2\ g^{-1}$	OH groups on the surface/mmol g^{-1}	OH groups on 100 Å^2
Nb_2O_5	124	0.84	4.2
Al_2O_3	218	2.29	6.3
TiO_2	177	1.14	3.9
ZrO_2	234	1.43	3.7

In terms of the density of OH groups, niobic acid does not differ from other oxides, but its specific surface is smaller.

The formation of highly acid centres on the surface of niobic acid cannot be explained solely by its structure. The elucidation of this problem would help in the development of new types of solid acid materials.[1]

It was of interest that the acidity of niobic acid evacuated at 300 and 400 °C virtually returns to the initial value after its treatment with water vapour for 3 h and subsequent evacuation at 100 °C, while the number of OH groups on the surface increases.[1,2] This finding is explained by the fact that, on heating to 400 °C, the process involving the removal of OH groups from the surface is almost completed and the acid passes to an unstable state in which crystallisation does not yet begin.

In this state, there is a possibility of hydration by water vapour.[2]

Even in the presence of components with a reducing capacity, the acidity of niobic acid does not fall,[1] since the oxide Nb_2O_5 is stable and is reduced with difficulty, in contrast to the related oxides V_2O_5 and MoO_3. Niobium pentoxide is reduced by hydrogen only at 800–1350 °C.

Niobic acid contains Fe, Cl, Na, and K as impurities. With decrease in their amount to several parts per million, very strong acid centres ($H_0 \leqslant -8.2$) are observed in niobic acid and are retained even in the presence of water vapour.[2] This phenomenon is of interest from the practical point of view.

It has also been noted[13] that, on promotion with 1 M phosphoric acid, the crystallisation of niobic acid begins at 570 °C and not at 435 °C, which is the temperature of the onset of crystallisation in the absence of the promoting agent. Under these conditions, there is also an increase in the number of strong acid centres ($H_0 \leqslant -5.6$).

The specific surface and hence the catalytic activity increase simultaneously. This effect has been explained by the formation of an amorphous layer of niobium phosphate on the surface of niobic acid.

Niobic acid is formed as an intermediate in the synthesis of niobium and its compounds. Very pure niobic acid is obtained on hydrolysis of the readily available and cheap chloride $NbCl_5$.[2] Different methods of preparation of niobic acid and of catalysts based on it have been described in greater detail in a review.[2]

III. The use of niobic acid as a catalyst

Niobic acid subjected to a preliminary vacuum heat treatment up to 200–220 °C exhibits a high activity in the hydration of ethylene to ethanol.[1,14] In the stationary state at 200–220 °C, it is 2–3 times more active than solid phosphoric acid, widely used as a catalyst in industry. The selectivity in the conversion of ethylene into ethanol exceeds 97%, acetaldehyde being formed as a side product. Niobic acid ($Nb_2O_5 \cdot nH_2O$, purity 99.8%), produced by the CBMM Company, was used in the reaction after being washed with distilled water, dried at 100 °C, and then evacuated at different temperatures for 2 h. The reaction was carried out in a reactor with a stationary catalyst bed and ethylene and water vapour pressures of 48 and 7.3 kPa. The unreacted ethylene was recycled. The activity of niobic acid gradually increased during the process and attained a constant value after 6 h. Deactivation of the catalyst was not observed. Best results were obtained at 200–220 °C. At 180 °C, the activity of niobic acid was lower. Ogasawara et al.[14] concluded that niobic acid is suitable for the industrial hydration of ethylene to ethanol. Niobic acid is active even in the hydration of isobutene and propene.[2]

A solid acid catalyst for the hydration of ethylene to ethanol and the conversion of methanol into dimethyl ether was obtained by treating niobic acid with phosphoric acid.[15,16] Niobic acid was kept without stirring in 0.5 M H_3PO_4 and was then dried in air. Such treatment increased its thermal stability: crystallisation occurred at ~600 °C (instead of 435 °C) and the specific surface and the concentration of strong acid centres with $H_0 \leqslant -5.6$ increased. Phosphoric acid was found to be dispersed on the surface of niobic acid.

Niobic acid exhibited a high activity also in the hydration of dicyclopentadiene.[17] At 170 °C and atmospheric pressure, the degree of conversion of dicyclopentadiene was 17%, which is 3–10 times higher than in the case where ion-exchange resins, SiO_2, TiO_2, Al_2O_3, TiO_2–SiO_2, and SiO_2–Al_2O_3 are used (Table 2). At 400 °C the activity of niobic acid fell sharply with a simultaneous decrease also in the acidity of its surface ($H_0 \leqslant 0.5$).[17]

Table 2. The activities of niobic acid and other catalysts in the hydration of dicyclopentadiene.[17]

Catalyst	Temperature of preliminary treatment/°C	Reaction temperature/°C	Conversion into alcohol (%)
Amberlist	–	100	2.0
Nafion H	–	150	0.3
Nafion H	–	170	0.4
SiO_2	400	170	2.0
TiO_2	400	170	5.2
Al_2O_3	400	170	3.1
$SiO_2-Al_2O_3$	500	170	4.0
TiO_2-SiO_2 {[Ti]/[Si] = 9}	500	170	4.3
Niobic acid	300	170	17.0

Niobic acid heat-treated at 100–600 °C is a highly active and selective catalyst of the isomerisation and hydration of phenyloxiran under mild conditions.[18] The isomerisation occurs on Lewis acid centres, while hydration occurs on Brønsted centres. In terms of its hydrophilic properties, niobic acid is more suitable for hydration than the $SiO_2-Al_2O_3$ system, H-ZSM, and H-silicalite, because it exhibits affinity both for water and the organic substrate. The hydrophilicity of the surface of niobic acid and the concentrations of the Brønsted and Lewis acid centres are regulated by the heat treatment temperature.[18] The monoamide $NC(CH_2)_nCONH_2$ has been obtained by hydrating the dinitrile $NC(CH_2)_nCN$ (n = 2–6) with niobic acid as the catalyst.[19]

Niobic acid is also an active and selective dehydration catalyst. $Nb_2O_5 \cdot nH_2O$ specimens evacuated at 100–200 °C showed a high activity, close to that of the $SiO-Al_2O_3$ system, in the dehydration of 2-butanol. The yield of but-2-ene was then higher than that of but-1-ene. Heat treatment of niobic acid at 300 °C induced a sharp decrease in its activity in the dehydration reaction, since this entailed a decrease in the number of Brønsted acid centres catalysing the dehydration reaction.[1] The high selectivity in the formation of olefins is due to the fact that Nb_2O_5 is a very stable oxide, which is hardly reduced under the reaction conditions. Niobic acid exhibited also a high activity and selectivity in the dehydration reactions of butane-1,4-diol and cyclopentanol.[2]

Niobic acid treated with 0.05–5 M H_3PO_4 solution exhibits a catalytic activity in the dehydration of cyclohexanol and in the alkylation of benzene by methanol.[13,20] The dehydration was carried out in a flow reactor at 180 °C, while benzene was alkylated in a pulse reactor at 400 °C using the ratio $[CH_3OH]/[C_6H_6]$ = 3. Best results were obtained when niobic acid was treated with 1 M H_3PO_4 solution (quantitative data are not quoted).[20] The addition of H_3PO_4 prevents the crystallisation of niobic acid and increases the acidity of its surface by virtue of the formation of an amorphous layer of niobium phosphate on the latter.[13]

Niobic acid is an effective catalyst of the esterification of acetic acid by ethanol at 120–160 °C (Table 3). When the reaction was carried out in the gas phase at 120 °C in the course of 1 h using the ratio $[C_2H_5OH]/[CH_3COOH]$ = 1, a rate of supply of 2.3 ml h^{-1}, and a niobic acid heat treatment temperature of 200 °C, the degree of conversion was 72% and the selectivity was 100%. The catalyst retained its activity throughout the period of 60 h during which the tests were carried out. In terms of its activity, it is superior to ion-exchange resins, $SiO_2-Al_2O_3$, and the solid superacids $ZrO_2-SO_4^{2-}$, $TiO_2-SO_4^{2-}$, and $Fe_2O_3-SO_4^{2-}$. A high and stable activity is also manifested by the zeolite H-ZSM-5 (the degree of conversion was 82%–99%, but the selectivity was lower, amounting to 72%–92%), diethyl ether and ethylene being formed as side products.

An increase in the heat treatment temperature of $Nb_2O_5 \cdot nH_2O$ from 120 to 300 °C leads to an increase in the number of acid centres with $H_0 = -8.2$. The active centres of the catalyst heat-treated at 120 °C are the numerous centres with H_0 up to -5.6. The likely usefulness of niobic acid as the catalyst of esterification reactions is due to its stability, activity, selectivity, and the ability to replace sulfuric acid, which is corrosive, leads to the appearance of a large amount of waste, and is difficult to regenerate. Cation-exchange resins are also inferior to niobic acid: they have a lower acidity and thermal stability, tend to swell, are fairly expensive, difficult to utilise in the spent state, etc.[1]

Esterification of methacrylic and acrylic acids by methanol occurred especially effectively on niobic acid with strong acid centres formed as a result of its heat treatment at 200 °C.[1]

Niobic acid subjected to preliminary heat treatment at 200–400 °C exhibits a high activity in the hydrolysis of acrylate in the presence of a large amount of water in the reaction medium.[1,21] The selectivity is 100%.

Table 3. The activities and selectivities of $Nb_2O_5 \cdot nH_2O$ and other solid acids in the esterification of ethanol by acetic acid.[1]

Catalyst	Heat treatment temperature/°C	Reaction temperature/°C	Conversion of ethanol (%)	Selectivity (%)	Side products
$Nb_2O_5 \cdot nH_2O$	200	120	72	100	–
		140	86	100	–
Sulfonic acid cation exchange resin	120	120	38	<99	–
		140	50	<98	–
$ZrO_2-SO_4^{2-}$	500	140	56	90	$(C_2H_5)_2O$
$Fe_2O_3-SO_4^{2-}$	500	140	13	93	$(C_2H_5)_2O$
$TiO_2-SO_4^{2-}$	500	120	95 (94)[a]	99 (98)[a]	
		140	100	95	C_2H_4
$SiO_2-Al_2O_3$	–	120	4	99	$(C_2H_5)_2O + C_2H_4$
		140	14	98	
H-ZSM-5	–	120	82	92	$(C_2H_5)_2O + C_2H_4$
		140	99	72	

Note. The mass of the catalyst was 1 g and the reaction time was 1 h.
[a] The reaction time was 2 h.

Niobic acid is an active and selective catalyst of condensation reactions.[2,3]

Isoprene can be obtained in 61% yield in one stage from isobutene and formaldehyde on $Nb_2O_5 \cdot nH_2O$ at 350 °C. After 50 h the yield falls to 54%.[22]

Condensation of butyraldehyde at 160 °C on $Nb_2O_5 \cdot nH_2O$ affords 2-ethylhexanol. The degree of conversion is 92% and the selectivity is 96%.[23]

2,5-Dimethylhexa-2,4-diene has been obtained[24] on condensing isobutene and isobutyraldehyde at 200 °C in the presence of niobic and sulfuric acids:

Catalyst	Conversion (%)	Selectivity (%)
$Nb_2O_5 \cdot nH_2O$	97	82
H_2SO_4 (16 mass%)	99	21

Evidently, niobic acid ensures a higher selectivity than sulfuric acid.

According to Japanese workers,[25] isobutyl methyl ketone can be obtained from acetone and H_2 in the presence of 0.1% $Pd/Nb_2O_5 \cdot nH_2O$. At 160 °C and a pressure of 2 mPa, the degree of conversion of acetone was 41.8% and the selectivity was 93.5%. Under the same conditions, the degree of conversion in the presence of the 0.1% Pd/Al_2O_3 catalyst did not exceed 3.8% and the selectivity did not exceed 62.3%.

Niobic acid catalyses also olefin isomerisation and polymerisation processes. $Nb_2O_5 \cdot nH_2O$ evacuated at 100 °C proved to be the most active catalyst in the isomerisation of but-1-ene.[1] After evacuation at 300 °C, the activity of the catalyst fell sharply, but it was almost completely restored after the introduction of water vapour and subsequent evacuation at 100 °C (Fig. 4). Hence it was concluded that the isomerisation reaction is activated mainly by the Brønsted acid centres, the number of which diminishes with increase in the evacuation temperature. After evacuation at 500 °C, treatment with water vapour does not restore the activity of the specimen. The phase transition, occurring at 500 °C and accompanied by a decrease in surface area, precludes the regeneration of the Brønsted acid centres.[1]

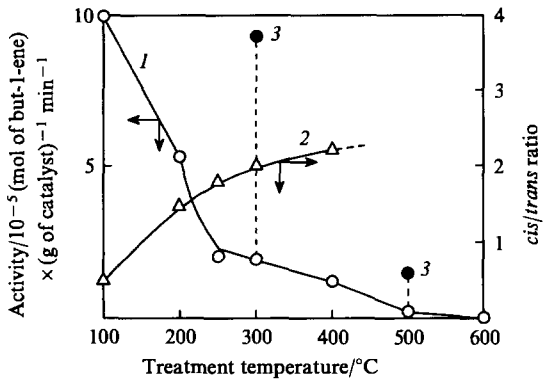

Figure 4. The activity (curve *1*), and selectivity (curve *2*) of niobic acid in the isomerisation of but-1-ene; the activity of the catalyst after its treatment with water and subsequent evacuation at 100 °C (curve *3*).

In the polymerisation of propene, niobic acid exhibits a high activity after being evacuated at 100 °C. Evacuation at 150–200 °C lowers the activity and after heat treatment at 250–300 °C the activity again increases (Fig. 5). After heat treatment at 500 °C, the activity vanishes.[1,12] Such a change in activity is explained by the fact that in the low-temperature heat treatment the polymerisation is catalysed by the Brønsted centres, but when the temperature of the heat treatment is 250–300 °C the catalysis is effected by the Lewis centres.[1]

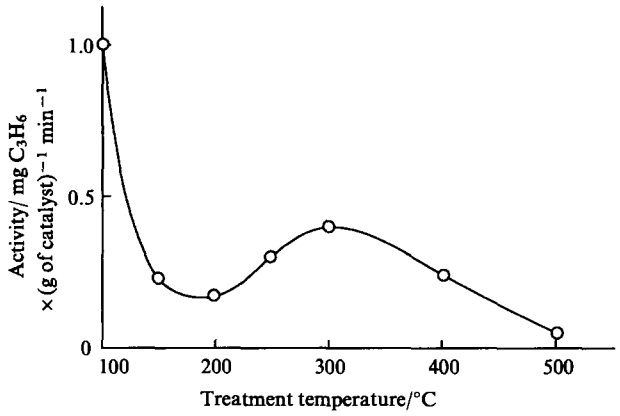

Figure 5. Dependence of the activity of $Nb_2O_5 \cdot nH_2O$ in the polymerisation of propene on the temperature of the heat treatment of the catalyst.

Much attention has been devoted to deposited catalysts based on niobic acid.[26–33] The stability of these catalysts is satisfactory and they crystallise and are reduced at higher temperatures than niobic acid. Catalysts obtained by depositing niobic acid on SiO_2 are especially effective. It has been suggested that the change in the properties of the deposited Nb_2O_5 is caused by the strong interaction at the $SiO_2-Nb_2O_5$ interface with formation of the Nb–O–Si linkage.

Amorphous Nb_2O_5, formed as a monolayer on SiO_2, has been tested[26] as a catalyst of the dehydration of ethanol to ethylene. The catalyst was prepared by depositing $Nb(OC_2H_5)_5$ on SiO_2 and subsequent treatment with H_2O and O_2. Its activity was manifested at 100–300 °C and exceeded by 1–2 orders of magnitude the activity of niobic acid without a carrier. The selectivity was 100%. The catalytic properties of mononuclear, dinuclear (0.1%–1% Nb_2O_5), and monolayer (2%–8% Nb_2O_5) niobium oxide catalysts, deposited on SiO_2 via the interaction of the OH groups with $Nb(\eta^3\text{-}C_3H_5)$, $[Nb(\eta^5\text{-}C_5H_5)H\text{-}\mu\text{-}(\eta^5,\eta'\text{-}C_5H_4)]_2$ and $Nb(OC_2H_5)_5$ respectively, have also been investigated.[27]

Analysis by the method of extended X-ray absorption fine structure (EXAFS) established that the niobium centres are fixed on the surface via the oxygen atoms (Nb–O–Si). The mononuclear niobium oxide centres are active in the dehydrogenation of ethanol at 250 °C, the selectivity in the formation of CH_3CHO reaching 96.1%. Dehydration with formation of 45% of ethylene and 52.7% of diethyl ether takes place on the dinuclear niobium centres at 250 °C.[27,28] The monolayer niobium catalyst 8% Nb_2O_5/SiO_2 is 20 times more active at 300 °C than niobic acid in the esterification of acetic acid by ethanol.[29] It has been suggested that its activity is determined by the Lewis acid centres. The catalyst is stable up to 600 °C. For a niobium content in the catalyst up to 8%, a thin homogeneous amorphous layer of niobic acid is formed on the SiO_2 surface.[29] The structure, acidity, and reactivity of Nb_2O_5 deposited on the MgO, Al_2O_3, TiO_2, ZrO_2, and SiO_2 surfaces have been investigated in the model methanol oxidation reaction.[30,31] Lewis acid centres are present on the surfaces of all the systems but, when niobic acid is deposited on the SiO_2 and Al_2O_3 surfaces, their activity is highest. On the SiO_2 surface, the Lewis acid centres exhibit oxidation-reduction properties, formaldehyde, and methyl formate being formed preferentially from methanol. On the other hand, on the Al_2O_3 surface they behave as acid centres, dimethyl ether being formed from methanol.[30] Brønsted acid centres are also present on the surfaces of the Nb_2O_5/SiO_2 and Nb_2O_5/Al_2O_3 catalysts.

The acidity of niobic acid and its capacity for crystallisation and reduction depend on the starting materials employed, the presence of impurities, and the method of deposition of niobic

acid on carriers.[32] Whereas pure amorphous Nb_2O_5 crystallises as the T-Nb_2O_5 phase after treatment at 500 and 600 °C and as the H-Nb_2O_5 phase at 1000 °C and begins to be reduced at temperatures above 600 °C, Nb_2O_5 present in catalysts obtained by impregnating SiO_2 with a solution of ethoxyniobium in hexane and sputtered onto the SiO_2 surface from the gas phase crystallises and is reduced at higher temperatures.[33] The catalyst obtained by impregnation is particularly effective. It has been suggested[33] that the change in the properties of the deposited Nb_2O_5 is caused by the strong interaction at the $SiO_2-Nb_2O_5$ interface, which influences not only the first monolayer but also the subsequent Nb_2O_5 layers as a consequence of the formation of Nb–O–Si linkages.

IV. The use of niobium oxide as a carrier and promoting agent

Hydrated niobium oxide is not the only niobium compound of interest for catalysis. Niobium oxides can also be used as promoting agents and carriers. For example, Nb_2O_5 used as a carrier in rhodium catalysts for the synthesis of higher hydrocarbons from CO and H_2 exerts a strong influence on the activity and selectivity.[3] The effectiveness of the carriers diminishes in the sequence $Nb_2O_5 > ZrO_2 > Al_2O_3 > SiO_2 > MgO$. At 220 °C the degree of conversion of CO on Rh/Nb_2O_5 reaches 76%,[3] whereas on Rh/Al_2O_3 it is only 1.4%.

The $Rh-Nb_2O_5$ interaction in the niobium pentoxide-promoted Rh/SiO_2 catalyst has been investigated by X-ray powder diffraction, X-ray photoelectron spectroscopy, IR spectroscopy, the EXAFS method, and the method based on the chemisorption of H_2 in relation to the test reaction involving the hydrogenolysis of ethane.[34,35] The degree of interaction of Rh with Nb_2O_5 depended on the heat treatment temperature. After heat treatment in air at 700 and 900 °C, strong interaction of rhodium with Nb_2O_5, involving the formation of the $RhNbO_4$ phase, was observed. Heat treatment at 500 °C did not give rise to this effect.

The strong metal–carrier interaction influences the hydroformylation of ethylene in the presence of palladium catalysts deposited on Nb_2O_5.[36] The influence of the temperature in the reduction with hydrogen on the chemisorption and catalytic properties of the 5% Pd/Nb_2O_5 and 5% Pd/SiO_2 catalysts has been investigated by X-ray powder diffraction and IR spectroscopy. The amounts of H_2 and CO chemisorbed on Pd/Nb_2O_5 reduced at 500 °C were respectively almost 4 and 2.5 times smaller than on Pd/Nb_2O_5 reduced at 200 °C. A strong metal–carrier interaction was observed in the catalyst reduced at 500 °C and the main product of the reaction of ethylene, CO, and H_2 at 64 °C was 2-methylpenten-2-al. Ethylene was hydrogenated to ethane on Pd/Nb_2O_5 reduced at 200 °C and on Pd/SiO_2.[36]

A strong promoting influence of Nb_2O_5 has been observed in a number of reactions.[3,37–39] For example, the $Pt/Nb_2O_5/SiO_2$ catalyst, in which the degree of coverage of Nb_2O_5 did not exceed the monolayer coverage, proved to be 40 times more active than Pt/SiO_2 and 1000 times more active than Pt/Nb_2O_5 in the hydrogenation of ethylene.[37]

The addition of Nb_2O_5 to V_2O_5/TiO_2 and to Fe_2O_3 appreciably improved the activity of the latter in the decomposition of NO using NH_3 as the reducing agent.[3]

$$4NO + 4NH_3 + 3O_2 \longrightarrow 4N_2 + 6H_2O.$$

On the catalyst having the composition (5% V_2O_5 + 2.7% Nb_2O_5)/TiO_2, the degree of conversion of NO at 200 °C was 100% whereas on the catalyst 7.5% V_2O_5/TiO_2 it was 40% at the same temperature and reached 100% only at 300 °C. The degrees of conversion of NO (expressed as percentages) on these catalysts varied as a function of the duration of the process in the following way:[3]

	Initial	After 15 h	After 30 h
$(V_2O_5-Nb_2O_5)/TiO_2$	99	94	89
V_2O_5/TiO_2	40	12	7

The use of the Rh/SiO_2 catalyst modified with Nb_2O_5 for the reduction of NO by ammonia has been examined.[38]

An active catalyst for the Fischer–Tropsch synthesis includes Ru/TiO_2 modified with 0.5%–25% of the oxide of a metal belonging to the Nb, V, and Ta group or their mixture in a non-crystalline form.[39]

V. Other niobium compounds used in catalysis

Other niobium compounds have also found applications in catalysis. Niobium sulfides, prepared by direct synthesis from the elements, are extremely active in the reactions involving the hydrogenation of biphenyl, toluene, and cyclohexene.[40] Their activity diminishes in the sequence $NbS_3 > NbS_2 > Nb_{1.12}S$. They exhibit the highest activity and selectivity (> 80%) in the cracking reaction.[40] Niobium sulfides are much more active than vanadium and ruthenium sulfides in the cracking and hydrodenitrogenation reactions.[41,42]

A series of niobium compounds exhibit a photocatalytic activity on irradiation with visible light.[43–45] Thus $K_4Nb_6O_{17}$ is extremely active in the photolysis of water.[44,45]

$$H_2O \longrightarrow H_2 + \tfrac{1}{2}O_2.$$

When 1% Ni is deposited on $K_4Nb_6O_{17}$, the activity of the latter increases.[45] A niobium-based catalyst for the metathesis of propene has been described.[46] A heterogeneous catalyst based on molybdenum or niobium chlorides deposited on SiO_2 is active in the reactions of unsaturated compounds—metathesis, cyclotrimerisation, and alkylation.[47] The catalytic and sorption properties of an aerosilogel modified with $NbCl_5$ in the ethanol decomposition reaction at 300 °C have been examined.[48]

The isomerisation and oligomerisation of olefins on the Nb_2O_5 and Nb_2O_5/SiO_2 catalysts reduced in a mixture of H_2 and H_2O at 600 °C have been investigated. The catalysts exhibited an activity in the isomerisation of *cis*-but-2-ene at 25 and 100 °C. It has been established by the EPR method[50] that the active catalytic centres are isolated coordinatively-unsaturated Nb^{4+} cations, which are more stable on the SiO_2 surface.

The high concentration of strong acid centres on the surface of crystalline β-Nb_2O_5, obtained by dissolving Nb_2O_5 in concentrated H_2SO_4 and subsequent crystallisation at 120 °C, is responsible for its activity in dehydration and esterification reactions.[51]

Amorphous and crystalline niobium phosphates,[52–54] which can be readily synthesised from niobium sulfate and phosphoric acid, may be of practical interest as acid catalysts.[52,53] The influence of the temperature of the preliminary treatment on the texture and acid and catalytic properties of niobium phosphate has been investigated by differential thermal analysis, thermogravimetric analysis, X-ray powder diffraction, the adsorption and indicator methods, the IR spectroscopy of adsorbed pyridine, and the test reactions involving the dehydration of 2-butanol, the isomerisation of but-1-ene, and the polymerisation of propene.[54] An increase in the heat treatment temperature diminishes the specific surface and the pore volume in the catalyst (Table 4). After heat treatment in the temperature range 100–500 °C, both Lewis and Brønsted acid centres with $H_0 = -8.2$ are present on the surface of the phosphate (Fig. 6). The catalyst treated at 150 °C is most active in the dehydration of 2-butanol, while the catalysts treated at 250 and 300 °C respectively are most active in the but-1-ene isomerisation and propene polymerisation reactions. Niobium phosphate is a more stable and active catalyst than niobic acid.

Table 4. The specific surfaces, pore volumes, and average pore diameters of niobium phosphate treated at different temperatures (niobium concentration in the specimen 43.44%).[54]

Treatment temperature/°C	Specific surface/$m^2\ g^{-1}$	Pore volume/$cm^3\ g^{-1}$	Average pore diameter/Å
150	277	0.352	34.8
300	230	0.310	39.0
500	182	0.287	39.0

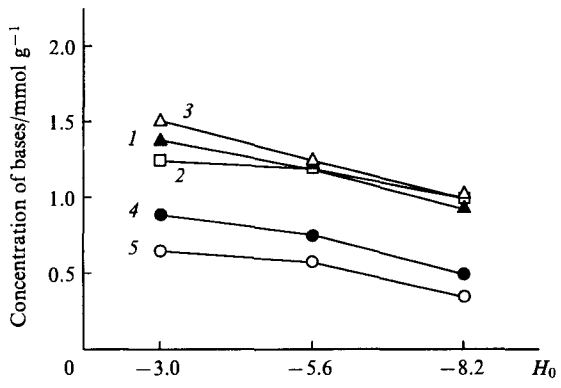

Figure 6. Distribution of the centres with respect to their acid strength in niobium phosphate heat-treated at different temperatures (°C): *1*, 100; *2*, 150; *3*, 300; *4*, 400; *5*, 500.

By adding phosphoric acid to a solution obtained when Nb_2O_5 is dissolved in concentrated H_2SO_4 in the presence of $(NH_4)_2SO_4$ and by subsequent addition of NH_4OH until the attainment of pH 1, the crystalline niobium(V) phosphate was isolated. It crystallises in a pseudocubic lattice with a_0 = 10.244 Å and has the rigid three-dimensional structure of a zeolite.[53] Its empirical formula was determined as $Nb_2O_5 \cdot 1.5P_2O_5 \cdot 7.5H_2O$, while its chemical formula was found to be $(NbO)_2(HPO_4)_3 \cdot 6H_2O$. The crystalline niobium phosphate was characterised by pH titration, IR and X-ray photoelectron spectroscopy, X-ray powder diffraction, thermogravimetric analysis, and differential scanning calorimetry. It was established that its chemical stability is higher than that of the amorphous phosphate and that it has a high exchange capacity, reaching 4.6 mmol g^{-1} for K^+ (the theoretical value is 4.8 mmol g^{-1}). According to Okazaki,[2] both the amorphous and crystalline niobium(V) phosphates can be used either as catalysts or as carriers in many processes.

Methods of synthesis of acrolein and its α-substituted derivatives

N A Keiko, M G Voronkov

Contents

I. Introduction 751
II. Methods of synthesis of acrolein and α-alkylacroleins 751
III. Methods of synthesis of α,β-unsaturated aldehydes α-substituted by functional groups 758

Abstract. The methods of synthesis of acrolein and its α-alkyl-substituted derivatives are examined: (a) catalytic oxidation of propene, isobutene, propane, isobutane, propyl and *tert*-butyl alcohols, *tert*-butyl alkanoates, propionaldehyde isobutyraldehyde, and allyl alcohol and its ethers and esters; (b) condensation of formaldehyde with aliphatic aldehydes by the Mannich reactions and also in the vapour phase over heterogeneous catalysts. Both general methods (the Mannich reaction, *ipso*-substitution of a α-halogen in the acrylic system, and interaction of 1-bromo–2-ethoxycyclopropyl-lithium with electrophiles) and various special methods are used in the synthesis of α,β-unsaturated aldehydes with functional-group-substitutents. The bibliography includes 323 references.

I. Introduction

Acrolein and methoacrolein and industrial products produced on a large scale. The world production of the former compounds runs into hundreds of thousands of tonnes annually. The acrylic and methacrylic acids obtained from acrolein and methacrolein, as well as their esters have found extensive applications as monomers in the manufacture of various polymeric materials, synthetic fibres, emulsions, adhesives, etc. Industrial methods of synthesis of acrylonitrile, methionine, glycerol, allyl alcohol, glutaraldehyde, β-picoline, pheromones, pesticides, perfumes, and medicinal drugs from acrolein have been developed. The high reactivity of acrolein and its substituted derivatives has created extensive possibilities for its use in fine organic synthesis. During the last decade up to 300 articles and patents devoted to the methods of synthesis of acrolein and its derivatives and their involvement in various syntheses have been published annually. Acrolein itself is used as a herbicide and algicide and prevents the growth of biomass on technical water supply systems, as a slimicide which destroys slime in the manufacture of paper, as a binder in solutions for building purposes, as a component for the purification of waste water containing hydrogen sulfide and cyanide ions, as an ingredient in compositions for the protection of wood against water, as a stabiliser used in the finishing of textile materials, etc. It has been shown recently that latex microbeads based on polyacrolein can be used in immunoanalysis. All the expanding applications of acrolein and its derivatives have made it necessary to improve the known methods and to seek new ones for their synthesis using cheaper and more readily available raw materials.

The principal industrial method for the synthesis of acrolein and methacrolein available at present involves the incomplete selective vapour-phase oxidation of propene and isobutene respectively on heterogeneous catalysts. The last systematic review devoted to the oxidation of propene to acrolein covers the literature published up to 1981.[1] Review articles on other methods of synthesis of acrolein and its derivatives were published even earlier.[2–6] We therefore had to deal in the present review with studies published mainly during the last 15–20 years. In addition α,β-unsaturated aldehydes α-substituted by functional groups, the chemical reactions of which are extremely varied and frequently unexpected, have been scarcely represented in the review literature (with the exception of one publication by the authors of the present review[7]). As far as possible, they will be considered exhaustively in the text below.

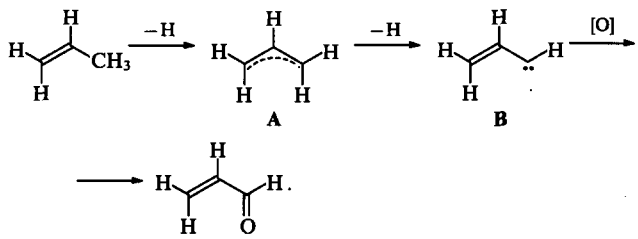
II. Methods of synthesis of acrolein and α-alkylacroleins



1. Oxidation of propene and isobutene

The partial vapour-phase oxidation of propene and isobutene on heterogeneous catalysts is at present the main industrial method of synthesis of acrolein and methacrolein respectively:

$$CH_2=CR-CH_3 + O_2 \longrightarrow CH_2=CR-CHO + H_2O;$$
$$R = H, Me.$$

This reaction constitutes the first stage of the large scale industrial production of acrylic and methacrylic acids from which acrylates and polyacrylates are obtained in their turn. Data on the improved methods of the oxidation of propene and isobutene available up to 1981 are surveyed in the existing reviews.[1,4–6,8–14]

The catalytic oxidation of propene is one of the most important allylic oxidation reactions.[12] In allylic oxidation, the alkene, for example propene, is activated as a result of the elimination of a hydrogen atom from the methyl group with formation of the allyl intermediate A. This stage determines the rate of the entire process.[12,15–18]

The intermediate B formed subsequently interacts with the oxygen of the catalyst lattice and is converted into acrolein. All the known selective oxidation catalysts have oxidation-reduction properties. They must be capable of not only being reduced during the formation of acrolein but also of being reoxidised with incorporation of oxygen from the gas phase into the catalyst lattice in the form of the O^{2-} ions, which results in the refilling of the free vacancies. A procedure in which the properties of various polyvalent oxides are combined has become one of the fruitful methods for the selection of catalysts of the process under consideration.[12] The participation of oxygen from the crystal lattice of bismuth molybdate or the three-component bismuth–vanadium–molybdenum oxide catalyst in the oxidation of propene has been confirmed experimentally using $^{18}O_2$ as the oxidant.[19,20]

Among the complex oxide catalysts for the selective oxidation of propene, molybdenum-containing catalysts have come to be most widely used during the last 20 years.[21–26] However, molybdenum catalysts are frequently used only for research purposes, for example, in the study of the dependence of the activity on the surface structure[27] or for the determination of the orientation of MoO_3 in the catalyst layers, which influences the selectivity of the reaction.[28,29] Bimetallic catalysts, which contain, apart from molybdenum oxide, also bismuth,[30] cobalt,[31] or vanadium[32] oxide, are much more active. The incorporation of bismuth in an amount of even several tenths per cent increases the conversion of butene and the reaction selectivity with respect to methacrolein by tens per cent.[33] The addition of bismuth increases the effectiveness of the oxidation of propene on $PbMoO_4$[34] or on the multicomponent molybdenum catalysts $Mo_{12}Bi_xFe_yTl_z$ and $Mo_{12}Bi_xFe_yTl_zNi_6Zn_3$.[35]

Systematic studies have been made on the oxidation of isobutene on Fe–Mo–Te and Fe–Mo–Sb oxide catalysts,[36–39] as well as on Co–Mo–Bi–Fe oxides.[40] On one of the specimens of the Fe–Mo–Te catalysts, it has been possible to attain the virtually complete conversion of the olefin in the oxidation of an isobutene–air mixture containing 1.8 vol.% of isobutene at 370 °C. The selectivity with respect to methacrolein was then 77% and the yield of the latter relative to the isobutene passed through the system was 75%–80%.

However, the multicomponent oxide catalysts containing added Co, Ni, Fe, K,[21] Ni, Co, Fe, K, P, Si,[41] and certain other elements,[42–43] apart from molybdenum and bismuth, are the most effective and selective. With the aid of such catalysts, it has been possible to achieve 93%–98% conversion of propene and a 79%–88% yield of acrolein.[41,44] Equally high parameters were obtained in the oxidation of butene, but the catalysts employed had a more complex composition:

$$Mo–Co–Fe–Bi–Tl–X–Y–Z–O,$$

where X = V and/or NB, Y = La and/or Ce, and Z = Cs and/or Te;[45]

$$Mo–Co–Fe–Ni–Pb–X–SmO,$$

where X represents two elements from the Rb, Cs, Tl triad:[46]

$$Mo–Bi–M^1–M^2–M^3–M^4–M^5–ZnO,$$

where M^1 = In, La, Ga or Al; M^2 = Fe or Fe and Cu; M^3 = Ni and/or Co; M^4 represents several elements from the P, W, Cr triad (usually W + P or W + Cr) and sometimes B, As, or V, and M^5 is one or several of the elements from the set Cd, Ta, Sm, Nb, Ag, Pb, Mn, Re, Sn, Ge, Mg, Ca, or Ba.[47] Each of the eight or nine elements is a necessary component for the attainment of a high productivity. For example, the last of the catalysts enumerated, with added zinc, is distinguished by an increase in selectivity and a higher stability.[47]

Since the catalysts are multicomponent systems, the choice of the composition ensuring the attainment of the optimum activity and selectivity is a task of enormous difficulty.

The stability and activity of the catalyst play an important role in the industrial manufacture of acrolein. For example, at the start of the catalyst bed, where the temperature has increased owing to the evolution of the heat of the reaction with the water present in the reacting gas, molybdic acid is formed and vaporises.[48] The vaporised molybdenum condenses in the colder part of the reactor. As a result of this, the yield of methacrolein is low at the beginning of the bed.

Apart from molybdates, metal anitmonates[49] and tellurates as well as multicomponent systems based on them[50,51] and phosphates of the type $2Bi_2O–P_2O_5$ [17] are active catalysts. The introduction of 0.2%–0.8% of Na_2O into the last catalyst increases the amount of basic surface centres and leads to the conversion of propene not into acrolein but into hexa-1,5-diene and benzene.[52]

Vanadium and titanium–vanadium oxide catalysts exhibit an increased selectivity, which depends on the presence of nonstoichiometric V–Na compounds.[53,54]

Iron–tin[16] and tin–antimony[27,55–58] catalysts constitute a separate group of effective catalysts of the oxidation of propene. The latter exhibit an especially high activity in the oxidation of isobutene to methacrolein.[59–64] Depending on the composition, the optimum temperature at which the highest activity of the catalyst is attained is in the range from 430 to 675 °C.[59] The activity and selectivity of the tin–antimony catalysts depend greatly on the method of their preparation. The dissolution of the metal in boiling nitric acid,[64] the coprecipitation of the corresponding Sn and Sb salts followed by heat treatment of the deposits,[49] the deposition of Sb oxides onto the SnO_2 matrix, mixing of SnO_2 and Sb_2O_4 or Sb_6O_3,[27] and spray drying of an aqueous suspension of the initial oxides with subsequent heat treatment at 800 °C [65] are most often used. The Sb–Sn oxide catalyst obtained in the last case exhibits a high mechanical strength and ensures a high yield of methacrolein (up to 85% relative to the initial isobutene). Highly active and selective tin–antimony catalysts of the gas-phase oxidation of isobutene to methacrolein (yield up to 72%) are obtained from a moist paste of tin(II) and antimony (preferentially Sb_2O_5) oxides by drying it and subsequent heat treatment.[61] The conditions in the preparation of the tin–antimony catalysts influence their structure and properties so significantly that the method of preparation of the catalyst is frequently more important than its chemical composition.[66]

It has been suggested that catalysts be compared in terms of their maximum selectivity attained for a specified conversion of isobutene and yield of methacrolein.[62] According to this criterion, the catalysts investigated can be arranged in the following series:

$$Sn–Sb > Bi–Mo–V–O > Bi–Mo–W–O.$$

The Sn–Sb–O mixed oxide catalyst is 1.5–2 times less active at 425 °C than the analogous Mo–Bi–O catalyst for the same initial selectivity with respect to methacrolein (80%).[67]

A series of the catalysts of the oxidation of propene to acrolein described in the literature have been compared using the thermal desorption method: $Co_6Mo_{12}Bi_{0.5}Fe_{0.75}O_x$, Bi_2MoO_6, 5 at.% Sb in SnO_2, USb_3O_3, $BiFeMoO_x$, $Bi_3FeMo_2O_x$, Cu_2O, $CoMoO_4$.[68]

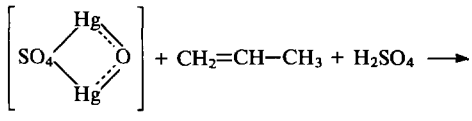
It was established that the active intermediates arising from propene can be converted into acrolein via two pathways: they interact either with the oxygen of the catalyst lattice or with the adsorbed oxygen. The rate of the selective oxidation of propene on modified cobalt molybdate is determined by the acrolein desorption stage.

Overall, the idea that it is mainly the oxygen ions of the crystal lattice which participate in the selective oxidation of alkenes over the $MoO_3-Bi_2O_3$ or $Bi_{1-x/3}V_{1-x}Mo_xO_4$ catalysts while gaseous oxygen reoxidises the catalyst became firmly established towards the beginning of the 1990s.[19,20,34] The use of oxides with a scheelite structure of the type $Pb_{1-3x}Bi_{2x}\Phi_xMoO_4$ (Φ = cationic vacancy, x = 0 and 0.04) as the catalysts in the electrochemical oxidation of the alkenes made it possible to determine the mobility of the lattice oxygen ions, which is satisfactorily correlated with the catalytic activity.[20,34] The electrolyser cell incorporating the yttrium oxide-stabilised zirconium oxide (Y–s–Zr) as the solid electrolyte, namely $P(O_2)$, M/Y–s–Zr/M′, $P(O_2)'$, where M and M′ are electrodes, can perform the function of an oxygen pump, in which the oxygen stream passing through the electrolyte is regulated by the electric potential applied to the electrodes.[34,69] Under the conditions of the partial oxidation of alkenes in this system at 450–475 °C, the gaseous oxygen chemisorbed on the catalyst surface dissociates into ions, which diffuse into the bulk phase and are then incorporated in the allyl intermediate, forming oxidised compounds. On the other hand, the chemisorbed oxygen remaining on the surface accelerates only the more extensive oxidation of the alkenes to CO and CO_2. The ideas concerning the mechanisms of the oxidation of propene to acrolein current up to 1976 have been examined in detail in a monograph[13] (pp 81–102 and 120–132).

The copper catalyst for the oxidation of propene to acrolein, which was most effective in the 1940s, is little used. Nevertheless, the influence of reoxidation and of water vapour on the ion-exchange process catalysed by copper(II)-containing zeolites was studied recently.[70]

Apart from the composition of the catalysts and the method of mixing the components,[39,71] the valence state of the elements and hence the activity of the catalyst are influenced decisively by the heat treatment temperature,[33,50] the size and geometrical shape of the particles employed, and also their specific surface.[13,33,72]

The oxidation of olefins is usually carried out at 250–450 °C at a pressure close to atmospheric. A stationary catalyst bed is most often employed, but sometimes a fluidised bed is also used.[16,57] The effectiveness of reactants of different types in the oxidation process can be estimated by mathematical modelling methods.[60]



In order to make industrial processes more economical, it is essential to achieve in the latter a high conversion of the olefin and a greater selectivity with respect to the aldehyde in order to eliminate the cost of the recirculation of the unreacted initial alkene. An excess of oxygen 2–20 times greater than the concentration of the alkene is used for this purpose.[16,39,45,46,73] In order to prevent the overheating of the catalyst and to reduce the formation of the extensive oxidation product, the reacting gases are diluted with 10%–40% of water vapour,[23,24,36–39,45,46,74,75] nitrogen,[32,47,76] helium or argon,[46] or inert hydrocarbons — for example, but-1-ene.[73]

An increase in the conversion and selectivity during the oxidation of olefins to unsaturated aldehydes on a catalyst of the type $Mo_{12}BiCo_3NiFeK_{0.1}O_x$ is attained by introducing an inert material into the catalyst (up to 75% by volume). This promotes a more uniform distribution of the heat of reaction throughout the catalyst bed and the attainment of the optimum rate of the process.[74] The inert carriers employed are porcelain, quartz,[3,39,77] α-Al_2O_3,[37] SiO_2,[46,78] and 'inert' glass particles.[79] The Fe–Sb–O catalyst was diluted with silica gel containing 30% of SiO_2 (the SiO_2 content in the heat-treated catalyst was 2, 10, or 25 mass%).[16]

Acetone and acetaldehyde[53] and acetic and acrylic or methacrylic acids are encountered in small amounts, in addition to CO and CO_2,[46] among the side products of the oxidation of lower alkenes to acrolein and methacrolein respectively.[36,37,39,46,47] The side reactions involving the extensive oxidation of the initial alkenes and the unsaturated aldehydes formed can be suppressed by introducing promoting agents, for example thallium,[33,80] or by reducing the contact time.[39] The crystal structure,[27–30] phase composition,[75,81–83] and a number of other physicochemical properties of the catalysts of the vapour phase oxidation of lower alkenes[16,84,85] were investigated by IR, Raman,[51,86] UV, visible[87] and Mössbauer spectroscopy, electron microscopy,[88] and also X-ray diffraction.[61,88] The study of the kinetics of this process showed that the rate of formation of acrolein on a multicomponent molybdenum catalyst at 320 °C is independent of the partial oxygen and water vapour pressures, increasing with increase in the propene pressure.[89] The reaction involving the oxidation of propene to acrolein on a bismuth–molybdenum oxide catalyst with added Ni, Co, Fe, K, and P in the temperature range 300–390 °C is autocatalytic. Water vapour promotes the formation of acids as side products, but suppresses the extensive oxidation reactions of acrolein and acrylic acid.[64] Optimisation of the catalytic composition containing Mo, Co, Fe, Bi, and K oxides by Fabian's statistical method made it possible to attain the maximum selectivity with respect to acrolein.[90] The π-complexes of the allyl anion with transition metals have been investigated *ab initio* by the molecular orbital method.[91]

Technological schemes for the partial oxidation of propene on a multicomponent oxide catalyst have been developed with the aid of the mathematical modelling method.[21,60,89,90,92]

An effective laboratory liquid-phase method for the oxidation of propene to acrolein (in 85% yield) in an acid aqueous solution of mercury salts (preferentially the sulfate and perchlorate)[93] can be described schematically as follows:

$$\longrightarrow CH_2{=}CH{-}CHO + 2Hg_2SO_4 + 2HgSO_4 + 2H_2O.$$

An electrochemical process involving the allylic oxidation of propene to acrolein and acrylic acid has been patented.[94] When a palladium anode and 25% phosphoric acid as the electrolyte were used in this process, a high selectivity with respect to acrolein could not be attained.[95]

Acrolein and methacrolein are also formed in the oxidation of butadiene to isopropene by molecular oxygen in the presence of a rhodium catalyst (80 °C, 50 atm). However, the yield of the unsaturated aldehyde is only ~1%, so that this reaction is of no practical interest.[96]

2. Oxidation of propane and isobutane

Attempts were made in the 1980s to select a catalyst for the direct oxidation of propane by oxygen to the corresponding unsaturated aldehydes and acids.[97–99] The highest conversion (20%–30%) for a selectivity with respect to C_3 oxidation products of 13%–40% was attained on mixed oxide catalysts containing boron and phosphorus or molybdenum and tellurium at 500–550 °C. The selectivity with respect to acrolein of silver-doped bismuth vanadomolybdate exceeded 60%, but the conversion of propane was only 13%.[100]

Isobutane is oxidised by atmospheric oxygen to methacrolein at 250–450 °C over a reduced catalyst prepared from heteropolyacids, for example $H_3PMo_{12}O_{40} \cdot 30H_2O$.[101] The conversion of the alkane is 7%–8%, under these conditions, while the selectivity with respect to methacrolein and methacrylic acids is 12% and 48% respectively. Unsaturated aldehydes may be synthesised from the corresponding alkanes more conveniently in two stages without the isolation of intermediates.[102] The first stage involves the dehydrogenation of the mixture of alkanes (propane, isobutane, etc.) at 650 °C (approximately 45% conversion), while the second involves the oxidation of the products in another reactor at 340 °C (82% conversion).

3. Oxidation of propanol and *tert*-butyl alcohol

The vapour-phase oxidation of propanol by atmospheric oxygen to acrolein has been achieved using a two-bed catalyst.[103] Dehydration and oxidation occurred in the first and second catalyst beds respectively. BPO_4 coprecipitated with SiO_2 and Al_2O_3 and also WO_3 and Al_2O_3 were used as the dehydration catalyst. The second bed contained either the Fe–Co–Bi–P–Mo–K, Fe–Co–W–Bi–Mo–Mg, and Sb–U mixed oxides or a mixture of bismuth molybdate and phosphoromolybdate. The mixture of propanol and oxygen supplied to the reactor was diluted with an inert gas (N_2, He, CO_2) or water vapour and the process was carried out at 350–500 °C and pressures in the range 0.5–10 atm.

tert-Butyl alcohol is a side product of the processing of the butane–butene fraction and in many other industrial processes. A highly efficient process involving the direct oxidation of the alcohol to methacrolein without the preliminary dehydration to isobutene has been proposed for its utilisation.[104] The yield of methacrolein on the Fe–Te–Mo (1 : 0.85 : 1) oxide catalyst[36] is more than 80%. The reaction is carried out at 400–420 °C, a space velocity of 0.1–0.15 s^{-1}, and an alcohol concentration in the initial reaction mixture of 4–5 vol.%. The synthesis of methacrolein by the partial oxidation of *tert*-butyl alcohol is similar to the oxidation of isobutene examined above.[22,25,26,45,46,105,106] Both processes are carried out on the same incomplete oxidation catalyst. Comparison of the dependence of the selectivities of the processes (with respect to methacrolein and CO and CO_2) on the degree of conversion of the initial isobutene or *tert*-butyl alcohol showed that the oxidation reaction proceeds by a consecutive-parallel mechanism. *tert*-Butyl alcohol is initially dehydrated to isobutene, which is converted into methacrolein and extensive oxidation products.[105–107] The selectivity with respect to methacrolein in the oxidation of *tert*-butyl alcohol on the Co–Mo–Bi–Fe–Sb–K–O catalyst is somewhat higher than in the oxidation of isobutene.[105] As in the oxidation of isobutene, the initial mixture of the alcohol and oxygen is diluted with water vapour and nitrogen.[25,26,105,108–110] A yield of methacrolein of 80%–90% for a virtually complete conversion of *tert*-butyl alcohol can be achieved on modern multicomponent oxide catalysts based on Mo–Co–Bi.[45,46] The use of complex catalytic compositions of the type $Sm_aFe_bBi_cX_dNi_eZ_fQ_gMo_{12}O_h$, where X = K, Rb, Cs, or Tl, Z = B, Co, Si, Au, Ag, Cd, Hg, V, Ti, Zr, Nb, Ta, Cr, W, U, Tc, Re, Be, Mg, Ca, Sr, or Ba and Q = Gd, Sc, Tb, Ho, Hf, Lu, or Dy, and a selection of catalyst carriers (SiO_2, SiC_2, Al_2O_3) and partial pressures of $(CH_3)_3COH$, O_2, N_2 and H_2O make it possible to raise the conversion of the alcohol to 92% for a selectivity of 90%.[111] According to patent data, the modified Mo–Fe–Co catalyst to which other elements have been added exhibits a high resistance to compression and wear, has a high catalyst activity, and is long lived.[112] Silicon dioxide is the commonest carrier for multicomponent catalysts of the processes described[22,108,113] but granulated activated charcoal can be used instead.[114]

In contrast to the one-reactor method described, it has been suggested that, in order to obtain methacrolein from *tert*-butyl alcohol, the latter should be dehydrated to isobutene over the γ-Al_2O_3 (90%)–SiO_2 (10%) catalyst at 80 °C. The isobutene obtained in this way is oxidised further to methacrolein. This greatly increases the lifetime of the second catalyst bed prepared from the Mo–Bi–Fe–Co–Cs oxide composition.[115]

A method of synthesis of methacrolein involving the oxidation of *tert*-butyl alcohol and/or its isobutyl ether as well as isobutene by oxygen-containing gases at 100–300 °C with the Hg, Ba, Cr, Mo, V, Mn oxides and halides as catalysts has been described.[114]

Highly effective catalysts of the oxidation of methyl and butyl ethers of *tert*-butyl alcohol, having the composition $Mo_aW_bBi_cFe_dX_eY_fZ_gQ_hO_x$ (X = Ni and/or Co; Y is an alkali or alkaline earth metal and/or Tl; Z = P, Te, Sb, Sn, Ce, Pb, Nb, Mn, Zn, Ge, Ga, La, In, Cd, V, Cr, U and/or Ag; and Q = Si, Al, Ti, or Zr) have been proposed. The conversion of the ethers is 98% and the selectivity with respect to methacrolein is 82%.[116]

Acetic and methacrylic acids, but-1-ene or but-2-ene, buta-1,3-diene, CO, CO_2, and polymers are side products of the oxidation of *tert*-butyl alcohol.[117,118]

4. Oxidation of *tert*-butyl alkanoates

A continuous method of synthesis of methacrolein by the gas-phase oxidation of *tert*-butyl alkanoates with oxygen or air over the isobutene oxidation catalyst in the presence of water vapour has been proposed.[119]

$$RCOOC(CH_3)_3 \xrightarrow{[O]} CH_2{=}C(CH_3){-}CHO.$$

The Mo–Co, Mo–Bi, Mo–Fe, Mo–P, Mo–Bi–Fe–Co oxide mixtures, preferably with added Ni, Sb, W, Te, Cs, K, Cu, or their mixtures, are used as catalysts. The reaction is carried out at 200–600 °C with the molar ratio oxygen : ester = (0.5–10) : 1. Under optimum conditions, the conversion of the ester is 61% and the selectivity with respect to methacrolein is 88%.

5. Oxidative dehydrogenation of propionaldehyde and isobutyraldhyde

The vapour phase oxidative dehydrogenation of propionaldehyde and isobutyraldehyde to acrolein and methacrolein respectively can be carried out at 280–390 °C over catalysts containing Mo, P, and O as well as Zn, Cu, or Ag on Al_2O_3 or Si–C.[120]

$$CH_3CHRCHO + 0.5O_2 \longrightarrow CH_2{=}CRCHO + H_2O;$$

R = H, Me.

It is recommended that the initial aldehyde–air mixture be diluted with water vapour or nitrogen. When the mixture of isobutyraldehyde, air, steam, and nitrogen is used in proportions of 3.4 : 18.6 : 70 : 8.0, it is possible to obtain methacrolein in 61.5% yield. The corresponding unsaturated acid is a side product. There has been no demand for isobutyraldehyde, which is a waste product in the manufacture of 2-ethyl-hexanol[121] and a side product in oxo-synthesis,[122] but there arises now the prospect of using it to obtain polyacrylates via methacrolein and methacrylic acid. The competitiveness of the oxidative dehydrogenation process depends greatly on the efficiency of the catalyst. The most effective catalytic systems for the oxidative dehydrogenation of isobutyraldehyde are presented in Table 1.

Table 1. Conditions in the oxidative dehydrogenation of isobutyraldehyde (IBA) to methacrolein.

Catalytic system	Initial reactants	T/°C	Yield (%)	Conversion (%)	Selectivity (%)	Ref.
Bi–P–Mo–O	IBA + air	320	80 [a]			123
Mo–Co–O (W or W + Te)	IBA : O_2 : H_2O : N_2 = 5 : 10 : 30 : 55		21			124
Mg–Cr–Fe–O_4	IBA : O_2 = 1 : (1.5–3)	350		68	88	125
Zn–Cr–Fe–O_4	IBA : O_2 = 1 : (1.5–3)	350		65	87	125
$H_5Mo_{10}V_2PO_{40}$	IBA : O_2 : N_2 = 4.7 : 12.7 : 82.6	288	68			126
Bi_2O_3 + Group I and II metal oxides	IBA + lattice oxygen	450	47		65.5	127
Mo–P–Zr–V–X–X′–O (X = K, Pb, Cs or Tl; X′ = Li, Na, Mg or Ca)	IBA + air + water	260	76.5	100	65.5	128
		310	17			
	IBA : air : H_2O = 4 : 40 : 56	320	18.1			129
		280	65.3	10		
$A_aFe_bP_cO_x$ (A = Cs, Tb, Mn, U, Ag, Tl)	IBA : O_2 : H_2O = 1 : 3.7 : 26	250–600	80	100		130
$H_5Mo_{10}V_2PO_{40}$	IBA + air + nitrogen	205–210	100	>90		131
$H_5Mo_{10}V_2PO_{40}$	O_2 : IBA = 1.23–1.92					122
Sb_2O_5	IBA + air	325	81.5	20		134
Fe, Te, and Mo oxides (1 : 0.85 : 1)	IBA : air = 2.5 : 97.5	285		88	42	132
Fe, Te, Mo, and Mg oxides (1 : 0.85 : 1 : 0.1)	IBA : air = 2.5 : 97.5	340		100	39	132
$Mo_3Sb_2Te_{0.1}O_x$	IBA : air = 2.5 : 97.5	310		12	67	132
		420		53	40	132
$Mo_{12}Sb_2Te_{0.2}O_x$	IBA : air = 2.5 : 97.5	385		100	41	132
$Mo_{12}SbTe_2O_x$	IBA : air = 0.5 : 10	360		>90	60	133

[a] The overall yield of methacrolein and methyl methacrylate is quoted.

The table shows that catalysts based on heteropolyacids of the type $H_{3+x}Mo_{12-x}V_xPO_{40}$ ensure the highest conversion and selectivity of the process at a comparatively low temperature. However, for technological use, they must be deposited on inert supports. The problem of the long time stability of the catalyst, associated mainly with retention of molybdenum, must then be solved.[131]

The study of the kinetics and mechanism of the oxidative dehydrogenation of isobutyraldehyde[131,135,136] on the Sb_2O_3 and MoO_3 catalysts by a pulsed method showed that the aldehyde reacts with the catalyst oxygen, forming methacrolein. The catalyst surface is then reduced. The methacrolein molecule is also adsorbed and, when oxygen is passed over the system, the latter is oxidised by gaseous oxygen to side products. The catalyst surface is reoxidised.[135]

The influence of the alternate changes in the composition of the gases entering the reactor on the selectivity of the oxidative dehydrogenation of isobutyraldehyde (IBA) over the heteropolyacid catalyst $H_5Mo_{10}V_2PO_{40}$ has been investigated. The alternation of two gas streams—IBA/N_2 and O_2/N_2 (for the reoxidation of the catalyst)—ensures the conversion of isobutyraldehyde into methacrolein with a greater selectivity than for the continuous supply of oxygen under comparable conditions.[137]

6. Synthesis of acrolein from allyl alcohol and its ethers and esters

Acrolein and methacrolein can be readily obtained by the vapour-phase oxidation of allyl alcohol, allyl acetate, and methylallyl acetate over a heterogeneous catalyst containing Pd with added Cu or Ag and Au at 150–200 °C.[138–140]

$$CH_2{=}CH{-}CH_2OH + 0.5O_2 \longrightarrow CH_2{=}CH{-}CHO + H_2O.$$

Methacrolein, suitable for oxidation to the acid without further purification, has also been obtained in a high yield by oxidising 2-methylallyl alcohol in the presence of the $A_aFe_bBi_eX_dMo_eO_f$ catalyst, where A = Co and/or Ni and X = Li, Na, K, Rb, Cs, or Tl.[141] However, this reaction, to which numerous studies have been devoted, has not found extensive application.[142]

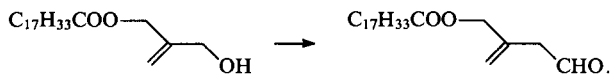
The mechanism of the oxidation of allyl alcohol on MoO_3, $Bi_2O_3 \cdot nMoO_3$ (n = 1, 3), and multicomponent molybdenum-bismuth oxide[15] and silver[142] catalysts has been investigated. In the last case, the π-allyl intermediate, of the kind observed in the case of the oxide catalyst, is not observed, and the process should be regarded as oxidative dehydrogenation.

Much more attention has been devoted to the liquid-phase oxidation of allyl alcohol with the aid of special oxidants. Thus, by oxidising it in an aqueous acid medium by divalent silver ions at 20 °C, it is possible to obtain acrolein in 70% yield.[143] Oxidation of allyl alcohol by palladium chloride in aqueous solution at 25 °C leads to the formation of acrolein and α-hydroxyacetone in 30% and 15% yields respectively.[144] The use of deuteriated derivatives in this reaction showed that the reaction mechanism includes a stage involving the transfer of a hydride ion from the carbon atom linked to the hydroxyl.

A convenient method of synthesis of acrolein (and some of its derivatives) is based on the oxidation of allyl alcohol (and its γ-substituted derivatives) with chromic acid adsorbed on silica gel.[145]

$$RR^1C{=}CHCH_2OH \xrightarrow{H_2CrO_4/SiO_2,\ CCl_4} RR^1C{=}CHCHO; \quad (70\%-80\%)$$

R = R^1 = H; R = H, R^1 = Me; R = H, R^1 = Cl.



In the laboratory, acrolein can be obtained by oxidising alkyl allyl ethers with atmospheric oxygen in the presence of palladium chloride at 50–60 °C.[146] It has been demonstrated by the EPR method that an intermediate allyl radical is formed in this reaction.

$$CH_2{=}CH{-}CH_2{-}OR \xrightarrow[-RO^{\bullet}]{PdCl_2} CH_2{=}CH{-}CH_2^{\bullet} \xrightarrow{0.5\,O_2} CH_2{=}CH{-}CHO;$$

R = Me, Et, Bu^t, $C(C_2H_5)_3$.

The electrochemical oxidation of allyl alcohol to acrolein in a water–acetonitrile mixture is possible. By maintaining a potential difference of 2.3–2.6 V, it has been possible to attain a yield of acrolein of 30%.[147]

The oxidation of the α-substituted allyl alcohol **1** with manganese dioxide in hexane leads to the corresponding methacrolein **2** derivative in 60% yield.[148]

1 **2**

It has been found possible to obtain α-(4-methylcyclohexyl)acrolein in yields up to 50% by oxidising the corresponding α-substituted allyl alcohol **3** with lead tetraacetate in a non-polar solvent.[149]

$$CH_2{=}CR{-}CH_2OH \xrightarrow{80\,^{\circ}C} CH_2{=}CR{-}CHO;$$

3

R = 4-MeC_6H_{10}.

Highly effective oxidation of the allyl alcohols **4** to the corresponding aldehydes **5** has been achieved in the presence of the bis(η^5-cyclopentadienyl)zirconium(IV) complexes Cp_2ZrH and $Cp_2Zr(OPr^i)_2$ (the Oppenauer reaction).[150,151] The reaction is carried out in boiling toluene in the presence of 0.02 molar equivalent of the catalyst and an equimolar amount of benzaldehyde or benzophenone[15] as hydrogen acceptors (A). The yields of α,β-unsaturated products are 75%–95%.

$$R^1R^2C{=}CR^3CH_2OH + A \xrightarrow[\text{boiling toluene, 8 h}]{\text{Cat.}} R^1R^2C{=}CR^3CHO + AH_2$$

4 **5**

7. The aldol-crotonic condensation of formaldehyde with aliphatic aldehydes

The vapour-phase catalytic condensation of acetaldehyde with formaldehyde was the main industrial method of synthesis of acrolein in 1940–1960.[5,8]

$$H_2CO + CH_3CHO \xrightarrow{SiO_2} CH_2{=}CHCHO + H_2O.$$

In this process, formaldehyde (in the form of a 30% aqueous solution) and acetaldehyde, in proportions of 1 : 1 or 2 : 1, are passed over silica gel impregnated with NaOH,[152] Na_2SiO_3,[153] Li_2CO_3,[154] or KOH[155] at 260–320 °C. The yields of acrolein are 75%–90%.[8,156] Other catalysts have also been proposed: TiO_2,[155] Al_2O_3/SiO_2 mixtures in various proportions including catalysts impregnated with HF solution,[157,158] Ni, Mn, Fe, and V phosphates,[159] and a cation-containing diatomite.[160] CsOH proved to be the most active catalyst.[161]

Acetone, propionaldehyde, and ethyl methyl ketone are side products of the process considered.[157,162] The factorial experimental design method can be used to optimise the technological process involving the condensation of CH_2O with CH_3CHO.[163]

The study of the catalytic reactions of mixtures of formaldehyde with ethanol on metal phosphates and W, Zn, Ni, and Mg oxides deposited on silica gel at 240–320 °C[164] led to the conclusion that ethanol is dehydrogenated to acetaldehyde under these conditions.

Instead of acetaldehyde, its homologues can react with formaldehyde. This results in the formation of α-alkyl-substituted α,β-unsaturated aldehydes in 88%–94% yields.[165–167]

$$H_2CO + RCH_2CHO \xrightarrow{180-500\,^{\circ}C} CH_2{=}CRCHO + H_2O;$$

R = H, Me, Et.

The molar ratio H_2CO : RCH_2CHO ranges from 6.8 : 0.7 to 1 : 20. The catalysts may be phosphorus and vanadium pentoxides,[168] borosilicate molecular sieves on the Al_2O_3 carrier,[165] and even unmodified silica gel (its impregnation with KOH or alkali metal carbonates lowers the yield of α,β-unsaturated aldehydes).[166,169]

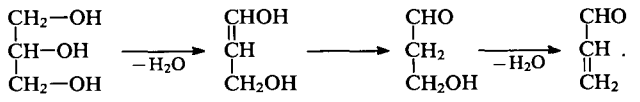
8. Condensation of formaldehyde with aldehydes in the presence of amines

Systematic study of the condensation of formaldehyde with aldehydes in an aqueous medium in the presence of an equimolar amount of an amine (preferably a secondary amine) salts made it possible to develop a method of synthesis of α,β-unsaturated aldehydes in nearly quantitative yields.[5] The hydrochloride of the Mannich base is an intermediate of this reaction:

$$RCH_2CHO + CH_2O + R'_2NH\cdot HCl \xrightarrow[-H_2O]{40-120\,^{\circ}C} [RCH(CHO)CH_2NR'_2\cdot HCl] \xrightarrow[90\%-99\%]{} RC(CHO){=}CH_2 + R'_2NH\cdot HCl;$$

R = Me, Et, Pr^i.

This process was developed up to the technical application stage.[170,171] Later this method was used to synthesise higher α-alkylacroleins.[172–179]



A convenient and economical version of the above procedure for the synthesis of α,β-unsaturated aldehydes involves the condensation of CH_2O with RCHO in the presence of only catalytic amounts of a secondary ammonium salt (10.3 and even 0.05 mol.%).[170,180–182]

Judging from patent data, the duration of the syntheses of α-alkylacroleins under the conditions of the Mannich reaction can be greatly reduced by carrying out the interaction between the reagents above 150 °C under pressure.[183]

9. Catalytic vapour-phase thermolysis of glycerol, 3-alkoxypropanal, and 3-acetoxypropanal

The method of synthesis of acrolein by the dehydration of glycerol, preferably in the presence of $KHSO_4$ or other acid catalysts, which was developed as early as the past century, is nowadays recognised as uneconomical. Furthermore, it proved cheaper to synthesise glycerol from acrolein.[10] However, the inevitable return to the renewable nature sources of organic raw materials in connection with the exhaustion of the resources of petroleum and gas will apparently again draw attention to the use of glycerol and then possibly also of biomass as sources of acrolein.[184,185] The replacement of $KHSO_4$ as the catalyst of the thermal dehydration of glycerol by phosphoric acid made it possible to obtain acrolein at 250 °C in 95% yield.[186]

The thermal conversion of glycerol into acrolein in 'supercritical' water, which has unusual properties, has been investigated recently.[184,185] At 360 °C under a pressure of 335 atm and in the presence of $NaHSO_4$, glycerol is converted into acrolein and acetaldehyde. The yield of acrolein reaches 70% and its formation is represented by the following scheme:

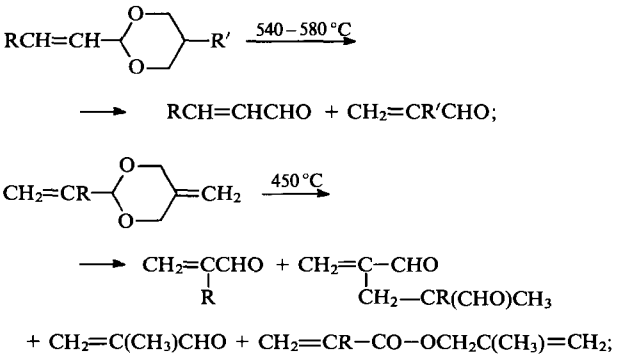
A method of synthesis of acrolein in yields up to 87% by the catalytic vapour-phase thermolysis of 3-alkoxypropanals, which are side products in the synthesis of acrylates, has been patented.[187,188] This reaction is catalysed by Al, Cu, Ca, Mn, Fe, Co, and Zn sulfates or their mixtures.

$$ROCH_2CH_2CHO \xrightarrow{250\,^\circ C} CH_2{=}CH{-}CHO + ROH.$$

Methacrolein has been obtained by the catalytic decomposition of 3-acetoxy-2-methylpropanol in the presence of tertiary amines, aluminosilicates, or zeolites.[189]

10. Thermolysis of unsaturated ethers, acetals, acylals, and other oxygen-containing compounds

The thermolysis of diallyl and allyl methylallyl ethers leads to the formation of the corresponding aldehydes together with other decomposition products.[190]



$$CH_2{=}CRCH_2OCH_2CH{=}CH_2 \xrightarrow{430-560\,^\circ C} CH_2{=}CRCHO + CH_3CH{=}CH_2.$$

When R = H, the yield is 88%, whereas for R = Me it is 28%. α,β-Unsaturated aldehydes are also obtained on thermal decomposition of diallyl acetals of alkenals.[191-193]

$$RCH{=}CR^1CH(OCH_2CR^2{=}CH_2)_2 \xrightarrow{360-420\,^\circ C} CH_2{=}CR^2CHO + RCH{=}CR^1CHO + CH_2{=}CR^2CH_2CR^1(CH_2R)CHO + RCH{=}CR^1{-}CO{-}OCH_2{-}CR^2{=}CH_2;$$

R = H, Me; R^1 = H, Me, $(CH_2)_2CN$; R^2 = H, Me.

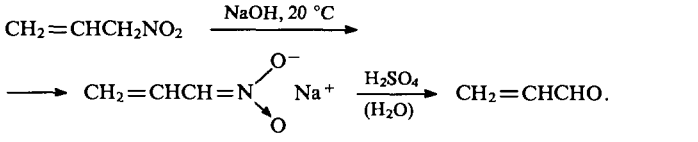
The thermolysis of 2-(1-alkenyl)-5-alkyl-1,3-dioxanes[191] and 2-(2-alkenyl)-5-methylene-1,3-dioxanes leads to α,β-unsaturated aldehydes.[193,194]

R = H, Me.

Acrolein is formed together with acetic anhydride in the catalytic thermolysis of 3,3-diacetoxypropene (and also 1,3-diacetoxypropane) in the presence of palladium or zinc halides.[195] The conversion and selectivity reach 98%.

$$CH_2{=}CHCH(OCOMe)_2 \xrightarrow{100-150\,^\circ C} CH_2{=}CHCHO + O(COMe)_2.$$

Acrolein and methacrolein can also be obtained in low yields (5%–30%) by the thermolysis of many oxygen-containing organic compounds. Thus, for example, dihydropyran decomposes preferentially to acrolein and ethylene over activated charcoal, platinised charcoal, or quartz.[196]

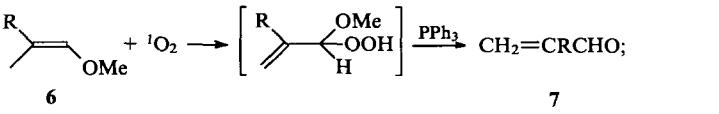


The thermal decomposition of formylcyclobutane also leads to the formation of acrolein and ethylene.[197]

Small amounts of acrolein and methacrolein (up to 10%) are produced on thermal decomposition of acrylates,[198] glucose,[199] allyl and methylallyl benzoates,[200] and diorganyl(2-propenyl)-*N*-oxides[201] and also on joint thermolysis of methanol with 1,2-dichloropropane.[202]

11. Other methods of synthesis

A novel method of synthesis of acrolein from 3-nitropropene is based on the Nef reaction.[203,204]

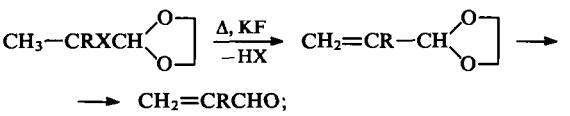


Acrolein is formed on photochemical oxidation of allyltrimethylsilane in the presence of palladium(II) salts.[205]

$$CH_2{=}CHCH_2SiMe_3 \xrightarrow{Pd^{2+},\ h\nu,\ O_2} CH_2{=}CHCHO.$$

The photochemical reaction of allene and ozone at 12 K leads to the formation of acrolein together with cyclopropane.[206]

The photochemical oxidation of the (*E*)-forms of the methyl ethers of corresponding enols **6** in the presence of triphenylphosphine made it possible to obtain α-cyclopropyl- and α-benzyl-acroleins **7** in 75%–90% yield. The addition of singlet oxygen in the (*Z*)-forms of the same ethers leads to a mixture of hydroperoxides, which are converted on treatment with PPh_3 not only into the α,β-unsaturated aldehydes mentioned above but also to their isomers cyclo-PrHC=CMeCHO and PhCH=CMeCHO.[207,208]



R = $(CH_2)_2CH-$, $PhCH_2-$.

The synthesis of α,β-unsaturated aldehydes by the dehydrohalogenation of the corresponding saturated aldehydes[209] was improved by using tetramethylammonium dimethyl phosphate as the hydrogen halide acceptor. The use of this reagent makes it possible to obtain methacrolein and its β-alkyl substituted derivatives.[210]

$$(CH_3)_2C(X)CHO \xrightarrow[-HX]{} CH_2=C(CH_3)CHO;$$

X = Br, Cl.

Acrolein and its α-organyl substituted derivatives can be obtained by dehalogenating 2-(1-haloorganyl)-1,3-dioxolans.[211]

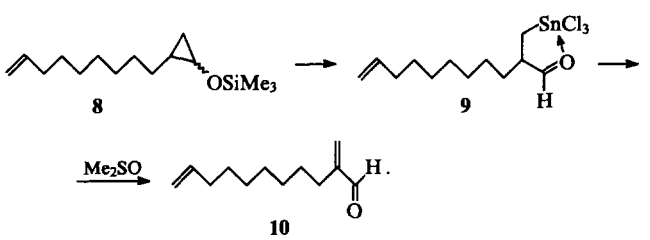
$$\longrightarrow CH_2=CRCHO;$$

R = H, Me, Ph; X = Cl, Br.

Propargyl alcohol isomerises to acrolein over Mo, W, and Re oxides deposited on silica gel.[215-217] The yields of acrolein reach 70%–90%.

$$HC\equiv C-CH_2OH \xrightarrow[10-15\ mmHg]{300-400\ ^\circ C} CH_2=CHCHO.$$

The hydroformylation of acetylene catalysed by a mixture of $Co_2(CO)_8$ with polyvinylpyridine also leads to the formation of acrolein.[218]



$$HC\equiv CH + CO + H_2 \longrightarrow CH_2=CHCHO.$$

Acrolein can be obtained in 81%–91% yield by the reaction of vinylacetic or crotonic anhydride with pyridine *N*-oxide.[219]

$$(H_2C=CHCH_2CO)_2O + 2C_5H_5N\rightarrow O \xrightarrow{140\ ^\circ C}$$

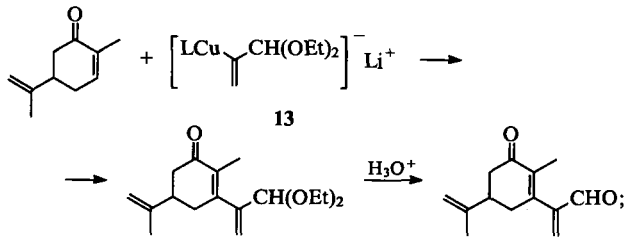
$$\longrightarrow CH_2=CHCHO + CH_2=CHCH_2COOH + 2C_5H_5N + CO_2.$$

The reaction of 1-(8-nonenyl)-2-(trimethylsiloxy)cyclopropane **8** with $SnCl_4$ in CH_2Cl_2 leads to 2-trichlorostannylmethylundecan-10-al **9**. Treatment with dimethyl sulfoxide in hexane converts it into α-(8-nonen-1-yl)acrolein **10**.[220]

8 **9**

10

It has been suggested that α-alkylacroleins be obtained by the reaction of substituted enamines **11** with phenylselenyl chloride and subsequent oxidative elimination of α-phenylselenoaldehyde **12** by treatment with *m*-chlorobenzoic acid or sodium periodate.[221]

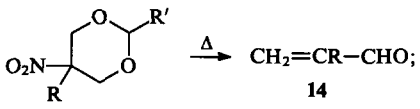


$$CH_3CR=CH-NC_5H_{10} \xrightarrow{PhSeCl} CH_3-CR(SePh)CHO \longrightarrow$$

11 **12**

$$\longrightarrow CH_2=CR-CHO;$$

R =  -Me.



It is recommended that 3,3-diethoxyisopropenylcuprates **13**, which are carriers of the carbonyl functional group in a latent form, be used as synthons which make it possible to introduce the acrolein fragment into an organic molecule.[222,223] Their condensation with cycloalkenones and subsequent hydrolysis of the acetal formed permit the quantitative synthesis of acrolein derivatives containing a complex substituent in the α-position.

13

L = PhS–, $CH_2=\overset{|}{C}-CH(OEt)_2$.

Thermolysis[224] of 5-alkyl-5-nitro-1,3-dioxanes at 390 °C or their interaction with polyphosphoric acid at 160 °C in the presence of copper powder[225] leads to the formation of α-alkylacroleins **14.**

14

R = Me, Et; R′ = H, Pr^i.

It has been suggested that acrolein be stored and transported in the form of linear or cyclic acetals $CH_2=CHCH(OR')OR''$, where R′ and R″ are C_{1-6} alkyls or R′ + R″ are cycloalkyls $(CH_2)_{2-6}$. It can be regenerated quantitatively from these products by hydrolysis in the presence of perfluorinated ion-exchange resin.[226]

The synthesis of acrolein by the 'alcohol–aldehyde' exchange reaction catalysed by the microbial aldehyde dismutase from *Pseudomonas putida* has been described recently.[227] An equimolar mixture of allyl alcohol and isobutyraldehyde is converted into acrolein and isobutyl alcohol to the extent of 69% at 30 °C in 1 h:

$$CH_2=CHCH_2OH + Pr^iCHO \longrightarrow$$

$$\longrightarrow CH_2=CHCHO + Pr^iCH_2OH.$$

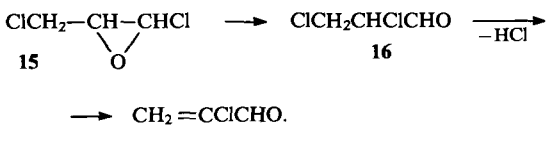
The microorganism *Coryne bacterium*, which transforms glycerol into acrolein, has been isolated from sugar cane.[228] It is suggested that the odour which sometimes appears in rum is due to the vital activity of this microorganism.

III. Methods of synthesis of α,β-unsaturated aldehydes α-substituted by functional groups

1. α-Haloacroleins

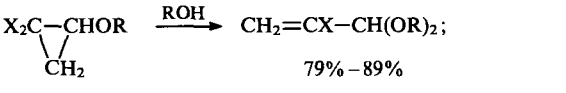
An effective method of synthesis of 2-chloropropenal is based on the dehydrochlorination of 2,3-dichloropropenal, which is obtained in its turn by chlorinating acrolein.

$$CH_2=CHCHO + Cl_2 \longrightarrow ClCH_2CHClCHO \longrightarrow$$



$$\longrightarrow CH_2=CClCHO.$$

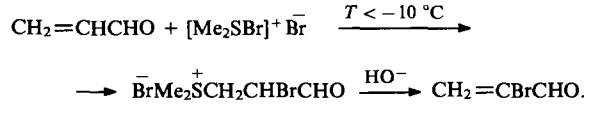
Hydrogen chloride may be eliminated by a thermal method involving the passage of a mixture of acrolein vapour, chlorine, and nitrogen through a quartz tube at 75–200 °C. The maximum yield of α-chloroacrolein (91%) is obtained for the acrolein : chlorine ratio = 1 : 1.7 and for a contact time of 3 s.[229,230]



The liquid-phase dehydrochlorination of 2,3-dichloropropanal at 0–5 °C [231,232] or 20 °C [233,234] is more widely used. Diethylaniline is usually employed as the HCl acceptor. The yield of α-chloroacrolein reaches 80%.

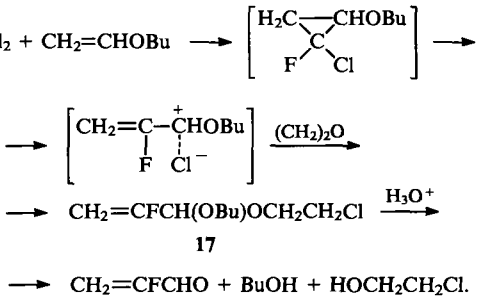
α-Bromoacrolein is obtained by a similar procedure: by brominating acrolein and subsequent dehydrobromination of 2,3-dibromopropanal.[233,235,236] The yield of α-bromoacrolein is appreciably lower (45%–68%).

1,3-Dichloro-1,2-epoxypropane **15** is converted at 200 °C into α-chloroacrolein in 23% yield.[237] The isomerisation of 1,3-dichloro-1,2-epoxypropane to 2,3-dichloropropanal **16** and the subsequent dehydrochlorination of the latter to α-chloroacrolein in aqueous tetrahydrofuran in the presence of a phosphate buffer occur already at 37 °C.[238]



The ethanolysis of 2-alkoxy-1,1-dihalocyclopropanes in the presence of bases (K_2CO_3, NaOR) is widely used to obtain the acetals of 2-halopropenals.[239–241] The subsequent hydrolysis of the acetal makes it possible to obtain pure α-haloacrolein.[240]

X = Cl, Br, F; R = Et, Bu.

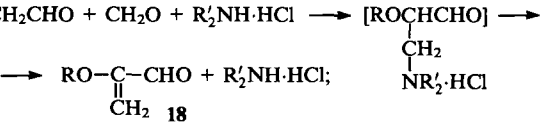


The interaction of bromodimethylsulfonium bromide with acrolein constitutes an elegant and simple method of synthesis of α-bromoacrolein in a satisfactory yield:[242]

Account must be taken of the fact that α-chloro- and α-bromo-acroleins are powerful direct-action mutagens.[243,244] The latter was identified in the organism as the metabolite of certain domestic preparations, for example the fumigant 1,2-dibromo-3-chloropropane and the fire extinguishing agent tris(2,3-dibromopropyl)phosphate.[243,245]

Traces of α-acrolein are formed on chlorination of humic acids.[246] It has been suggested that this induces a mutagenic activity in chlorinated drinking water. α-Chloroacrolein is also obtained by treating 2-chloroallyl alcohol with dehydrogenase.[247] It is also formed when the carcinogenic herbicide *S*-2,3-dichloroallyl diisopropylthiocarbamate (diallate) is treated with liver microsomal monoxygenase of *m*-chloroperbenzoic acid.[231,248,249] The photochemical decomposition of diallate also leads to α-acrolein.[250]

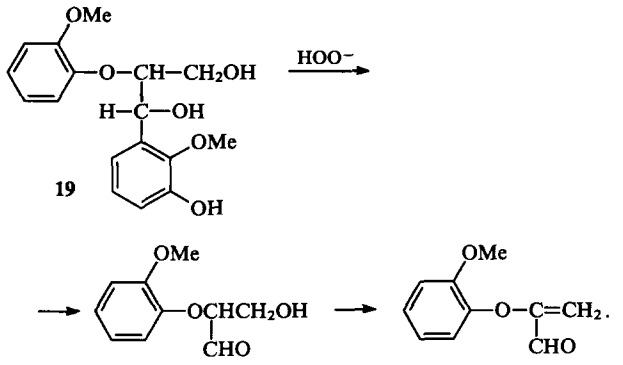
Like other α-haloacroleins, α-fluoroacrolein was first obtained by opening the ring in 2-alkoxy-1,1-difluorocyclopropanes.[239] A modified version of this method constitutes a continuous process proceeding in a single reactor (autoclave) and involves the formation of chlorofluorocarbene *in situ*.[251] For this purpose, a mixture of dichlorofluoromethane, butyl vinyl ether, epoxyethane, and tetraethylammonium bromide is heated at 150 °C.



The resulting acetal **17** is hydrolysed with 5% H_2SO_4, which leads to the formation of α-fluoroacrolein (yield 41%). This lachrymatory substance polymerises rapidly during storage (in the absence of hydroquinone) and explodes during combustion when it is subjected to elemental analysis. When an attempt is made to synthesise more than one mole of α-fluoroacrolein, the pressure in the autoclave suddenly rises sharply from 20 to 300 atm, which makes this method too dangerous.[252] It has therefore been suggested that α-fluoroacrolein be synthesised in two stages using the mild phase transfer catalytic conditions.[252–255] The yield reaches 53% relative to the initial butyl vinyl ether. This method may be used on a large scale (for the synthesis of up to 200 moles of α-fluoroacrolein).

3-Alkyl-2-halo-2-alkenals can also be readily obtained by converting the corresponding enol ethers into cyclopropane derivatives under the conditions of phase transfer catalysis[256,257] or in the presence of potassium butoxide[258] with subsequent stereoselective opening of the ring in the cyclopropanes produced.

2. α-Organyloxy- and α-acetoxy-acroleins



α-Alkoxy- and α-phenoxy-acroleins were first obtained by the aminomethylation of the corresponding organyloxyacetaldehydes followed by the decomposition of the hydrochloride of the Mannich base.[259–262]

Under optimum conditions (equivalent reactant proportions) at 60 °C, pH 7–7.1, 1.5–2 h), the yields of acroleins reach 66%–78%.

R = Me (**a**), Et (**b**), Pr (**c**), Bu (**d**), Ph (**e**), 2-$MeOC_6H_4$ (**f**), $PhCH_2$ (**g**).

This convenient method of synthesis of α-alkoxy-(phenoxy)acroleins using the Mannich reaction was subsequently used frequently.[263–267] For example α-guaiacoxyacrolein was obtained by this procedure from 2-(2′-methoxyphenoxy)-acetaldehyde and formaldehyde.[267] This acrolein derivative is also an intermediate in the oxidation of guaiacylglyceryl β-guaiacyl ether **19**—the most common structural fragment of lignin—in the technical peroxide bleaching process.[267,268]

Like aryloxyacroleins, α-benzyloxyacrolein **18g** can be obtained by the aminomethylation of benzyloxyethanal.[265]

2-Phenoxybutenal is formed from the diethyl acetal of 3-ethoxy-2-phenoxybutanal as a result of acid hydrolysis accompanied by the elimination of ethanol.[269]

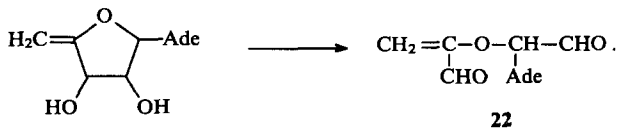
$$MeCH(OEt)-CH(OPh)-CH(OEt)_2 \xrightarrow{H_3O^+} MeCH=C(OPh)-CHO.$$

However this procedure is unsuitable for the synthesis of α-ethoxycrotonaldehyde apparently owing to the hydrolytic instability of this compound in an acid medium.

2-Methoxypropenal was synthesised in 69% yield by the β-elimination of methanol from 2,3-dimethoxypropanal in an alkaline medium.[270,271]

$$MeOCH_2CH(OMe)CHO \xrightarrow{25\,^\circ C,\ pH\ 12} CH_2=C(OMe)CHO + MeOH.$$

69%



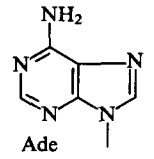
We shall now consider the kinetics and the proposed mechanism of this reaction.[272] α-Alkoxyacroleins **21** with functional group substituents are obtained from 2-alkoxy-3-vinylthiopropanols **20** by the mild Swern oxidation followed by the elimination of ethylenethiol.[273]

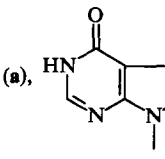
$$CH_2=CHSCH_2CH(OR)CH_2OH \xrightarrow[2.\ Et_3N\ (10\ equiv.)]{1.\ DMSO/ClCOCOCl/-78\,^\circ C} CH_2=C(OR)CHO$$

20 → **21**

R = $O(CH_2)_2OCH_3$, $CH=CH_2$, $\overline{CH_2OCH}$, $(CH_2)_3Br$, $(CH_2)_3N_3$.

Certain α-organyloxyacroleins containing an organic moiety with a functional group substituent play a definite role in biochemical reactions. They include the α-organyloxy-α,β-unsaturated aldehyde **22** – the first representative of the group of the so called nucleoside dialdehydes. It was obtained by the periodate oxidation of 9-(5-deoxy-*b*-D-*erythro*-pent-4-enofuranosyl)adenine.[274]

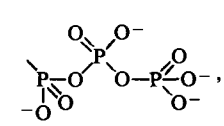


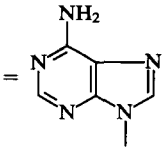


22

Purine-containing α-organyloxyacroleins **24a, b** are readily formed on heating the nucleoside dialdehydes **23a, b** to 100 °C.[275]

$$HOCH_2CH(CHO)OCHRCHO \xrightarrow[H_2O(EtOH)]{100\,^\circ C,\ 1\ h} CH_2=C(CHO)OCHRCHO;$$





23 → **24**

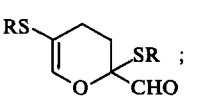
R =  (a),  (b), —OMe (c).

This reaction was first observed in enzymic studies involving adenosinedeaminase. The purine ring does not play a significant role in the process described and elimination takes place readily also in the case of the aldehyde **23c**, which have been confirmed by UV spectroscopic data. The adenosine triphosphate oxidised by periodate (*o*-ATP) at 20 °C and pH 7 slowly gives rise to the adenosine-containing β,β-dihydroxyethoxyacrolein **25** as a result of the β-elimination of the triphosphate group.[276]

$$ROCH_2CH(CHO)OCH(CHO)-Ade \xrightarrow{Na_2B_2O_7} CH_2=C(CHO)O-CH(Ade)-CH(OH)_2;$$

ortho-ATP → **25**

R =  , Ade =  .

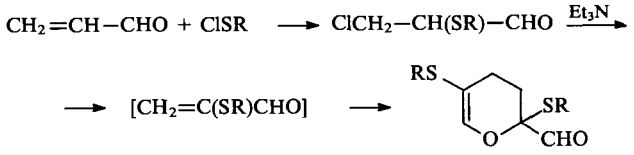


α-Acetoxyacrolein has been synthesised by acetylating the diethyl acetal of acetoxymercuriomethylglyoxal.[277] The reaction is accompanied by the formation of a number of side products, the principal of which is the hemiacylal of acetoxymethylglyoxal.

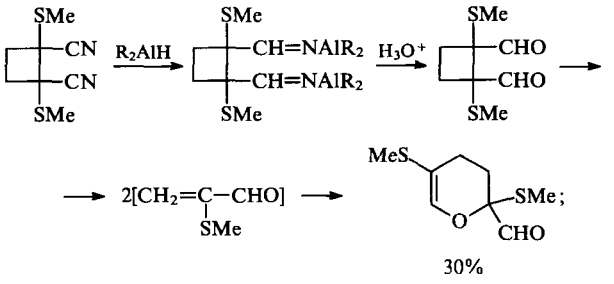
$$AcOHgCH_2COCH(OEt)_2 + CH_3COCl \longrightarrow [CH_2=C(OAc)CH(OEt)_2] \xrightarrow{Ac_2O} CH_2=C(OAc)CHO.$$

3. α-Organylthio- and α-organylseleno-acroleins

The attempts to obtain α-organylthioacroleins by the Mannich reaction (by analogy with α-alkoxyacroleins) led to the isolation of their cyclic dimers — 2,5-dialkylthio-2-formyl-2,3-dihydro-4*H*-pyrans (yield 31% – 61%).[278-280]



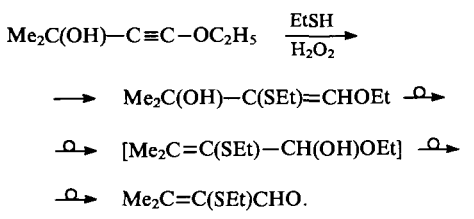
$$RSCH_2CHO + CH_2O + R^1_2NH\cdot HCl \longrightarrow RSCH(CHO)CH_2NR^1_2\cdot HCl \longrightarrow [CH_2=C(SR)CHO] \longrightarrow$$



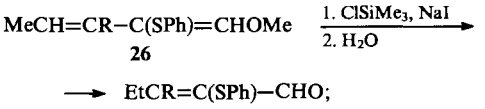
R = Me, Et, Pr, Bu, Bu^i, Pe^t, C_6H_{13}; R^1 = Et, Me.

The study of this process by the ^1H NMR method at 6 – 10 °C made it possible to observe the intermediate formation of the monomeric α-alkylthioacrolein.[281]

The extreme instability of α-alkylthioacroleins has been confirmed when an attempt was made to obtain them by the reaction of alkanesulfenyl chlorides with acrolein.[282] The labile alkylthiochloropropanals formed afford only the dimers of α-alkylthioacroleins in approximately 50% yield on dehydrochlorination with triethylamine at −15 °C.



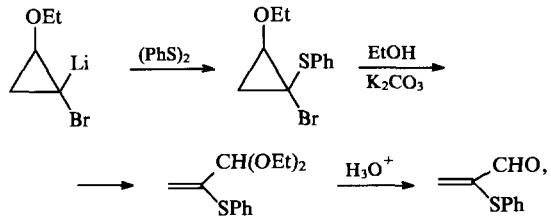
A cyclic dimer of α-methylthioacrolein has been obtained from 1,2-bis(methylthio)-1,2-dicyanocyclobutane.[283]



R = Bu^i.

In contrast to α-alkylthioacroleins, their β-alkyl derivatives exist in a monomeric form. Thus α-ethylthio-β,β-dimethylacrolein has been obtained from ethoxyethynyldimethylcarbinol by carrying out consecutive reactions involving thiylation, rearrangement, and elimination of the alcohol in accordance with the following scheme:[284]

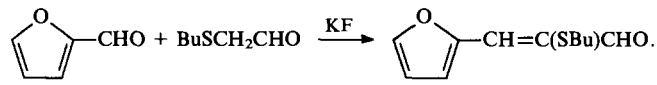
The specially synthesised dienes **26** have been used to synthesise β-alkyl-α-phenylthioacroleins.[285]



R = H, Me.

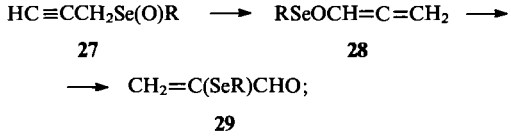
The synthesis of 2-phenylthio-2-alkenals in 65% yield by the dehydrochlorination of α-chloro-α-phenylthioaldehydes has also been described.[286]

The possibility of obtaining α-phenylthioacrolein by treating 1-bromo-2-ethoxycyclopropyllithium with diphenyl disulfide with subsequent transformation of the reaction product via the scheme



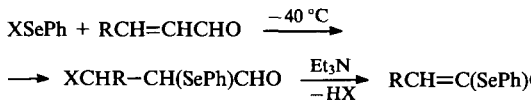
which is universal for the synthesis of 2-substituted alkenals, has been reported.[240]

The *ipso*-substitution of the halogen in vinyl halides activated by a geminal aldehyde group can also be used to synthesise β-alkyl-α-organylthioacroleins.[287,288]



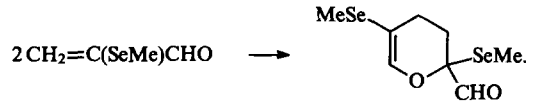
R = Bu, Ph.

The use of the aldol-crotonic condensation of butylthioacetaldehyde with furfural in the presence of KF with added tetraethoxysilane made it possible to obtain 2-butylthio-3-(2′-furyl)propenal in 60% yield.[289]

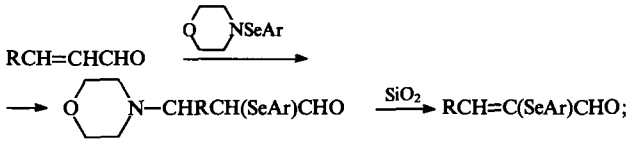


The formation of the α-phenylselenoacrolein **29a**, which is unstable at room temperature, was observed for the first time on isomerisation of phenylpropargyl selenoxide **27a** in methylene chloride at −31 °C.[290–292]

R = Ph (**a**), *m*-$F_3CC_6H_4$ (**b**), *o*-$O_2NC_6H_4$ (**c**).



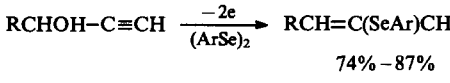
The trifluoromethyl analogue **27b** rearranges 1.6 times faster than the selenoxide **27a**. In both cases, the intermediate reaction product was not detected. The existence of the intermediate **28c** with the allenol structure, formed on isomerisation of 2-nitrophenylpropargyl selenoxide **27c**, has been demonstrated by ^{1}H NMR and IR spectroscopy and mass spectrometry. The allene **28c** was identified at −45 °C. Above −10 °C, it rearranges to the aldehyde **29c**.



R = H (**a**), Me (**b**); X = Br, Cl.

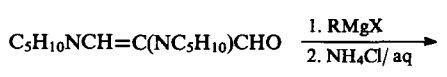
Later α-phenylselenoalkenals were obtained in 68% yield by the haloselenation of the corresponding unsaturated aldehydes and subsequent elimination of hydrogen halides with triethylamine.[293,294]

In contrast to the unstable phenylselenoacrolein **29a**, its homologue **29b** can be vacuum-distilled. In order to obtain α-methylselenoacrolein in accordance with a scheme similar to that presented above, the dehydrohalogenation stage was carried out at −40 °C, but the expected aldehyde cyclodimerised fully and very rapidly (in 20 min at 20 °C). It was characterised only by the NMR method.[294,295]



N-Arylselenomorpholines are effective α-selenating agents for α,β-unsaturated aldehydes.[296,297]

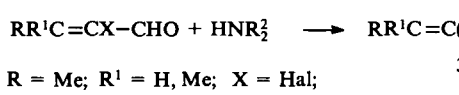
R = H, Me, Pr, MeCH=CH, Ph;
Ar = Ph, 4-ClC_6H_4.



A single-stage method of synthesis of α-arylseleno-α,β-unsaturated aldehydes is based on the electrochemical oxidation of 3-hydroxyalkynes in the presence of diaryl diselenides.[298,299]

R = Me, Et, Pe, Ph.

4. α-Dialkylaminoacroleins and their homologues

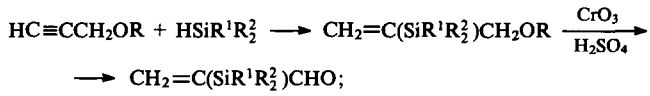


β-Alkyl-α-piperidinoacroleins were first synthesised by treating β-dialkylamino-α-piperidinoacroleins with Grignard reagents.[300]

R = Me, Et, Pr, Bu.

Although the yields of the final products are fairly high (60%−80%), the initial diaminoacroleins can be obtained in only 10%−30% yield by formylating the corresponding diaminoethylenes.

Subsequently the reaction involving the *ipso*-substitution of the halogen atom in 2-halo-2-alkenals was used to synthesise 2-dialkylamino-2-alkenals.[301-304] The interaction takes place even at room temperature and the substitution products **30** are formed as a mixture of (*E*)- and (*Z*)-isomers.



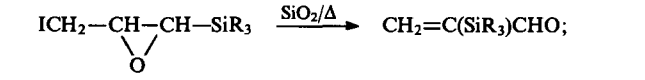
30

R = Me; R^1 = H, Me; X = Hal;

NR_2^2 = 

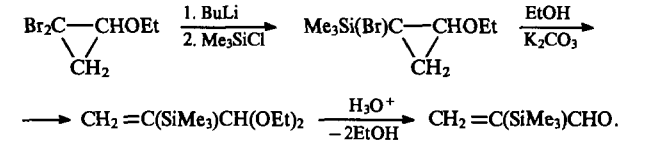
5. Organosilicon derivatives of acrolein

α-Trialkylsilylacroleins (in a mixture with the β-isomers) are formed when the product of the hydrosilylation of propargyl alcohol or its trimethylsilyl ether by trialkylsilanes is oxidised by chromium trioxide.[305,306]

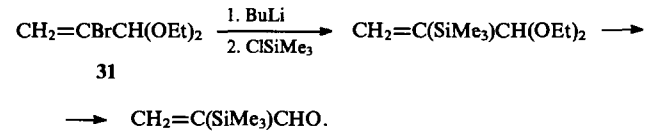


R = H, $SiMe_3$; R^1, R^2 = Me, Et.

A mixture of α- and β-triethylsilylacroleins is also formed on hydrosilylation of propynal,[307] the yields of the α- and β-adducts being 28% and 26% respectively.

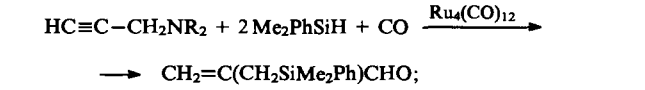


α-Triisopropylsilylacrolein is formed in a low yield from 2-iodomethyl-3-triisopropylsilyloxiran together with 3-iodo-2-triisopropylsilylpropanal.[308]



R = Pr^i.

α-Trimethylsilylacrolein has been synthesised in 80% yield from 1,1-dibromo-2-ethoxycyclopropane in accordance with the following scheme: [240,309]



The most convenient method of synthesis of α-trimethylsilylacrolein is based on the reaction of 2-bromo-3,3-diethoxypropene **31** with butyllithium and subsequent interaction with chlorotrimethylsilane.[310] The removal of the acetal protecting group in an acid aqueous acetone solution leads to the formation of α-trimethylsilylacrolein from the initial acetal **31** in 73% yield.

α-Trimethylsilylmethacrolein has been obtained by oxidising α-trimethylsilyl methylallyl alcohol with oxalyl chloride in dimethyl sulfoxide (DMSO) [311] (cf. also Trost and Grese [312]).

2-Dimethylphenylsilylmethylpropen-2-al has been synthesised in a yield up to 94% by the reaction of diorganylpropargylamines with a twofold excess of dimethylphenylsilane and carbon monoxide in the presence of ruthenium carbonyl.[313]

R = Me, CH_2Ph.

α-(*tert*-Butyldimethylsiloxymethyl)acrolein **32** has been synthesised from acrolein, the latter part of the synthesis being[314]

$$CH_2{=}CBrCH(OEt)_2 \xrightarrow[2.\ H_2CO]{1.\ BuLi} CH_2{=}C(CH_2OH)CH(OEt)_2 \longrightarrow$$

72%

$$\xrightarrow[2.\ (COOH)_2]{1.\ ClSiMe_2(Bu^i)} CH_2{=}C(CH_2OSiMe_2Bu^i)CHO.$$

32 (87%)

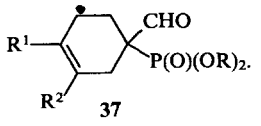
The reaction of methylglyoxal with chlorotrimethylsilane in the presence of triethylamine leads to α-trimethylsiloxyacrolein.[315]

$$CH_3COCHO + Me_3SiCl \xrightarrow[-HCl]{Et_3N} CH_2{=}C(OSiMe_3)CHO.$$

6. Dialkylphosphonoacroleins

α-Dialkylphosphonoacroleins **36** have been synthesised by hydrolysing a mixture of the corresponding organophosphorus derivatives **33**–**35**, obtained in their turn by phosphorylating alkyl allyl ether with phosphorus pentachloride.[316] The unstable individual α-phosphorylated acroleins **36** were not isolated and were identified as products of the diene synthesis **37**.

$$(RO)_2P(O)C(=CHOR)CH_2OR + (RO)_2P(O)CH(CH_2OR)CH(OR)_2$$



33 **34**

$$+ (RO)_2P(O)C(=CH_2)CH(OR)_2 \xrightarrow{H_3O^+}$$

35

$$\longrightarrow [(RO)_2P(O)C(=CH_2)CHO] \xrightarrow{CH_2=CR^1-CR^2=CH_2}$$

36

$$\longrightarrow$$ 

37

7. Oxygen and sulfur derivatives of α-alkylacroleins

Hydrolysis of the diethyl acetal of 3-hydroxy-2-hydroxymethylpropanal leads to the formation of the free aldehyde **38**, which is readily hydrated in the presence of bases to α-hydroxymethylacrolein **39**.[317]

$$(HOCH_2)_2CHCH(OEt)_2 \xrightarrow[-2\,EtOH]{H_3O^+} (HOCH_2)_2CHCHO \longrightarrow$$

38

$$\longrightarrow CH_2{=}C(CH_2OH)CHO.$$

39

An elegant method of synthesis of α-hydroxyalkylacroleins **42** is based on the condensation of the organolithium derivative of the diethylacetal of α-bromoacrolein **40** with various aldehydes at a low temperature. The subsequent cautious removal of the acetal protecting group in the acetals **41** leads to the formation of α-hydroxyalkylacroleins in 95% yield.[318]

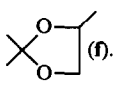
$$CH_2{=}CLiCH(OEt)_2 + RCHO \longrightarrow$$

40

$$\longrightarrow CH_2{=}C[CH(R)OH]CH(OEt)_2 \xrightarrow[H_2O]{H_2SO_4} CH_2{=}C[CH(R)OH]CHO;$$

41 **42**

R = Me, Et, Pe, Ph.



The single-stage alkylcarbonylation of 3,3-diethoxy-2-lithiopropene **40** with dimethylformamide or the dimethylamides of other carboxylic acids makes it possible to obtain α-diethoxymethylacrolein **43a** or the diethyl acetals of α-alkylcarbonylacroleins in 20%–70% yields.[319]

$$CH_2{=}CLiCH(OEt)_2 + RCONMe_2 \longrightarrow$$

40

$$\longrightarrow CH_2{=}C(COR){-}CH(OEt)_2;$$

43

R = H (**a**), Me (**b**), Bu^i (**c**), Pe (**d**), Ph (**e**),  (**f**).

Unfortunately the hydrolysis of the latter to the corresponding acroleins has not been achieved.

The reaction of 1-bromo-2-ethoxycyclopropyllithium **44** (the synthetic equivalent of 2-lithiopropenal) with heptanol leads to the intermediate **45**, the interaction of which with alcohol on heating in the presence of K_2CO_3 makes it possible to obtain the diethyl acetal of α-(1-hydroxy)heptylacrolein **46**. Hydrolysis of the latter leads to the corresponding aldehyde **47** (yield 77%).[240,309]

$$Li(Br)C{-}CHOEt + C_6H_{13}CH_2OH \longrightarrow X(Br)C{-}CHOEt \longrightarrow$$

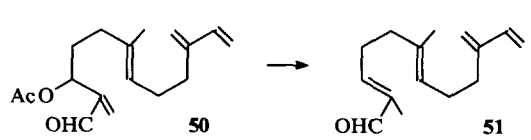
44 **45**

$$\xrightarrow[K_2CO_3]{EtOH} CH_2{=}CX{-}CH(OEt)_2 \longrightarrow CH_2{=}C(X)CHO;$$

46 **47**

X = $-CH(OH)C_6H_{13}$.

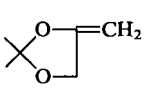
The aldehyde **49** was synthesised by acetylating the acetal **46** with subsequent hydrolysis of the resulting acetal **48**.



$$\mathbf{46} \xrightarrow[-AcOH]{Ac_2O} CH_2{=}C[CH(OAc)C_6H_{13}]CH(OEt)_2 \xrightarrow{H_3O^+}$$

48

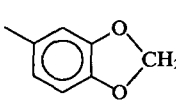
$$\longrightarrow CH_2{=}C[CH(OAc)C_6H_{13}]CHO.$$

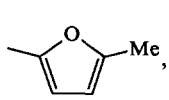


49

The method developed for the synthesis of α-substituted acroleins has been used to synthesise β-sinensal **51**, which determines the taste and smell of the oil of Chinese oranges.[309] The initial triene aldehyde **50** was obtained in the same way as the aldehyde **49**, from 4-methyl-8-methylenedecene-4,9-dienal:

50 **51**





Various α-hydroxyalkylacroleins **54** can be synthesised in 65%–77% yield by adding to aldehydes a nucleophile such as allenoxylithium **53** (equivalent of 2-lithiopropenal), obtained from 2,2-dimethyl-4-methylene-1,3-dioxolan **52**.[320]

 $\xrightarrow{Bu^tLi,\ -78\,^\circ C}$ $CH_2{=}C{=}CHOLi$ $\xrightarrow{RCHO}$

52 **53**

$$\longrightarrow CH_2{=}C(CHO)CH(OH)R;$$

54

R = C_6H_{13}, Ph,  ,  ,

—CHMeOCH$_2$OMe.

The reaction of α-(methoxymetoxyethyl)acrylonitrile with diiso-propylaluminium hydride in toluene leads to the formation of the corresponding α-substituted acrolein in 73% yield.[321]

$$CH_2{=}CR{-}CN \xrightarrow{HAlR^1_2} CH_2{=}CR{-}CH{=}NAlR^1_2 \xrightarrow{5\%\ H_2SO_4} CH_2{=}CR{-}CHO;$$

R = $CH_2CH_2OCH_2OCH_3$; $R^1 = Pr^i$.

α-Carboxyacrolein has been obtained from the diethyl acetal of α-bromoacrolein by successive treatment with butyllithium, carbon dioxide, and water.[322]

$$CH_2{=}CBrCH(OEt)_2 \xrightarrow{BuLi} CH_2{=}CLiCH(OEt)_2 \xrightarrow[2.\ H_2O]{1.\ CO_2} CH_2{=}C(COOH)CHO.$$

The β-alkylthioacetals **55** are converted into the enals **56** on treatment with formalin and dimethylamine hydrochloride.[179, 323]

$$RSCH_2CH(OEt)_2 + CH_2O \xrightarrow[-H_2O]{Me_2NH\cdot HCl} CH_2{=}C(CH_2SR)CHO;$$

55 **56**

R = Et, Ph.

Thiols as synthons

I V Koval'

Contents

I. Introduction	769
II. The structure and physicochemical properties of thiols	769
III. Methods for preparing thiols	770
IV. Preparations based on thiols	773

Abstract. The results of recent research in the field of thiol chemistry are arranged systematically and summarised. The structure and physicochemical properties of thiols and their methods of preparation are described and their use as synthons in the preparation of various sulfur-containing compounds is discussed. The bibliography comprises 419 references.

I. Introduction

Thiols play a very important part in living organisms and they are also used in many areas of science and technology. Glutathione and cysteine are known[1] to form part of proteins that are involved in biochemical reactions that take place by an oxidation-reduction scheme, and to bind free radicals. Dihydrolipoic acid takes part in the processes of photosynthesis[2] and metabolism in mitochondria[3] and also in other biochemical reactions.[4] A number of thiols have found applications as pharmaceutical preparations,[5] accelerants of the vulcanisation of rubber,[6,7] polymer stabilisers,[8] and additives to rocket fuels.[9,10] However the most important field of application of thiols is fine-organic synthesis. The lability of S–H and C–S bonds, their ability to undergo fission under the action of both nucleophilic and electrophilic reagents, and the presence of an active reaction centre with sulfur of variable valence all make thiols valuable synthons that are widely applicable in fine-organic synthesis.

The interest being shown in thiols by many investigators has in due course resulted in the appearance of a number of reviews,[4,11–19] which to some or other extent reflect particular aspects of the chemistry of thiols; however many experimental data have been accumulated since the publication of these reviews and these data need futher summarising.

II. The structure and physicochemical properties of thiols

The S–H and C–S bonds in thiols have fairly high dissociation energies but these bonds are not so strong as the O–H and C–O in the oxygen analogues of thiols, i.e. alcohols.

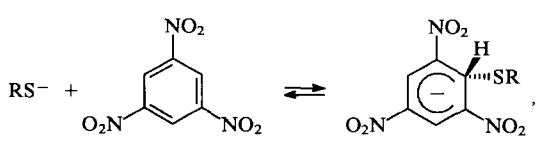
Received 4 January 1993
Uspekhi Khimii **62** (8) 813 – 830 (1993); translated by G J Bullen

The structure of the alkyl groups bonded to the sulfur atom in the alkanethiols has almost no effect on the strength of the S–H and C–S bonds; the strength of these bonds is greatly influenced by conjugation of the *p* electrons of the sulfur atom with the π electrons of the system (*p*,π-conjugation).[20,21]

As the electronegativity of the sulfur atom (2.6) is lower than that of the oxygen atom (3.5) thiols have a considerably smaller tendency than alcohols to form hydrogen bonds, as is confirmed by the IR and ^{1}H NMR spectroscopy.[22] This lower tendency to hydrogen-bond formation is responsible for the greater volatility of thiols as compared to alcohols (the boiling points of alkane thiols are 40 – 60 °C lower than the boiling points of the corresponding alcohols) and also the lower solubility of thiols in water. Thiols are stronger acids than alcohols,[23–27] the S–H bond being more polar than the O–H bond owing to the increased *s* character of the central atom.

Aromatic thiols have a higher acidity than aliphatic thiols owing to the increased polarity of the S–H bond due to *p*, π-conjugation.

The complexes of thiols with shift-reagents[28,29] are less stable than in the case of alcohols, as is shown by the much smaller values of the induced shifts of the resonance signals of the protons in the SH groups as compared to the corresponding values for the protons in OH groups.



Thiols have a smaller proton affinity than alcohols. The rate of transfer of a proton to thiols in their reaction with trifluoromethanesulfonic acid is several orders of magnitude (10^4–10^5) smaller than the rate of the same reaction for alcohols,[30] as is consistent with the hard-soft-acid-base principle.[31]

$$RSH + CF_3SO_3H \rightleftharpoons \overset{+}{R}SH_2 + CF_3SO_3^-$$

Thiolate anions are weaker bases than alkoxide anions. If the basicity of thiolate anions is judged on the basis of the protonic scale of acidity, using the equilibria

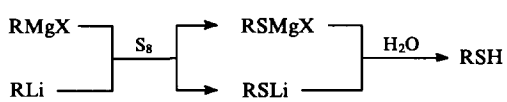
$$RS^- + H^+ \rightleftharpoons RSH; \qquad RO^- + H^+ \rightleftharpoons ROH,$$

the following order of basicities is obtained: $MeO^- > EtS^- > PhO^- > PhS^-$.[4] However, with respect to CH-acids, on the basis of the equilibrium

the order obtained is: $EtS^- > MeO^- > PhS^- > PhO^-$.[32,33]

With respect to CH-acids the thiophenolate anion is a weaker base than the hydroxide anion by a factor of 10^3; this is due to the smaller degree of solvation of thiolate anions as compared to the hydroxide ion.[34] However, thiolate anions are more nucleophilic than either alkoxide anions or the hydroxide anion.

The greater the nucleophilicity of the less basic thiolate anion as compared to the corresponding alkoxide anion may be attributed to the greater polarisability of the sulfur atom as compared to the oxygen atom and also to the transition state in reactions involving a thiolate anion (in the stabilisation of which the *d* orbitals of the sulfur atom are involved) being energetically more favourable. However, one cannot discount the fact that in a protonic solvent oxygen will form a stable hydrogen bond, with the result that it becomes less nucleophilic.

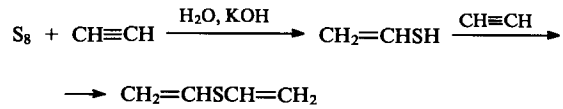


Photolysis, radiolysis, and thermolysis of thiols, and also the action of peroxides and diazo-compounds on them, lead to the production of thiyl radicals.[19] The nature and structure of the groups on the sulfur atom of the thiol have a considerable effect on the enthalpy of formation of the thiyl radicals. For example, arylthiyl radicals have higher enthalpies of formation than alkylthiyl radicals; for the phenylthiyl radical the value is 56.8 ± 2.0 kcal mol^{-1}.[35] The enthalpy of formation of alkylthiyl radicals decreases as the alkyl chain becomes longer and more branched: from 31 kcal mol^{-1} for the methylthiyl radical to 15 kcal mol^{-1} for the butylthiyl and 11 kcal mol^{-1} for the *tert*-butylthiyl radicals.[19] Thiyl radicals have higher electron affinities than oxyl radicals owing to the presence of vacant *d* orbitals on the sulfur atom. Their energy of stabilisation is significantly lower than that of oxyl radicals. For example, Macki[35] quoted 9.6 and 17.5 kcal mol^{-1} respectively for the energies of stabilisation of the phenylthiyl and phenoxyl radicals. The MNDO method has been used to calculate the molecular and electronic structures of the MeS$^{\bullet}$ and EtS$^{\bullet}$ radicals, which have C_s symmetry.[36]

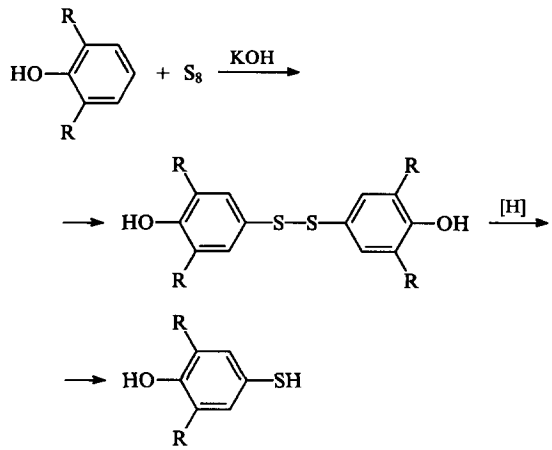
S–H stretches occur in the IR spectra in the 2560 to 2592 cm^{-1} region for alkanethiols and in the 2538–2568 cm^{-1} region for thiols of the aromatic series.[37,38] In the NMR spectra of thiols the signal from the proton of the mercapto-group occurs as a singlet at 1.5–3.5 p.p.m. (δ scale).[39,40] In cyclohexanethiols the mercapto-group occupies an equatorial position preferentially.[41,42] For methanethiol and its carbanion the effective charges on the atoms and the bond orders have been calculated by the CNDO/2 method.[43,44]

III. Methods for preparing thiols

1. Syntheses using elemental sulfur and its inorganic derivatives



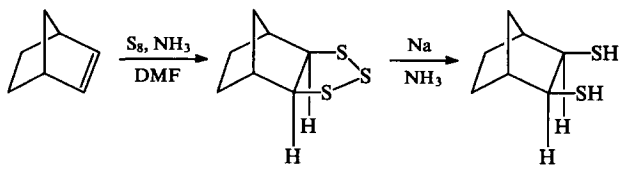
Reactions of elemental sulfur with aromatic hydrocarbons[12,45,46] and some heterocyclic compounds[47] have not been widely used in the synthesis of thiols. This is primarily due to the especially specific conditions for these reactions which are not always reasonable in practice in the laboratory. The reaction of elemental sulfur with organomagnesium and organolithium compounds[4,48,49] proved to be more promising in a preparative respect.



R = Alk, Ar, Het.

The relatively mild conditions for this reaction, and also the availability of the organomagnesium and organolithium compounds, enable a wide range of different thiols to be obtained.

In the reaction of elemental sulfur with acetylene, vinyl thiol is formed[50] and is then converted to divinyl sulfide.



Some reactions of elemental sulfur with organic compounds lead to the formation of disulfides and polysulfides which are readily reduced to the corresponding thiols, e.g. the reaction with dialkylphenols.[51,52]

R = Me, Et, Bu^t.

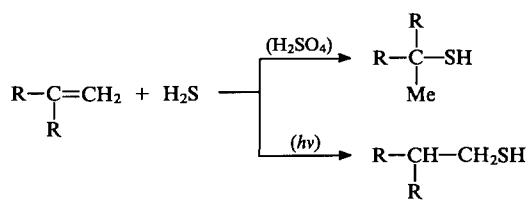
The addition of elemental sulfur to the double bond in norbornene[53] gives the corresponding trisulfide which can be reduced to the dithiol using sodium metal in liquid ammonia.

When mixed with sodium sulfide elemental sulfur also reacts with alkyl halides and highly reactive aryl halides to form polysulfides,[54] the reduction of which gives thiols.

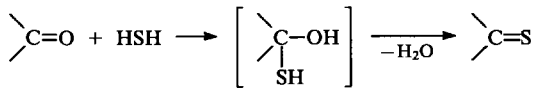
R = Alk, Ar, Het; x = 2–4.

Because of the availability of a wide range of different halide derivatives and also the ease of reduction of the polysulfides, this method is fairly promising in a preparative respect.

Of the inorganic sulfur derivatives the most widely used in the preparation of thiols is hydrogen sulfide. Several variants of thiol preparations based on hydrogen sulfide have been developed. One of these is based on substitution reactions in which halogens, hydroxyl, arenesulfonyl, and other good leaving groups are replaced by a mercapto-group.[55–60]

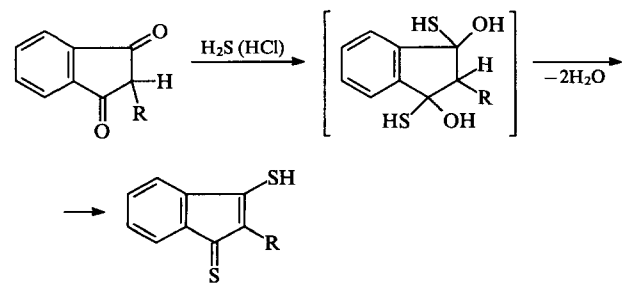


R = Alk, Ar, Het; X = Cl, Br, OTs, OH, NR_2.



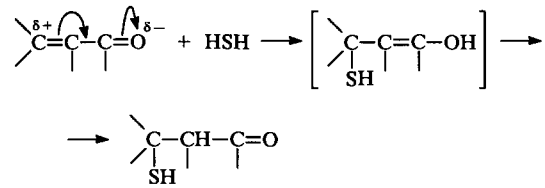
Replacement of a low-activity halogen atom by a mercapto-group in benzene[61-68] and thiophen[69] rings, and also in the vinyl chloride molecule,[70-72] will occur in the vapour phase under relatively severe conditions (400–700°C). In addition to the thiols, the corresponding sulfides and other products are formed, so hindering the isolation of the thiols. These methods therefore have no preparative importance.

The replacement of halogens by a mercapto-group can also be achieved by the action of alkali metal hydrosulfides[73-76] and other inorganic sulfur compounds[77-79] on the corresponding halogen derivatives. As a rule these reactions occur under relatively mild conditions and the wide range and availability of the initial reagents make these methods very valuable in a preparative respect. P_4S_{10} is sometimes used to replace a hydroxyl group by a mercapto-group (see Ref. 80).

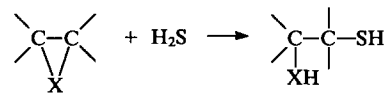


A second variant of thiol preparations based on hydrogen sulfide involves the addition of the latter to unsaturated C≡C, C=C, and C=O bonds. Using irradiation with X-rays, addition of hydrogen sulfide to substituted acetylenes takes place to form dithiols together with other products.[58] The addition of hydrogen sulfide to unsymmetrical ethylene hydrocarbons in the presence of catalysts (H_2SO_4, $AlCl_3$ etc.) takes place preferentially in accordance with Markovnikov's rule but under the action of UV-radiation or in the presence of peroxides the addition is anti-Markovnikov.[55,81-83]

Addition of hydrogen sulfide to the carbonyl group in aldehydes and ketones leads to the formation of 1-hydroxythiols[4] which are stable only if there are strong electron-acceptor groups on the carbonyl carbon atom.



When the molecule of the carbonyl compound contains a labile α-H-atom that can participate in the dehydration process the addition of hydrogen sulfide to the carbonyl group can occur with preservation of a mercapto-group. An example is the preparation of 3-mercaptoindene-1-thiones which are formed in an 85%–90% yield by treating the corresponding diketones with hydrogen sulfide in the presence of hydrogen chloride.[84,85]



R = H, Et, Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4.

In the presence of catalysts ($ZnCl_2$, HCl etc.) addition of hydrogen sulfide to α,β-unsaturated ketones takes place readily to form relatively stable 3-oxoalkanethiols.[86]

A third variant of the use of hydrogen sulfide in the preparation of thiols involves the opening of unstable rings in certain heterocyclic compounds by the action of hydrogen sulfide. Three-membered heterocyclic compounds, such as thiairans,[87] oxirans,[88] and aziridines[89-91] are used most frequently.

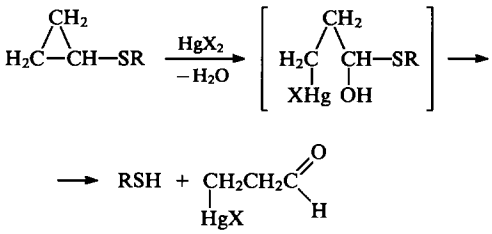
X = S, O, NH.

This method is very important for the preparation of multifunctional thiols containing such groups as NH_2, OH, SH, etc. in addition to the mercapto-group.

2. Alkylation (or arylation) of sulfur(II) compounds with subsequent breakdown of the products

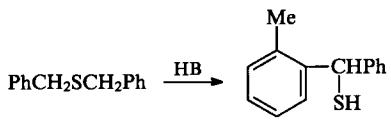
This method of preparing thiols, which is widely used in practice in the laboratory, is based on forming a C–S bond and then converting the products to thiols. Formation of a C–S bond by means of nucleophilic substitution of a halogen can occur in the reaction of the corresponding alkyl and aryl halides with derivatives of thiocarbonic acid, thiourea, thiocarbamates, dithiocarbamates, xanthogenates, thiophosphonates, and thiosulfonates.[4,77,92,93] These methods are valuable in that the intermediate compounds are readily hydrolysed to thiols; this is very advantageous in a preparative respect and the method is often used in the laboratory to obtain very diverse thiols.

Alcohols in the presence of HBr and dialkyl sulfates are also used for the alkylation of thiourea.[77] Arylation of thiourea and xanthogenates can also be accomplished using diazonium salts.[77]



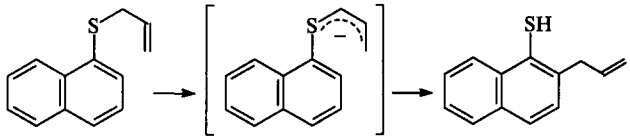
3. Cleavage of sulfides

Although cleavage of a C–S bond occurs more readily than that of a C–C bond or an unactivated C–H bond, the reductive cleavage of sulfides has not been widely used in the preparation of thiols with the exception of special cases. In these cases, as a rule, use is made of sulfides in which there is a distinct tendency to the preferential cleavage of only one of the two C–S bonds, i.e. unsymmetrical sulfides with groups such as allyl, benzyl, nitrile etc. on the sulfur atom.[4]



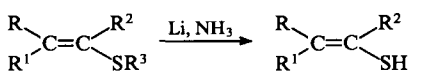
R′ = $ArCH_2$, $CH_2{=}CH{-}CH_2$, CN.

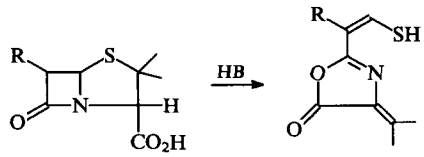
Reducing agents that have been used are lithium in ethylamine, sodium in liquid ammonia, Raney nickel in boiling ethanol, $NaBH_4$ in isopropanol, and also $LiAlH_4$.[94] Cleavage of cyclopropyl-alkyl or -aryl sulfides will take place in the presence of mercury halides or mercury acetate.[95]



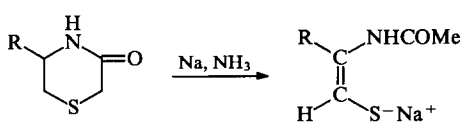
R = Alk, Ar; X = Cl, MeCOO.

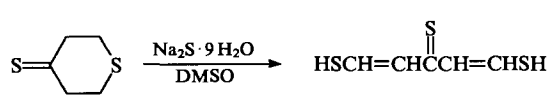
Cleavage of alkyl trichloromethyl sulfides[96] is carried out in the presence of hydrochloric acid and that of trifluoromethyl silyl sulfides[97] in the presence of hydrogen iodide. In certain instances reductive cleavage is accompanied by various rearrangements. For example, the cleavage of dibenzyl sulfide in the presence of bases is accompanied by a Sommelet rearrangement.[98]



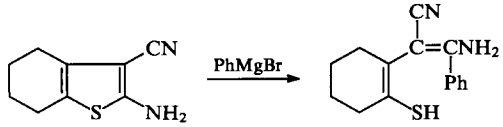


The cleavage of allyl naphthyl sulfides is accompanied by a (3,3)-sigmatropic rearrangement.[99]

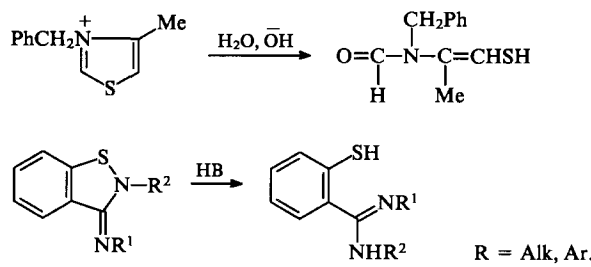




The cleavage of vinyl sulfides by lithium in liquid ammonia[100] provides a method for preparing enethiols, which are also formed by the cleavage of certain heterocyclic compounds.[101-106]



Other heterocyclic compounds, such as penicillin,[107] cyclic allyl sulfides,[108] and thiophene-2-carboxylic acids,[109] will also undergo reductive cleavage to form the corresponding thiols.



R = Alk, Ar.

4. Reduction of S-functions

The reduction of disulfides and sulfonyl chlorides is of primary importance in the preparation of thiols. The reduction of disulfides is used to prepare aliphatic, aromatic and heterocyclic thiols.

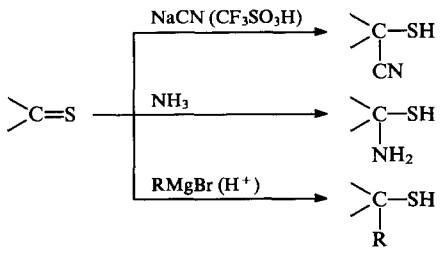
Reducing agents that have been used are zinc in acetic,[110] hydrochloric[111,112] and sulfuric[113] acids, sodium metal in xylene,[114] diethyl ether[115] and liquid ammonia,[116,117] lithium tetrahydroaluminate in ether or tetrahydrofuran,[118] sodium hydrosulfide in alcohol,[119,120] and formamidinesulfinic acid.[121] Triphenylphosphine and sodium hydroborate are also used for the reduction of some disulfides and polysulfides to thiols, and salicylic acid type reagents for the reduction of the disulfide grouping in proteins.[4]

The addition of sulfur monochloride to alkenes followed by reduction of the di-(2-chloroalkyl)disulfides is one of the methods of preparing 2-chloroalkanethiols.[121]

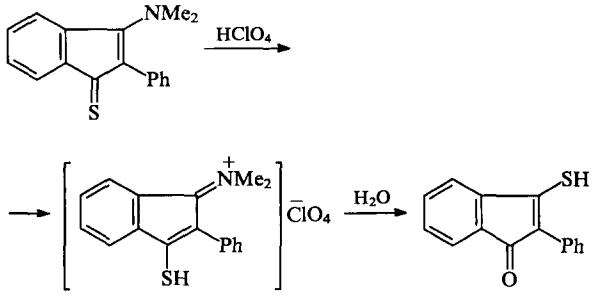
The reduction of sulfonyl chlorides is most often used to prepare aromatic[4,77] and heterocyclic[122] thiols but considerably less often for the preparation of aliphatic thiols.[77]

The reducing agents used are zinc dust in hydrochloric and sulfuric acids,[123-126] tin in hydrochloric acid,[127] tin dichloride,[128] iron powder,[129] aluminium amalgam,[130,131] alkali metal sulfides,[132] red phosphorus and iodine in acetic acid,[133] and lithium tetrahydroaluminate.[134] The last is sometimes used to reduce sulfonic acid to thiols.[135] In rare instances thiols have been prepared by the reduction of sulfinic acids with zinc in an acidic medium[136-138] and of dithiocarbamates with the complex $BH_3 \cdot SMe_2$ in toluene,[139] and also by the reductive cleavage of thiol sulfonates with zinc in an acidic medium.[4]

5. Preparation of thiols from thiones

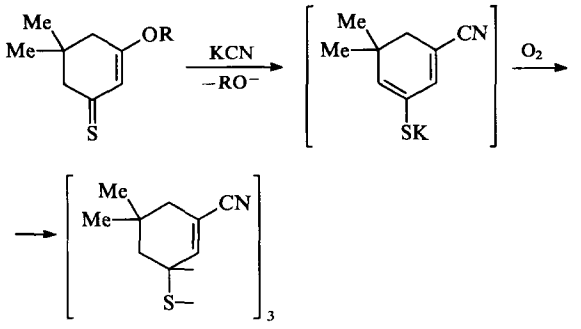


Several variants of thiol preparations based on thiones have been developed. One of these involves the conversion of the thiocarbonyl group to a mercapto-group by the reaction of thiones with butyllithium and also other organometallic compounds.[4,140]

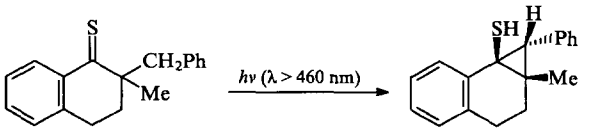


The reaction mixture contains other products as well as thiols, especially sulfides which are formed by the addition of the organometallic compounds at the C = S bond.

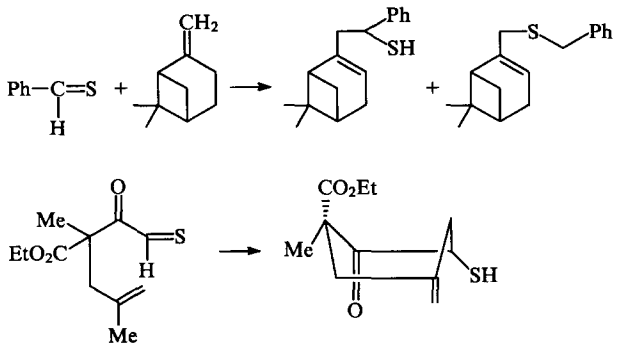
It is presumed[4] that the intermediate products in this reaction are dianions formed by the reaction of the thiones with the organometallic compounds. This hypothesis is confirmed to some extent by the fact that the dianion of thiobenzaldehyde is converted to the corresponding thiols and sulfides by reaction with electrophilic reagents.[141]



The corresponding thiols are also formed by the reaction of a thiocarbonyl group with hydrocyanic acid,[142,143] ammonia,[144] or Grignard reagents.[145]



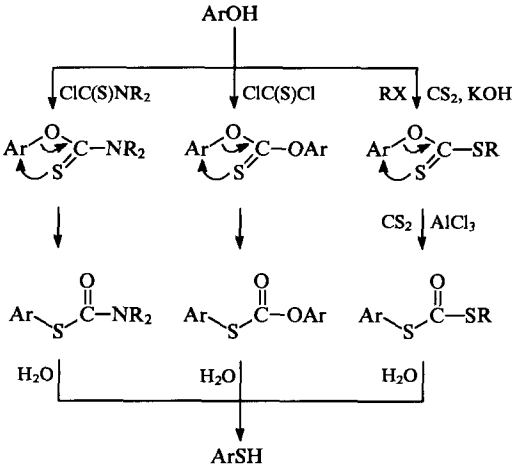
Participation of the thiocarbonyl group in a conjugated bond system facilitates its conversion to a mercapto-group. For example, 3-(*N*,*N*-dimethylamino)-2-phenylindene-1-thione is readily converted, in the presence of perchloric acid in acetone, to *N*,*N*-dimethyl-3-mercapto-2-phenylinden-1-iminium perchlorate which undergoes hydrolysis at the C=N bond to form 3-mercapto-2-phenylinden-1-one.[146]



3-Alkoxy-5,5-dimethylcyclohex-2-ene-1-thiones are readily converted, by reaction with potassium cyanide in methanol, to potassium 3-cyano-5,5-dimethylcyclohexa-2,6-diene-1-thiolate, which trimerises to a 1,3,5-trithiane.[147]

2-Benzyl-2-methyltetralin-1-thione is readily converted to an isomeric thiol by UV-irradiation.[148]

A thiocarbonyl group as a 2π-component can participate in an addition reaction to a C=C bond to form thiols.[149,150]



6. Other methods for preparing thiols

One of the methods for converting methyl aryl sulfides to thiophenols is exhaustive chlorination of the methyl group followed by methanolysis of the chlorination product.[151]

The Newman–Kwart rearrangement forms the basis of a method for converting phenols to thiophenols.[4]

The condensation of thiourea with various bifunctional compounds and also the reaction of carbon disulfide with amino- and hydroxyl-containing compounds are widely used in the preparation of heterocyclic thiols.[4,77,152–154]

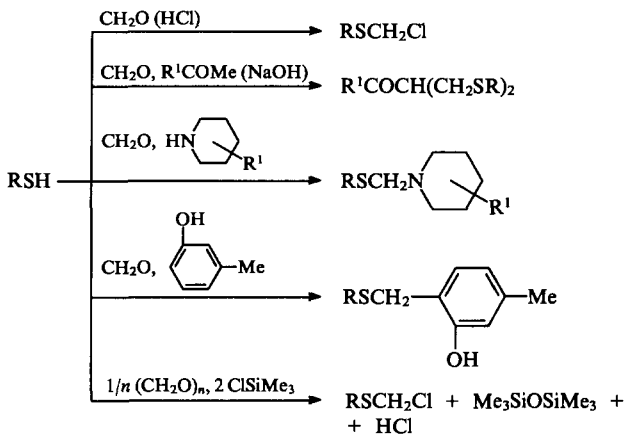
IV. Preparations based on thiols

1. Preparation of sulfur(II) compounds

a. Preparation of sulfides

Several methods have been developed for preparing sulfides from thiols.

Alkylation or arylation of thiols. Symmetrical and unsymmetrical sulfides are formed relatively easily by the reaction of thiols[77,155–159] and metal thiolates[160–171] with alkyl and aryl halides.



M = H, Na, K, Ag; X = Cl, Br, I;
R = Alk, Ar, Het; R^1 = Alk, Ar.

It is preferable to use alkyl bromides in these reactions because alkyl chlorides are not always sufficiently reactive and alkyl iodides may cause side reactions in which disulfides are formed.[4,77]

$$2RSH + R^1I \longrightarrow RSSR + R^1H + HI$$

The formation of disulfides is also observed when certain alkyl chlorides, especially diphenylchloromethane[172] and carbon tetrachloride,[173] are used. In certain instances the following can be used as alkylating agents: alcohols in the presence of mineral acids,[77,174,175] sodium alkoxides in the presence of phosphonium salts,[176] dialkyl sulfates,[4] dialkyl carbonates,[177,178] alkyl esters of phosphorus acid,[179] phosphoric acid,[180] nitric acid[181] and alkylsulfinic acids,[182] alkoxyformamidines,[183] methyl esters of phenols,[184] alkylamines[185] and diamines,[186] epoxy-[187,188] and thioepoxy-compounds,[4] ethyleneimines,[77] and pyridinium,[189] sulfonium,[190] iodonium[191] and diazonium[77] salts. For the preparation of sulfides containing a methylene group formaldehyde,[192-195] paraformaldehyde[196,197] and trioxane[198] are widely used in a variety of reactions.

The alkylation of thiols by alkyl halides with a normal structure usually takes place by an S_N2 mechanism in which the transition state is additionally stabilised by *d*-orbital resonance.[4]

The reaction of triphenylchloromethane with thiophenol in the presence of bronze filings takes place by a radical mechanism.[199]

$$Ph_3CCl \xrightarrow{\text{bronze}} Ph_3C^{\cdot} + Cl^{\cdot}$$

$$Ph_3C^{\cdot} + PhSH \longrightarrow Ph_3CH + PhS^{\cdot}$$

$$PhS^{\cdot} + Ph_3C^{\cdot} \longrightarrow PhSCPh_3$$

The reactions of perfluoroiodomethanes[200-208] and perfluorobromomethanes[209] with thiolates take place in ultraviolet light by an ion-radical mechanism $S_{RN}1$ (see Ref. 210).

$$RS^- + CF_3I \longrightarrow RS^{\cdot} + [CF_3I]^{\cdot -}$$

$$[CF_3I]^{\cdot -} \longrightarrow \dot{C}F_3 + I^-$$

$$RS^- + \dot{C}F_3 \longrightarrow [RS^{\cdot} + \bar{C}F_3] \longrightarrow [RSCF_3]^{\cdot -}$$

$$[RSCF_3]^{\cdot -} + CF_3I \longrightarrow RSCF_3 + [CF_3I]^{\cdot -}$$

It has been shown[211,212] that the ion-radical perfluoroalkylation reaction is of a general character and can be used with perfluoroalkyl iodides and bromides of any chain length and structure, and also with α,ω-di-iodoperfluoroalkanes.

The reaction of CF_2Br_2 with thiophenoxides takes place by a chain-type carbene mechanism.[213]

$$RS^- + BrCF_2Br \longrightarrow \bar{C}F_2Br + RSBr$$

$$\bar{C}F_2Br \longrightarrow :CF_2 + Br^-$$

$$:CF_2 + RS^- \longrightarrow RS\bar{C}F_2$$

$$RS\bar{C}F_2 + BrCF_2Br \longrightarrow RSCF_2Br + \bar{C}F_2Br$$

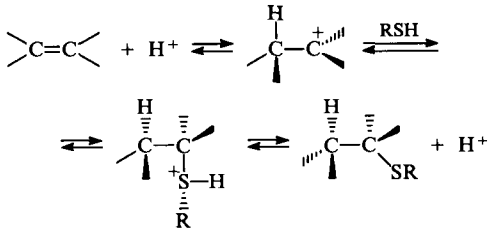
It has been shown[206,213] that in the reaction of CF_2BrCl and $PhSCF_2Br$ with thiolates two mechanisms, a carbene and an ion-radical mechanism, may coexist whereas the reaction of $ClCH_2CF_2Cl$, $BrCH_2CF_2Cl$, and $CHCl_2CF_2Cl$ with thiolates takes place via a stage in which hydrogen chloride is eliminated and addition of the thiolate anion to the difluoromethylene group of the halogeno-olefin occurs.[214] One cannot exclude the possibility that replacement of a halogen atom on an unsaturated carbon atom also takes place via a stage in which the hydrogen halide is eliminated.[215-218]

Thus the alkylation of thiols by alkyl halides may take place by different mechanisms, depending primarily on the structure of the initial alkyl halide and also the conditions under which the alkylation reaction is carried out; this has been discussed in detail in a monograph.[219]

The arylation of thiols (or thiolates) by aryl halides in which the halogen atom is activated by the presence of strong electron-acceptor groups in the *ortho* and *para* positions take place relatively easily by an S_N2ar mechanism, the *d* orbitals of the sulfur atom being involved in the stabilisation of the σ-complex.[4,77,220-222] Not only halogen atoms but also other atoms or groups (NO_2, H etc.) which are activated by strong electron-acceptor *ortho* and *para*-substituents can be replaced by an RS group.[34,223] Replacement of an unactivated halogen atom in an aromatic ring by an RS group will take place under relatively severe conditions,[224-232] presumably by an elimination-addition mechanism.[227] Arylation of the silver salt of trifluoromethanethiol can be accomplished using aryldiazonium salts.[228]

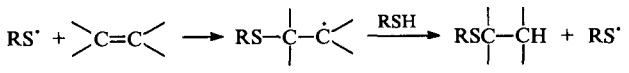
Thiylation of unsaturated compounds. Sulfides are formed relatively easily by the addition of thiols to unsaturated bonds (C=C, C=O, and C=N). The addition of thiols to compounds containing a C=C bond has been known for a long time and has been comparatively well studied.[4,11,12] Many of these reactions form the basis of methods for preparing sulfides.

Depending on the conditions, the addition of thiols to an ethylenic bond may occur by a nucleophilic, an electrophilic, or a radical mechanism. Nucleophilic addition of a thiol to an ethylenic bond usually takes place in an alkaline medium or in the presence of basic catalysts and the species attacking the sp^2-hybridised carbon atom are thiolate anions.



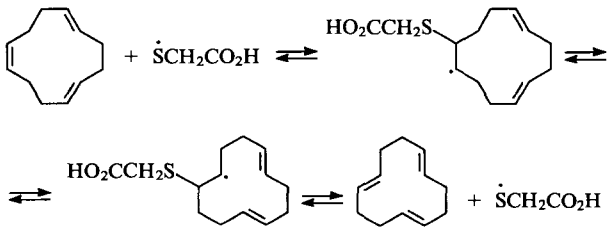
$$RSH + \bar{O}H \longrightarrow RS^- + HOH$$

$$RS^- + \rangle C{=}C\langle \longrightarrow RS{-}\overset{|}{C}{-}\overset{|}{\bar{C}}{-} \xrightarrow{HOH} RS{-}\overset{|}{C}{-}\overset{|}{C}H{-}$$



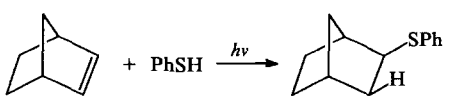
Nucleophilic addition of thiols to a polarised double bond will therefore take place readily if there are electronegative atoms or electron-acceptor groups present at the double bond. The thiyl fragment is attached to the electron-deficient carbon atom in the double bond which is usually in the β position (addition in accordance with Markovnikov's rule). There have been reports of the nucleophilic addition of thiols to acrolein,[77] vinylidene chloride[229,230] acrylonitrile,[231,232]

unsaturated carboxylic acids and their esters,[232–235] also other unsaturated carbonyl compounds,[235–239] unsaturated sulfones,[240,241] vinylpyridines,[242] vinylpyrroles,[243] and vinylpyrazoles.[244] The nucleophilic addition of thiols to maleinimides is used for the modification of thiol enzymes in studies of the interrelation of their structure and function.[4] For example, to determine the number of SH groups in proteins, and also to ascertain the reactivity of these groups, use is often made of the fluorescing agent *N*-(fluoranthen-3-yl)maleinimide, which combines with the protein by reacting with its SH groups.

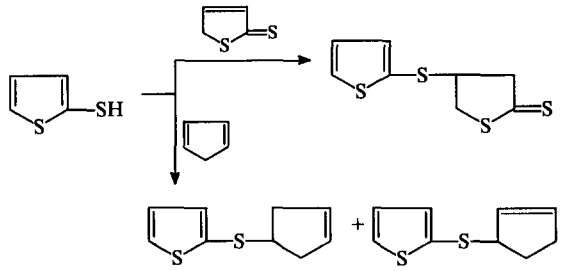


Electrophilic addition of thiols to a double bond[244,245] takes place in an acidic medium or in the presence of acidic catalysts (HCl, $AlCl_3$, SO_2Cl_2 etc.) via a stage in which a carbocation is formed.[12]

Anti-Markovnikov radical addition of thiols to a double bond takes place in the presence of peroxides or under the influence of ultraviolet light (photo-addition) and is often accompanied by isomerisation of the initial unsaturated compounds.[11,12,246]



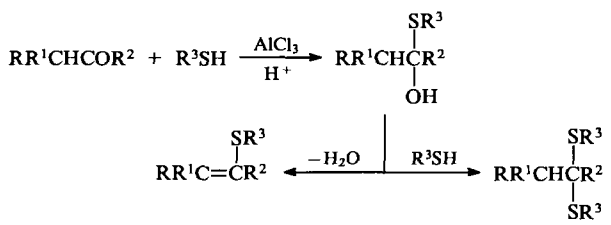
The involvement of thiyl radicals in the isomerisation of unsaturated compounds has been noted.[4] For example, in the presence of 1 equivalent of thioglycolic acid (*Z*, *E*, *E*)-cyclododeca-1,5,9-triene is readily converted to the corresponding (*E*, *E*, *E*)-isomer by an 'insertion–detachment' mechanism.[247]



On account of the unusual tendency of thiyl radicals to react preferentially with the (*Z*)-alkene grouping, this method of isomerisation has been used in organic syntheses, especially for the conversion of oleic acid to (*E*)-octadec-9-enoic acid which will take place in the presence of ethanethiol.[248]

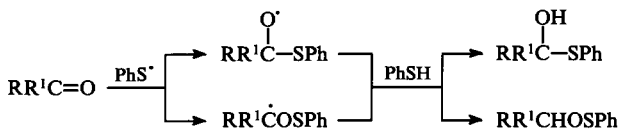
The photo-addition of thiols to a C=C bond usually gives products whose stereochemistry is dependent on the structure of the initial unsaturated compound. For example, in the photothiylation of norbornene an *exo-cis* adduct is formed.[4]

In view of the fact that thiyl radicals are easily obtained from thiols, e.g. by irradiation with light of wavelength 253.7 nm, it is likely that the autothiylation of thiophen-2-thiol[249,250] and the addition of the latter to cyclopentadiene[251] also take place by a radical addition mechanism.

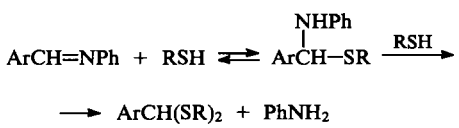


Unsaturated sulfides are also readily formed by the addition of thiols to acetylenic hydrocarbons.[4,11,12] The addition of thiols to a triple bond may take place by either a nucleophilic or a radical mechanism. Nucleophilic addition of thiols to an acetylenic bond takes place in an alkaline medium and, depending on the reaction conditions, the type of solvent, and also the structure of the reagents, it can give products with different steric structures. There have been reports of the nucleophilic addition of thiols to acetylene,[252,253] phenylacetylene,[254,255] alkoxyacetylenes,[256–258] acetylacetylenes,[259,269] acetylenecarboxylic acids and their derivatives,[261–263] diethoxyphosphonylacetylene,[264] alkylsulfonylacetylenes,[265] trialkylgermylacetylenes,[266] and diacetylenes.[267] The nucleophilic addition of thiols to alkylthioacetylenes,[12,268] occurs particularly easily due to the additional stabilisation of the intermediate carbanion involving the 3*d* orbitals on the sulfur atom.

Radical addition of thiols to a triple bond takes place on irradiation with ultraviolet light or in the presence of initiators of radical processes (peroxides, hydroperoxides, azo-compounds etc.) that facilitate the generation of thiyl radicals. The radical addition of thiols to acetylene[269,270] will occur under severe conditions but the addition of thiols to prop-2-yn-1-ol,[12] phenylacetylene,[12] ethoxyacetylene,[271] ethoxycarbonylacetylene,[271] acetylenecarboxylic acid,[271] 1-carboxy-2-ethylthioacetylene,[272] vinylacetylene,[273] trialkylsilylacetylene,[274,275] and 1-phenyl-2-trialkylsilylacetylene[276] takes place comparatively easily by a radical mechanism.



The addition of thiols to the C=O bond in carbonyl compounds in the presence of acidic catalysts produces unstable sulfides containing an α-hydroxyl group which can undergo dehydration to form unsaturated sulfides[277] or react with excess of the thiol to give thioacetals.[278,279] This method of obtaining thioacetals has been widely used in the laboratory for preparative purposes.



The addition of thiols to carbonyl compounds in the presence of trialkylchlorosilanes results in the formation of sulfides containing a trialkylsiloxy group in the α-position.[280]

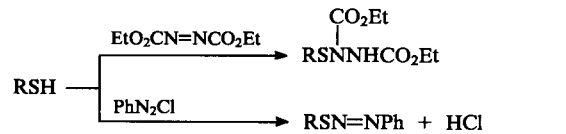
In the radical addition of thiols to the C=O bond in carbonyl compounds the thiyl radical may be attached to either the carbon or the oxygen atom of the carbonyl group.[281,282]

The addition of thiols to the C=N bond in imines results in the formation of α-aminosulfides which, in the presence of excess of the thiol, can also be converted to thioacetals;[283-287] this method is of preparative importance and is widely used in the laboratory.

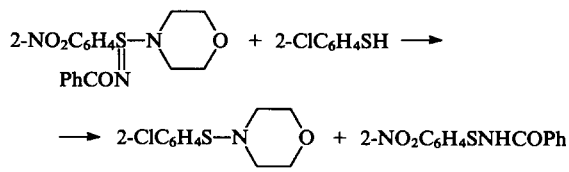
Condensation of thiols. The intermolecular condensation of thiols, which occurs at high temperatures or in the presence of catalysts, is sometimes used to obtain sulfides.

In the case of β-mercaptoanthraquinone condensation takes place with little heating[77] but with other aromatic thiols it occurs at higher temperatures.[224] By using such catalysts as cadmium or zinc sulfide, aluminium oxide[77] or aluminium trichloride[286,287] the temperature of this reaction can be reduced slightly.

b. Preparation of sulfenamides.



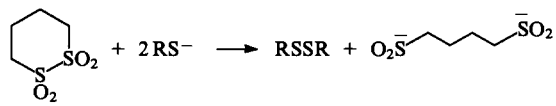
The amination of thiols by *N*-chloroamines,[288-290] *N*-chloroamides,[291] or *N*-chloroimides[292-294] is one of the methods of preparing sulfenamides that are either unsubstituted or substituted at the nitrogen atom.



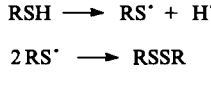
R = Alk, Ar, Het;

X = Na, H.

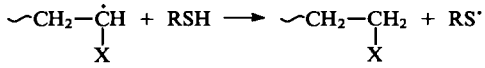
Rather more rarely aliphatic amines in the presence of oxidising agents,[290,295] the sodium salt of hydroxylaminosulfonic acid,[296] and derivatives of oxaziridine[297] have been used as aminating agents. Sulfenamides are also formed by the reaction of thiols with azo- and diazo-compounds[4] and with certain derivatives of iminosulfinic acids[298] but these methods have no preparative value.



c. Preparation of disulfides



The oxidation of thiols using various oxidising agents is one of the most common methods of preparing disulfides.[4]



A wide range of reagents can be used as oxidants, including oxygen,[299] hydrogen peroxide,[300] halogens and halogenating agents,[4,301-304] *N*-halogenoamines and *N*-halogenoamides,[4,305] iron trichloride,[77] 1,3-di-iodopropyne,[306] carbon tetrachloride,[307] and other organic and inorganic reagents. On account of the possible further oxidation of the disulfides the choice of a suitable oxidant is of considerable importance and is conditional on the ease of oxidation, which increases from tertiary to secondary and primary mercaptans and even more for thiophenols.[77] The oxidation of a mercapto-group to a disulfide group plays an important role in the formation of the tertiary structure of proteins and also in other biochemical processes. Flavins will anaerobically oxidise an excess of a thiol to a disulfide and are reduced to dihydroflavins.[308] The tetraoxide of 1,2-dithiane oxidises thiolate ions to the disulfide quantitatively.[309]

This reaction is presumed to occur in biological systems.[4] In the presence of pyridine the dimethyl ester of dithiobis(thioformic acid) oxidises thiols to disulfides in a quantitative yield.[310] Photolysis or radiolysis of thiols and sulfides gives thiyl radicals which form disulfides by recombination or reaction with the solvent molecules.[4,311,312]

Owing to the ease with which thiyl radicals are formed, thiols are used as radical interceptors in various processes such as radiation protection,[4] the stabilisation of polymeric materials,[8] and the control of chain growth in radical-chain reactions.[313] For example, dodecyl mercaptan is widely used in industry as a regulator of molecular mass.[314] The basis of this process is the reaction:

A whole series of methods for preparing both symmetrical and unsymmetrical disulfides is based on nucleophilic substitution involving thiols or thiolate anions and various sulfenyl derivatives such as sulfenyl halides,[315-327] sulfenyl thiocyanates,[4,77,328] sulfenamides,[329-333] symmetrical disulfides[334-336] and tri-sulfides,[337] thiosulfonates,[4,77] and Bunte salts.[4,77]

$$RSX + R^1SY \longrightarrow RSSR^1$$

R = Alk, Ar, Het; R^1 = Alk, Ar; X = H, Na, Ag;
Y = Cl, Br, NR^2, NHAr, N-phthalimido,
SR^2, SSR^2, SO_2Ar, SO_2Na, SCN.

In view of the extensive possibilities for varying R and R^1, some of these methods, especially the reaction of thiols with sulfenyl halides, have become irreplaceable for the synthesis of unsymmetrical disulfides.

The esters $RSSCO_2Me$, which are obtained by the reaction of thiols with methoxycarbonylsulfenyl chloride, readily react with thiols to form disulfides.

$$RSH + MeO_2CSCl \longrightarrow RSSCO_2Me \xrightarrow{R^1SH} RSSR^1 + HO\overset{\overset{S}{\|}}{C}OMe$$

The so-called cyanogen bromide method for converting thiols to unsymmetrical disulfides[339] involves the reaction of the thiol with a sulfenyl bromide which is formed by the reaction of cyanogen bromide with a sodium thiolate.

$$RSNa + BrCN \xrightarrow[-NaCN]{} [RSBr] \xrightarrow[-HBr]{R^1SH} RSSR^1$$

A convenient method for obtaining unsymmetrical disulfides is the reaction of thiols with the diethyl ester of azodicarboxylic acid followed by cleavage of the resultant adduct.[4]

$$RSH + EtO_2CN{=}NCO_2Et \longrightarrow EtO_2CNH\overset{\overset{SR}{|}}{N}CO_2Et \xrightarrow{R^1SH} RSSR^1 + (EtO_2CNH)_2$$

d. Preparation of thiocyanates and sulfenyl thiocyanates.
The reaction of thiolate anions or heavy metal thiolates with cyanogen halides leads to the formation of thiocyanates.[4] This reaction has been used as a basis for developing the synthesis of labelled thiocyanates.[340]

$$RSH + BrCN \xrightarrow[-HBr]{} RSCN \xrightarrow{^{35}\bar{S}H} R^{35}SH \xrightarrow{BrCN} R^{35}SCN$$

4-Dimethylamino-1-cyanopyridinium perchlorate and fluoroborate[341] and 2-nitro-5-thiocyanatobenzoic acid[342] have also been used as cyanating agents.

The reaction of thiols with thiocyanogen gives sulfenyl thiocyanates and the further reaction of these products with the thiol can give a disulfide. This sequence of reactions has been proposed as a basis for synthesising cystine.[343]

$$XSH + (SCN)_2 \longrightarrow XSSCN \xrightarrow{HSY} XSSY$$

X = $HO_2C\overset{\overset{NH_2}{|}}{C}HCH_2$; Y = $HO_2C\overset{\overset{NH_2\cdot HCl}{|}}{C}HCH_2$

e. Preparation of thionitriles and thionitrates
Thiols react with nitrous acid in the cold to form *S*-nitroso-compounds or thionitrites; these are comparatively stable only in the case of tertiary thiols.[344]

$$RSH + HONO \xrightarrow{0\,^\circ C} RSNO + H_2O$$

R = Bu^t, MeCO.

Nitrosyl chloride and esters of nitrous acid are also used as nitrosating agents.[344] The reaction of thiols with an equivalent quantity of nitrogen(IV) oxide also results in the formation of thionitrites which, in the presence of excess of the oxide, are converted to thionitrates.[345]

$$RSH \xrightarrow{N_2O_4} RSNO \xrightarrow{N_2O_4} RSNO_2$$

R = Bu^t, MeCO.

f. Preparation of thiolic esters
The acylation of thiols with acyl chlorides is the main method of preparing thiolic esters of carboxylic acids.[77]

$$RSH + R^1COCl \xrightarrow[-HCl]{} RS\overset{\overset{O}{\|}}{C}R^1$$

This reaction often proceeds very smoothly even in the absence of bases but it is usually carried out by the Schotten–Baumann method[77] or in the presence of pyridine and triethylamine. Thiolates of alkali metals[346] and other metals[347] are sometimes used instead of thiols, and carboxylic acids[348,349] and their anhydrides[350] and acyl azides[346] are also used as acylating agents. The addition of thiols to ketene gives thiolic esters of acetic acid[4] but this method is hardly used in the laboratory because ketene is not readily available.

$$RSH + CH_2{=}C{=}O \longrightarrow RSCOMe$$

The preparation of thiolic esters of benzenesulfinic acid by the reaction of thiols with benzenesulfinyl azide has been reported.[351]

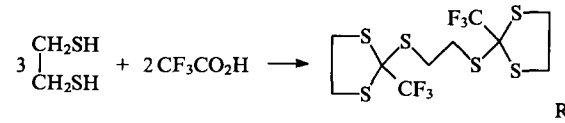
$$PhSON_3 + RSH \xrightarrow[-HN_3]{20\,^\circ C} PhS\overset{\overset{O}{\|}}{S}R$$

Thiolic esters of sulfonic acids are formed by the reaction of sodium thiolates with sulfonyl chlorides.[352]

$$RSNa + PhSO_2Cl \xrightarrow[-NaCl]{} PhSO_2SR$$

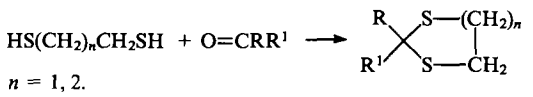
g. Preparation of compounds containing Si–S bonds
Alkali metal thiolates react with silicon tetrachloride comparatively easily to form tri(alkylthio)chlorosilanes or tetra(alkylthio)silanes, depending on the reagent ratio.[353,354]

$$SiCl_4 \xrightarrow[-3\,NaCl]{3\,RSNa} (RS)_3SiCl$$
$$SiCl_4 \xrightarrow[-4\,NaCl]{4\,RSNa} (RS)_4Si$$



R = Me, Et, Pr.

Trihalogenoalkylsilanes,[355] trialkylchlorosilanes,[356,357] and alkylsilazanes[358,359] can also be used for the silylation of thiols.



h. Preparation of heterocyclic compounds

A whole series of syntheses of various heterocyclic compounds have been developed on the basis of reactions characteristic of SH groups. These syntheses usually involve the use of thiols containing two SH groups or polyfunctional thiols.

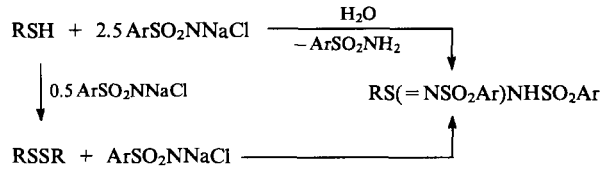
2. Preparation of sulfur(IV) compounds

a. Preparation of sulfinic acids and their derivatives

The oxidation of thiols in order to obtain sulfinic acids is only used in rare instances because the sulfinic acids formed can easily be oxidised to sulfonic acids. However in certain instances[4,377-379] oxidation is nevertheless used for the preparation of sulfinic acids.



The oxidising agents used are chlorine, bromine, iodine, hydrogen peroxide, and *m*-chloroperbenzoic acid. Oxidative chlorination of thiols is sometimes used to prepare sulfinyl chlorides.[380,381] Esters of sulfinic acids are formed by oxidising thiols with lead tetra-acetate in the presence of alcohols.[4]

b. Preparation of amides of iminosulfinic acids

Oxidative imination of thiols with *N*-chloro-compounds. The first examples of amides of iminosulfinic acids, viz. *N*-(arenesulfonyl)amido-*N'*-(arenesulfonyl)-iminosulfinic acids or *N*,*N'*-bis(arenesulfonyl)sulfinamidines, were obtained by the reaction of thiols with sodium salts of chloroamides or sulfonic acids in aqueous solution.[382]

The yield of the sulfinamidine in this reaction is low because some of the sodium salt of the chloroamide is used to oxidise the thiol to a disulfide.

The formation of disulfides as intermediates has also been observed in the oxidative imination (using sodium salts of the chloroamides of sulfonic acids) of alkanethiols,[383] arylthiols,[384] 8-mercaptoquinoline,[385] and arylcarbamoyl-[386] and alkoxycarbonyl-methanethiols.[387] It follows that the imination of thiols and of disulfides by sodium salts of chloroamides of sulfonic acids are similar processes and the first stage of the imination of a thiol is its oxidation to a disulfide. This stage is not rate-determining because the rate of oxidation of the thiols to disulfides by various oxidising agents decrease in the order ArSH > $ROOCCH_2SH$ > AlkSH,[82] whereas the reactivity of thiols towards the sodium salts of chloroamides of sulfonic acids varies in the reverse order and is dependent on their acidic properties.[384] Thiols with $pK_a > 7$ undergo imination by the sodium salts of chloroamides comparatively readily. A reduction in the pK_a of the thiol to 5–6 leads to a reduction in the rate of imination and in the yield of the sulfinamidine. Thiols with $pK_a < 5$ do not undergo imination by the sodium salts of the chloroamides of sulfonic acids. Such thiols usually have strong electron-acceptor groups on the sulfur atoms, so making it less nucleophilic. Imination of thiols by *N*-chloroamides of carboxylic acids[388,389] and phosphoric acids[390] can be carried out in anhydrous organic solvents in the presence of pyridine.

$$2\,RSH + 5\,AcNHCl + 4\,C_5H_5N \longrightarrow$$
$$\longrightarrow 2\,RS(=NAc)NHAc + AcNH_2 + C_5H_5N\cdot Cl_2 + 3\,C_5H_5N\cdot HCl$$

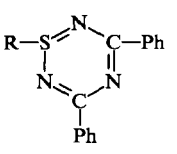
R = Alk, Ar, Het; Ac = ArCO, $(PhO)_2PO$.

Oxidative imination of sodium thiolates with *N*-dichloro-compounds. The reaction of sodium thiolates with the dichloroamides of sulfonic acids in anhydrous organic solvents gives the sodium salts of *N,N'*-disubstituted amides of iminosulfinic acids.[391]

$$5\,RSNa + 2\,ArSO_2NCl_2 \xrightarrow[-4\,NaCl]{}$$
$$\longrightarrow RS(=NSO_2Ar)N(Na)SO_2Ar + 2\,RSSR$$

This reaction has been widely used for alkanethiols,[383,392] derivatives of thiourea,[393] 8-mercaptoquinoline,[394-397] and other heterocyclic thiols.[398-400] The dichloroamides of carboxylic acids[401-404] and phosphoric acids[405] and also *N,N*-dichlorodicyanoethylurea[406] have been used as iminating agents. The reactivity of the sodium thiolates towards the *N*-dichloroamides is dependent on the acidic properties of the thiol.[407] The sodium salts of thiols with $pK_a > 8$ undergo imination by *N*-dichloroamides comparatively readily but a reduction in the pK_a of the thiol to 5–7 lead to a reduction in the reactivity of the sodium thiolate towards *N*-dichloroamides. The sodium salts of thiols with $pK_a < 5$ do not undergo imination by *N*-dichloroamides. The intermediates in this reaction were found[408] to be *N*-(arylsulfenyl)-*N,N'*-bis(arenesulfonyl)arylsulfinamidines which are also formed in the reaction of sodium thiophenolates with dichloroamides of sulfonic acids in anhydrous carbon tetrachloride when the reagents are in a 4:2 ratio.[409]

$$4\,RSNa + 2\,ArSO_2NCl_2 \xrightarrow[-4\,NaCl]{}$$
$$\longrightarrow RS(=NSO_2Ar)N(SR)SO_2Ar + RSSR$$



It is presumed[408] that these compounds are formed due to the following reactions:

$$2\,RSNa + 2\,ArSO_2NCl_2 \longrightarrow 2\,RSCl + 2\,ArSO_2NNaCl;$$
$$2\,RSCl + 2\,RSNa \longrightarrow 2\,RSSR + 2\,NaCl;$$
$$2\,ArSO_2NNaCl + RSSR \xrightarrow[-2\,NaCl]{} RS(=NSO_2Ar)N(SR)SO_2Ar.$$

In the presence of an additional mole of the sodium thiophenolate cleavage of the *N*-(arylsulfenyl)-*N,N'*-bis(arenesulfonyl)arylsulfinamidine takes place to form a disulfide and the sodium salt of the *N,N'*-bis(arenesulfonyl)arylsulfinamidine.[408]

$$RS(=NSO_2Ar)N(SR)SO_2Ar + RSNa \longrightarrow$$
$$\longrightarrow RS(=NSO_2Ar)N(Na)SO_2Ar + RSSR$$

The reaction of sodium thiolates with *N*-chloro- and *N*-bromobenzamidines gives cyclic amides of iminosulfinic acids.[410]

$$RSNa + 2\,PhC(=NH)NHX \longrightarrow$$
$$\longrightarrow$$  $$+ NH_4X + NaX$$

X = Cl, Br.

c. Preparation of iminosulfinyl chlorides

The formation of iminosulfinyl chlorides by the reaction of thiophenols with dichloroamides of sulfonic acids may take place via the following reactions, depending on the reagent ratio and the order in which the reagents are mixed[484] [incorrect reference (Ed. of Translation)]:

$$2\,ArSH + PhSO_2NCl_2 \longrightarrow 2\,ArSCl + PhSO_2NH_2;$$
$$2\,ArSCl + 2\,PhSO_2NCl_2 \longrightarrow 2\,ArS(=NSO_2Ph)Cl + Cl_2;$$
$$2\,ArSCl + 2\,ArSH \xrightarrow[-2\,HCl]{} 2\,ArSSAr;$$
$$ArSSAr + 2\,PhSO_2NCl_2 \longrightarrow 2\,ArS(=NSO_2Ph)Cl + Cl_2.$$

The formation of arenesulfonamides as by-products makes it difficult to isolate the iminosulfinyl chlorides. Consequently the preparation of iminosulfinyl chlorides from disulfides and *N*-dichloro-compounds is more convenient for preparative purposes.[411-417]

$$RSSR + 2\,R^1NCl_2 \xrightarrow[-Cl_2]{} 2\,RS(=NR^1)Cl$$

R = Alk, Ar; R^1 = $ArSO_2$, ArCO, Bu^t.

3. Preparation of sulfur(VI) compounds

a. Preparation of sulfonic acids

Thiols are readily converted to sulfonic acids by the action of strong oxidising agents.[77] A number of methods for preparing sulfonic acids have been developed on the basis of this reaction.

$$RSH \xrightarrow{Ox} RSO_3H$$

R = Alk, Ar, Het.

The oxidation of thiols to sulfonic acids takes place via a number of stages in which the intermediate compounds are disulfides, sulfinic and sulfonic acids. For example, the oxidation of thiols by the $Ti^{III}-H_2O_2$ system or Ce^{IV} salts leads to the successive generation of thiyl, sulfinyl and sulfonyl radicals, from which the final products are formed.[4] In biological systems inclusion of sulfur in the metabolism occurs starting with the oxidation of cysteine to alanine-3-sulfinic acid, which is subsequently converted to a β-sulfenylpyruvate, sulfite ions, and finally sulfate ions.

A method for preparing aliphatic sulfonic acids is based on the addition of thiols to alkenes followed by oxidation of the resultant thioethers by hydrogen peroxide in acetic acid.[4]

$$RCH{=}CH_2 + AcSH \xrightarrow{h\nu} RCH_2CH_2SAc \xrightarrow{H_2O_2}$$
$$\longrightarrow RCH_2CH_2SO_3H$$

b. Preparation of sulfonyl chlorides

Oxidative chlorination of aromatic and heterocyclic thiols with chlorine in glacial acetic acid gives the corresponding sulfonyl chlorides.[77]

$$RSH + Cl_2 \xrightarrow[-HCl,\,MeCOCl]{MeCOOH} RSO_2Cl$$

Oxidative chlorination of aliphatic thiols occurs in aqueous solution.[418]

$$RSH + 3\,Cl_2 + 2\,H_2O \longrightarrow RSO_2Cl + 5\,HCl$$

Oxidative chlorination of thioglycolic acid in concentrated hydrochloric acid gives dichloromethanesulfonyl chloride.[419]

$$HO_2CCH_2SH + Cl_2 \xrightarrow{HCl\,+\,H_2O} HO_2CCH_2SO_2Cl \xrightarrow[-2\,HCl]{Cl_2}$$
$$\longrightarrow [HO_2CCCl_2SO_2Cl] \xrightarrow[-CO_2]{} CHCl_2SO_2Cl$$

In this review an attempt has been made to demonstrate the great synthetic potentialities for fine-organic synthesis which lie hidden in a class of organosulfur compounds that is, on the face of it, just ordinary, viz. thiols. In the review thiols are discussed only as synthons although there are other reactions involving thiols which have no synthetic value but play an important role in various fields of human activity (e.g. the purification of petroleum from sulfur compounds etc.).

Abstract. A survey is presented of literature data concerning the development and application of the immunochemical methods for the assay of alkaloids — one of the classes of physiologically active compounds of plant origin most widely used in medical practice. The bibliography includes 141 references.

I. Introduction

Alkaloids are nitrogen-containing organic compounds which are encountered in plants and which as a rule exhibit physiological activity. Similar compounds have been detected also in certain animal organisms, in higher and lower fish, and in algae. More than 5000 different alkaloids have now been described and the chemical features of many of them have been fully established.

One of the most important branches of the modern science of medicinal plants involves the analytical determination of the content of biologically active substances in plant tissues. Not only the economic parameters of the manufacture of a number of medicinal preparations but also their quality depend on the content of physiologically active substances in the plant raw material.

Another important application of the analytical methods is the study of the biosynthesis of alkaloids in plant tissues.

Furthermore, analytical methods are widely used in the study of the metabolism and pharmacokinetics of the alkaloids used in medical practice.

A series of alkaloids possess narcotic properties, so that the rapid and reliable detection of these compounds in the human organism is very important from the medical point of view. Assay of narcotics is important also from the criminological standpoint.

The methods of synthesis of biologically active compounds in cell and plant tissue cultures have been vigorously developing in recent years. Theoretically this may make it possible to abandon the laborious operations involving the collection of plant material, especially wild species, and the use of large areas of fertile soil for the cultivation of such plants. The successful development of biotechnological methods is also associated with the analytical determination of the content of the target substances.

The necessity for a large number of analyses, especially in selection studies, has given rise to the need for the automation of analytical methods.

The methods for the quantitative assay of the substances present in plants can be divided into three groups: photometric, chromatographic, and protein-binding.

The photometric analytical methods have found the greatest application in the assay of biologically active substances of plant origin. These methods are relatively insensitive and non-specific, but, by virtue of their simplicity, they are still being used.

Chromatographic methods [thin-layer chromatography (TLC), gas – liquid chromatography (GLC), chromatography-linked mass spectrometry (GLC-MS), and high performance liquid chromatography (HPLC)] make it possible to determine fairly rapidly and accurately several substances being assayed in a single sample. However, these methods are fairly laborious. The most accurate and reliable of these is GLC-MS, but the application of this method is restricted by the high cost and complexity of the assay, which requires specially trained service personnel.

The protein-binding methods include the receptor and immune methods. The receptor assay method is based on the competitive inhibition by the compound assayed of the binding of a radioactively labelled ligand by membrane receptors specific to it.[1-3] This method is hardly used in the assay of substances present in plants. The reason for this is the difficulty in the identification and isolation of specific receptors.

The immunoassay methods are based on the specific interaction of the molecules of the substance assayed with the antibodies produced by the animal organism in response to the entry of foreign substances into the latter.

The protein-binding and in particular immune methods have a number of advantages over the photometric and chromatographic analytical methods: they do not require a large amount of work on the preparation of the specimen to be analysed, are highly sensitive, do not need complex and expensive equipment, and permit the simultaneous analysis of a large number of specimens.

The principal disadvantage of the immunoassay methods for low-molecular-mass substances is the necessity for preliminary work associated with the synthesis and purification of the antigen, the immunisation and maintenance of the animals, and the isolation, purification, and characterisation of the antibodies. Another significant disadvantage of the immunoassay methods is the possibility of the cross-interaction of the antibodies with a number of compounds having a structure similar to those of the antigen.

II. Immune methods for the assay of low-molecular-mass compounds

A fairly large number of reviews and monographs have been devoted to the immunoassay methods. They deal in detail with various procedures whereby the analyses are set up and carried out.[4-14]

There exist at present fairly numerous versions of immunoassay. The heterogeneous immunoassay methods used in the assay of low-molecular-mass compounds are as follows: radioimmunoassay, direct competitive enzyme immunoassay, and indirect enzyme immunoassay using secondary antibodies.

In radioimmunoassay (RIA), a standard amount of a radioactively labelled hapten is mixed with the specimen analysed. The radioactive hapten and the molecules of the specimen interact competitively with the antibodies, the degree of binding of the radioactive hapten to the antibodies being inversely proportional to the number of molecules assayed in the specimen. After equilibration, the hapten molecules bound to the antibodies are separated from the remaining free molecules either by the rapid adsorption of the haptens or by the precipitation of the proteins, after which the radioactivity of a particular phase is measured.

In the direct competitive enzyme immunoassay (EIA), an enzyme label and not a radioactive label is used. Antibodies present in a limited amount are bound to the solid phase, usually a polystyrene test tube or the walls of the microtitration tray. Competition between the substance assayed in the specimen and the enzyme-bound hapten leads to the immobilisation of a proportion of the enzyme on the solid phase. The free enzyme is removed and the amount of bound enzyme is determined, after adding the substrate, from the intensity of the colour of the solution caused by the substrate decomposition product.

In the analysis by the indirect immunoassay method using secondary antibodies [enzyme-linked immunosorbent assay (ELISA)], the hapten conjugated with the protein is sorbed on a solid phase — usually on the walls of the microtitration tray. The conjugate with which the animal was immunised is not used in this stage; instead one employs a conjugate with a protein unrelated to that of the immunogenic conjugate. Next the substance to be assayed, containing the free hapten and the antiserum, is added. The antibodies are distributed between the free hapten of the specimen and the immobilised hapten–protein conjugate. The liquid is decanted and an excess of secondary antibodies conjugated to the enzyme and specific to the immunoglobulins G (Ig G) of the immunised animal is added. The secondary antibodies are bound to the primary antibodies and are retained on the solid phase. The liquid phase is again decanted and the amount of secondary antibodies is determined after adding the substrate to the conjugated enzyme and the formation of the coloured product.

The homogeneous immunoassay methods most frequently used are those based on the measurement of the degree of polarisation of the fluorescence and the change in the activity of the enzyme.

In the immunoassay based on the measurement of the degree of polarisation of the fluorescence [fluorescence-polarisation immunoassay (FPIA)], a hapten conjugated to fluorescein or another molecule which fluoresces when irradiated with a beam of polarised light is employed. In the free state, the hapten–fluorescein conjugate in solution is mobile and the degree of polarisation of the light transmitted through the solution is low. In the form bound to the antibodies, the mobility of the hapten–fluorescein conjugate is restricted, which increases the degree of polarisation of the light. The amount of the hapten in the specimen is determined from the degree of substitution by the latter of the hapten–fluorescein conjugate in the interaction with the antibodies, which lowers the degree of polarisation of the light.

In the immunoassay based on the change in the activity of the enzyme [enzyme-multiplied immunoassay (EMIA)], one uses a hapten conjugated with the enzyme in such a way that the binding of the hapten to the antibodies lowers the activity of the enzyme owing to the blocking of its active centre. Thus the degree of recovery of the enzyme activity of the specimen analysed in the presence of the free hapten permits the determination of its amount.

Each of these methods has its advantages and disadvantages. Radioimmunoassay requires the synthesis of the radioactively labelled hapten. Fairly expensive equipment is also necessary — a centrifuge which permits the simultaneous centrifugation of up to 100–200 specimens and a liquid-scintillation (in the case of the ^{3}H isotope) or a γ-emission (in the case of the ^{125}I isotope) counter. The advantage of the ^{3}H isotope consists in the fact that the native structure of the molecule is retained.

The fluorescent and chemiluminescent labels, which make it possible to avoid the use of radioactive isotopes, appreciably alter the native structure of the hapten. These methods also require expensive equipment.

The use of enzyme labels in the stationary phase in the direct competitive enzyme immunoassay simplifies the analysis, since the phases can be separated very simply and only a colorimeter is required for the quantitative determination. However, this method requires the synthesis of the hapten–enzyme conjugate and the selection of the necessary hapten/enzyme ratio. Furthermore, owing to the incomplete adsorption of the enzyme, the antiserum — the most important component in the method — is not consumed in a rational manner. Another disadvantage of this method is that the enzyme and the specimen analysed, which frequently contains a multiplicity of components, are incubated together, which can lead to the inactivation of the enzyme. Furthermore the homogeneous methods are also less sensitive.

Direct immunoassay with the use of secondary antibodies is free from many of the above disadvantages. In this method, the antiserum is consumed fairly economically, since only dilute solutions are used. The high affinity and specificity of the antibodies make it possible to achieve a high sensitivity and specificity of the assay. Although in this method there is an additional stage involving incubation with the secondary antibodies, the employment of the latter makes it possible to increase the sensitivity of the assay and to extend the range of the measurable concentrations. The conjugates of enzymes with secondary antibodies to immunoglobulins from various sources are fairly readily commercially available. This method is the most popular and perhaps the best of all the immune methods which exist at the present time. The highest sensitivity of the method, attained in the analysis of the cholera toxin, amounts to 10^{-16} g, i.e. 600 molecules of this toxin is sufficient for the determination.[15]

The principal advantage of the homogeneous immunoassay methods is that, by performing the assay in one phase, it is possible to automate it and this makes them particularly attractive for routine assays of large numbers of specimens. It is more difficult to automate heterogeneous analytical methods, although here too the use of laboratory robots makes it possible to attain a productivity of up to 1000 specimens per day.

Analysis of the studies published during the period from 1959 to 1982 revealed a change in 1979–1981 from the radioimmunoassay to the enzyme immunoassay methods, which have virtually predominated since 1985.[14]

Analysis of chemical compounds by immune methods presupposes the employment of antibodies which recognise specifically the compounds to be analysed. However, substances with a molecular mass below 1000, including alkaloids, do not induce an immune response and formation of antibodies when they enter an animal organism. In order to stimulate an immune response, such substances must be bound covalently to large molecules (usually to a protein); the resulting conjugates are then used to immunise the animals. The antiserum produced after immunisation contains a mixture of antibodies, some of which may prove to be capable of recognising the hapten not only in the bound state but also in a free state.

A number of methods based on the use of various functional groups of the hapten have been proposed for the synthesis of immunogenic conjugates. The specificity of the antibodies thus obtained is determined by the sections of the molecule most remote from the conjugation point.[16] Careful study of the structure and properties of the hapten molecule and the correct selection of the conjugation point make it possible in many instances to obtain an antiserum with the required selectivity.[17] Many natural products contain several functional groups, which permits in many instances the variation of the way in which the conjugation is achieved. If there is no suitable group, it is possible to employ derivatives containing a functional group in the required site in the molecule.

Carboxy- or hydroxy-groups of the hapten frequently participate in the formation of the immunogenic conjugate. When the protein molecule is bound to the hapten via the carboxy-group, a two-stage synthesis takes place as a rule. In the first stage, a derivative of the hapten with a free carboxy-group is obtained with the aid of a bifunctional reagent. The mixed anhydride and carbodiimide methods are used for this purpose.

The mixed anhydride method,[18] widely known in organic chemistry, has been used to obtain ajmalicine conjugates as early as 1959,[19] while the carbodiimide method,[23] proposed for the synthesis of immunogenic conjugates in 1981, has been used to obtain the conjugates of serpentine,[19] cotinine,[20] vinblastine, vincristine,[21] and colchicine.[22]

Bifunctional reagents, for example succinic anhydride, are used in the synthesis of conjugates with participation of a hydroxy-group of the hapten. The anhydride has been used to obtain the conjugates of nicotine,[20] vindoline,[24] quinine,[25] and quinidine.[26] Glutaric anhydride has also been used to synthesise the vindoline conjugate.[27]

The presence of a phenolic hydroxyl in the hapten molecule permits the use of carboxymethylation in order to attach such a molecule to a protein; morphine conjugates have been obtained in this way.[28-30]

The presence of an amino-group in the hapten molecule makes it possible to obtain conjugates with the aid of the Mannich reaction or acrylic acid. The Mannich reaction has been used to synthesise the conjugates of vinblastine,[31, 32] while acrylic acid has been used to synthesise the conjugate of nor-(−)-scopolamine.[33]

The conjugation procedures described presuppose the insertion of a fairly short intervening chain (spacer) between the hapten and the protein molecule. However, in those cases where the spacer contains a chain of only 2–3 carbon atoms, it is not always possible to obtain an antiserum capable of recognising the hapten. In such cases, it is useful to increase the length of the spacer to 5–6 methylene units. An increase in the length of the spacer can be achieved, for example, by using 6-amino-n-hexanoic acid, the amino-group of which is attached to the hapten, while the carboxy-group is attached to the protein. A quinidine conjugate has been obtained in precisely this way.[26] The introduction of a spacer with a length corresponding to 4 or 5 carbon atoms is achieved using succinic or glutaric anhydride. A more rigid spacer is obtained when *trans*-cyclohexane-1,4-dicarboxylic dichloride is used, whilst a longer spacer can be secured with the aid of 4-aminohippuric acid.[34]

The nature of the spacer has a significant influence on the characteristics of the assay method. It has been established in relation to polarisation fluoroimmunoassay of methamphetamine by means of its conjugate with fluorescein that the best results are obtained when a spacer fully identical with that in the immunogenic conjugate used to obtain the antibodies is employed.[35]

The majority of conjugation methods are based on the interaction between the activated functional groups of the hapten and the amino-groups of the protein. Therefore one of the requirements which must be met by the protein is the accessibility of the ε-amino-groups of the lysine residues. Proteins such as bovine serum albumin (BSA), human serum albumin (HSA), and keyhole limpet hemocyanin (KLH) are most often used for conjugation. In certain cases, poly-L-lysin was employed for conjugation,[20, 29] but it was found that it has no appreciable advantages over the proteins listed above. It has been demonstrated empirically that it is preferable to conjugate the hapten with KLH rather than albumin in order to obtain antibodies to small compounds.[36]

In enzyme immunoassay methods, where there is conjugation with two proteins, it is important that these proteins should not be related and that the immunised animal should not have come into contact previously with these proteins.

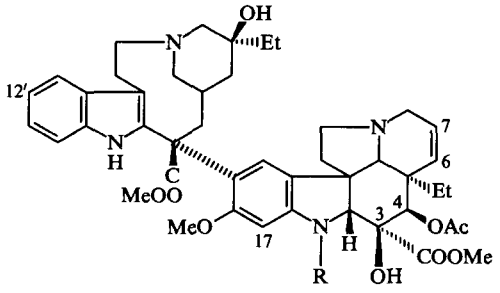
The conjugate synthesised is usually purified by gel filtration on a column with Sephadex G-25 or by dialysis, which makes it possible to separate the unreacted low-molecular-mass components.

The molar ratio of the components of the conjugate — the hapten density — is determined in the purified conjugate. It has been established experimentally that one must avoid both very high and very low hapten densities. Thus the hapten : protein ratio for BSA should be in the range from 10 : 1 to 25 : 1, whereupon one usually obtains an antiserum of good quality. The hapten density can be frequently determined by UV or fluorescence spectroscopy, but in some cases it may be necessary to split off the hapten chemically and to determine its amount by other methods.[37]

Experiments with conjugates of low-molecular-mass compounds of plant origin hardly differ from the usual manipulations involving traditional (protein) antigens.

Since low-molecular-mass organic substances have a small and rigorously defined antigen determinant, highly specific polyclonal antibodies can be obtained successfully for them and can also be used successfully for routine assays of low-molecular-mass compounds. The monoclonal antibodies to haptens do not as a rule have special advantages and their preparation requires considerable effort and expense.

Immunochemical methods for the assay of a number of low-molecular-mass compounds (alkaloids, terpenes, vitamins, steroids, and regulators of the growth and development of plants) and biologically active compounds of plant origin such as phytohormones, cytokinins, phytoalexins, and enzymes have now been developed.



The therapeutic properties of medicinal plants are known to be largely determined precisely by low-molecular-mass compounds. The range of such compounds of plant origin, for which immunoassay methods have been developed, is being constantly expanded and these methods have now come to be fairly usual in clinical practice and are finding increasing application in plant cultivation and in the manufacture of medicinal preparations of plant origin. Immunochemical methods are used widely for the selection of the most productive plant species. Antisera to several of the low-molecular-mass biologically active substances isolated from plants and contaminating plant material are now produced industrially by a number of companies.[36, 38]

The high specificity of the antibodies makes it possible to determine individual substances in the presence of a multiplicity of other compounds or their metabolites by immunochemical methods, but in many instances it may be necessary to assay not just any one compound but a whole class of substances. The method employing mixtures of several highly specific antibodies is used for the simultaneous assay of several compounds. Thus a homogeneous polarisation fluoroimmunoassay using a mixture of antibodies to determine the majority of the classes of narcotics usually employed — amphetamines, barbiturates, and cannabinoids — has been described.[39]

III. Immune methods for the assay of alkaloids

1. Indole alkaloids of *Catharanthus roseus*

The extremely great pharmaceutical value of the alkaloids of *C. roseus*, especially vinblastine **1** and vincristine **2**, has aroused continuous interest by investigators of these alkaloids. The great demand for the alkaloids of *C. roseus*, and especially compounds **1** and **2**, has stimulated intense research designed to increase the manufacture of the alkaloids. The two main approaches to the solution of this problem—the selection of the most productive plants and the cultivation of *C. roseus* cells in fermenters—required the development of new rapid and accurate assay methods.

R = Me (**1**), CHO (**2**)

a. Vinblastine and vincristine

These bisindole alkaloids, which are minor components of the total alkaloid extract from *C. roseus*, are believed to be some of the most important biologically active substances of plant origin and are used widely in medical practice as antineoplastic agents. In view of their high activity and the presence of side effects such as neurotoxicity and myelosuppressivity, the clinical use of these alkaloids requires careful monitoring, for which immune methods are ideally suitable.

In terms of the site of the conjugation of the alkaloid molecule, the immunoassay methods for compounds **1** and **2** can be divided into several groups.[40]

Chronologically the first and most widely used procedure involves conjugation at the C(3) atom. A brief communication was published in 1975[41] concerning the development of a radioimmunoassay method for compounds **1** and **2**. Using the method for the conjugation of compound **1** to a protein, the Eli Lilly and Company Corporation (USA) began to manufacture an antiserum to the antigen obtained by converting compound **1** initially into the 3-hydrazide and then into the 3-carboxazide (4-desacetylvinblastine), which was conjugated to the protein.[42]

The antibodies to such conjugates, even monoclonal antibodies, exhibit as a rule a low specificity: cross reactions of the antibodies with derivatives of compound **1** (vindesine and its derivatives) and to compound **2** and its derivatives (leurosine and leurosidine) are observed. Polyclonal antibodies also participate in cross reactions with the monomeric alkaloids vindoline and catharanthine.

Polyclonal antibodies to the conjugates of compounds **1** and **2** via the C(3) atom have been used to develop radioimmunoassay[43] and enzyme immunoassay[32] methods for these compounds. In the radioimmunoassay method using [^{3}H]-**1** and [^{3}H]-**2**, the specimen analysed is incubated beforehand with the immune serum and is then treated with the radioactively labelled substance. This makes it possible to increase the sensitivity of the determination of the alkaloids: the concentration range in which compounds **1** and **2** can be determined is 0.2–30 ng. In the enzyme immunoassay method, compounds **1** and **2** are determined in microtitration trays the wells in which are coated by antibodies (dilution 1 : 10 000); the concentration range in which compounds **1** and **2** can be determined is 0.01–0.1 ng. However, none of these methods makes it possible to distinguish between the alkaloids **1** and **2**.

An RIA method[44] for the determination of compound **1**, also based on the use of the conjugate at the C(3) atom and used in the study of the pharmacokinetics and metabolism of compound **1** in humans, makes it possible to determine compound **1** in the concentration range 0.2–100 μg litre^{-1}. The monoclonal antibodies to the conjugates of compound **1** at the C(3) atom have been used in the development of solid-phase and liquid-phase RIA methods and an EIA method.[46] The latter permits the determination of compound **1** in the concentration range 1–100 μg litre^{-1}; the limit of the determination of compound **1** is 0.64 μg litre^{-1}. However, cross reactions with vindesine (3%), vinblastine (75%), leurosine (152%), and a number of other derivatives take place in this instance.

The conversion of compound **1** into an azide activated in the 3-position and its conjugation with the dipeptide Gly-Tyr made it possible to devise a radioimmunoassay method for vincristine and vindesine using a [^{125}I]-labelled conjugate.[47]

A conjugation method which makes it possible to determine both alkaloids and to distinguish reliably compound **1** from compound **2** was developed in 1979.[21] This method is based on the oxidation of the double bond between the C(6) and C(7) atoms with a mixture of potassium permanganate and sodium periodate.[48] Such oxidation leads to the formation of a dicarboxy-derivative, which affords a conjugate with the protein.

The antibodies formed in response to the introduction of such a conjugate into the organism are more specific: the antibodies to the conjugate of compound **1** interact with compound **2** five times more weakly than with compound **1**, whereas those to the conjugate of compound **2** interact with compound **1** 200 times more weakly than with compound **2**.

The two alkaloids **1** and **2** were converted in different ways into the 6,7-dicarboxy-derivatives, which were in their turn added to HSA. These conjugates were used to develop radioimmunoassay methods using [^{3}H]-**1** and [^{3}H]-**2**. The 'bound' and 'free' phases were separated with the aid of goat antibodies to the rabbit immunoglobulins G and the radioactivity of the 'bound' phase was measured. One of the antisera obtained proved to be specific to compound **2** and the contribution of the cross reaction with compound **1** was only 0.05%; compound **2** can be determined in the range 1–10 ng. Another antiserum was moderately selective to compound **1** and the contribution of the cross reaction with compound **2** was 25%; the range for the determination of compound **1** is 1–15 ng and the limit in its determination is 0.4 pg litre^{-1}.[21] These antisera can be used to select plants in terms of their content of compounds **1** and **2**.

A further increase in the sensitivity and selectivity of the determination of compounds **1** and **2** was achieved using an enzyme immunoassay method employing compound **1** attached by the Mannich reaction to BSA via the C(17) atom.[31, 32] The C(17) atom of the aromatic ring, which is close to the carbon atom carrying the methoxy-group, proves to be activated and is capable of interacting with formaldehyde.

The antibodies to the conjugate via the C(17) atom were used to develop a method for the radioimmunoassay of compound **1**. The method makes it possible to determine compound **1** in the plasma in the concentration range from 1 to 200 to 300 μg litre^{-1}.[31] An enzyme method for the immunoassay of compound **1** with the aid of monoclonal antibodies was developed later. This method made it possible to determine compound **1** in the concentration range 1–100 μg litre^{-1}; the limit in the determination of compound **1** is 0.54 μg ml^{-1}.[32]

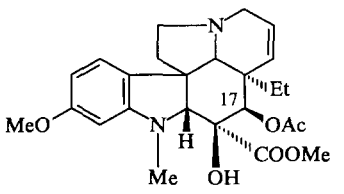
The monoclonal antibodies to the conjugate via the C(17) atom are somewhat more specific than the antibodies to the conjugate via the C(3) atom, but appreciable contributions of the cross reactions with the derivatives of compound **1** (vindesine) compound **2** and its derivatives (leurosine, and leurosidine) have been noted for them also.[32]

Studies using the method involving the conjugation of compound **2** via the C(12′) atom of the aromatic ring of the molecule have been published in recent years.[49-51] The antibodies to the conjugate via the C(12′) atom are highly selective and there are virtually no cross reactions with compound **1**. For this purpose, *p*-aminobenzoic acid was added to the C(12′) atom [corresponding to the C(10) atom according to the biogenetic numbering] of compound **2** after nitration and the resulting derivative was attached to the protein via the amino-groups by the carbodiimide method.[49]

This conjugation procedure makes it possible to distinguish more reliably compounds **1** and **2**: the antibodies to the conjugate of compound **2** interact with compound **1** and vindoline 1500 times more weakly than with compound **2**.[50, 51]

The antiserum to this conjugate was used to develop a method for the radioimmunoassay of compound **2**.[51] The range of the determination of the latter is 0.1–100 ng; the contributions of the cross reactions with compound **1** and vindoline are 0.03% and 0.09% respectively. A method for the enzyme immunoassay of compound **2** was developed on the basis of the same conjugate;[50] the range of the determination is 5–500 pg.

A study in which compound **1** was attached to the protein with the aid of glutaraldehyde[53] was published in 1989.[52] The use of this conjugate leads to the formation of an antiserum, which recognises mainly compound **1**. This made it possible to develop a method for the radioimmunoassay of compound **1** in the range 0.5–10 ng ml^{-1}. The contributions of the cross reactions with compound **2** and leurosine are 30% and 0.23% respectively and that of the cross reactions with all the remaining alkaloids of *C. roseus* is less than 0.1%.



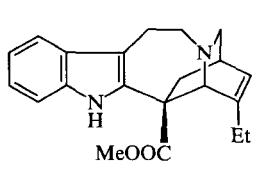
This conjugate was used in the development of a method for the radioimmunoassay of compound **1** in *C. roseus* tissue cultures.[52]

It is noteworthy that almost all the methods for the immunoassay of compounds **1** and **2** were developed and used to determine the content of these alkaloids in the blood sera of patients injected intraveneously with the preparations **1** and **2**[31, 43, 45, 50] and for the investigation of the pharmacokinetics and metabolism of these alkaloids.[32, 44, 54] Immunoassay methods have not so far found extensive application in the determination of the contents of compounds **1** and **2** in plants. Only radioimmunoassay[21] and enzyme immunoassay[50] methods have been used for the quantitative assay of the alkaloids in various parts of the *C. roseus* plant. It was established that the maximum concentration of the alkaloids is detected in the flowers, but, owing to the small absolute mass of the flowers, almost the total amount of the alkaloids is contained in the leaves.[21] The content of compound **2** in the extracts from the leaves of *C. roseus* was determined by an enzyme immunoassay method.[50] The total amount of the dimeric indole alkaloids in *C. roseus* was likewise determined by an enzyme immunoassay method.[46] The immuno methods are used somewhat more widely in the quantitative assay of compounds **1** and **2** in *C. roseus* cell cultures.[52, 55-57]

The high cost and pharmaceutical value of compounds **1** and **2** have led to the intensification of the development of methods for the immunoassay of these substances. This led to the appearance in the world market of primary antisera to compounds **1** and **2** manufactured by companies such as Bioanalysis Ltd and Guildhay Antisera (Great Britain) and Eli Lilly and Company.

b. Vindoline

Vindoline **3** is an indole alkaloid which is a biogenetic precursor of compounds **1** and **2** and can be used for the chemical synthesis of compound **1**.[58] In the development of a method for the immunoassay of compound **3**, 17-desacetylvindoline was initially activated by succinic anhydride and the resulting hemisuccinate was then attached to BSA by the carbodiimide method.[27] The antiserum obtained with the aid of this conjugate was used in the radioimmunoassay of compound **3**; the range of its determination is 0.2–45 ng. The conjugate of 17-desacetylvindoline with BSA was also synthesised with the aid of succinic anhydride.[24] This conjugate was used in the development of a method for the radioimmunoassay of compound **3**, but it proved to be less sensitive: the range of the determination of compound **3** is 10 to 1000 ng.



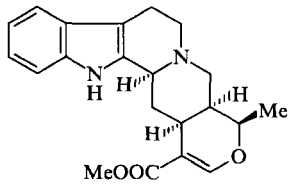
3

The use of the antiserum to the conjugate of compound **1** with BSA, obtained by reaction via the C(12′) atom, made it possible to develop methods for the enzyme immunoassay and radioimmunoassay of compound **3**.[59, 60] The range in which compound **3** can be determined by enzyme immunoassay is 5 to 500 pg.

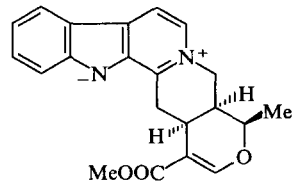
These methods were used to determine the content of compound **3** in various parts of the *C. roseus* plant[27] and in *C. roseus* cell cultures.[27, 59, 61]

c. Catharanthine

Like compound **3**, catharanthine **4** is a biogenetic precursor of compounds **1** and **2** and constitutes, as it were, the 'upper' half of the molecules of the dimeric alkaloids and, like compound **3**, can be used for the chemical synthesis of the dimeric alkaloids. A method for the radioimmunoassay of compound **4** in the range 0.02–20 ng has been developed.[61] In order to obtain an antiserum, rabbits were immunised with a conjugate of catharanthic acid with HSA. [^{3}H]-**4** was used as the radioactive ligand. The limit in the radioimmunoassay of compound **4** is 66 pg. Cross reactions with catharanthic acid and the dihydro- and carboxy-derivatives of compound **4** have been noted.



4



The radioimmunoassay has been used to determine compound **4** in *C. roseus*.[62]

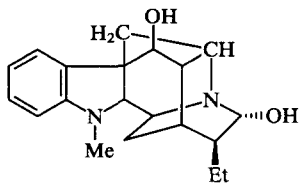
d. Ajmalicine and serpentine

Ajmalicine **5** is one of the principal alkaloids isolated from plants of the *Catharanthus* and *Rauwolfia* species. It is used widely in the treatment of the blood circulation system — in particular in the pathology of the vessels in the brain. Serpentine **6**, which is an alkaloid related to ajmalicine, is not used as a medicinal drug but can serve as a source of compound **5**.

5

6

For the effective production of compound **5**, it is important to select plants in terms of the maximum contents of compounds **5** and **6**. Antisera to each of these alkaloids were therefore



obtained.[19] For this purpose, ajmalinic acid was obtained by the alkaline hydrolysis of compound **5** and was attached to HSA by a modified mixed anhydride method. The resulting conjugate was used to produce an antiserum; the antiserum proved to be specific to compound **5** and was insensitive to compound **6**. The radioimmunoassay, developed using this antiserum makes it possible to determine compound **5** in the range 2–50 ng.[19]

Serpentinic acid, obtained by the alkaline hydrolysis of compound **6**, was conjugated with HSA via the *N*-hydroxysuccinimide ester modified by a carbodiimide method. The antiserum to this conjugate proved specific to compound **6** and insensitive to compound **5**. The radioimmunoassay makes it possible to detect compound **6** in the range 2–50 ng.[19]

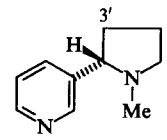
Both these methods were used in the study of the distribution of compounds **5** and **6** in plant tissues. It was shown that, in contrast to compound **3**, the maximum concentration of both alkaloids is found in the plant roots immediately under the surface of the soil, the concentration of compound **6** being approximately five times higher than that of compound **5**. Radioimmunoassay was used in selection,[19] which made it possible to select a population of plants with an increased overall content of alkaloids and an increased **5/6** ratio, and also in the determination of these alkaloids in the cultivation of *C. roseus* cells by the suspension method.[62] The same methods have been used in the study of the biosynthesis of compound **5**.[63]

e. Ajmaline

In order to obtain an antiserum specific to the alkaloid ajmaline **7**, the hemisuccinate of compound **7** was conjugated with BSA and rabbits were immunised with this conjugate.[64] The resulting antiserum made it possible to develop a radioimmunoassay for compound **7**. [^{3}H]-**7** was used as the radioactive ligand. The range in which compound **7** can be determined is 0.05–20 ng. Appreciable cross reactions with 17-chloroacetylajmaline, sandwicine, and isoajmaline have been noted.

7

The method developed has been used to determine the content of compound **7** in the plants of the *Rauwolfia* family.[64]

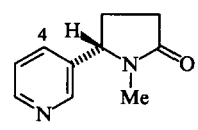


2. Tobacco alkaloids

One of the best known alkaloids of tobacco (*Nicotiana tabacum*, *Nicotiana rustica*, etc.) is nicotine **8**. At the present time compound **8** is isolated from plants mainly in order to oxidise it to nicotinic acid and to synthesise preparations based on it, while the alkaloid itself has found a limited application as an insecticide and an ectoparasitocide in veterinary practice.

In 1973 a radioimmunoassay was developed for compound **8** and its principal metabolite in the organism—cotinine **9**.[20]

a. Nicotine

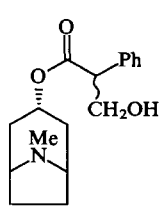


In order to synthesise an antigen for the assay of compound **8**, 3′-hydroxymethylnicotine, synthesised by the procedure described by Cushman and Castagnoli,[65] was activated with succinic anhydride and *trans*-3′-succinylmethyl niccotine was obtained and attached to HSA, KLH, and poly-L-lysine by the carbodiimide method. [^{3}H]-**8** was obtained by the catalytic ^{3}H exchange involving the pyridine ring. In the radioimmunoassay, the 'bound' and 'free' phases were separated by immunoprecipitation using goat antibodies to the rabbit Ig G and the radioactivity of the 'bound' phase was measured. The method makes it possible to determine compound **8** in the range 0.35 to 7 ng and an appreciable cross reaction has been observed only with *dl*-amino-**8** (2.4%). Cotinine is not detected if its content in the sample does not exceed 50 ng.[20]

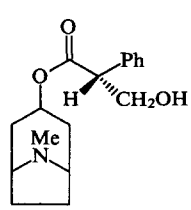
8

b. Cotinine

In the synthesis of an immunogen for the assay of cotinine **9**, *trans*-4-carboxy-**9** was conjugated by the carbodiimides method with HSA, KLH, and poly-L-lysine. Radioactive ^{125}I was introduced into *N*-(4-hydroxyphenylethyl)-*trans*-carboxamide derived from compound **9**. The assay was carried out as for compound **8**. The sensitivity of the method corresponds to 0.01–1 ng. An appreciable cross reaction has been observed only for *dl*-desmethyl-**9** (0.9%); at a level below 70 ng, compound **8** is not detected.[20]

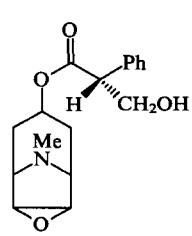


9



These methods have been used to investigate the conversion of compound **8** into compound **9** by extracts from rabbit liver. It was shown that compound **8** is not fully oxidised: after 10 h, only 37% of compound **8** is converted into compound **9**. These methods were also used to analyse the conversion of compound **8** into compound **9** *in vitro*, using extracts from cultivated liver cells, and for the determination of the content of these alkaloids in the biological liquids of smokers. It was established that the principal metabolite of compound **8** present in the blood serum and urine of smokers is compound **9**. Its content in the blood serum and urine falls after smoking has stopped. Compound **9** was not detected in the biological liquids of non-smokers.[20] The same method has been used to determine the content of nicotine and its metabolites in hair.[66] The method has not been used to determine compound **8** in plant tissues.

3. Tropane alkaloids



The structures of these alkaloids are based on the tropane skeleton. The most familiar of these are atropine **10**, hyoscyamine **11**, and scopolamine **12**. The alkaloids of the cocaine group, which will be examined below, can also be included with them. Antropine constitutes the racemic form of hyoscyamine formed when the alkaloids are isolated from plants.

10

11

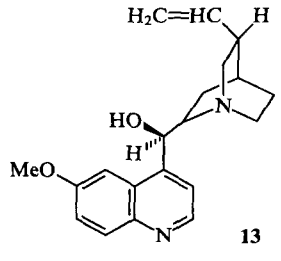
12

Scopolamine, produced by plants of the *Datura* and *Duboisia* (*Solanaceae*) species, is used as a parasympatolytic, antiemetic, and anticholinergic agent. Being a typical agent blocking *m*-cholinoreceptors, it resembles compound **10** as regards its physiological activity, but its influence on the central nervous

system is much stronger and it is frequently used as a calming agent in psychiatry, in narcology, and in sea sickness. Together with the alkaloid **12**, plant tissues usually contain large amounts of compound **11** – the biogenetic precursor of compound **12**.

In the synthesis of the immunogenic conjugate, compound **12** was attached to HSA via the hydroxy-group with the aid of glutaric anhydride, but an active antiserum to this conjugate was not obtained.[33] A satisfactory antigen was synthesised by the reaction of nor-(−)-**12** with acrylic acid and subsequent attachment of the resulting derivative to HSA by the mixed anhydride method or the carbodiimide method. The antiserum to this conjugate, specific to compound **12** and nor-**12**, made it possible to develop a method for the radioimmunoassay of compound **12** in the range 0.5 – 50 ng. The contribution of the cross reaction with compound **12** is only 0.8%.

The method has been used to investigate the distribution of compound **12** in the tissues of *D. innoxia* and *D. sanguinea*. The maximum concentration of compound **12** was detected in unripe seeds, but, owing to the small absolute amount of the seeds, almost the entire alkaloid **12** is contained in the leaves. A similar method has been used to assay compound **12** in *Datura* tissue cultures.[67]



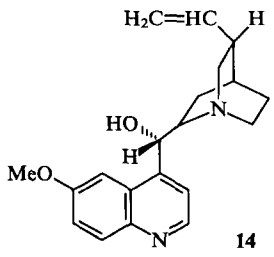
It was later reported[68] that an immunoassay had been developed using the rabbit antiserum to the conjugate of tropic acid with BSA. The method permits the simultaneous determination of the principal tropane alkaloids **10** – **12**. The detection limit of compound **10** is 0.1 ng. In the determination of compounds **11** and **12**, the latter are first racemised.

4. Quinoline alkaloids

Certain plant species of the genus *Cinchona* (*Rubiaceae*) produce the isomeric alkaloids quinine **13** and quinidine **14**. From the pharmacological point of view, compound **13** is an antibiotic. It is effective against the gametocytic forms of *Plasmodium vivax* and *Plasmodium malariae* in erythrocytes, the mechanism of its biological activity, which consists in the selective suppression of the replication of DNA and the transcription of RNA, being typical for antibiotics. Quinine is widely used as an antimalarial agent and as a bitter and has also found limited application in the treatment of certain cardiac affections and in midwifery. Quinidine, a stereoisomer of compound **13**, is a powerful antiarrhythmic agent.

a. Quinine

Activation of compound **13** with succinic anhydride and its attachment to BSA by the mixed anhydride method afford an immunogenic conjugate, which makes it possible to obtain an antiserum specific to compound **13**. A radioimmunoassay[25, 26] and an enzyme immunoassay[26] were developed on the basis of the antiserum and permitted the determination of compound **13** in the ranges 1 – 50 and 0.1 – 10 ng respectively. The detection limit of compound **13** is 10 pg for the enzyme immunoassay and 50 pg for the radioimmunoassay.[26]



13

The enzyme immunoassay method was used to determine compound **13** in specimens of human biological liquids.[69]

b. Quinidine

There exist at present analytical sets for the immunoassay of compound **14**. The Beckman Company (USA) has developed an analytical set for nephelometric immunoassay, which makes it possible to determine compound **14** and a number of its physiologically active metabolites in mammalian organisms.[70] The Syva Corporation manufactures an analytical set for the immunoassay of compound **14**.[71] Both methods are designed to use special equipment, require a large amount of antiserum, and their sensitivity is fairly low (1 – 10 ng ml^{-1}). However, the complete automation of the assay process makes them very convenient for clinical application.

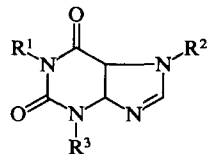
14

The immunoassay method developed by the Syva Corporation has been compared with the method using reversed-phase HPLC combined with detection by the fluorescence method.[72] It has been established that, in the determination of the content of compound **14** in the blood sera of patients receiving it, the enzyme immunoassay method yields values higher by a factor of 1.2 than the chromatographic method. An automatic system has been developed for the immunoassay with a fluorescence-labelled ligand, which makes it possible to determine compound **14** in the presence of other substances.[73]

Radioimmunoassay and enzyme immunoassay methods were developed in 1985 using the antiserum to the conjugate of 9-hemisucinylquinidine attached to BSA via 6-amino-n-hexanoic acid.[26] The ranges in which compound **14** can be determined by the radioimmunoassay and the enzyme immunoassay methods are 1 – 1000 ng and 0.1 – 10 ng. The radioimmunoassay method has been used for the screening of the clonal cultures of *C. ledgeriana* in analysis designed to determine compound **13**.[25]

The immune method based on the measurement of the degree of polarisation of fluorescence has been used to investigate the pharmacokinetics of compound **14**.[74] The rapid combined autofiltration – immunoenzyme and dialysis – immunoenzyme methods for the assay of compound **14** in the blood sera of patients yielded results which agreed well with those obtained by the autofiltration – liquid- chromatographic and dialysis – liquid-chromatographic methods.[75]

The immunoenzyme and immunofluorescence methods for the assay of compound **14** have come to be fairly widely used, principally in clinical practice.[76–78] An automatic system 'optimate', which makes it possible to assay compound **14** by the immunofluorescence method, has been developed and is being actively employed.[73]



5. Purine alkaloids

This group includes derivatives of xanthine ($R^1 = R^2 = R^3 = H$): caffeine **15** ($R^1 = R^2 = R^3 = Me$), theophylline **16** ($R^1 = R^3 = Me$, $R^2 = H$), and theobromine **17** ($R^1 = H$, $R^2 = R^3 = Me$). Caffeine is present in tea leaves and coffee beans, theobromine was first detected in cocoa beans, and theophylline was detected in tea.

The mechanism of the physiological activity of these alkaloids involves the inhibition of phosphodiesterase and the accumulation of an intracellular mediator — cyclic adenosine-3′,5′-monophosphate (cAMP).

Two groups of methods are used for the quantitative assay of xanthine derivatives: the immune methods and methods based on HPLC.[79]

The presence in the molecules of these compounds of a large number of functional groups makes it possible to obtain fairly readily immunogenic conjugates of these alkaloids with proteins.

15–17

a. Caffeine

Caffeine is a typical psychostimulator. It also excites cardiac activity, dilates coronary blood vessels, and intensifies the respiratory activity and diuresis.

Immunoassay methods for the determination of compound **15** are used nowadays only in medical practice — in particular, the method for the enzyme immunoassay of compound **15** in the serum is used in pediatrics.[80]

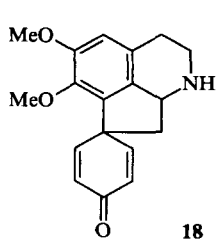
Results of assays of compound **15** in serum and plasma by the immunoenzyme and HPLC methods have been compared and it has been shown that they are virtually identical.[80, 81]

b. Theophylline

Theophylline exhibits a physiological activity similar to that of compound **15**, but its broncholytic and diuretic activities predominate.

The fairly wide use of compound **16** as a medicinal drug has promoted the development of a large number of immunoassay methods for this alkaloid. The immunoenzyme,[82–86] immunofluorescence,[73, 87–90] immunochromatographic,[91] and immunoturbidimetric[92, 93] methods, the immunochromatographic methods using apoenzyme reagent strips,[94–98] and an immunoenzyme method employing an enzyme encapsulated in liposomes[99] are most widely used nowadays. The 'Optimate' system, based on the immunofluorescence method, is used for the automatic assay of compound **16**.[73]

These methods have been used in the study of the pharmacokinetics of compound **16**,[100–102] in the determination of the content of compound **16** in dry blood spots,[83, 84] in whole blood,[97] in urine,[103] in saliva,[88] in blood serum,[82, 83, 93–95, 104–106] and in the plasma.[89–91, 107–111]



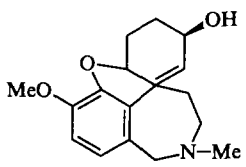
The influence of substances usually encountered in the specimens analysed on the results of the determination of compound **16** has been investigated.[108, 112–115]

Various immunoassay methods and the method based on the HPLC have been compared.[92, 98, 101, 104–107, 109–111] It has been established that the immunoenzyme method, the immune method based on the measurement of the degree of polarisation of fluorescence, and the method based on HPLC are best in terms of the accuracy and reproducibility of the results.[103, 109]

6. Proaporphine alkaloids

The structure of these alkaloids is based on that of aporphine.

Stepharine **18** is an alkaloid isolated from *Stephania glabra*. It exhibits a cholinesterase activity and is used in the treatment of diseases of the peripheral nervous system, myopathy, lateral amyotrophic sclerosis, and paresis of the facial nerve.

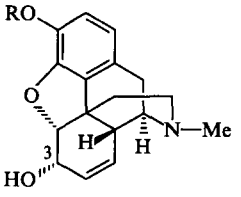


18

In order to obtain antibodies, compound **18** was treated with succinic anhydride and then with *N*-hydroxysuccinimide and *N,N'*-dicyclohexylcarbodiimide and was conjugated with BSA. The antibodies obtained with the aid of this conjugate were used in the development of a solid-phase enzyme immunoassay method with a sensitivity of 10 pg ml^{-1}. The method was used to assay compound **18** in a plant tissue culture and also for its determination in the blood of patients.[116]

7. Alkaloids of the physostigmine group

Galanthamine **19** is an alkaloid isolated from the tubers of the snowdrops *Galanthus woronowii* and *Galanthus nivalis*. The mechanism of its physiological activity is associated with the intensification of the influence of acetylcholine on the *n*-cholinergic synapses as a result of the inhibition of cholinesterase. It is used in medical practice to reduce the pressure within the eyeball and also for the treatment of certain nervous diseases and for the intensification of peristalsis on paresis of the intestine.



19

There exists a specific method for the radioimmunoassay of compound **19**. In order to obtain an immunogenic conjugate, the alkaloid **19** was treated with succinic anhydride and galanthamine 2-*O*-hemisuccinate was obtained and conjugated with BSA with the aid of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide. The method makes it possible to determine compound **19** in the range 0.5–100 ng.[117]

8. The poppy alkaloids

This group includes morphine **20**, codeine **21**, narcotine, papaverine **22**, thebaine, and about 20 other alkaloids.

R = H (**20**), Me (**21**)

a. Morphine

Morphine is the main alkaloid isolated together with 20 other alkaloids from the opium poppy (*Papaver somniferum*). Morphine belongs to the class of analgesic substances — narcotic analgesics. It also exhibits sedative and soporific activities, stimulates the smooth muscle, and at high concentrations induces vomiting and constipation, hinders diuresis, and inhibits the thermal regulation and respiration centres. It has been established that compound **20** influences specific receptors in the cortex of the cerebral hemispheres; it is widely used as an analgesic narcotic.

b. Codeine

Codeine also forms part of the composition of *P. somniferum*. It exhibits a weak narcotic activity and is widely used as an analgesic and also as an anti-cough preparation.

In view of the difficulties in the cross cultivation and selection of strains of *P. somniferum*, it was desirable to have a rapid method for the assay of compound **20**, which led at the beginning of the 1970s to the development of methods for the immunoassay of compound **20**.

Radioimmunoassay methods[28, 29, 118, 119] and methods based on the inhibition of haemagglutination[30, 120] were developed for the determination of compounds **20** and **21**. In all cases the immunogenic conjugate was obtained by the carboxymethylation of compound **20** at the hydroxy-group in the 3-position and by the attachment of the resulting derivative to the protein, as well as conjugation by the carbodiimide method. The antiserum to this conjugate was isolated from rabbit or guinea pig blood.

The most sensitive and specific method proved to be the radioimmunoassay employing the copolymer of L-Glu, L-Lys, L-Ala, and L-Tyr, to the ε-amino-groups of the lysine residues of which 3-*O*-carboxymethylmorphine had been attached and which had been [^{125}I]-labelled in the tyrosine residues, as well as the antiserum from the guinea pig blood. The range in which compound **20** can be determined is 0.05–5 ng. A disadvantage of this method[29] is the impossibility of distinguishing between compounds **20** and **21**. The method has been used to determine the lifetime of compound **20** in the blood[118] and also in the analysis of blood serum specimens taken in the case of the so called 'sudden death'. It has been shown that the results of the radioimmunoassay agree well with the results obtained by chromatographic methods.[29]

A homogeneous method for the enzyme immunoassay of compound **20**, based on the use a of conjugate of morphine with lysozyme and antiopiate antibodies, was developed at the beginning of the 1970s.[121, 122] This method makes it possible to determine compound **20** in the concentration range 0.5 to 3 μg ml^{-1}. Subsequently lysozyme was replaced by other enzymes (malate dehydrogenase and glucose-6-phosphate dehydrogenase), which made it possible to increase the sensitivity by a factor of 10.[123–125]

The antibodies to compound **20** were used to develop a method and a reagent set for the simultaneous automatic enzyme immunoassay of a number of narcotic preparations in urine microspecimens.[126] The concentration limit for the detection of compound **20** is 0.3 mg ml^{-1}.

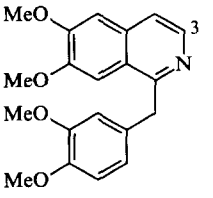
The enzyme immunoassay method has been used for the determination of compound **20** in specimens of the blood of persons who died as a result of the consumption of heroin.[127]

A brief communication about the development of methods for the radioimmunoassay of (*S*)- and (*R*)-reticuline, salutaridine, thebaine, and compounds **20** and **21** appeared in 1984. All the antisera obtained were highly specific and made it possible to determine the above substances in the range 0.01–10 ng.[128] These methods make it possible to investigate the pathways leading to the biosynthesis of the above alkaloids and to select plants or cell cultures in terms of the productivity of the biosynthesis of these alkaloids.

Methods for the immunoassay of compound **20** are used mainly in clinical practice.[129] An immunoassay method involving the use of indicator strips has been used successfully to detect compound **20** in urine.[130]

A method based on latex agglutination has found extensive application in the screening assay of opiates.[131]

A heterogeneous enzyme immunoassay method is also used for the detection of opiates.[132] Competitive solid-phase enzyme immunoassay of opiates makes it possible to attain a high sensitivity — up to 0.25 ng ml^{-1}. When the method is used in its qualitative version without instrumental enhancement, the sensitivity of the determination is 300 ng ml^{-1}, which is comparable to the sensitivity of the homogeneous enzyme immunoassay.



Information concerning the development of highly sensitive immunofluorescence methods for the assay of compound **20** in urine was published subsequently.[133, 134]

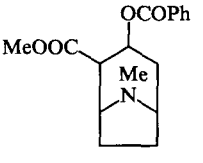
The Hofmann La Roche Company (Switzerland) produced a reagent set for a qualitative visual assay of opiates with a sensitivity of 300 ng ml^{-1}.[135]

Immunoassay methods are used for the determination of opiates in serum, urine, and saliva specimens as well as other human biological liquids.[135] There exists a highly sensitive method which makes it possible to determine compound **20** in hair;[136] the sensitivity reaches 0.2 ng ml^{-1} under these conditions.

c. Papaverine

Papaverine **22** is also one of the most valuable alkaloids isolated from the poppy plant. It exhibits spasmolytic and moderate vasodilating activities and increases the consumption of oxygen by the myocardium. Papaverine is administered in the hypertonic state, in stenocarditis, and in the treatment of the spasms of the coronary and brain blood vessels, the smooth muscle of the abdominal cavity, and other diseases.

22



A conjugate of synthetic 3-aminopapaverine has been used to obtain antibodies to compound **22**.[137] For this purpose, 3-aminopapaverine was treated with glutaric anhydride and converted into 1-(3,4-dimethoxybenzyl)-3-*N*-(4-carboxybutyryl)-amino-6,7-dimethoxypapaverine, which was attached to BSA with the aid of *N*-hydroxysuccinimide and *NN'*-dicyclohexylcarbodiimide. A solid-phase enzyme method for the immunoassay of compound **22** was developed on the basis of the antibodies obtained.[138] Its sensitivity is 10^{-6} g ml^{-1}.

9. Alkaloids of the cocaine group

These alkaloids are present in the leaves of the coca plant (*Erythroxylon coca*). Their structure is based on the bicyclic tropane skeleton and in terms of this feature they can be included among tropane alkaloids.

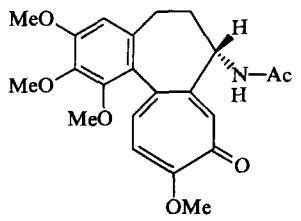
As in the case of the purine alkaloids, the large number of functional groups in the molecules of these alkaloids makes it possible to obtain readily immunogenic conjugates with proteins.

Cocaine **23** exhibits a powerful local analgesic activity and is a local anaesthetic. It has a paralysing effect on the parasympathetic nervous system.

23

There exists at present a fluorescence-polarisation immunoassay method which makes it possible to determine compound **23** in urine at a concentration of 1 mg ml^{-1} and above.[40]

As for other narcotics, methods for the immunoassay of compound **23** and its metabolites are used virtually only in medical practice.[139]



The attempts to simplify and accelerate the assay of narcotics have led to the appearance of methods involving the simultaneous assay of a broad spectrum of narcotics. Mixtures of antibodies to each substance or group of substances are used in these procedures. Among them, one may note the fluorescence-polarisation method which permits the simultaneous determination of the metabolites of compound **23**, amphetamine, and certain barbiturates in urine,[39] as well as an immunoenzyme method for the simultaneous assay of amphetamine, quinalbarbitone, oxazepam, benzoylecgonine, methadone, methaqualone, compound **20**, phencyclidine, phenytoin, propoxyphene, and nortriptyline in urine.[126]

Methods for the determination of narcotics proposed by the Syva Corporation and based on homogeneous immunoassay have come to be widely used in narcological practice.[98, 121, 124, 136, 140] Subsequently these methods have been automated.[140]

10. Alkaloids of the colchicine group

Colchicine **24** and colchamine are present together with other alkaloids in the pods of plants of the *Colchicum* and *Merendera* genera.

Colchicine is widely used in selection procedures as an agent which induces the doubling of the number of chromosomes and the formation of polyploid forms of plants and also in the study of the cytoskeleton of plants. Being a poison with a neuroparalytic activity, it is used at the same time for the treatment of the cancer of the gullet and skin and as an anticonvulsant and is in addition the best drug for the treatment of Mediterranean fever available at present.

24

A method for the radioimmunoassay of compound **24** was developed in 1975 using a conjugate of *N*-desacetylthiocolchicine, attached by the carbodiimide method to BSA, and [^{3}H]-**24**. The method makes it possible to determine compound **24** in the range 5–50 ng.[22] Cross reactions with *N*-desacetylthiocolchicine and *N*-desacetyl-*N*-colchicine (8%) have been noted. A method has been developed for the assay of compound **24** in human blood serum; it has not been used for the determination of compound **24** in plants.

A similar method, based on the use of monoclonal antibodies, which made it possible to increase appreciably the specificity of the assay, was developed subsequently.[141]

IV. Conclusion

Immunochemical methods for the assay of alkaloids are becoming increasingly popular. They are superior to chromatographic methods as regards sensitivity and speed of preparation of the analytical samples and are scarcely inferior to them as regards accuracy and reproducibility.

In the development of methods for the immunoassay of alkaloids, it is possible in most cases to obviate the difficulties associated with the preparation of immunogenic conjugates of the alkaloids with proteins and to obtain fairly specific antisera.

The methods for the radioimmunoassay of alkaloids, which were in the forefront in the 1960s–1970s, yielded the leading position in the 1980s to the enzyme immunoassay method; immunofluroescence methods are beginning to be used with increasing frequency.

The widest field in which immunoassay methods for alkaloids are used involves the measurement of their concentrations in the physiological fluids of patients receiving alkaloids preparations. This is associated both with the necessity for the rapid and accurate monitoring of the course of treatment and with the study of the pharmacokinetics and metabolism of alkaloids.

Rapid and accurate methods for the assay of alkaloids exhibiting narcotic properties are important from both medical and criminological points of view. Here too immunoassay methods are being employed to an increasing extent.

Since in many instances alkaloids are still being obtained from plant raw material, it is frequently necessary to know their content in such material. However, the lack in most countries of norms for the content of biologically active substances in plant raw material is an inhibiting factor in the development of immunoassay methods for plants. However, in a number of instances immunoassay methods have been used in studies on the biosynthesis of certain alkaloids in plants.

The deficiencies of the traditional procedure for the isolation of alkaloids from plant raw material—the dependence of the content of the alkaloids on the climatic and weather conditions, the difficulties in the collection of the plants (for plants growing under wild conditions), and the need for fertile soil (for cultivated plants)—have led to the active development at the present time of biotechnological methods for the synthesis of alkaloids in plant cell and tissue cultures. It is in the field of the monitoring of the content of alkaloids in such cultures that the immunoassay methods are being increasingly widely used and are replacing the chromatographic methods traditionally employed for such purposes.

VII.	Conclusion	835

Abstract. The principal advances and trends in the application of diazomethane as a methylenating agent in synthetic chemistry using transition and non-transition metal compounds as catalysts are surveyed and analysed. The catalytic reactions of diazomethane with olefins, acetylenes, aromatic compounds, ketones, alcohols, and amines are examined. A systematic account is given of data concerning the influence of the structure of the initial substrates and of the nature of the catalyst components on the regio- and stereo-selectivity of the reactions considered. The possibilities of the catalytic conversion by diazomethane (generated *in situ*) of unsaturated compounds into cyclopropane derivatives are considered. The bibliography includes 284 references.

I. Introduction

Diazomethane, which is the simplest representative of diazo-compounds, was first obtained by Pechmann[1] in 1894 and since then it has been firmly established as one of the popular reagents in synthetic organic chemistry, which are widely used to effect under mild conditions reactions involving the conversion of unsaturated compounds into cyclopropane derivatives, the conversion of carbonyl compounds into higher homologues, and the methylation of carboxylic acids, alcohols, and phenols. The present review is devoted mainly to the reactions of diazomethane with various organic compounds which occur as a rule in the presence of homogeneous metal complex catalysts.

Depending on the conditions, diazomethane can be regarded as an acid or base, as an electrophile or a nucleophile, and as a 1,3-dipole or a source of carbene (methylene). The linear structure of diazomethane has been established by electron diffraction[2] and by microwave spectroscopy.[3] It has a dipole moment of 1.4 D and carbon–nitrogen and nitrogen–nitrogen bond lengths of 0.132 and 0.112 nm respectively. These values are averages of the C–N and C=N bond lengths and the N=N and N≡N bond lengths respectively. Thus the structure of diazomethane can be represented by the following resonance structures, among which structures **1a** and **1b** make the greatest contribution:

1a **1b** **1c** **1d** **1e**

Other structural characteristics and spectroscopic data for diazomethane have been fairly fully presented in another review.[4]

The constant interest of investigators in diazomethane despite its high toxicity and explosive nature is due to the fact that it is a unique source of the simplest carbene — methylene, the high reactivity of which makes it possible to regard it as a promising one-carbon synthon for the creation of non-traditional chemical technologies. Furthermore, the development of the chemistry of diazomethane in relation to the problem of the synthesis and investigation of the reactivity of methylene has assisted in many respects in the understanding and determination of the mechanisms of important processes such as the metathesis of olefins, the Fischer–Tropsch reaction, the activation of alkanes, etc.[5–7] Finally, the majority of the methods of synthesis of diazomethane itself are based on the use of readily available compounds, in particular *N*-methyl-*N*-nitrosoamides, and extremely simple procedures for its generation.[4,8]

Diazo-compounds can be decomposed by three main methods — thermal, photochemical, and catalytic.[9,10] However, the first two are relatively unsuitable for preparative purposes, primarily because such processes are unsafe and there is an increased likelihood of side reactions, for example, those involving insertion in various C–H bonds. The progress in the chemistry of diazomethane during the last 10–15 years has been indissolubly linked with the application of metal complex

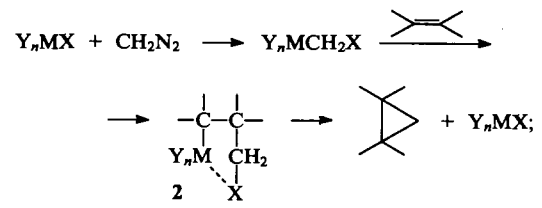
catalysts, which not only promote the formal generation of methylene under mild conditions but also make it possible to regulate its reactivity within wide limits. The results have made, in particular, a significant contribution to the development of modern highly efficient methods of synthesis of many cyclopropane derivatives from readily available olefins and the factual data accumulated make it possible to elucidate in greater depth the mechanistic aspects of the catalytic cyclomethylenation of various unsaturated compounds.

It is noteworthy that the use of diazomethane in catalytic reactions involving the conversion of various unsaturated compounds into cyclopropane and cyclopropene derivatives has developed virtually in parallel with the application for such purposes of well-known aliphatic diazo-compounds such as diazoacetic acid esters. Whereas in the 1950s–1960s, mainly copper compounds were used as the traditional catalysts for the decomposition of the above diazo-compounds, since the middle of the 1970s catalysts based on rhodium and palladium have begun to be vigorously introduced into laboratory practice. A series of monographs and reviews[10–22] devoted to the synthetic possibilities of the catalytic methods for the conversion of unsaturated substrates into cyclopropane derivatives with the aid of diazo-compounds and to the consideration of the probable mechanisms of these processes appeared during this period. However, the majority of the publications do not yield a complete picture concerning the use of metal complex catalysis in the chemistry of diazomethane and do not deal with the specific features of diazomethane itself which distinguish it from other aliphatic diazo-compounds.

On the basis of the factual data accumulated, an attempt is made in the present review to present as fully as possible the advances and prospects in the application of metal complex catalysis in the chemistry of diazomethane.

II. Interaction of diazomethane with metal salts and complexes



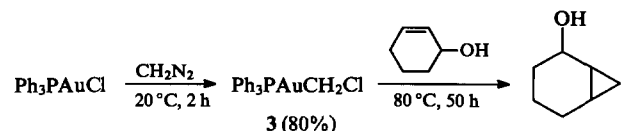
Diazomethane readily decomposes on treatment with many transition and non-transition metal compounds.[15,22–26] This includes its decomposition on the active surface centres of pure metals (Ni, Pd, Cu, Fe, Co, Ru, U),[27–28] heterogeneous catalysts, and various sorbents,[29,30] which by no means always involves the transfer of methylene to the double bonds of olefins or other substrates and this process is extremely sensitive to the nature of both the substrate and the catalyst. In most cases the decomposition of CH_2N_2 is accompanied by the liberation of ethylene and other volatile products, although it can also lead to the preferential formation of polymethylene.[31–33] For example, the dediazotisation of CH_2N_2 by nickelocene yields polymethylene almost quantitatively even in the presence of olefins.[31]

The interaction of CH_2N_2 with compounds of the majority of the elements in the Periodic Table with the properties of Lewis acids and primarily with their halides leads to the initial formation of organometallic (organoelement) compounds via the insertion of methylene in M–X bonds.

$$MX_n \xrightarrow{CH_2N_2} MX_{n-m}(CH_2X)_m \xrightarrow{CH_2N_2} M(CH_2X)_n.$$

According to data surveyed in a number of reviews[15–23], Zn, Cd, Hg, Al, In, Tl, Sn, Pb, Sb etc. interact via this mechanism and compounds of the Group IV and V elements in the highest oxidation states, for example Sn(IV), Pb(IV), and Sb(V), are initially reduced by diazomethane to the corresponding Sn(II), Pb(II), and Sb(III) compounds.

The conversion of olefins into cyclopropane derivatives by halomethylmetal compounds of this kind has been investigated most thoroughly for Zn and Al derivatives:[34–36] these compounds are relatively unstable and are in essence intermediates capable of adding to the double bond of olefins. Since the three-carbon ring is formed stereospecifically, the reaction mechanism implies the selectivity of the stages involving the addition of the halomethyl derivative and the γ-elimination of the metal halide, as well as the stability of the steric configuration of the organometallic intermediate **2**.

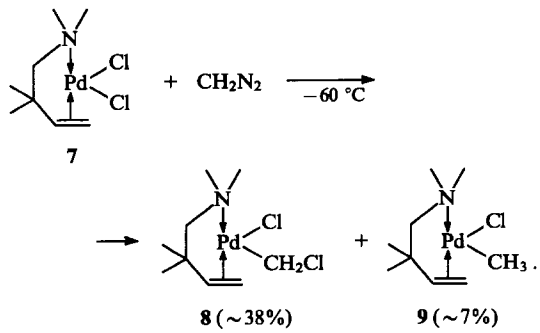


2

Y = Alk, Ar, Hal; X = Cl, I.

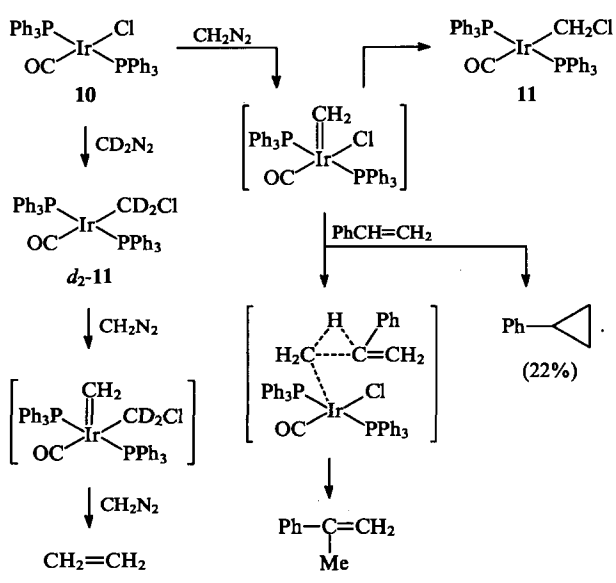
Thus, according to Hoberg's data,[36] diethylaluminium iodide reacts with CH_2N_2 in pentane at −80 °C with the evolution of nitrogen and the formation of crystalline Et_2AlCH_2I. By interacting with olefins, this compound affords the corresponding cyclopropane (for example, norcarane in the case of cyclohexene). Zinc compounds react via the same mechanism and the regeneration of the initial metal halide makes it possible to use it in catalytic amounts. The conversion of olefins into cyclopropane derivatives by CH_2N_2 in the presence of ZnX_2 is one of the versions of the Simmons–Smith method, various aspects of which have been considered in another review.[37]

It is noteworthy that virtually all the reactions involving the conversion of olefins into cyclopropane derivatives by diazomethane in the presence of zinc- or aluminium-containing catalysts are carried out under anhydrous conditions—mainly in ether. A disadvantage of the above catalysts is their high reactivity in relation to the initial olefins, which induces their oligomerisation or conversion into the corresponding halides.



The insertion of methylene, generated from CH_2N_2, in the M–X bond occurs also when transition metal compounds are used. In certain cases, it was then possible not only to isolate the products of such insertion but also to demonstrate the possibility of converting olefins into cyclopropane derivatives by such products. Thus, according to Nesmeyanov et al.,[38] the interaction of Ph_3PAuCl with CH_2N_2 at 20 °C leads to the chloromethyl derivative **3**, which is capable of subsequently methylenating cyclohexenol to form 2-hydroxynorcarane **4**, albeit in low yield.

Halomethyl derivatives have also been obtained when complex palladium and platinum dihalides were used. The interaction of the platinum complex **5** with an excess of CH_2N_2 then affords a high yield of the bishalomethyl derivative **6**,[39] while the palladium complex **7** unexpectedly affords also the methyl complex **9** together with the chloromethyl derivative **8**.[40]



$$(COD)PtX_2 + CH_2N_2 \longrightarrow \underset{\mathbf{5}}{(COD)Pt(CH_2X)_2} \xrightarrow{PPh_3} \underset{\mathbf{6}}{(Ph_3P)_2Pt(CH_2X)_2};$$

COD =  ; X = Cl, I.

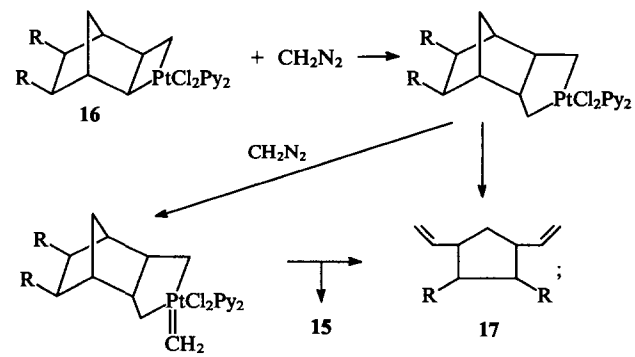
7 **8** (~38%) **9** (~7%)

It is noteworthy that, apart from the halomethyl derivatives of transition metals, products may be obtained in which the methylene fragment is coordinated to the metal atom. Thus the addition of CH_2N_2 to the iridium complex **10** at −30 °C leads to the adduct **11** (or d_2-**11**).[41] The formation of ethylene on subsequent addition of CH_2N_2 to the deuteriated complex d_2-**11** as well as the formation of phenylcyclopropane and α-methylstyrene on interaction of compound **11** with styrene have been attributed[41] in this instance to the involvement in the reaction of the methylene complexes of pentacoordinate iridium.

The complex chromium halides **12** interact with CH_2N_2, affording a high yield of the corresponding halomethyl derivatives **13**, which are converted in the presence of $AgBF_4$ into the cationic complexes **14**.[42] The attempt to convert cyclohexene into a cyclopropane derivative by compounds **14** proved successful only in the case of the pentamethylcyclopentadienyl ligand, the yield of norcarane not exceeding 5% under these conditions.

$$\underset{\mathbf{12}}{(C_5R_5)Cr(NO)_2X} \xrightarrow{CH_2N_2} \underset{\mathbf{13}}{(C_5R_5)Cr(NO)_2CH_2X} \xrightarrow{AgBF_4} \left[(C_5R_5)\overset{CH_2}{\overset{\|}{Cr}}(NO)_2\right]^+ BF_4^-;$$

14



R = H, Me; X = Cl, Br.

The possible methods of the synthesis of cationic methylene complexes of transition metals not involving the use of CH_2N_2 as well as certain reactions with transfer of the methylene fragment from these complexes to the substrate, including the conversion of olefins into cyclopropane derivatives by such complexes, have been considered in a review.[43]

In contrast to complexes **5**, the pyridineplatinum complex, formed on controlled addition of pyridine to bis(ethyleneplatinum dichloride), interacts with a threefold excess of CH_2N_2, affording not the halomethyl derivatives of platinum but two enantiomeric forms of the ylide **15**.[44] The same compound is obtained also in the reaction of CH_2N_2 with the derivatives of platinacyclobutanes **16**, but in this case the main process reduces, according to Jennings et al.,[45] to the insertion of methylene into the Pt−C bond with subsequent conversion of the resulting platinacyclopentanes into *cis*-divinylcyclopentanes **17**.

$$[C_2H_4PtCl_2]_2 \xrightarrow{1\text{ eq. Py}} C_2H_4PtCl_2Py \xrightarrow[1\text{ eq. Py}]{3\text{ eq. }CH_2N_2} PyCl_2\overset{-}{P}t{-}CH_2{-}\overset{+}{P}y;$$

15 (95%)

R = H, R−R is a chemical bond or CH_2.

The dediazotisation of CH_2N_2 by stable methoxycarbene complexes of chromium and tungsten is accompanied by the transfer of methylene to the carbene ligand, which results in the formation of the vinyl ethers **18** in satisfactory yields.[46,47]

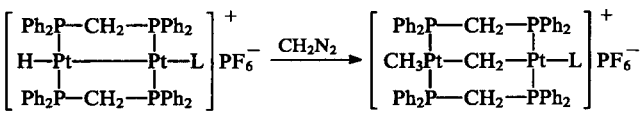
$$(CO)_5M{=}C(OMe)R + CH_2N_2 \longrightarrow H_2C{=}C(OMe)R$$

18

M = W; R = Ph (97%), Me (93%),  (80%);

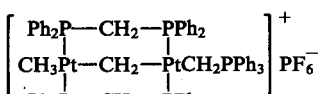
M = Cr; R =  (78%).

Copper and palladium compounds constitute another group of transition metal compounds catalysing the decomposition of CH_2N_2 and ensuring the successful transfer of methylene to the substrate (in particular, the conversion of



olefins into cyclopropane derivatives under mild conditions). The involvement of carbene complexes of metals in these reactions with the methylene generated from CH_2N_2 has so far been only postulated. However, despite the absence of direct experimental evidence for the formation of these complexes under the real conditions of the conversion of olefins into cyclopropane derivatives by CH_2N_2, their participation in the reactions is indicated by the existence of stable carbene complexes of other transition metals[6,43,48] as well as the detection of complexes of CH_2N_2 and methylene with atomic copper at 11 K in an argon matrix.[49]

Catalysts based on transition metals can be regarded as centres on which CH_2N_2 is coordinated and methylene is generated from it. The nature of the metal and the ligand environment of the central catalyst atom, which influence the strength of the bond linking the coordinated methylene, make it possible to vary its reactivity under these conditions, which leads in its turn to the possibility of regulating the regio- and stereoselectivity of the addition of methylene to various substrates.



Finally, the reactions of CH_2N_2 with di- and poly-nuclear transition metal complexes, leading to the formation of μ-methylene complexes as a result of the addition of methylene to the metal–metal bond, are of independent interest:

Compound	Ref.
$(\mu\text{-}CH_2)[C_5H_5(NO)Fe]_2$	50
$(\mu\text{-}CH_2)[C_5Me_5(CO)Co]_2$	51
$(\mu\text{-}CH_2)[(C_5H_4Me)Mn(CO)_2]_2$	52, 53
$(\mu\text{-}CH_2)[C_5Me_5(CO)Rh]_2$	54, 55
$(\mu\text{-}CH_2)(\mu\text{-}CF_3C{\equiv}CCF_3)[ClRh(Ph_2PCH_2PPh_2)]_2$	56
$(\mu\text{-}CH_2)[ClPt(Ph_2PCH_2PPh_2)]_2$	57
$(\mu\text{-}CH_2)H_2Os_3(CO)_{10}$	58
$(\mu\text{-}CH_2)Os_3PtH_2(CO)_{10}\{P(C_6H_{11})_3\}$	59

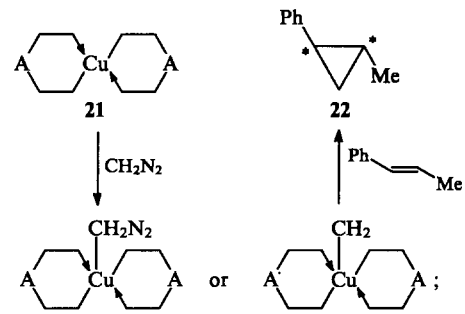
The structural features of the μ-methylene complexes of transition metals have been analysed and the methods of their synthesis have been described in a review.[60] It is of interest to note that in the case of the hydridoplatinum complexes **19**, the insertion of CH_2 into the Pt–H bond with formation of complexes **20**, and into the Pt–P bond on interaction of compound **19c** with an excess of diazomethane, was observed simultaneously with its insertion in the Pt–Pt bond.[61]

19 **20a, b**

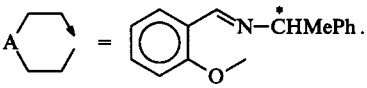
20c

L = CO (**a**), PMe_2Ph (**b**), PPh_3 (**c**).

The dinuclear complex $Mn_2(CO)_{10}N_2CH_2$, in which the Mn atoms are linked by a nitrogen bridge, while the methylene fragment is attached to one of the nitrogen atoms, was synthesised by the reaction of CH_2N_2 with $Mn(CO)_5H$ in tetrahydrofuran (THF) at −85 °C.[62]



It is noteworthy that the interest in the stable μ-methylene complexes of transition metals has been mainly induced by the possibility of the involvement of such complexes as intermediates in the Fischer–Tropsch reaction. Unfortunately the reactions involving the transfer of the methylene fragment from these complexes to various substrates have been scarcely investigated.

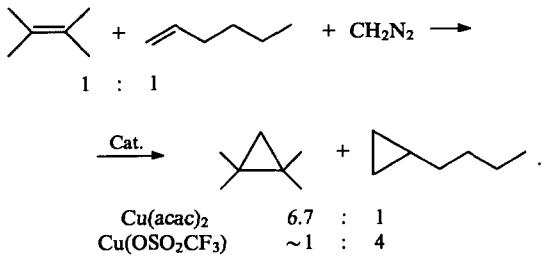


III. Catalytic conversion of unsaturated compounds into cyclopropane derivatives

1. The mechanism of the catalytic conversion of olefins into cyclopropane derivatives by diazomethane

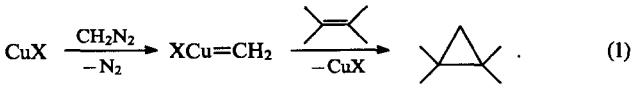
Despite the abundance of compounds inducing the decomposition of diazomethane, copper and palladium compounds are the commonest and most effective agents for the catalytic conversion of olefins into cyclopropane derivatives by diazoalkanes. The experimental data accumulated hitherto have shown[63–66] that, among copper compounds, the salts of copper(I) are catalytically active in these reactions. The copper(II) salts, in particular $CuCl_2$ or $Cu(OSO_2CF_3)_2$, are initially reduced by diazomethane to the corresponding univalent copper compounds.[34,65]

According to Nefedov et al.,[66] when $Cu(acac)_2$ is used for the conversion of alkenes into cyclopropane derivatives, it is initially reduced by diazomethane to the relatively unstable Cu(acac), which is characterised primarily by the disappearance of the initial colour of the catalyst as a consequence of the conversion of Cu(II) into Cu(I). In view of this, one can assume that copper(I) compounds with one singly charged chelate anion are catalytically active in the case of other copper chelate compounds, in particular those with optically active ligands. Nevertheless, the pentacoordinate state of copper(II) has been considered[67] as an intermediate and the induction of the optical activity in the resulting cyclopropane **22** (yield 62%, optical yield 8%) is explained by the influence of the two optically active ligands in the initial complex **21**.

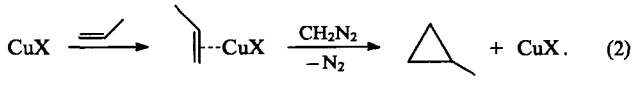


When palladium(II) compounds are used as the catalysts in the dediazotisation of CH_2N_2, a catalytically active species involving a change in the valence state of the palladium is also formed initially. Thus palladium halides or acetate are reduced to zerovalent palladium, which is either precipitated as a black deposit or is present in solution in the form of complexes stabilised by suitable ligands.[68] Under particular conditions, certain olefins, affording the corresponding π-olefin complexes, can also play the same role. However, the thermal stability of zerovalent palladium complexes is as a rule low[69] and depends significantly on the nature of the double bonds in the unsaturated compound. Inner complexes of palladium, for example $Pd(acac)_2$, apparently form more complex catalytically active structures with formally univalent palladium.[25]

There are two possible mechanisms of the catalytic conversion of olefins into cyclopropane derivatives by diazocompounds, in particular by diazomethane, in the presence of copper and palladium derivatives, the principal difference between which consists in the different sequences of the stages involving the interaction of the catalyst with the diazocompound and the olefin.[17,65,70,71]

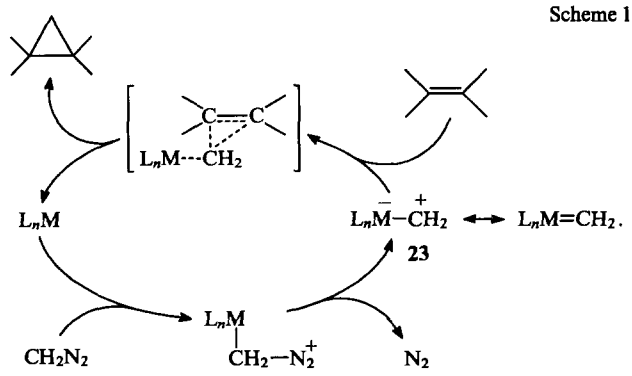


In relation to the conversion of mono- and tetra-substituted alkenes into cyclopropane derivatives, Salomon and Kochi[65] showed that regioselectivity in the conversion of various double bonds into cyclopropane groups differs depending on whether copper acetylacetonate or triflate is used as the catalyst. The more substituted double bond is converted into a cyclopropane group in the presence of $Cu(acac)_2$, whereas in the presence of $Cu(OSO_2CF_3)_2$ the terminal double bond undergoes such conversion.



On these grounds, it was claimed that the change in the basicity of the anion affects the ability of the copper ion to form π-complexes with particular double bonds of olefins and is therefore capable of altering the sequence of the stages in the interaction of the catalyst with the diazo-compound and the olefin.

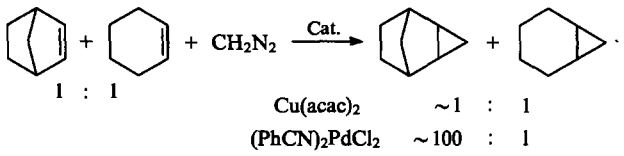
According to the first and commonest mechanism of the conversion of olefins into cyclopropane derivatives by diazoalkanes, a complex between the catalyst and the diazo-compound is formed initially. This is followed by the formation of a complex with the carbene, after which the double bond of the unsaturated compound is converted into a cyclopropane group by this complex.[17,65,70,71]



According to the other mechanism, a π-complex of the active form of the catalyst with the unsaturated compound is formed initially, interacting subsequently with the diazo-compound.[17,65,70]

In our view, the conversion of olefins into cyclopropane derivatives in the presence of copper compounds should be considered within the framework of one mechanism, because the key stage in both cases is the generation of the carbene complex (Scheme 1). The electrophilicity of the metal (Cu^+) induces, by analogy with the protonation of diazo-compounds, a shift of electron density towards the formation of an unstable diazonium cation, which readily eliminates a nitrogen molecule. The electrophilicity of the carbene species is in its turn largely determined by the contribution of the polarised structure **23**. Next, this complex reacts preferentially either with the more nucleophilic tetraalkyl-substituted double bonds, if the catalyst is incapable of effecting selectively the coordination of any one of the double bonds, or with monosubstituted double bonds. The latter reaction is less vigorous, but such bonds are present in excess in the coordination sphere of the metal as a consequence of complex formation. Here one should note that the regioselectivity of the conversion of double bonds into cyclopropane groups in the presence of copper catalysts is not high and the observed differences are of the same order of magnitude.

Scheme 1



On the other hand, the effectiveness of the cyclopropane formation reaction is influenced very greatly in both cases by the competing side reaction between the methylene complex and yet another diazomethane molecule. This process involves the intermediate formation of organocopper compounds, which readily decompose with liberation of active metallic copper on which unsaturated compounds are scarcely converted into cyclopropane derivatives by diazomethane.[66] Obviously the ease of such reactions depends both on the nature of the olefin to be converted into a cyclopropane derivative and on the nature of the catalyst. The probability of the insertion of the methylene generated into the Cu−X bond of the catalyst is then found to be highest for nucleophilic anions. Thus, in the case of CuCN or CuI, this side reaction apparently plays a dominant role, which virtually rules out the possibility of the transfer of methylene to the olefin.[66] Furthermore, in order to reduce the probability of side reactions in catalysis by copper compounds, a very slow addition of CH_2N_2 to a mixture of the olefin and the catalyst is essential.

Within the framework of the mechanism considered, the possibility of the reverse polarisation of the carbene complex $L_nM{=}CH_2 \longleftrightarrow L_nM^+ - {}^-CH_2$ has been postulated in order to account for the preferential conversion of the electron-deficient double bond into a cyclopropane group.[72] Thus, in the interaction of CH_2N_2 with methyl acrylate, styrene, cyclohexene, and hex-1-ene, catalysed by zerovalent nickel complexes, the formation of a cyclopropane adduct was observed only for methyl acrylate. However, in such cases one must not apparently fail to take into account the active formation of complexes between the electron-deficient alkenes themselves and the central atom of the catalyst, which can influence significantly the nature of their interaction with CH_2N_2. The conversion of unsaturated compounds into cyclopropane derivatives by diazomethane in the presence of zerovalent nickel and especially zerovalent palladium complexes, which exhibit a series of significant and fundamental differences from the catalysis by copper compounds, should in fact be regarded as an alternative mechanism, in which the initial formation of π-olefin complexes is indeed an important stage of the entire process.

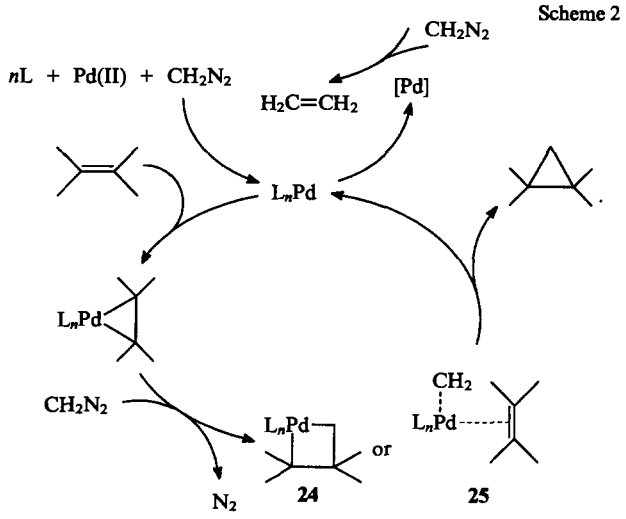
In contrast to the copper compounds, catalysts based on palladium compounds display an extremely high regio-selectivity in the conversion of individual double bonds into cyclopropane groups. This has no analogue among other methods for the conversion of unsaturated compounds into cyclopropane derivatives (without taking into account the influence of steric factors). The use of various palladium compounds as catalysts under these conditions hardly affects the regioselectivity of the cyclopropane formation reaction.

Instances of reactions exhibiting different stereoselectivities in the conversion of the same cycloolefins into cyclopropane derivatives under the influence of copper or palladium catalysts have also been observed (see Section III.3.b).

Finally, in contrast to copper catalysts, the conversion of double bonds into cyclopropane groups in the presence of palladium compounds proceeds without special complications up to the total conversion of the olefin into the corresponding cyclopropane even when the order in which the reactants are mixed is altered, for example when the catalyst is added to a mixture of the unsaturated compound and an excess of CH_2N_2.

Thus the results show that the mechanism of the action of palladium catalysts differs significantly from that of the catalysis of the cyclopropane formation reaction by copper compounds.

As mentioned above, the palladium compounds used as catalysts are initially reduced by diazomethane to low-valence palladium complexes stabilised in solution by suitable olefin ligands. In contrast to the olefin copper(I) complexes, where the coordinated ligand undergoes only slight changes compared with the initial olefin, in the π-olefin complexes of zerovalent palladium considerable changes occur in the coordinated ligand: the double bond is lengthened, the bond angles of the substituents are altered, and there is intense reverse donation of electrons from the metal to the olefin.



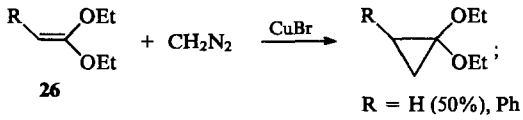
Thus the observed high selectivity in the conversion of various double bonds into cyclopropane groups by diazomethane in the presence of palladium compounds is undoubtedly due to their high selectivity in the formation and stabilisation of π-olefin complexes of zerovalent palladium.[68] According to Green et al.,[69] these complexes contain three equivalent olefin ligands. Furthermore, one can imagine two versions of the interaction of the π-olefinpalladium complexes with CH_2N_2.

In the first case, CH_2N_2 reacts directly with the polarised Pd–C bond of the π-olefin complex, affording the unstable palladiacyclobutane **24**, from which the cyclopropane adduct is eliminated and the initial π-olefin complex is regenerated under the influence of the next olefin molecule. Other complex-forming groups, for example the triphenyl phosphite or acetylacetonate groups, can also be present under these conditions as one or two ligands.

In the second version, CH_2N_2 substitutes one of the olefin ligands, eliminating the N_2 molecule and affording the metal–olefin–carbene complex **25**, from which the cyclopropane adduct is obtained either directly or via the palladiacyclobutane intermediate **24** (Scheme 2). The involvement of the latter in the reaction actually makes it possible to account for certain regio- and stereo-specific features of the conversion of olefins into cyclopropane derivatives by diazomethane in the presence of palladium catalysts. The existence of both metal–olefin–carbene complexes and metallacyclobutanes is now known.[73,74] However, the involvement of these intermediates in the conversion of olefins into cyclopropane derivatives, catalysed by copper and palladium compounds, is as yet tentative.

Unfortunately, under real experimental conditions, the yields of the cyclopropane adducts are determined not only by the contributions of the above mechanisms of the cyclopropane formation reaction but also by the possibility of the occurrence of side reactions associated primarily with the change in the active form of the catalyst. Thus the principal cause of the loss of catalytic activity by both copper and palladium compounds in the cyclopropane formation reaction is the liberation of the free metal and, as noted above, in the former case this is determined by the ease of the formation and α-decomposition of the organocopper intermediates, whilst in the latter it is due to the use of olefins with a low complex-forming capacity. The

Scheme 2



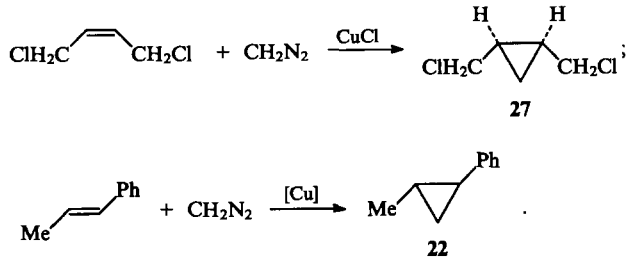
principal product of the decomposition of CH_2N_2 under these conditions is ethylene, which means that even the use of CH_2N_2 in manyfold excess does not lead to the complete conversion of olefins into the corresponding cyclopropane adducts.

2. Conversion of olefins into cyclopropane derivatives by diazomethane in the presence of copper catalysts

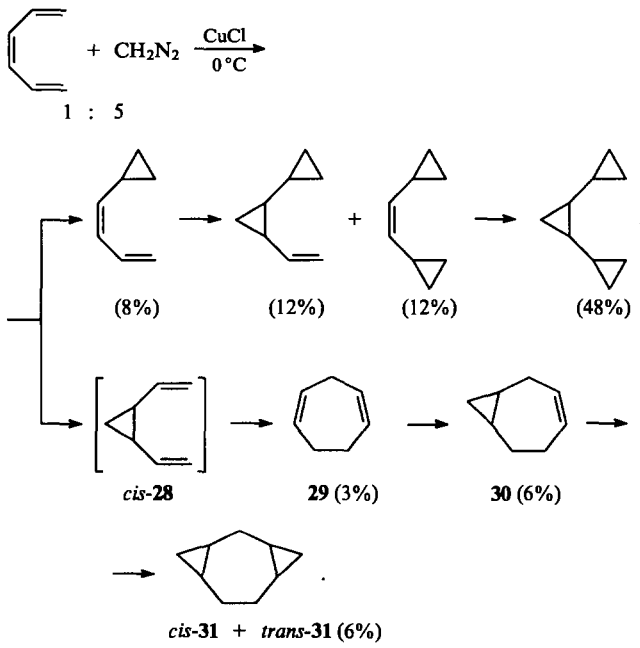
Copper compounds, in particular, CuCl and CuBr, were some of the first and commonest catalysts of the conversion of olefins into cyclopropane derivatives by diazomethane. Universality and the ability to catalyse the conversion of monosubstituted and polysubstituted olefins of different structure into cyclopropane derivatives are characteristic features of the above catalysts. In the copper salt-catalysed decomposition of CH_2N_2, the possibility of side reactions of the initial olefins and the resulting cyclopropanes is almost completely ruled out and there is also no insertion of the methylene fragment into the C–H bonds of these compounds.[11,12,71] However, the degree of conversion of olefins into cyclopropanes varies within wide limits even in the presence of an excess of the added diazomethane and depends significantly on the nature of the double bonds and the experimental conditions.

a. Conversion of unsaturated aliphatic compounds into cyclopropane derivatives

The conversion of unsaturated compounds into cyclopropane derivatives by diazomethane using copper catalysts was first achieved in 1959 by Dull and Abend,[75] who investigated the interaction of CH_2N_2 with ketene acetals **26** in the presence of CuBr in hexane.



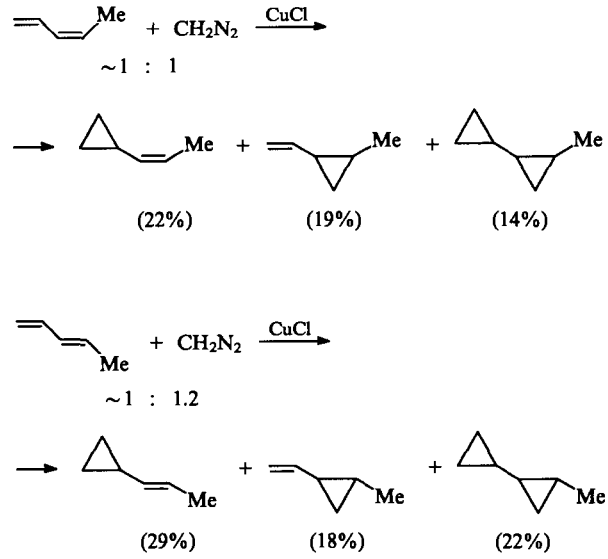
26



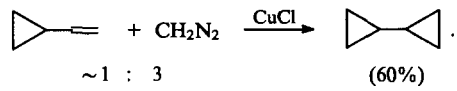
R = H (50%), Ph (12%).

Numerous studies, in which the method involving the catalytic conversion of multiple bonds into cyclopropane groups by diazomethane in the presence of copper compounds had been applied to a wide variety of unsaturated compounds containing both isolated and conjugated double bonds, were published in the 1960s. In order to eliminate or diminish the amount of solvent employed, particularly in the conversion of polyene compounds into polycyclopropane derivatives, which requires a large amount of CH_2N_2, the Gaspard–Roth method was frequently resorted to.[76] It consists in passing CH_2N_2 diluted with an inert gas into the olefin or its solution in a saturated hydrocarbon containing a catalytic amount of the copper salt at a temperature of about 0 °C.

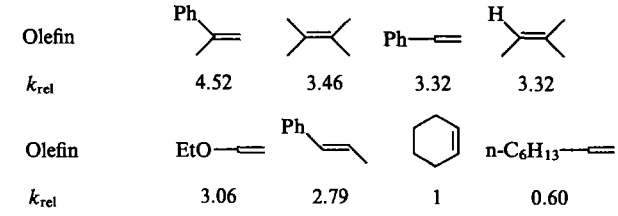
The catalytic conversion of olefins into cyclopropane derivatives by diazomethane in the presence of various copper compounds proceeds stereospecifically with retention of the configuration of the initial unsaturated compound. Thus the interaction of CH_2N_2 with *cis*-1,4-dichlorobut-2-ene [77] in the presence of CuCl leads exclusively to *cis*-1,2-bis(chloromethyl)-cyclopropane **27**, while the conversion of *trans*-propenylbenzene into cyclopropane [67] in the presence of the copper complex **21** leads to *trans*-2-methyl-1-phenylcyclopropane **22**.



The regioselectivity of such reactions is as a rule low, which has been noted in relation to the conversion of a highly unsaturated hydrocarbon, namely hexa-1,3,5-triene, into a cyclopropane derivative.[76] Thus the interaction of *cis*-hexatriene with CH_2N_2 in the presence of CuCl leads to the formation of all the possible products of the addition of methylene to the double bonds in both the initial triene and in the mono- and di-adducts formed from it. The absence of *cis*-1,2-divinylcyclopropane **28** from the reaction mixture and the formation of the cyclic hydrocarbons **29–31** under these conditions has been explained[76] by the ready rearrangement of *cis*-**28** to the cyclodiene **29** and its subsequent conversion into cyclopropane derivatives.

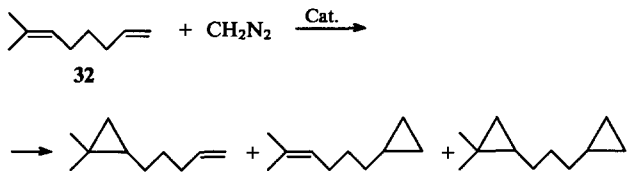


In contrast to the *cis*-isomer, *trans*-hexatriene affords only the expected linear cyclopropane formation reaction adducts, including also *trans*-1,2-divinylcyclopropane.[76] Despite the excess of CH_2N_2, the complete conversion of the hexatrienes is not then attained in both cases.



The interaction of *cis*- and *trans*-penta-1,3-dienes with CH_2N_2† in the presence of CuCl also takes place non-selectively[78] (but, as in the case of other olefins, with retention of the configuration of the double bond) and leads to a mixture of different products of the cyclopropane formation reaction. Despite the postulated electrophilic nature of the carbene intermediate, the conversion of the less substituted double bond into a cyclopropane group is somewhat preferred.

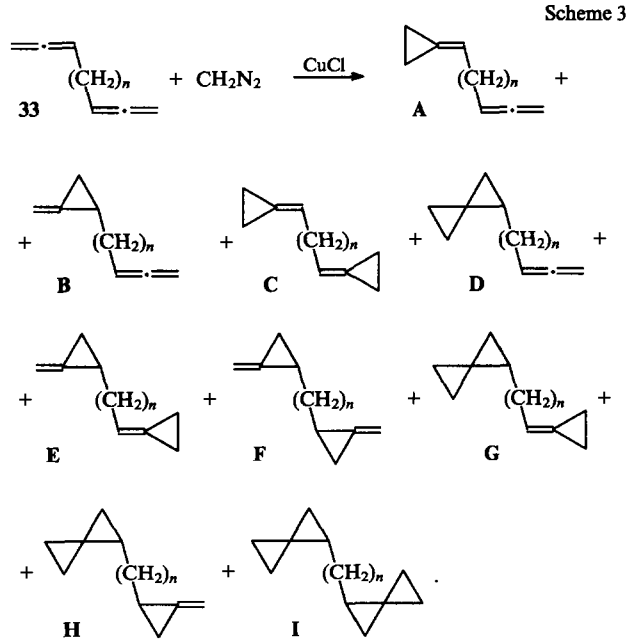
As was to be expected, the conversion of vinylcyclopropane itself by an excess of CH_2N_2 into bicyclopropyl proceeds fairly smoothly, which makes it possible to regard this method of synthesis of bicyclopropyl as preparative.[79]



The constants of the relative reactivity of olefins of different structure in relation to CH_2N_2 have been published[67] (the reaction was carried out in the presence of copper salicylaldiminate **21**; the degree of conversion of the olefins was ~10%):

Interesting results as regards the relative reactivity of the double bonds have been obtained using copper catalysts containing anions with different basicities.[65] Thus passage of CH_2N_2 into a mixture of 2,3-dimethylbut-2-ene and hex-1-ene in proportions of 1 : 1 in the presence of a catalytic amount of $Cu(acac)_2$ leads to tetramethylcyclopropane and butylcyclopropane in proportions of 6.7 : 1. The same reaction in the presence of $Cu(OSO_2CF_3)_2$ leads to the formation of the above cyclopropanes in the reverse proportions (~1 : 4) (see Section III.1).

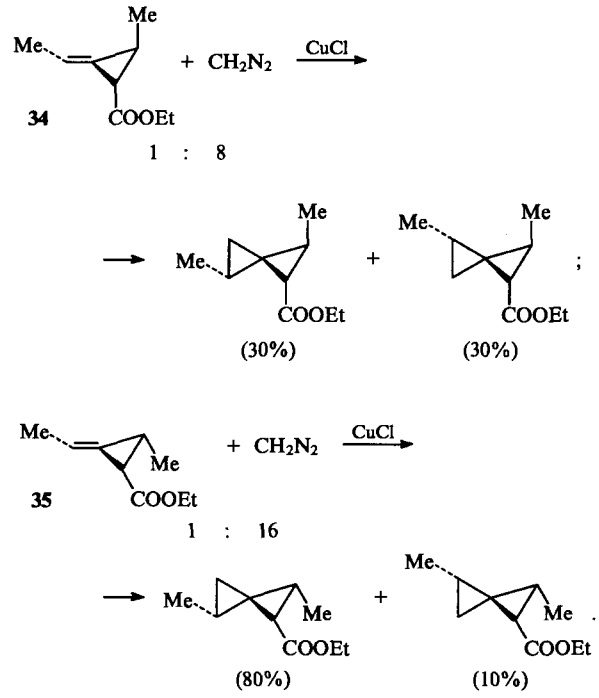
† Instead of the absolute amount of CH_2N_2, the amount of *N*-methyl-*N*-nitrosourea used to generate it has been stated in a number of communications. Therefore here and henceforth in specifying the olefin : CH_2N_2 molar ratio it is postulated that CH_2N_2 is formed in a yield of 55% – 60% on average.[66]



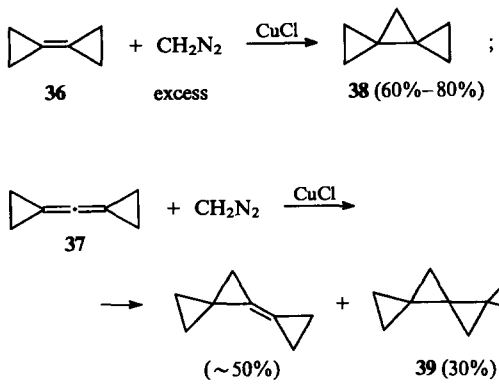
A similar dependence of the mode of the cyclopropane formation reaction on the degree of substitution of the double bond and the copper salt employed is manifested also in the conversion of 2-methylocta-2,7-diene **32** into a cyclopropane derivative.[65] In the presence of copper acetylacetonate, the more substituted double bond is converted into a cyclopropane group, while in the presence of copper triflate the terminal double bond is thus converted.

Cat.	Conversion of diene (%)	Adducts ratio
$Cu(acac)_2$	~10	6.1 : 1 : ~0.1
	90	10 : 1 : 6
$Cu(OSO_2CF_3)_2$	10	1 : 2 : ~0.1
	50	1 : 2.5 : 0.4

The results are probably associated with the unequal abilities of the catalyst to effect the coordination of different double bonds: copper ions coordinated to the acetylacetonate ligand are hardly involved in the formation of π-olefin complexes by reaction with the double bonds, whereas copper ions containing only the weak nucleophilic $CF_3O_2SO^-$ anion are capable of the selective formation of complexes by reacting with the less substituted (or strained) double bonds.[80,81] For this reason, the electrophilic methylene complex formed on decomposition of CH_2N_2 in the coordination sphere of copper reacts preferentially with the more nucleophilic (i.e. alkylated) C=C bonds in the former case, while in the latter case it reacts with the unsubstituted or strained double bonds, which, although less nucleophilic, show instead a greater tendency towards the formation of complexes with the metal atom and are therefore more accessible.

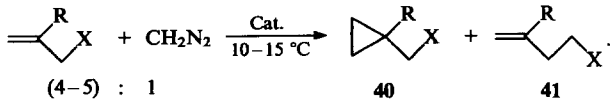


Scheme 3

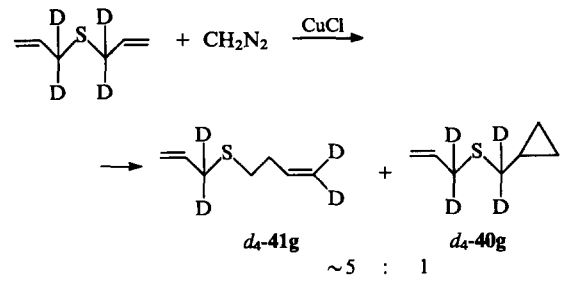


n	Reagents ratio	Yield of products (%)								
		A	B	C	D	E	F	G	H	I
0	1 : 5	8	13	3	15	9	8	13.5	17	11.5
2	1 : 8	8	9	4	10	7	6	14	14	14

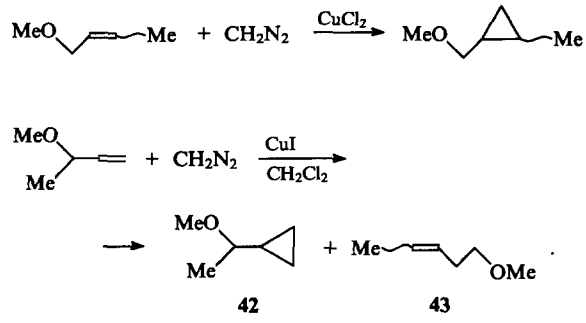
The copper salt-catalysed interaction of CH_2N_2 with allenes and methylenecyclopropanes has been investigated in a number of studies.[82–88] Although this method is fairly general for the synthesis of spiropentanes which are difficult to obtain, it nevertheless frequently leads to the formation of a complex mixture of compounds in relatively low yields or requires the use of a large excess of CH_2N_2. Thus a more than tenfold excess of CH_2N_2 has been used to convert tetradeuterioallene into the corresponding spiropentane at −80° C,[82] while the conversion of hexa-1,2,4,5- or octa-1,2,6,7-tetraenes **33** with a fivefold to eightfold molar excess of CH_2N_2 in the presence of CuCl led to the formation of a complex mixture of hydrocarbons containing all the possible products of the conversion of the double bonds into cyclopropane groups (Scheme 3).[83,84]



The conversion of methylenecyclopropanes into the corresponding spiropentane derivatives takes place significantly more smoothly under these conditions. Thus (in the presence of CuCl) the catalytic conversion of the esters of propylidenecyclopropanecarboxylic acid esters into cyclopropane derivatives by a large excess of CH_2N_2 was used as the basis of the synthesis of ethoxycarbonylspiropentanes.[85,86] Each individual isomer of the initial methylenecyclopropanes, for example compounds **34** and **35**, then forms two stereoisomeric spiropentanes. The steric disposition of the substituents can affect the degree of addition of the methylene attacking the double bond from different sides of the latter.



Fitjer and Conia[87,88] synthesised the polyspirane hydrocarbons **38** and **39**, consisting exclusively of cyclopropane fragments, from the bicyclopropylidene **36** and the allene **37** in 80% and 30% yields respectively. However, according to the data of Zefirov et al.,[89] who repeated the conversion of compound **36** into tercyclopropyl **38** in the presence of CuCl, the maximum yield of the latter was only 60%. As in all the previous cases, when copper compounds are used as catalysts, the target cyclopropane formation reaction proves to be extremely sensitive to the conditions under which it is carried out. One of the causes of the loss of catalytic activity of CuCl on transfer of methylene to the double bond of the olefin is probably its reduction to metallic copper.



The catalytic interaction of CH_2N_2 with allyl derivatives in the presence of copper salts has been widely investigated by Kirmse and coworkers.[77,90–94] It was found that in the case of allyl halides as well as *O*- and *S*-allyl derivatives, the reaction leads to both the products of the conversion of the double bond into a cyclopropane group with formation of methylcyclopropanes **40** and to the products of formal insertion into the carbon–heteroatom bond with formation of 4-X-but-1-enes **41**, the yield and proportions of which depend significantly on the nature of the heteroatom and the reaction conditions (Table 1). Thus, when the reaction is carried out in pentane, allyl chloride affords predominantly chloromethylcyclopropane **40a**, whereas allyl bromide in CH_2Cl_2 gives rise to 4-bromobut-1-ene **41b**.

According to some data,[77,92] the formation of the homoallyl derivatives **41** proceeds via the stage involving the allyl rearrangement of the metastable ylide produced as a result of the addition of methylene to the heteroatom, which agrees well, in particular, with experimental data concerning the interaction of the deuteriated diallyl sulfide with CH_2N_2, as a result of which two deuterium atoms in compound d_4-**41g** formed are attached to the double bond.

It has also been noted[92] that the interaction of 1-methoxybut-2-ene with CH_2N_2 leads only to the conversion of the double bond into a cyclopropane group, whereas both the cyclopropane adduct **42** and a considerable proportion of the products of the allyl rearrangement—the isomeric 1-methoxypent-3-enes **43**—are formed from 2-methoxybut-3-ene.

The interaction of CH_2N_2 with allyl azide in the presence of CuCl affords 1,3,5-triallylhexahydro-*s*-triazine **44** together with cyclopropylmethyl azide.[93] This elegant synthesis of the *N*-allylaldimine trimer probably also proceeds via the intermediate formation of the ylide **45**.

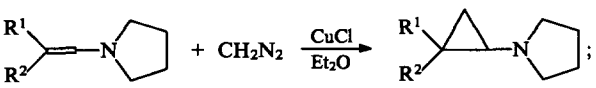
Under analogous conditions, vinyloxiran and CH_2N_2 give rise to the cyclopropane adduct **46**, the product of the allyl rearrangement—5,6-dihydropyran **47**, and also 3-vinyloxetan **48**, formed as a result of the formal insertion of methylene into the C–O bond of the initial epoxide.[94]

46 (64%) **47** (7%) **48** (29%)

The catalytic interaction of CH_2N_2 with vinyl halides in the presence of CuCl or $(PhO)_3P \cdot CuCl$ leads to the corresponding cyclopropanes **49**, but, even in the presence of a fivefold molar excess of CH_2N_2, the degree of conversion of the vinyl halides into compounds **49** did not exceed 35%. An appreciable amount of CH_2N_2 then decomposed with formation of volatile products (mainly ethylene).[95]

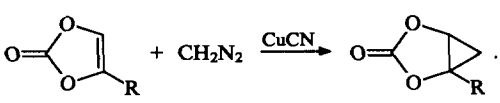
1 : 5 **49**



R = H (35%), CH(cyclo-C_3H_5)Me (24%), CH_2CH_2Cl (19%).

The conversion of vinyl bromide into a cyclopropane under the same conditions proceeds with a much lower degree of conversion.[95]

1 : 5 (13%)



The conversion of vinylamines into cyclopropane derivatives occurred much more successfully. It was then noted[96] that the addition of CH_2N_2 to a mixture of the corresponding vinylamine **50** and 20 mol% of CuCl was accompanied by the appearance of a red colour, which vanished as CH_2N_2 was consumed. When a three–four-fold molar excess of CH_2N_2 was used, the yields of cyclopropylamines **51** were 69%–80% after isolation.

50 **51**

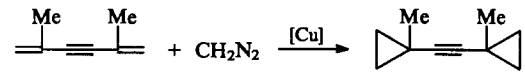
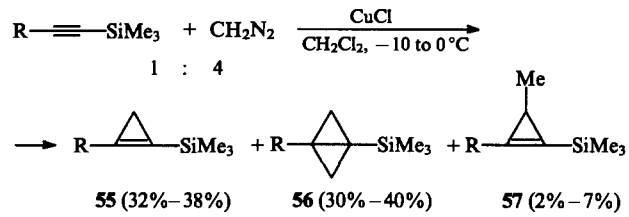
$R^1 = H$, $R^2 = Et$ (80%);
$R^1 + R^2 = (CH_2)_4$ (70%).



The conversion of ethylene carbonates **52** into cyclopropane derivatives was achieved under unusual conditions. In this case, the vapour of a mixture of CH_2N_2 with ether was passed into the unsaturated compounds **52** heated to 110–120 °C and containing CuCN as the catalyst.[98]

52



R	Reagents ratio	Yield of product (%)
H	4.2 : 1	28
Me	1.3 : 1	19

The simultaneous presence in the molecule of double and triple carbon–carbon bonds makes it possible under certain conditions to direct cyclopropane formation processes selectively to the double bonds. Thus a preparative method of synthesis of bis(1-methylcyclopropyl)acetylene **54** by the reaction of CH_2N_2 with the dienyne **53** in the presence of copper salicylaldiminate has been proposed.[99]. The triple bond in the product **54** is not involved despite the excess of diazomethane.

53 1 : 10 **54** (60%)

Nevertheless we were able to achieve for the first time the direct cyclomethylenation of the carbon–carbon triple bond with diazomethane in alkyl(trimethylsilyl)acetylenes using CuCl or $(PhO)_3P \cdot CuCl$ as the catalyst.[100,101] The reaction did not then stop with the formation of the cyclopropenes **55** but proceeded further, leading to the accumulation of the corresponding bicyclobutanes **56** in the mixture. Furthermore, the formation of methylcyclopropenes **57** as a result of the insertion of methylene in a C–H bond in the cyclopropenes **55** formed was an unexpected feature for the given reaction.

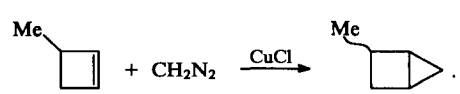
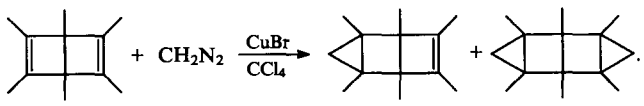
55 (32%–38%) **56** (30%–40%) **57** (2%–7%)

R = Me, Pr, cyclo-C_3H_5.

Before the above study, the only example of the catalytic cyclomethylenation of cyclopropenes by diazomethane was the interaction of 1,2-dimethylcyclopropene with CH_2N_2 in the presence of the modified bimetallic catalyst Cu/Bu_3SnCl.[102]



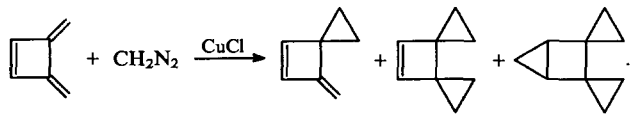
(13%)



b. Conversion of cyclic unsaturated compounds into cyclopropane derivatives

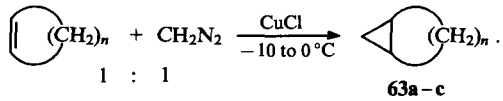
The catalytic decomposition of CH_2N_2 on copper catalysts has been used widely for the conversion of cyclic and bicyclic hydrocarbons with one or several double bonds (conjugated and non-conjugated, endocyclic and exocyclic) into cyclopropane derivatives and also for the specific synthesis of compounds which are relatively unstable or difficult to obtain.

The possibility of the catalytic conversion of the C=C bond in cyclopropenes into a cyclopropane group was already mentioned above. Several examples of the conversion of the double bonds present in a four-membered ring into cyclopropane groups have been described.[103–105] Thus the interaction of CH_2N_2 with 3-methylcyclobutene leads to a mixture of *cis*- and *trans*-2-methylbicyclo[2.1.0]pentanes.[103]



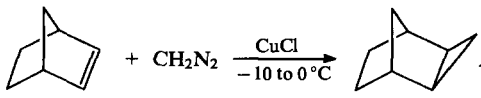
The tricyclic and tetracyclic hydrocarbons **58** and **59** have been synthesised by the reaction of hexamethylbicyclo[2.2.0]-hexa-2,5-diene with an excess of CH_2N_2 in the presence of CuBr.[104]

58 **59**



Reagents ratio	Yield of **58** (%)	Yield of **59** (%)
1:2	30	5
1:5	57	22

The spiro hydrocarbons **60–62** have been obtained by the reaction of 1,2-dimethylenecyclobut-3-ene with CH_2N_2 (in the proportions **60** : **61** : **62** = 5.8 : 1 : 1.7).[105] The absence of the mono- and di-adducts, produced by the conversion of the endocyclic double bond into a cyclopropane group, among the reaction products indicates the preferential conversion of the exocyclic bonds in the initial triene into cyclopropane groups.

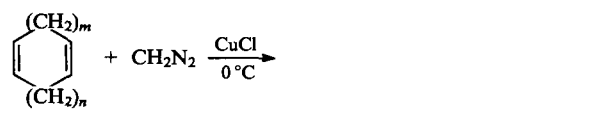


1 : 10 **60** **61** **62**

The interaction of C_6-C_8 cycloalkenes and norbornene with CH_2N_2 in the presence of CuCl leads to the corresponding bicyclo[*n*.1.0]alkanes **63** or the tricyclooctane **64**.[66] The yields of the cyclopropane derivatives under the same conditions increase on passing from cyclohexene to cyclooctene and norbornene, which is probably due to the ability of the strained cycloolefins to stabilise the catalyst in the form of π-olefin complexes.

1 : 1 **63a–c**

Product	*n*	Yield (%)
63a	4	20–25
63b	5	50–55
63c	6	75–80



1 : 1 **64** (80%–85%)

This difference is manifested also in the competing reactions (CuCl, −5 °C) of norbornene and cyclohexene with CH_2N_2 (molar ratios 1 : 1 : 0.1)—the degree of conversion of the former into a cyclopropane derivative is greater by a factor of 2.7 than that of the latter. On the other hand, the conversion of the same mixture of cycloolefins into cyclopropanes in the presence of $Cu(acac)_2$ results in the formation of equal amounts of the cyclic adducts **64** and **63a** at any stage of the reaction, their yields amounting to 50%–55% for reactant ratios of ~1 : 1 : 2. In all cases, the cyclopropane formation reaction proceeds most effectively at the beginning of the addition of CH_2N_2, after which it is sharply retarded, particularly when the reaction mixture blackens.[66]

The conversion of cyclopentadiene,[106,107] cyclohexa-1,3-diene,[108] cycloheptа-1,3-diene, and cyclohepta-1,4-diene,[76] as well as cycloocta-1,5-diene [66] in the presence of CuCl into cyclopropane derivatives leads, as expected, to a mixture of mono- and di-adducts, namely to the bicycloalkenes **65** and the tricycloalkanes **66** (Table 2). The tricycloalkanes **66** are formed from the non-conjugated dienes in the form of a mixture of the *cis*- and *trans*-isomers (~1 : 1), whereas the *trans*-isomers predominate in the products of the reaction involving the double cyclopropane formation from conjugated dienes.

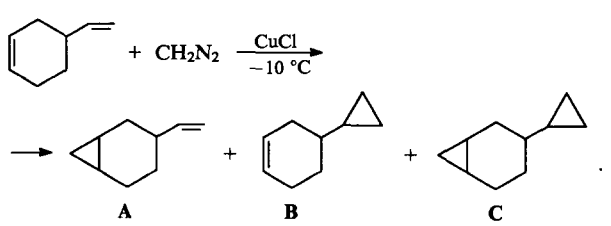


Table 2. Composition of the products of the conversion of cyclic dienes into cyclopropane derivatives by diazomethane in the presence of 5–6 mol% CuCl.

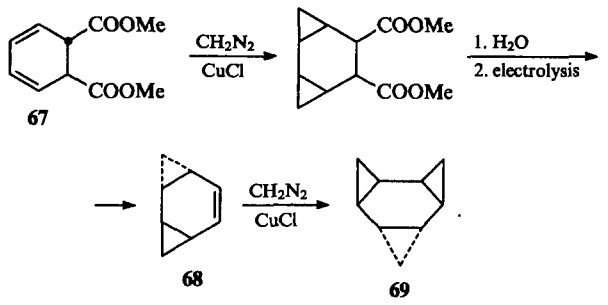
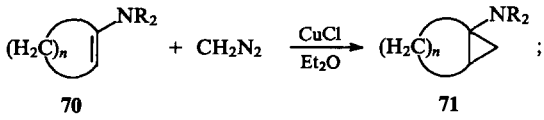
2	2	1:2	35	24	27	66

65 *trans*-**66** *cis*-**66**



The catalytic conversion of 4-vinylcyclohexene into cyclopropane derivatives in the presence of CuCl proceeds via both the endocyclic and exocyclic double bonds, leading to mono- and di-adducts, the yields of which were found to be determined not only by the ratio of the olefin and CH_2N_2 but also by the amount of the catalyst employed.[66]



A **B** **C**

Olefin : CH_2N_2 : CuCl	Yield (%)		
	A	**B**	**C**

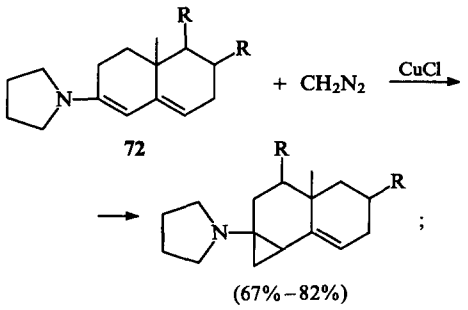
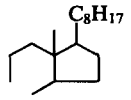
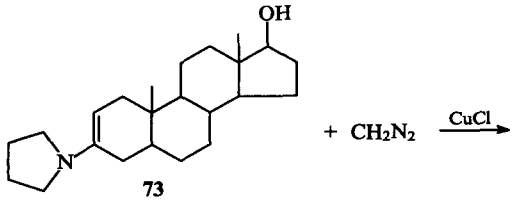
1:2:0.03	13	10	3–4
1:2:0.40	17	21	~20

The diazomethane method for the catalytic conversion of cyclic double bonds into cyclopropane groups has been used successfully for the specific synthesis of trishomobenzene **69** from dimethyl *trans*-dihydrophthalate **67**, which cannot be obtained by the direct conversion of benzene into a cyclopropane derivative because of the ready isomerisation of the norcaradiene formed initially (see Section IV). For this purpose, the cyclodiene **67** was converted into the corresponding product of the double cyclopropane formation reaction by treatment with an excess of CH_2N_2 in the presence of CuCl, the ester groups were split off, and the resulting *trans*-tricyclooctene **68** was again subjected to the cyclopropane formation reaction by treatment with diazomethane and was converted into *trans*-**69**.[109]

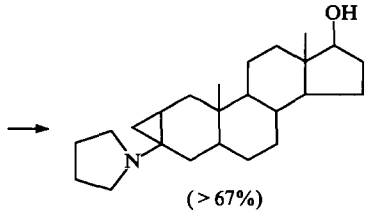


Like their aliphatic analogues **50**, the cyclic enamines **70** can also be fairly successfully converted into cyclopropane derivatives by treatment with an excess of CH_2N_2, which leads to high yields of the corresponding 1-aminobicyclo[*n*.1.0]alkanes **71**.[96,110]

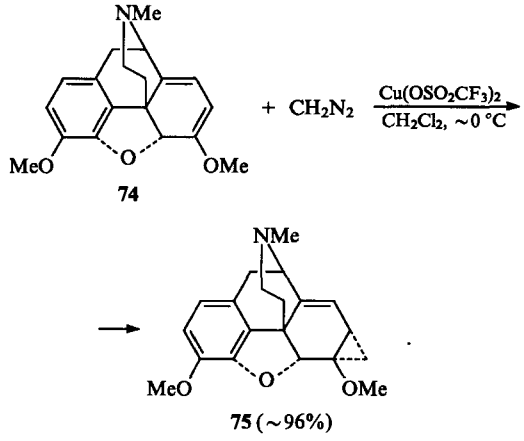




R = Me, Et; n = 3 (65%–72%);
R + R = $(CH_2)_4$; n = 3, 4 (72%–75%);
R + R = $CH_2CH_2OCH_2CH_2$; n = 3, 4 (86%–87%).

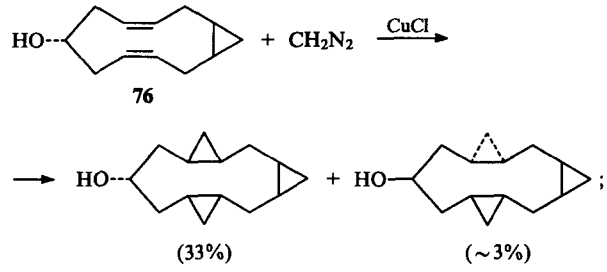


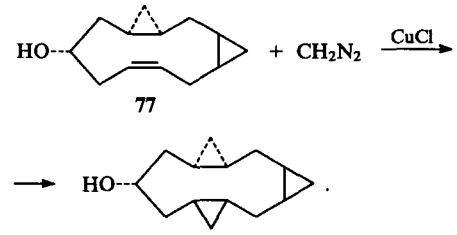
Under analogous conditions, the conversion of cyclic dienamines **72** into cyclopropane derivatives proceeds regioselectively despite the presence of an excess of CH_2N_2 and involves mainly the C=C bond conjugated with a nitrogen atom. As in the formation of a cyclopropane from the enamine **73**, one of the geometrical isomers is formed preferentially.[110]



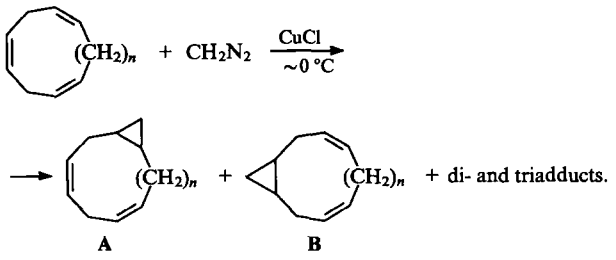
72 : CH_2N_2 = ~1 : (2.5–3);

R = H or R + R = 

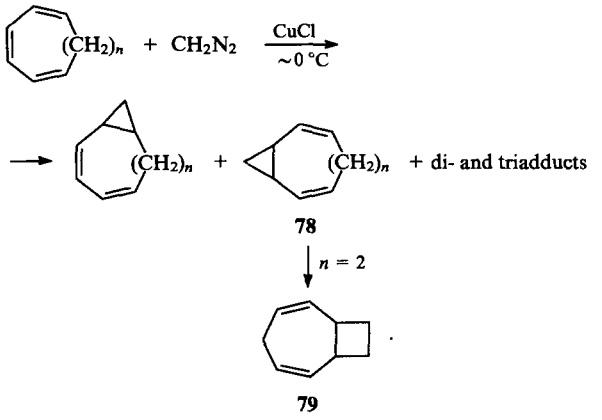




Generally speaking, the presence of bulky substituents and the configuration of the ring in the unsaturated compound can influence significantly the reactivity of the substrate and the stereochemical result of the addition of the methylene fragment to the double bond. Furthermore, the presence in the molecule of heteroatomic substituents capable of being coordinated to the catalyst also apparently affects the mode of addition of CH_2 to the double bond. Thus, in the reaction of thebaine **74** with an excess of CH_2N_2 in the presence of copper triflate, a high regio- and stereo-selectivity of the addition of the CH_2 fragment to the $C^6=C^7$ bond of thebaine **74** with formation of the previously unknown hydrophenanthrene alkaloid **75** was observed.[111]

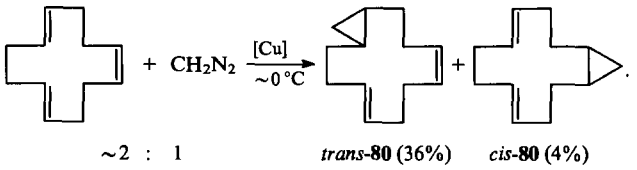


The high stereoselectivity of the conversion of endocyclic double bonds into cyclopropane groups has also been observed in the reaction of the unsaturated alcohols **76** and **77** with an excess of CH_2N_2 in the presence of CuCl.[112]



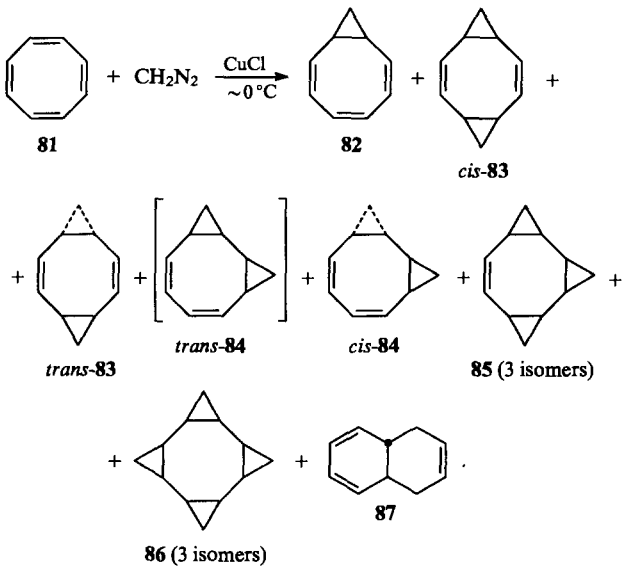
one isomer
(yield has not been given)

Cyclic trienes are converted into cyclopropane derivatives by treatment with diazomethane in the presence of CuCl similarly to cyclic dienes, the ratios and yields of the mono-, di-, and tricyclic adducts being determined mainly by the amount of the CH_2N_2 employed.[76,113]



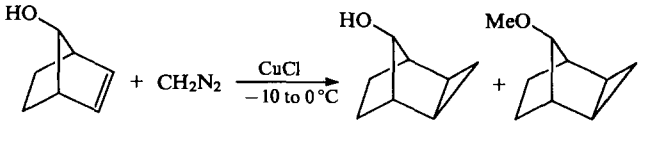
n	triene : CH_2N_2	Yield of adducts (%)		
		mono	di	tri
1	1 : 2.8	34	34	13

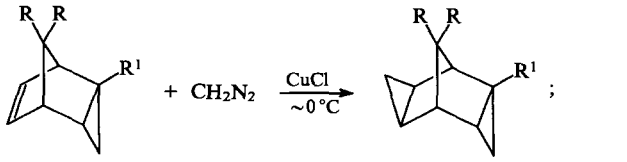
Furthermore, it has been shown[113] that the adduct **78** ($n = 2$), formed in 3% – 4% yield in the cyclopropane formation reaction from cycloocta-1,3,5-triene, isomerises to the bicyclic diene **79** (yield 8%) already during the course of the reaction.



n	triene : CH_2N_2	Yield of adducts (%)		
		mono	di	tri
1	~1 : 4	18	45	28
2	1 : 2	34	31	8

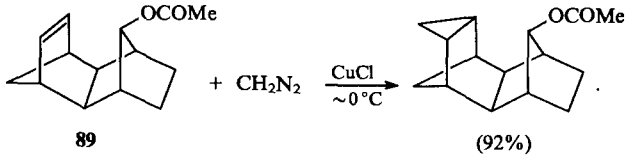
In the cyclopropane formation reactions of unsaturated compounds with different configurations of the double bonds, the preferential conversion of the *trans*-C=C bond into a cyclopropane group has been noted. Thus the reaction of an excess of (*E*,*Z*,*Z*)-cyclododeca-1,5,9-triene with CH_2N_2 in the presence of the chelate copper complex **21** leads to the monocyclopropane derivatives **80** with a ratio *trans* : *cis* ≃ 9 : 1.[67]





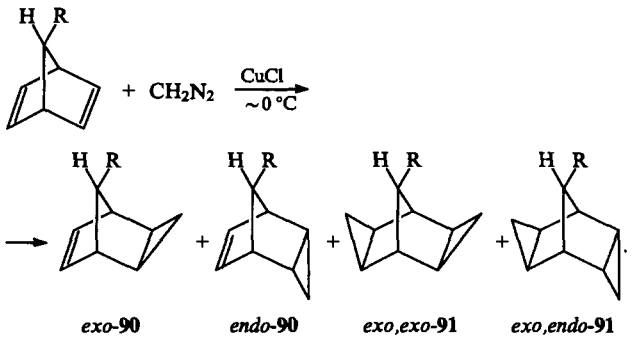
The catalytic conversion of cyclooctatetraene **81** into a cyclopropane derivative by treatment with diazomethane in the presence of CuCl was first achieved as early as the middle 1960s,[114,115] but only bicyclo[6.1.0]nona-2,4,6-triene **82** was isolated in ~30% yield and identified together with some products of the double cyclopropane formation reaction — *cis*-tricyclo[7.1.0.0^{4,6}]deca-2,7-diene (*cis*-**83**) and tricyclo[7.1.0.0^{2,4}]-deca-5,7-diene **84**, in which the configuration of the cyclopropane fragments was not established. Later the catalytic interaction of compound **81** with CH_2N_2 was investigated in detail by Nefedov and coworkers[116] and the stereochemistry of the cyclopropanes formed was established. In order to achieve a higher degree of conversion of compounds **81** and **82** into the tri- and tetra-cyclic adducts **85** and **86**, the reaction mixture was filtered twice under argon, as CH_2N_2 was added, and a fresh portion of CuCl (3–4 mol%) was introduced. It is of interest to note that the conjugated diene *trans*-**84** could not be detected in the double cyclopropane formation products **83** and **84** probably because of its ready isomerisation to the triene **87**, which was isolated in 2% – 3% yield.

81 : CH_2N_2	Yield of adducts (%)						
	82	*cis*-**83**	*trans*-**83**	*cis*-**84**	**85**	**86**	**87**
1 : 1	44	3–4	2–3	8	5	1–2	~2
1 : 3	13	~7	~5	14	36	15–17	~3



The fairly effective conversion of norbornene into a cyclopropane derivative by treatment with diazomethane in the presence of CuCl has already been mentioned.[66] It has been established recently[117] that, regardless of the nature of the catalyst [Cu(OTf)$_2$, CuCl, Cu(acac)$_2$], the main product is the *exo*-isomer **64**, while the fraction of the *endo*-isomer does not exceed 2%. The exclusive *exo*-addition of methylene to the norbornene double bond was observed also in the catalytic conversion into cyclopropanes of norbornene derivatives as well as other polycyclic compounds, for example compounds **88** and **89**, containing this fragment, on treatment with diazomethane.[118–122] It is striking that the *exo*-conversion of the

88

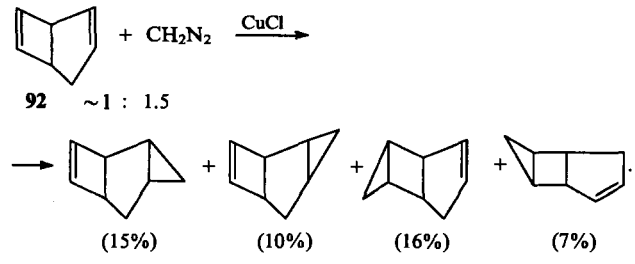


R = H, OMe; R^1 = H, Me (61% – 80%);
CR_2 = C=O; R^1 = H, Me (30% – 41%);
R + R = OCH_2CH_2O; R^1 = H (54%).

89 (92%)

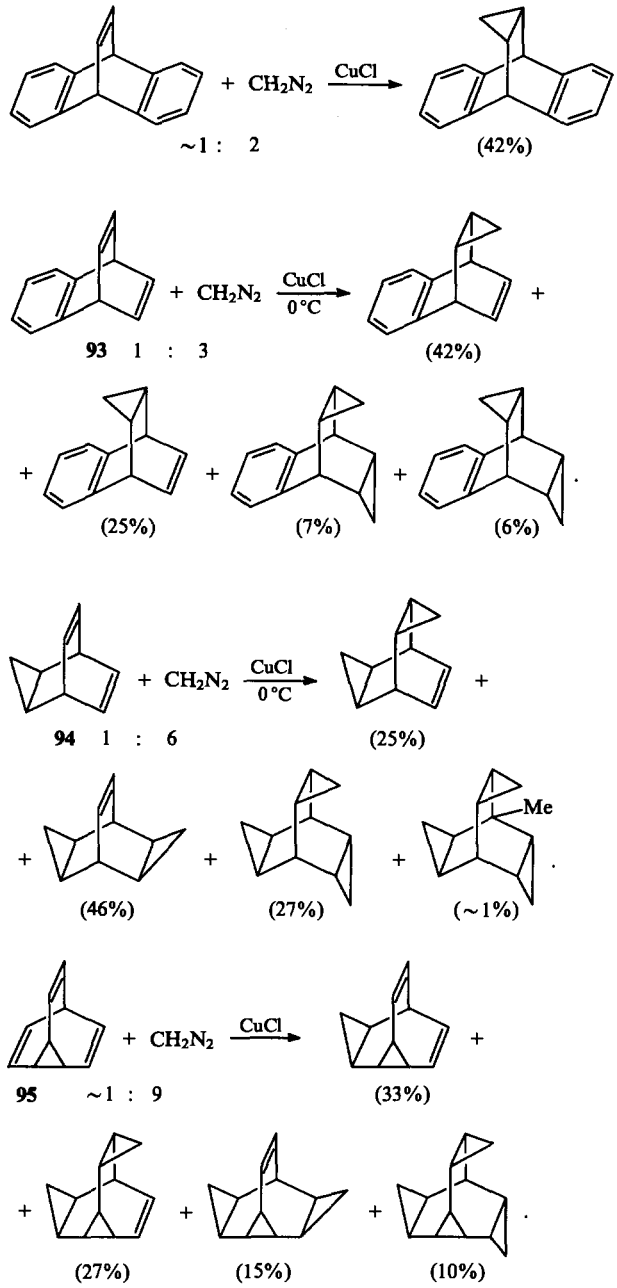
double bond into a cyclopropane group occurs for both *anti*- and *syn*-orientations of the substituent in the 7-position of the bicyclo[2.2.1]heptene fragment and that the partial (~10%) formation of the corresponding methoxy-derivatives has been observed, together with conversion into a cyclopropane, for the hydroxy-derivatives.[119,121]

In contrast to norbornenes, the interaction of CH_2N_2 with norbornadiene and its derivatives in the presence of copper catalysts proceeds non-selectively and leads to a mixture of the mono- and di-adducts **90** and **91** containing both *exo* and *endo*-isomers.[117-119,123,124]



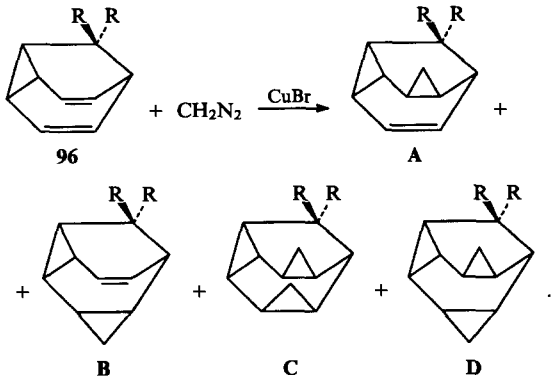
For a 1 : 1 norbornadiene (R = H) : CH_2N_2 ratio, the yields of the monoadducts (*exo*- and *endo*-) and triadducts (*exo,exo*- and *exo,endo*-) were respectively 33%, 15%, 8%, and ~4%. For R = OCOMe and OCOPh, the ratio *exo*-90 : *endo*-90 is ~5:1.

It was found that the partial formation of the *endo*-isomer is characteristic not only of norbornadienes but also of *exo*-tricyclo[3.2.1.$0^{2,4}$]octene (*exo*-**90**, R = H).[117] Whereas the subsequent conversion of *endo*-**90** (R = H) into a cyclopropane derivative in the presence of copper compounds leads exclusively to *exo,endo*-**91** (the *endo,endo*-isomer was not detected at all), the conversion of *exo*-**90** (R = H) into a cyclopropane derivative under the same conditions affords a mixture of the isomeric diadducts **91** in proportions of ~6:1.



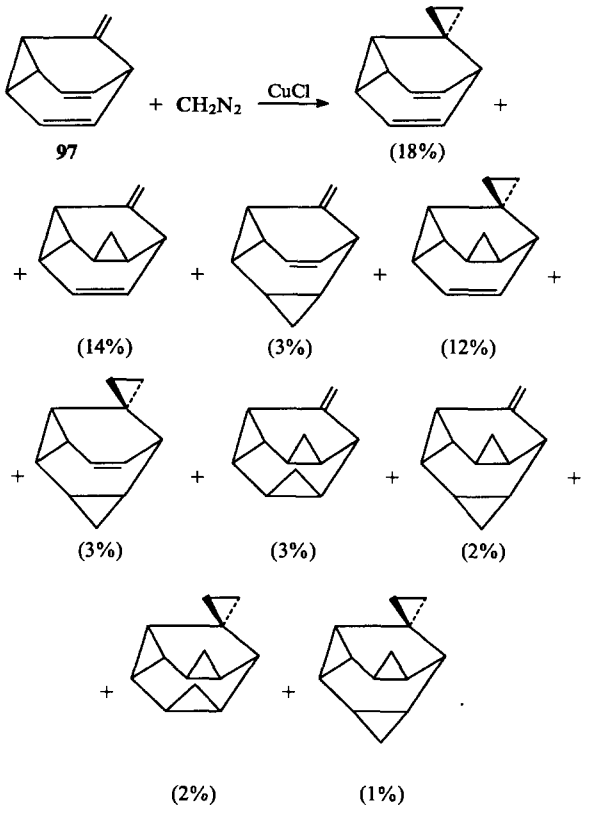
The increased content of the *endo*-isomer, compared with norbornenes, on conversion of norbornadiene into a cyclopropane derivative in the presence of copper catalysts is apparently associated with the characteristics of the geometry of the double bonds. Thus, according to calculations,[125] the angle of the *endo*-deformation of the vinyl C–H bonds in norbornadiene is smaller than in norbornene (2.3° and 4.9° respectively), so that the probability of the attack on the double bond by the carbene complex from the side of the *endo*-position is greater for the former compound. The detailed stereochemical aspects of the addition of methylene to the norbornene double bond in the presence of various catalysts will be examined in Section III.3.b (Table 5).

The conversion of the asymmetric bicyclo[3.2.0]hepta-2,6-diene **92** into a cyclopropane derivative in the presence of CuCl involves both double bonds and affords mixtures of the corresponding *syn*- and *anti*-isomers. The authors[126] observed the formation of four diadducts, in an overall yield of ~27%, together with the monoadducts.



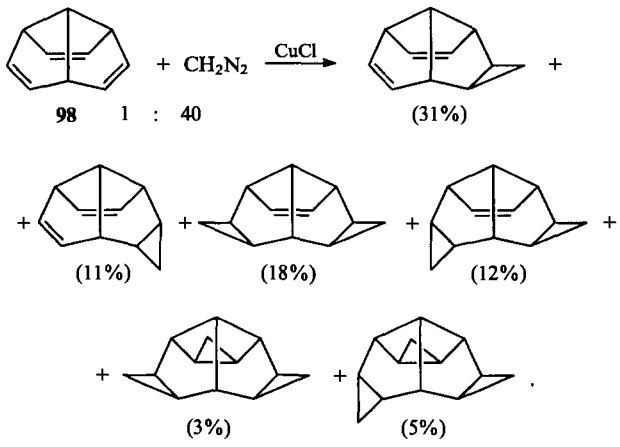
The mild conditions for the conversion of unsaturated compounds into cyclopropanes by diazomethane in the presence of copper compounds have been used widely for the synthesis and study of the chemical reactions of cyclopropane derivatives of bicyclo[2.2.2]octa-2,5,7-triene (barrelene),[127-130] tricyclo-[3.3.0.$0^{2,8}$]octa-3,6-diene (semibullvalene),[128] tricyclo[3.3.2.$0^{2,8}$]-deca-3,6,9-triene (bullvalene),[130] tricyclo[3.3.1.$0^{2,8}$]nona-3,6-diene (barbaralane),[131,132] and tricyclo[5.2.1.$0^{4,10}$]deca-2,5,8-triene (triquinacene).[133]

It is striking that, among the products of the conversion of benzobarrelene **93**, homobarrelene **94**, and also bullvalene **95** into cyclopropane derivatives, no *endo,endo*-isomers corresponding to the addition of methylene fragments oriented in opposition to one another were detected. However, in the case of the diene **94** deMeijere et al.[130] observed, in addition to the expected adduct, the appearance of a minor product corresponding to the formal insertion of methylene into the angular C–H bond.

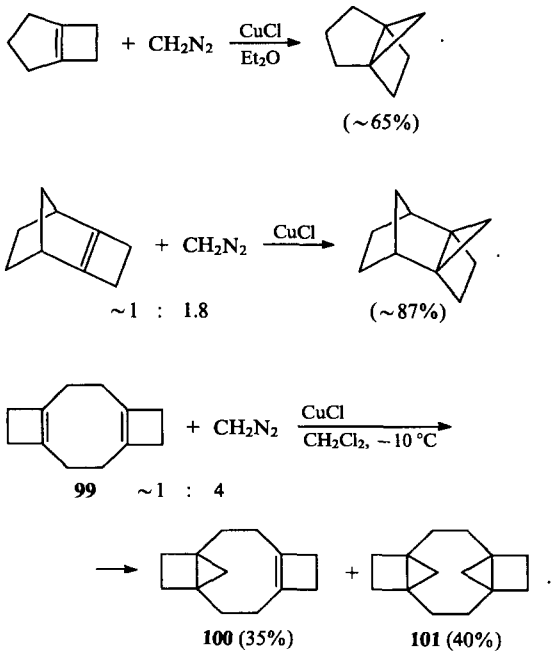


The high selectivity of the addition of methylene to the endocyclic double bonds is also characteristic of the structure of barbaralane, as for norbornene. Thus the interaction of the

tricyclodienes **96** with an excess of CH_2N_2 in the presence of CuBr leads to the mixture of the mono- and di-adducts with an appreciable predominance of the *exo*-isomers.[131]

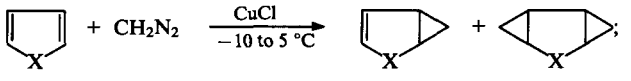


CR_2	Yield of adducts (%)			
	A	B	C	D
C=O	43.5	0.6	43.5	2.5
	~63	2.1	4.2	0.2



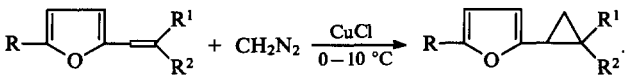
The conversion of 9-methylenebarbaralane **97** into a cyclopropane derivative proceeds in a more complex manner owing to the possibility of the conversion into cyclopropane groups of both endocyclic and exocyclic double bonds and leads to a mixture of nine cyclic adducts with different numbers and disposition of the cyclopropane fragments.[132] However, as in the case of norbornadiene, hydrocarbons with two *endo,endo*-oriented cyclopropane rings in the molecule were not detected in the products of the catalytic conversion of the polycyclenes **96**–**98** into cyclopropanes.

In many instances, the yields of cyclopropane adducts (particularly the products of the double and triple cyclopropane formation reactions) are significantly lower than might have been expected on the basis of the amount of CH_2N_2 employed and the structure of the unsaturated compounds. In particular, an unjustifiably large (40-fold) excess of CH_2N_2 was used in the formation of a cyclopropane derivative from triquinacene **98** [133] (cf the interaction of CH_2N_2 with cyclo-octatetraene[116]). The low degree of conversion of olefins into cyclopropanes is probably associated with the rapid change during the reaction of the nature of the catalyst, for example, with a gradual conversion of copper(I) salts by diazomethane into organometallic compounds or metallic copper, which, according to Nefedov et al.,[66] is reflected significantly in the target cyclopropane formation reaction.



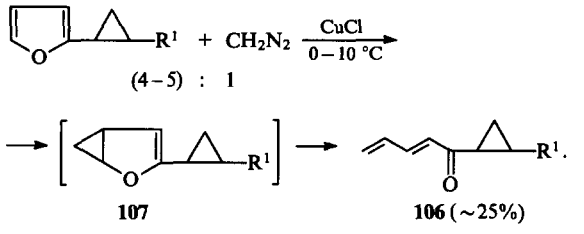
The ability of copper compounds to catalyse the formation of cyclopropanes on treating with diazomethane olefins with different degrees of substitution of double bonds, including tetrasubstituted olefins, proved useful for the synthesis of carbocyclic propellanes which are difficult to obtain and are highly strained.[134–136] In particular, isomeric polycyclic hydrocarbons **101**, containing two propellane fragments in the molecule (isomer ratio ~6 : 1), were synthesised, together with the monoadduct **100**, by the reaction of the diene **99** with CH_2N_2 in the presence of CuCl.[136]

c. Conversion of unsaturated heterocyclic compounds into cyclopropane derivatives



In the presence of copper salts, diazomethane is also capable of converting the double bonds in heterocyclic compounds into cyclopropane groups. Five-membered unsaturated heterocyclic compounds (furan, thiophene, pyrrole, and their derivatives) are then converted into the corresponding bicyclic and tricyclic compounds.[137-139] Thus the interaction of CH_2N_2 with an excess of furan in the presence of CuBr or CuCl leads to 2-oxabicyclohexene **102a** in 50%–65% yield; for the stoichiometric reactant ratio, the diadduct **103a** is formed in ~5% yield together with compound **102a**. The conversion of thiophene into a cyclopropane derivative proceeds less effectively probably owing to the lower stability of the adduct **102b**, the yield of which ranges from 6% to 22% according to different estimates.[137,138]

102 **103**



X = O (**a**), S (**b**).

The presence of substituents in the furan ring influences both the regioselectivity in the conversion of the double bonds into cyclopropane groups and the stability of the resulting adducts. Thus the interaction of CH_2N_2 with 2-alkenylfurans **104** leads in the first place to the conversion of the exocyclic double bonds into cyclopropane groups with formation of the corresponding 2-cyclopropylfurans **105**.[140] However, the subsequent interaction of compound **105** (R = H) with CH_2N_2 in the presence of CuCl affords 1-cyclopropylpenta-2,4-diene-1-ones **106**, apparently as a result of the addition of CH_2 to the unsubstituted double bond of the furan ring and the subsequent opening of the oxabicyclic adduct **107**.[140]

In the catalytic reaction of CH_2N_2 with *N*-methylpyrrole in the presence of CuCl, the products of the formal insertion of methylene into the C–H bonds of the pyrrole ring were obtained instead of the cyclopropane adduct (see Section VI). On the other hand, *N*-methoxycarbonylpyrrole forms the bicyclic and tricyclic compounds **108** and **109** in moderate yields under similar conditions, the *trans*-isomer of the diadduct **109** predominating appreciably.[141,142]

~1 : 3 **108** (39%) **109** (12%)

In the reactions with 2-alkenylpyrroles **110**, diazomethane leads to the formation, in the presence of CuCl, of both the cyclopropane adducts **111** involving the exocyclic double bond and of the products **112** of the insertion of methylene into the C–H bonds of the pyrrole ring.[143] Together with the monoadducts **111** and **112**, a complex mixture of products of the addition (or insertion) of a second CH_2 fragment to the monoadducts formed was then obtained in an overall yield of 6%–10%.

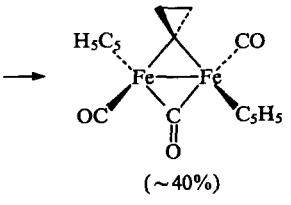
Finally one should note that, in the presence of CuCl, diazomethane is capable of converting into cyclopropane groups the double bonds in unsaturated ligands forming part of the composition of mononuclear or dinuclear metal complexes, for example compounds **117** and **118**.[147,148]



117

(~28%)

118

(~40%)

It follows from the results presented above that, in the presence of copper compounds, diazomethane is capable of converting into cyclopropane derivatives an extremely wide range of unsaturated compounds containing C=C bonds of different nature and with different degrees of substitution. However, the tendency of copper compounds to be readily 're-reduced' by diazomethane with the formation of highly active metallic copper, which leads to a vigorous side reaction involving the decomposition of CH_2N_2 and hence results in a low degree of conversion of the olefins into the corresponding cyclopropanes and limits the preparative use of this reaction.

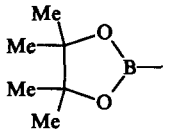
3. Conversion of olefins into cyclopropane derivatives by diazomethane in the presence of palladium catalysts

One can say without exaggerating that the wide scale preparative use of diazomethane in the synthesis of cyclopropane derivatives from olefins has been recently associated with the employment of various palladium compounds as catalysts of the decomposition of CH_2N_2. The available literature data give grounds for the assertion that the nature of the cycloaddition of methylene to the double bonds is associated to a large extent with the ability of the initial olefins to be coordinated to the palladium atom, the regio- and stereo-selectivity in the conversion of various double bonds into cyclopropane groups differing significantly from those in their conversion into cyclopropane derivatives in the presence of copper compounds.[10,19,68,70] $Pd(OAc)_2$, $Pd(acac)_2$, and $(PhCN)_2PdCl_2$ are most often employed as palladium catalysts.

The catalytic activity of palladium compounds in the conversion of olefins into cyclopropanes was first noted in 1968 by Kirmse and Kapps,[92] who investigated the interaction of diallyl ether with CH_2N_2 in the presence of bis[η-allylpalladium chloride]. They then obtained the cyclopropane adduct **40f** in 38% yield without an admixture of the product **41f**, in contrast to catalysis by copper salts. In the next year, the same workers[94] reported the interaction of vinyloxiran with CH_2N_2, leading to the formation of the adducts **46** and **47** in proportions of ~6 : 1. However, at that time the above studies still failed to encourage investigators to employ palladium catalysts on a wider scale in the conversion of olefins into cyclopropanes.

Appreciable progress in the conversion of unsaturated compounds into cyclopropanes by treatment with diazomethane in the presence of palladium compounds and primarily in the presence of $Pd(OAc)_2$ is associated with the work of Teysie and coworkers,[149] who converted styrene into phenylcyclopropane in ~90% yield, and with the work of Vorbruggen and coworkers,[150,151] who demonstrated the possibility of the effective conversion into cyclopropanes of norbornene and norbornadiene as well as monosubstituted α,β-unsaturated carbonyl compounds by this method. Since then, the number of studies in this field began to increase sharply.

In the first place, it was established that the nature of the palladium catalyst {$PdCl_2$, $Pd(OAc)_2$, $[\eta\text{-}C_3H_5PdCl]_2$, $(PhCN)_2PdCl_2$} does not influence significantly the nature of the reaction of olefins when the latter is carried out in CH_2Cl_2, while the yields of the cyclopropane formation products are determined under identical conditions mainly by the nature of the C=C bonds.[68,152] Nevertheless, more detailed differences in the nature of the catalysts,[25] influencing the yield of the products of the cyclopropane formation reaction, in particular the formation of tricyclooctane **64** from norbornene, were discovered under conditions where the ethereal solution of CH_2N_2 was rapidly mixed with the olefin and the catalyst. Thus the introduction into $Pd(acac)_2$, which affords the highest yield of compound **64** under these conditions, of electron-donating ligands, for example NEt_3, Me_2S, PPh_3, etc., in the proportions $Pd(acac)_2$: L = 1 : 2 lowers the yield of the cyclopropane adducts from 72% to 23%.[25]



The observed dependence of the yields of compound **64** on the structure of the palladium compounds can be explained by the increasing hindrance by the ligands to the coordination of the olefin and also by the retardation of the formation of the catalytically more active low-valence palladium complexes when palladium(II) compounds are reduced by diazomethane (see Section III.1).

a. Conversion of aliphatic unsaturated compounds into cyclopropane derivatives

It has been established by numerous investigations that in the series of unsaturated aliphatic compounds those with terminal double bonds are most successfully converted into cyclopropane derivatives by diazomethane. The yields of the cyclopropane adducts are then determined by the amount of the added CH_2N_2 and in some cases are 88%–97% when a two–three-fold excess of CH_2N_2 is employed (Table 3).

It is noteworthy that the nature of the substituents at the C=C bond affects appreciably the nature of its conversion into a cyclopropane group. Thus the conversion of olefins with electron-donating substituents attached directly to the C=C bond, for example ethyl vinyl ether,[158] into cyclopropanes proceeds with an extremely low degree of conversion, whereas the conversion of oxygen- and nitrogen-containing allyl derivatives into cyclopropanes takes place fairly successfully. Furthermore, the results concerning the relative reactivities of various unsaturated compounds have demonstrated[159] that styrene and allyl alcohol are 15–20 times less reactive than alk-1-enes in their conversion into cyclopropanes by diazomethane.

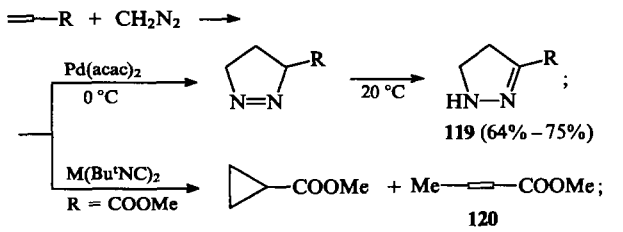


Table 3. Conversion of the monosubstituted olefins $CH_2=CHR$ into cyclopropane derivatives by treatment with diazomethane in the presence of 0.4–1.0 mol% of palladium compounds.

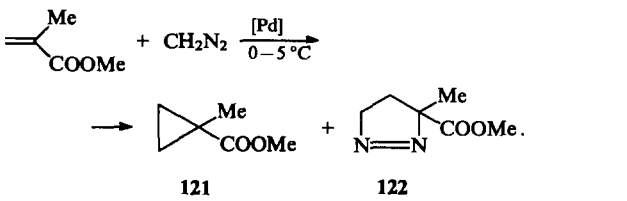
[b] The ratio of the olefin to *N*-methyl-*N*-nitrosourea is indicated.

In contrast to allyl alcohol and its ethers, allyl halides (allyl chloride, allyl bromide, methylallyl chloride) are not converted into cyclopropanes by diazomethane in the presence of palladium compounds and do not afford the products of the formal insertion of methylene in the C–Hal bond, as happens when copper compounds are used as catalysts.

The interaction of CH_2N_2 with unsaturated compounds containing strong electron-accepting substituents (CN, COOR) at the double bond takes place in a more complex manner. In this case, there is competition between the possible formation of cyclopropanes and the readily occurring 1,3-dipolar cycloaddition of CH_2N_2. The nature of the palladium catalyst can then influence significantly the composition of the reaction products. Thus, in the presence of $Pd(OAc)_2$, ethyl acrylate and CH_2N_2 afford a high yield of ethyl cyclopropanecarboxylate,[160] whereas acrylonitrile and methyl acrylate react with CH_2N_2 in the presence of $Pd(acac)_2$ to form the pyrazolines **119**.[25]

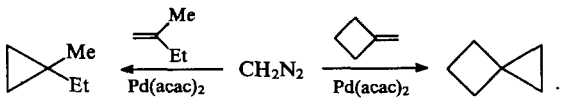


R = CN, COOMe.

M	Yield of C_3H_5COOMe (%)	Yield of **120** (%)
Pd	0.9	24.4
Ni	66.5	20.4

Finally, it has been noted[72] that methyl crotonate **120** is formed together with the cyclopropane adduct in the reaction of CH_2N_2 with methyl acrylate in the presence of $Pd(Bu^tNC)_2$.

It is noteworthy that a decrease in the polarity of the double bond in α,β-unsaturated ethers favours the formation of cyclopropane adducts.



The interaction of CH_2N_2 with methyl methacrylate containing both electron-donating and electron-accepting substituents at the same carbon atom proceeds mainly with formation of the cyclopropane adduct **121** and even in the presence of $Pd(acac)_2$ its yield is fairly high compared with that of the 1-pyrazoline **122** formed simultaneously.[25,151]

121 **122**

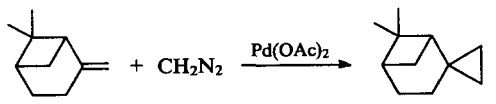
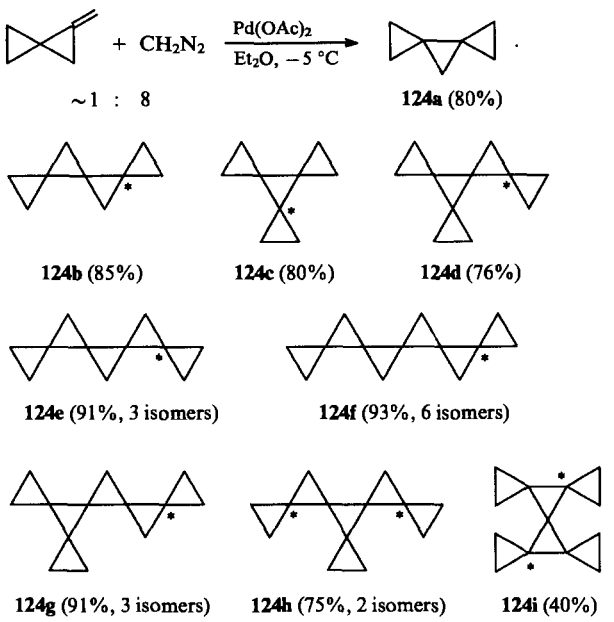
The conversion of 1,1-disubstituted double bonds into cyclopropane groups occurs also in the case of *gem*-dialkylethylenes, but, in order to attain a high yield of cyclopropanes it is necessary to use a large excess of CH_2N_2 in virtually all cases.[25,89,151,153]



(18%) (48%)

Olefin : CH_2N_2 = 1 : 1



~1 : 3 (82%)

It is of interest to note that β-pinene **123** reacts with CH_2N_2, affording the cyclopropane adduct in 63% yield,[153] whereas derivatives of 2-methylenenorbornane are hardly converted into cyclopropanes even in the presence of a four–six-fold excess of CH_2N_2.[25, 163]

123 ~1 : 3 (63%)

The cyclomethylenation of methylenecyclopropanes by treatment with diazomethane in the presence of $Pd(OAc)_2$ is one of the stages in the general method of synthesis of linear and branched triangulanes **124**, made up of spiroannelated cyclopropane fragments. It was developed by Zefirov and coworkers.[89, 164–168]

~1 : 8 **124a** (80%)

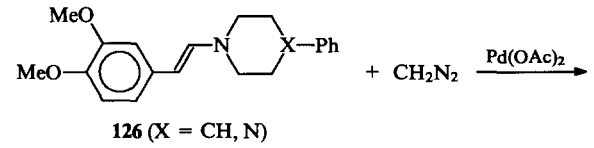
124e (91%, 3 isomers) **124f** (93%, 6 isomers)

124g (91%, 3 isomers) **124h** (75%, 2 isomers) **124i** (40%)

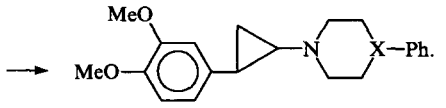
(The asterisks designate the carbon atoms constituting the methylene fragment in the initial methylenecyclopropanes.)

As a rule, the conversion of the corresponding olefins into cyclopropanes was then carried out under isotypical conditions using a large excess of an ethereal solution of CH_2N_2 and 4–5 mol% of $Pd(OAc)_2$ as the catalyst.

In the presence of palladium compounds, diazomethane is also capable of converting 1,2-disubstituted double bonds into cyclopropane groups, but in this case the reaction is even more sensitive to the nature of the substituents than in the case of terminal olefins. Thus hept-3-ene, *cis*- and *trans*-1,2-dichloroethylenes, as well as tri- and tetra-substituted alkenes (3-methylhept-3-ene, tetramethylethylene) do not give rise to cyclopropanes on reaction with CH_2N_2 in the presence of palladium compounds.[25] On the other hand, α,β-unsaturated carbonyl compounds afford satisfactory yields of the corresponding cyclopropanes **125** in the presence of $Pd(OAc)_2$.



1 : (2.5–3) **125**



R^1	R^2	R^3	Yield of **125** (%)	Ref.

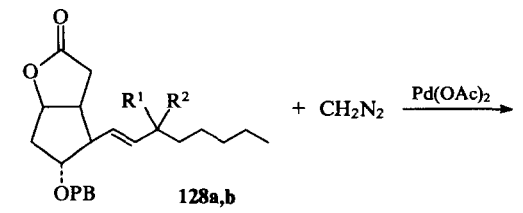
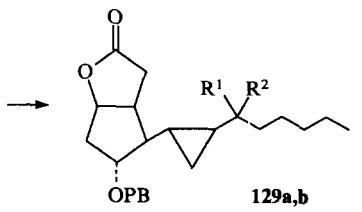
Me	Me	Me (OMe)	0	151

In contrast to internal alkenes, the esters of non-conjugated unsaturated carboxylic acids are also capable of being converted into cyclopropanes by treatment with diazomethane in the presence of palladium acetate and their reactivity depends on the configuration of the double bond. Thus methyl elaidate, containing a *trans*-C=C bond, is more reactive than methyl oleate containing a *cis*-C=C bond.[154]

In contrast to the esters of unsaturated carboxylic acids, the conversion of β-arylvinylamines into cyclopropane derivatives in the presence of palladium catalysts proceeds less successfully and in the case of the enamine **126** leads to the cyclopropane adduct **127** in only 10% yield.[172]



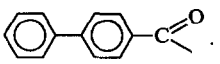
126 (X = CH, N)



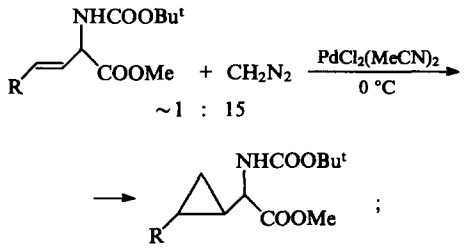
127 (~10%)

In this reaction, palladium compounds are apparently less effective than CuCl.[110]

The catalytic interaction of CH_2N_2 with unsaturated compounds makes it possible to synthesise certain prostaglandin preparations containing a cyclopropane ring.[173] Under these conditions, the reaction involving the formation of a cyclopropane from the hydroxy-derivative **128b**, containing, in contrast to allyl alcohol, a disubstituted double bond,[155] leads to the formation, together with the cyclopropane adduct **129b** (yield ~20%), of the methoxy-derivative **129** (R^1 = H, R^2 = OMe).



128a,b

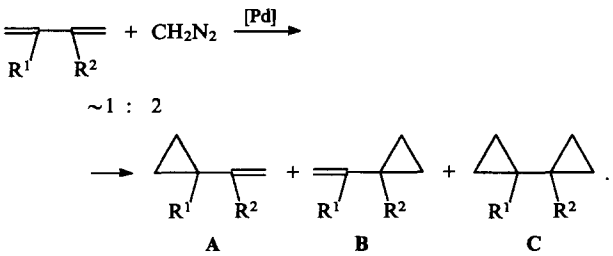


129a,b

CR^1R^2 = C=O (**a**) (92%);
R^1 = H, R^2 = OH (**b**) (20%);

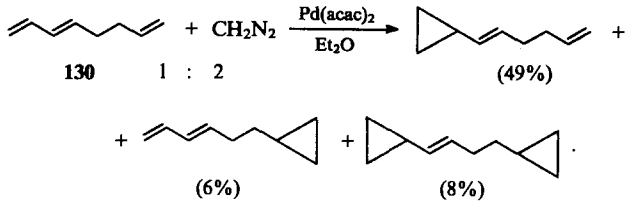
A method of synthesis of cyclopropyl-L-alanines and their derivatives—intermediates in the synthesis of food additives, medicinal drugs, and pesticides—has also been developed on the basis of the catalytic conversion of unsaturated compounds into cyclopropanes by diazomethane in the presence of palladium compounds.[174,175]

R = H (98%), CH_2OAc (68%).



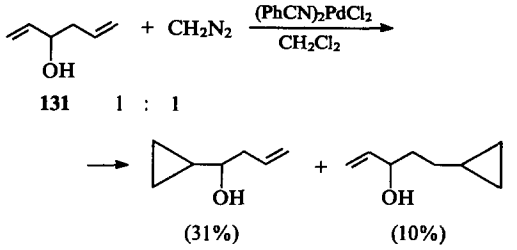
The regioselectivity of the conversion of various double bonds into cyclopropane groups and the possibility of obtaining polycyclopropane adducts are manifested most clearly in the interaction of CH_2N_2 with dienes and trienes.

The conversion of 1,3-dienes such as piperylene[25,68] as well as 1-cyclopropyl- and 1-alkoxy-butadienes[25,156,158] into cyclopropane derivatives in the presence of $Pd(acac)_2$ or $(PhCN)_2PdCl_2$ involves the terminal double bond and leads to the corresponding vinylcyclopropanes in high yields already in the presence of a (1.5–2)-fold excess of CH_2N_2.

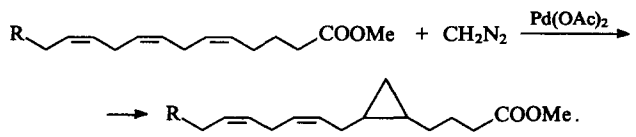


1 : 2 R = Me (90%), cyclo-C_3H_5 (91%), OMe, OEt, OAc, $OSiMe_3$ (80%–86%).

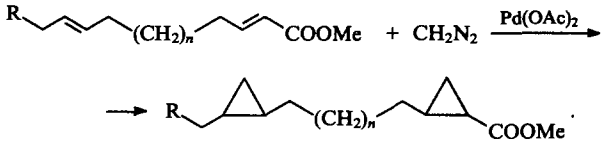
Under analogous conditions, the conversion of isoprene into a cyclopropane derivative proceeds less selectively, although a tendency towards the preferential formation of cyclopropanes from the less substituted C=C bond is retained.[68] In this case and also in the interaction of butadiene with 2,3-dimethylbutadiene[25] with an excess of diazomethane, the second double bond is converted into a cyclopropane group, which is accompanied by the partial formation of the corresponding bicyclopropyls, in agreement with the general tendency in the conversion of the terminal double bonds of alkenes into cyclopropyl groups.



R^1	R^2	Yield of adducts (%)		
		A	B	C
H	H	67	–	29
H	Me	70	12	9
Me	Me	65	–	15

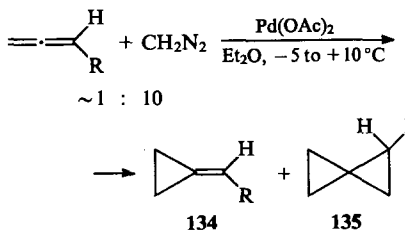


A terminal vinyl group conjugated with a double bond, as happens, for example, in octa-1,3,7-triene **130**, is approximately eight times more reactive than a terminal non-conjugated double bond.[25]

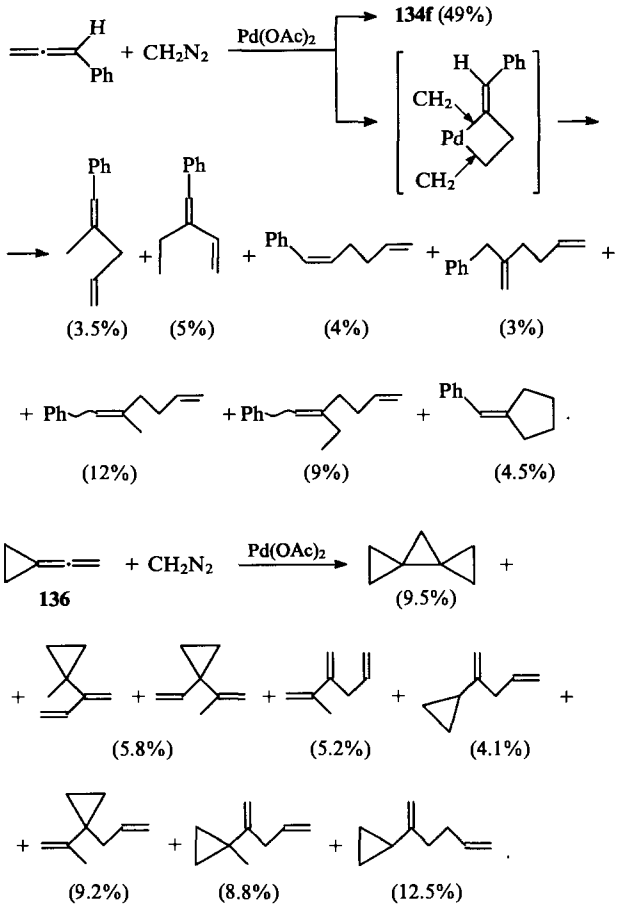


The catalytic reaction of CH_2N_2 with hexa-1,5-dien-3-ol **131**, containing different terminal double bonds, gives rise to the preferential conversion of the allyl C=C bond into a cyclopropyl group, in contrast to the homoallyl bond.[155]

The reactivity of vicinally substituted double bonds depends both on their position in the linear hydrocarbon chain and on their configuration. Thus the conversion of derivatives of arachidonic acid, containing *cis*-double bonds, into cyclopropanes involves only the C=C bond closest to the carboxy-group with formation of the cyclopropane adduct **132**, whereas the conversion into cyclopropanes of the esters of the *trans*-polyunsaturated acids affords satisfactory yields of the polycyclopropane adducts **133**.[176]

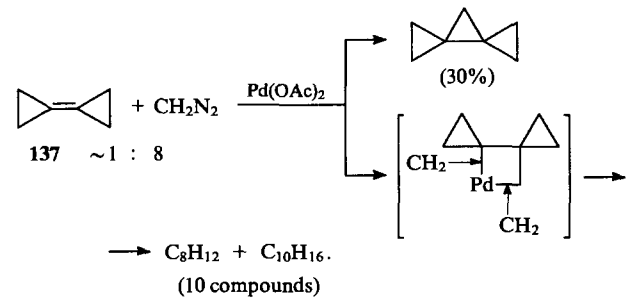


132 (~90%)



133 (80%–90%)

The conversion of allenes into cyclopropanes by treatment with diazomethane in the presence of $Pd(OAc)_2$ takes place most successfully when the catalyst is added to an ethereal solution of the allene and CH_2N_2, taken in a large excess.[177] The reaction then takes place fairly selectively with formation of adducts involving the least substituted double bond. However, in the conversion of alka-1,2-dienes into cyclopropanes, the corresponding spiropentanes **135** (yields up to 60%) are also formed together with the monoadducts **134**,[177,178] which indicates the possibility of the conversion into cyclopropyl groups of tri-substituted double bonds in the presence of palladium compounds.



Compound	R	Yield of **134** (%)	Yield of **135**(%)
a	Bu	67	25

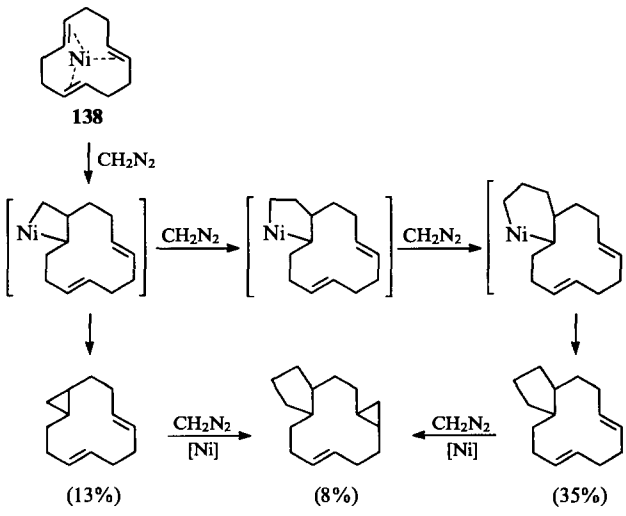
d	CH_2CH_2Br	63	27
e	CH_2CH_2OTs	78	–
f	Ph	49	–



In a study of the interaction of CH_2N_2 with phenylallene (~10:1) and vinylidenecyclopropane **136** (~20:1) in the presence of $Pd(OAc)_2$, an unusual oligomethylenation reaction was discovered. It leads to the incorporation of several equivalents of methylene into the molecule with formation of a complex mixture of unsaturated hydrocarbons.[179,180] The use of a smaller relative amount of CH_2N_2 then affords the same mixture of products in approximately the same proportions as in the presence of an excess of CH_2N_2,[179] which is probably due to the possibility of their formation from the same intermediates.

A similar oligomethylenation reaction takes place also in the case of bicyclopropylidene **137**, which indicates, on the one hand, the possibility of the conversion of a tetrasubstituted double bond into a cyclopropyl group by diazomethane in the presence of palladium compounds,[181] and, on the other, the possibility of the existence of palladiacyclic intermediates stabilised by the spiro-linked cyclopropane ring and capable of reacting subsequently with several equivalents of methylene until their decomposition into the corresponding hydrocarbons, in which the bicyclopropyl fragment is largely retained.

The results agree with the non-trivial reaction of CH_2N_2 with *trans, trans, trans*-cyclododeca-1,5,9-trienenickel **138**, discovered previously, which resulted in the formation not only of cyclopropane derivatives but also of trimethylenation products, which are converted into compounds with a condensed five-membered ring.[182]

The formation of cyclopentane derivatives indicates that the reaction proceeds via a stage involving the formation of a metallacyclobutane fragment, the subsequent insertion of methylene in the Ni–C bond of which actually leads to the cyclopentane derivatives. The absence of a cyclobutane adduct is apparently due to the different stabilities of the four-, five-, and six-membered metallacycles and, in particular, the greater stability of nickelacyclopentanes (the reaction of which with CH_2N_2 goes to completion) compared with the other two metallacycles containing an odd number of carbon atoms in the ring, which they can readily eliminate in the form of the corresponding cycloalkane adducts.

b. Conversion of cyclic unsaturated compounds into cyclopropane derivatives

The possibility of the conversion of cyclic unsaturated compounds into cyclopropanes by treatment with diazomethane has led to extensive prospects for the synthesis of various cyclopropanes. The nature of the double bonds, determined primarily by the degree of strain in the cyclic system, exerts a significant influence on the nature of their conversion into cyclopropyl groups.

Thus, in the series of cycloolefins cyclohexene, cycloheptene, cyclooctene, and norbornene, the yields of cyclopropanes increase from 15% to 95% respectively under the same conditions (for example, when an equimolar amount of CH_2N_2 is passed at a uniform rate into the solution of the olefin in the

Table 4. Conversion of norbornene derivatives into cyclopropane derivatives by treatment with diazomethane in the presence of 0.3–1.2 mol% of palladium compounds in ether.

presence of 0.1–0.5 mol% of the palladium catalyst in CH_2Cl_2 at −10 to 0 °C).[68] As in the case of monosubstituted olefins, the use of $PdCl_2$, $Pd(OAc)_2$, $(PhCN)_2PdCl_2$, and $[\eta\text{-}C_3H_5PdCl]_2$ in these reactions hardly exerts a significant influence on the yields of the cyclic adducts.

The interaction of a mixture of cyclohexene and norbornene with CH_2N_2 in the presence of $(PhCN)_2PdCl_2$ proceeds, in contrast to copper compounds, regioselectively and leads to the almost complete conversion of norbornene into the adduct **64** without an appreciable conversion of cyclohexene into a cyclopropane derivative. Furthermore, a characteristic feature of palladium catalysts is their ability to propagate the reaction at a high CH_2N_2 concentration and to retain a high activity in the conversion of strained olefins into cyclopropanes virtually up to the completion of the reaction. These results undoubtedly indicate the preferential formation of π-olefin complexes in the conversion of unsaturated compounds into cyclopropanes with participation of palladium catalysts.[68]

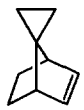
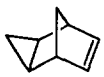
One can now say without exaggeration that the conversion of polycyclenes into cyclopropanes by treatment with diazomethane, catalysed by palladium compounds, is one of the most promising methods of synthesis of polycyclic hydrocarbons of the norbornane series with a condensed cyclopropane fragment in the molecule (Table 4). The relative reactivities of certain unsaturated compounds in the reaction with CH_2N_2 in the presence of the palladium catalysts $Pd(OAc)_2$, $Pd(acac)_2$, and $(PhO)_3P \cdot PdCl_2$ have been investigated[159] and a significant difference between the rates of conversion of the norbornene and aliphatic mono- and di-substituted double bonds into cyclopropyl groups has been demonstrated.



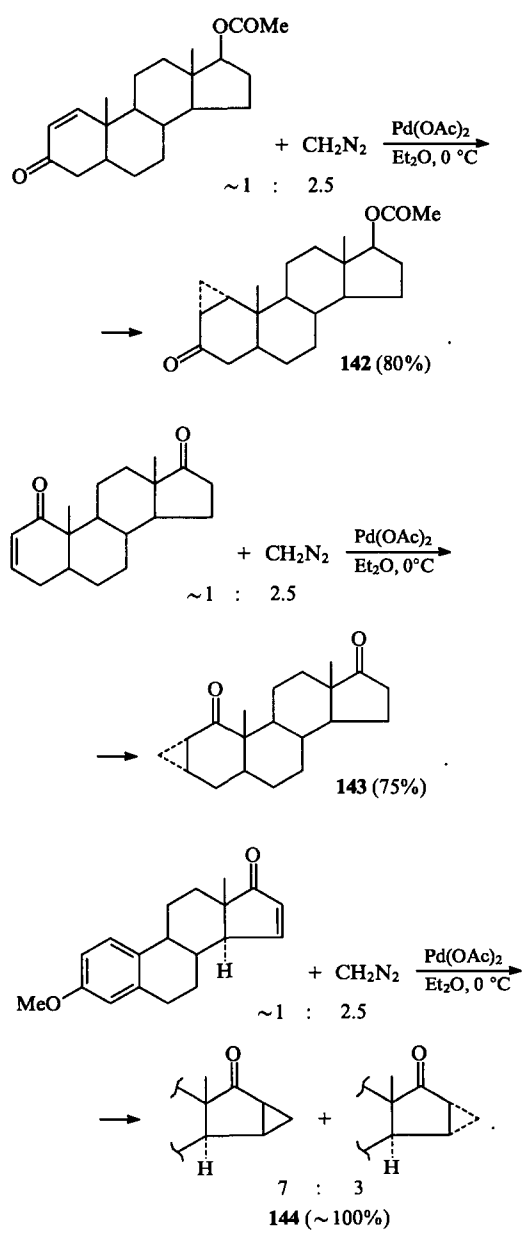


The substituted norbornene double bond proves to be more reactive than the terminal aliphatic double bond,[159, 183] which is in its turn an order of magnitude more reactive than cyclohexene. This is clearly illustrated by the catalytic conversion of 4-vinylcyclohexene into the cyclopropyl derivative.[68]

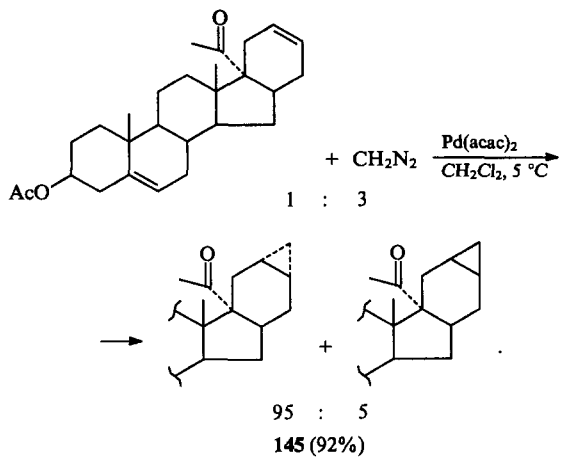
70% 3% 7%

The stereochemistry of the addition of methylene, generated by the catalytic decomposition of CH_2N_2, to certain norbornene hydrocarbons has been investigated;[117] comparative estimates of the degrees of *exo*- and *endo*-conversion of the double bonds into cyclopropyl groups are given in Table 5. The results combined with other data for the conversion of norbornene derivatives into cyclopropanes in the presence of various catalysts based on palladium compounds confirm the high stereoselectivity in the formation of the *exo*-adducts (the fraction of the *endo*-isomers does not exceed 1.5%). On the other hand, when copper compounds and especially $Rh_2(OCOCF_3)_4$ are used as catalysts, the formation of *endo*-isomers is observed. Their amount increases significantly on passing from norbornene to norbornadiene and reaches 36%–42%.[117]

Table 5. Stereochemistry of the conversion of norbornene hydrocarbons into cyclopropane derivatives by treatment with diazomethane in the presence of various catalysts (0.5 – 1.0 mol%).



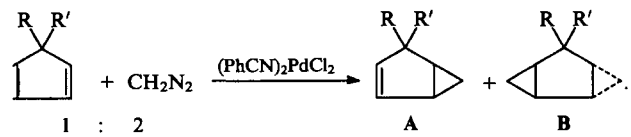
Original olefin	Reaction products	Ratio of *exo*- and *endo*-isomers [overall yield of isomers (%)]						
		$Pd(acac)_2$	$(PhCN)_2PdCl_2$	$Pd(OAc)_2$	$Cu(OTf)_2$	CuCl	$Cu(acac)_2$	$Rh_2(OCOCF_3)_4$
	*exo*- and *endo*-**64**	100:0 (87)	100:0 (81)	100:0 (78)	98:2 (73)	97:3 (58)	97:3 (38)	90:10 (18)
	*exo*- and *endo*-**141**	100:0 (32)	100:0 (36)	99:1 (18)	99:1 (23)	97:3 (38)	98:2 (18)	77:23 (20)
	*exo,exo*- and *exo,endo*-**91** (R = H)	99:1 (83)	100:0 (90)	99:1 (71)	95:5 (56)	86:14 (78)	96:4 (55)	74:26 (20)
	*exo*- and *endo*-**90** (R = H)	99:1 (52)	99:1 (54)	99:1 (48)	75:25 (34)	70:30 (48)	64:36 (36)	58:42 (19)
	exo,exo- and *exo,endo*-**91** (R = H)	98:2 (16)	99:1 (16)	98:2 (14)	72:28 (9)	65:35 (12)	62:38 (9)	53:47 (4)



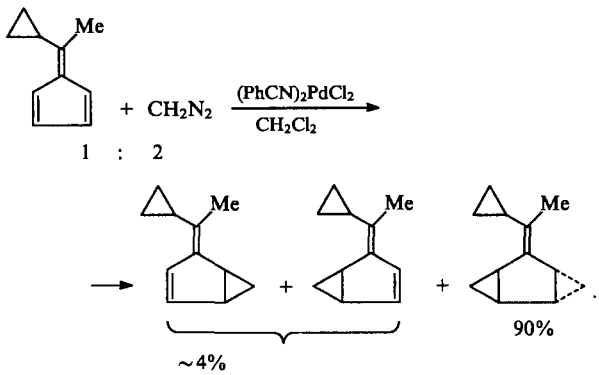
The *exo*-stereoselectivity in the conversion of norbornenes into cyclopropanes under the influence of palladium catalysts is probably associated with the ability of norbornenes to form initially coordinated π-complexes with the central metal atom, which react subsequently with CH_2N_2.[68,70] In view of the *endo*-deformation of the vinyl hydrogen atoms (the angle of deviation of the C–H bonds from the C–CH=CH–C plane of the norbornene fragment is 3°–5°),[125,192] this coordination is undoubtedly extremely sensitive to the electronic state of the double bond and takes place exclusively in the *exo*-position. In the case of copper and particularly rhodium catalysts, the double bond is attacked by metal–carbene complexes, as a result of which the interaction of the carbene centre with the double bond is less sensitive to the electronic state of the latter and takes place partially in the *endo*-position.

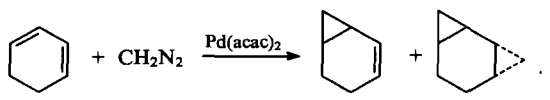
The increased content of the *endo*-isomers in the conversion of the norbornadiene into cyclopropane derivatives compared with norbornenes) in the presence of copper and rhodium catalysts is also apparently associated with the characteristic features of the geometry of the double bonds. Thus, according to calculations,[125] the angle of the *endo*-deformation of the vinyl C–H bonds in norbornadiene is smaller than in norbornene (2.3° and 4.9° respectively) and the probability of the attack on the double bond by the carbene complex from the direction of the *endo*-position is therefore increased for the former compound. This explanation is apparently valid also for many other cycloaddition reactions involving norbornadiene, accompanied by the formation of *exo*- and *endo*-isomers.

The conversion of an unsubstituted double bond in five-membered and six-membered rings into cyclopropyl groups, which is ineffective for the hydrocarbons themselves, is significantly activated by the presence of a conjugated carbonyl group. Thus the use of a comparatively small excess of CH_2N_2 led to the synthesis in high yields of the steroids **142**–**144** containing the cyclopropane ring in the molecule.[151]



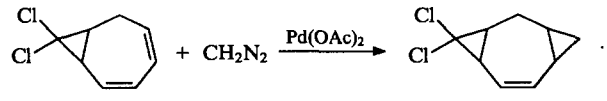
It has been established recently[176] that, when $Pd(acac)_2$ is used as the catalyst, it is possible to achieve the conversion into a cyclopropyl group, also of a non-conjugated endocyclic double bond in a six-membered ring, which is illustrated, in particular, by the formation of the isomeric adducts **145**. Trisubstituted double bonds in Δ^5-, Δ^7-, Δ^{11}-, and Δ^{14}-steroids do not give rise to cyclopropyl groups under the chosen conditions.





145 (92%)

The double bonds in cyclopentadiene,[68] spiro[2,4]heptadiene,[193] 6,6-disubstituted fulvenes,[68] cyclohexa-1,3-diene,[25,194] and cycloocta-1,5-diene[68,194] are fairly readily converted into cyclopropyl groups by diazomethane in the presence of palladium compounds and the formation of a cyclopropyl group from one of the double bonds sometimes accelerates the similar conversion of the second double bond, which is probably due to the increase in its strain as a result of the additional introduction of a cyclopropane fragment into the cyclic structure. The conversion of the second double bond in five- and six-membered cyclic dienes into a cyclopropyl group then occurs with formation of only the corresponding *trans*-isomers,[68,194] whereas in the case of cycloocta-1,5-diene, small amounts of the *cis*-isomer are also produced (*trans* : *cis* ≃ 7 : 1).



R	R′	Yield of A (%)	Yield of B (%)
H	H	15	75

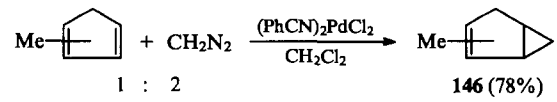
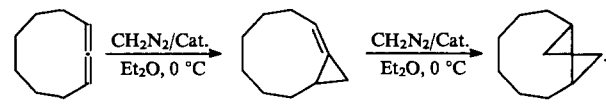
1:2	53	13

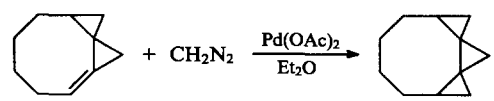


It is of interest to note that neither cyclohepta-1,3,5-triene[194] nor cycloocta-1,3,5,7-tetraene[116] are converted into cyclopropane derivatives by diazomethane in the presence of $Pd(OAc)_2$ despite the use of an excess of CH_2N_2.



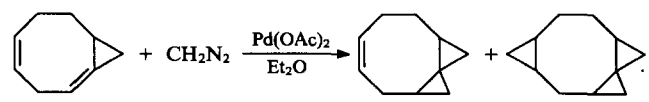
Reagents ratio	Yield of products (%)		
	A	B	C
1:1	5	38	5.5
1:2	6	72	10

The substituents in the cyclodienes exert the same influence on the regioselectivity of the addition of methylene as in alkenes. Thus the conversion of a mixture of methylcyclopentadienes into cyclopropane derivatives in the presence of palladium compounds involves only the unsubstituted double bond with formation of 2- and 3-methylbicyclohexenes **146**.[68]

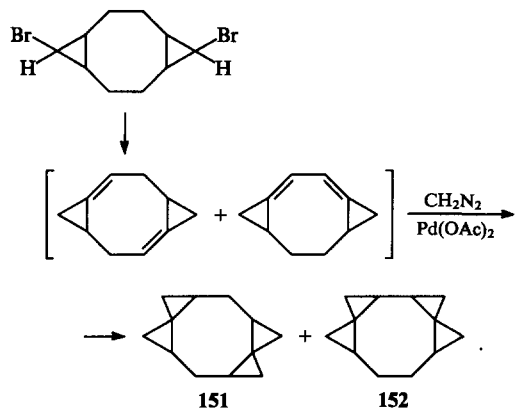


146 (78%)

The allene group in cyclonona-1,2-diene is converted into a cyclopropyl group by an excess of CH_2N_2 in the presence of the palladium catalysts $Pd(OAc)_2$ and $(PhCN)_2PdCl_2$, affording bicyclodecene **147** in a preparative yield (~60%). Repeated treatment of the reaction mixture with diazomethane leads to the partial formation of the spiran adduct **148**, the yield of which does not, however, exceed 10%.[177]

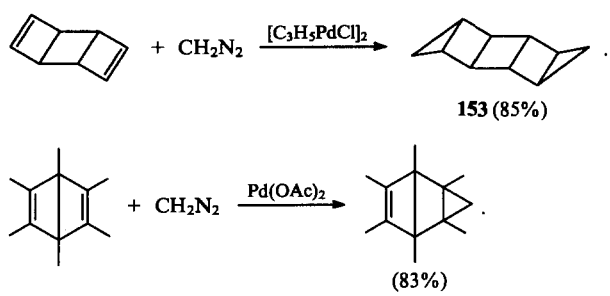


147 (~60%) **148** (~10%)



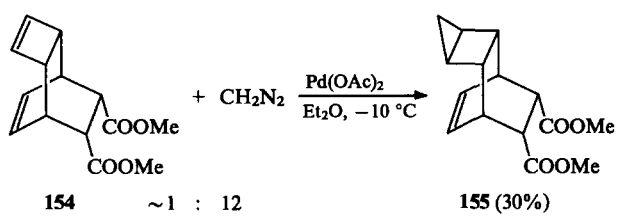
A similar approach, involving the catalytic introduction of an additional cyclopropyl group into alkylidenecyclopropanes, has been used recently to synthesise the polyspiran hydrocarbons **149–152** containing several three-membered rings in the molecule.[195]

149



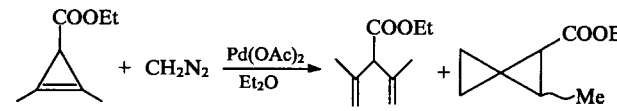
150

151 152



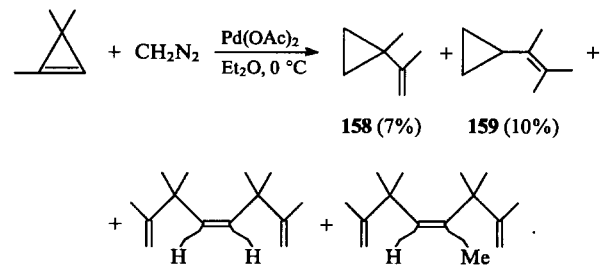
Polycyclic structures containing a C=C bond in a four-membered ring are also converted into cyclopropane derivatives by treatment with diazomethane in the presence of palladium compounds and the nature of the cyclopropane formation reaction involving such substances has a number of specific features. Thus, whereas the formation of the diadduct **153** in a high yield in the cyclopropane formation reaction involving tricyclo[4.2.0.0^{2,5}]octa-3,7-diene appears fairly evident,[188] the conversion of the tetrasubstituted double bond of the permethylated Dewar benzene into a cyclopropyl group using a palladium catalyst appears to be non-trivial.[150]

153 (85%)



(83%)

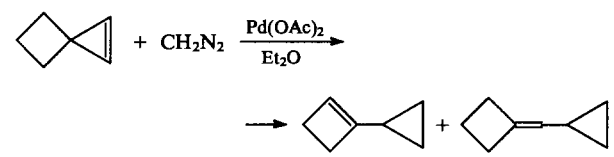
The cyclobutene fragment in the polycyclic diene **154** is converted into a cyclopropyl group less effectively, which leads to the monoadduct **155** in a yield of ~30% even in the presence of a large excess of CH_2N_2.[196] The absence of the formation of a cyclopropane adduct from the second double bond is apparently associated with the steric hindrance generated by the four-membered ring and the methoxycarbonyl substituents. It is noteworthy that, according to Dzhemilev et al.,[25] bicyclo-[2.2.2]oct-2-ene itself affords the cyclopropane adduct in 64% yield.



154 ~1 : 12 **155** (30%)

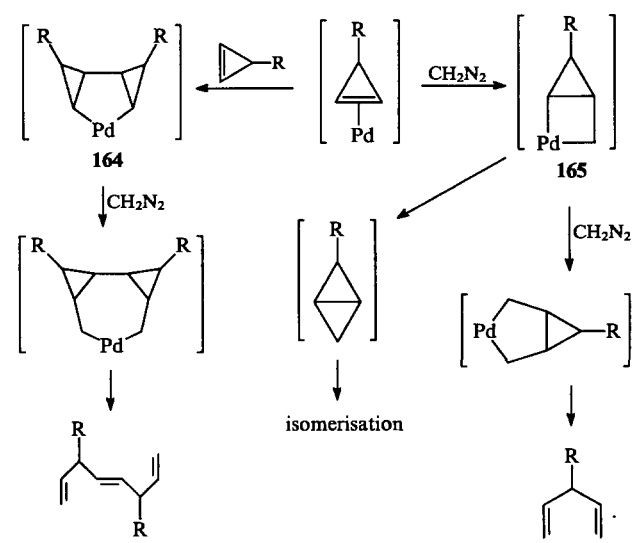
In contrast to the unsaturated compounds examined, the interaction of cyclopropenes with CH_2N_2 catalysed by palladium compounds proceeds in a more complex manner and is accompanied by the formation of appreciable amounts of oligomeric products. The nature of the compounds synthesised then depends to a large extent on the degree of substitution of the cyclopropenes, the electron-accepting properties of the substituents, and the reaction conditions.[197–199] Thus ethyl 1,2-dimethylcyclopropenecarboxylate reacts with an excess of CH_2N_2 to form the diene **156** and the spiropentane **157** in an overall yield of ~25%.[197,199] The appearance of the spiropentanes **157** (isomer ratio ~1 : 1.2) can be explained by the partial isomerisation of the initial cyclopropene ester to the corresponding ester of 2-methylene-3-methylcyclopropenoic acid and its subsequent conversion into a cyclopropane derivative.

156 (15%) **157** (10%)



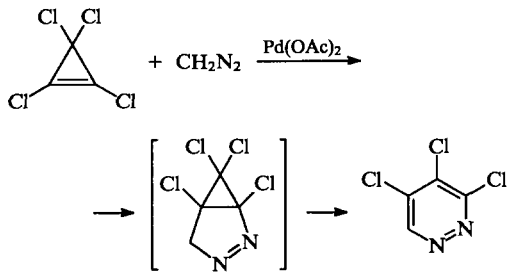
The addition of a catalytic amount of $Pd(OAc)_2$ to a mixture of an ethereal solution of CH_2N_2 and 1,3,3-trimethylcyclopropene leads to the vinylcyclopropanes **158** and **159** and the trienes **160** and **161** in an overall yield of ~40% (for the total conversion of the initial cyclopropene).[198,199]

158 (7%) **159** (10%)



160 (8%) **161** (15%)

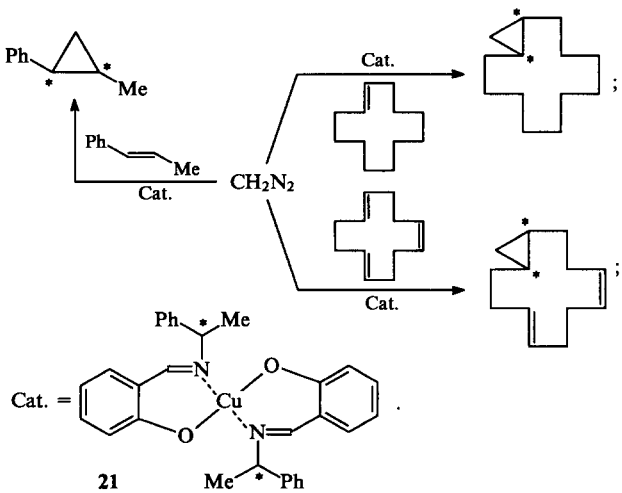
The monomeric products **162** and **163** are obtained in an even lower yield in the catalytic reaction of CH_2N_2 with spirohex-1-ene.[199]



162 (3%) **163** (5%)

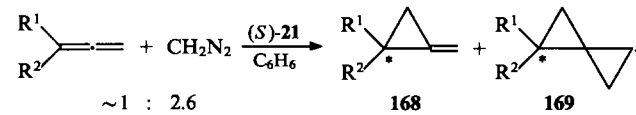
A probable mechanism of the observed reactions has been proposed.[197–199] It explains the formation of compounds **158–163** as a result of the catalytic conversion of the bicyclobutanes and/or metallacycles formed initially. The difference between the coordinating capacities of trimethylcyclopropene and the cyclopropenecarboxylate ester is then attributed to the possibility of the formation of two different intermediates—the metallacycles **164** and **165**. The subsequent

insertion of methylene in the Pd–C bonds leads to the expansion of the metallacycles and is completed by their decomposition with the opening of the cyclopropane fragment and the elimination of palladium.



In contrast to the cyclopropenes mentioned above, the interaction of tetrachlorocyclopropene with CH_2N_2 leads to trichloropyridazine **166**. Owing to the combination of the low coordinating capacity of the tetrasubstituted cyclopropene with its high electron deficiency, the only reaction pathway in this instance is 1,3-dipolar addition with subsequent conversion of the resulting adduct **167** into the pyridazine **166**.[199]

167 **166** (75%)

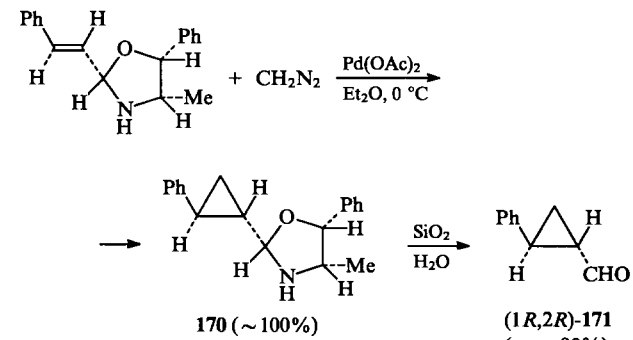


4. Asymmetric conversion of olefins into cyclopropane derivatives by diazomethane

The catalytic chiral [1 + 2]-cycloaddition of methylene, generated from CH_2N_2, to olefins with formation of optically active cyclopropanes was achieved for the first time in 1968 by Nozaki et al.,[67] who used salicylideneaminecopper complexes (*R*)- or (*S*)-**21**, obtained from chiral 1-phenylethylamines, as the catalyst. Thus (*E*)-propenylbenzene is converted on treatment with compound **21** into *trans*-2-methyl-1-phenylcyclopropane **22** in 62% yield with an enantiomeric excess of ~8%. Partial optical activity of the products formed in the presence of the optically active catalysts **21** has been observed also in the conversion of *trans*-cyclododecane and *Z*,*Z*,*E*-cyclododeca-1,5,9-triene into cyclopropane derivatives.[67]

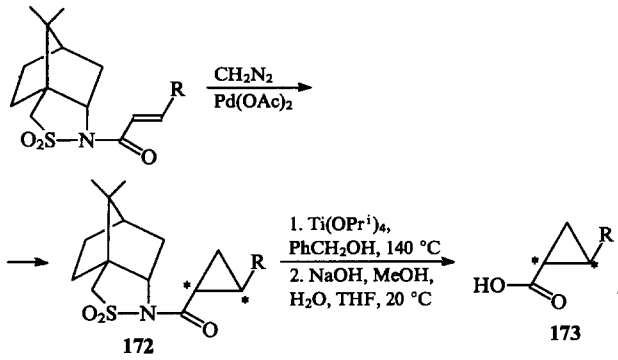
21

Asymmetric induction has been observed also in the decomposition of CH_2N_2 on treatment with (*S*)-**21** as catalyst in the presence of phenyl-, 1-methyl-1-phenyl-, and hexylallenes.[200,201] Both the methylenecyclopropanes **168** and the corresponding spiropentanes **169** were then obtained in satisfactory yields. In the case of phenylallene,[201] the absolute configuration of the methylenecyclopropane **168a** was determined and the optical yield of compounds **168a** and **169a** was estimated as ~12%.



~1 : 2.6 **168** **169**

Compound	R^1	R^2	Yield of **168** (%)	Yield of **169** (%)
a	Ph	H	30	45
b	Ph	Me	43	52
c	C_6H_{13}	H	7	43



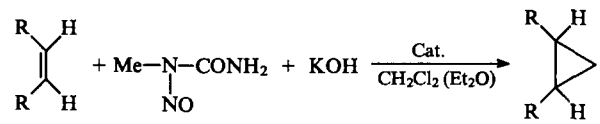
After the publication of these studies, which demonstrated only the possibility, in principle, of the induction of optical activity in the cyclopropanes produced, there were virtually no publications concerning the use of catalysts containing optically active ligands for the conversion of unsaturated compounds into cyclopropane derivatives by diazomethane. On the other hand, studies on the synthesis and use of chiral catalysts, in the first place rhodium compounds, for the decomposition of other diazo-compounds, especially alkyl diazoacetates, developed extensively.[202]

Nevertheless the interest in the synthesis of optically active compounds based on the catalytic conversion of olefins into cyclopropane derivatives by diazomethane has persisted in connection with the possibility of the effective conversion of suitable chiral substrates into cyclopropanes. The usual palladium catalysts, especially $Pd(OAc)_2$, are used in this instance and the optical activity is induced in the resulting *trans*-1,2-disubstituted cyclopropane by the presence in the initial olefin of an optically active substituent, which can be transformed, when necessary, into a suitable functional group. Thus a method of synthesis of (1*R*,2*R*)-phenylformylcyclopropane **171** with an optical purity not less than 90% from cinnamaldehyde and L-ephedrine has been proposed. The key stage of the reaction is the synthesis of the oxazolidine derivative **170**.[203]

170 (~100%) (1*R*,2*R*)-**171** (ee > 90%)

It has been shown recently[204] that *trans*-*N*-enoylsultams—derivatives of α,β-unsaturated carboxylic acids and bornane[10.2]sultam—undergo the stereoselective cyclopropane formation reaction on treatment with diazomethane in the presence of $Pd(OAc)_2$, forming the corresponding *trans*-disubstituted cyclopropanes **172** in high yields (the enantiomeric excess of the nonrecrystallised reaction products is 67%–91%). The subsequent hydrolysis of the cyclopropanes **172** in the presence of titanium tetraisopropoxide leads to the optically active cyclopropanecarboxylic acids **173**.[204]

R	Ph	2-MeOC$_6$H$_4$	3-MeOC$_6$H$_4$	Me	C$_{10}$H$_{21}$
Yield of **172** (%)	73	73	63	72	62

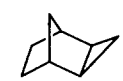


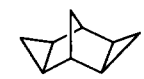
R	3,4,5-(MeO)$_3$C$_6$H$_2$		
Yield of **172** (%)	62	67	67

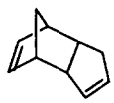
The authors [204] also noted that the diastereomeric excess of the cyclopropane products, for example **172** (R = Ph), increases from 53% to 87% when the reaction temperature is raised from −30 to 0 °C and remains almost unchanged on its further increase (from 0 to +30 °C).

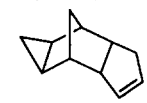
5. Conversion of unsaturated compounds into cyclopropane derivatives by diazomethane generated *in situ*

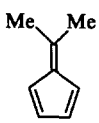
The results presented above show that the catalytic reaction of diazomethane with unsaturated compounds constitutes a universal and fairly simple (from the standpoint of the initial reactants) method of synthesis of various cyclopropanes and that the use of palladium catalysts is especially promising. However, the standard procedure in the cyclopropane formation reaction suffers from a number of significant disadvantages and limitations, the main ones being the necessity for the preliminary preparation and transport of the toxic and explosive diazomethane, which renders it suitable only for laboratory purposes.

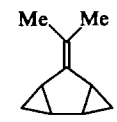












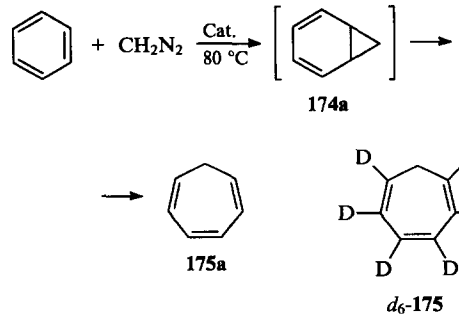
In 1987 we showed for the first time [205] that the conversion of allyl alcohol and allyl ethers into cyclopropane derivatives can be carried out successfully with the direct generation of CH_2N_2 by the alkaline hydrolysis of *N*-methyl-*N*-nitrosourea in the presence of the unsaturated compound and the palladium catalyst. In our subsequent studies [157,206] this method was developed further. In particular, it proved extremely effective for the conversion into cyclopropane derivatives of the majority of unsaturated compounds containing monosubstituted and strained endocyclic double bonds. In the method proposed, *N*-methyl-*N*-nitrosourea is added gradually at 10–20 °C to a mixture of the unsaturated compound, the palladium catalyst, an organic solvent, and 40%–50% KOH solution.

Cat. = $(PhCN)_2PdCl_2$, $Pd(OAc)_2$, $Pd(acac)_2$, $[(PhO)_3P]_2PdCl_2$, $[(PhO)_3P]_4Pd$.

The successful use of palladium catalysts in this method for conversion into cyclopropane derivatives, which involves the use of a concentrated solution of alkali, is apparently due to the involvement in the reaction of non-hydrolysable low-valence π-olefinpalladium complexes. The activity of the catalytic system hardly diminishes under these conditions and makes it possible to achieve conversion into cyclopropane in preparative yields,

Table 6. Catalytic conversion of unsaturated compounds into cyclopropane derivatives by the diazomethane generated *in situ* from *N*-methyl-*N*-nitrosourea (MNU) and KOH [catalyst : 0.2 mol% $(PhCN)_2PdCl_2$, temperature 12–15 °C].

Unsaturated compound	MNU : substrate	Solvent	Product	Yield (%)
	1.5 : 1	CH_2Cl_2		95
	2.9 : 1	CH_2Cl_2		92
	1.5 : 1	CH_2Cl_2–hexane		94
	3 : 1	CH_2Cl_2–Et_2O		84
	1.6 : 1	CH_2Cl_2		92
	1.9 : 1	Et_2O		92
	1.7 : 1	CH_2Cl_2		91
	1.8 : 1	CH_2Cl_2–Et_2O		88
	1.9 : 1	CH_2Cl_2–Et_2O		88



which are the same as in the *ex situ* procedure.[157] Table 6 presents the results of the conversion into cyclopropanes of certain unsaturated hydrocarbons and alkenes with functional group substituents under the conditions of the simultaneous generation and catalytic decomposition of diazomethane.

Thus the creation of a convenient and safe method for the conversion of unsaturated compounds into cyclopropane derivatives by diazomethane generated *in situ* has provided a powerful instrument in synthetic organic chemistry for the formation of cyclopropanes from the corresponding olefins (predominantly monosubstituted and disubstituted). Furthermore, the elimination of the need to employ large quantities of diazomethane to maintain the efficiency of the cyclopropane formation stage itself makes this method promising for application on an industrial scale.

IV. Catalytic interaction of diazomethane with aromatic compounds

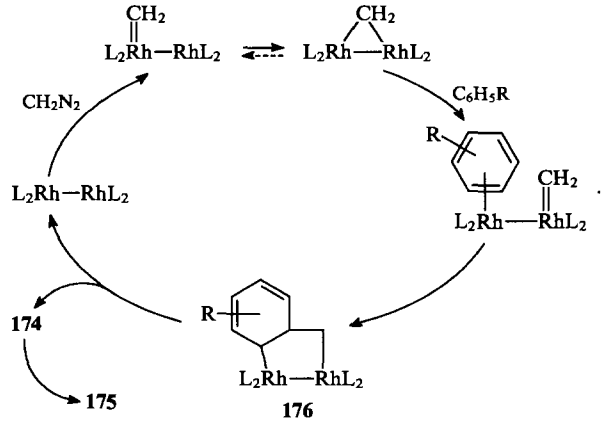
The transition metal complex-catalysed interaction of diazomethane with aromatic compounds is accompanied by the dediazotisation of CH_2N_2 and the addition of the methylene fragment to the aromatic system. In the case of compounds of the benzene series, the main products of these reactions are cyclohepta-1,3,5-trienes.[207-213] The reaction involving the expansion of a six-membered ring to a seven-membered one is characteristic also of the catalytic decomposition of other diazo-compounds (for example, alkyl diazoacetates[214]) in different benzene derivatives. This leads to extensive possibilities in the synthesis of cyclohepta-1,3,5-trienes, which are otherwise difficult to obtain. Among the large number of metal salts and complexes tested as catalysts of the methylenation of aromatic compounds by diazomethane, those based on rhodium and copper are the most effective [$Rh_2(OCOCF_3)_4$, $Rh_2(OAc)_4$, Rh/C, $CuCl_2$, CuCl, CuBr].[207-210] On the other hand, the mononuclear rhodium complexes [$RhCl_3$, $Rh(acac)_3$, $Rh(PPh_3)_3Cl$] as well as palladium compounds and copper *N*-(1-phenylethyl)salicylaldiminate proved to be altogether inactive in this reaction.[210]

The catalytic interaction of CH_2N_2 with benzene was first achieved by Müller and coworkers.[207,208] Cycloheptatriene **175a** was obtained in this reaction in 85% yield (relative to CH_2N_2) by adding a benzene solution of CH_2N_2 to a suspension of CuCl or CuBr in benzene at 80 °C. The use of $Rh_2(OCOCF_3)_4$ instead of copper halides with the ratios C_6H_6 : CH_2N_2 : Cat. = 4000 : 200 : 1 makes it possible to increase the yield of compound **175a** to 95% and to carry out the process under milder conditions (~20 °C).

d_6-**175**

According to the data of Dzhemilev et al.,[210] the catalytic cycle in the formation of cycloheptatrienes by the reaction of CH_2N_2 with benzene in the presence of rhodium catalysts presupposes the involvement of dinuclear rhodium complexes,[215] which facilitate the multistage addition of CH_2 to the aromatic system via the formation of metallacyclic intermediates. The subsequent reductive elimination of the dinuclear rhodium complexes from complex **176** is accompanied by the formation of bicyclo[4.1.0]hepta-2,4-dienes (norcaradienes), which are converted into the corresponding cycloheptatrienes under the reaction conditions as a result of the synchronous electrocyclic opening of the cyclopropane ring (Scheme 4). This mechanism has been confirmed by the selective distribution of deuterium in the adduct d_6-**175**, obtained by the reaction of CH_2N_2 with perdeuteriobenzene in the presence of $Rh_2(OCOCF_3)_4$.[210]

Scheme 4



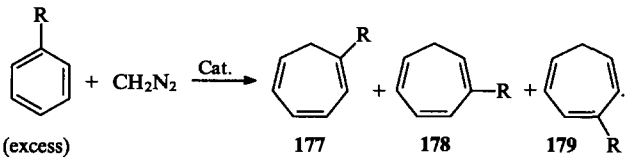


Table 7. The formation of substituted cyclohepta-1,3,5-trienes in the reaction of monosubstituted benzenes with CH_2N_2 in the presence of CuBr or $Rh(OCOCF_3)_4$.

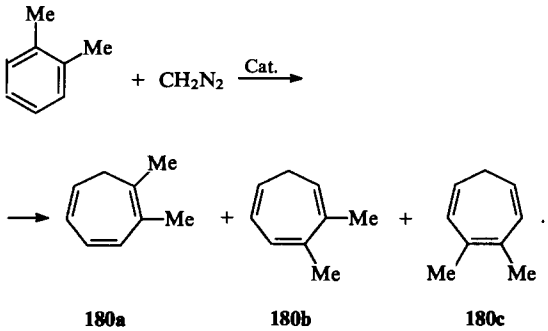
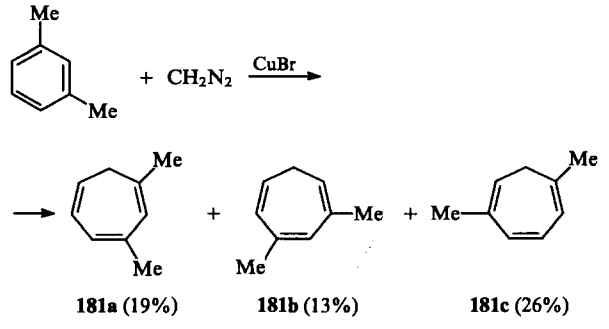
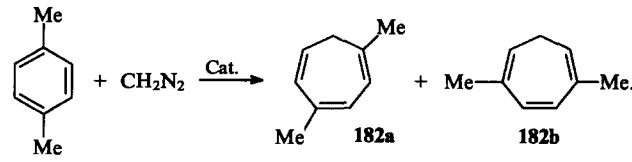


Catalyst (0.5-2 mol%)	Substituent R	Overall yield (%)	k_{rel} (PhR/PhH)	Proportions of isomeric products (%)		
				177	**178**	**179**
CuBr	Me	75	–	21	43	36
	Et	68	–	20	38	42
	Pr^i	64	–	17	37	46
	Bu^t	50	–	13	35	52
	F	41	–	23	25	52
	Cl	50	–	15	43	42
	Br	25	–	8	54	38
	OMe	75	–	30	25	45
$Rh_2(OCOCF_3)_4$	Me	98	1.02	24	26	50
	Ph	92	0.93	23	28	49
	Cl	20	0.16	25	11	64
	Br	8	0.06	19	27	54
	COOEt	7	0.07	12	33	55

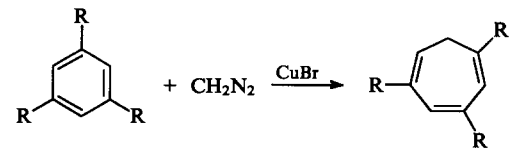
Benzene derivatives react with CH_2N_2 similarly to benzene itself and in the presence of both copper and rhodium catalysts a mixture of isomeric 1-, 2-, and 3-substituted cycloheptatrienes **177–179** is then formed from monosubstituted benzenes (Table 7).[210–213]



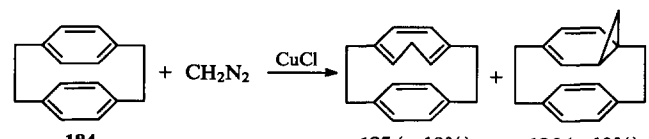


The introduction of bulky and electron-accepting substituents into the benzene ring lowers significantly the overall yield of the reaction products. Whereas in the case of halobenzenes the use of CuBr is preferred in this reaction, for benzene derivatives with electron-donating substituents a greater activity is shown by $Rh_2(OCOCF_3)_4$. It is striking that the preferential formation of 3-substituted cycloheptatrienes **179** is observed in virtually all instances. It has been suggested[210] that the cycloaddition of methylene to the six-electron π-system of substituted aromatic compounds largely involves the C(3)–C(4) bond of the benzene ring, where, according to Dewar,[216] the highest electron density is concentrated. Benzaldehyde, benzonitrile, nitrobenzene, and pyridine do not react with CH_2N_2 in the presence of $Rh_2(OCOCF_3)_4$; surprisingly, anisole behaves in the same way.[210]

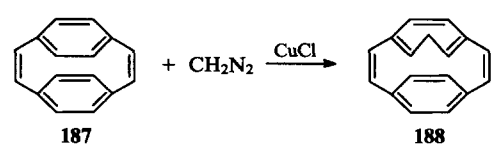
Preparative methods of synthesis of isomeric dimethylcycloheptatrienes **180–182**, with a fixed relative disposition of the methyl groups, and of individual 1,3,5-trialkylcyclohepta-1,3,5-trienes **183** have been developed on the basis of the catalytic interaction of diazomethane with xylenes and 1,3,5-trialkylbenzene.[210–212] As was to be expected, the overall yield of cycloheptatrienes increases appreciably under these conditions when $Rh_2(OCOCF_3)_4$ is used as the catalyst.



Cat.	Yield of **180** (%)		
	a	**b**	**c**
CuBr	8	31	12
$Rh_2(OCOCF_3)_4$	18	29	51



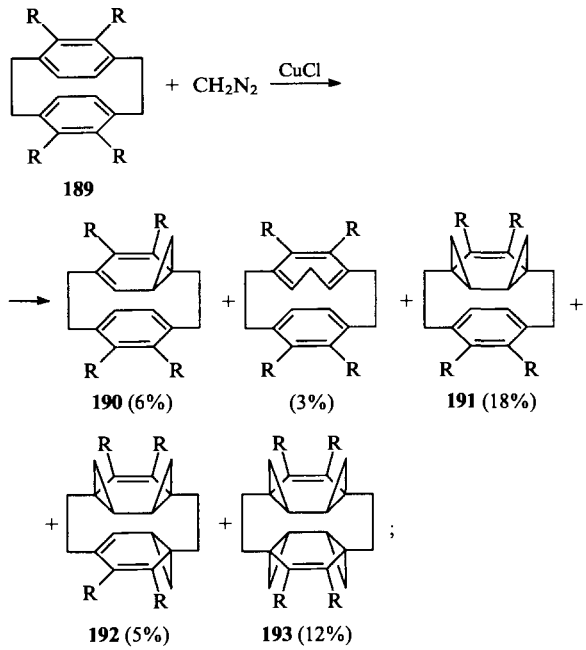
Cat.	Yield of **182** (%)	
	a	**b**
CuBr	25	37
$Rh_2(OCOCF_3)_4$	73	24



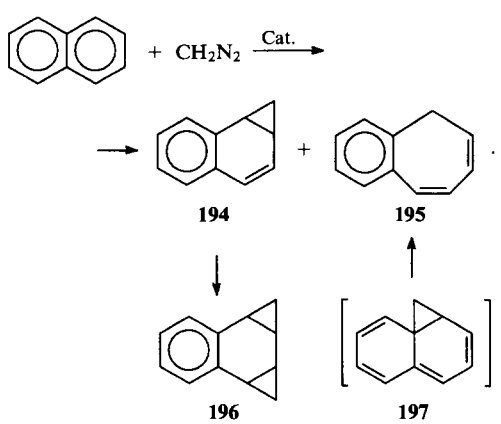
R = Me (75%), Et (59%), Pr^i (45%).

Like *p*-xylene, 1,4-dimethoxybenzene interacts with CH_2N_2, affording in the presence of CuCl two isomers — 1,4- and 2,5-dimethoxycyclohepta-1,3,5-trienes in an overall yield of ~65%.[213]

The catalytic methylenation of the aromatic ring by diazomethane occurs also in the case of cyclophanes.[217–220] Thus the interaction of CH_2N_2 with [2,2]paracyclophane **184** in the presence of CuCl leads to a mixture of different methylenation products, among which monoadducts are formed as a mixture of approximately equal amounts of compounds **185** and **186** containing both the cycloheptatriene and norcaradiene fragments.[217,218]

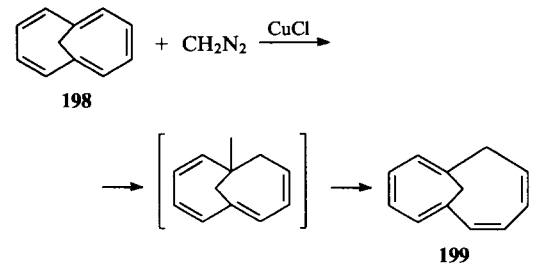


The methylenation of [2,2]paracyclophane-1,9-diene **187** takes place unexpectedly selectively under similar conditions; methylene then attacks benzene rings much faster than the double bond, adding preferentially to the unsubstituted bond with formation of the cycloheptatriene derivative **188**.[217]

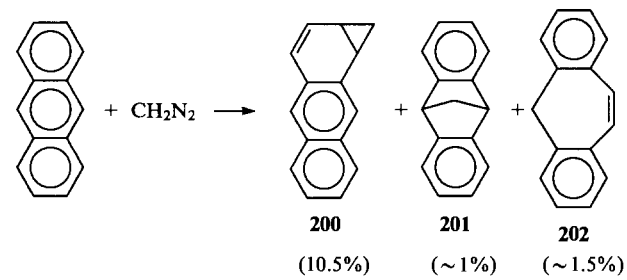


On the other hand, tetrakis(methoxycarbonyl)paracyclophane **189** reacts with a large excess of CH_2N_2 in the presence of CuCl and affords mainly the CH_2N_2 adducts **190–193** as a result of the addition of methylene to the monosubstituted bonds of the benzene ring.[219,220]

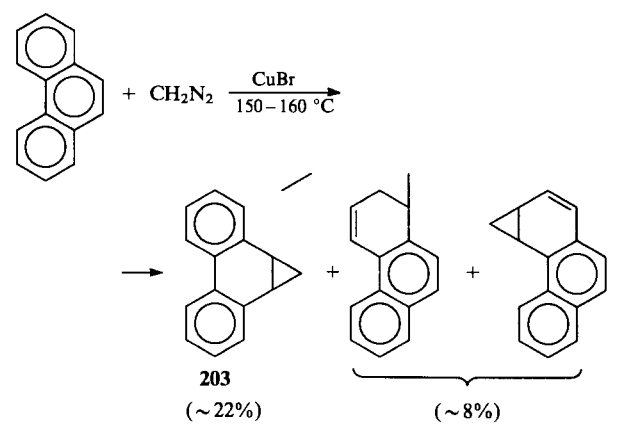
In contrast to benzene and its derivatives, the interaction of polynuclear aromatic compounds with CH_2N_2 in the presence of both copper and rhodium catalysts leads mainly to the formation of fairly stable cyclopropane adducts and in a number of instances the reaction proceeds with a high regioselectivity. Thus the interaction of CH_2N_2 with an excess of naphthalene at 80 °C in the presence of $Rh_2(OCOCF_3)_4$ affords 2,3-benzobicyclo[4.1.0]hepta-2,4-diene **194** in a yield of 98%, the relative reactivity of naphthalene in this reaction being higher by a factor



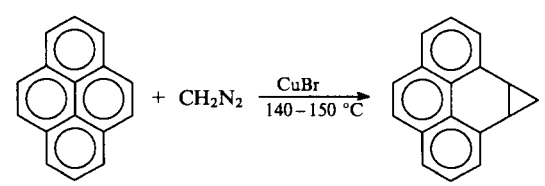
R = COOMe.



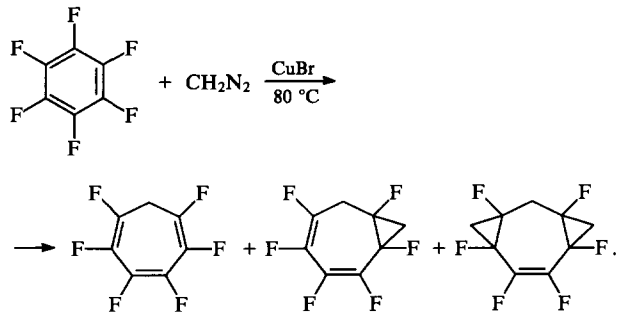
of 1.7 than that of benzene.[210] The same reaction in the presence of CuBr leads to an overall yield of about 30% of a mixture of the cyclopropane **194** and benzocycloheptatriene **195**, the ratio of which varies from 95 : 5 at 120–140 °C to 40 : 60 at 170–190 °C.[221] When a fourfold molar excess of CH_2N_2 was used, the product **196** of the double cyclopropane formation reaction was obtained with a yield of 18%. Since all attempts to isomerise compound **194** to compound **195** were unsuccessful,[210] one may assume that compound **195** is formed as a result of the isomerisation of another cyclic methylene–naphthalene adduct, for example compound **197**, formed at an elevated temperature as a consequence of the decrease in the regioselectivity of the reaction.



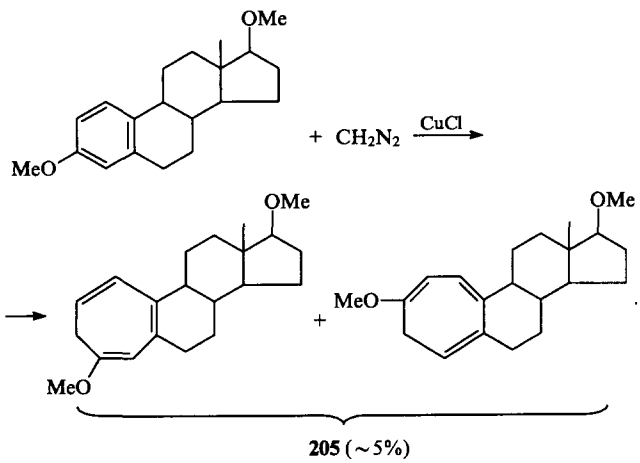
The catalytic interaction of diazomethane with another 10-electron aromatic system—bicyclo[4.4.1]-undeca-1,3,5,7,9-pentaene **198**[222,223]—apparently involves wholly the most substituted double bond, since, according to the data of Vogel et al.,[223] the reaction results in the formation of only bicyclo[5.4.1]dodeca-2,4,7,9,11-pentaene **199**.



The interaction of CH_2N_2 with anthracene in the presence of CuBr has been carried out at 25 °C using CH_2Cl_2 as the solvent. A mixture of the products **200**–**202**, in which the cyclopropane adduct **200** predominated, was then obtained in an overall yield of 13%.[224]

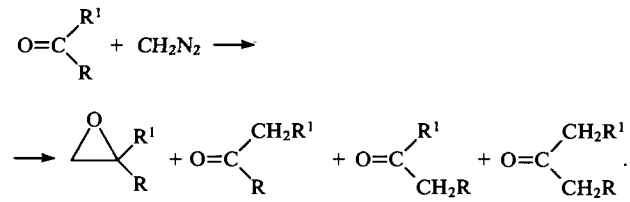


The catalytic addition of methylene to phenanthrene also leads to a mixture of compounds,[221,225] in which, according to the data of Müller et al.,[225] the dominant component is the cyclopropane adduct **203** formed as a result of the addition of methylene to the C(9)–C(10) bond. The higher reactivity of the bonds in the central rings of condensed aromatic systems compared with the bonds in the peripheral benzene rings is indicated also by the formation of only one isomer **204** in the catalytic conversion of pyrene into a cyclopropane derivative.[226]



When diazomethane reacted with a boiling solution of hexafluorobenzene in the presence of CuBr, a complex mixture of compounds was obtained in which hexafluorocyclohepta-1,3,5-triene and the products of its further conversion into cyclopropane derivatives—hexafluorobicyclo[5.1.0]octa-2,4-diene and hexafluorotricyclo[6.1.0.$0^{3,5}$]-non-6-ene—were identified.[227]

The catalytic conversion of the benzene ring into the cycloheptatriene system in the series of steroids on treatment with CH_2N_2 has been achieved by Müller and coworkers[212,228] as early as 1963 in relation to the dimethyl ether of β-oestradiol.



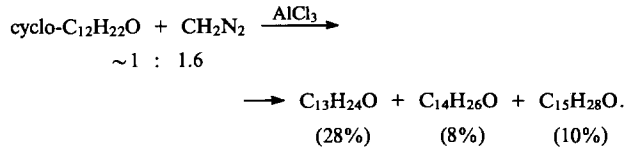
The low yield of the steroids **205** and the lack of other similar data did not promote further research on these lines. However, one may be optimistic about the possibility of converting complex aromatic compounds into higher homologues by varying the substituents in the aromatic ring and by using other catalytic systems, in particular rhodium compounds.

205 (~5%)

V. Synthesis of ketones by converting carbonyl compounds into higher homologues

The study of the reactions of diazomethane with aldehydes and ketones began with the discovery of diazomethane itself and embraced virtually all classes of organic compounds containing the carbonyl group—aliphatic, alicyclic, aromatic, and heterocyclic ketones, aldehydes,[229-234] ketosteroids,[235-238] and polycyclic ketones.[239] As a rule, the non-catalytic interaction of CH_2N_2 with aldehydes leads to ketones and epoxides, while its interaction with ketones leads to the higher homologues of the latter and/or the corresponding epoxides, ketones reacting with CH_2N_2 more slowly than aldehydes. The reaction is carried out predominantly in methanol and lasts from several hours to several days.

In this section, the results of catalytic reactions of diazomethane with carbonyl compounds will be briefly described. Interest in such reactions arose for the first time in the 1960s.



In 1960, two groups of investigators[240-242] established independently that boron trifluoride etherate increases appreciably the yield of higher homologues of ketones and the corresponding carbonyl compounds in the reactions of diazomethane with carbonyl compounds, suppressing at the same time the formation of epoxides. For example, the yield of cyclononanone, obtained from cyclooctanone and CH_2N_2 in the ring expansion reaction catalysed by $BF_3 \cdot OEt_2$, increases from 20% to 46% compared with the noncatalytic version.[243]

Together with boron trifluoride etherate, effective catalysts of the conversion of carbonyl compounds into higher homologues by diazomethane are also $ZnCl_2$, AlX_3 (X = Cl, Br, I), $GaCl_3$, $ZrCl_4$, HBF_4.[240-243] Table 8 presents examples of the catalytic conversion of cyclooctanone into its higher homologues on treatment with CH_2N_2.[243]

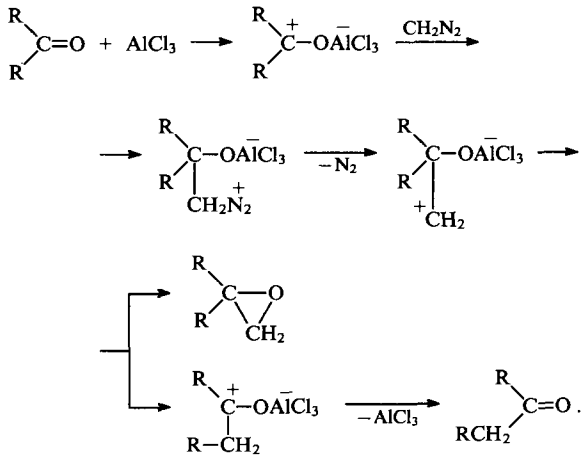


Table 8. Catalytic interaction of cyclooctanone with diazomethane.

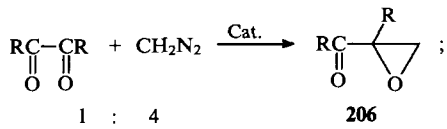
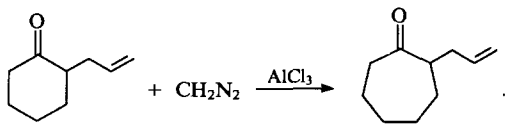
Catalyst		Yield of cycloalkanones (%)	
(2–4 mol%)	Ketone : CH_2N_2	C_9	C_{10}
$ZnCl_2$	1 : 1.2	25	–
AlX_3 (X = Cl, Br, I)	1 : 1.3	48–49	11–14
$AlEt_3$	1 : 1.3	49	19
$GaCl_3$	1 : 1.4	42	5
$ZrCl_4$	1 : 1.3	49	13
HBF_4	1 : 1.2	33	–
$TiCl_4$	1 : 1.2	10	–



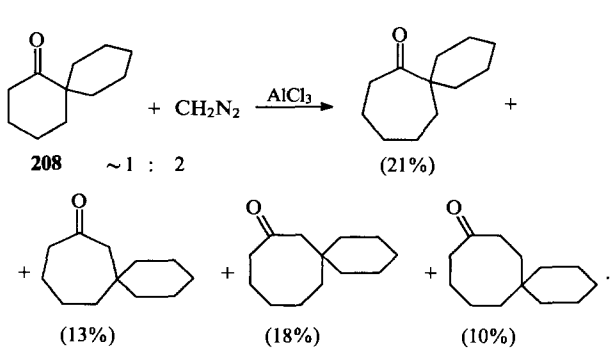
It has been noted[243] that the reactivity of cyclic ketones falls appreciably on passing from cyclohexanone to cycloundecanone. Starting with the latter, ketones with an odd number of carbon atoms in the ring are less reactive than ketones with an even number of carbon atoms. This rule is illustrated, in particular, by the reaction of CH_2N_2 with cyclododecanone, as a result of which cyclopentadecanone is actually formed in a somewhat higher yield than cyclotetradecanone.

The mechanism of the conversion of ketones into higher homologues presupposes the initial activation of the carbonyl group by Lewis acids and the addition of CH_2N_2 to the resulting complex with elimination of a nitrogen molecule and subsequent 1,2-migration of the alkyl group.[243]



Depending on the nature of the carbonyl compound, the primary carbenium ion may be stabilised also by the carbonyl oxygen atom, which leads to the formation of the corresponding oxiran. In particular, the interaction of CH_2N_2 with α-diketones in the presence of both BF_3 and $AlCl_3$ leads mainly to the ketooxirans **206**.[242,243]

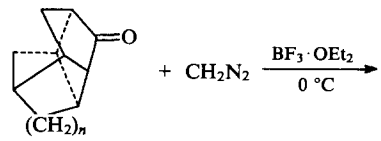
1 : 4 **206**



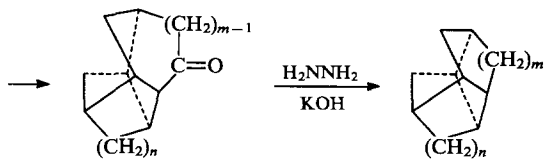
R = Ph, Me (54%, Cat. = $BF_3 \cdot OEt_2$).

The proposed mechanism has been confirmed also by the fact that the interaction of CH_2N_2 with 2-allylcyclohexanone in the presence of $AlCl_3$ involves predominantly the carbonyl group with formation of 2-allylcycloheptanone **207**, whereas the products of the conversion of the double bond into a cyclopropyl group were not detected.[243]

207 (~60%)

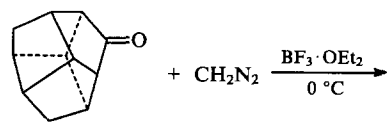


It is noteworthy that the insertion of methylene in the α-C–C bond takes place mainly from the side without substituents. However, in a number of instances such regioselectivity is not maintained. For example, the conversion of the spiran ketone **208** into a higher homologue leads to a mixture of cyclic ketones containing a carbonyl group in different positions relative to the spiran carbon atom.[244]

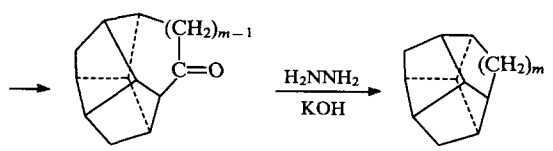


208 ~1 : 2 (21%)

(13%) (18%) (10%)

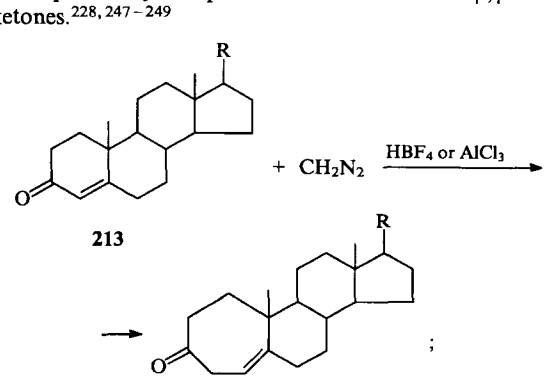


An example of the use of the ring expansion reaction on treatment with CH_2N_2 in the series of polycyclic ketones is provided by the synthesis of triblattanes—analogues of the D_3-twist-form of bicyclo-[2.2.2]octane, linked by different numbers of diagonal bridging groups. Thus the interaction of tetracyclo[4.3.0.$0^{2,5}$.$0^{3,8}$]nonan-9-one **209a** with an excess of CH_2N_2 in the presence of 1 equivalent of $BF_3 \cdot OEt_2$ and the subsequent Wolff–Kishner reduction of the resulting ketones leads to [*m*.0]-triblattanes **210a** (*m* = 2–4).[245] A mixture of [*m*.1]triblattanes **210b** (*m* = 2–7) and [*m*.1.1]-triblattanes **212** (*m* = 2–7) and [*m*.1.1]-triblattanes **212** (*m* = 2–6) has been obtained similarly from tetracyclodecanone **209b** and trishomocubanone **211** and it has been noted that in the absence of a catalyst the ketone **209b** does not react with diazomethane.[245,246]

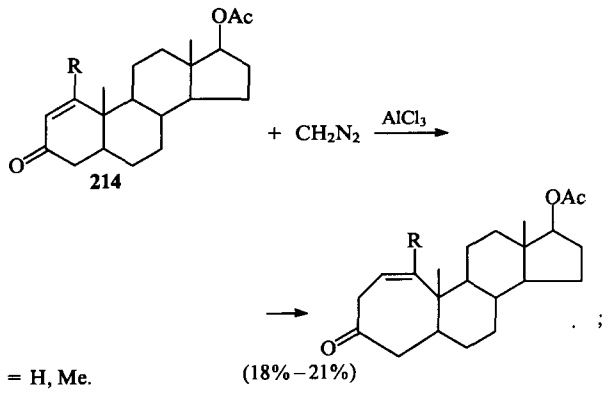


209 *n* = 0 (**a**), 1 (**b**)

210

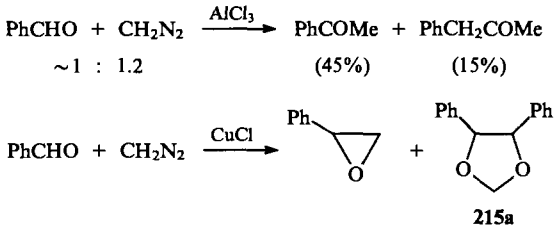


211



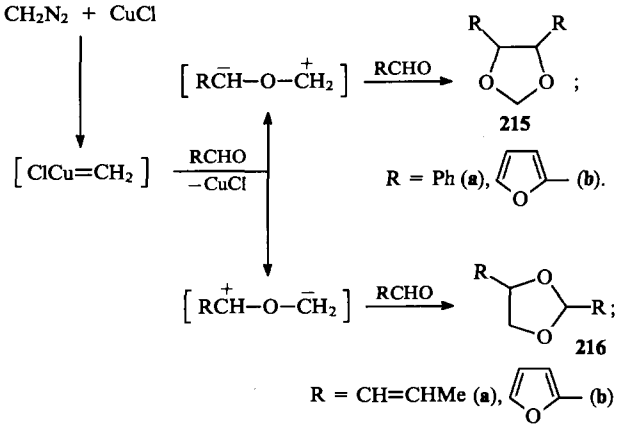
212

The non-catalysed reaction of diazomethane with α,β-unsaturated ketones usually proceeds as 1,3-dipole cycloaddition and leads to the formation of pyrazolines. On the other hand, the catalytic interaction of CH_2N_2 with conjugated ketones, carried out for the 3-ketosteroids **213** and **214**, proceeds as in the case of cycloalkanones—with ring expansion accompanied by the preferential formation of β,γ-unsaturated ketones.[228,247–249]



213

R = C_8H_{17} (40%); OAc (20%–30%); Ac (29%); $COCH_2OAc$ (31%).

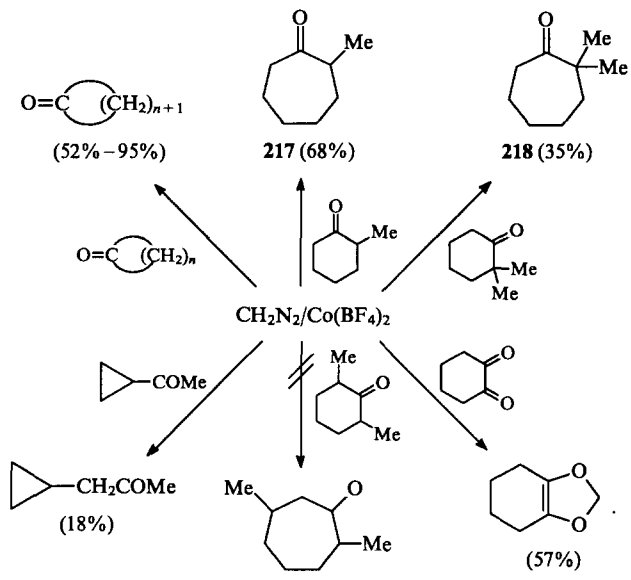


R = H, Me. (18%–21%)

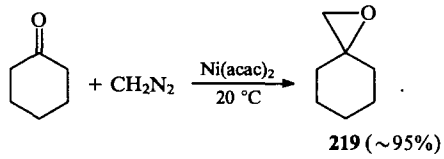
In certain cases, the use of transition metal Lewis compounds instead of acids alters significantly the mode of reaction of carbonyl compounds with CH_2N_2. Thus the interaction of benzaldehyde with CH_2N_2 in the presence of $AlCl_3$ leads to acetophenone and phenylacetone,[250] whereas in the presence of CuCl diazomethane reacts with an excess of benzaldehyde to form phenyloxiran and a mixture of isomeric 4,5-diphenyl-1,3-dioxolans **215a**.[251]

215a

Crotonaldehyde and furfural react similarly with CH_2N_2 in the presence of CuCl, affording respectively the isomeric 2,4-dipropenyl-1,3-dioxolans **216a** in 18% yield, on the one hand, and 2,4-difuryl-1,3-dioxolans **216b** and 4,5-difuryl-1,3-dioxolans **215b** in an overall yield of 7%, on the other.



The formation of 1,3-dioxolans presupposes the addition of the methylene complex [ClCu=CH_2] to the carbonyl group of the aldehydes and then the addition of a second aldehyde molecule to the intermediate 1,3-dipoles.[251]



Cobalt tetrafluoroborate also behaves as an effective catalyst of the conversion of linear and cyclic carbonyl compounds into higher homologues by reaction with diazomethane. It makes it possible to obtain ketones with a specified number of carbon atoms in the chain under mild conditions, in one stage, with a high selectivity, and in high yields.[252] Thus the reaction of cyclohexanone with a threefold excess of CH_2N_2 in the presence of $Co(BF_4)_2$ at 0 °C leads to cycloheptanone in 81% yield. The formation of only an insignificant amount of polymethylene was noted under these conditions.

The catalytic activity of $Co(BF_4)_2$ depends extremely significantly on the structure of the initial cyclic ketone. The formal insertion of methylene, accompanied by ring expansion, involves the sterically least hindered C–C bond in the initial carbonyl compound. Thus α-methylcyclohexanones afford only α-methylcycloheptanones, for example compounds **217** and **218**, while α,α′-disubstituted cyclic ketones, for example 2,6-dimethylcyclohexanone, do not react at all under these conditions (Scheme 5).[252]

Scheme 5

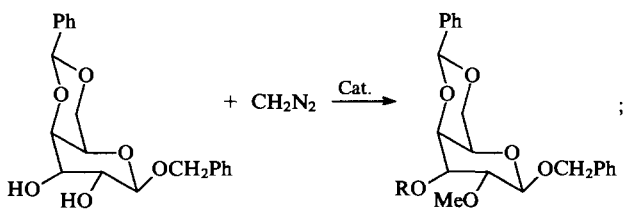
The interaction of CH_2N_2 with cyclohexanone in the presence of $Ni(acac)_2$ takes place in a completely different manner. In this case, the only reaction product is oxiranylcyclohexane **219**, the yield of which reaches 95%.[252,253]

Thus the catalytic conversion of ketones into higher homologues with the aid of diazomethane is of preparative importance — especially in the synthesis of macrocyclic ketones.

VI. Catalytic methylation of alcohols and amines by diazomethane

In this section we do not claim to provide a complete description of the available data on the reactions of diazomethane with compounds containing a mobile hydrogen atom at the nitrogen and oxygen atoms. Only a general assessment of the catalytic interaction of CH_2N_2 with alcohols and amines is given.

Alcohols are as a rule inert to CH_2N_2, but in the presence of Lewis acids such as $BF_3 \cdot OEt_2$, HBF_4, $AlCl_3$, $SnCl_2$, etc. they form methyl ethers in fairly satisfactory yields (40%–92%).[254–272] The effectiveness of the methylation is then to a large extent determined by the nature of the hydrocarbon substituents. In particular, it has been shown in relation to the methylation of pentyl and butyl alcohols in the presence of HBF_4 and $BF_3 \cdot OEt_2$ that the yield of the corresponding methyl ethers falls on passing from primary to tertiary alcohols ($k_{rel} \simeq 2 : 1.5 : 1$).[255–258] The shielding influence of the substituents is manifested to an even greater extent in the

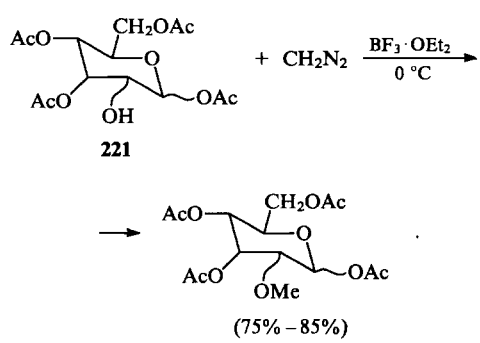


methylation of cyclic alcohols. Thus in the presence of BF_3 or $AlCl_3$, unhindered cycloalkanols afford the methyl ethers in 80%–84% yields,[259] while, for example, isoborneol is not methylated at all under these conditions.[258]

According to the data of Bawn and Ledwith,[260] the mechanism of the methylation of alcohols by diazomethane in the presence of boron compounds involves the formation of boron alkoxides and the insertion of methylene in the B–O bond with the subsequent cleavage of the boron–carbon bond by the alcohol.

$$BX_3 \xrightarrow{CH_2N_2} X_2BCH_2X \xrightarrow{ROH} X_2BOR \xrightarrow{CH_2N_2}$$

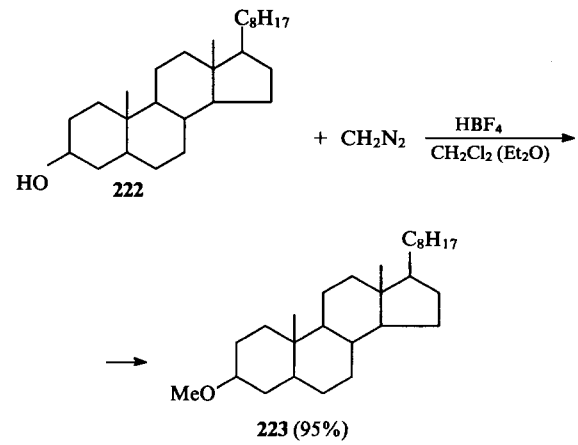
$$\longrightarrow X_2BCH_2OR \xrightarrow{ROH} X_2BOR + ROMe.$$



Diazomethane combined with boron trifluoride etherate or $SnCl_2 \cdot 2H_2O$ has been used in the carbohydrate chemistry for the complete or partial methylation of the hydroxy-groups.[261–265] For example, the methylation of the galacto-pyranoside **220** in the presence of $SnCl_2 \cdot 2H_2O$ involves preferentially one of the OH groups, whereas in the presence of $BF_3 \cdot OEt_2$ both hydroxy-groups are methylated.[261]

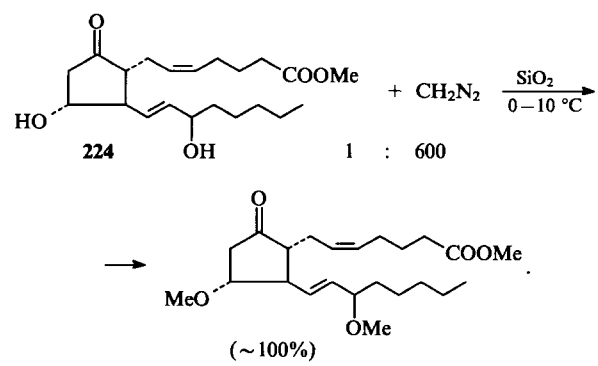
220

Cat. = $SnCl_2 \cdot 2H_2O$, R = H (91%);
Cat. = $BF_3 \cdot OEt_2$, R = Me (84%).



In the presence of $BF_3 \cdot OEt_2$, diazomethane proved to be an effective reagent also for the methylation of partially acylated carbohydrates, for example compound **221**, which in the case where the usual methylating agents (MeI, Me_2SO_4) are employed are readily hydrolysed by the bases used for this purpose.[263–265]

221

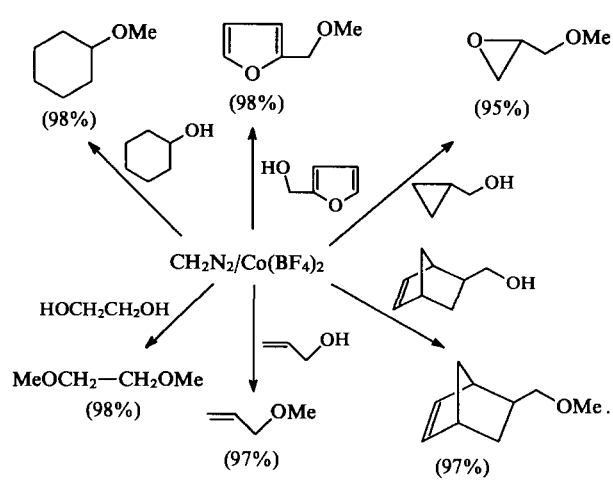


(75%–85%)

Catalytic methylation of steroid alcohols by diazomethane also takes place with high degrees of conversion.[258,266] Thus the interaction of cholestanol **222** with an excess of CH_2N_2 in the presence of HBF_4 leads to the formation of the methyl ether **223** in 95% yield.[266]

222 **223** (95%)

Alcohols, including prostaglandins, terpene alcohols, and carbohydrates, are fairly successfully methylated by an excess of CH_2N_2 when acted upon by silica gel suspended in ether.[267] Despite the large excess of CH_2N_2, methylene is inserted selectively in the O–H bonds of prostaglandin **224** without affecting the keto-group and the double bonds.



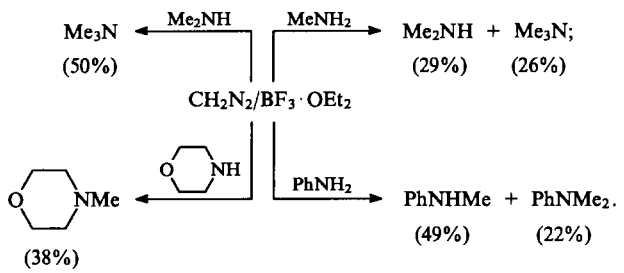
224 1 : 600

(~100%)

Later another method was proposed, according to which the alcohol adsorbed on silica gel was treated with gaseous diazomethane.[268] Even tertiary alcohols or sterically hindered phenols, such as 1-methylcyclohexanol or 2,6-di-isopropyl-phenol, afforded the corresponding methyl ethers in 99% and 79% yields on treatment with a large excess of CH_2N_2 (68 and 34 molar equivalents respectively) under these conditions.

Cobalt tetrafluoroborate also exhibits a high catalytic activity in the methylation of alcohols.[269,270] The use of 3–4 equivalents of CH_2N_2 then leads to *O*-methyl derivatives in high yields (Scheme 6). Reactivity of alcohols in the presence of

Scheme 6



$Co(BF_4)_2$, can be arranged in the following sequence: secondary > primary > tertiary.[269] The double bonds of the unsaturated aliphatic or cyclic alcohols are then hardly involved, whereas under similar conditions palladium compounds catalyse mainly the conversion of double bonds into cyclopropyl groups.[155,156]

Like alcohols, primary and secondary amines are methylated by diazomethane in the presence of $BF_3 \cdot OEt_2$ or HBF_4, affording the corresponding methylamines in yields not exceeding 50%. The *N*-methylation of primary amines results in the formation as a rule of a mixture of the corresponding mono- and di-methylamines.[271-275]

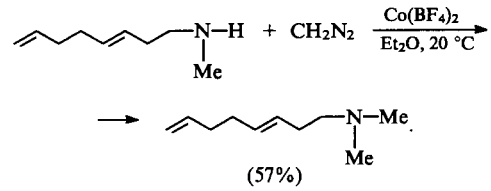
Certain examples of the methylation of various amines by an excess of CH_2N_2 in the presence of $BF_3 \cdot OEt_2$ are presented in Scheme 7.

Scheme 7

Copper compounds (CuCN, CuCl) are also capable of catalysing the methylation of amines by diazomethane. The yields of the corresponding *N*-methylamines are then 32% and 25% respectively in the case of piperidine and morpholine.[276]

The use of $CF_3SO_3H-NEt_3$ as the catalyst of the methylation of secondary amines makes it possible to increase the yields of the methylamines to 68%–98%.[277,278]

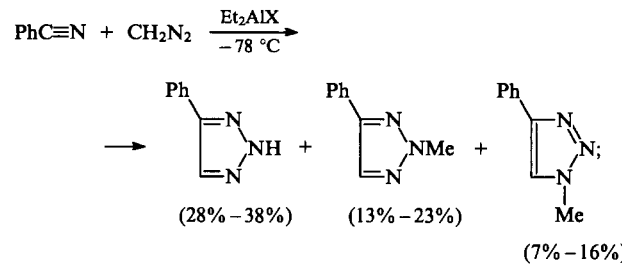
$$R^1R^2NH + CH_2N_2 \xrightarrow[CH_2Cl_2]{CF_3SO_3H/Et_3N} R^1R^2NMe;$$



$R^1 = PhCH_2, Me_2CH, Me$; $R^2 = MeC_6H_4, PhCH_2, Ph$.

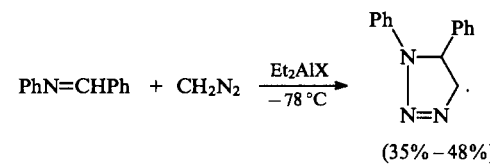
Cobalt compounds exhibit a high effectiveness in reactions of this kind. One of the best catalysts of the methylation of amines available at present is apparently $Co(BF_4)_2$, the use of which increases the yield of the methylated amines to 86%–98% even in the presence of a comparatively small excess of diazomethane.[269,279]

$$R^1R^2NH + CH_2N_2 \xrightarrow[Et_2O,\ 10-30\ ^\circ C]{Co(BF_4)_2} R^1R^2NMe;$$



1 : (1–4)

$R^1 = R^2 = Et$ (89%), Pr^i (86%);
$R^1 = Me$, $R^2 = Ph$ (98%);
$R^1 + R^2 = (CH_2)_5$ (88%),
$(CH_2)_2O(CH_2)_2$ (97%).



There are few data concerning other reactions of heteroatomic compounds with diazomethane, including those involving the use of catalysts, and they date back mainly to the 1950s–1960s.

For example, it has been noted that the interaction of CH_2N_2 with benzonitrile or benzylideneaniline in the presence of alkylalanes ($AlEt_3$, Et_2AlCl, etc.) is accompanied by the addition of CH_2N_2 to the C≡N and C=N bonds with formation of five-membered heterocycles — triazoles and triazolines.[280]

$PhC{\equiv}N : CH_2N_2 : Et_2AlX = 2 : 1 : 1$

According to the results of a number of studies,[281-284] diazomethane interacts with silanes, germanes, and stannanes in the presence of copper powder, affording the products of the insertion of methylene in Si–Cl, Ge–Cl, Si–H, and Sn–H bonds, the reactions with chlorogermanes and hydrostannanes being much more effective than those with the corresponding silanes.

$$MCl_4 + CH_2N_2 \xrightarrow[Et_2O,\ -60\ ^\circ C]{Cu} Cl_3MCH_2Cl;$$

1 : 1 M = Ge (93%); Si (45%–47%).

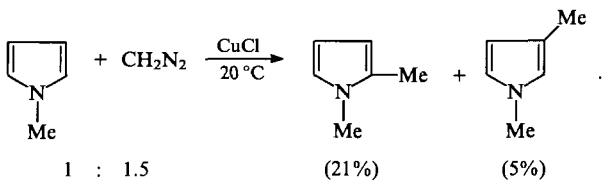
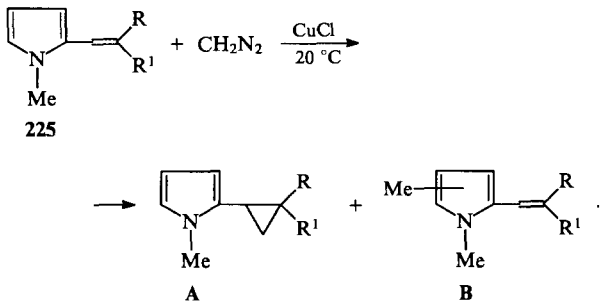
1 : 3 (28%)

$$Cl_3C{-}SiCl_3 + CH_2N_2 \xrightarrow[-60\ ^\circ C]{Cu} Cl_3C{-}SiCl_2CH_2Cl.$$



1 : 1 (22%)



Despite the fact that the catalytic decomposition of CH_2N_2 does not generally yield the products of the insertion of methylene in the C–H bonds, nevertheless there is a possibility of the occurrence of such reactions. Thus the decomposition of CH_2N_2 in pentane or cyclohexane catalysed by $Rh_2(OCOCF_3)_4$, leads to the partial methylation of the latter.[252]

The formation of an appreciable amount of the products of the insertion of methylene in the C–H bonds in the CuCl-catalysed decomposition of CH_2N_2 has been observed also in the case of *N*-methylpyrroles.[143] Even when CH_2N_2 interacts with 2-alkenyl-*N*-methylpyrroles **225**, the products of the insertion of methylene into the vinyl C–H bonds of the pyrrole ring are formed together with the cyclopropane adducts.[143]

R	R¹	Yield of **A** (%)	Yield of **B** (%)
H	H	18	6
H	Me	6	15
Me	Me	8	18

VII. Conclusion

The data presented demonstrate the great potential possibilities of the use of diazomethane in laboratory practice for the modification of various classes of organic compounds. Furthermore, convincing evidence has been obtained recently for the possibility of the simultaneous generation and catalytic decomposition of diazomethane, which significantly enhances the prospect for its application in fine organic synthesis. In the first place, this applies to the reactions involving the direct conversion of unsaturated compounds into cyclopropane derivatives, which leads to the formation of cyclopropane synthons. Systematic study of these reactions in the presence of a number of catalytic systems made it possible not only to establish the characteristic features of the conversion of various double bonds into cyclopropyl groups, to estimate the effectiveness of the catalysts based on transition and non-transition metals, and to put forward the mechanisms of their reaction with diazomethane, but it has also been possible to develop a safe method for the conversion of many unsaturated compounds, including those with functional groups in the molecule, into cyclopropane derivatives.

Considerable advances in the attainment of this aim have been associated with the use of palladium compounds as process catalysts, which ensure a high degree of conversion of the initial olefins into cyclopropanes combined with a minimal consumption of diazomethane and hence of *N*-methyl-nitrosoamides used for its generation *in situ*.

The employment of metal complex catalysis in the chemistry of diazomethane has also made it possible to achieve the conversion of benzenes into cyclohepta-1,3,5-trienes and the selective conversion of ketones into higher homologues and the methylation of alcohols and amines. Apart from the copper compounds and Lewis acids put forward for these purposes as early as the end of the 1950s, other more effective catalysts are being used nowadays, for example $Rh_2(OCOCF_3)_4$ for the synthesis of cycloheptatrienes and $Co(BF_4)_2$ for the conversion of ketones into higher homologues and the methylation of alcohols and amines.

The successive development of studies on these lines will be determined by the further search for active and highly selective catalysts of the decomposition of diazomethane and of the transfer of the methylene fragment to the substrate molecule, including procedures involving the modification of the ligand sphere of transition metal compounds, and also by the advances in the elucidation of the mechanisms of the catalytic reactions with participation of diazomethane.

Activated cyclopropanes in the synthesis of five-membered carbocycles and heterocycles

O G Kulinkovich

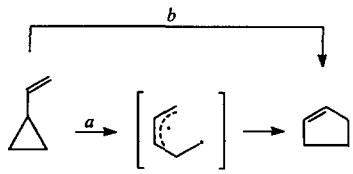
Contents

I. Introduction 839
II. Synthesis of five-membered carbocyclic compounds 839
III. Synthesis of five-membered heterocycles 844

Abstract. The conversion of functionalised cyclopropane compounds to derivatives of cyclopentane and five-membered heterocycles is described. Topics discussed include reaction conditions, the regio- and stereo-selectivity of the reactions depending on the type of substituents in the three-membered ring, and also the main procedures for obtaining appropriate cyclopropane substrates. The bibliography comprises 174 references.

I. Introduction

Although the history of the chemistry of cyclopropane compounds stretches back more than a hundred years[1] the extensive use of this class of compounds as intermediates in organic synthesis began not much more than thirty years ago. Owing to the development of carbene methods for converting olefins to cyclopropane and to other effective approaches to the construction of a three-membered carbon ring,[2-8] various functional derivatives of cyclopropane have become accessible and in addition many synthetically useful reactions that involve opening of a three-membered ring have been found.[2,5-15]



The main problem in using cyclopropane compounds in organic synthesis lies in securing high selectivity for two types of reaction: the formation and opening of a three-membered ring of carbon atoms. In many instances the nature of the substitution in the ring presupposes the possibility of both the straightforward production of the corresponding cyclopropane derivative and also chemo- and regio-selective cleavage of one of the three carbon–carbon bonds. A large amount of data has already been accumulated on the effect of substituents on the geometry of a three-membered carbon ring[16-21] and its energy characteristics.[16,20-24] Rules for predicting variations in the carbon–carbon bond lengths in a cyclopropane ring have been summarised:[20] π-electron-acceptor substituents, and also π- and σ-electron-donor substituents, that occur in a favourable conformation with respect to the cyclopropane ring cause lengthening of the adjacent bonds and shortening of the opposite bond whereas σ-electron-acceptor substituents have the opposite effect. Bearing in mind the normally observed direct correlation between the length of a carbon–carbon bond and its tendency to rupture, and also the predominant influence on this process of the π-electronic effects of substituents in a 'bisectrix' conformation for electron acceptors and a 'perpendicular' conformation for electron donors,[7,16,21] we may expect preferential rupture of the bonds in the ring that are adjacent to such substituents. Many experimental data are compatible with these conclusions,[7-12,15,16,25] so enabling us, in many instances, to make a reliable prediction of the results of possible conversions of 'activated cyclopropanes' and to design synthesis schemes involving them effectively. In the present review published data on the conversion of activated cyclopropanes to cyclopentane derivatives and five-membered heterocycles containing one hetero-atom (one of the best developed areas of the use of cyclopropanes in organic synthesis) are arranged systematically.

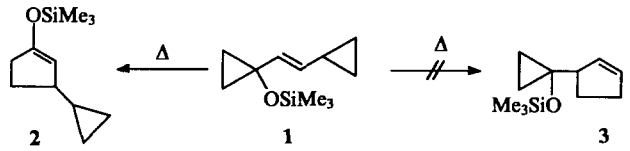
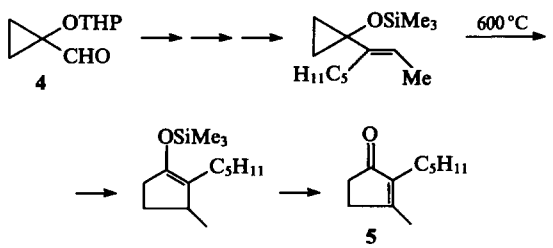
II. Synthesis of five-membered carbocyclic compounds

The most important approach to the construction of five-membered carbocycles on the basis of cyclopropane precursors is the vinylcyclopropane–cyclopentene rearrangement.[26,27] The thermal version of this rearrangement[27] is usually effected at temperatures above 250 °C and can take place by a biradical mechanism (*a*)[28] or a concerted mechanism (*b*).[26-31]



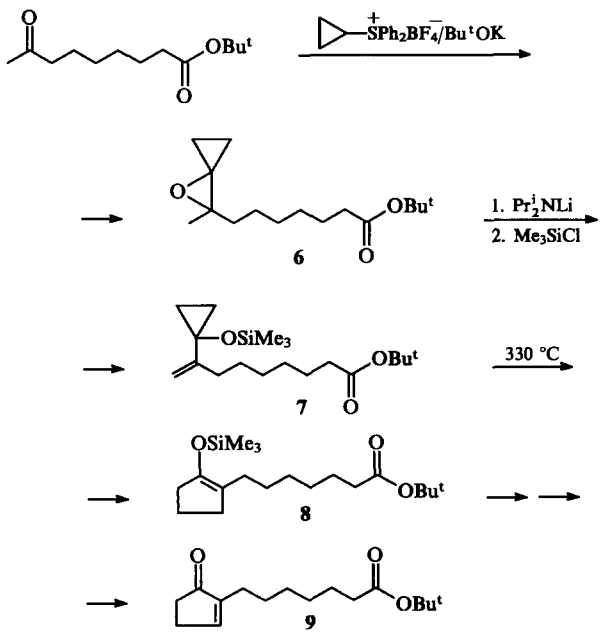
Considerable progress has also been achieved in the development of methods for synthesising cyclopentane systems using intra- and inter-molecular cyclisations, such as [3 + 2]-cycloaddition and intramolecular ring formation, with one or two carbon atoms from a cyclopropane ring incorporated in the newly generated cyclic system.[9-15,32-35]



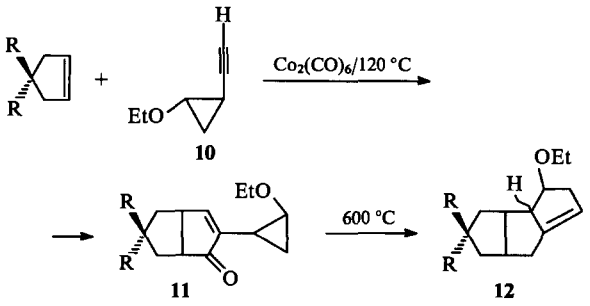
1. The vinylcyclopropane–cyclopentene rearrangement

Electron-donor substituents in the three-membered carbon ring, in either geminal or vicinal positions with respect to the vinyl group, considerably facilitate the occurrence of this rearrangement.[26] For example, the activating effect of a trimethylsiloxy group on the opening of a cyclopropane ring to which it is attached is clearly illustrated by the thermal

rearrangement of 1-(2-cyclopropylvinyl)-1-trimethylsiloxycyclopropane **1** which gives 3-cyclopropyl-1-trimethylsiloxycyclopent-1-ene **2** exclusively, but none of the isomeric compound **3**.[36]

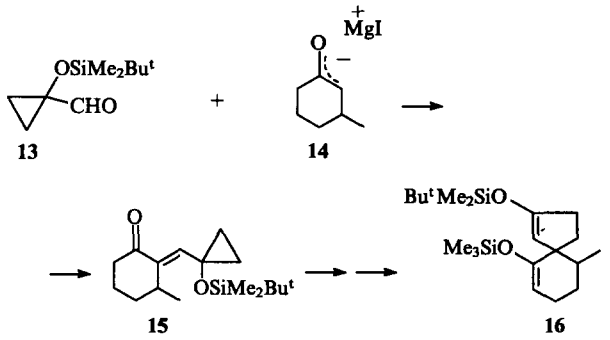


Several ways of obtaining substituted 1-trimethylsiloxyvinylcyclopropanes have currently been developed, starting from accessible hemiacetals of cyclopropanone,[12] oxaspiropentanes,[37] silyl ethers of enols,[38] 1-hydroxycyclopropylcarbonyl compounds[39] and certain other substrates.[40] This has enabled methods for synthesising different types of the cyclopentane system, including a number of natural compounds, to be proposed.[36,39,41-43] The methodology of the production of 2,3-disubstituted cyclopentenones starting from the available 1-tetrahydropyranyloxy-1-formylcyclopropane **4** can be followed using as an example the synthesis of dihydrojasmone **5** (with a total yield of 61%).

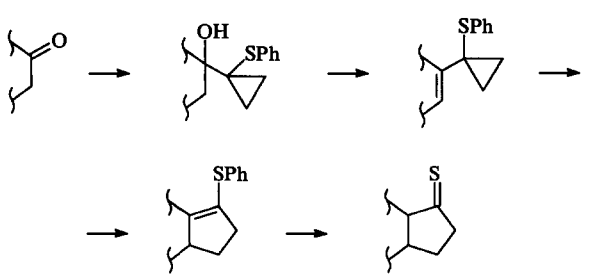


THP = tetrahydropyranyl.

The conversion of the keto-group in esters of 8-oxononanoic acid to a vinylcyclopropane group is accomplished via the intermediate formation of the corresponding oxaspiropentane **6**, isomerisation of the epoxide ring, and then silylation of the hydroxyl group. Thermal rearrangement of the resultant substituted trimethylsiloxycyclopropane **7** gives an ester of an enol **8** that is readily converted to the 2-substituted cyclopentenone **9**, which is used as a precursor of homoprostaglandins.[44] The use of cyclic ketones as the initial substrates enables the corresponding condensed systems to be synthesised.[33]

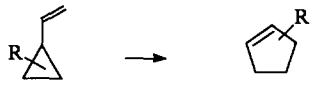


A combination of the cycloaddition of the dicobalt hexacarbonyl complex of the cyclopropylalkyne **10** to olefins and the vinylcyclopropane–cyclopentene isomerisation of the resultant cycloaddition products **11** makes it possible to carry out successive fusion of cycloalkenes to form tricyclic systems **12**.[45]

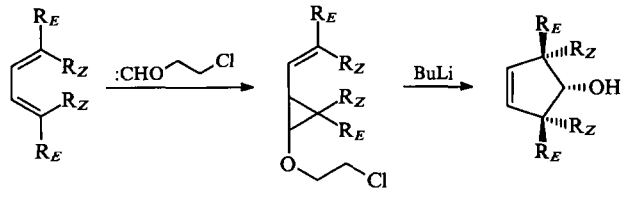


R = H, Me.

The *tert*-butyldimethylsilyl ether of 1-hydroxy-1-formylcycloproane **13** can be used for the synthesis of substituted vinylcyclopropane systems by a Wittig reaction or an aldol condensation.[47] For example, if the enolate anion **14**, which is obtained by the copper-iodide-catalysed addition of methylmagnesium iodide to cyclohex-2-enone, is captured by the aldehyde **13** the corresponding ketol is obtained and after its dehydration the siloxyvinylcyclopropane **15** can be isolated in a 73% yield (based on the aldehyde **13**). After a trimethylsilylation stage and vinylcyclopropane–cyclopentene rearrangement, **15** is converted to the spirocyclic derivative **16**.[47]

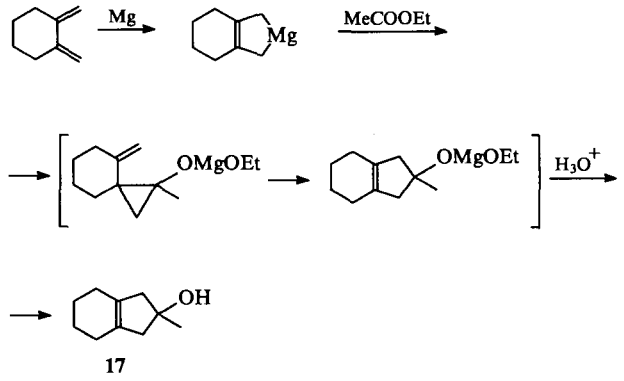


The main limitations of the methods described above for constructing cyclopentane systems on the basis of 1-oxo-substituted vinylcyclopropanes are usually due to difficulties in obtaining the latter. There is therefore considerable interest in the possible use of available 1-(phenylthio)cyclopropyllithium reagents for the introduction of a cyclopropane fragment into ketonic substrates.[48-50] For the formation of a cyclopentane ring the successive stages are indicated in a general form by the following scheme:[51,52]



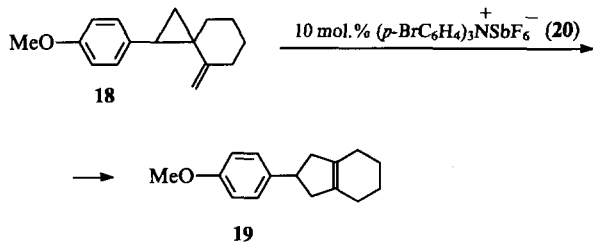
The yields are high at each of these stages and the vinylcyclopropane–cyclopentene rearrangement of 1-(phenylthio)-cyclopropyl derivatives takes place at even lower temperatures than in the case of the corresponding oxo-compounds.[27]

Electron-donor substituents in position 2 of the vinylcyclopropanes facilitate the thermal rearrangement of these compounds to a greater extent than the same substituents in position 1.[53–55]



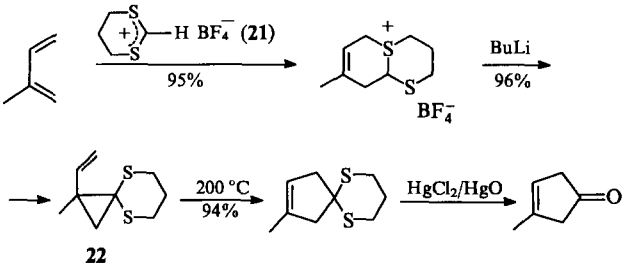
R	E_a/kcal mol^{-1}
H	49.7
1-OMe	44.7
2-OMe	38.7
2-NMe_2	31.1

When there are anionic substituents present in the ring the vinylcyclopropane–cyclopentene rearrangement takes place at room temperature or below.[56,57] In this case the reaction is by and large highly selective [4 + 1]-ring formation[57] whereas in the usual versions the rearrangement often takes place with only moderate stereoselectivity.[58]



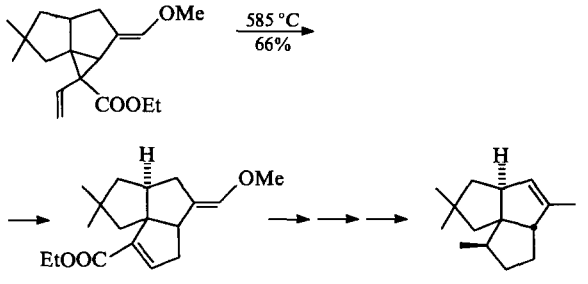
An alternative version involving the conversion of 1,3-dienes to the corresponding 3-cyclopentenols was proposed recently.[59] An example of this is the production of the bicyclic derivative **17** by treatment of the magnesium complex of 1,2-bis-(methylene)cyclohexane with esters followed by rearrangement of the resultant magnesium alkoxides of vinylcyclopropanols, which also occurs under exceptionally mild conditions.

17



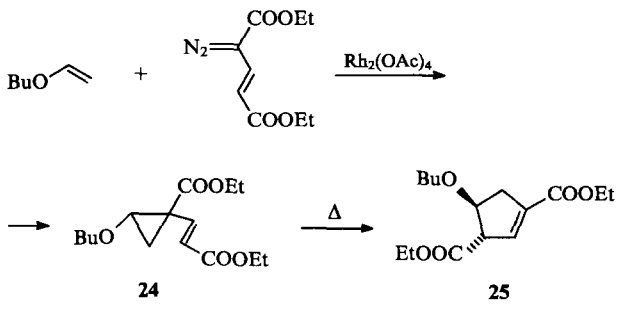
Ring expansion in vinylcyclopropane systems containing electron-donor substituents can also be expedited by the previous one-electron oxidation of the hetero-atom, an example being rearrangements of *p*-anisyl-substituted vinylcyclopropanes.[60] Thus in the presence of catalytic quantities of the one-electron oxidant **20**, rearrangement of **18** to the bicyclic derivative **19** will occur in 5 min at room temperature, with an 86% yield.

18



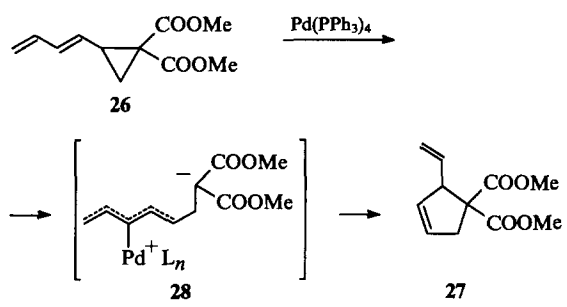
19

The 1,3-dithienium tetrafluoroborate **21** can also be used as a source of the single-carbon component in [4 + 1]-ring formation processes proceeding via a stage in which the corresponding activated vinylcyclopropane **22** is formed.[61]



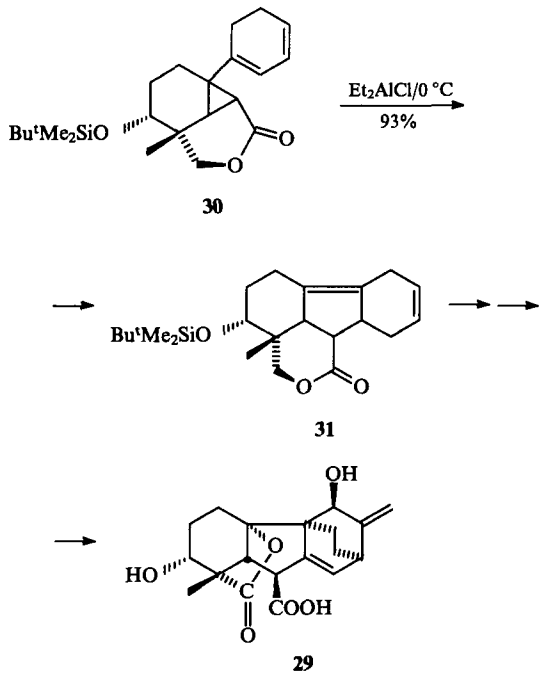
22

There are many examples of rearrangements of vinylcyclopropanes containing acceptor substituents in the ring; these usually occur under more mild conditions than the rearrangements of the corresponding unsubstituted compounds (see Refs 26 and 32). An example of the use of this type of rearrangement in the synthesis of natural compounds is the key stage in the construction of the non-linear tricyclic pentalene system **23**.[62]



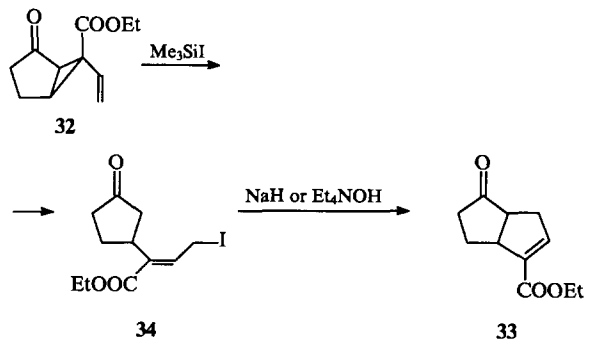
23

Compounds containing *p*-electron-donor and π-acceptor substituents in vicinal positions in the cyclopropane ring undergo the vinylcyclopropane–cyclopentene rearrangement particularly easily.[26,63] For example, the butoxyvinylcyclopropane **24**, unlike compounds with a similar structure that contain no alkoxy substituent, is unstable under chromatographic conditions and when its distillation is attempted it undergoes a smooth rearrangement to give the substituted cyclopentene **25** (total yield 61%).[63]

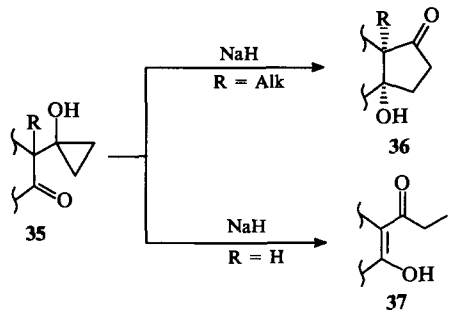


24 **25**

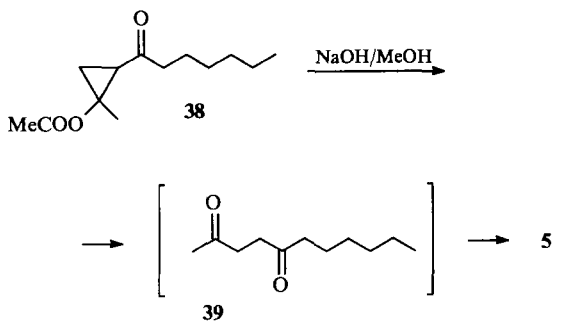
The presence of carbonyl substituents linked to the cyclopropane ring enables catalytic variants of the vinylcyclopropane–cyclopentene rearrangement to be carried out.[26,64–70] For example, the butadienylcyclopropane **26**, which contains two activating methoxycarbonyl groups, undergoes rearrangement to the corresponding vinylcyclopentene **27** at 50 °C (with an 87% yield) in the presence of catalytic quantities of $Pd(PPh_3)_4$. With other acceptor substituents the rearrangement can take place at even lower temperatures.[71] It is proposed[71] that the reaction occurs via nucleophilic attack by Pd^0 on the diene group to form the zwitter-ion **28**.



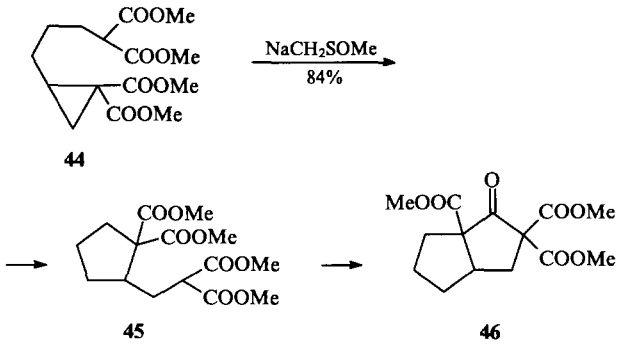
An extremely effective catalyst of the rearrangement of vinylcyclopropanes containing an ester function is diethylaluminium chloride.[66–88] It has been used to synthesise the tricyclic system of antheridic acid (**29**) (see Refs 67 and 68) via a stage in which the lactone **30** undergoes rearrangement to **31**, whereas an attempt to achieve this conversion by heating was unsuccessful.



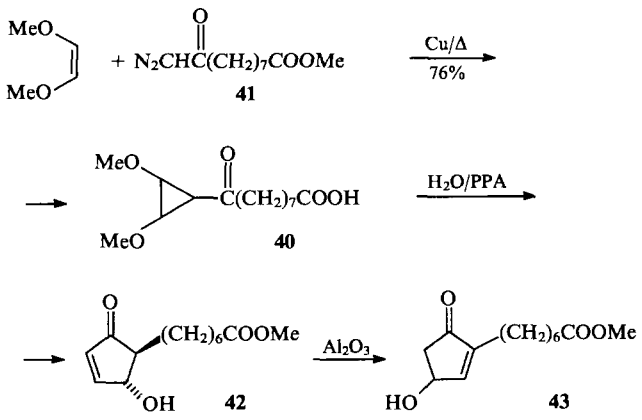
2. Other reactions that are accompanied by intramolecular cyclisation



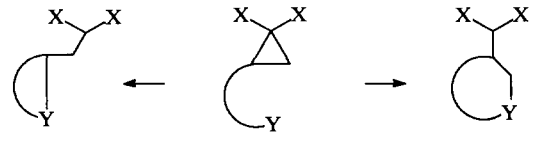
Complementary to the single-stage versions of the vinylcyclopropane–cyclopentene rearrangement considered above are procedures in which expansion of the ring in activated cyclopropanes to the corresponding cyclopentane derivatives is often accomplished by using consecutive heterocyclic ring opening and closure reactions, which are usually achievable in two or more stages. For example, conversion of the vinylcyclopropane derivative **32** to the bicyclanone **33** can be carried out under exceptionally mild conditions by opening the three-membered ring (which is activated by acceptor substituents) with trimethyliodosilane and then carrying out cyclisation of the iodoketone product **34** under the action of strong bases.[72,73]



The ketone **32**, as well as a number of its analogues, are easily accessible and are readily formed by the reaction of the corresponding unsaturated cyclic ketones with the lithium dienolates of esters of α-bromocrotonic acid or its derivatives. In general, a sequence of conversions of cycloalkenones to the corresponding bicyclic derivatives is an effective method of [3 + 2]-ring formation which has been used successfully to synthesise a number of natural compounds.[72–74] A new variant of [3 + 2]-ring formation that has been developed recently for the synthesis of steroids[75] is based on intramolecular capture of the homoenolate anion that is generated when the cyclopropane ring in the 1-(2-ketoalkyl)cyclopropanols **35** is opened by the action of sodium hydride,[75–77] forming the corresponding cyclopentanols **36** or products obtained from them in further reactions. When a hydrogen atom is present in the position α to the carbonyl group and to the three-membered ring isomerisation to the ethyl ketones **37**, which is normal for substituted cyclopropanols, is observed.[76]

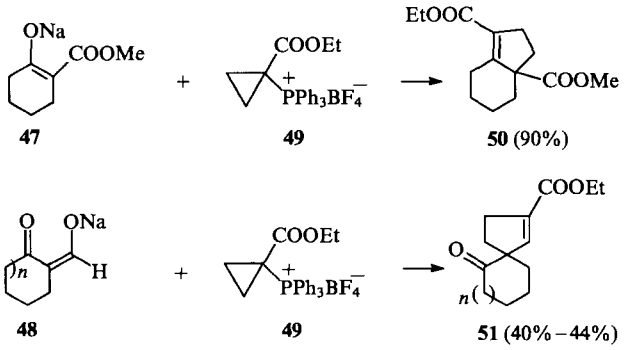


Carbonyl derivatives of cyclopropane with electron-donor substituents in a vicinal position will undergo solvolytic ring opening reactions under exceptionally mild conditions to give the corresponding 1,4-dicarbonyl derivatives or their latent forms.[7,11,25] These compounds are, as is well known, one of the most effective sources for obtaining substituted cyclopentenones by intramolecular cyclisation;[35] this provides a basis for using a sequence of such transformations in the development of effective methods for synthesising a number of cyclopentane derivatives.[78–81] For example, the reaction of the acetoxycyclopropyl ketone **38** with sodium hydroxide gives an 83% yield of dihydrojasmone **5** via the formation of the diketone **39** as an intermediate.[78]



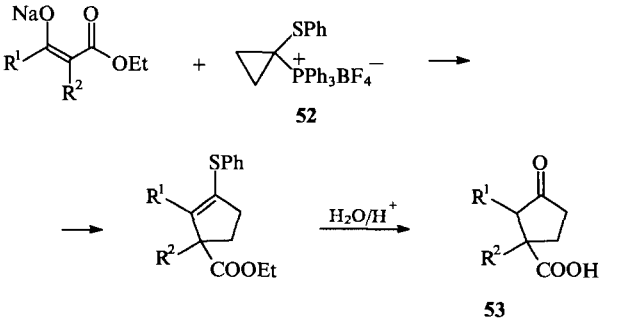
The dimethoxycyclopropyl ketone **40**, which is produced by the reaction of *cis*-1,2-dimethoxyethylene with the diazoketone **41**, will react with polyphosphoric acid in aqueous acetone in a single stage to give the hydroxycyclopentenone **42**, owing to the solvolytic opening of the cyclopropane ring, intramolecular aldolisation, and the elimination of methanol. Isomerisation of **42** on basic aluminium oxide gives the cyclopentanone **43** which is a well known key intermediate in the synthesis of PGF_1.[79]

Methods for synthesising cyclopentane structures with one or two carbon atoms from the initial cyclopropane incorporated into the five-membered ring have been developed to a considerably lesser extent than the reactions for expanding a three-membered carbon ring that have been discussed above (see Refs 9, 34, and 35). Of the two alternative versions of nucleophilic opening of an activated cyclopropane ring, called spirocyclisation and fused cyclisation respectively, spirocyclisation is kinetically preferred.[82]



spirocyclisation fused cyclisation

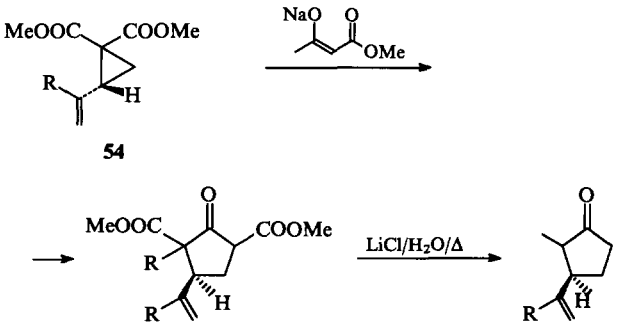
For example, the reaction of the cyclopropane tetraester **44** with $NaCH_2 \cdot SO \cdot Me$ in dimethyl sulphoxide at room temperature gives the thermodynamically more stable cyclopentane tetraester **45** which undergoes smooth cyclisation to the bicyclo[3,3,0]octanone derivative **46** when the temperature is raised.[82]



It was established in the same work that spirocyclisation is kinetically preferred in the formation of a four-membered ring but under conditions where there is thermodynamic control the corresponding cyclopentane derivatives can also be obtained.

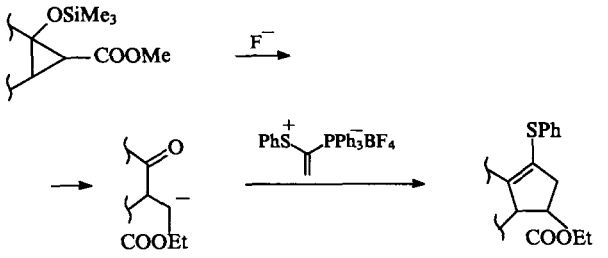
3. Intermolecular ring formation reactions

The approaches to the synthesis of cyclopentane structures relying on intermolecular reactions of activated cyclopropanes that are known at the present time are based on the strategy of [3 + 2]-ring formation. For example, tetracyanoethylene forms the relevant cyclopentane adducts with donor or donor-acceptor cyclopropanes.[25] However this method has not achieved significant use in synthesis because it is not flexible enough. Another approach uses a series of homo-Michael addition reactions of enolate anions to cyclopropane derivatives doubly activated by acceptor substituents and intramolecular condensation.[83-91] For example, the sodium enolates of α-methoxycarbonylcyclohexanone **47** (data from Ref. 84) or the α-formylcycloalkanones **48** (data from Ref. 85) react with 1-(ethoxycarbonyl)cyclopropyltriphenylphosphonium tetrafluoroborate **49** to give condensed **50** or spiran **51** derivatives respectively. The latter approach has been used successfully in the synthesis of a number of natural sesquiterpenes.[85]

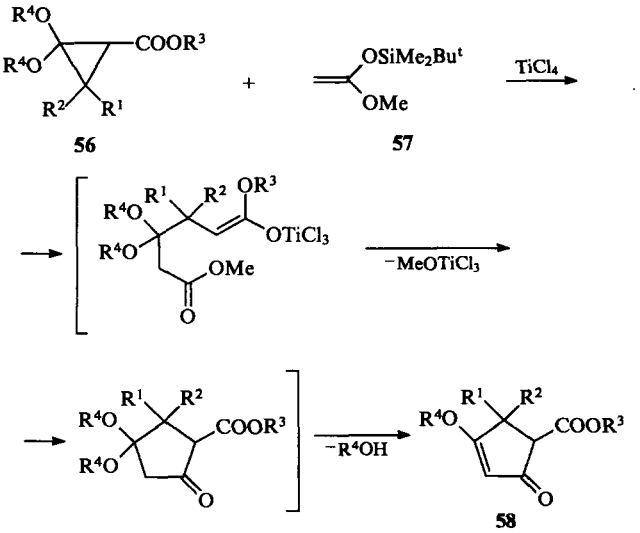


The use of [1-(phenylthio)cyclopropyl]triphenylphosphonium tetrafluoroborate **52** as the Michael acceptor opens up a simple route to substituted 2-carboxycyclopentanones **53**.[86,87]

R^1, R^2 = H, Me, Ph, CH_2Ph.



Similar transformations of the *R*-dimethyl-2-vinylcyclopropane-1,1-dicarboxylate **54** have been used as a basis for developing effective approaches to the complete asymmetric synthesis of certain steroids[88,89] and prostaglandins.[90] A key stage in the construction of a cyclopentane ring in these schemes is the stereospecific opening of the ring in **54** by enolates based on derivatives of malonic or acetoacetic ester as, for example, in the production of the enantiomerically pure vinylcyclopentanones **55**.[91]



54

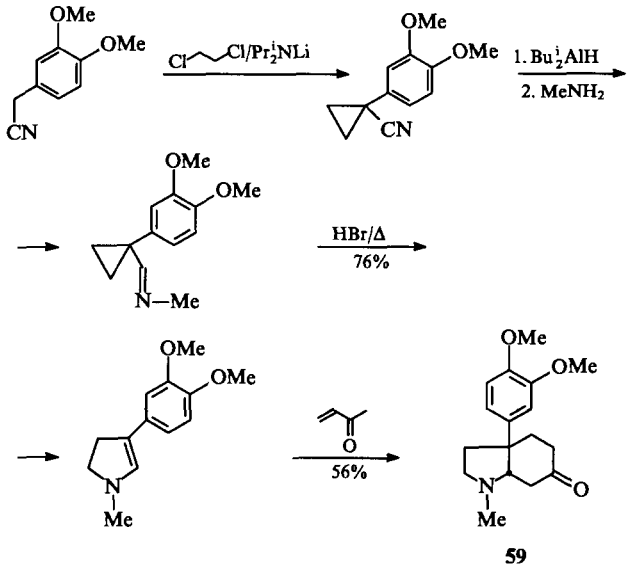
R = H, Me. **55**

The possible simultaneous generation of a carbanion centre and a carbonyl function by the action of fluoride ions on adducts of an ethoxycarbonylcarbene with silyl ethers of enols[25] provides a basis for developing an alternative strategy for [3 + 2]-ring formation.[92-94]

[3 + 2]-Cycloaddition of the donor-acceptor cyclopropanes **56** to the *tert*-butyldimethylsilylacetal of keten **57** is catalysed by titanium tetrachloride, resulting in the formation of derivatives of 3-alkoxycyclopentenones **58** with yields of 28%–75%.[95]

56 **57**

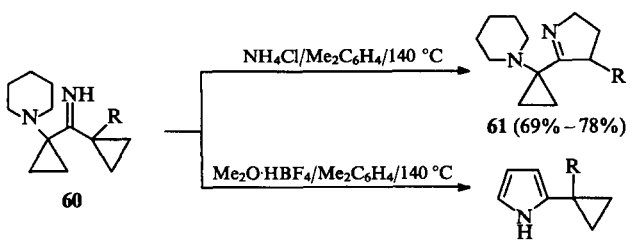
58



R^1–R^4 = Me, Et.

III. Synthesis of five-membered heterocycles

The number of publications devoted to the conversion of activated cyclopropane compounds to five-membered heterocycles is considerably greater than the number concerned with the production of cyclopentane derivatives from such compounds. However there are, to our knowledge, no papers in which data on the use of activated cyclopropanes in the synthesis of heterocycles are arranged especially systematically although there are a number of reviews devoted to particular aspects of this subject.[6,7,9,11,96]

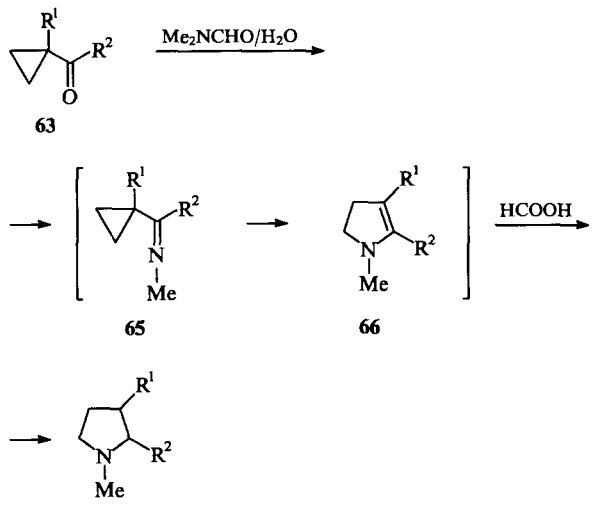


1. Ring expansion reactions in hetero-analogues of vinylcyclopropanes

The ring expansion reactions that have been studied most extensively are those in carbonyl and heterocarbonyl cyclopropane derivatives and a number of effective preparative methods for synthesising five-membered heterocycles have been developed on their basis. For example, the acid-catalysed rearrangement of cyclopropylketimines is one of the most flexible methods for obtaining 2-pyrrolines with various degrees of substitution (see Ref. 96). The use of this reaction for the synthesis of alkaloids is illustrated by the simple scheme for obtaining (±)-mesembrine **59**.[97-99]

59

The hetero-substituents in the cyclopropane ring have an appreciable effect on the course of the reaction but this effect is not always in accord with their effect on the thermal vinylcyclopropane–cyclopentene rearrangement.[100-103] For example, the thermolysis of the di(cyclopropyl)ketimines **60** in boiling xylene in the presence of ammonium chloride gives the pyrrolines **61** as a result of opening of the cyclopropane ring that has no piperidine substituent.[102]

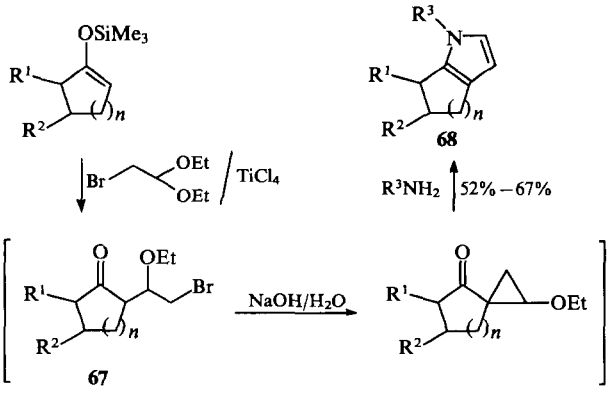


60

R = H, SPh. **61** (69%–78%) **62** (32%–42%)

The use of the dimethyl etherate of tetrafluoroboric acid as an acid catalyst gives the opposite result as regards selectivity of opening of the three-membered ring. The rearrangement of the di(cyclopropyl)ketimines **60** now gives the pyrrole derivatives **62** owing to opening of the three-membered carbon ring that has the electron-donating piperidyl substituent. These differences are attributed to the greater role of the nitrogen atom of the piperidyl radical in stabilisation of the positive charge in the transition state when an acid with a weakly nucleophilic tetrafluoroborate counter-ion is used as a catalyst.[103]

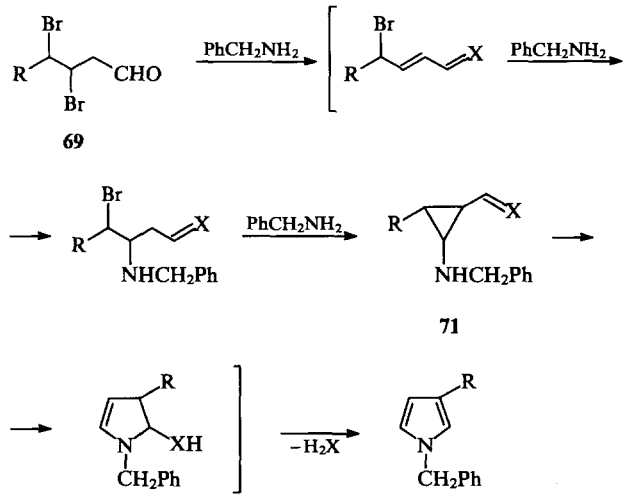
Cyclopropylimines often act as intermediates in the ring expansion reactions of cyclopropane carbonyl compounds with primary amines. For example, boiling the cyclopropyl ketones **63** in dimethylformamide in the presence of magnesium chloride gives the pyrrolidines **64**.[104] It is likely that the reaction proceeds via the formation of intermediate cyclopropylimines **65** and their rearrangement to substituted pyrrolines **66** which are reduced *in situ* by formic acid to give the final products.



63 **65** **66**

64 (31%–72%)

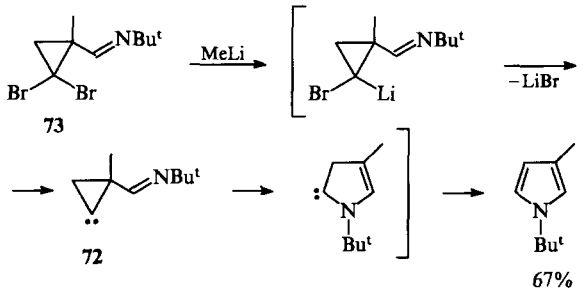
R^1 = H, Ph; R^2 = Alk, cyclo-Alk, Ar.



Cyclopropylcarbonyl compounds with electron-donor substituents in a β position to the carbonyl group will react with primary amines under mild conditions to give the corresponding pyrrole derivatives.[105–108] A convenient preparative method for obtaining this type of activated cyclopropane is 1,3-dehydrohalogenation of accessible 3-bromo-2-alkoxypropyl ketones.[105,106] The use of the cyclic ketones **67** as initial substrates in this reaction enables pyrrole derivatives condensed with cyclopentane and cyclohexane rings **68** to be synthesised.[106]

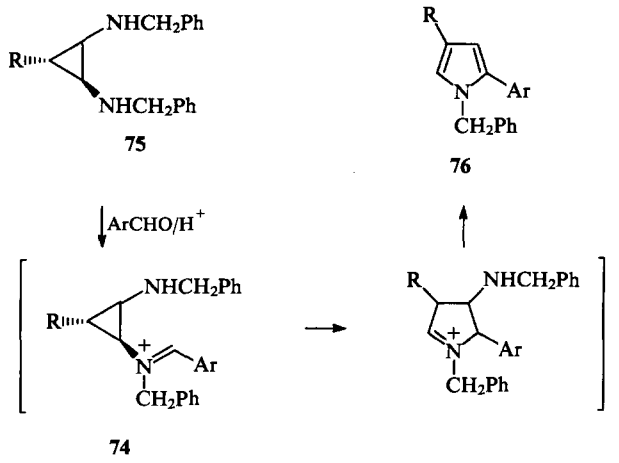
67 **68**

R^1, R^2 = H, Bu; R^3 = H, Me, CH_2Ph; n = 1, 2.



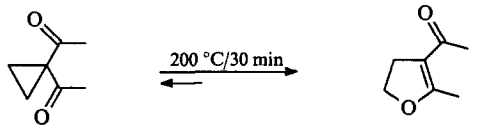
A similar approach was used in a convenient scheme for converting β,γ-dibromoaldehydes **69** to the inaccessible 3-alkyl-β-benzylpyrroles **70**.[108,109] The rearrangement of the linear carbon-carbon skeleton of the initial aldehyde **69** to give the branched structure of the 3-alkyl-pyrrole **70** is effected via the intermediate formation of the donor-acceptor cyclopropanes **71** by closure of the three-membered ring initiated by a Michael addition.

69 **71** **70**



R = Alk; X = O, NCH_2Ph.

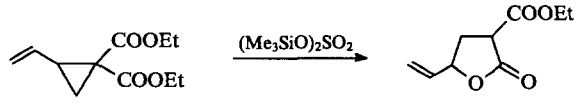
The role of the activating electron-donor substituent in the β position to the imine function can, at least formally, be performed by the lone pair of electrons of the carbene centre in the intermediate **72** which is formed when the dibromocyclopropylimine **73** is converted to 1-*tert*-butyl-3-methylpyrrole by the action of methyllithium.[110,111]



73 **72** 67%

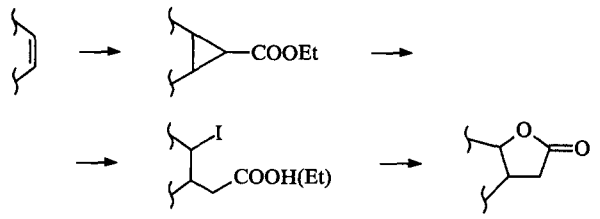
Aza-analogues of vinylcyclopropanes in which the nitrogen atom is directly bonded to the three-membered ring are also able to undergo rearrangement to pyrrole derivatives.[112,113] In the case of the activated cyclopropanes **74**, which are intermediate products of the reaction of the 1,2-diaminocyclopropanes **75** with aromatic aldehydes, the rearrangement proceeds smoothly at room temperature to give the 2-arylpyrroles **76** as final products.[113]

R = H, Me.



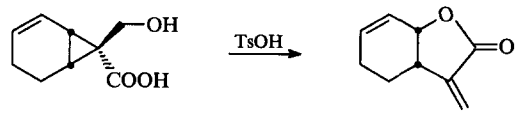
Rearrangements of cyclopropylcarbonyl compounds to give furan derivatives have been studied more thoroughly and there are many examples of their use in synthesis (see Refs 7, 11, 23, and 114). Formylcyclopropane[115] and acetylcyclopropane[116] undergo rearrangement reversibly in the gas phase at 400–500 °C to form 2,3-dihydrofuran and 2,3-dihydro-5-methylfuran respectively. The reaction is accompanied by the irreversible formation of a number of by-products and is of no preparative importance. On the other hand, 1,1-diacetylcyclopropane **77** will isomerise at 200 °C to give a high yield of the dihydrofuran **78**.[117,118]

77 **78** (92%)



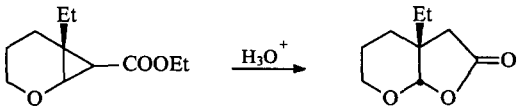
Other 1-acylcyclopropanes with electron-acceptor substituents in the α position to the acyl group undergo a similar isomerisation.[118,119]

Cyclopropanecarboxylic acid[120] and its derivatives[121–124] isomerise in the presence of various acid catalysts to give the corresponding γ-butyrolactones. The best yields of the final products are obtained by opening the three-membered ring in the carbonyl-substituted cyclopropanes using organosilicon reagents such as trimethyliodosilane or bis(trimethylsilyl) sulfate.[125] For example, treating 1,1-bis(ethoxycarbonyl)-2-vinylcyclopropane **79** with bis(trimethylsily) sulfate in 1,2-dichloroethane gives an excellent yield of the butyrolactone **80**.[126]

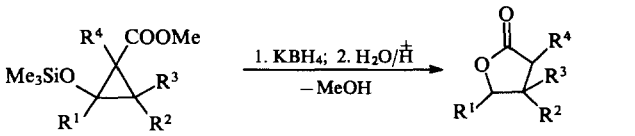


79 **80** (98%)

Other 1-carbonyl-substituted cyclopropanecarboxylates will also enter into reaction; the thermodynamically more stable butyrolactones with predominant inversion of the configuration of the reaction centre are formed.[126] A reaction in two stages, viz. opening the ring in the cyclopropanecarboxylic ester with trimethyliodosilane and closure of the lactone ring, is an effective method for converting olefins to γ-butyrolactones.[127]



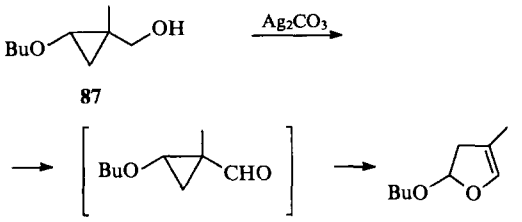
The use of 1-hydroxymethyl-,[128,129] 1-halogenomethyl-,[129] and 1-dialkylaminomethyl-substituted cyclopropanecarboxylate esters[130] enables α-methylene-γ-butyrolactones to be obtained. The regio-selectivity of the reaction is determined by the type of substituents in positions 2 and 3 of the three-membered ring.[128,129] For example, the rearrangement of the cyclopropylcarbinol substrate **81** to the lactone **82** takes place owing to rupture of the carbon–carbon bond in the cyclopropane ring that is adjacent to the double bond[128] whereas for the corresponding methoxyl analogue the reverse selectivity is observed.[129]



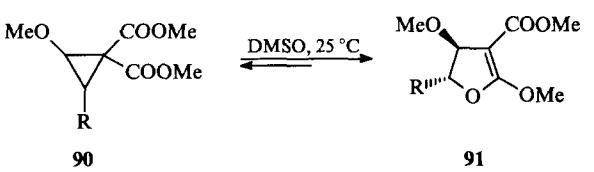
81 **82** (89%)

Cyclopropylcarbonyl compounds undergo rearrangement to furan derivatives especially easily when electron-donor substituents are present in the β position of the cyclopropane ring.[25] One of the most effective approaches to the synthesis of this type of substrate involves formation of the cyclopropane from esters of enols of diazocarbonyl compounds.[11,14,25,130] In certain instances not only the carbonylcyclopropanes are formed in these reactions but also the corresponding dihydrofurans. The latter may be obtained by 1,3-dipolar cycloaddition of ketocarbenes to olefins or isomerisation of the initially formed cyclopropane derivatives.[131–136] A typical example of this type of transformation is the synthesis of the bicyclic lactone **83** which is used as a key intermediate in the synthesis of certain indole alkaloids.[134] The cyclopropane precursor **84**, which is obtained from β-ethyldihydropyran, undergoes rearrangement to the lactone **83** smoothly when it is heated with dilute sulfuric acid.

84 **83** (93%)

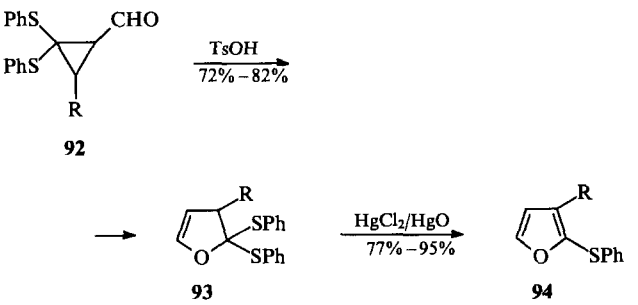


In certain instances, under the reaction conditions used, the hydroxylactones formed initially undergo dehydration to give the corresponding unsaturated lactones.[137] On the other hand, the reaction of the methyl 2-siloxycyclopropanecarboxylates **85** with potassium hydroborate in methanol enables the substituted saturated γ-butyrolactones **86** to be synthesised in a different way in a one-step procedure with a high yield. This multi-stage procedure evidently includes initial desilylation of **85** by potassium methoxide (generated *in situ* from potassium hydroborate and methanol), opening of the activated cyclopropane ring to form the corresponding 4-oxoalkanoates, their reduction and lactonisation.[138]



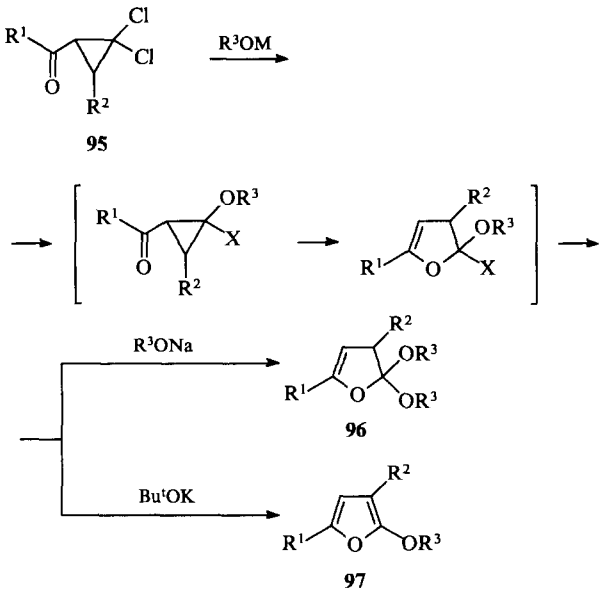
85 **86** (78%–95%)

R^1–R^4 = Alk, cyclo-Alk, Alkenyl.



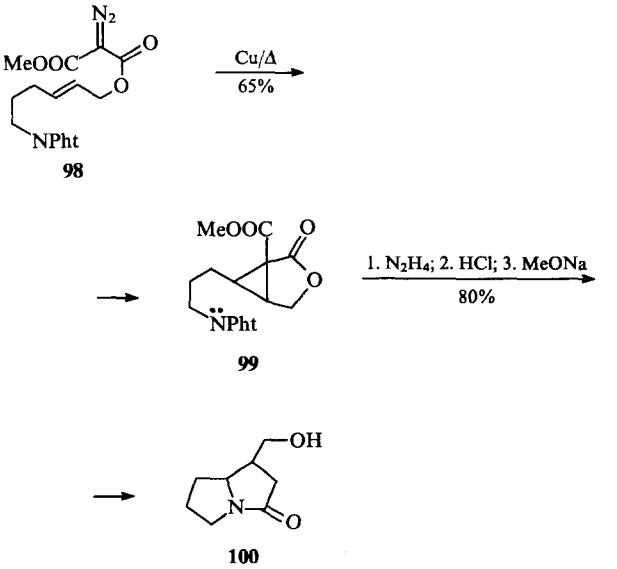
2-Oxy-substituted cyclopropyl ketones and aldehydes are considerably less stable and will undergo rearrangement to the corresponding dihydrofurans smoothly in the presence of acid catalysts or *in situ*.[131,133,139-141] For example, oxidation of the butoxycyclopropylcarbonyl **87** with silver carbonate on a zeolite gives a high yield of the dihydrofuran **88**, probably via the intermediate formation of the corresponding aldehyde **89**.[139,140] The reaction is of a general nature and in some instances the corresponding activated cyclopropanecarbaldehydes and cyclopropyl ketones can be identified.[139-141]

Cyclopropanes in which the three-membered ring has two geminal acceptor[132,135] or donor substituents and a substituent of the opposite type in a third position[142,143] will undergo rearrangement to dihydrofuran derivatives under very mild conditions. For example, in solutions of derivatives of 2-methoxycyclopropanecarboxylic acids **90** in dimethyl sulfoxide an equilibrium with the corresponding dihydrofurans **91** is established rapidly even at room temperature. The rearrangement typically takes place with retention of the stereochemical configuration at the reaction centre[132] (see also Ref. 136).

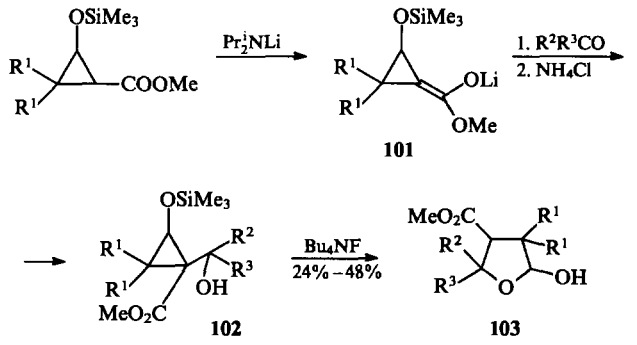


In the presence of catalytic quantities of *p*-toluenesulfonic acid the *gem*-di(phenylthio)cyclopropanecarbaldehydes **92** isomerise to the 3-substituted 2,2-di(phenylthio)-2,3-dihydrofurans **93** rapidly at room temperature and the latter can readily lose thiophenol to form the phenylthiofurans **94**.[144,145] Note that *gem*-di(phenylthio)cyclopropyl ketones with a similar structure isomerise smoothly under the same conditions to give acyclic products.[146]

R = Me, Ar.



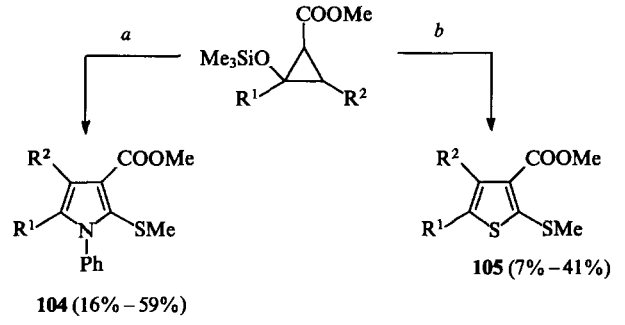
Nucleophilic substitution of the halogen atoms in 1-acyl-2,2-dichlorocyclopropanes **95** by reaction with alkali metal alkoxides leads directly to 2,2-dialkoxy-2,3-dihydrofurans **96**[147-150] or substituted 2-alkoxyfurans **97**,[151] depending on the type of alkoxide and the reaction conditions. 2-Dialkylaminofurans can be obtained by a similar scheme of reactions.[152]



R[1], R[2] = Alk, Alkenyl, Ar; R[3] = Alk; M = Na, K; X = Cl, OR[3].

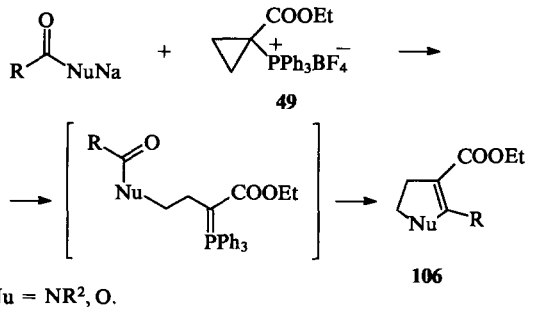
2. Other intramolecular cyclisation reactions

Intramolecular nucleophilic ring opening reactions in activated cyclopropanes also provide an effective approach to the production of five-membered heterocycles.[7,9,11,15,25] The intramolecularity factor has an additional activating effect on the opening of the three-membered ring[9] and the main problem in using this approach in directed synthesis is to obtain appropriate cyclopropane derivatives that contain suitable nucleophilic centres in the substituents. This approach has been used successfully in the synthesis of natural compounds,[9] particularly in the stereospecific synthesis of certain alkaloids where one of the stages involves intramolecular formation of cyclopropane from the multiple bond in **98**. The removal of the shielding phthalimide (NPht) group in the resultant cyclopropane derivative **99** using hydrazine hydrate leads to the formation of the key bicyclic product **100** due to spiro-opening of the cyclopropane ring with inversion of the configuration of the reaction centre.[153]



An alternative method of introducing nucleophilic substituents into activated cyclopropanes involves alkylation of deprotonated derivatives of a cyclopropanecarboxylic acid by using suitable substrates.[154-158] For example, the reaction of the ester enolates **101**, which are readily generated from methyl 2-siloxycyclopropanecarboxylates by the action of lithium diisopropylamide, with carbonyl compounds gives the trifunctional derivatives **102**. The latter are unstable and are converted, either spontaneously or by the action of desilylating agents, to the lactols **103** which are readily convertible to the corresponding tetrahydrofuran or γ-butyrolactone derivatives.[155]

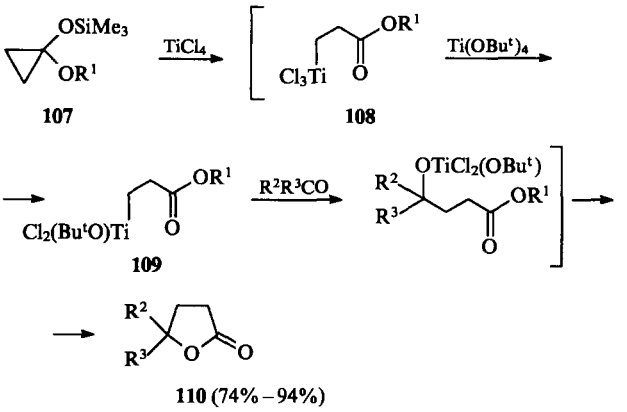
R^1_2 = Me_2, $-(CH_2)_5-$; R^2, R^3, = H, Me, Ph, $-(CH_2)_5-$.



The use of hetero-analogues of carbonyl compounds, such as phenyl isothiocyanate and carbon disulfide, as electrophiles opens up a route to the corresponding derivatives of pyrrole **104** [158] and thiophen **105**.[156,157]

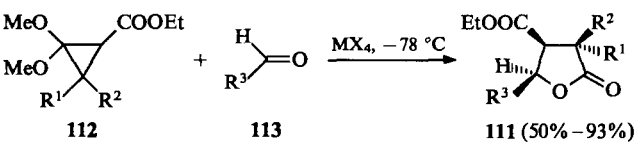
a — 1. Pr^i_2NLi, 2. PhNCS, 3. MeI, 4. CF_3COOH;
b — 1. Pr^i_2NLi, 2. CS_2, 3. MeI, 4. CF_3COOH
R^1, R^2 = Alk, cyclo-Alk.

3. Intermolecular hetero-ring formation reactions



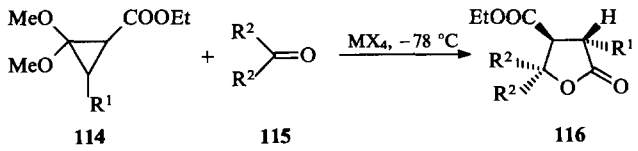
The synthesis of five-membered heterocycles by means of intermolecular hetero-ring formation, like that of cyclopentane derivatives (see above), is based on [3 + 2]-ring formation reactions. 1-Ethoxycarbonylcyclopropyltriphenylphosphonium tetrafluoroborate **49** will react with α-carbonyl-containing nucleophiles to give the corresponding five-membered heterocyclic compounds **106**. The stages in the reaction are nucleophilic opening of the three-membered carbon ring (which is doubly activated by the electron-acceptor substituents) and then olefination of the carbonyl group.[159-163]

Nu = NR^2, O.



The reaction of anions of cyclic imides with the phosphonium salt **49** opens up a means of obtaining bicyclic lactams with a bridgehead nitrogen atom.[159,160,162]

The cyclopropanone acetals **107**, which are doubly activated by electron-donor substituents, are suitable precursors of homoenolate anions[40,164,165] which react with carbonyl compounds to give derivatives of γ-hydroxycarboxylic acids or γ-butyrolactones.[166,167] In the homoenolate anions an intramolecular back reaction with the carbonyl group is favoured to a considerable extent by the entropy factor and hence for the reaction with an external electrophile to take place a substantial gain in enthalpy is required. It is known that in reactions with carbonyl compounds titanium and zinc homoenolates of esters satisfy these conditions.[164,167] The addition of 0.5 equiv. of tetra(*tert*-butoxy)titanium to the trichlorotitanium homoenolate **108**, which is obtained by the reaction of the silylacetal of cyclopropanone **107** with titanium tetrachloride, gives an alkoxide derivative **109** that is more reactive than the initial enolate **108**. The reaction of **109** with ketones does not stop at the stage where the corresponding γ-oxyesters are formed but leads to their cyclisation *in situ* to give the γ-lactones **110**.[167-170]



R^1 = Alk; R^2, R^3 = Alk, cyclo-Alk, Ar.

Cyclopropanes containing donor and acceptor substituents simultaneously are able to enter into a similar condensation with aldehydes and ketones in the presence of titanium tetrachloride, giving γ-hydroxyketones and dihydrofurans respectively.[168-170] There are also reports of the diastereoselective synthesis of *cis*-3,4-disubstituted γ-lactones **111**[171,172] and *cis*-3,4-disubstituted-γ-lactams[172] using the Lewis-acid-catalysed reaction of 2,2-dialkoxy-3,3-dialkylcyclopropanecarboxylic esters **112** with aldehydes **113** and *N*-toluenesulphonylaldimines respectively.[173]

R^1, R^2, R^3 = Alk; MX_4 = $TiCl_4$, $TiBr_4$, or $SnBr_4$.

The reaction of 2,2-dialkoxy-3-alkylcyclopropanecarboxylic esters **114** with symmetrical ketones **115** under the same conditions gives *cis*-2,3-disubstituted lactones **116**, also with high selectivity.[173]

114 **115** **116**

R^1, R^2, R^3 = Alk.

* * *

It is clear from the data presented in this review that the methods for synthesising five-membered carbocycles and heterocycles using activated cyclopropanes as intermediates are in many instances highly flexible and stereoselective. Since there are simple and effective methods for obtaining cyclopropane compounds of different structures, including individual optical isomers,[174] it is safe to say that these methods for synthesising cyclic compounds are undoubtedly of preparative importance. The majority of the publications are concerned with ring expansion reactions in vinylcyclopropanes and their oxa- and aza-analogues, and also other types of intramolecular cyclisation, as these have been used extensively to obtain five-membered rings. However the use of reactions that entail intermolecular [3 + 2]- and [4 + 1]-ring formation is no less promising.

Abstract. Experimental and theoretical aspects of the application of steady and transient electrical birefringence methods to dilute solutions of rigid-chain polymers are examined. The prospects of using the Kerr effect to study the conformational and the structural characteristics of macromolecular chains are analysed. The effect of the polarity of the medium on the electro-optical properties of polymeric molecules is discussed. The bibliography includes 117 references.

I. Introduction

The wide interest which studies of the molecular properties of rigid-chain polymers have attracted is due partly to the extensive industrial applications of materials based on these polymers and partly to the increasing need for general concepts concerning the structure and the physical properties of macromolecular compounds.

Latterly we have witnessed an increasing interest in studies of rigid-chain polymers able to undergo thermotropic and lyotropic mesomorphism, such as aromatic polyesters and polyamides, and also cellulose esters. This interest has been stimulated by the applications of substances of this type in various electronic devices and by improvements in the technology of polymer processing.

The structure and the conformation of the molecules of rigid-chain polymers, which are responsible for the unique properties of the materials prepared from these polymers, are determined by studying the behaviour of their macromolecules in very dilute solutions, in which the intermolecular interaction of the polymer chains is negligibly small. The measurement of electrical birefringence (EBR, the Kerr effect) is one of the most important methods of studying the conformational and the kinetic characteristics of rigid-chain polymers in dilute solutions, since it provides information on the structural and the dynamic properties of rigid-chain macromolecules which is needed in order to identify the interrelationship between the molecular structure and the physical properties of the polymers. This information is an essential first step in the creation of new materials having prescribed properties.

II. Theoretical aspects and experimental procedure

1. Theory of the steady Kerr effect for rigid molecules

In 1875 Kerr established[1] that a transparent isotropic substance exposed to an electric field acquires the optical properties of a uniaxial crystal with its axis parallel to the field. In the case of weak DC fields the optical anisotropy generated in the substance is proportional to the square of the field intensity (Kerr's law):

$$\frac{\Delta n}{n} \equiv \frac{n_p - n_s}{n} = K_e E^2 . \quad (1)$$

Here $\Delta n = n_p - n_s$ is the difference between the refractive indices (extraordinary n_p and ordinary n_s) for two light rays with electric vectors oscillating in directions parallel and perpendicular to the electric field respectively; E is the intensity of the electric field, directed at right angles to the light rays; n is the average refractive index of the substance; K_e is the Kerr constant.

The electro-optical properties of substances are often described in terms of the specific Kerr constant K_ρ defined as

$$K_\rho = \frac{\Delta n}{\rho E^2} , \quad (2)$$

where ρ is the density of the liquid.

In the case of a solution the EBR caused by the presence of the solute can be characterised by the Kerr constant of the latter, defined by the expression

$$K = \lim_{E \to 0,\, c \to 0} \frac{\Delta n}{cE^2} , \quad (3)$$

where Δn is the excess difference in refractive indices, due to the solute, and c is the concentration of solute (g cm^{-3}).

The molar Kerr constant ${}_mK$, defined (according to Debye[2]) by the expression

$${}_mK = \frac{6K_\rho Mn}{[(n^2+2)(\varepsilon+2)]^2} , \quad (4)$$

is sometimes used to characterise the molecular properties of liquids. Here M is the molecular weight of the liquid and ε is its dielectric permittivity.

The molar Kerr constant ${}_mK_{12}$ of a two-component solution is an additive quantity, expressed in terms of the molar Kerr constants of the solvent ${}_mK_1$ and of the solute ${}_mK_2$ (see Stuart[3]):

$$ {}_mK_{12} = (1-f_2){}_mK_1 + f_2\,{}_mK_2 , \tag{5}$$

where f_2 is the mole fraction of the solute.

It follows from Eqns (3)–(5) that the molar constant of the solute extrapolated to zero concentration (${}_mK_{c\to 0}$) is given by

$$ ({}_mK)_{c\to 0} = \frac{6KnM}{[(n^2+2)(\varepsilon+2)]^2} . \tag{6}$$

Here n and ε are the refractive index and the dielectric permittivity of the solvent respectively.

The theories of Langevin[4] and Born,[5] developed for gases, relate the constant ${}_mK$ of a substance to the principal components of the tensor of the optical (γ_1, γ_2, γ_3) and the dielectric polarisabilities (δ_1, δ_2, δ_3) of the molecule and to the corresponding components (μ_1, μ_2, μ_3) of its dipole moment by the expression

$$ {}_mK = \frac{2\pi N_A}{405kT}\left[\sum_{i,j=1}^{3}(\gamma_i-\gamma_j)(\delta_i-\delta_j) + \frac{1}{kT}\sum_{i,j=1}^{3}(\gamma_i-\gamma_j)(\mu_i^2-\mu_j^2)\right] , \tag{7}$$

where N_A is Avogadro's number.

It should be noted that Eqn (7) does not contain terms explicitly dependent on the state of aggregation of the substance. This explains the many reported attempts to use the equation in descriptions of the electro-optic properties not only of gases but also of liquids and solutions. Experiments have shown[3] that Eqn (7) adequately describes those properties in the case of polar molecules and of nonpolar substances not only in the gas phase but also in their solutions in nonpolar solvents, but in the case of polar (conducting) liquids and of solutions in polar solvents the equation is unacceptable.

For substances in dilute solutions and consisting of molecules having axially symmetrical optical and dielectric properties the constant K in Eqns (6) and (7) is given by

$$ K = \frac{2\pi N_A}{135kTn}\left[\frac{(n^2+2)(\varepsilon+2)}{3}\right]^2 \frac{\gamma_1-\gamma_2}{M} \times\left[\delta_1-\delta_2+\frac{\mu^2}{kT}\,\frac{3\cos^2\theta-1}{2}\right] , \tag{8}$$

where θ is the angle defined by the dipole μ and the axis of symmetry of the optical and of the dielectric polarisability (γ_1 and δ_1).

Eqn (8) shows that the sign of K depends on the magnitude and direction (angle θ) of the dipole moment of the molecule. Thus for nonpolar molecules ($\mu = 0$) the Kerr constant is always positive, because the signs of $(\gamma_1-\gamma_2)$ and $(\delta_1-\delta_2)$ are the same. For strongly polar molecules, in which the term $\delta_1-\delta_2$ can be ignored, the Kerr effect is positive for $\theta < 54.72°$ and negative for $\theta > 54.72°$.

We should stress the fact that the Langevin–Born theory, which leads to Eqns (7) and (8), relies on the assumption that the potential energy of the molecules associated with their rotation in an electric field is small in comparison with the energy of the thermal motion, $\mu\epsilon/kT \ll 1$ and $(\delta_1-\delta_2)\epsilon^2/kT \ll 1$, where ϵ is the field acting on the molecule [according to Lorentz $\epsilon = E(e+2)/3$]. In the opposite case the dependence of Δn on E^2 reaches saturation (see Kuhn et al.[6] and O'Konski et al.[7]).

2. Transient electrical birefringence

The study of the electro-optical properties of molecules under the influence of electrical pulses of various forms yields valuable information on their rotational mobility and justifies a number of conclusions on the nature of the EBR under study (is it due mainly to the presence of a constant dipole moment in the molecule, or to the anisotropy of its dielectric polarisability, or even to a combination of these factors).

These possibilities arise because the reorientation of the molecules under the influence of the electric field is not instantaneous, but requires a certain time, depending both on the rotational diffusion coefficient of the particles D_r and on the nature of the observed effect. Experiments of this type are difficult when the samples under study are low-molecular substances, because the molecular reorientation times are very short in these materials (10^{-11}–10^{-9} s). However, in solutions containing supermolecular species or rigid macromolecules the reorientation times are significantly longer, and they can be measured electrooptically.

Rectangular-pulse and sinusoidal periodic fields are the types of field most often used in studies of the relaxation processes. The pulsed field method was proposed independently by Russian[8] and by French physicists.[9,10]

The disappearance of the EBR in a monodispersed system of rigid particles or molecules with an axial symmetry of form and of optical properties following the instantaneous switching off of the field is determined only by their spontaneous disorientation as a result of thermal rotation, is independent of the electrical properties of the species, and is described by the expression[9,10]

$$ \Delta n = \Delta n_0\, e^{-t/\tau_0} , \tag{9}$$

where Δn_0 is the initial EBR of the system in a steady field, t is the time, and τ_0 is the relaxation time,

$$ \tau_0 = \tfrac{1}{6}D_r . \tag{10}$$

Here D_r is the diffusion coefficient of the particles rotating round their short axis (normal to the axis of symmetry). The rate of the establishment of the EBR by switching on the electric field is determined not only by the thermal motion of the particles but also by the electrical properties of the molecules.

For axially symmetric particles, in which the vector or the dipole moment μ is parallel to the axis of symmetry, the dependence of Δn on t when the field has been switched on ($\mu\epsilon/kT \ll 1$) is described by the expression[9,10]

$$ \frac{\Delta n}{\Delta n_0} = 1 - 3\frac{\alpha^2}{\beta}\left(\frac{2\alpha^2}{\beta}+4\right)^{-1} e^{-t/\tau} + \left(\frac{2\alpha^2}{\beta}+4\right)^{-1}\left(\frac{\alpha^2}{\beta}-4\right)e^{-t/\tau_0} , \tag{11}$$

where

$$ \tau = \tfrac{1}{2}D_r ; \quad \alpha = \frac{\mu\epsilon}{kT} ; \quad \beta = \frac{(\delta_1-\delta_2)\epsilon^2}{2kT} . \tag{12}$$

If the particle has no dipole moment ($\alpha = 0$) and the EBR is determined exclusively by the anisotropy of its polarisability ($\delta_1-\delta_2$), Eqn (11) becomes

$$ \Delta n = \Delta n_0(1 - e^{-t/\tau_0}) . \tag{13}$$

In this case the growth of Δn on switching on the field (curve *1* of Fig. 1) corresponds exactly to its decay (curve *3*). If the molecules are oriented by the field E only because of the dipole moment μ we find from (11)

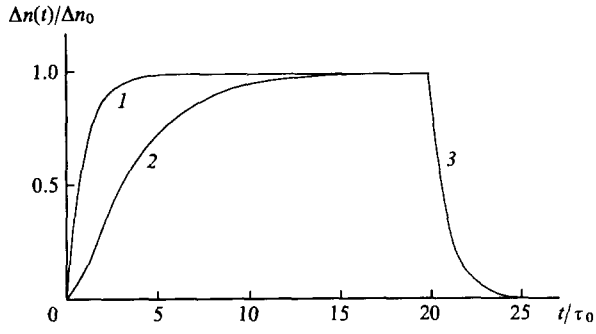

Figure 1. Dependence of the relative value of the EBR on the relative time for instantaneous switching the electric field on (*1*, *2*) and off (*3*): (*1*) and (*3*) nondipolar ($\alpha = 0$) and electrically anisotropic particles, (*2*) and (3) dipolar and electrically isotropic particles ($\beta = 0$).

$$\frac{\Delta n}{\Delta n_0} = 1 - \frac{3}{2}e^{-t/\tau} + \frac{1}{2}e^{-t/\tau_0} . \tag{14}$$

In this case Δn increases more slowly than in the case of inductive orientation, and the $\Delta n(t)$ dependence (curve *2* of Fig. 1) is tangential to the t axis for $t = 0$.

In the more general case, Δn increases more slowly when the steady dipole of the particles plays a dominant role in the EBR.

In a sinusoidal electric field of voltage $E = E_0 \cos\omega t$ the orientation distribution function of dielectrically anisotropic and polar particles should be time-dependent. Accordingly, the observed excess birefringence Δn stimulated by the dissolved substance is also time-dependent.

For dielectrically isotropic particles the instantaneous value of the excess EBR of the solution $[\Delta n(t)]$ and the corresponding instantaneous value of the Kerr constant $[K(t)]$ are defined by the expressions[11]

$$K(t) = \frac{2\Delta n(t)}{cE^2} = K\left\{1 + \left[\frac{\cos(2\omega\tau - \varphi)}{(1+\omega^2\tau_0^2)^{1/2}}\right]\right\} , \tag{15}$$

$$\tan\varphi = 2\omega\tau_0 ,$$

where ω and E_0 are the angular frequency and the amplitude of the electric field.

If follows from this expression that in a sinusoidal field $\Delta n(t)$ and $K(t)$ oscillate symmetrically with respect to the mean value of K with a doubled frequency, and that their sign at any instant is the same as that of K. The amplitude of these oscillations falls to zero as the frequency ω increases. When the time-average value of Δn is the monitored quantity the measured EBR is independent of the frequency of the field, and remains equal to its equilibrium value in a steady field of amplitude $E = E_0/\sqrt{2}$.

If particles having constant dipoles are exposed to a sinusoidal electric field the expression for their Kerr constant takes the form

$$K(t) = \frac{2\Delta n(t)}{cE^2}$$

$$= K\left[\frac{1}{1+\omega^2\tau^2} + \frac{\cos(2\omega t - \varphi)}{(1+4\omega^2\tau_0^2)^{1/2}(1-\omega^2\tau^2)^{1/2}}\right] , \tag{16}$$

$$\tan\varphi = \frac{5\omega\tau}{3 - 2\omega^2\tau^2} .$$

The first term in Eqn (16) is time-independent. It is a time-averaged value of the Kerr constant for a fixed field frequency ν:

$$K_\nu = \frac{K}{(1+\omega^2\tau^2)} . \tag{17}$$

This average value of K_ν decreases with increasing frequency of the field, and vanishes at high frequencies because of the relaxation of the rotational motion of the dipolar particles. According to Eqn (17) τ can be determined from the dispersion curve by using the condition

$$\tau = \frac{1}{\omega_m} , \tag{18}$$

where ω_m is the angular frequency for which $\Delta n_\nu = (\Delta n_0 + \Delta n_\infty)/2$ (Δn_0 and Δn_∞ are the values of Δn for $\omega = 0$ and $\omega = \infty$ respectively).

If a particle (or a rigid molecule) has both a steady dipole and dielectric anisotropy the time-dependent value of $K(t)$ is determined by the sum of the expressions (15) and (16) with appropriate weighting coefficients. If the quantity monitored in the experiment is the time-averaged value of the EBR as a function of the frequency of the external field the plot of K has the form shown in Fig. 2:

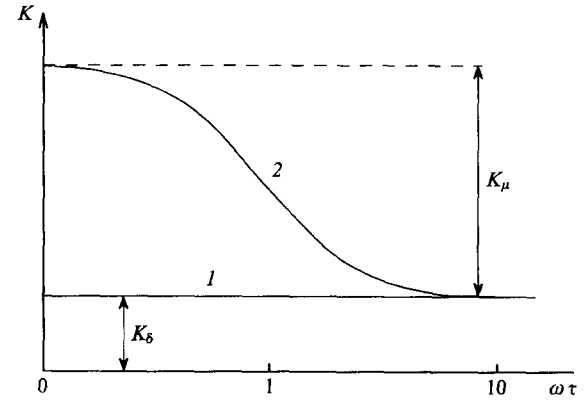

Figure 2. Frequency dependence of the mean Kerr constant for a solution of dielectrically anisotropic dipolar particles: (*1*) K_δ, the anisotropic part of the Kerr constant, (*2*) overall effect $K = K_\delta + K_\mu$ (K_μ is the dipolar part of the Kerr constant).

However, it should not be forgotten that the expressions (9)–(18) are valid only for monodispersed systems of particles or of rigid molecules. Substances studied experimentally are usually polydispersed in relaxation time. In this case the total value of $\Delta n(t)$ is a superposition of the $\Delta n_i(t)$ values (where i is the number of the group of molecules having identical relaxation times, allowing for their mass fractions in the sample). For rigid polar molecules Eqns (9) and (14) can be re-written

$$\frac{\Delta n(t)}{\Delta n_0} = \int_0^\infty \varphi(\tau) f(t,\tau)\, d\tau , \tag{19}$$

where $f(t,\tau) = e^{-3t/\tau}$ for the decay and $f(t,\tau) = 1 - (3/2)e^{-t/\tau} + (1/2)e^{-3t/\tau}$ for the growth of $\Delta n(t)$, and the function $\varphi(\tau)$ allows for the contribution to the EBR from molecules having relaxation times between τ and $\tau + d\tau$. The areas delinated by the growth and decay curves are, respectively,

$$Q_g = \int_0^\infty \left(1 - \frac{\Delta n(t)}{\Delta n_0}\right) dt \quad \text{and} \quad Q_d = \int_0^\infty \frac{\Delta n(t)}{\Delta n_0} dt .$$

Starting from Eqns (13) and (14) for monodispersed rigid particles or molecules we obtain

$$Q_d = \tfrac{1}{3}\tau = \tau_0 ,$$

for the decay curve and

$$Q_g = \tfrac{4}{3}\tau = 4Q_d$$

for the growth curve. In this case Q_d is the 'free relaxation' time.

In the presence of polydisperseness with respect to the molecular mass M or to the relaxation time τ the areas Q_g and Q_d are altered (in this case $Q_d = \langle\tau_0\rangle$ is the mean free relaxation time), but according to Eqn (19) their ratio stays the same: $Q_g/Q_d = 4$, irrespective of the form of the function $\varphi(\tau)$.

Often the experimental dispersion curves are wider than predicted by Eqn (17), suggesting polydisperseness of the ensemble of molecules with respect to the relaxation times. These dispersion curves can be described by replacing Eqn (17) by

$$\frac{\Delta n_\nu}{\Delta n_0} = \int_0^\infty \varphi(\tau)(1+\omega^2\tau^2)^{-1}\,d\tau. \tag{20}$$

3. Relationship between the relaxation times and the hydrodynamic and the structural properties of the molecules

Studies of the dynamics of the Kerr effect yield information on the rotational mobility of particles or of rigid molecules, and therefore on their size and shape, thus allowing meaningful conclusions on the nature of the observed EBR to be made. The same is true of studies of the time-dependent EBR in dilute solutions of polymers, but in this case the possibilities offered by the method are much wider: it can evaluate both the structural (equilibrium) and the kinetic rigidity of the macromolecules. The term kinetically rigid denotes a polymeric molecule whose orientation time (τ_{or}) under the stimulus of an external field is smaller than the time needed for its deformation (τ_{def}) in the same field. This definition suggests that a given macromolecule can behave both as kinetically rigid and kinetically flexible, depending on the nature of the forces acting on it. The length of the Kuhn segment (A)[12,13] can be used as a measure of the equilibrium rigidity ($\langle \boldsymbol{h}^2\rangle$). If the beginning and the end of a real polymeric molecule are super-imposed on the beginning and the end of a model, freely coupled Kuhn chain having the same contour line L the equilibrium rigidity can be evaluated by the equation[12-14]

$$\langle \boldsymbol{h}^2\rangle = LA\,; \quad L = NA\,, \tag{21}$$

where $\boldsymbol{h}$ is a vector connecting the end-points of the chain, and N is the number of Kuhn segments in the chain. The angle brackets in Eqn (21) denote averaging over all the conformations of the macromolecule.

Depending on their A value all polymers are usually classified into two groups: rigid-chain polymers (with a large A) and flexible-chain polymers (with a small A). Experimental data[13] show that macromolecules having a high equilibrium rigidity also show kinetic rigidity, and are oriented in externally applied fields by a mechanism involving the large-scale rotation of the molecule as a whole. Conversely, the molecules of flexible-chain polymers have a small kinetic rigidity,[13] and therefore their orientation in an electric field takes place by the deformation mechanism.

The study of the dependence of the relaxation time of the EBR on the molecular weight of the polymer is of fundamental importance for determining the character of the motion of the molecules in an electric field. This dependence can be described approximately by the following empirical expression, which is valid over a reasonably narrow range of molecular masses:

$$D = K_{D_r} M^{-b}\,, \tag{22}$$

where D is the rotational diffusion coefficient, K_{D_r} is a constant [$D_r = 1/2\tau$]; b lies between 3 (for infinitely thin kinetically rigid rods) and 1.5 (for kinetically rigid nonpercolating Gaussian tangles).

A more general expression relates the relaxation time τ of a kinetically rigid molecule to its molecular mass and to its characteristic viscosity $[\eta]$ in solution:[13]

$$\tau = \frac{M[\eta]\eta_0}{2FRT}\,, \tag{23}$$

where η_0 is the viscosity of the solvent and $R = kN_A$. The coefficient F depends on the hydrodynamic properties of the particles used as models of the molecules: its limiting values are 2/15 for thin rods and 5/12 for spherical tangles.

A quantitative description of the equilibrium conformational properties of polymeric molecules can be based on the theory of the rotational friction of kinetically rigid vermiform chains.

In the first variant, developed by Hearst[15] for the vermiform necklace model, the theoretical expressions were reduced to the form

$$\tau = \tau_r f(x)\,, \tag{24}$$

$$\tau_r = \frac{(6kT)^{-1}\pi\eta_0 L^3}{\ln(L/d) - 0.877 + 7[(1/\ln(2L/d)) - 0.28]^2}\,.$$

Here τ_r is the rotational relaxation time of the rod-like molecule[16] whose length L and diameter d are equal (respectively) to the contour line and to the hydrodynamic diameter of the molecule; $f(x)$ is a function which allows for the equilibrium flexibility of the chain, and $x = 2L/A$.

In Hearst's theory[15] the function $f(x)$ is a linear correction (with respect to x) applied to the τ_r value of a rod-like molecule and valid only for $x \ll 1$, which seriously limits the prospects of using this variant in conjunction with experimental data.

Hearst's theory was subsequently developed by Hagerman and Zimm,[17] who used it in conjunction with the Monte Carlo method to express the function $f(x)$ as a power series in x, thus markedly extending its region of validity to $0.1 \leqslant x \leqslant 5$:

$$f(x) = (1.0120 - 0.24813x + 0.033703x^2 - 0.0019177x^3) \times (1 - 0.06469x + 0.01153x^2 - 0.0009893x^3)\,. \tag{25}$$

By varying the parameters d and A we can construct a theoretical curve offering the best description of the experimental data [$\tau = \tau(M)$], and thus determine the equilibrium rigidity and the hydrodynamic diameter of the molecule. This calculation was carried out[18,19] for a group of DNA samples, and gave results satisfactorily consistent with data obtained by translational diffusion methods.

4. The Kerr effect in solutions of vermiform chains

As was pointed out above, macromolecules of rigid-chain polymers behave as kinetically rigid chains in an electric field. Furthermore, it was found that the EBR and the flow birefringence (FBR) had the same sign for solutions of this class of polymer in the Gaussian region. This shows that the character of the orientation of their molecules in electrical and in mechanical (shear) fields is the same, and involves a large-scale rotation mechanism. Therefore the use of data obtained by the FBR method for interpreting EBR results is fully justified. The equilibrium electro-optical properties of solutions of rigid-chain polymers can be described by starting from the theory of the Kerr effect for rigid dipolar particles with axially symmetrical optical and dielectric polarisabilities, using the $\boldsymbol{h}$ axis (which connects the ends of the chain) as a symmetry vector. The latter postulate is consistent with the basic conformational characteristics of polymer chains discussed in the original papers by Kuhn et al.[20-22]

Thus Eqn (8) becomes the starting expression for the Kerr constant of a rigid-chain polymer. However, in order to establish the quantitative dependence of K on the conformation and structure of the macromolecule we need a specific molecular model to describe its electro-optical properties. A large volume of experimental and theoretical information[13] confirms that the most universal model of the conformational, hydrodynamic, and dynamic-optical properties of rigid-chain polymeric molecules is the vermiform chain model, and that this model can reasonably be used also to describe the electro-optical properties of these molecules.

The theory of the equilibrium Kerr effect in dilute solutions of vermiform chains has been fully developed.[23,24] Since in the ensemble of unfolded vermiform polymer molecules the dipolar, the optical, and the dielectric terms which appear in Eqn (8) are statistical quantities, averaged over all the conformations of the macromolecules, a similar averaging is needed also for Eqn (8). In this case the difference between the two principal optical polarisabilities of the vermiform molecule (along the $\boldsymbol{h}$ axis and at right angles to it) is given by the expression[25]

$$\langle \gamma_1 - \gamma_2 \rangle = \frac{3}{5} \frac{\Delta a S x f_1(x)}{f_2(x)} , \tag{26}$$

where Δa is the optical anisotropy of the monomer unit of the chain, and S is the number of monomer units in the Kuhn segment. Throughout this review angle brackets will be used to denote quantities averaged over conformations. The functions $f_1(x)$ and $f_2(x)$ take the form

$$f_1(x) = x - 1 + e^{-x} ; \quad f_2(x) = x^2 - 0.8 f_1(x) . \tag{27}$$

The difference between the two principal dielectric polarisabilities $\langle \delta_1 - \delta_2 \rangle$ of a vermiform chain is also given by formula (26) when Δa is replaced by Δb (where Δb is the dielectric anisotropy of the monomer unit).

In addition to the geometric segment A, the electrical (dipolar) segment has been used to describe the properties of a freely coupled Kuhn chain: it consists of a rigid linear combination of uniformly oriented dipole moments μ_0 of the monomer units of the chain,[26] in which the 'dipolar' and the 'geometric' rigidities are assumed to be equal. However, allowance was made for the difference in the vector sum of the segment dipoles μ_s parallel to the axis of the geometric segment ($\mu_{s\parallel}$) and of the dipoles perpendicular to that axis ($\mu_{s\perp}$). In the former, the dipole moment of the molecule is parallel to the vector $\boldsymbol{h}$, and its mean square value is given by the expression

$$\langle \mu_\parallel^2 \rangle = N \mu_{s\parallel}^2 . \tag{28}$$

Eqn (28) reflects the 'accumulation' of the longitudinal components of the dipoles of the monomer units, resulting in an increase of the macromolecular dipole with increasing length of the polymer chain. In the latter case the overall dipole of the molecule is no longer parallel to $\boldsymbol{h}$, but has a longitudinal (parallel to $\boldsymbol{h}$) and a perpendicular component, whose mean square values are given by

$$\langle \mu_\parallel^2 \rangle = N \mu_{s\perp}^2 \left(\frac{h}{L}\right) \alpha^*\left(\frac{h}{L}\right) ;$$

$$\langle \mu_\perp^2 \rangle = N \mu_{s\perp}^2 \left[1 - \left(\frac{h}{L}\right) \Big/ \alpha^*\left(\frac{h}{L}\right)\right] , \tag{29}$$

where $\alpha^*(h/L)$ is the inverse Langevin function of the convolution parameter (h/L) of the chain.[22]

These ideas have been applied[23,24] to vermiform chains by considering the general case of the dipole moment μ_0 of the monomer unit at an angle ϑ to the tangent to the contour of the chain. It has also been pointed out[24] that the dipolar and the geometric rigidity of the chain can differ for reasons not allowed for in Kuhn's theory. The equality of the geometric and of the longitudinal (dipole) rigidity (characterised by the number $S_\parallel = S$ of longitudinal components $\mu_{0\parallel}$ of monomeric dipoles in the electrical segment) is beyond doubt. However, this hypothesis may not be applicable to many rigid-chain molecules met in practice: for example, *para* aromatic polyamides and polyethers. The high geometric rigidity of the chains of these polymers is due to their 'crankshaft' conformation,[27] one of whose features is a substantial freedom to undergo intramolecular rotations round the *para* aromatic axes. Allowance for the possible differences between the longitudinal and the transverse dipole rigidity can be made by introducing the parameter $\alpha \geqslant 1$;

$$S_\parallel = \alpha S_\perp = S ; \quad \mu_{s\parallel} = S_\parallel \mu_{0\parallel} = S_\parallel \mu_0 \cos\vartheta ; \tag{30}$$

$$\mu_{s\perp} = S_\perp \mu_{0\perp} = S_\perp \mu_0 \sin\vartheta .$$

Furthermore, noting that

$$\left\langle \mu^2 \frac{3\cos^2\vartheta - 1}{2} \right\rangle = \left\langle \mu_\parallel^2 - \frac{\mu_\perp^2}{2} \right\rangle , \tag{31}$$

using Eqn (30), and inserting into (29) $\langle h^2 \rangle / L$ for a vermiform chain, we obtain

$$\left\langle \mu^2 \frac{3\cos^2\vartheta - 1}{2} \right\rangle = \frac{M S \mu_0^2}{M_0} \frac{f_1(x)}{x} \left[\cos^2\vartheta \frac{3 f_1^2(\alpha x) \sin^2\vartheta}{5\alpha f_2(\alpha x) f_1(x)}\right] , \tag{32}$$

where M_0 is the molecular weight of the monomer unit in the polymer.

Inserting (26) and (32) into (8) gives an expression for the Kerr constant of the vermiform chain:

$$\frac{K}{K_\infty} = \frac{3\langle h^4 \rangle f_1^2(x)}{5\langle h^2 \rangle^2 f_2(x)} \times \left[1 - \frac{3 f_1^2(\alpha x)}{5\alpha^2 f_1(x) f_2(\alpha x)} \tan^2\vartheta + \frac{6 k T x \Delta b}{5\mu_{0\parallel}^2 S f_2(x) \cos^2\vartheta}\right] . \tag{33}$$

Here K_∞ is the limiting value of the Kerr constant in the region of $x \to \infty$:

$$K_\infty = \left(\frac{B \Delta a}{M_0 k T}\right) \mu_0^2 S^2 \cos^2\vartheta . \tag{34}$$

Using the Lorentz internal field multiplier gives the following expression for the coefficient B:

$$B = \left(\frac{2\pi N_A}{1215 k T n}\right) (n^2 + 2)^2 (\varepsilon + 2)^2 . \tag{35}$$

Eqn (33) contains the term

$$\frac{\langle h^4 \rangle}{\langle h^2 \rangle^2} = \frac{11}{3} x^2 - (2x + 8) f_1(x) + \frac{2}{27} \frac{f_1(3x)}{f_1^2(x)} , \tag{36}$$

introduced in order to allow for the polydisperseness with respect to conformations in the ensemble of vermiform chains; it varies from 1 to 5/3 as x is varied from 0 to ∞.

It follows from Eqn (34) that the sign of K_∞ is the same as the sign of Δa, since in a solution of kinetically rigid vermiform chains the signs of the EBR and of the FBR should coincide in the Gaussian region. We should stress that in order to achieve a quantitative characterisation of the dipole structure of macromolecules the parameter Δa must be known. For polymers Δa can be found by the FBR method, starting from the experimentally

determined value of the optical shift coefficient in the Gaussian region.

$$\left(\frac{\Delta n}{\Delta \tau}\right)_{\infty} = \frac{4\pi(n^2+2)^2}{45kTn}\Delta a S ,$$

where $\Delta\tau$ is the shear stress in the flow.

Fig. 3*a* shows plots of the relative Kerr constant $K/K_{\infty,\vartheta=0}$ against x for $\alpha = 1$ in the case of kinetically rigid vermiform chains. The curves differ not only in their asymptotic value (which is proportional to $\cos^2\vartheta$) but also in their shape. If the dipole is perpendicular to the direction of the chain ($\vartheta = 90°$) the Kerr effect is opposite in sign to Δa for all values of x, and decreases to zero (in absolute value) as x is increased. This is because the correlation in direction between the dipole moment of the chain molecule (obtained by summing all the perpendicular components of the dipole moments of the monomer units) and the direction of $\boldsymbol{h}$ decreases as x is increased, and disappears in the Gaussian region.

An entirely different situation is observed on summing the longitudinal components of the dipole moments of the monomer units, since in this case the dipole of the molecule is parallel to $\boldsymbol{h}$ and increases with x. These effects produce a sign inversion (at $90° > \vartheta > 54.74°$) in the plots of the relative Kerr constant against x (see Fig. 3*a*).

Possible effects of the difference between the longitudinal and the transverse dipole rigidity on the Kerr constant are illustrated in Fig. 3*b*, which shows plots of the ratio K/K_{∞} for fixed angles $\vartheta = 0°$ and 70° and different values of α.

The most widely used methods of measuring the EBR rely on monitoring changes in the light flow.[28-30] The methods therefore cannot be applied when the light flow undergoes time changes unrelated to the effect of interest. In these circumstances EBR measurements are possible only by the null method, in which an elliptical compensator is used to identify the effect due to birefringence.

Most of the rigid-chain polymers are soluble only in strongly polar, conducting solvents, and therefore their EBR can be studied only by using pulsed electric fields. The most widely used fields consist of rectangular pulses. However, in order to identify unambiguously the nature of the EBR we must use electric fields of varying sign: in this case sinusoidal-pulse fields are the most convenient.

The apparatus for measuring EBR in sinusoidal-pulse and in rectangular-pulse fields is shown diagrammatically in Fig. 4. The operating principle of its electrical part has

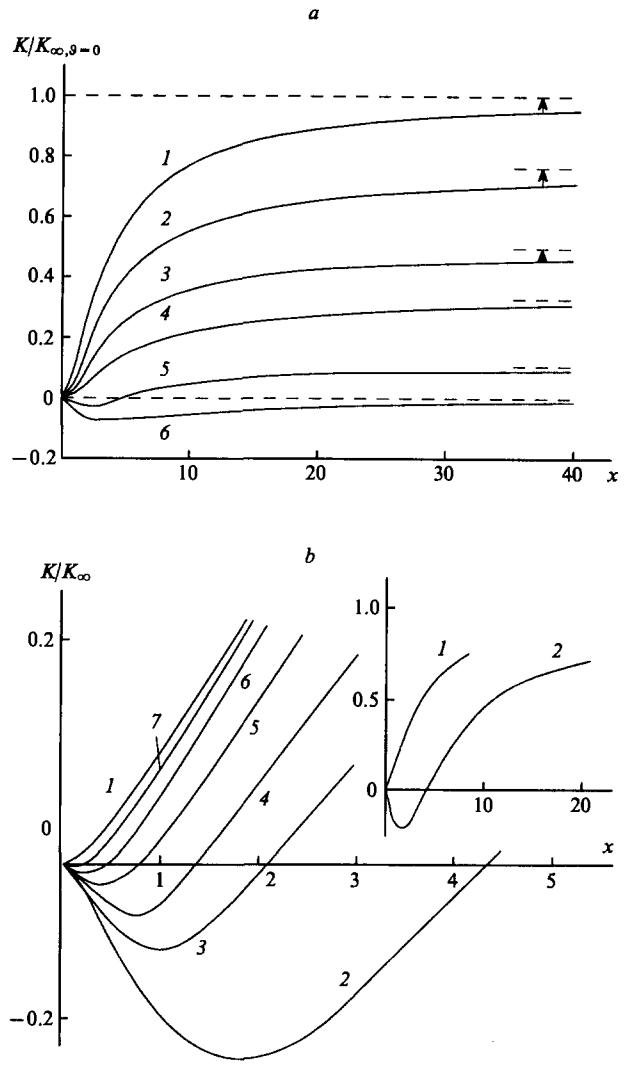

Figure 3. Plots of the relative Kerr constant against x for a kinetically rigid vermiform chain with $\alpha = 1$ (*a*) and different values of α (*b*): ϑ is the angle between the dipole of the monomer unit and the direction of the chain a: $\vartheta = 0°$ (*1*), 30° (*2*), 45° (*3*), 54.43° (*4*), 70° (*5*), 90° (*6*); *b*: $\vartheta = 0°$ (*1*), 70° (2–7); $\alpha = 0$ (*1*), 1.0 (*2*), 1.5 (*3*), 2.0 (*4*), 3.0 (*5*), 5.0 (*6*), 10.0 (*7*).

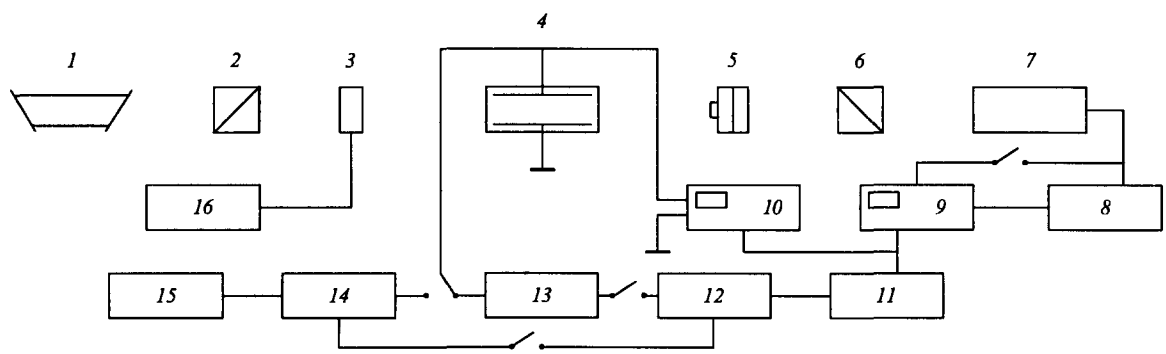

Figure 4. Apparatus for measuring the EBR by the compensation method in pulsed (sinusoidal and rectangular) electric fields: (*1*) helium–neon laser (λ = 632.8 nm); (*2*) and (*6*) polariser and analyser (Franck–Ritter prisms); (*3*) piezoceramic modulator of the ellipticity of the polarised light; (*4*) Kerr cell; (*5*) elliptical compensator with a path difference of 0.01 λ; (*7*) photodetector; (*8*) selective system; (*9*) and (*10*) oscillographs; (*11*) pulse delay generator; (*12*) rectangular pulse generator; (*13*) rectangular pulse former; (*14*) sinusoidal pulse former; (*15*) sinusoidal voltage generator; (*16*) generator for exciting the oscillations of the modulator.

already been described in detail.[31,32] The light flow Φ emerging from the analyser depends on the difference in phase between the mutually perpendicular oscillations of the two light waves created by the passage of light through the birefringent elements of the system. The azimuths of the optical axes of the birefringent layer and of the modulator form an angle of $\pi/4$ with the axis of the polariser. At low phase differences $\delta \ll 1$ we have the following expression for the light flux at the outlet to the photodetector:[31]

$$\Phi = \Phi_0 \frac{(\delta_E + \delta_m + \delta_0 \sin 2\varphi)^2}{4} . \quad (37)$$

Here Φ_0 is the amplitude of the light flux at the inlet to the system, δ_E is the phase difference generated by the solution ($\delta_E = 2\pi l \Delta n/\lambda$, where l is the optical length of the birefringent layer, and λ is the optical wave length), δ_0 and φ are the phase difference and the azimuth angle of the optical axis of the compensator, and $\delta_m = \delta_{m_0} \cos \Omega t$ is the phase difference introduced by the modulator ($\delta_{m_0} \ll 1$, $\Omega/2\pi = 5 \times 10^5$ Hz).

By using a selective system, tuned to the modulation frequency Ω, we can isolate the component of the light flux Φ',

$$\Phi' = \frac{\Phi_0}{2} (\delta_E + \delta_0 \sin 2\varphi) \delta_{m_0} \cos \Omega t , \quad (38)$$

which is linearly dependent on the azimuth angle φ of the rotation of the compensator. The compensation condition is defined by the expression

$$\delta_E = -\delta_0 \sin 2\varphi_c , \quad (39)$$

where φ_c is the azimuth angle for compensation.

In measurements of the growth and decay of the EBR the selective system is switched off, and the signal from the photodetector is taken directly to the input of the oscilloscope amplifier. However, the compensation condition (39) at the instant corresponding to the beginning of the pulse (determined by the time-delay of the master generator) stays unchanged. Under these conditions a signal at double the modulation frequency Ω is observed on the oscilloscope screen at the compensation instant.

Under the influence of an electric field of intensity $E = E_0 \cos \omega t$ the oscillations of the two light waves linearly polarised parallel and perpendicular to the voltage vector in the Kerr cell acquire a phase difference

$$\delta_E = \frac{\bar{\delta}_{E_0}}{2} + \left(\frac{\tilde{\delta}_{E_0}}{2}\right) \cos(2\omega\tau - \psi) , \quad (40)$$

where $\bar{\delta}_{E_0}$ is the phase difference characteristic of the constant component of the EBR, and $\tilde{\delta}_{E_0}$ is the amplitude of the oscillations in the EBR of frequency 2ω. These two values coincide under equilibrium conditions at low enough frequencies ω, and $\psi = 0$, but they differ in the frequency dispersion region corresponding to the Kerr effect.

The amplitude Φ of the oscillations in the flow of frequency Ω is linearly dependent on $\bar{\delta}_{E_0}$ and on $\sin 2\varphi$, and vanishes at the compensation point[31]

$$\bar{\delta}_{E_0} = -2\delta_0 \sin 2\varphi_k . \quad (41)$$

Eqn (41) is valid also when a sinusoidally pulsed field is applied.

The magnitude and the sign of the Kerr constant can be determined from Eqns (39) and (41). Various designs of the Kerr cell have been proposed.[28,29] In studies of the EBR in solutions of many rigid-chain polymers glass tubes fitted with titanium electrodes and with quartz side windows (held in position with springs or with adhesive) are most convenient. The length of the electrodes varies between 1 and 10 cm, and the interelectrode gap between 0.33 and 1.2 mm, depending on the chosen solvent.

The compensation method of measuring EBR by modulating the ellipticity of polarisation of the light gives the Kerr constants, the characteristic growth and decay times of the EBR, and also the dispersion relaxation times τ, with relative errors of 10%, 30%, and 20% respectively.

III. Transient electrical birefringence in solutions of rigid-chain polymers. Experimental data

1. Study of the dynamics of macromolecules in rectangular-pulse electric fields

Most of the recent studies of the rotational mobility of polymer molecules by the transient EBR method have used rectangular-pulse fields.[18,19,33-40] The free relaxation of the EBR following the removal of the field is usually monitored. The study of macromolecular dynamics by the free relaxation method offers information on the rotational mobility and on the conformational characteristics of polymer chains, and in this case, as was stated above, the nature of their orientation and of the observed EBR are unimportant. The combined study of the EBR growth and decay processes offers more information.

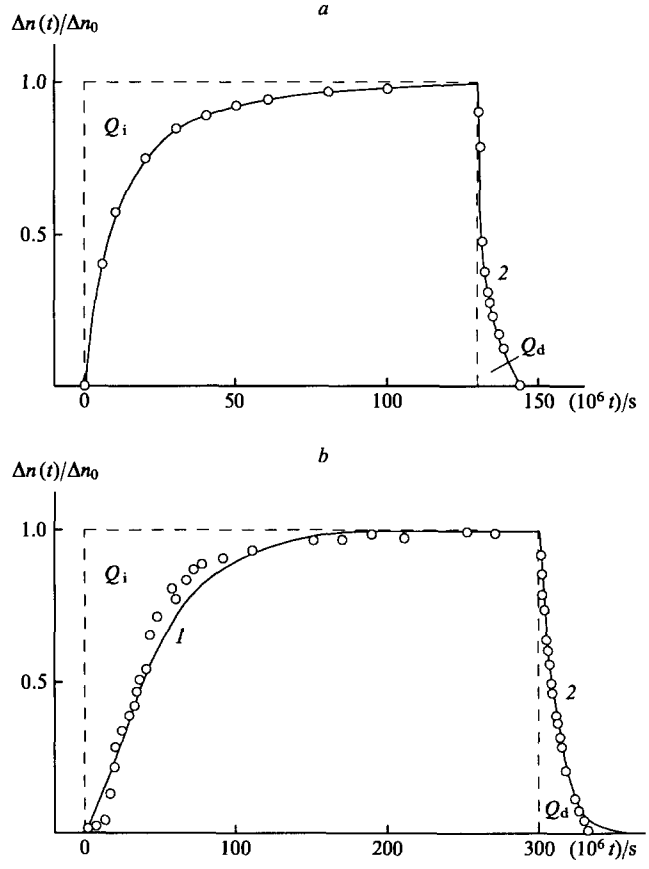

Figure 5. Time dependence of the relative EBR from the instant of switching on (*1*) and off (*2*) a rectangular electric pulse for a solution of the poly(butyl isocyanate) fraction with $M = 58 \times 10^3$ in tetrachloromethane[41] (*a*) and for a sample of polyamidohydrazide ($M = 26.6 \times 10^3$) in dimethyl sulfoxide[42] (*b*). Concentration of solution/g cm^{-3}: (*a*) 1×10^{-4}; (*b*) 0.11×10^{-2}.

Plots of the growth and decay of EBR following the instantaneous switching on and off of an electric field are shown in Fig. 5 for poly(butyl isocyanate) and poly(amido hydrazide). It can be seen that the growth of the EBR is markedly slower than its decay. This behaviour is characteristic of most of the rigid-chain polymers in which

[a] Data obtained in our laboratory.

the EBR is determined by the presence of a large steady dipole moment in the molecules.

The slight deviation of the experimental points in Fig. 5 from the theoretical curves for a monodispersed ensemble of rigid dipolar molecules indicates a relatively small polydisperseness of the sample in relaxation times. From the $\Delta n(t)/\Delta n_0$ curves obtained in this way we can determine the growth and decay times of the EBR whose values (extrapolated to infinite dilution) are listed in Table 1.

As can be seen from Table 1 the $\langle\tau_0\rangle$ values are strongly dependent on the molecular mass M, which is typical of rigid-chain polymers. The ratio $Q_g/\langle\tau_0\rangle$ is close to 4 for most of the fractions of poly(butyl isocyanate) and poly(amido hydrazide), as required by the theory for kinetically rigid dipolar molecules or particles. However, for the fractions of these polymers having the highest molecular mass we find $Q_g/\langle\tau_0\rangle < 4$. Two interpretations of this observation are possible. First, according to Eqns (11) and (12) the ratio $Q_g/\langle\tau_0\rangle$ should be less than 4. The development of kinetic flexibility in the macromolecules when M becomes very large can lead to the same result. An unambiguous choice between these two alternative explanations can be made by using only electric fields of variable sign, which immediately show whether or not the molecule has a substantial induced dipole. Studies based on sinusoidal-pulse electric fields[41,42] have indicated a preference for the second of these alternatives, which was shown to be responsible for a decrease in the ratio $Q_g/\langle\tau_0\rangle$.

2. Study of the dynamics of rigid-chain polymeric molecules in sinusoidal and in pulsed sinusoidal electric fields

As pointed out above, unambiguous conclusions on the nature of the EBR can be formulated by using electric fields of varying sign. Sinusoidal fields are the most convenient for this purpose. An additional advantage of a sinusoidal field as compared with a rectangular pulse field is that in studies of the dynamics of macromolecules of relatively low molecular weight in solutions the relaxation times can be so small as to be impossible to measure reliably by the free relaxation method. This shortcoming is almost totally eliminated in the method of determining τ in sinusoidal fields, which can be used at any frequency in the radio-frequency band: in other words, the sinusoidal field method can be used to determine τ over a much wider range of values.

The dynamics of macromolecules in electrically conducting polar solvents can be studied only in pulsed sinusoidal electric fields.

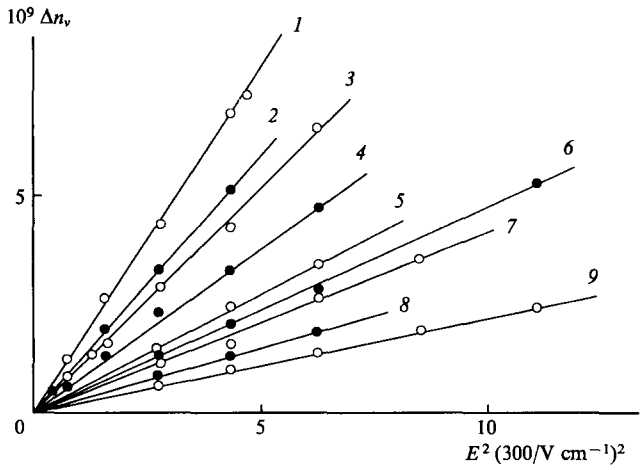

Figure 6. Dependence of the EBR on the effective intensity of a pulsed sinusoidal field for a solution of a sample of polyamidobenzimidazole ($M = 43 \times 10^3$) in dimethylacetamide ($c = 0.23 \times 10^{-2}$ g cm^{-3}) at different frequencies;[42] ν/kHz: (*1*) 0.5, 1, 3; (*2*) 7; (*3*) 10; (*4*) 20; (*5*) 50; (*6*) 70; (*7*) 100; (*8*) 200; (*9*) solvent at the same frequencies.

In Fig. 6 we show as an example the dependence of Δn on the square of the effective voltage of a pulsed sinusoidal field for a sample of polyamidobenzimidazole in dimethylacetamide. These plots can be used to determine the constant K_v of the polymer [Eqns (16) and (17)] for a fixed frequency ν of the pulsed field.

Figs 7 and 8 show dispersion plots of $\Delta n_v/\Delta n_0$ and of $K_v/K_{v\to 0}$ (where $K_{v\to 0}$ is the equilibrium value of the Kerr constant) against lg ν for several rigid-chain polymers. Similar data for other samples can be found in published reports.[13,53] It can be seen that all the plots in Figs 7 and 8 decay almost to zero as the frequency of the sinusoidal field is increased, and that they are strongly shifted towards lower frequencies by an increase in the molecular mass M of the polymers. These observations suggest that the mechanism mainly responsible for the observed EBR in solutions of rigid-chain polymers in both polar and non-polar solvents is a large-scale rotation of their dipolar molecules under the influence of the applied electric field. Furthermore, in the region of frequencies corresponding to the dispersion of the EBR dispersions of the dielectric increment $\Delta\varepsilon$ of the solutions have also been observed for cellulose poly(chlorohexyl isocyanate)[55] and carbanilate,[56] the dielectric dispersion curves almost coinciding with those of the Kerr effect. This indicates an identity of the molecular motion mechanisms and corresponds to the dispersion equation (17) for kinetically rigid molecules.

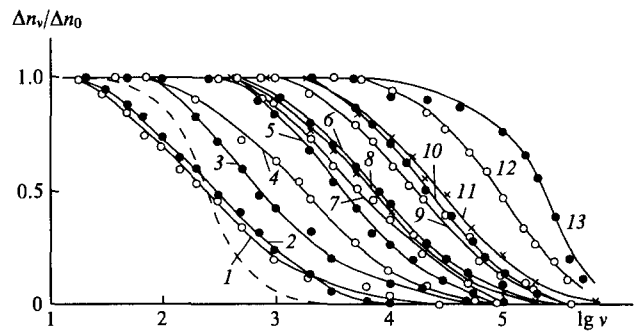

Figure 7. Dispersion plots of the EBR for the poly(butyl isocyanate) fractions in tetrachloromethane. The broken line is the Debye dispersion curve[41] with a relaxation time τ for the fraction *1*. 10^{-3} M: (*1*) 770; (*2*) 700; (*3*) 200; (*4*) 103; (*5*) 86; (*6*) 58.9; (*7*) 57.8; (*8*) 48.4; (*9*) 29.6; (*10*) 28.6; (*11*) 21.2; (*12*) 10.9; (*13*) 8.4; concentration of solutions 1×10^{-4} g cm^{-3}.

3. Kinetic and equilibrium rigidity of polymeric molecules

By using dispersion curves the 'mean' dispersion relaxation time τ can be calculated by Eqn (18). Typical concentration dependences of τ are shown in Fig. 9. Analogous data for several rigid-chain polymers have been published recently.[37] Values of τ for several rigid-chain polymers extrapolated to infinite dilution are shown in Table 1.

As can be seen from Table 1, the relaxation times τ increase rapidly as the molecular mass M of the polymers is increased. The model coefficient F can be calculated by using Eqn (23) in conjunction with the characteristic viscosities $[\eta]$.

An analysis of the dependence of F on the molecular mass for different classes of polymer is of interest. In a homologous series of fractions of a given polymer we note a tendency for F to increase with M in keeping with the accompanying change in the shape of the molecule from rod-shaped to tangle-shaped. Furthermore, it has been shown that in the fractions of these polymers having the highest molecular mass the F values exceed the maximum theoretical value for rigid particles. This is evidence of a weakening of the dependence of τ on M at high values of M. The weakening can be attributed to the general conditions of orientation and deformation of the chain molecule moving in an electric field.[57] Since τ_{or} increases with M in proportion to $M[\eta]$,

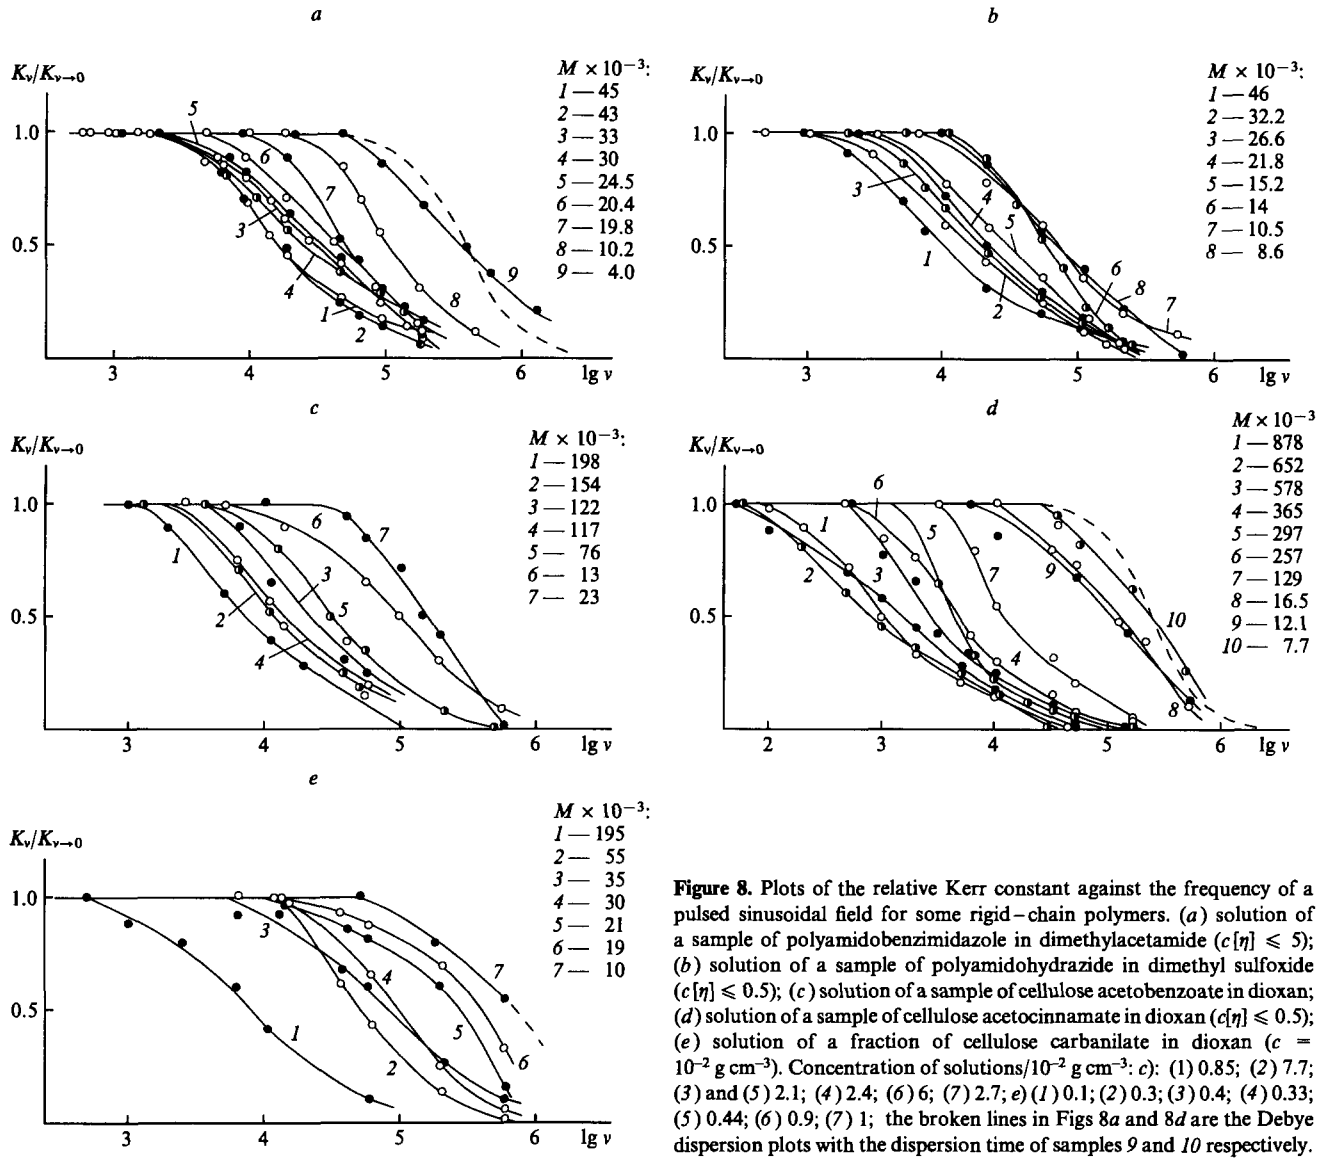

Figure 8. Plots of the relative Kerr constant against the frequency of a pulsed sinusoidal field for some rigid-chain polymers. and τ_{def} is almost independent of *M*, we can expect to find $\tau_{or} > \tau_{def}$ for high enough values of *M*, and therefore the anisotropy of the solution in an electric field is produced by the deformation mechanism. The transition from an orientation to a deformation process as *M* is increased should result in an increase in *F*.

The results of Lewis, et al.[19] are of interest in this context. Starting from data on the free relaxation of the EBR in monodispersed samples of DNA of relatively high molecular mass these workers obtained the spectra of the times τ_0. The longest relaxation time in the spectrum corresponded to the large-scale motion of the DNA molecules, whereas the shortest times were determined by the small-scale motion and the corresponding deformation of the macromolecules. The largest relaxation time increased rapidly with the degree of polymerisation of the molecules, whereas the smallest was almost independent of *M*, though its contribution increased with *M*. These results are a clear illustration of the increased role of the deformation factor in the EBR of a polymer solution when *M* is increased.

A large increase in the *F* coefficient with *M* has been observed[46] in samples of cellulose carbanilate of high molecular mass ($M > 350 \times 10^3$). This effect was also treated as a manifestation of the intramolecular motion of the cellulose carbanilate molecules at large *M*, and it was described in terms of Zimm modes.[58,59]

An increase in the *F* coefficient upon changing the nature of the solvent has been reported[47,50] for cellulose carbanilate

and poly(butyl isocyanate). This was treated as an increase in the kinetic flexibility of these polymers in a polar medium, resulting from the specific interactions of the macromolecules with the dipolar[47] or the aromatic[50] solvent molecules.

However, for the majority of rigid-chain polymers of not too high molecular mass the F coefficient lies between the limits predicted by the theory in the case of kinetically rigid molecules. This shows that the EBR in these solutions is due mainly to the large-scale motion of the macromolecules in an electric field.

This phenomenon allows us to use data on the transient EBR to determine the conformational characteristics (length A of the Kuhn segment) of polymers by using the theory of rotational friction in kinetically rigid vermiform chains.[17]

In Fig. 10 we show plots of the cube root of the dispersion relaxation time against the molecular mass M (or the chain length L) for several rigid-chain polymers. In addition to the experimental data we show theoretical dependences for a straight cylinder and for vermiform chains of the same diameter. The presence of experimental points in the region of $x < 1$ allows us to determine the hydrodynamic diameter of these macromolecules. These results can be obtained from measurements by molecular hydrodynamics methods (translational diffusion, viscometry).

[a] Data obtained in the writers' laboratory.

These constructions can be used to determine the equilibrium rigidity (the length A of the Kuhn segment) in the polymers. The results are shown in Table 2, together with data obtained by molecular hydrodynamics and light scattering methods, included for comparison.

It is evident from Table 2 that the data obtained by the transient EBR method for rigid-chain polymers (in both polar and nonpolar solvents) agree reasonably well with the results of other methods, and can be used for a quantitative characterisation of the conformation properties of macromolecules.

IV. Steady electrical birefringence in solutions of rigid-chain polymers. Experimental data

1. The problem of choosing the internal field multiplier

As we know, many rigid-chain polymers are soluble only in strongly polar solvents, and therefore when discussing the electro-optical properties of macromolecules in these solvents we must allow for the difference between the electric field externally applied to the solution and the electric field experienced by the solvent molecules and by the macromolecules of the polymer dissolved in it. Formally this difference can lead to a definition of a suitable 'internal field' multiplier, which can be reasonably assumed to be the same for studies of dilute solutions of rigid-chain polymers in low-molecular polar solvents and for studies of the electro-optical properties of the solvents themselves.

In the expression for the molar Kerr constant ${}_mK$ defined by Eqn (4) allowance for this difference is made by introducing an internal field multiplier of the Lorenz type, $[(\varepsilon + 2)/3]^2$.[66] As was stated above, the results obtained from the expressions (4) and (7) agree well with the experimental data for substances studied in the gas phase,[3] and the agreement is reasonable for substances (both polar and nonpolar) dissolved in a nonpolar solvent.[67,68] However, attempts to apply these equations to concentrated polar liquids (while retaining the Lorenz multiplier) led to unacceptable results.[69,70,71]

An analogous situation was observed in studies of the dielectric properties of polar liquids. The widely used Debye theory,[72] which relates the dielectric permittivity ε of a liquid to the polarisability δ and dipole moment μ of its molecules, and which uses a Lorenz internal field multiplier, was found not to be applicable to undiluted polar liquids because it leads to physically unacceptable values of μ calculated from experimental values of ε. Much better results were obtained by using Onsager's theory,[73] which offers a more successful macroscopic model of the dielectric properties of a polar liquid by allowing for the long-range electrostatic interactions of the polar molecules, averaged over the volume of the liquid. The difference between the electric field applied to the sample and the electric field acting on an individual molecule was allowed for by using two multipliers: for the internal field P (the cavity field) and for the reactive field Q:

$$P = \frac{3\varepsilon}{2\varepsilon + 1}\ ; \qquad Q = \frac{(n^2 + 2)(2\varepsilon + 1)}{3(2\varepsilon + \varepsilon^2)}\ . \tag{42}$$

Onsager's theory can be used to calculate with acceptable precision the dipole moments of the molecules of polar liquids from the dielectric permittivity of the liquid.[74]

Further attempts to improve Onsager's model theory by introducing corrections for the non-sphericity of the molecules[75] or by allowing for the orientational correlations between nearest neighbours[76,77] proved to be ineffective because the final equations included unknown structural parameters of the liquid.

The successful application of the Onsager theory to describe the dielectric polarisation of polar liquids stimulated attempts to apply it also to the Kerr effect in the same systems. In some special cases these attempts were successful.[78]

According to currently held views[79-82] the EBR in polar liquids can be influenced by molecular 'hyperpolarisability'. It is assumed that in a polar liquid the field acting on a molecule from long-range and short-range neighbours is many orders of magnitude greater than the external field E (both electrical and optical) used in studies of the Kerr effect. Therefore the effective polarisability of the molecules γ_e in the electric field should be treated as a series in powers of E.

A two term expression for the specific Kerr constant has been obtained[80,81] by using this approach and allowing for the internal field by Onsager's theory in the special case of a molecule having a dipole moment μ parallel to its optical symmetry axis. The first (quadratic) term depends on μ and is proportional to the optical anisotropy of the molecule, whereas the second term is proportional to the first power of μ and provides a contribution for the hyperpolarisability in the Kerr effect. According to Buckingham[82] the first term plays a dominant role in the equation for K_ρ in the case of molecules in which $\mu \approx 1$ D, and the contribution from the second term is only $\sim 15\%$.

This allows us to ignore hyperpolarisability effects and to base the discussion of the EBR on the more general and more firmly established expressions (2), (4), and (7), replacing the Lorenz multiplier $(\varepsilon + 2)/3$ by the Onsager multiplier PQ:

$$K_\rho = \frac{\pi N_A}{135kTM}(PQ)^2\frac{(n^2+2)^2}{n} \times \left[\sum_{i,j=1}^{3}(\gamma_i - \gamma_j)(\delta_i - \delta_j) + \frac{1}{kT}\sum_{i,j=1}^{3}(\gamma_i - \gamma_j)(\mu_i^2 - \mu_j^2)\right]. \tag{43}$$

Eqn (43) is formally applicable to both polar and nonpolar liquids, since for the latter $\varepsilon = n^2$ and the multiplier PQ reduces to the Lorenz multiplier.

We have recently tested[83] Eqn (43) with a wide range of substances. Experimental values of K_ρ for polar and for nonpolar liquids were used in conjunction with (43) to calculate the optical anisotropies of the molecules. The results were compared with published data[3,68,84] or with data calculated by the valence-optical approach. This analysis led to the conclusion that the Onsager internal field multiplier can be used to describe the electro-optical properties of low-molecular liquids.

On the basis of these results[83] we obtained[85] an expression for the molar Kerr constant of polar liquids by using the Onsager internal field multiplier.

$${}_mK = K_\rho M\frac{2n}{3(n^2+2)^2(PQ)^2} \equiv \frac{2}{3}K_\rho Mn\left[\frac{2\varepsilon + n^2}{\varepsilon(n^2+2)^2}\right]^2. \tag{44}$$

Obviously, Eqn (44) is applicable also to non-polar liquids ($\varepsilon = n^2$), since under these conditions it reduces to Eqn (4). For an experimental demonstration of the validity of Eqn (44) we can examine the data in Table 3, which lists the ${}_mK$ values for several liquids calculated[85] from the K_ρ, ε, and n values by using the expressions (4) and (44). For comparison the table also gives the ${}_mK$ values obtained in dilute solutions in nonpolar tetrachloromethane or in the gas phase. It can be seen that the ${}_mK$ values calculated by using the Onsager internal field multiplier are reasonably well correlated with the values obtained in a dilute solution or in the gas phase, whereas the ${}_mK$ values calculated by Eqn (4) for polar substances are smaller (by a large factor) than the values for a solution or a gas.

We may therefore conclude that the Onsager internal field multiplier can justifiably be used to describe the electro-optical properties of low-molecular-mass polar or nonpolar liquids as well as those of rigid-chain polymers dissolved in these media.

2. Dependence of the Kerr constant on the molecular mass

According to the theory of the Kerr effect in solutions of vermiform chains the characteristic Kerr constant of rigid-chain polymers should be sensitively dependent on the molecular mass [Eqns (33), (34), and (36)]. The expected dependences have been observed in cellulose poly-γ-benzyl-L-glutamate,[87] poly-

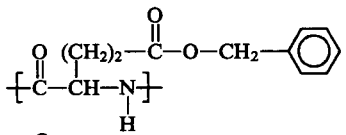
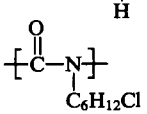
(chlorohexyl isocyanate),[49] and nitrate,[38, 48, 88, 89] and in cyanoethylcellulose,[39] and cellulose carbanilate.[90]

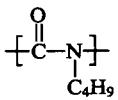
Some interesting results were reported by Kolomiets, et al.[91] For the nitrates of flax cellulose in ethyl acetate and in cyclohexanone a change in sign of the Kerr constant with increasing molecular mass of the polymer was observed, as predicted by Eqn (33). This observation demonstrates the difference between the contributions to the EBR from the longitudinal and the transverse components of the dipole moments of the monomer units, and also reflects the accumulation of the longitudinal components of the molecular dipole $\mu_{0\parallel}$ when the chain length is increased.

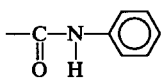
In all the work discussed above the experimental points describing the homologous dependence of the Kerr constant for the polymer can be reconciled with the theoretical curve (33), which allows the A parameters of the equilibrium rigidity of the molecular chains to be determined. The values of A are shown in Table 4: they are reasonably well correlated with the lengths of the Kuhn segment, determined by hydrodynamic methods.

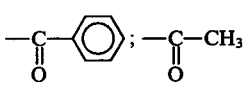
In Fig. 11 we show as an example plots of K against M for cellulose poly(butyl isocyanate) in tetrachloromethane,[92] for cellulose acetobenzoate,[43, 94] acetocinnamate,[44] and carbanilate in dioxan, and also the theoretical dependences (33) for the corresponding values of A and K_∞. The values of A for these polymers are given in Table 4.

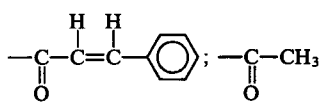


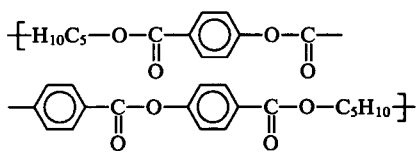




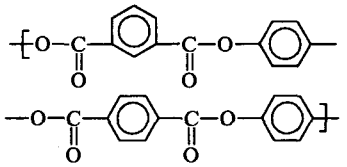


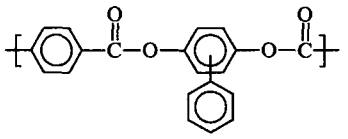


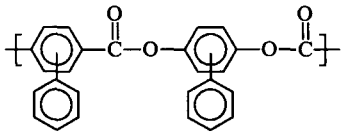




Interesting results have been reported[99, 101, 103, 105, 106] for various aromatic polyesters, mesogenic in the main chain. The mesogenic nuclei in these macromolecules are a sequence of ester groups separated by benzene rings introduced into the chain in the *para* position. Introducing into the same chain (as 'spacers') methylene groups which make the chain more flexible, as well as benzene rings in *meta* and *ortho* positions, markedly lowers the equilibrium rigidity of the chain. Furthermore an aromatic polyester containing an *ortho* benzene ring as a spacer[105] is known to orient itself in an electric field by the small-scale motion mechanism. At the same time an aromatic polyester with a decamethylene spacer,[99] in spite of its relatively low equilibrium rigidity, orients itself in an electric field by the large-scale motion mechanism (as a result of the accumulation of the longitudinal components of the dipoles of the monomer units as the chain length is increased).







A large difference between the longitudinal-dipolar and the transverse-dipolar rigidity has been observed in mesogenic aromatic polyesters. This effect is illustrated by Eqn (33), which takes account of this difference by using the factor α. The difference is specially notable in the polyester 13 (Table 4), for which $\alpha \approx 3$. This finding is not unexpected, since the molecule of the polymer 13 is a good representation of the ideal *para*-aromatic polyester, i.e. it is structurally close to the ideal 'crankshaft' model. In Fig. 12 we show the molecular mass dependences of K for mesogenic polyesters.

We have studied[107] the equilibrium electro-optical properties of two aromatic polyamides: polyamidobenzimidazole and polyamidohydrazide, which are soluble only in strongly polar (conducting) solvents such as dimethylacetamide and dimethyl sulfoxide. A study of the kinetics of the orientation of these polymers by the transient EBR method showed that their molecules become oriented in an electric field by a large-scale mechanism. The Kerr constant for these substances shows a marked dependence on the molecular mass, characteristic of rigid-chain polymers. However, the experimental points cannot be fitted to the theoretical dependence (33) for any set of adjustable parameters. This is interpreted as a manifestation of an orientational correlation between the polar molecules and the dipolar bonds of the polymer chain.

We have calculated[107] the longitudinal component of the macromolecular dipole $\langle\mu_\parallel^2\rangle^{1/2}$ in these polymers. It was found to increase steeply as the chain length is increased (curve *1* of Fig. 13). Curve *2* of the same figure is the theoretical dependence for $\langle\mu_\parallel^2\rangle^{1/2}$, which can be calculated from the geometrical parameters of the macromolecules. It can be seen that curves *1* and *2* approach each other only in the region of small M, and that they are strongly divergent for large M. The large values of $\mu_\parallel^2$, for polyamidobenzimidazole and polyamidohydrazide cannot be attributed wholly to their dipole structure, and must be explained at least

Table 4. Length of the Kuhn segments of some rigid-chain polymers, determined by the equilibrium EBR method (A_1) and by hydrodynamic methods (A_2).

partially by the influence of the strongly polar solvent on the electro-optical properties of the polymer chains.

Even more unexpected and instructive results have been obtained[40] for the diphenyl-substituted poly(*p*-phenylene terephthalate) (compound 14 in Table 4). This polymer differs from compound 13 by the presence of an additional benzene substituent in the self-repeating unit of the main chain. This additional benzene ring greatly improves the solubility of the polyester, which becomes soluble even in the nonpolar dioxan. Its

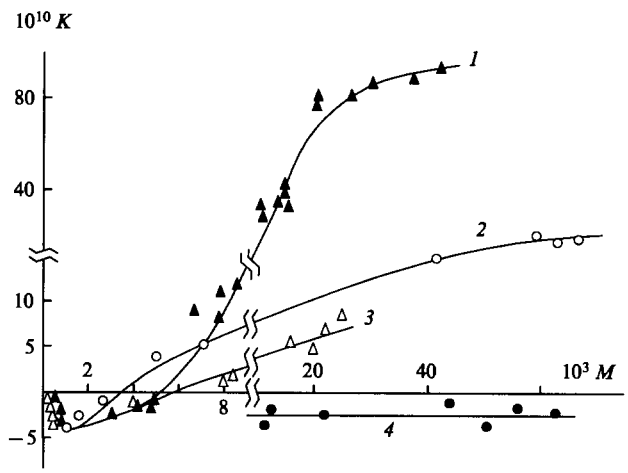

Figure 12. Dependence of the Kerr constant on the molecular mass for aromatic polyesters.[106] Polymer number (see Table 4); (*1*) 13; (*2*) 11; (*3*) 12; (*4*) analogue of 13, containing a benzene ring in the *ortho* position as a spacer; the points are experimental, the curves are calculated by Eqn (33) for α = 3 (*1*), 1 (*2*), 1.3 (*3*).

solubility is even higher in various polar solvents: for example, in dichloroacetic acid. In Fig. 14 we show the molecular-mass dependence of the Kerr constant for this polyester in dichloroacetic acid. It can be seen that K increases steeply with M, as expected for rigid-chain polymers oriented by a large-scale mechanism in an electric field. Furthermore K changes sign during the growth, suggesting an accumulation of the longitudinal components of the dipoles of the monomer units and a weakening of the correlation of the dipole formed by the normal components $\mu_{0\perp}$ with the direction of the vector $\boldsymbol{h}$ when M is increased. Lastly, the experimental points can be fitted to the theoretical curve with a reasonable choice of the parameters ϑ, A, and α.

However, in the nonpolar dioxan the Kerr constant of this polyester is almost unaffected by an increase in M, and remains close to the K value of the corresponding monomer. Furthermore

it is negative, i.e. its sign is the opposite of the sign of the flow birefringence of the same solution, and its magnitude is very small (see Fig. 14). All this suggests a small-scale orientation of the polyester (in its equilibrium state of rigidity) when exposed to an electric field in a nonpolar solvent. Noting the dipolar structure of the macromolecules of this polymer we can expect to find a substantial perpendicular component of the dipole of the monomer unit $\mu_{0\perp}$, with a negligibly small longitudinal component $\mu_{0\parallel}$. Data obtained by the steady EBR method for solutions of the *para-aromatic* polyester in dioxan point to the same conclusion, suggesting that in a solution of this polymer the EBR is due to the local reorientations of $\mu_{0\perp}$ accompanying the rotations round the *para*-aromatic axes.

The electrical birefringence in solutions of the same polymer in dichloroacetic acid is produced by the large-scale motion mechanism. This shows that a strongly polar solvent not only alters the dipole structure of the macromolecule, inducing the appearance of a substantial $\mu_{0\parallel}$ component, but also affects the process by which the EBR is created, replacing the small-scale by a large-scale mechanism. The latter effect may be due to an orientational correlation between the dipolar molecules of the solvent and the polar units of the polymer chain, leading to the formation in the polymer chain of an 'effective' electro-optical dipole which determines the mechanism, magnitude, and sign of the EBR in solutions of the polyester in a polar solvent.

3. Effect of polar solvents on the electro-optical properties of polymer chains

The results discussed in the previous section show that a polar solvent can strongly affect the electro-optical properties of rigid-chain polymers. This phenomenon has been examined in our laboratory[108] by studying the viscometric, dynamo-optical, and electro-optical characteristics of a cellulose carbanilate sample ($M = 4 \times 10^5$, degree of substitution 2.7), which is readily soluble in both the nonpolar dioxan and in various polar solvents such as ethyl acetate, cyclohexanone, and dimethylacetamide.

An analysis of these results suggests that the equilibrium rigidity of the polymer chain is decreased when a nonpolar solvent is replaced by a polar solvent. This is because the mechanism of formation of the equilibrium rigidity of the macromolecules of cellulose esters is strongly influenced by the interaction between side groups (substituents in neighbouring glucoside rings of the chain), which powerfully suppresses the intramolecular rotations. The bonds produced by the interaction of the side groups are weakened (and become easily broken) under the influence of the polar solvent molecules, capable of forming intermolecular bonds. A decrease in the optical anisotropy of the monomer unit of cellulose carbanilate in ethyl acetate has been noted and ascribed to microform effects.

The most interesting results were obtained in a study of the equilibrium electro-optical properties of cellulose carbanilate in various solvents. It was found that the Kerr constant of this polymer increases steeply with the polarity of the solvent (Table 5). The transient EBR data unambiguously show that the Kerr effect in solutions of this polymer is determined, in all the solvents examined, by the large-scale motion of its macromolecules under the influence of the electric field produced by the presence of a steady dipole moment in its chain.

In the calculation of the longitudinal component of the dipole moment of the monomer unit $\mu_{0\parallel}$ of cellulose carbanilate in various solvents allowance was made for two effects in addition to those mentioned above. Firstly, the molecular mass of the experimental sample is relatively high, and therefore its molecules are in a Gaussian tangle conformation and the EBR of its solutions is determined only by the longitudinal component of the dipole in the monomer unit $\mu_{0\parallel}$ [see Eqn (34)]. Secondly, we must note that in the description of the electro-optical properties of rigid-chain polymers in polar solvents it is reasonable to use the Onsager internal field multiplier. In these circumstances Eqn (34) can be re-written

$$K_\infty = (PQ)^2 2\pi N_A (n^2+2)^2 S^2 \Delta a \frac{\mu_{0\parallel}^2}{135 n (kT)^2 M_0} . \qquad (45)$$

Starting from (45) we calculated the $\mu_{0\parallel}$ values shown in Table 5. It can be seen that these values increase rapidly with the dipole moment of the solvent molecules. At the same time the $\mu_{0\parallel}$ value obtained for cellulose carbanilate in dioxan is reasonably well correlated with the dipole structure of the polymer chain. The large values of $\mu_{0\parallel}$ for cellulose carbanilate in polar solvents cannot be explained in terms of a single dipole structure of the macromolecule, and must be treated as effective quantities, denoting the presence of orientational correlations between the polar molecules of the solvent and the dipolar bonds in the polymer chain.

Table 5. Electro-optical characteristics of the solvents (ε, μ, K_ρ) and of the solutions (K,$\mu_{0\parallel}$) of cellulose carbanilate.

Solvent	ε	μ/D	$10^{12}K_\rho$/ g^{-1} cm^5 (300 V)$^{-2}$	$10^9 K$/ g^{-1} cm^5 (300 V)$^{-2}$	$\mu_{0\parallel}$/D
Dioxan	2.3	0	0.39	−7	0.95
Ethyl acetate	6.4	1.8	11.1	−10	1.4
Cyclo-hexanone	16	2.8	86.2	−45	2.8
Dimethyl-acetamide	40	3.8	351	−200	5.6

The present writers have recently carried out additional studies, aimed at explaining the effect of polar solvent molecules on the electro-optical properties of rigid-chain polymer molecules. The cellulose carbanilate sample ($M = 195 \times 10^3$, degree of substitution 2.3) was studied by viscometric, dynamo-optical, and electro-optical methods in mixed solvents (dioxan–ethyl acetate). The relative mole fraction of the components f was varied from 0 to 1. A dispersion of the EBR in the radio-frequency range was observed in all the solutions, the dispersion curves falling almost to zero whereas the relaxation times were reasonably well correlated with the size of the macromolecules. These observations suggested a large-scale motion in the orientation of the cellulose carbanilate macromolecules in an electric field for all the mixed solvents examined.

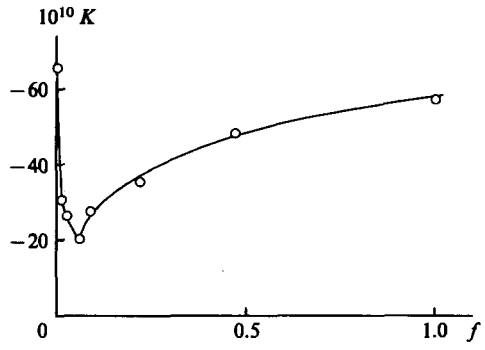

Figure 15. Plot of the Kerr constant of cellulose carbanilate (M = 195 × 10^3) against the mole fraction of ethyl acetate in the ethyl acetate–dioxan mixed solvent.

The dependence of the Kerr constant of the ester on the mole fraction f of ethyl acetate is shown in Fig. 15. The changes in K with f are strongly non-monotonic. In principle this behaviour could be due to changes in the dipole moment of the molecule, in its equilibrium rigidity, and in its optical anisotropy with changes in composition of the solvent. An analysis of these results led to the conclusion that all three parameters listed above are operating in the system. Noting that the molecular mass of the sample is relatively high, i.e. that the macromolecule is in the conformation of a Gaussian tangle, we can calculate $\mu_{0\parallel}$ from Eqn (45), allowing for changes in both S and Δa.

The dependence of $\mu_{0\parallel}$ for cellulose carbanilate on the mole fraction f of ethyl actate is shown in Fig. 16. The non-monotonicity of the changes in $\mu_{0\parallel}$ is evident. We specially note that for $f \geqslant 0.1$ $\mu_{0\parallel}$ value increases (within experimental error) almost linearly with f. This observation evidently suggests that the effective electro-optical dipole formed by the polar polymer chain with the dipole moments of the ethyl acetate molecules increases in direct proportion to the number of molecules of the polar component in the mixed solvent. The slight decrease in $\mu_{0\parallel}$ with increase of f at $f < 0.1$ can be ascribed to the partial screening of the dipole moment of the macromolecule by the polar solvent molecules.

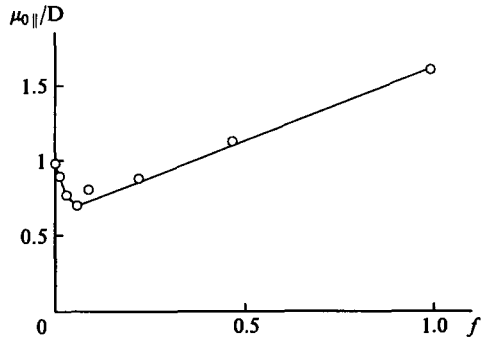

Figure 16. Plot of the longitudinal component of the dipole moment of the monomer unit of cellulose carbanilate against the mole fraction of ethyl acetate in a mixed ethyl acetate–dioxan solvent.

From the whole of this discussion we may conclude that the EBR in solutions of rigid-chain polymers is determined not only by the polar structure of their macromolecules but also (and to a large extent) by the dipole structure of the chosen solvents, the latter factor playing a dominant role in the case of strongly polar liquids. This can lead to a change in the dipole moment of the polymer chain, and also (as was pointed out above) to a change in the very nature of the observed EBR, depending on the choice of solvents. Therefore we can obtain quantitative information on the magnitude and direction of the dipole in the monomer unit of the macromolecules of rigid-chain polymers using only nonpolar solvents.

V. Effect of the structure of side groups and of the degree of substitution on the electro-optical properties of cellulose esters

Cellulose esters are an important class of polymers of the rigid-chain type. One property of these materials is particularly attractive to research workers: the possibility of changing the electro-optical characteristics of their molecules over a reasonably wide range by varying the chemical structure of the substituents and the extent of the esterification reaction (i.e. the average degree of substitution γ).

It has been firmly established [38, 49, 52, 88, 97, 98, 109] that both the optical shear coefficients $\Delta n/\Delta\tau$ in FBR effects and the Kerr constants for cellulose nitrates are sensitively dependent on the degree of substitution. Thus, for cellulose nitrate containing 10.7% of nitrogen the optical shear coefficients $(\Delta n/\Delta\tau)_\infty$ and the Kerr constant K_∞ in the Gaussian region are small and positive.[48, 109] At the same time in nitrates containing a larger percentage of nitrogen $(\Delta n/\Delta\tau)_\infty$ and K_∞ are negative, and K_∞ is greater by two orders of magnitude (in absolute value) than K_∞ for the less highly substituted nitrate.[38, 52, 88, 97, 98] The same papers point out a steep increase in the dipole moment of the monomer unit μ_0 of the cellulose nitrates with the nitrogen content of the side groups, but these results should be viewed with caution because they were obtained in a strongly polar, electrically conducting solvent, cyclohexanone, and this could introduce significant errors in the dipolar characteristics of the polymer chains.

We have reported [51] a study of the optical and the electrical properties of two substituted cellulose esters (the acetodiphenylacetate and the acetocinnamate) as a function of their degree of substitution. The measurements of EBR, FBR, and viscosity were carried out in a nonpolar, poorly conducting solvent (dioxan), and the molecular masses of the polymers corresponded to the Gaussian region. In both these cellulose esters we observed a steep increase in the optical shear coefficients $(\Delta n/\Delta\tau)_\infty$ and in the Kerr constant K_∞ upon increasing the degree of substitution γ (with respect to the benzene-containing radical). The results are shown in Fig. 17. The nonlinearity of the plot of $(\Delta n/\Delta\tau)_\infty$ against γ for cellulose acetodiphenylacetate may be related to a change in the rigidity of the polymer chain with changes in γ or to an incomplete equivalence of the contributions to the optical anisotropy from the large diphenylacetate radicals, attached to the second and to the third or sixth carbon atom in the glucoside ring.

A study of the transient Kerr effect of these two cellulose esters showed that the mechanism mainly responsible for the EBR observed in solutions of cellulose acetocinnamate and aceto-diphenylacetate at all degrees of substitution is the large-scale rotation of their macromolecules under the influence of the electric field, due to the presence of a steady dipole moment. However, as was stated above, the absolute value of K_∞ for these esters increases rapidly with γ. This dependence of the Kerr constant on the degree of substitution may be due to an increase in the optical anisotropy of the macromolecules (positive for the diphenylacetate and negative for the cinnamate) with increasing γ, as was also inferred from the dependence of $\Delta n/\Delta\tau$ on γ, or alternatively it may be due to changes in the dipole moment of the molecular chain.

By using Eqn (45) we have calculated [51] the $\mu_{0\|}$ values of the esters for different degrees of substitution γ. It can be seen from the results (Fig. 18) that in these esters $\mu_{0\|}$ increases with γ, especially in the acetocinnamate. This suggests that the dipole moment

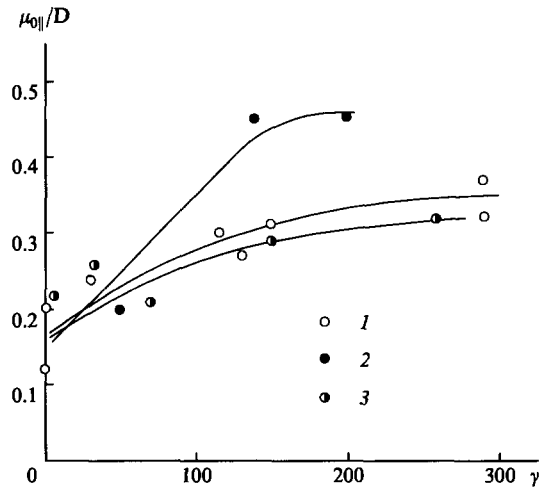

Figure 18. Dependence of the longitudinal component of the dipole moment of the monomer unit in cellulose acetodiphenylacetate (*1*), aceto-cinnamate (*2*), and acetophenylacetate (*3*) upon the degree of substitution.

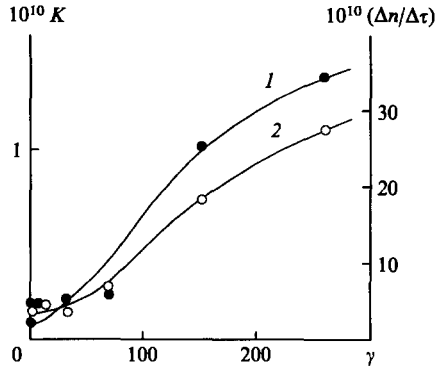

Figure 19. Plots of the Kerr constant (*1*) and of the optical shear coefficient (*2*) of cellulose acetophenylacetate against the degree of substituion.

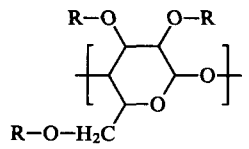
contributed by the ester group in a side group of the glucose ring to the longitudinal component of the dipole moment of the monomer unit of the cellulose chain is strongly dependent on the structure of the side substituent. In fact, it follows from these results[51] that the presence of benzene groups in the substituent leads to an increase in the longitudinal component of the dipole of the monomer unit $\mu_{0\|}$ in the polymer chain as a result of the change in the contribution from the OCO group, whereas the presence of alkyl radicals lowers the $\mu_{0\|}$ value.



We have recently studied the effect of the degree of substitution on the electro-optical properties of cellulose acetophenylacetate in dioxan (Figs. 18, 19). The results were similar to those obtained previously.[51] The optical shear coefficients and the Kerr constants of these high-molecular samples were found to be strongly dependent on the degree of substitution γ with respect to the phenylacetate group. This dependence of $\Delta n/\Delta\tau$ upon γ is not unexpected, since the introduction of strongly anisotropic groups containing benzene rings should markedly increase the optical anisotropy of the whole molecule in comparison with that of cellulose acetate, which is not large. By using Eqn (45) we calculated the longitudinal component of the dipole moment of the monomer unit $\mu_{0\|}$ for the cellulose acetophenylacetates at different degrees of substitution (see Fig. 18). It can be seen from this figure that $\mu_{0\|}$ increases with γ. This effect should be interpreted in the same way as for the cellulose acetodiphenylacetate.

Thus we may conclude that the presence of conjugated bonds in the side chains increases the contribution from the ester group of the side chain to the overall $\mu_{0\|}$ value of the cellulose ester macromolecules.

Meaningful results were obtained for acetotritylcellulose (compound 29 in Table 6). It was found that changing the degree of substitution γ with respect to the trityl radical from 0 to 145 increases $(\Delta n/\Delta\tau)_\infty$ by an order of magnitude, whereas the Kerr constant increases by more than two orders of magnitude, corresponding to an increase in $\mu_{0\|}$ from 0.2 to 1.5 D. This large increase in $\mu_{0\|}$ suggests that the contribution to $\mu_{0\|}$ from the ether group is more substantial than the contribution from the ester group.

The other results in Table 6 also show that $\mu_{0\|}$ for compounds containing a simple ether group in a side group is usually higher than for compounds having an ester group in the side chains (exceptions to this rule are provided by the polymers 3 and 4, whose side substituents contain the strongly polar amide group). In a similar way, replacing the ester groups by hydroxyl groups increases $\mu_{0\|}$, as can be seen by comparing the data for cellulose acetobenzoate and cellulose benzoate (compounds 9 and 10). The strong effect of the structure of the side chain on the longitudinal component of monomeric dipole can be illustrated by comparing data for cellulose carbanilate and cellulose acetobenzhydroxamate (compounds 4 and 33). Passing from the structure of polymer 4 to that of polymer 33 decreases the negative value of $(\Delta n/\Delta\tau)_\infty$ and therefore also of the anisotropy Δa by a factor of two, whereas the modulus of K_∞ decreases 200-fold and $\mu_{0\|}$ decreases 10-fold.

In various studies of the EBR of cellulose esters it has been assumed that the parameter $\mu_{0||}$ is determined by the dipoles of the polar O–C bonds of the glucopyranose ring in the main chain and is practically independent of the dipole structure of its side substituents.[52] The experimental information accumulated in more recent work (and discussed above) is not inconsistent with this assumption. As can be seen from the previous discussion the characteristics mainly responsible for the electro-optical properties of cellulose esters include not only the optical anisotropy but also the dipole structure of the side substituents in these molecules.

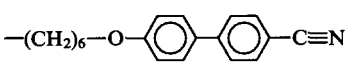
The parameter $\mu_{0||}$, which can be varied ten-fold by changes in the structure of the substituent groups and in the degree of substitution (see above), is determined by the sum of the dipole moments of all the polar bonds included in the monomer unit of the polyglucoside chain. Often the main part of this sum of moments is the contribution from the polar groups of the side substituents. Thus, in spite of the presence of some degree of rotational mobility of the polar groups in the side substituents, the dipolar contribution from these groups to the longitudinal component $\mu_{0||}$ of the dipole of the monomer unit is effectively 'fastened' in this unit and gives rise to the large-scale orientation of the polymer chain in an electric field.

Nevertheless the appearance of a freer 'small-scale' motion of the anisotropic polar groups in the side chains cannot be excluded in the EBR of solutions of cellulose esters. An obvious example is provided by the results (unexpected for rigid-chain polymers) obtained in solutions of celluiose acetonitrobenzoate (compound 36 in Table 6). The dynamic birefringence of this polymer is negative, whereas the EBR of its solutions is positive. Further-more in the radio-frequency band its EBR does not show dispersion, and K_∞ (allowing for the degree of substitution) is close to the value of the Kerr constant for a solution of nitrobenzene in dioxan at a corresponding concentration. All these observations suggest that the EBR in solutions of this polymer is produced by a large-scale orientation mechanism involving the polar nitrobenzene groups in the side substituents.

VI. Electro-optics of solutions of branched polymers with mesogenic groups in the side chains

Specific electro-optic properties are found in solutions of polymers of the branched type, whose molecular basis is a flexible polyacrylate or polymethacrylate chain with side groups also having a chain structure and containing mesogenic fragments of aromatic esters (Table 7).

Because of their dipole structure the monomer units of polyalkylacrylates and polyalkylmethacrylates (like those of other carbon-chain polymers) do not have a component of the dipole moment parallel to the polymer chain. Accordingly, the orientation of their chains in an electric field takes place by a mechanism involving local small-scale motions of the polar groups. The electrical birefringence observed in solutions of these polymers is quite small, and its sign is not correlated with that of the FBR.[13] The equilibrium rigidity of the molecules in these polymers also corresponds to the rigidity of ordinary polymers with flexible chains.



However, the physical properties of the polymethacrylate or polyacrylate chain are markedly affected if the alkyl part (R) of its side groups is replacd by the mesogenic chain of an aromatic ester (see Table 7). This leads to an increase in the equilibrium rigidity of the main chain of the resulting branched polymer to $A \simeq 50 \times 10^{-8}$ cm,[13] exceeding 2–4-fold the rigidity of typical flexible-chain polymers. This effect is related to the steric interactions of the large side groups (a phenomenon well known in other flexible-chain polymers[12]).

However, the strongest effect of mesogenic side radicals is observed in the electro-optical characteristics of branched molecules, many of which are soluble in nonpolar solvents. Thus, the study of the transient EBR in solutions of the polymers 1 and 2 (see Table 7) in a nonpolar solvent, using sinusoidal fields, showed a dispersion of the Kerr effect in the radio-frequency region ($\nu = 10^2 - 10^6$ Hz). As the frequency is increased in this band the Kerr constant falls almost to zero.[111,112] This result shows that the dominant contribution to the observed Kerr effect comes from the large-scale rotation of the dipolar macromolecules of these polymers in an electric field.

At the same time, though they show a tendency to increase with M, the F coefficients for polymer 2 exceed the theoretically maximum values for kinetically rigid molecules by a substantial factor.[112] Furthermore, for the high-molecular mass fractions of polymer 1 the relaxation time τ is independent of the molecular mass.[111] These observations show that (in addition to the rotation of the molecule as a whole) a deformation mechanism of molecular motion contributes to the development of the EBR in these polymers. Its role increases with the molecular mass of the fraction. The lack of dependence of τ on M for the polymer 1 is evidence that the condition $\tau_{or} > \tau_{def}$ applies to this polymer and that the motion of the molecular chain takes place by a

deformation mechanism, in which only part of the molecule acts as the 'kinetic unit', oriented in the electric field. However, under these conditions the rotational mobility of the kinetic unit is lower by 5 or 6 orders of magnitude than in ordinary flexible-chain polymers. Therefore this motion (though intramolecular) is similar in nature to a large-scale motion, since it is correlated through the chain.

A study of the equilibrium EBR in solutions of the polymers 1–3 (see Table 7) showed that the Kerr constant is strongly dependent on M: this behaviour is typical of monomers whose molecular chain

can accommodate an 'accumulation' of the longitudinal component μ of the monomeric dipoles. Further-more in these samples (as in compounds 4 and 5) the signs of K and of $\Delta n/\Delta\tau$ coincide in the region of high molecular masses (Table 7, see over), suggesting identical orientation mechanisms of their macromolecules in electrical and in hydrodynamic shear fields.

Thus both the transient and the steady-state electro-optical properties of branched polymers unambiguously show that the insertion of mesogenic side groups in the main methacrylate chain of polymers 1–5 (see Table 7) produces longitudinal components of the monomeric dipoles $\mu_{0||}$, uniformly oriented along the chain. The $\mu_{0||}$ values calculated by formula (45) from the Δa and K_∞ values in nonpolar solvents are shown in Table 7. They can account for only a small part of the total dipole moment μ_0 of the monomer unit of the branched macromolecule. However, these $\mu_{0||}$ components contributed by mesogenic side groups in the polymeric molecule can accumulate along its main chain and induce the orientational–polar ordering responsible for the Kerr effect in the polymer solution. The formation mechanism of the $\mu_{0||}$ dipoles uniformly oriented along the main chain of the branched polymer can be understood if one allows for the orientational interaction between the side chains, whose mesogenic nuclei contain dipolar components $\mu_\perp$ normal to these chains. In the presence of orientational order of the nematic type between the mesogenic side chains the $\mu_\perp$ components can contribute to the $\mu_{0||}$ component parallel to the main chain of the polymer.

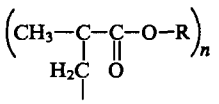
The important role of the mesogenic structure of the side groups in the formation of the longitudinal components ($\mu_{0||}$) of the dipoles is clearly illustrated by the electro-optical properties of polymer 6 (Table 7), whose side chains are long, polar, and anisotropic, but not mesogenic. The equilibrium K values for this polymer are small and similar in order of magnitude to the K value for its monomer in tetrachloroethane, and also for low-molecular substances with a structure similar to that of its side groups. For sinusoidal fields at radio-frequencies no dispersion of the EBR has been detected [114] in solutions of the polymer. These results show that the branched molecules of polymer 6, whose side chains are not mesogenic in an electric field, behave as kinetically flexible and orient themselves by a deformation mechanism of the chain (relying on the local motion of the polar groups).

As the mesogenic nucleus of the side group in a branched polymer is moved further away from the main chain [by introducing a flexible segment (the spacer) between them] the correlation between the orientations of the main chain and of the side chains becomes less close. Therefore the large-scale motion of the macromolecule is replaced by a small-scale (local) motion, in which the orientation of the side chains in an electric field takes place as in a solution of the corresponding monomer: by the more or less independent rotation of the polar side groups. This conclusion is well illustrated by data [112] obtained for the polymer 7, whose solutions do not show radio-frequency dispersion of K: the equilibrium value of this constant is close to the K value for sample 6.

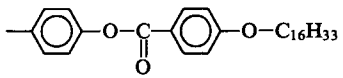
The weakening of the orientational correlation between the main chain and mesogenic side groups is of fundamental importance in demonstrating the mesomorphism of the branched polymer in a pure sample. As we know, branched polymers form a thermotropic nematic phase only if the orientation of the mesogenic side nucleus relative to the main chain is reasonably free, i.e. in the presence of a spacer. Thus, we have studied [115] the equilibrium and the transient EBR in the isotropic phase of a branched polymer containing mesogenic cyanobiphenyl groups in the side chains.

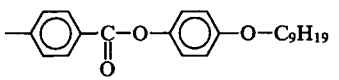
The relaxation time corresponding to a more or less independent (local) orientation of the mesogenic side groups has been obtained. Data on the equilibrium EBR confirmed these results: its magnitude and its positive sign corresponded to the magnitude and sign of the EBR in the isotropic phase (or in solution) of the mesogenic low-molecular analogue.

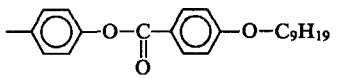
VII. Conclusions

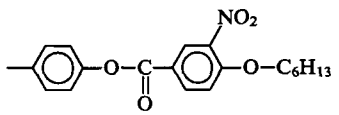


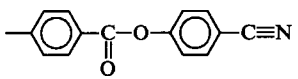
We have discussed the electro-optical properties of polymers whose macromolecules differ strongly in their equilibrium rigidity. The terms 'semirigid' and 'rigid-chain' polymers have been proposed for these materials. As we have pointed out, [116, 117] semirigid molecules cannot be treated as a class of polymers having a well defined structure. It is better to characterise them as a group of structures displaying a recognisable group of physicochemical properties. One of the most important of these properties is the large-scale orientation of the molecular chain in an electric field. The necessary condition for the appearance of this mechanism is the presence of a longitudinal component of the dipole moment of the monomer unit $\mu_{0||}$, correlated over the contour of the molecular chain.

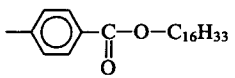


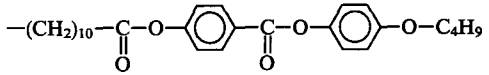












The maximum value of the Kerr effect for polymers (in the Gaussian region) is determined by the parameters Δa,, $\mu_{0||}^2$, and S^2. Depending on the possible values of these quantities the Kerr constant can vary over several orders of magnitude in absolute value, but the signs of K_∞ and $\Delta n/\Delta\tau$ are the same whenever $\mu_{0||}$ is orientationally correlated over the chain. For many flexible-chain polymers the fundamental condition for the formation of large-scale EBR is not fulfilled, and therefore in these cases K is small and is determined by the local orientation of the monomer units, and the signs of K and $\Delta n/\Delta\tau$ are not correlated. However, even in the presence of monomeric dipoles $\mu_{0||}$ uniformly oriented over the chain the Kerr effect can be difficult to observe because S^2 (and therefore also K) is small. In addition, the presence of anisotropic and of polar side groups interacting specifically in a flexible polymer chain can produce both a slight increase in S and Δa as well as some increase in the $\mu_{0||}$ parameters, and therefore it can lead to the development in these solutions of an EBR effect by the large-scale motion mechanism. A clear example of this behaviour is seen in the branched polymers with anisotropically interacting mesogenic side groups.

The nature of the development of a longitudinal component of the dipole of the monomer unit in a polymer can differ in different systems, but in nonpolar solvents $\mu_{0||}$ for the polymer is always determined by the dipolar structure of the macromolecules. Under these conditions $\mu_{0||}$ can be strongly dependent on the polar structure of the main chain [for example, in poly(alkyl isocyanates)] as well as on the dipolar properties of the side substituents, as is clearly seen in the cellulose esters.

When polar solvents are used the origin of the $\mu_{0||}$ component is not so well understood. Under these conditions $\mu_{0||}$ can be formed by the specific interactions between the polymer and the solvent, leading to the orientational correlation of the dipolar solvent molecules and of the polar bonds in the polymer chain, and resulting in the formation of an effective 'electro-optical' dipole in the macromolecule.

In studies of the transient EBR in dilute solutions of polymers the nature of the formation of $\mu_{0||}$ is unimportant in principle. Studies of the dependence of the relaxation times on the molecular

mass for rigid-chain polymers have yielded some quantitative conclusions on the equilibrium rigidity of macromolecules without introducing data obtained by other methods, and it also allowed their kinetic rigidity to be characterised qualitatively.

An analysis of the dependence of the Kerr constant on the molecular mass in rigid-chain polymers allows us to determine the equilibrium rigidity of the chain. Under these conditions the result is relatively unaffected by the choice of solvent. The problem is simplified when the contribution to the electro-optical effect from the normal component of the dipole of the monomer unit $\mu_{0\perp}$ is small, which corresponds either to a small value of ϑ or to a large value of α. Equilibrium EBR data can be used in studies of the dipole structure of a polymer chain (the magnitude of the dipole of the monomer unit μ_0 and its slope ϑ with respect to the contour of the macromolecule) only when nonpolar solvents are chosen. To determine the angle ϑ reliably it is important to include a change in sign of the dependence of K on M, which should be observed for $\vartheta > 54°$, since unless this is done the dependence of the Kerr constant on the molecular mass is an insensitive function of the angle ϑ and cannot be used to calculate it. Unfortunately, experimental data indicating a change in sign of K upon increasing M have not so far been obtained in nonpolar solvents.

Abstract. The mechanisms of new catalytic reactions leading to the formation of di- and tri-alkyl phosphates, di- and tri-alkyl phosphites, phosphoramidites, phosphazenes, phosphines, and phosphine oxides from hydrogen, copper, and zinc phosphides and white and red phosphorus are analysed. The mechanisms of the activation of the reactants by metal complexes and of the reactions involving the oxidative P–O, P–N, and P–C coupling of organic compounds to phosphorus and phosphides are considered. The bibliography includes 124 references.

I. Introduction

The products of the P–C, P–N, and P–O coupling, namely di- and tri-alkyl phosphates, di- and tri-alkyl phosphites, phosphazenes, phosphorinanes, phosphines, and phosphine oxides, are stable organic compounds[1,2] and are widely used as extractants for the lanthanides, the actinides, and other heavy metals from mineral raw materials and the waste from atomic power plants,[3,4] as monomers for the synthesis of organophosphorus fire- and heat-resistant polymers,[5,6] as additives to fuels and lubricating materials, as corrosion inhibitors, etc.

The available methods for the synthesis of the above compounds are based on the P–C, P–N, and P–O coupling of organic substances to the high-valence phosphorus compounds $POCl_3$, and PCl_5, which are synthesised using the expensive and extremely toxic chlorine.[1–7] Dorfman et al[8] discovered the reactions involving the P–C, P–N, and P–O coupling of organic compounds to low-valence inorganic phosphorus compounds, which lead to the formation of some of the substances listed above. Low-valence phosphorus compounds, namely phosphine, transition metal phosphides, hypophosphite, tetraphosphorus, and polyphosphorus are highly toxic waste from modern phosphorus and hypophosphite manufacturing plants produced on a large scale.[9–11] White phosphorus is present in weak phosphorus sludge, which is not utilised nowadays and is stored in sludge accumulators.

Important advantages of the new reaction involving the oxidative P–C, P–N, and P–O phosphorylation of organic substances by low-valence inorganic compounds are mild conditions, a high rate, and a high selectivity, which facilitates the isolation technology of the pure product.[8] This makes it possible to use the waste from phosphorus undertakings in which phosphorus-containing compounds are present in small amounts.

The wide variety of the products formed in P–C, P–N, and P–O oxidative coupling to aliphatic and aromatic compounds (phosphine, transition metal phosphides, tetraphosphorus and polyphosphorus, and hypophosphite) and reaction conditions do not rule out the existence of a series of common features of interest in the organic chemistry of low-valence phosphorus compounds, which have been extremely little investigated, and in the metal complex catalysis of homogeneous and topochemical processes.

II. Oxidative P–O coupling of tetraphosphorus to alcohols

Despite the evident usefulness of tetraphosphorus in organic synthesis, there are as yet no data concerning the processes based on it.[12–40] Homolytic reactions are characteristic of tetraphosphorus, whereas heterolytic reactions proceed with

Received 24 May 1993
Uspekhi Khimii **62** (9) 928–948 (1993); translated by A K Grzybowski

difficulty.[10] It has been observed[41-43] that, when tetraphosphorus is placed in an arene–alcohol solution of divalent copper salts under a O_2 atmosphere at 50–150 °C, reactions involving the oxidative P–O coupling of P_4 to ROH proceed very rapidly and with a high selectivity.

Reactions (1) and (3) predominate in the arene–alcohol solutions of $CuHal_2$ (Hal = Cl, Br), while reaction (2) predominates in $CuSO_4$, and $Cu(CO_2R)_2$ solutions (R = CH_3, C_3H_7, $C_{17}H_{35}$; arene = benzene, toluene, xylene).[8] Copper(II) sulfate and carboxylate complexes stimulate also the formation of dialkyl phosphite, in contrast to the halide complexes. The product ratio $(RO)_3PO/(RO)_3P$ depends not only on the nature of the ligands but also on the ROH concentration. If the amount of ROH diminishes, the ratio $(RO)_3PO/(RO)_3P$ also falls. Dialkyl phosphate is obtained at elevated temperatures.

$$P_4 + 5O_2 + 12ROH \longrightarrow 4(RO)_3PO + 6H_2O; \quad (1)$$

$$P_4 + 3O_2 + 12ROH \longrightarrow 4(RO)_3P + 6H_2O; \quad (2)$$

R = CH_3, C_2H_5, C_3H_7, C_4H_9, *iso*-C_4H_9, C_5H_{11}, *iso*-C_5H_{11}, C_8H_{17}, C_6H_5.

$$P_4 + 3O_2 + 8R'OH \longrightarrow 4(R'O)_2HPO + 2H_2O; \quad (3)$$

R′ = *iso*-C_3H_7.

The catalytic activity of copper(II) complexes also depends on the nature of the anions and increases when the halides are replaced by the sulfates, acetates, and especially butyrates and stearates. Both the rate of reduction of copper(II) by tetraphosphorus and the rate of oxidation of copper(I) by oxygen increase in this series of ligands. In contrast to the sulfate and acetate complexes, the butyrate and stearate complexes are readily soluble in benzene–alcohol solutions and in their presence the oxidative P–O coupling of P_4 to ROH proceeds selectively and at a high rate. The acidopyridinecopper(II) complexes have a higher activity.[41] The addition of pyridine to arene–alcohol solutions of $CuHal_2$, $CuSO_4$, and $Cu(CO_2R)_2$ leads to a sharp increase in the rate of reaction and in the $(RO)_3PO/(RO)_3P$ ratio and to a decrease in the yield of $(RO)_2(HO)PO$.

$$P_4 + 5O_2 + 8ROH \longrightarrow 4(RO)_2(HO)PO + 4H_2O. \quad (4)$$

Under an argon atmosphere, tetraphosphorus reacts almost instantaneously with arene–alcohol solutions of copper(II) complexes.

Reactions (5)–(8) take place over a period of 30–50 s.[41-43] The univalent and metallic copper formed is readily reoxidised by air to the divalent state. During the regeneration period, the alkyl halides and sulfates are hydrolysed to the alcohol by the water formed in this process, while alkyl carboxylates accumulate in the system. In the presence of acids, trialkyl phosphites are dealkylated to dialkyl phosphites. The rate of dealkylation increases with increase in the acidity of the medium (on passing from the sulfate and carboxylates to the halides) and also with decrease in the molecular mass of the group R. The dealkylation of trialkyl phosphites ends in the stage involving the formation of dialkyl phosphites, which are dealkylated very slowly. The

$$P_4 + 16ROH + 20CuX_2 \longrightarrow 4(RO)_3PO + 20CuX + 4RX + 16HX; \quad (5)$$

$$P_4 + 16ROH + 20CuX_2 \longrightarrow 4(RO)_2(HO)PO + 20CuX + 8RX + 12HX; \quad (6)$$

X = Cl, Br.

$$P_4 + 12ROH + 6CuY_2 \longrightarrow 4(RO)_3P + 6Cu + 12HY; \quad (7)$$

$$P_4 + 12R'OH + 6CuY_2 \longrightarrow 4(R'O)_2HPO + 6Cu + 4R'Y + 8HY; \quad (8)$$

Y = SO_4^{2-}, RCO_2^-.

oxygen-containing acido-ions (OH^-, SO_4^{2-}, RCO_2^-) are relatively unreactive in these reactions. Trialkyl phosphites form[44] stable complexes with copper(I) halides of the type $CuX \cdot P(OR)_3$ and $CuX \cdot 2P(OR)_3$. Copper(I) trialkyl phosphite complexes are greasy substances with melting points from 90 to 180 °C depending on the nature of the alkoxy-group. They are soluble in ether, benzene, acetone, and alcohols, can be readily detected by ^{31}P NMR spectroscopy in the range −6 to −10 ppm,[44,45] and are readily decomposed by chlorine with formation of trialkyl phosphates and copper(II) complexes.

Reactions (3) and (4) have been investigated in detail by kinetic and potentiometric methods.[41-43] The introduction of an arene solution of P_4 into an alcoholic solution of CuX_2 or CuY_2 under a O_2–Ar atmosphere is accompanied by a sharp shift of the redox potential of the Cu(II)/Cu(I) couple in the cathodic direction. At the same time, the pressure falls in a closed system and the absorption of O_2 begins. As O_2 is absorbed, the redox potential gradually returns to the anodic region. Analysis of the reaction mixture during the experiment by gas chromatography and ^{31}P NMR spectroscopy showed that the sharp shift of the redox potential in the cathodic direction is caused by the rapid reduction of Cu(II) to Cu(0) by tetraphosphorus in conformity with reactions (5)–(8). At the end of the process, when P_4 has been consumed, the redox potential shifts in the anodic direction as a result of the oxidation of Cu(0) to Cu(I) by oxygen. The rate constant for the reduction of Cu(II) by tetraphosphorus to Cu(0) was calculated from the magnitude and time of the cathodic shift of the redox potential at the beginning of the experiment:

$$k_{red} = \frac{W}{[Cu(II)][P_4]} \text{ litre mol}^{-1} \text{ s}^{-1} \quad (9)$$

(in C_2H_5OH, k_{red} = 1–5 litre mol^{-1} s^{-1}), while the rate constant for the oxidation of CuX and CuY by oxygen was found from the magnitude and time of the anodic shift of the redox potential:

$$k_{ox} = \frac{W}{[Cu(I)][O_2]} \text{ litre mol}^{-1}\text{s}^{-1} \quad (10)$$

(in C_2H_5OH, k_{ox} = 0.1–0.9 litre mol^{-1} s^{-1}). Tetraphosphorus is sparingly soluble in polar solvents and readily soluble in weakly polar and non-polar solvents. Thus the solubility of P_4 is 10^4 g $litre^{-1}$ s^{-1} in carbon disulfide, 10^2 g $litre^{-1}$ in arenes, 50 g $litre^{-1}$ in alkanes, 40 g $litre^{-1}$ in carbon tetrachloride, 30 g $litre^{-1}$ in alcohol, and 10^{-3} g $litre^{-1}$ in water. Owing to the sparing solubility of P_4 in alcohol, benzene–alcohol and toluene–alcohol mixtures, which readily dissolve P_4 and copper(II) complexes, which only sparingly dissolve in H_2O, were used. Without the arene (in alcohol) and without alcohol (in the arene), the oxidation of P_4 by oxygen with formation of P_4O_{10} is slow.

The water formed by reactions (1)–(4) inhibits the reaction of P_4 with ROH and stimulates the P–O coupling to H_2O, affording phosphoric acid. Water is coordinated to copper(II) compounds more readily than ROH. According to UV spectroscopic data for water–alcohol solutions of copper(II) compounds, the alcohol complexes of copper(II) are formed at a H_2O concentration less than 10%.[46] In arene–alcohol solutions of copper(II) compounds, water exerts the least influence on the composition of the complexes. Owing to the presence of the arene, the water generated during reactions (1)–(4) does not affect the course of the oxidative *O*-phosphorylation of alcohols by tetraphosphorus. As a result of its sparing solubility in the arene–alcohol mixture (0.6 g $litre^{-1}$), water forms a separate phase. The arene can function as a phase transfer catalyst. It dissolves selectively ROH, P_4, and the copper(II) complexes, ensures the occurrence of the reaction between P_4 and ROH, and prevents the reaction between P_4 and H_2O.

An excess of acido-anions interferes with the coordination of P_4 to copper(II) complexes and has a negative influence on the rates of reactions (5)–(8). At a high concentration of

acido-ligands, P_4 does not reduce copper(II) complexes. In non-aqueous solvents, acido-ligands form stable complexes with copper(II) anions. On passing from aqueous to non-aqueous solutions, the stability constants of these acido-complexes increase by several orders of magnitude in opposition to the change in the dielectric constant [relative permittivity] and in the donor number (DN) of the solvent. Table 1 lists the formation constants (β_j) of the copper(II) chloride complexes in various solvents.

Table 1. The equilibrium constants (β_j) of the reaction $Cu^{2+}_{sol} + jCl^- \rightleftarrows CuCl_j^{2-j} + sol.$

Solvent (DN)	$CuCl^+_{sol}$	$CuCl_{2\,sol}$	$CuCl^-_{3\,sol}$	$CuCl^{2-}_{4\,sol}$
H_2O (18)	0.4	0.6	0.1	−0.8
DMF (24)	4.4	3.0	12.0	12.9
TMF (23)	7.3	12.4	16.8	19.4
$(CH_3)_2CO$ (17)	8.4	14.5	19.9	21.5
THF (20)	10.7	20.3	23.9	25.7
$(CH_3)_2SO$ (30)	3.4	5.2	7.3	7.9
PC (15)	12.0	22.7	29.0	34.0

Complexes saturated by acido-ligands are already obtained[47] at a ratio ligand/Cu(II) > 6. The maximum rates of reactions (1)–(4) are attained when coordinatively unsaturated copper(II) complexes predominate in the arene–alcohol solution. Coordinatively saturated copper(II) complexes do not react with tetraphosphorus.[41–43] The ligand effect observed is due to the fact that the η^1-tetraphosphorus complexes are characterised by a lower reactivity than the η^2-tetraphosphorus complexes. Since two free coordination sites in the equatorial plane are necessary for the η^2-coordination of P_4, an excess of acido-ligands interferes with the addition of P_4 to copper(II) ions. Only electron-donating ligands (Cl^-, Br^-, NH_3, SO_4^{2-}, RCO_2^-) interfere with the η^2-coordination of P_4, whilst electron-accepting ligands (CH_3CN, ROH, H_2O, Py) stimulate the incorporation of P_4 into the coordination sphere of Cu(II).[41–43] An important feature of reactions (1)–(4) is the fact that the O_2/P_4 ratio is equal to the stoichiometric coefficient and is independent of the O_2 concentration, temperature, and the composition of the system. Oxygen is consumed only in the oxidation of P_4 and does not participate in the alcohol oxidation reaction.[41–43]

The rate constants for the reduction of copper(II) salts by tetraphosphorus increase [k_{red} = 2.24 (CH_3OH) and 1.47 (C_4H_9OH) litre mol^{-1} s^{-1}], while the rate constants for the oxidation by oxygen change little [k_{ox} = 0.12 (CH_3OH) and 0.17 (C_4H_9OH) litre $mol^{-1}s^{-1}$], in parallel with increasing acidity of the alcohols. Such variation indicates the participation in the reaction of acidoalkoxophosphorus complexes of copper(II).

A decrease in the concentration of ROH in the system as a result of its replacement by $(C_4H_9O)_3PO$ leads to a fall in the yield of trialkyl phosphates [from 66% to 20% for tetrahydrofuran (THF)], to an increase in the yield of trialkyl phosphites, and to a slight change in the rate constants for reactions (5)–(7). After the addition of $(C_4H_9O)_3PO$ (c = 1.83 mol $litre^{-1}$), k_{red} changes from 2.35 to 2.63 litre mol^{-1} s^{-1} and k_{ox} changes from 0.1 to 0.09 litre mol^{-1} s^{-1}.

Acido-complexes of copper(II) not containing ROH react with P_4 to form acyl phosphates, which can be readily detected by ^{31}P NMR spectroscopy:[45] Cl_3PO (5 ppm), $(RCO_2)_3PO$ (−20 ppm), $(RCO_2)_2HPO$ (7 ppm), $(RCO_2)_2(OH)PO$ (−6 ppm), and $(RCO)_2(OH)_2PO$ (−3 ppm).

In an arene–acetic acid solution and other systems of the type arene–carboxylic acid, the previously unknown oxidative P–O coupling of P_4 to carboxylic acids takes place.

$$P_4 + 20Cu(RCO_2)_2 \longrightarrow 4(RCO_2)_3PO + 20Cu(RCO_2) + 4(RCO_2)O. \quad (11)$$

Triacyl phosphates partly decompose with formation of diacyl and monoacyl phosphates.

$$(RCO_2)_3PO + RCO_2H \longrightarrow (RCO_2)_2(HO)PO + (RCO_2)O; \quad (12)$$

$$(RCO_2)_2(HO)PO + RCO_2H \longrightarrow (RCO_2)(HO)_2PO + (RCO_2)O. \quad (13)$$

In the absence of copper(II) complexes, tetraphosphorus in an arene–alcohol solution is slowly oxidised by oxygen to the phosphorus oxide P_4O_{10}, the esterification of which proceeds extremely slowly and only as far as primary and secondary phosphoric acid esters.

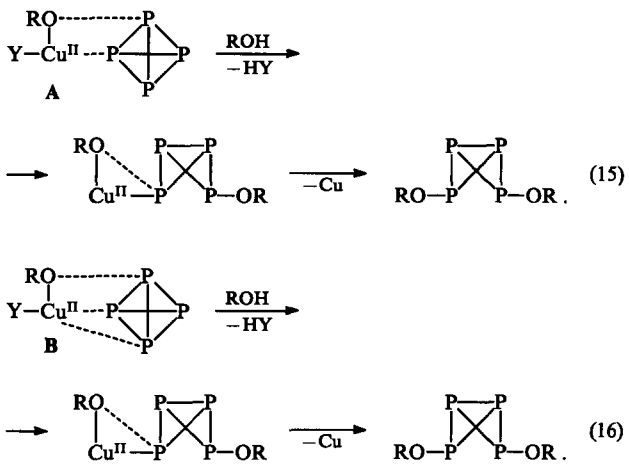
$$P_4O_{10} + 6ROH \longrightarrow 2(RO)(HO)_2PO + 2(RO)_2(HO)PO. \quad (14)$$

The chain oxidation of P_4 by oxygen does not occur owing to the low O_2 and P_4 concentrations in the liquid phase.[48]

The influence of the acidity of the medium has been investigated by the method involving the addition of pyridine and by varying the HCl/LiCl ratio in the reaction system. With increase in the acidity of the medium, the rate of reactions (5)–(7) falls (k_{red} diminishes from 4.53 to 0 litre mol^{-1} s^{-1} in C_2H_5OH) and the yield of dialkyl phosphates increases (from 3.3% to 53.3% for diethyl phosphate). The addition of pyridine increases significantly the rates of reactions (5)–(7) and the yields of trialkyl phosphates.[41–43]

It follows from the data presented that P_4 reacts better with acidoalkoxocopper(II) complexes than with the acidoalcohol-copper(II) complexes. Iron(II) and iron(III) halides, sulfates, and carboxylates are an order of magnitude less reactive then the analogous copper(II) complexes.

The experimental data enumerated above indicate a coordination mechanism of the reduction of copper(II) complexes by tetraphosphorus.



The reduction of acidoalkoxocopper(II) complexes by tetraphosphorus to Cu(0) consists of two stages: the insertion of P_4 in the Cu–OR bond with formation of the monoalkoxytetraphosphine anion $P_4(OR)^-$ and the reductive coupling of the RO^- and $P_4(OR)^-$ ligands with formation of dialkoxytetraphosphine.

The coordination mechanism is supported by the low activation energies (50–60 kJ mol^{-1}) compared with the dissociation energies of the bonds P–P (230 kJ mol^{-1}) and Cu–OR (260 kJ mol^{-1}) as well as the negative entropies of activation ($\Delta S^{\neq}_{red}$ = −82 J mol^{-1} K^{-1} and $\Delta S^{\neq}_{ox}$ = −80 J mol^{-1} K^{-1} in C_2H_5OH). The driving forces of the reaction involving the insertion of P_4 in the Cu–OR bond and the reductive dimerisation of the hydroxo- and polyalkoxyphosphine anions are the high energy of the P–O bond (340 kJ mol^{-1}) and the high redox potential of the Cu(II)/Cu(0) couple (0.34 V).

The subsequent stages of the oxidative alkoxylation of cyclic and linear dialkoxy- and tetraalkoxy-phosphides and dialkoxy- and tetraalkoxy-diphosphines by acidocopper(II) complexes are faster.

According to recent data,[29–33] P_4 can function both as a η^1- and η^2-ligand. On η^1-coordination (**A**) [(15)], the tetrahedral P_4 molecule is activated, being converted into a trigonal pyramid the vertex of which is directed towards the metal atom. The $P_{base}-P_{apex}$ distance (2.20 Å) is longer than the $P_{base}-P_{base}$ distance (2.09 Å). As a result of η^2-coordination (**B**), the edge linked to the metal is lengthened by 0.25 Å compared with the P–P bond in the free molecule (2.21 Å). Bidentate coordination of P_4 promotes a greater activation of the molecule than monodentate coordination. On bidentate binding of P_4, the P–P distance increases to an extent greater by 0.14 Å than on monodentate binding,[29–33] ensuring a greater loosening of P_4. The coordinatively saturated copper(II) complexes, incapable

of effecting the η^2-coordination of tetraphosphorus, are therefore characterised by a lower catalytic activity than the coordinatively unsaturated complexes, which are capable both of η^1- and η^2-coordination.[41-43]

(15)

(16)

The stages involving the insertion of P_4 in the Cu–OR bond and the reductive coupling of the OR^- and $P_4(OR)^-$ ligands have been investigated in detail by the CNDO method (complete neglect of differential overlap).[43] Calculations have been carried out for anionic acidoalkoxotetraphosphorus and acidomonoalkoxytetraphosphine complexes and cationic pyridinehydroxoaminoalkoxotetraphosphorus, aminoalkoxomonoalkoxytetraphosphine, aquoalkoxotetraphosphorus, and aquoalkoxomonoalkoxytetraphosphine complexes of copper(II).

The nature of the P_4 activation depends on the denticity of the ligands and the overall charge of the copper complex. The non-polar P_4 molecule is activated as a result of coordination: the energies of the P–P bonds diminish non-uniformly and effective charges appear on the P atoms, where they were absent before complex formation. In contrast to free P_4, the coordinated tetraphosphorus becomes an electron acceptor and interacts vigorously with ligands having an unshared electron pair (RO^-, HO^-, Hal^-). The HO^- ion models the behaviour of sulfate and carboxylate ligands. The ligands having no free unshared electron pair after coordination with copper(II) (H_2O, ROH, NH_3, Py) interact only weakly with P_4.[43]

The effective charges on the P atoms and the total, covalent, and ionic energies of the bonds between the ligands (between the chemically non-bonded atoms) were used to determine the composition of the many-centre transition state. The ligands in the copper(II) complex interact most strongly with the P atoms of the P_4 molecule which are not linked to the central copper atom. The energies of the bonds between the atoms and the ligands increase significantly with increase in the total positive charge on the complexes: in the anionic copper(II) complexes, the ligands interact much more weakly with P_4 than in the cationic complexes.[43]

The reductive coupling of the RO^- and $P_4(RO)^-$ ligands takes place with participation of the P atom bound covalently to the Cu(II) ion. If P_4 is inserted in the Cu–OR bond via a four-centre cyclic transition state (**A**) or (**B**), then the reductive elimination of the ligands RO^- and $P_4(RO)^-$ takes place via a three-membered cyclic intermediate. On the other hand, according to CNDO calculations, a covenient situation for the stage involving the reductive dimerisation of the alkoxo- and monoalkoxotetraphosphine ligands occurs in anionic complexes in the presence of electron-donating ligands. In such complexes the Cu–P bond, ruptured during the reductive coupling of the RO^- and $P_4(RO)^-$ ligands, is weakest.

$$P_4(OR)_2 \xrightarrow[-Cu]{Cu(OR)_2} P_4(OR)_4 \xrightarrow[-Cu]{2Cu(OR)_2} \longrightarrow 2P_2(OR)_4 \xrightarrow[-Cu]{2Cu(OR)_2} 4(RO)_3P. \quad (17)$$

Since cationic and anionic complexes are respectively more suitable for the stage involving the insertion of P_4 in the Cu–OR bond and the reductive coupling stage, optimum conditions are attained when uncharged copper(II) complexes are used. The rate of reaction therefore passes through a maximum when the number of acido-ligands is varied.[43]

III. Oxidative P–N coupling of tetraphosphorus to amines

Copper(II) complexes exhibit a high catalytic activity in oxidative P–N coupling of P_4 to primary and secondary amines.[49] Tetraphosphorus reacts with amines in the presence of oxygen with formation of phosphazo-compounds.

$$P_4 + 16RH_2N + 5O_2 \longrightarrow 4(RHN)_3P{=}NR + 10H_2O. \quad (18)$$

$$P_4 + 16R_2HN + 5O_2 \longrightarrow \longrightarrow 4(R_2N)_3P{=}NR + 6H_2O + 4ROH; \quad (19)$$

R = C_2H_5, C_6H_{11}, $C_6H_5CH_2$.

Under argon, tetraphosphorus reduces Cu(II) to Cu(0).

The zerovalent copper formed by reactions (20) and (21) is instantly regenerated by air. The new reactions (18)–(21) are very rapid. When primary ($C_6H_5CH_2NH_2$, $C_6H_{11}NH_2$) and secondary ($C_5H_{10}NH$) amines are used, we have the ratio $O_2/P_4 \simeq 5$. The formation of phosphazo-compounds by reactions (18)–(21) is of preparative value.[50,51] The new method of synthesis of triaminophosphazoalkyls is much simpler than that already available,[50] which is based on the P–N coupling of primary amines to trichlorophosphazohydrocarbons and the oxidative imination of phosphorus(III) compounds by *N*-chloroamines.[50-52]

$$P_4 + 10CuX_2 + 16RH_2N \longrightarrow \longrightarrow 4(RHN)_3P{=}NR + 10Cu + 20HX. \quad (20)$$

$$P_4 + 10CuX_2 + 16R_2HN \longrightarrow \longrightarrow 4(R_2N)_3P{=}NR + 10Cu + 4RX + 16HX. \quad (21)$$

Amines react with P_4 faster by one to two orders of magnitude than alcohols. In solutions in amines, the rate constants for the reduction of copper(II) by tetraphosphorus and for the oxidation of copper (I) by oxygen, calculated by Eqns (9) and (10), are higher than in alcoholic media. According to ^{31}P NMR spectroscopic data, reactions (18)–(21) proceed selectively. The ^{31}P NMR spectra contain only peaks characteristic of phosphazenes (10–20 ppm) and phosphorous triamide complexes of copper(I): $CuX[P(NR_2)_3]$ (10 ppm).[45]

The behaviour of amine systems under an oxygen atmosphere is similar to that of the alcohol systems. The kinetic ($W-\tau$) and conversion ($W-Q$) curves [τ is the time (s), W the rate of reaction (mol g^{-1} s^{-1}), and Q the degree of conversion of P_4] pass through an extremum for the ratio $Cu/P_4 < 10$ and have a descending form for $Cu/P_4 > 10$. When solutions of P_4 in an arene and of CuX_2 in an amine are mixed, the potential undergoes a sharp shift in the cathodic direction. As O_2 is absorbed, the redox potential of the Cu(II)/Cu(I) couple returns to the initial value. The rates of reactions (18)–(21) increase with increase in the concentrations of copper(II), NR_2H (or NRH_2), and O_2 and in temperature, whereas the addition of pyridine causes their increase by two orders of magnitude. It has been established by IR spectroscopy that the amine complexes of copper(II) in pyridine form acidoamino-complexes;[53] the reaction is accelerated in an excess of the amine and particularly after the addition of pyridine.[54]

The many-electron synthesis of phosphazo-compounds consists of stages involving the oxidative amination of tetraphosphorus and the oxidative imination of phosphorous triamide. In the rate-limiting stage, P_4 is inserted in the Cu–NRH or Cu–NR_2 bond. The diaminotetraphosphine is then rapidly oxidised by acidocopper(II) complexes in the presence of an amine to phosphorous triamide.

$$Cu(NRH)_2P_4 \longrightarrow Cu + P_4(NRH)_2. \quad (22)$$

$$P_4(NRH)_2 + 5CuX_2 + 10NRH_2 \longrightarrow$$
$$\longrightarrow 5Cu + 4P(NRH)_3 + 10HX. \quad (23)$$

In the presence of acids HX, phosphorous amides undergo acidolysis via a stage involving the formation of acyl phosphites, which acylate the amine produced. In order to prevent the acidolysis of phosphorous triamides, an excess of the amine was added to the reaction medium. The HX molecules generated as a result of reaction (23) are hydrolysed to the alcohol. The phosphorous triamides are oxidised further by the acidocopper(II) complexes to alkylaminophosphonium halides.

$$(R_2N)_3P + CuX_2 \longrightarrow Cu + (R_2N)_3PX_2. \quad (24)$$

The alkylaminophosphonium halides formed split off the alkyl halide by the Arbuzov reaction[55] with formation of dialkylaminohalophosphazoalkyl.

$$(R_2N)_3PX_2 \rightleftharpoons (R_2N)_2XP{=}NR + RX. \quad (25)$$

The dealkylation of alkylaminophosphonium halide takes place because of the considerable difference between the P–N (65–70 kcal mol^{-1}) and P=N (100–125 kcal mol^{-1}) bond energies. In contrast to the irreversible reactions of alkoxyphosphonium halides, leading to the conversion of P–O bonds into P=O, i.e. reaction (25) is reversible.

$$(RO)_3PX_2 \longrightarrow (RO)_2XP{=}O + RX.$$

The extent of reaction (25) depends on the reactivity of the reaction products—phosphazo-compounds and alkyl halides. Since dialkylaminohalophosphazoalkyls are highly basic,[51] the equilibrium constant of reaction (25) is small at the normal temperature. Aminophosphonium chlorides, containing only amino-groups, decompose fully at temperatures above 150 °.

In the catalytic process, the equilibrium in reaction (25) shifts to the right, since dialkylaminochlorophosphazoalkyl forms complexes with the copper(II) ion and reacts with the excess of dialkylamine, affording triaminophosphazoalkyl.

$$(R_2N)_2XP{=}NR + R_2HN \longrightarrow (R_2N)_3P{=}NR + HX. \quad (26)$$

Thus triaminophosphazoalkyls can be obtained from tetraphosphorus and primary and secondary amines in a high yield and at a high rate. Methods of synthesis of specific substances are being developed at the present time.

The phosphorus–nitrogen bond in triaminophosphazoalkyls is very stable and is not ruptured even after prolonged refluxing with water. According to ^{31}P NMR spectroscopic data,[51] triaminophosphazoalkyls react with water to form only phosphonium bases.

$$(R_2N)_3P{=}NR + H_2O \rightleftharpoons (R_2N)_3P(NHR)OH.$$

The hydrolytic stability of triaminophosphazo-compounds permits their extensive use for preparative purposes.[51]

IV. Oxidative P–O coupling of red phosphorus to alcohols

Despite the expansion in recent years of the scale of its manufacture, red phosphorus (P_n), is hardly used in organic synthesis because of its low reactivity.[12–40] It is inert in both homolytic and heterolytic reactions.[39,40]

In alcoholic solutions of CuX_2 and 80–200 °C, the topochemical oxidation of polyphosphorus by oxygen to trialkyl and dialkyl phosphates takes place at a high rate and with a high selectivity. This process was first described by Dorfman and coworkers.[56–59]

$$P_n + 3n\,ROH + 1.25n\,O_2 \longrightarrow n(RO)_3PO + 1.5n\,H_2O. \quad (27)$$

$$P_n + 2n\,ROH + 1.25n\,O_2 \longrightarrow$$
$$\longrightarrow n(RO)_2(HO)PO + 0.5n\,H_2O; \quad (28)$$

R = CH_3, C_2H_5, C_3H_7, C_4H_9, *iso*-C_4H_9, C_5H_{11}, *iso*-C_5H_{11}, C_8H_{17}.

In the absence of O_2 (and Ar), red phosphorus reacts with an alcoholic solution of CuX_2.

$$P_n + 5n\,CuX_2 + 4n\,ROH \longrightarrow$$
$$\longrightarrow n(RO)_3PO + 5n\,CuX + 4n\,HX + n\,RX. \quad (29)$$

$$P_n + 4n\,ROH + 5n\,CuX_2 \longrightarrow$$
$$\longrightarrow n(RO)_2(HO)PO + 5n\,CuX + 2n\,RX + 3n\,HX. \quad (30)$$

The ratio $(RO)_3PO/(RO)_2(HO)PO$ diminishes from 20.0 to 0.7 with decrease in the amount of ROH.

Oxygen and red phosphorus are consumed only in the formation of organic phosphates, the yields of which relative to P_n and O_2 are always equal and amount to ~100%. The reaction products—trialkyl and dialkyl phosphates—are good solvents for reactions (27) and (28), so that the organic phosphates can be synthesised virtually until the complete consumption of the alcohol. The organic phosphates are separated from the catalyst by extraction with heptane and subsequent vacuum distillation: at 4–5 Torr, trialkylphosphate is distilled away, whilst dialkyl phosphate remains in the still residue. The copper(I) ions formed by reactions (29) and (30) are rapidly oxidised by oxygen. During regeneration, copper(I) is oxidised to copper(II) and alkyl halides are hydrolysed by water to the alcohols.

The oxidative P–O coupling of P_n to glycols (glycerol, ethylene and diethylene glycols, butanediol) in dioxane leads to the formation of linear and cyclic alkyl phosphates.

In isopropyl alcohol, dialkyl phosphites are formed.

$$P_n + 0.75O_2 + 2n\,R'OH \longrightarrow n(R'O)_2HPO + 0.5n\,H_2O; \quad (31)$$

$$P_n + 3n\,CuX_2 + 3n\,R'OH \longrightarrow$$
$$\longrightarrow n(R'O)_2HPO + 3n\,CuX + 2n\,HX + n\,RX; \quad (32)$$

R' = *iso*-C_3H_7.

The organic phosphates obtained in reactions (27) and (28) were investigated by IR and ^{31}P NMR spectroscopy and gas chromatography. Their boiling points, densities, and refractive indices were also measured.

Red phosphorus purified with a hot NaOH solution was used for the investigations [according to spectroscopic emission analysis, the amount of the impurity (Si) did not exceed 0.1%–1.0%]. The existence of long-range order in P_n was established by X-ray powder diffraction, but the state of the substance is nearly amorphous.The surface of P_n is made up of chains of interlinked P_4 molecules.

The kinetic ($W-\tau$) and conversion ($W-\alpha$) curves (α is the degree of conversion of red phosphorus), having the shape typical of topochemical reactions,[60] pass through a maximum. With increase in temperature and the concentrations of CuX_2, O_2, ROH, and other reaction components, the maximum on the ($W-\tau$) curves becomes more distinct and is attained at lower values of τ. On the other hand, the position of the maximum on the ($W-\alpha$) curves, manifested at lower degrees of conversion (α = 0.01–0.1), changes little when the reaction temperature and the solution components are varied.

For alcohols ranging from CH_3OH to *iso*-C_5H_{11}, the activation energies for reactions (27) and (28) in the kinetic regime

(in the region of the maximum rate) are 50–140 kJ mol^{-1}, while the activation entropies are −145 to −75 J mol^{-1}K^{-1}. The kinetic and activation parameters depend on the composition of the solution. Studies with the aid of the Coulter counter and X-ray photoelectron spectroscopy showed that the specific surface and particle size of P_n do not change during the experiment and are 1200 cm^{3}g^{-1} and 24 μm respectively. During the reaction, the P_n surface is oxidised and is 90% covered by phosphorus(V) compounds. Intermediates in the phosphorus oxidation reaction were not detected.[56–59]

The maximum rate of reaction was used to calculate the specific surface by the formula

$$W_{sp} = \frac{2W_{max}}{\pi g S}, \text{ mol m}^{-2}\text{s}^{-1}, \quad (33)$$

where g is the sample weight, S is the specific surface of P_4, and W_{max} the maximum reaction rate.

The specific rates of reactions (27) and (28) are independent of the mass of P_n and increase with increase in the concentrations of O_2, ROH, and CuX_2 in the liquid phase. Furthermore, the rate of the reaction is influenced by the nature of the solvent. Thus reactions (27) and (28) are faster in benzonitrile than in $(RO)_3PO$, and the topochemical process is appreciably affected by pyridine, H_2O, HCl, LiCl, P_2O_5, H_2SO_4, and $C_6H_5CH_2N$ [$C_6H_5CH_2NH_2$?Ed. of Translation]. When the HCl concentration is varied, the specific rate curve passes through a sharp maximum (i.e. the promoting and inhibiting effects are manifested mainly by H^+ions), while variation of the LiCl concentration results in a broad maximum on the reaction rate curve. The amine inhibits reactions (27) and (28), whilst pyridine slightly reduces their rates. A small amount of added H_2SO_4 (up to a concentration of 1 mol litre^{-1}) leads to the formation of alkyl and dialkyl sulfates. However, large amounts of P_2O_5 (in excess of 1 mol litre^{-1}) induce the conversion of alcohols into olefins. The specific rates of reactions (27) and (28) and the yields of products change only slightly after the addition into an alcoholic solution of $CuCl_2$ of even large amounts of Br^- and I^- ions. However after the replacement of $CuHal_2$ by $CuSO_4$, $Cu(RCH_2CO_2)$, $MnCl_2$, $CoCl_2$, $Mn(AcO)_2$, $Co(AcO)_2$, $Fe(AcO)_3$, oxygen ceases to be absorbed.[56–59]

The data presented indicate the activation of the surface of red phosphorus by HX as a result of the rupture of the P–P bonds between the molecules of tetraphosphorus.

$$P_n + HX \rightleftharpoons P_n(HX). \quad (34)$$

Subsequently HX-activated red phosphorus adsorbs the heterovalent dimer $Cu_2X_3(ROH)$, which predominates, according to UV spectroscopic data,[47] in alcoholic solutions of the CuX_2–CuX mixture.

$$P_n(HX) + Cu_2X_3(ROH) \rightleftharpoons Cu_2X_3(ROH)P_n(HX). \quad (35)$$

The two-electron redox decomposition of the surface complex formed in stage (35) leads to the formation of polyphosphonite and metallic copper on the surface.

$$Cu_2X_3(ROH)P_n(HX) \longrightarrow$$
$$\longrightarrow Cu + CuX + P_n(OR)_2HX + 2HX. \quad (36)$$

In the presence of CuX_2, copper dissolves rapidly[49] and is oxidised by O_2 via reaction (37).

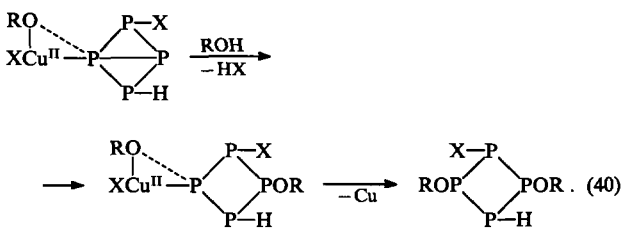
$$4CuCl + O_2 + 4HCl \longrightarrow 4CuCl_2 + 2H_2O. \quad (37)$$

According to ^{31}P NMR spectra,[45] reactions (27) and (28) proceed relatively selectively. Mainly trialkyl and dialkyl phosphates are obtained (chemical shifts of −1 and −2 ppm respectively), while in *iso*-C_3H_7OH peaks corresponding to derivatives of tetracoordinate phosphorus, i.e. $(RO)_2HPO$ (1 ppm), are observed. On the basis of these data, one can postulate that trialkyl phosphate is formed from dialkyl phosphite produced on dealkylation of trialkyl phosphite.

$$(RO)_3P + HCl \longrightarrow (RO)_2HPO + RCl. \quad (38)$$

According to the results of Okamoto et al.,[61,62] dialkyl phosphite is readily oxidised by $CuCl_2$ in alcohol to trialkyl phosphate.

$$(RO)_2HPO + 2CuCl_2 + ROH \longrightarrow$$
$$\longrightarrow (RO)_3PO + 2CuCl + 2HCl. \quad (39)$$



Thus reactions (29)–(37) include acid–base and oxidation-reduction stages. Copper(II) ions oxidise fairly rapidly the surface atoms of red phosphorus by virtue of the high potential of the two-electron Cu(II)/Cu(0) transition, which is 0.34 V. Iron(II), cobalt(II), and manganese(II) carboxylates, for which the potentials of such transitions are low (approximately −0.3 V), do not catalyse the reaction. Iron(III) ions, which tend to undergo only a one-electron transfer, do not exhibit an activity either. A distinctive characteristic of all the oxidants, under the influence of which the oxidative P–O and P–N coupling of low-valence phosphorus compounds to ROH, NRH_2, and H_2O,takes place, is the ability to transfer an even number of electrons.[63]

The acid–base stage is accelerated with increase in the acidity of the medium and of the alcohols (*iso*-$C_5H_{11}OH$ < *iso*-C_4H_9OH < C_4H_9OH ≪ C_3H_7OH < C_2H_5OH < CH_3OH), the pK values for which vary from 19 to 15. However, the oxidation-reduction stage is retarded with increase in the acidity of the medium, which hinders the formation of haloalkoxocopper(II) complexes. In the presence of an excess of Cl^- ions, the penta- and hexa-halo-complexes predominate. These are inactive in reactions (29) and (30) as a consequence of the absence of ROH in the coordination sphere.

On the one hand, water accelerates the acid–base stage owing to the increased acidity (pK_a = 14) and, on the other, it displaces the ROH molecules from the copper(II) complexes. Therefore, on raising the concentrations of HX, H_2O, and LiCl, the rate of formation of organic phosphates passes through a maximum.

The results obtained provide grounds for the assumption that the oxidation-reduction stage (36) takes place in two substages: the insertion of $P_n(HX)$ in the Cu–OR bond and the reductive coupling of the RO^- and $P_n(HX)(OR)^-$ ions with formation of the dialkoxypolyphosphine $P_n(HX)(OR)_2$ and metallic copper. The transition states in both substages have a cyclic structure. This is indicated by the low activation energies (~50 kJ mol^{-1}), negative activation entropies (~ −100 J mol^{-1} K^{-1}), and the nature of the dependence of the rates of reactions (29) and (30) and of the yields of products on the composition of the coordination sphere of copper(II). The subsequent stages in the oxidative alkoxylation of cyclic and linear di- and tetraalkoxypolyphosphines by haloalkoxocopper(II) complexes are fast.

The coordination mechanism (40) of reaction (41) has been investigated quantum-chemically by the CNDO method using the cluster model of adsorption.[59] The organic fragment of the solid (cluster) was used in the cluster models. The rupture of bonds in

(40)

$$P_4(OR)_2(HX) \xrightarrow[-Cu,\ HX]{Cu(OR)_2} P_4(OR)_4 \xrightarrow[-2Cu]{2Cu(OR)_2}$$
$$\longrightarrow 2P_2(OR)_4 \xrightarrow[-2Cu]{2Cu(OR)_2} 4(RO)_3P. \quad (41)$$

the tetraphosphorus clusters was compensated by the formation of bonds between the valence-unsaturated phosphorus atoms via a hydrogen atom (P_4H_2). This is the usual way of taking into account the boundary conditions in small clusters and of eliminating the influence of the bond dissociation between the atom clusters and the solid which is employed in cluster models.[64] It was assumed that the atoms of the tetraphosphorus clusters on the surface have the same structure as in the bulk phase.

In order to select the structure of the cyclic transition intermediate of the inner-sphere reaction (40), use was made of the method proposed by Dorfman et al.,[59] based on the comparison of the energies of the total, covalent, and ionic bonds between the ligands (between the chemically non-bonded atoms of the complex). Calculations were performed for both anionic and cationic clusters with different numbers of anions and molecules in the coordination sphere of copper(II).

The coordination of the tetraphosphorus cluster to the copper(II) ion results in a non-uniform weakening of the P–P bonds of the $P_4(H)_2$ cluster. The coordinated $P_4(H)_2$ cluster becomes an electron acceptor and forms bonds with the inner-sphere ligands (HO, RO, X) having an unshared electron pair after coordination. The ligands, which lose a free electron pair as a result of coordination to copper(II) (H_2O, ROH), react weakly with $P_4(H)_2$.[59] For this reason, the rate of the P–O coupling of P_n to alcohols passes through a maximum as the acidity of the medium is varied (as the HCl concentration in CH_3OH is varied from 0 to 5.6 mol litre^{-1}, the maximum rate is attained at c_{HCl} = 0.6 mol litre^{-1}) and increases with increase in the acidity of ROH. The ligands form the strongest bonds with the P atoms of $P_4(H)_2$ which are not linked to the central atom. In the cationic complexes, the bonds between $P_4(H)_2$ and the ligands are stronger than in the anionic complexes.[59] Therefore the catalytic activity of copper(II) halides passes through a maximum as the number of halide ions in the coordination sphere is varied.[56–59]

V. Oxidative P–O coupling of phosphine to alcohols

Since phosphine reacts poorly with organic substances,[9,10] a considerable amount of the highly toxic PH_3 in phosphorus and hypochlorite factories is burnt in order to achieve detoxification.[11]

As early as 1972, it was observed[46] that PH_3 is absorbed very rapidly by an alcoholic solution of copper(II) chloride. It was later established that PH_3 reacts with alcohol to form the products of oxidative phosphorylation, the nature of which depends on temperature and the nature of the ligand.[8,63,65–79] Under a O_2 atmosphere at 25–70 ° in halide systems ($CuHal_2$), the main reaction product is trialkyl phosphate (yield up to 100%).

$$PH_3 + 2O_2 + 3ROH \longrightarrow (RO)_3PO + 3H_2O; \quad (42)$$

R = CH_3, C_2H_5, C_3H_7, C_4H_9, *iso*-C_4H_9, C_5H_{11}, *iso*-C_5H_{11}, C_8H_{17}, $NH(C_2H_4OH)(C_2H_4)$.

Dialkyl phosphites are obtained from secondary alcohols—for example:

$$PH_3 + 1.5O_2 + 2iso\text{-}C_3H_7OH \longrightarrow (iso\text{-}C_3H_7O)_2HPO + 2H_2O. \quad (43)$$

In carboxylate and sulfate systems [alcoholic solutions of $Cu(RCO_2)_2$ and $CuSO_4$] at 25–70 °, trialkyl phosphites are formed preferentially:

$$PH_3 + 1.5O_2 + 3ROH \longrightarrow (RO)_3P + 3H_2O. \quad (44)$$

In contrast to tetraphosphorus, phosphine forms at 100–150 °C a considerable amount of dialkyl phosphate (up to 98%) in both halide and carboxylate systems.[8]

$$PH_3 + 2O_2 + 2ROH \longrightarrow (RO)_2(HO)PO + 2H_2O. \quad (45)$$

Reactions (42)–(45) can be achieved both by a continuous method involving the supply of a dilute PH_3–O_2–Ar mixture into the reactor and by a periodic method in which a mixture of PH_3 and Ar is initially introduced into the reactor and then O_2 is added.[8,63–70] Under an argon atmosphere at 25–75 ° in halide systems, the absorption of PH_3 is accompanied by the formation of univalent copper and trialkyl phosphate.

$$PH_3 + 8CuX_2 + 2ROH \longrightarrow (RO)_3PO + 8CuX + RX + 7HX; \quad (46)$$

X = Cl, Br.

In the carboxylate and sulfate systems at a low temperature (25–70 °C), trialkyl phosphite and metallic copper are obtained.

$$PH_3 + 2CuY_2 + 3ROH \longrightarrow (RO)_3P + 3Cu + 6HY; \quad (47)$$

Y = SO_4^{2-}, $R'CO_2^-$; R′ = CH_3, C_3H_7, $C_{17}H_{35}$.

At a high temperature (100–150 °C), dialkyl phosphate is formed in both cases.

$$PH_3 + 8CuX_2 + 4ROH \longrightarrow (RO)_2(HO)PO + 8CuX + 2RX + 6HX. \quad (48)$$

$$PH_3 + 4CuY_2 + 4ROH \longrightarrow (RO)_2(HO)PO + 4Cu + 2RY + 6HY; \quad (49)$$

X = Cl, Br; Y = RCO_2, $0.5\,SO_4$.

In the presence of H_2O, reactions involving the oxidative phosphorylation of the alcohol and water take place.

$$PH_3 + 8CuX_2 + ROH + 3H_2O \longrightarrow (RO)(HO)_2PO + 8CuX + 8HX. \quad (50)$$

$$PH_3 + 8CuY_2 + ROH + 3H_2O \longrightarrow (RO)(HO)_2PO + 4Cu + 8HY. \quad (51)$$

The addition of acid (HCl) stimulates the formation of dialkyl phosphate (up to 86%), while the addition of a base (pyridine) stimulates the formation of trialkyl phosphite (at 25–70 °C) and trialkyl phosphate (at 100–150 °C), the yield of the latter increasing to 88 %–100%.[8,63,65–70]

The univalent or metallic copper formed by reactions (46)–(51) is oxidised by oxygen or air via reactions (37) and (52).

$$2Cu + 4HY + O_2 \longrightarrow 2CuY_2 + 2H_2O. \quad (52)$$

Simultaneously with the regeneration of copper(II), alkyl halides and sulfates are hydrolysed to the initial alcohols.

$$RX + 2H_2O \longrightarrow ROH + HX. \quad (53)$$

Alkyl carboxylates do not decompose, accumulating in the system. In the presence of pyridine, the mode of reaction is independent of the nature of the acido-ligand but does depend on temperature. At low temperatures, a reaction of type (47) takes place, whilst at high temperatures the following reaction occurs;

$$PH_3 + 4CuY_2 + 4ROH \longrightarrow (RO)_3PO + 4Cu + RY + 7HY. \quad (54)$$

On dilution of the alcohol with another organic solvent, mainly a dialkyl phosphate is formed. Copper salts are separated from other reaction products by vacuum distillation and can be reused.[8,63–70]

The rate of the oxidative P–O coupling of PH_3 to alcohols also depends on temperature, the nature of the acido-ions, and the concentrations of ROH, CuX, H_2O, HX, and pyridine. Reactions (46)–(51) are autocatalytic and begin only after the accumulation of a certain amount of CuX or CuY. When the initial copper(I) concentration is appreciably lower than the copper(II) concentration, the initial rate is close to zero. With increase in the amount of the absorbed PH_3 and time, the rate of reaction also increases,

reaching a maximum and then falling to zero. The conversion ($W-Q$) and kinetic ($W-\tau$) curves pass through an extremum.[8,63-70] The maximum rate is attained when the current copper(II) and copper(I) concentrations are equal. The conversion curves are described by the equation

$$W = k_1[Cu(II)]^{0.5}[Cu(I)]^{0.5}[PH_3]^{0.5}[ROH]^{0.5}, \quad (55)$$

where k_1 is the rate constant (litre mol^{-1} s^{-1}); $k_1 = (0.2-2.7) \times 10^{-2}$ in the presence of $CuCl_2$, $Cu(C_3H_7CO_2)_2$, and $Cu(C_{17}H_{35}CO_2)_2$ and $k_1 = (0.2-20) \times 10^{-3}$ when the process is catalysed by $CuSO_4$. The rates of reactions (46)–(51) were determined from the consumption of PH_3, copper(II) and from the accumulation of $(RO)_3PO$, $(RO)_2HPO$, $(RO)_2(OH)PO$ and RY.

In a mixed aqueous alcoholic solution of acido-complexes of copper(II), reactions (50) and (51) take place. The rates of these reactions in the $ROH-H_2O-CuY_2-NH_4OH-HX$ system are minimal at pH 2–5. They increase with increase in the concentrations of both NH_4OH and HX.[49] A high yield of trialkyl phosphate (up to 100%) is achieved only in anhydrous systems.[8,63-70] According to UV spectroscopic data, copper(II) complexes of alcohols exist only for a H_2O content less than 10%. As in other organic solvents, in alcohol the stability constants of the copper(II) compounds increase.

On the basis of UV and EPR spectroscopic, magnetic susceptibility, and potentiometric data, one can assume that phosphine is oxidised by acidoalcoholcopper(II) complexes in the halide, sulfate, and carboxylate systems and by acidoammine- and acidopyridinecopper(II) complexes in the ammonia and pyridine systems.[63]

According to ^{31}P NMR spectroscopic data, the products of the incomplete substitution of the H atoms in PH_3 by alkoxy- or hydroxy-groups [the phosphinite $(RO)H_2P$ and the phosphonite $(RO)_2HP$], characterised by chemical shifts in the region of 100 and180 ppm, do not accumulate. Hence it follows that in the rate limiting stage one H atom of PH_3 is substituted by an alkoxy- or hydroxy-group as a result of the two-electron reduction of copper(II) to the zerovalent state.[8,63-70] The subsequent substitution of the remaining H atoms by an alkoxy- or hydroxy-group is rapid. The metallic copper formed is oxidised by copper(II) ions via a reaction of the type:

$$Cu + CuCl_2 \rightleftarrows 2CuCl; \qquad K_c = 8 \times 10^6.$$

Since the products of the incomplete substitution of the H atoms of PH_3 by a functional group, which are characterised by a higher oxidation–reduction potential and in which the ligand properties are more pronounced,[44] are oxidised faster then phosphine, a coordination mechanism of the rate-limiting stage must be postulated.[8,63-70] This is indicated by the low activation energy, the negative entropy, and fractional exponents in Eqn (55).

It follows from the UV spectra and kinetic data that copper(I) ions catalyse the reduction of copper(II) by phosphine as a result of the formation of the dimer Cu_2^{3+}.

Copper(II) and copper(I) ions form the dimeric complexes $Cu_2L_6Y_3$ by virtue of the presence in the coordination sphere of copper of the acido-ions (X^-, Y^-) having an unshared electron pair and capable of functioning as bridges between the two copper atoms. Such complexes, which increase the solubility of copper(I), are formed in both aqueous and non-aqueous media.[44,47] Phosphine, water, pyridine, and ammonia, which have no free unshared electron pair after coordination to copper, cannot serve as bridging ligands and cannot participate in the formation of dimers. Therefore the heteronuclear Cu_2^{3+} dimers predominate in mixed Cu(II)–Cu(I) solutions in the absence of PH_3.[47]

$$CuL_4Y_2 + CuL_2Y \rightleftarrows Cu_2L_6Y_3; \quad (56)$$

L = ROH, H_2O, NH_3, Py.

The catalytic effect of copper(I) is due to its unusual tendency to form complexes with phosphine.[44] Together with other low-valence ions of d^{10} metals [Ag(I), Hg(II), Au(I), Pd(II)], copper(I) ions form stable complexes with PH_3.[44,63] The ions of metals having a different electronic configuration, such as those of copper(II), do not form complexes with PH_3.[44] Apparently copper(II) oxidises the phosphine coordinated to copper(I) via the formation of a dimer.

The oxidative hydroxylation of PH_3 in acid aqueous alcoholic and alcoholic solutions of CuX_2 proceeds via the following key stages:

$$\left[\begin{array}{l} X \\ | \\ Cu_2X_2{-}PH_3 \end{array}\right]^{\neq} \longrightarrow Cu_2X_2(PH_3X) \xrightarrow[-HX]{}$$

$$\longrightarrow Cu + CuX + XPH_2. \quad (57)$$

$$XPH_2 + ROH \longrightarrow (RO)PH_2 + HX. \quad (58)$$

The low activation energy (10–40 kJ mol^{-1}) and the negative activation entropy (−140 to −300 J mol^{-1} K^{-1}) show that PH_3 reacts with the X^- ion in the coordination sphere of the copper atom, forming a three-membered transition state.

In the rate-limiting stage (57), PH_3 is inserted in the Cu–X bond with formation of a phosphorane (or a quasi-phosphonium salt), which decomposes with formation of a halophosphine (XPH_2), Cu(0), and HX. This mechanism agrees with the properties of derivatives of trivalent phosphorus.[48,71-73] A characteristic feature of the latter [PH_3, PR_3, $P(C_6H_6)_3$, $P(OR)_3$, $(RO)H_2P$, $(RO)_2HP$, etc.] is reactions involving the formation of pentacovalent products, in which the phosphorus atom forms with the substrate simultaneously either two σ-bonds or a σ- and a π-bond.[48] An analogous stage in which PR_3 undergoes inner-sphere insertion in the M–O bond is rate-limiting in the reaction where trialkylphosphines are oxidised by oxygen in the presence of platinum, ruthenium, cobalt, iron, rhenium, and copper complexes.[71]

In the synthesis of vinylarenes from alkenes and aryl halides in the presence of $Pd(CH_3CO_2)_2-P(C_6H_5)_3$, the reductive elimination of the aryltriphenyl phosphonium salt is a side reaction,[73] which is accelerated when the aryl halide contains strong electron-donating substituents (a hydroxy- or amino-group).

Since the stability of the phosphonium salt increases with decrease in the number of P–H bonds, the rate of the stage of type (57) increases as the H atoms of PH_3 are replaced by alkoxy- or hydroxy-groups. The alcoholysis of the halophosphine [reaction (58)] is rapid.[48]

In neutral alcoholic and aqueous alcoholic media, the reduction of copper(II) involves a different mechanism. In the key stage of reaction (59), phosphine is inserted in the Cu–OR bond, as a result of which the tricoordinate phosphorus atom is converted into a pentacoordinate atom. The resulting phosphorane decomposes with formation of a phosphinite, zerovalent copper, and HY.[8,63-70]

$$Y_3Cu(ROH)PH_3 \xrightarrow[-HY]{} \left[\begin{array}{l} OR \\ | \\ Y_2Cu_2{-}PH_3 \end{array}\right]^{\neq} \longrightarrow$$

$$\longrightarrow Y_2Cu_2(PH_3OR) \xrightarrow[-HY]{} Cu + CuY + (RO)PH_2. \quad (59)$$

The valence of copper ions does not change on formation of the intermediate phosphorane $Cu_2Y_2(ROPH_3)$. Since the acidity of the phosphorane is appreciably higher than that of PH_3, the redox decomposition is accompanied by the dissociation of a P–H bond. The subsequent oxidation of the phosphinite $ROPH_2$ to trialkyl phosphite is faster than for PH_3.

$$ROPH_2 + 2Cu_2Y_3 + 2ROH \longrightarrow$$

$$\longrightarrow (RO)_3P + 2Cu + 2CuY + 4HY. \quad (60)$$

In alkaline alcoholic media, the phosphine is oxidised by copper(II) ions in a different way. Whereas in neutral media

[reaction (59)] only the coordinated ROH molecule is deprotonated, in alkaline media not only ROH but also the phosphine is ionised [reaction (61)]. In the rate-limiting stage of reaction (61), the reductive elimination of the phosphinite takes place on interaction of the phosphide with the alkoxide ion.

$$Y_3Cu_2(ROH)PH_3 \xrightarrow[-2HY]{} \left[\begin{array}{c} RO \\ | \\ YCu_2 \cdots PH_2 \end{array}\right]^{\neq} \longrightarrow$$

$$\longrightarrow (RO)PH_2 + CuY + Cu. \qquad (61)$$

This mechanism also agrees with the coordination properties of metal phosphides.[71] The acidity of the HZ molecules [Z = OH, OR, NH_2, NR_2, Hal, RCO_2, SH, CN, SR, PH_2, PRH, PR_2, $PO(OR)_2$, $P(OR)_2$, PH(OR), OPH(OR), etc.] increases by several orders of magnitude on complex formation.[74] According to Kukushkina[71] and Dohle et al.,[72] the phosphide ligand bound to osmium, chromium, molybdenum, and tungsten ions and formed on deprotonation of secondary and primary phosphines is alkylated by methyl iodide (an electrophile) or is alkoxylated by an alkoxide ion (a nucleophile).

Pyridine promotes the formation of copper(II) alkoxide and phosphide complexes because it increases the acidity of the coordinated HZ molecules.[54] Pyridine not only influences the mechanism of the inner-sphere reactions of the phosphine–alcohol complexes of copper(II) but also the behaviour of the intermediate organophosphorus compounds. Together with the bands corresponding to the chemical shifts characteristic of trialkyl phosphates, dialkyl phosphates, and trialkyl phosphate complexes of copper(I) (−1, −2, and 15 ppm respectively), the ^{31}P NMR spectra of the reaction products always contain bands typical for dialkyl phosphites (8 ppm).[45] When a secondary alcohol is used, for example *iso*-C_3H_7OH, a dialkyl phosphite becomes the main product. The yield of dialkyl phosphite in the sulfate and carboxylate systems is always higher than in the halide systems.[8,63–70]

It follows from the data presented that trialkyl and dialkyl phosphates are obtained when dialkyl and monoalkyl phosphites, formed on the dealkylation of trialkyl phosphite, are oxidised by copper(II) complexes.

The derivatives of tricoordinate phosphorus $(RO)_3P$ are dealkylated much more readily than the derivatives of tetracoordinated phosphorus $(RO)_2HPO$, (RO)(HO)HPO, $(RO)_2(HO)PO$, and $(RO)_3PO$.[48] The rate of dealkylation falls with increase in the pH of the medium and the length of the hydrocarbon group and on transition from the halide to the carboxylate and sulfate systems. Pyridine and an excess of the alcohol bind HX and HY, forming oxonium and pyridinium salts, and reduce the degree of decarboxylation of trialkyl phosphates.[48]

$$(RO)_3P + HY \longrightarrow (RO)_2HPO + RY. \qquad (62)$$

$$(RO)_2HPO + CuY_2 + ROH \longrightarrow$$
$$\longrightarrow (RO)_3PO + Cu + 2HY. \qquad (63)$$

$$(RO)_2HPO + HY \longrightarrow (RO)(HO)HPO + RY. \qquad (64)$$

$$(RO)(HO)HPO + CuY_2 + ROH \longrightarrow$$
$$\longrightarrow (RO)_2(HO)PO + Cu + 2HY. \qquad (65)$$

It has been shown by kinetic and physicochemical methods that the mechanism of the P–O coupling of PH_3 to the alcohol in the coordination sphere of copper(II) depends on the pH of the medium. In neutral and acid media, phosphine is inserted in the Cu–ligand (X^-, RO^-) bond in the rate-limiting stage with formation of a phosphorane, which decomposes with formation of a phosphinite, acid, and zerovalent copper. In ammonia and pyridine media, which promote the deprotonation of phosphine and the alcohol, the phophinite undergoes reductive elimination in the key stage as a result of the coupling of the phosphide and the alkoxide. In an alkaline medium, the rate of reduction of copper(II) by phosphine increases with increase in the positive charge of the complex, i. e. with increase in the number of NH_3 or pyridine molecules in the inner sphere of copper(II). In acid and neutral media, the rate of reaction increases with increase in the number of acido-ligands, i. e. with increase in the negative charge of the copper(II) complex.[8,63–70]

In order to elucidate the causes of the dependence of the mechanism of the P–O coupling of PH_3 to ROH in the composition of the copper(II) complex, the hypothetical intermediates in reactions (46)–(51), formed in acid, neutral, and alkaline media, and the free PH_3 and ROH molecules were subjected to a detailed quantum-chemical study.

The complexes were investigated by the CNDO [65] and Mulliken–Wolfsberg–Helmholtz (MWH) [75–77] methods. The CNDO method yields a total energy of the complex, from which it is possible to estimate the probability of the formation of the postulated intermediate, the charges on all the atoms (permitting a comparison of the electrophilic and nucleophilic properties of the coordinated molecules), and the total, covalent, and ionic energies of the bonds between all the atoms of the adduct.[78] A program, employing a semiempirical version of the parametrisation of the CNDO method and modified for the investigation of the structures of transition metal complexes, was developed for the calculations.[78] The 3*d*, 4*s*, and 4*p* orbitals of copper(II) and the valence *s* and *p* orbitals of the coordinated molecules were employed as the basis set. A distorted octahedral structure of the copper(II) complexes, in which the reacting molecules (ROH, PH_3) and ions (RO^-, PH_2^-, X^-) are located in the equatorial plane in the *cis*-positions relative to one another, was adopted. The standard geometry of the ligands was assumed.[65]

Alcohols and phosphines are extremely weak OH and PH acids ($pK_a \simeq 15–32$). They are activated by very weak bases in anhydrous solvents[79] and by metal complexes.[71,74] High-valence and low-valence metal cations are required respectively for the activation of alcohols and phosphines. Under the influence of metal complexes, the acid dissociation constants of the PH and OH acids increase by several orders of magnitude.[74] In selecting the intermediates, account was taken of the fact that the composition of the coordination sphere of copper(II) changes as a function of the pH of the medium. Cationic and anionic complexes predominate in ammonia and halide solutions respectively.[54] With increase in the basicity of the medium, there is an increase in the probability of alkoxo- and phosphido-reactions, i. e. reactions that result in the formation of alkoxo- and phosphido-ligands.[54]

In order to investigate the behaviour of the intermediates, the energies of the bonds between the atoms within the coordinated molecules (P–H, O–H), and between the copper atoms and the electron-donating atoms of the ligands (Cu–P, Cu–O, Cu–X), which are ruptured in the reactions involving the oxidative P–O coupling of PH_3 to ROH, were calculated. In addition, the P–O, P–X, H_P–X, H_P–O, H_O–X, H_O–P, H_O–O bond energies in the initial reactants before the formation of chemical bonds in the reactions involving the oxidative P–O coupling of PH_3 to ROH were evaluated (H_O and H_P are hydrogen atoms linked to O and P atoms).[67]

The key stages in the reactions involving the inner-sphere P–O coupling of PH_3 to ROH — insertion and reductive elimination of ligands — proceed via the intermediate formation of a polar many-centre metallacycle in which bonds are dissociated and new ones are formed simultaneously [reactions (57), (59), (61)].

By comparing the energies of the bonds between atoms which are and are not linked chemically, it is possible to find the probable structure of the cyclic many-centre transition state and the direction of the concerted redox decomposition of the intermediate complex and to estimate the influence of the solvent. The energy of the bonds between atoms separated by a distance greater than the sum of the covalent radii is low and is much lower than the energies of chemical bonds.[65]

The behaviour of intermediates in an acid medium was investigated with the aid of copper(II) complexes containing

different numbers of alcohol, phosphine and water molecules and halide ions. The properties of the neutral medium were inferred from the results of calculations for hydroxo- and alkoxo-phosphinecopper(II) complexes. The hydroxo-ligands in these complexes were modelled by sulfate, phosphate, and carboxylate anions. The copper–ammonia and copper–pyridine systems were investigated by means of calculations for the hydroxo- and alkoxo-pyridinephosphinecopper(II) and hydroxo- and alkoxo-aminephosphinecopper(II) complexes. The number of neutral molecules (PH_3, NH_3, Py, H_2O) and anions (PH_2^-, Cl^-, HO^-, RO^-) was varied in such a way that the charge on the complexes changed from +2 to −4.[65]

In the coordination sphere, the weakly polar PH_3 molecule is activated and becomes polar. Whereas in the free PH_3 molecules the effective charges on the P and H atoms are zero, coordination results in the appearance on these atoms of charges which depend on the composition and the overall charge of the complex. In the anionic complexes, the charge on the phosphorus atom is positive, while in the cationic complexes it is negative. The ionic character of the P–H in the coordinated PH_3 molecule is enhanced. On complex formation, the alcohol molecule is activated to a much greater extent. The ionic character of the O–H bond increases significantly as a result of coordination, the effective negative charge on the oxygen atom increases, and there is also an increase in the positive charge on the H atom, which varies as a function of the composition and overall charge of the complex.[65]

The nature of the activation of PH_3 depends to a greater extent on the composition and charge of the complex than in the case of alcohols. Judging from the charge on the phosphorus atom, phosphine acquires nucleophilic and electrophilic reactivity in the cationic and anionic complexes respectively. Judging from the charges on the oxygen atom, the alcohol and water exhibit a nucleophilic activity in both positively and negatively charged complexes. Owing to the relatively weak ionic character of the P–H bond in phosphine compared with the O–H bond in the alcohol, the activity of phosphine depends more on the dielectric constant of the medium.[80] It follows from the comparison of the ionic characters of the P–H and O–H bonds and the charges on the P, O, and H atoms that the hydroxo-reaction is preferable to the alkoxo-reaction and especially the phosphide-reaction. The formation of hydroxide ions in the coordination sphere of copper(II) is more probable than the formation of alkoxide and phosphide ions. The Cu–P, Cu–O and Cu–X bond energies increase sharply on passing from the phosphine and alcohol complexes to the phosphide, alkoxide, and hydroxide complexes. As a result of the deprotonation of phosphine, there is a sharp increase in the ionic character of the Cu–P bonds. Since in polar media ionic bonds are more reactive than covalent bonds,[80] an increase in the amount of ionic character of the bond entails an increase in its reactivity.

In the haloaquophosphinealcohol complexes, which predominate in acid media, the Cu–X bond is most ionic. For this reason, oxidative halogenation of phosphine and alcoholysis of the halophosphine formed take place in acid media [reactions (57) and (58)].[46]

The coordination character of the reaction is stimulated by the bond arising between the ligands. According to quantum-chemical calculations,[65] the coordinated phosphine forms fairly strong bonds with the ligands in anionic copper(II) complexes. Presumably the redox decomposition of the haloaquophosphine-alcohol- and alkoxophosphine-copper(II) complexes takes place as a result of the insertion of PH_3 in the Cu–X and Cu–OR bonds [reactions (57)–(61)].[65]

Cationic copper(II) complexes predominate in ammoniacal and pyridine media.[54] According to the results of a quantum-chemical study,[65] phosphine does not form bonds with the ligands in such complexes. Furthermore in alkaline media, phosphide and alkoxide ligands are produced.[79] Ammine- and pyridine–copper complexes undergo redox decomposition as a result of the interaction between the phosphide and alkoxide ions. The phosphinite formed as a result of the reductive coupling of the phosphide and alkoxide ligands is more readily deprotonated ($pK_a = 15$) than PH_3 ($pK_a = -14$). Phosphinite and phosphonite are therefore more rapidly oxidised by copper(II) ions than phosphine.

The inner-sphere reactions (65) are also promoted by ligands which do not participate directly in the redox decomposition of the intermediate complex.[65] According to quantum-chemical calculations, these ligands form fairly strong bonds with the hydrogen atoms of PH_3 and ROH, offering nucleophilic support to the phosphido- and alkoxo-reactions leading to the formation of phosphide and alkoxide ions in the coordination sphere. Particularly strong bonds are formed between the H atoms of phosphine and the alcohol in the cationic copper complexes.

Thus the mechanism of the activation of phosphine and the alcohol in the coordination sphere of copper(II) has been investigated by the CNDO method. It was shown that the probability of the insertion of PH_3 in the metal–ligand bond and of the reductive coupling of the phosphide and alkoxide ligands can be estimated from the energy of the bond between the reacting ligands. In acid and neutral media, which promote the formation of anionic copper(II) complexes, phosphine is inserted in the metal–ligand bond in the key stage: in ammonia and pyridine solutions, which ensure the formation of cationic complexes, the reductive coupling of the phosphide and alkoxide ligands takes place in the rate-limiting stage.

VI. Oxidative P–C coupling of phosphine to alcohols

A whole series of new organic reactions with participation of platinum(II) and platinum(IV) halides, e.g. the oxidation of alkanes, arenes, olefins, alcohols, carbon monoxide, etc., have been observed in recent years.[81–86] The oxidising activity of platinum(II) and platinum(IV) halides as a rule varies in parallel with the kinetic constants for the exchange of ligands and the thermodynamic stability constants and antiparallel to the redox potentials and Pt–X bond energies.[81–87] Platinum(II) halides usually catalyse the reduction of platinum(IV) by various substrates via the formation of dimers containing platinum(II) and platinum(IV). New reactions involving the oxidative alkoxylation and hydroxyalkylation of phosphine have been described.[63,88–90]

$$PH_3 + 3Na_2PtCl_6 + 3ROH \longrightarrow \longrightarrow 3Na_2PtCl_4 + (RO)_3P + 6HCl; \quad (66)$$

R = CH_3, C_2H_5, C_3H_7, C_4H_9, *iso*-C_4H_9, C_5H_{11}, *iso*-C_5H_{11}, C_8H_{17}.

$$PH_3 + 3RCH_2OH + 1.5Na_2PtCl_6 \longrightarrow \longrightarrow (RCH_2)(RCHOH)_2PO + 1.5Pt + 3NaCl + 6HCl. \quad (67)$$

$$PH_3 + 4RCH_2OH + 2Na_2PtCl_6 \longrightarrow \longrightarrow (RCH_2O)_3PO + 2Pt + 4NaCl + RCH_2Cl + 7HCl; \quad (68)$$

R = C_3H_7, C_4H_9, *iso*-C_4H_9.

When a PH_3–Ar gas mixture, even one containing only traces of phosphine, is passed at 25–150 ° through an alcoholic solution of the Na_2PtCl_6 complex, known to be very inert and stable,[87] trialkyl phosphites (at 25–70 °) as well as trialkyl phosphates and tertiary phosphine oxides (at 90–150 °C) are formed.[88,89]

The new reactions are very rapid. Reaction (66) terminates after the reduction of platinum(IV) to platinum(II), whilst reactions (67) and (68) terminate after the reduction of platinum(IV) to zerovalent platinum, which is precipitated as a black fine-grained deposit on the bottom of the reactor. During the absorption of PH_3 by an alcoholic solution of Na_2PtCl_6, the redox potential (φ) of the Pt(IV)/Pt(II) couple shifts in the cathodic direction.[88,89]

The changes in the PH_3–Na_2PtCl_6–ROH system are analysed in terms of the nature of the conversion ($W-Q$), kinetic ($W-\tau$), and potentiometric ($\varphi-Q$, and $\varphi-\tau$) curves. The conversion and kinetic curves pass through a maximum in all cases.

The rate of reaction (66) is described by the equation

$$W = k_1[\text{Pt(IV)}]^{0.5}[\text{Pt(II)}]^{0.5}[\text{PH}_3]^{0.5}[\text{ROH}]^{0.5} \quad (69)$$

After the reduction of platinum(IV) to platinum(II), the spent solution is readily regenerated with a dilute Cl_2–Ar gas mixture.

$$NaPtCl_4 + Cl_2 \longrightarrow Na_2PtCl_6. \quad (70)$$

During the regeneration of platinum, trialkyl phosphites are oxidised to the phosphates.

$$(RO)_3P + Cl_2 + ROH \longrightarrow (RO)_3PO + RCl + HCl. \quad (71)$$

The kinetic parameters of reactions (67) and (68) are characterised by a more complex formula:

$$W = k_1[\text{PH}_3]^{0.5}[\text{ROH}]^{0.5}([\text{Pt(IV)}]^{0.5}[\text{Pt(II)}]^{0.5}) + k_2[\text{Pt(II)}], \quad (72)$$

where k_1 and k_2 are the rate constants (litre mol^{-1} s^{-1}).

It follows from Eqns (69) and (72) that reactions (66)–(68) proceed in the coordination spheres of dimeric and mixed haloalkoxophosphineplatinum(IV) and the corresponding platinum(II) complexes. As platinum(IV) is reduced to platinum(II), the colour of the solution changes from bright orange to dark brown, which indicates the formation of heterovalent platinum complexes.[80] The coordination mechanism of reactions (66)–(68) is indicated by the low activation energies ($E^{\neq}$ = 28–56 kJ mol^{-1}) and entropies ($\Delta S^{\neq}$ = −140 to −20 J mol^{-1} K^{-1}), the fractional order with respect to the reactants [Pt(IV), PH_3, ROH)], the negative influence of H_2O, HCl, and NaCl, and the positive influence of NaBr, NaI, and platinum(II). Platinum(II) iodides and bromides catalyse the insertion of PH_3 and ROH in the coordination spheres of platinum(IV) chlorides.[87]

At a low temperature, the products [$(RO)_3P$ and Pt(II)] form the stable complexes [$Pt(P(OR)_3]/PtCl_4$, which are insoluble in alcohols. The composition of the complexes was established by X-ray [powder? PCMA in Russian (Ed. of Translation)] diffraction and X-ray photoelectron and IR spectroscopic methods.[88,89] The intermediate organophosphorus compounds, formed at a high temperature, were investigated by ^{31}P NMR spectroscopy.[45] Analysis of the reaction medium during the experiment demonstrated the occurrence of chemical shifts characteristic of $(RCH_2O)_3P$ (95–100 ppm), $(RCHOH)_3P$ (−40 to −30 ppm), $(RCH_2)(RCHOH)_2PO$ (40–50 ppm),$(RCH_2O)_2HPO$ (4–8 ppm), and $(RCH_2O)_3PO$ (−3 ppm).[45] Hence it follows that trialkyl phosphates are formed in the following way:

$$Pt_2X_5(PH_3)(RO)^- \longrightarrow 2PtX_2 + (RO)PH_2 + HX. \quad (73)$$

$$Pt_2X_5(ROPH_2)(RO) \longrightarrow 2PtX_2 + (RO)PH + HX. \quad (74)$$

$$Pt_2X_5[(RO)_2PH](RO) \longrightarrow 2PtX_2 + (RO)_3P + HX. \quad (75)$$

$$PtX_2[(RO)_3P] + HX \longrightarrow PtX_2[(RO)_2HPO] + RX. \quad (76)$$

$$Pt_2X_5[(RO)_2HPO](RO) \longrightarrow 2PtX_2 + (RO)_3PO + HX. \quad (77)$$

According to Eqns (73)–(77), the alcohol is activated as a result of deprotonation and the formation of the covalent Pt–O bond.[91] Reactions (74)–(77) are faster than reaction (73), since, in contrast to phosphine, phosphinite, phosphonite, and phosphite readily form complexes with platinum(IV) and platinum(II).[92,93] Platinum(II) promotes not only the insertion of PH_3 and ROH into the coordination sphere of platinum(IV) [87] but also the dealkylation of trialkyl phosphites.[92,93] Thus the hydrolysis of $(CH_3O)_3P$ in water at 25 °C takes more than 40 h, whilst in the presence of K_2PtCl_6 it reaches completion instantaneously.[92] Whereas the conversion of trialkyl phosphite into dialkyl phosphite [reaction (76)] is rapid, the subsequent hydrolysis of dialkyl phosphite is slow even in the presence of platinum(II).[92]

Since the phosphine chlorination products (PCl_3 and PCl_5), characterised by chemical shifts of 220 and −80 ppm respectively,[45] were not detected, presumably trialkyl phosphites are formed under the influence of platinum(IV) via the successive substitution of the hydrogen atoms of phosphine by alkoxy-groups, dealkylation of trialkyl phosphite to dialkyl phosphite, and the substitution of the hydrogen atoms in dialkyl phosphites by alkoxy-groups. Phosphine, phosphinite phosphonite, and dialkyl phosphite are inserted in the Pt–O bond, forming a phosphorane.

Phosphine, phosphinite, phosphonite and dialkyl phosphite behave similarly to unsaturated compounds (olefins, carbon monoxide), which typically undergo insertion in the metal–ligand bond.[74,81,82,94,95] Since the stability of the phosphorane increases as the hydrogen atoms of phosphine are replaced by a functional group,[48] the reactions involving the oxidation of phosphinite, phosphonite, and dialkyl phosphite by platinum(IV) are faster than the oxidation of phosphine.[88,89] The driving forces of reactions (78) are the appreciable Pt(IV)/Pt(II) redox potential and the high P–O bond energy. Similarly, trialkyl phosphates are formed from phosphine on treatment with platinum(II), but the reaction is faster, since platinum(II) halides enter relatively easily into ligand exchange, in contrast to platinum (IV) halides.[87]

$$\left[\begin{array}{l} RO \\ X_5Pt_2{-}PH_3 \end{array}\right]^{\neq} \longrightarrow X_5Pt_2(PH_3OR) \longrightarrow$$

$$\longrightarrow 2PtX_2 + (RO)PH_2 + HX. \quad (78)$$

According to ^{31}P NMR spectroscopic data, alkyl(dihydroxyalkyl)phosphine oxide is obtained from tri(hydroxyalkyl)phosphine.

$$(RCHOH)_3P \longrightarrow (RCHOH)_2(RCH_2O)P \longrightarrow$$

$$\longrightarrow (RCHOH)_2(RCH_2)PO.$$

Tri(hydroxyalkyl)phosphines with electron-donating substituents isomerise to tertiary phosphine oxides, in contrast to tri(hydroxyalkyl)phosphines with electron-accepting substituents, which are converted into phosphites.[9]

Tri(hydroxyalkyl)phosphine can be obtained from phosphine and the alcohol on treatment with platinum(IV) and platinum(II) halides. In the rate-limiting stage, a hydrogen atom of phosphine is replaced by a hydroxyalkyl group. The subsequent substitution of the hydrogen atoms of primary and secondary phosphines by a hydroxyalkyl group proceeds similarly but faster, since, in contrast to phosphine, alkylphosphines are readily coordinated to platinum(IV).[93] There are no chemical shifts characteristic of primary (−60 ppm) and secondary (−140 ppm) phosphines in the ^{31}P NMR spectra.[45]

$$Pt_2X_6(PH_3)(RCH_2OH) \rightleftharpoons Pt_2X_4(PH_2)(RCHOH) + 2HX. \quad (79)$$

$$Pt_2X_4(PH_2)(RCHOH) \longrightarrow 2PtX_2 + PH_2(RCHOH). \quad (80)$$

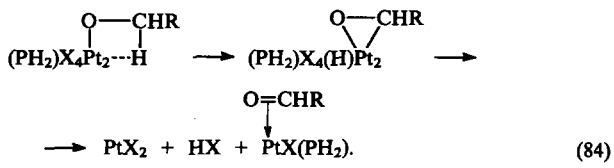
$$Pt_2X_4(PH_2)(RCHOH) \rightleftharpoons Pt_2X_3(PH_2)(\eta^2\text{-RCHO}) + HX. \quad (81)$$

$$Pt_2X_3(PH_2)(\eta^2\text{-RCHO}) \xrightarrow[-PtX_2]{HX}$$

$$\longrightarrow PtX(PH_2)(RCHO) \longrightarrow PH_2(RCHOH). \quad (82)$$

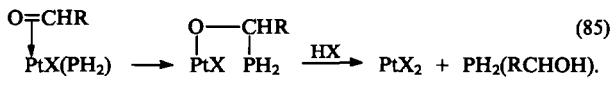
The alcohol is activated by the β-elimination of hydrogen, the formation of a bidentate (η^2-type) aldehyde bound to the metal,[94,95] and the formation of the organometallic Pt–C bond.[81,82] The β-elimination reactions are typical for transition metal compounds.

The β-hydrogen atoms are eliminated on treatment with either the metal, or nucleophiles, or electrophiles. The stabilisation of the transition state by the π-bond formed renders the β-position extremely reactive.[95]



$$\begin{array}{l} HOHRC{-}H \\ (PH_2)X_5Pt_2 \end{array} \xrightarrow[-HX]{} X_4(PH_2)Pt_2(RCHOH) \longrightarrow$$

$$\longrightarrow PH_2(RCROH) + 2PtX_2. \quad (83)$$



Mono(hydroxyalkyl)phosphine is formed as a result of the insertion of PH_3 in the Pt–C bond. Platinum(II) behaves similarly to platinum(IV), but all the stages involving platinum(II) are faster.[88,89]

The hydroxyalkylation of phopshine takes place as a result of the oxidation of the alcohol by platinum(IV) to the aldehyde and subsequent addition of phosphine to the carbonyl compound.

Studies have shown that reaction (84) without PH_3 proceeds very slowly,[85,86] whilst reaction (85) in the presence of platinum(IV) and platinum(II) occurs only when concentrated phosphine is employed.[9]

(84)

(85)

Reactions (66)–(68) take place not only in alcoholic but also in alcohol–pyridine solutions of Na_2PtCl_6. The pyridine complexes of platinum(IV) and platinum(II) activate PH_3 and ROH via deprotonation.

Phosphinite is formed as a result of the inner-sphere coupling of the ligands (the phosphide and alkoxide), the reaction being promoted by pyridine, which is a powerful π-acceptor.[54]

$$Pt_2X_4Py_2(PH_2)(RO) \longrightarrow 2PtX_2 + PH_2OR. \quad (86)$$

In a quantum-chemical study of the mechanism of the interaction of phosphine with the alcohol, the energies (total, covalent, and ionic) of the bonds between all the atoms of the platinum(IV) and platinum(II), containing different numbers of molecules (H_2O, ROH, NH_3, Py, PH_3) and ions (PH_2^-, RO^-, HO^-, X^-), were calculated by the CNDO method.[90] The total, covalent, and ionic bond energies were evaluated using the method described by Fischer and Kollmar.[78] Phosphine, the alcohol, and water in the coordination sphere of platinum(IV) and especially platinum(II) are appreciably activated as a result of the increase in the amount of ionic character of the P–H and O–H bonds, which increase the reactivity of molecules in polar media.[80] The energy of the bond between the alkoxide ion and phosphine increases on passing from platinum(IV) to platinum(II).[90] Platinum(II) activates the P–H dissociation process via the formation of the $Pt-H_P$ single bond. The deprotonation of the alcohol activates the halide ions, promoting the formation of the $X-H_O$.[90]

The mechanism of the reduction of platinum(IV) to platinum(II) by phosphine, including the stage in which PH_3 is inserted in the Pt–OR bond, operates only in alcoholic media, which promote the formation of ionic complexes distinguished by a high energy of the bond between the phosphorus atom of phosphine and the oxygen atom of the alkoxide ion. The mechanism of the oxidation of phosphine by platinum(IV) and platinum(II), including the stage in which the phosphide and alkoxide ions are coupled, operates only in alcohol–pyridine systems, where cationic complexes predominate. These are distinguished by the appreciable energy of the bond between the phosphorus and oxygen atoms of the phosphide and alkoxide ions.[90]

In order to elucidate the mechanism of the catalysis by platinum(II) complexes of the reduction of platinum(IV) by phosphine [reactions (66)–(68)], the quantum-chemical molecular orbital perturbation (MOP) method was used. The bond energy between atoms separated by a distance greater than the sum of the covalent radii was calculated by the MOP method, which had been first applied in the estimation of the reactivities of ligands.[75–77] The bond energy proved to be appreciably lower than the energies of chemical bonds.[96–98] By comparing the energies between the atoms of the intermediate complex which are not linked chemically, it was possible to find the probable structure of the multi-centre cyclic transition state.[96] The higher the bond energy between atoms not linked chemically (the more negative the stabilisation energy), the greater the probability of the chemical bond between them in the transition state.[97,98]

The stabilisation energies have been calculated by the MOP method for reactions in which the coordinated phosphine is the electron acceptor, while the alcohol (or the alkoxide ion) is the electron donor, and also for reactions where phosphine is the electron donor and the alcohol (alkoxide or chloride ion) is the electron acceptor.[67] On coordination to platinum(IV), phosphine is activated. The negative charge on the oxygen atom and the positive charge on the phosphorus atom increase. As a result of coordination, phosphine acquires electron-accepting properties, while the electron-donating properties of the alcohol are enhanced. In the case where PH_3 is the acceptor and the alcohol is the donor, the stabilisation energy is more negative than in the case where the above ligands act in the opposite directions. It becomes more negative when ROH is replaced by RO^- and Cl^- is replaced by Br^- and I^- ions.[67]

The stabilisation energies have been calculated by the MOP method for the reactions of phosphine coordinated to platinum(II) with the alcohol bound to platinum(IV) and of phosphine bound to platinum(IV) with the alcohol coordinated to platinum(II). It was found that the perturbation energies for the inner-sphere reactions are appreciably higher than for the outer-sphere reactions. Hence it follows that the reaction between phosphine and the alcohol occurs in the coordination sphere of platinum(IV), while platinum(II) catalyses the formation reactions of the platinum(IV) complexes of haloalkoxyphosphines by accelerating the ligand exchange processes.[87]

VII. Oxidative P–O coupling of phosphine to alcohols in the presence of chlorine

The reactions of chlorine with the halogens in aqueous media and in the gas phase have been investigated in fair detail.[99–102] It has been observed[49] that, on chlorination of PH_3 in an alcohol at 50–70 °C, trialkyl phosphate is formed rapidly and in a high yield.

$$PH_3 + 4Cl_2 + 4ROH \longrightarrow (RO)_3PO + RCl + 7HCl; \quad (87)$$

R = C_4H_9, *iso*-C_4H_9, C_5H_{11}, *iso*-C_5H_{11}.

At a low temperature (8–25 °C), reaction (87) takes place in the presence of pyridine.[49]

The development of the reaction via a branched-chain mechanism was suppressed by using dilute gaseous PH_3–Ar and Cl_2–Ar mixtures, which were mixed separately with the alcohol in a preliminary step. Phosphine and chlorine entered the reactor in a countercurrent, so that there was a high PH_3 concentration and a low Cl_2 concentration at the inlet to the reactor, while at the outlet the opposite situation obtained — a high Cl_2 concentration and a low PH_3 concentration. The rate of supply of Cl_2 and PH_3 was regulated by means of the Cl_2/Cl^- chlorine electrode potential.[103] For this purpose, the reactor was fitted with a potentiometric device consisting of platinum and calomel half-cells. The latter contained only Hg, Hg_2Cl_2, and a ground joint as the electrolytic bridge. Such a calomel electrode, without the traditional agar–agar bridge, did not break at high temperatures and did not affect the composition of the liquid phase.

The introduction of PH_3 into an alcoholic solution of Cl_2 is accompanied by a sharp shift of the potential in the cathodic direction up to a value which depends on the ratio Cl_2/PH_3 in the gas phase. On reducing the rate of supply of PH_3 or on increasing that of Cl_2, the potential shifted synchronously in the anodic direction, whilst on raising the rate of supply of PH_3 or reducing that of Cl_2 the shift was in the cathodic direction. Therefore the potentiometric method made it possible to follow continuously, during the experiment, the PH_3/Cl_2 ratio in the liquid phase and the reactivity of the system.[46]

The yield of alkyl phosphates in reactions involving different alcohols remained high up to high degrees of conversion of the alcohol. Chlorine reacted preferentially with phosphine and hardly reacted with the alcohol, since the rate constant for the chlorination of an alcohol is relatively low.[103]

The mechanism of reaction (87) was investigated by ^{31}P NMR spectroscopy.[45] Only trialkyl phosphate with a chemical shift of -2 ppm was formed in an excess of the alcohol. In the presence of a deficiency of the alcohol, small peaks due to the pentacoordinate phosphorus derivatives PCl_5, Cl_3PO, $(RO)_2ClPO$, $(RO)_4PCl$, $(RO)_3PCl_2$ (-40, 5, 4, -8, and -27 ppm respectively) appeared apart from the high $(RO)_3PO$ peak (-2 ppm). The tricoordinate phosphorus derivatives PCl_3, $(RO)_2PCl$, $(RO)_3P$ (219, 170, and 140 ppm) and pentaalkoxyphosphorus $(RO)_5P$ (-80 ppm) were not detected. Hence it follows that reaction (87) takes place with the rapid formation and subsequent reactions of phosphorus pentachloride.

The most important feature of the reactions of PCl_5 with alcohols as well as other hydroxylated compounds is the preliminary formation of phosphoryl chloride [reaction (89)]. The rate of the subsequent alcoholysis of Cl_3PO increases with increase in the pH of the medium.[48] This sequence of the reactions of PCl_5 with ROH and H_2O is caused by the formation of the stable phosphoryl group $P=O$.[48] The reactions of phosphoryl chlorides with H_2O and ROH take place as stepwise elimination of HCl [reactions (90) and (91)][104] and are accelerated in the presence of HCl binding agents (an excess of ROH and pyridine).[48] In the presence of a deficiency of the alcohol, reaction (92), leading to the formation of dialkyl phosphates, predominates.[104]

$$PH_3 + 4Cl_2 \longrightarrow PCl_5 + 3HCl. \quad (88)$$

$$PCl_5 + ROH \longrightarrow Cl_3PO + RCl + HCl. \quad (89)$$

$$Cl_3PO + 2ROH \longrightarrow (RO)_2ClPO + HCl. \quad (90)$$

$$(RO)_2ClPO + ROH \longrightarrow (RO)_3PO + HCl. \quad (91)$$

$$(RO)_2ClPO + ROH \longrightarrow (RO)_2(HO)PO + RCl. \quad (92)$$

By virtue of the very high rate and selectivity, reaction (87) can be applied to utilise even trace amounts of PH_3 and Cl_2.

VIII. Oxidative P–N coupling of phosphine to primary and secondary amines

The P–N coupling of primary and secondary phosphines to primary and secondary amines proceeds under severe conditions (only in the presence of formaldehyde) with formation of aminomethylation products.[9] The reaction involving oxidative P–N coupling of phosphine to primary and secondary amines, discovered by Dorfman et al.,[53] yields triaminophosphazoalkyls.

$$PH_3 + 4RH_2N + 4CuY_2 \longrightarrow (RHN)_3P{=}NR + 4Cu + 8HY. \quad (93)$$

$$PH_3 + 4R_2HN + 4CuY_2 \longrightarrow (R_2N)_3P{=}NR + 4Cu + 7HY + RY; \quad (94)$$

R = C_2H_5, $C_6H_5CH_2$, C_6H_{11}, .

A solution of CuY_2 in a primary or secondary amine at 15–30 °C rapidly absorbs even traces of PH_3 from the PH_3–Ar gas mixture.[53] When the reaction takes place in argon, phosphine is selectively converted into triaminophosphazoalkyl and copper(II) ions are reduced to zerovalent copper. The zerovalent copper formed by reactions (93) and (94) is almost instantaneously oxidiised by air. The following reactions take place in the presence of O_2:

$$PH_3 + 4RH_2N + 2O_2 \longrightarrow (RHN)_3P{=}NR + 4H_2O. \quad (95)$$

$$PH_3 + 4R_2HN + 2O_2 \longrightarrow (R_2N)_3P{=}NR + 3H_2O + ROH. \quad (96)$$

The rates of reactions (93) and (94) depend significantly on temperature and the concentrations of the reactants (CuY_2, RH_2N, R_2HN, PH_3) and reaction products [H_2O, CuX, $(RHN)_3P{=}NR$, $(R_2N)_3P{=}NR$]. The influence of the concentrations of the above substances on the reaction rate is described by the equation

$$W = k[Cu(II)]^{0.5}[Cu(I)]^{0.5}[PH_3]^{0.5}[RNH]^{0.5}, \quad (97)$$

where k is the rate constant (litre $mol^{-1}\,s^{-1}$). Pyridine is an effective solvent for reactions (93)–(96), which are two orders of magnitude faster in it.[53]

The fractional orders with respect to the reactants, the low activation energy ($E^{\neq}$ = 34 kJ mol^{-1}) and entropy ($\Delta S^{\neq} = -7160$ J $mol^{-1}\,K^{-1}$), and the negative influence of H_2O indicate a coordination mechanism for the rate-limiting stage. Only the products of the interaction of PH_3 with the components forming part of the composition of the coordination sphere of copper(II) are formed.

The composition of the copper(II) complexes in amines has been investigated by UV and IR spectroscopy.[80] The electronic spectra of solutions CuY_2 (Y = Cl, Br, OAc, RCO_2, etc.) in $C_6H_5CH_2NH_2$ contain an absorption band at 670 nm, indicating the identity of their structures regardless of the nature of the ligands. According to IR spectroscopic data, $Cu(OAc)_2$ induces a shift of the N–H absorption band from 1600 to 1550 cm^{-1} and the appearance in the stretching region of a new set of bands at 3210, 3290, 3320 and 3360 cm^{-1}. The decrease in the stretching vibration frequency of the carboxylate ion from 1405 to 1570 cm^{-1} indicates a decrease in the Cu–O bond order as a result of the formation of bridges in the dimeric copper(II) complexes. An additional absorption band at 660 cm^{-1}, due to the formation of the amide bond following the addition of benzylamine to the copper(II) ion, arises in the IR spectra of the complexes.

The nature of the intermediate organophosphorus compounds was investigated by ^{31}P NMR spectroscopy.[45] After the reduction of copper(II) with phosphine to copper(I), the regeneration of copper(II) with air, and the precipitation of copper ions with KI, the spectra of solutions of $Cu(OAc)_2$ and $CuCl_2$ in $C_6H_5CH_2NH_2$ and $C_2H_5NH_2$ contain only the bands at 30 and 20 ppm characteristic of phosphorous triamides. The products of the incomplete substitution of the hydrogen atoms of phosphine by amino-groups (phosphinamidite and phosphonamidite) do not accumulate. Characteristic narrow bands at 1000–1100 cm^{-1} (P–N); 1600, 1490, and 1450 cm^{-1} (C–H in C_6H_5); 3215, 3245 and 3230 cm^{-1} (N–H), and 695 and 740 cm^{-1} (H–C) were observed in the IR spectra of the product obtained in $C_6H_5CH_2NH_2$. The accumulation of HCl was inferred from the 2500–2700 cm^{-1} band and that of H_2O was inferred from the intense broad band at 3400, 1640 cm^{-1} (O–H). Hydrogen chloride appears as a result of reactions (93) and (94) and water is formed during the regeneration of the spent copper(II) solution with oxygen. According to IR spectroscopic data, amines are hardly oxidised by copper(II) chlorides and acetates. Amines are also not chlorinated by copper(II) chlorides.[53]

In solutions in primary and secondary amines, the reduction of copper(II) by phosphine includes the stage involving the deprotonation of the substrates.

Ammonia, amines, and phosphine are very weak NH and PH acids ($pK_a \simeq 31-35$) and are activated by strong bases in anhydrous solvents[79] and by metal complexes.[74] The activation of amines requires the high-valence Ti(IV), Pt(IV), Au(III), Rh(III), and Ir(III) metal cations,[74] while that of phosphines requires the low-valence Cu(I), Ag(I), Au(I), Hg(II), and Pd(II)metal cations.[63] The tendency of amines to enter into reactions involving the formation of amino- and phosphino-ligands on treatment with metal complexes becomes enhanced with increase in basicity on passing from ammonia to primary and secondary amines[54] and from phosphine to primary and secondary phosphines. Under the influence of metal complexes, the acid

dissociation constants of the PH and NH acids increase by several orders of magnitude.[74]

$$Cu_2X_3(R_2HN)_6PH_3 \longrightarrow Cu_2X(R_2HN)_5(PH_2)(R_2N) + 2HX. \quad (98)$$

The acid properties of coordinated amines and apparently phosphines increase by several orders of magnitude with increase in their number in the inner sphere or after the introduction of pyridine into the latter.[54] Pyridine therefore proved to be a convenient solvent for the oxidative P–N coupling of amines to phosphine.[53] The stepwise formation constants of the amine complexes of copper(II) and copper(I) are independent of the nature of the amines, but they are two orders of magnitude higher than the values of the constants of the pyridine complexes of copper(II) and copper(I) and for this reason the copper(II) and copper(I) ions contain the amine over a wide range of amine/pyridine ratios. This is indicated also by potentiometric data. The addition of amines to a pyridine solution of CuX_2 shifts the potential of the Cu(II)/Cu(I) couple in the cathodic direction. An amine does not inhibit reactions (93) and (94), whereas pyridine accelerates them, since it stimulates the amido- and phosphido[proton-loss]-reactions. The aminophosphino-copper(II) complexes undergo redox decomposition with formation of phosphinous amide.

Reaction (99), involving the reductive coupling of the phosphino- and amino-ligands, is consistent with the known tendency of the P–N bonds in organophosphorus compounds to dissociate under the influence of metal complexes with formation of oxidative addition products.[71] The mechanism of the reductive P–N coupling of phosphine to amine has been investigated by the CNDO method.[78]

$$Cu_2X(R_2HN)_5(PH_2)(R_2N) \longrightarrow$$
$$\longrightarrow Cu + CuX(R_2HN)_2 + 3R_2NH + R_2NPH_2. \quad (99)$$

The configurations of the PH_3 and NH_3 molecular orbitals are as follows: PH_3 $(a_1^2e^42a_1^22e^03a_1^0)$, NH_3 $(a_1^2e^42a_1^23a_1^02e^0)$.[98,105] In contrast to NH_3, the $2e$ orbital of PH_3 has a lower energy than $3a_1$, which indicates the inclusion of the $3d$ orbitals of phosphorus in the basis set, since the $2e$ molecular orbital has in the main $3d$ character. According to Pearson,[98] inversion in amines takes place readily, in contrast to phosphines, the barriers for NH_3 and PH_3 being respectively 5.2 and 37.2 kcal mol^{-1}. In the NH_3, PH_3, AsH_3, SbH_3 series, the ionisation potentials of the molecules change very little,[98] despite the fact that the energies of the atomic orbitals of the heteroatoms increase monotonically. In the above series of hydrides, the mixing of the s and p orbitals of the heteroatoms diminishes, which leads to an increase in the $2a_1 \rightarrow 3a_1$ energy difference, the stabilisation of the pyramidal form, the narrowing of the bond angle NH_3 (108°), PH_3 (93°)], a decrease in basicity [NH_3 (pK_a = 9.2), PH_3 (pK_a = −14)], and an increase in the total bond energy and in the positive charge on the heteroatom. For this reason, PH_3 differs from NH_3 by an appreciably lower reactivity.[63]

The weakly polar PH_3 molecule is activated in the coordination sphere and becomes polar. Whereas the effective charge on the phosphorus and hydrogen atoms in the free PH_3 molecule is zero, after coordination a charge, which depends on the composition and the total charge of the complex, arises on these atoms. In the anionic complexes, the charge on the phosphorus atom is positive, whilst in the cationic complexes it is negative. The ionic character of the P–H bond in the coordinated PH_3 molecule becomes more pronounced.

On complex formation, the amine molecule is activated to a much greater extent than the PH_3 molecule. As a result of coordination, there is a significant increase in the amount of ionic character of the N–H bond and negative and positive charges increase on the nitrogen and hydrogen atoms respectively, varying as a function of their composition and the overall charge of the complex.

The nature of the activation of PH_3 depends more on the composition and charge of the complexes than that of the activation of amines. Judging from the effective charge on the phosphorus atom, in the cationic and ionic complexes phosphine acquires nucleophilic and electrophilic reactivity respectively. Judging from the charges on the nitrogen atom, amines exhibit a nucleophilic reactivity in both positively and negatively charged complexes. Since the N–H bond is more polar than the P–H bond, the formation of amide ions in the coordination sphere of copper(II) is more realistic than the formation of phosphide ions.

The Cu–P and Cu–N bond energies increase sharply on passing from phosphine and amine complexes to phosphide and amide complexes. As a result of the deprotonation of the substrates, the amount of the ionic character of the metal–ligand bonds, especially the Cu–P bond, increases.

Since cationic copper(II) complexes, in which phosphine does not form bonds with the ligands, predominate in amine media, the mechanism which rules out the formation of phosphide and amide ions and their reductive coupling with formation of phosphinous amide predominates in the reactions. A three-centre transition state, characterised by a low activation energy and a negative activation entropy, is formed in the rate-limiting stage.

$$(R_2HN)_4Cu(R_2N)(PH_2) \longrightarrow \left[(R_2HN)_4Cu \begin{matrix} NR_2 \\ \diagdown\ \diagup \\ PH_2 \end{matrix} \right]^{\neq} \longrightarrow$$
$$\longrightarrow Cu + R_2NPH_2 + 4R_2HN. \quad (100)$$

Similarly phosphinous amide is oxidised by copper(II) ions to phosphonous diamide and the latter is oxidised to phosphorous triamide, but the reaction is faster since phosphinous amide and phosphonous diamide have a higher acidity ($pK_a \simeq 15$) than phosphine ($pK_a = -14$).[48]

Ligands which do not participate directly in the redox decomposition of the intermediate complex render considerable assistance in activating the substrates. According to CNDO data, these ligands form fairly strong bonds with the hydrogen atoms of PH_3, R_2HN, and RH_2N and are involved in nucleophilic cooperation with the amido- and phosphido-reactions, which lead to the appearance of amide and phosphide ions in the coordination sphere. Specially strong bonds are formed between the hydrogen atoms of phosphine and the amine in cationic complexes.

The driving forces of reactions (93)–(96), in which phosphine undergoes oxidative amination and oxidative imination, are the difference between the P–N and P=N bond energies as well as the high Cu(II)/Cu(0) redox potential, which increases after the addition of pyridine.[54] In contrast to trialkyl phosphites, phosphorous triamides are readily oxidised by oxygen and sulfur. They form stable pseudophosphonium salts because the P=N bond energy is appreciably lower than the P=O bond energy.[48] The state of the P=N bond depends on the electronegativity of the substituents at the nitrogen and phosphorus atoms. The multiplicity of the P=N bond increases with increase in the electronegativity of the substituents at the phosphorus atom and with decrease in the electronegativity of those at the nitrogen atom.[50,51]

IX. P–C coupling of phosphine to aldehydes

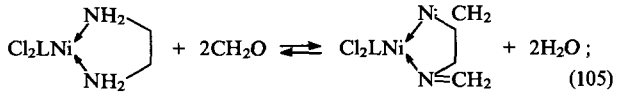
Reactions involving the P–C coupling of phosphine to carbonyl compounds lead to phosphines with functional group substituents.[9,106,107] It has been shown[108–110] that, when concentrated phosphine is passed through an aqueous solution of aldehydes and ethylenediaminenickel(II) complexes, reactions involving the hydroxymethylation of phosphine take place with a high selectivity and at a high rate. ($E^{\neq}$ = 10 kJ mol^{-1}, $\Delta S^{\neq} = -150$ J mol^{-1} K^{-1}).

$$PH_3 + 3CH_2O \longrightarrow P(CH_2OH)_3. \quad (101)$$

$$PH_3 + 4CH_2O + H_2O \longrightarrow (HO)P(CH_2OH)_4. \quad (102)$$

In $NiCl_2$ solution, the main product is tri(hydroxymethyl)-phosphine [reaction (101)], whilst in the presence of acidoamine-nickel complexes the main product is hydroxytetra(hydroxy-methyl)phosphine [reaction (102)]. Under optimum conditions, $(HO)P(CH_2OH)_4$ and $P(CH_2OH)_3$ are obtained in approximately 100% yields. The reaction products were isolated by distilling away the unreacted CH_2O and were analysed by ^{31}P, ^{13}C, and ^1H NMR and IR spectroscopic methods.

In the presence of $NiCl_2$, the rate of reaction (101) is given by the formula



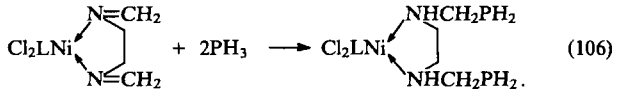
$$W = k[CH_2O]^{0.5}[NiCl_2]^{0.5}[PH_3]^{0.5}[P(CH_2OH)_3]^{0.5}. \quad (103)$$

The addition of primary and secondary amines to an aqueous formaldehyde solution of $NiCl_2$ leads to a significant increase in the rate of reaction (102), while the addition of tertiary amines inhibits this reaction.

In order to investigate the influence of the nature and concentration of the amine on the rate of reaction (102), primary monoamines (NH_2CH_3, $NH_2C_2H_5$) secondary monoamines [$NH(CH_3)_2$, $NH(C_2H_5)_2$], and tertiary monoamines [$N(CH_3)_3$, $N(C_2H_5)_3$] as well as the diamine $C_2H_4(NH_2)_2$ were used. The intermediate tri(hydroxymethyl)phosphine, aldehyde, amine, and mixed aminoaldehyde complexes of nickel(II) were investigated by ^{31}P NMR and UV spectroscopy. Ethylenediamine (En) complexes of nickel(II) showed the highest catalytic activity. The catalytic properties of this system are described by the formula

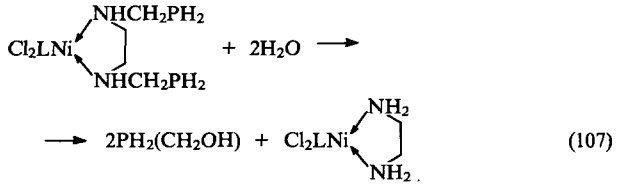
$$W = k[CH_2O]^{0.5}[NiCl_2]^{0.5}[PH_3]^{1.5}[En]^{0.5}[P(CH_2OH)_3]^{0.5}. \quad (104)$$

Investigations made it possible to put forward the following mechanism for the catalytic effects of ethylenediaminenickel(II) complexes in reaction (102):



(105)

L = $P(CH_2OH)_3$.



The outer-sphere condensation of coordinated ethylene-diamine with CH_2O [reaction (105)] leads to the formation of ethylenediaminenickel(II) complexes.[71]

Phosphine also reacts with the ethylenediamine complexes via an outer-sphere mechanism:

(106)

Ethylenebis(aminomethylphosphine) formed by reaction (106) decomposes subsequently with formation of the initial ethylenediaminenickel(II) complex and the reaction inter-mediate — mono(hydroxymethyl)phosphine.

(107)

Hydrolysis of ethylenebis(aminomethylphosphine) at the C–N bond occurs only in the presence of one methyl group. With increase in the number of these groups, the resistance of aminoalkylphosphines to hydrolysis at the C–N bond also increases.[9] The successive substitution of the hydrogen atoms in PH_3 by the hydroxymethyl group takes place in conformity with stages (105)–(107). The second and third hydrogen atoms are substituted faster since mono- and di-(hydroxymethyl)phosphines are appreciably more reactive than PH_3.

Tertiary amines deactivate nickel(II) complexes, since they do not contain a mobile hydrogen atom and do not form imines on interaction with CH_2O.

Thus the mechanism of the P–C coupling of phosphine to formaldehyde differs fundamentally from the mechanism of P–O and P–N coupling of phosphine to alcohols and amines. Whereas oxidative P–O and P–N coupling takes place via an inner-sphere mechanism, P–C coupling involves an outer-sphere mechanism. The catalytic cycle includes three key stages. In the first stage, ethylenediiminenickel(II) complexes are formed from the ethylenediamine complexes and formaldehyde, while in the second stage ethylenebis(aminomethylphosphine)nickel(II) complexes are produced from ethylenediiminenickel(II) complexes and PH_3. In the concluding stage, the ethylenebis(aminomethyl-phosphine)nickel(II) complexes are hydrolysed at the C–N bond with formation of mono(hydroxymethyl)phosphine and the regeneration of the initial ethylenediaminenickel(II) complex.

The effluent gas from hypophosphite factories, containing 70% of PH_3 and 30% of H_2, is an extremely suitable source of phosphine for reaction (102). The reaction product — hydroxy-tetra(hydroxymethyl)phosphine — is used as the monomer for the synthesis of fire-resistant and thermostable organophosphorus polymers. The reaction proceeds in aqueous media and the reaction product is a solid and can be readily separated from the reaction mixture after distilling away water.

X. Oxidative P–C coupling of phosphine and tetraphosphorus to nitriles

Copper(II) carboxylates and halides exhibit a high catalytic activity in the oxidative P–C coupling of phosphine and tetraphosphorus to acetonitrile.[49,63]

$$PH_3 + 3CuY_2 + 3CH_3CN \longrightarrow (CNCH_2)_3P + 4Cu + 6HY. \quad (108)$$

$$P_4 + 20CuX_2 + 16CH_3CN \longrightarrow 4(CNCH_2)_3P{=}NCX_2CH_3 + 20CuX + 12HX. \quad (109)$$

The Cu(0) and Cu(I) formed as a result of reactions (108) and (109) are oxidised by oxygen. Since acetonitrile coordinates more effectively to Cu(I) than to Cu(II), the redox potential of the copper couple in CH_3CN is much higher than in pyridine.[54] The rate of the Cu(II) → Cu(I) reduction stage therefore increases in CH_3CN but the Cu(I) → Cu(II) oxidation stage is retarded.

The nature of the products of the reaction of phosphine and tetraphosphorus with the nitrile depends on the nature of the ligand. Carboxylate ligands promote the formation of tri(cyano-methyl)phosphine, while halide ligands promote the formation of tri(cyanomethyl)phosphazoalkyl. In the former case, the ^{31}P NMR spectra contain only peaks in the region of −6 ppm, which are characteristic of phosphines, while in the latter case they contain peaks in the region of −6 and 14 ppm, which are typical for phosphines and phosphazo-compounds.[45]

Nitriles effectively activate transition[111] and non-transition[112] metal complexes. Complexes of the high-valence metals Ta(V), Nb(V), W(VI), U(IV), and Sn(IV), on the one hand, and the metals Pd, Pt, Rh, Cu, Ag, and Au,[74] on the other, induce respectively electrophilic and nucleophilic activities in the C≡N group. The low-valence metal complexes catalyse the dissociation of the C–C_α and C_α–H bonds in nitriles.[74] The α-cyano-carbanions (CH_2CN^-) formed under the influence of low-valence metal complexes are highly reactive and react rapidly with the coordinated electrophile.[71] When there are no hydrogen atoms in the α position and no coordinated electrophiles, low-valence metal complexes catalyse oxidative coupling of nitriles (C_6H_5CN) to phosphine with a break of the C–C_x bond.[74]

In the presence of high-valence non-transition metals, nitriles interact with a hydrogen halide and are converted into imines and amines.

$$RCN + HX \longrightarrow RCX{=}NH \xrightarrow{HX} RCX_2{-}NH_2. \quad (110)$$

The IR spectra of the products of the interaction of the nitrile with HX at 25 °C contain no bands due to the stretching vibrations of the C≡N bond of the nitrile, but the absorption bands due to the C–Cl, C=N and N–H bonds are observed.[112] Under the influence of high-valence metal ions, nitriles react at 70–90 °C with carboxylic acids to form primary and secondary amides.[112]

$$RCN + 2RCO_2H \longrightarrow RCONH_2 + (RCO)_2O. \quad (111)$$

$$RCN + RCO_2H \longrightarrow (RCO)_2NH. \quad (112)$$

Copper(I) ions effectively stimulate the hydration of nitriles.[113]

$$RCN + H_2O \longrightarrow RCONH_2. \quad (113)$$

In the presence of low-valence transition metals, reactions (111) and (112) are slow even at high temperatures (110–180 °C).[112]

The properties of the coordinated nitriles described above justified the assumption that copper(I) and copper(II) carboxylates stimulate the dissociation of the C_α–H bonds and the oxidative cyanoalkylation of phosphine, while copper(I) and copper(II) halides promote the dissociation of the C_α–H bonds, the oxidative cyanoalkylation of phosphine, and the oxidative imination of tri(cyanoalkyl)phosphine.

The new methods of synthesis of phosphines and phosphazo-compounds are simpler than the methods based on reactions of metallated alkyls with halophosphines or of alkali metal phosphides with alkyl halides.[1–6]

XI. Oxidative P–O coupling of zinc and copper phosphides to alcohols

The phosphides of *d* metals are not used in organophosphorus synthesis owing to their low reactivity.[114] Only alkali and alkaline earth metal phosphides are used in the chemistry of organophosphorus compounds because of their relatively high reactivity.[9] Bearing in mind that considerable amounts of waste containing transition metal phosphides (ferrophosphorus, copper and zinc phosphides, slags) are formed in the undertakings of the phosphorus industry, studies in the field of the organic chemistry of phosphides are of practical interest.

Dorfman and coworkers[115–122] established for the first time that zinc and copper phosphides can be used to obtain trialkyl and dialkyl phosphates. In an alcoholic solution of copper(II) chloride, Zn_3P_2 and Cu_3P are readily oxidised by oxygen to $(RO)_3PO$ and $(RO)_2(HO)PO$.

$$Zn_3P_2 + 6ROH + 4O_2 \longrightarrow 2(RO)_3PO + 3Zn(OH)_2. \quad (114)$$

$$Cu_3P + 3ROH + 2O_2 \longrightarrow (RO)_3PO + 3Cu(OH). \quad (115)$$

$$Zn_3P_2 + 8ROH + 4O_2 \longrightarrow 2(RO)_2(HO)PO + 3Zn(OH)_2 + 2R_2O. \quad (116)$$

$$Cu_3P + 4ROH + 2O_2 \longrightarrow (RO)_2(HO)PO + 3Cu(OH) + R_2O. \quad (117)$$

In the absence of O_2 (in argon) in alcoholic $CuCl_2$ solution, zinc and copper phosphides decompose rapidly with formation of $(RO)_3PO$ and $(RO)_2(HO)PO$.

Cyclic phosphates are formed from glycols, for example from butanediol. When a secondary alcohol (*iso*-C_3H_7OH) is used, dialkyl phosphites are obtained.

The copper(I) ions formed as a result of reactions (118)–(123) are oxidised by oxygen.

Alkyl halides, formed in reactions (118), (119), (122), and (123), hydrolyse [reaction (53)] during the regeneration of copper(II), while the alcohol is not oxidised by oxygen.

$$Zn_3P_2 + 16CuCl_2 + 8ROH \longrightarrow 2(RO)_3PO + 3ZnCl_2 + 16CuCl + 8HCl + 2RCl. \quad (118)$$

$$Cu_3P + 4ROH + 8CuCl_2 \longrightarrow (RO)_3PO + RCl + 11CuCl + 4HCl. \quad (119)$$

$$Zn_3P_2 + 16CuCl_2 + 12ROH \longrightarrow 2(RO)_2(HO)PO + 3ZnCl_2 + 4R_2O + 16CuCl + 10HCl. \quad (120)$$

$$Cu_3P + 8CuCl_2 + 6ROH \longrightarrow (RO)_2(HO)PO + 11CuCl + 2R_2O + 7HCl; \quad (121)$$

R = CH_3, C_2H_5, C_3H_7, *iso*-C_4H_9, C_4H_9, *iso*-C_5H_{11}, C_5H_{11}.

$$Zn_3P_2 + 6R'OH + 12CuCl_2 \longrightarrow 2(R'O)_2HPO + 2R'Cl + 12CuCl + 4HCl + 3ZnCl_2. \quad (122)$$

$$Cu_3P + 3R'OH + 6CuCl_2 \longrightarrow (R'O)_2HPO + R'Cl + 9CuCl + 2HCl. \quad (123)$$

$$Zn_3P_2 + 8R'OH + 3O_2 \longrightarrow 2(R'O)_2HPO + 3Zn(OH)_2 + 2R_2'O. \quad (124)$$

$$Cu_3P + 4R'OH + 1.5O_2 \longrightarrow (R'O)_2HPO + 3Cu(OH) + R_2O. \quad (125)$$

After regeneration, the solution can be reused to decompose Zn_3P_2 and Cu_3P. Trialkyl phosphates and dialkyl phosphonates can be extracted with heptane and separated by vacuum distillation.

Reactions (114)–(121) take place in the topochemical regime. The kinetic and conversion curves have the shape typical for topochemical reactions and pass through a sharp maximum at low conversions $\alpha = 0.1–0.3$.[60] The specific rate (W_{sp}, mol m^{-2} s^{-1}) of the topochemical reaction in the kinetic region was found from Eqn (33). The rate of the reaction was calculated having determined the consumption of O_2 and copper(II) and the accumulation of $(RO)_3P$, $(RO)_2(HO)PO$, Cu(I), $(R'O)_2HPO$, and RCl.

During the search for the optimum conditions and during the study of the mechanism of the oxidative P–O coupling of phosphides to alcohols, the influence of the concentrations of ROH, $CuCl_2$, CuCl, O_2, HCl, LiCl, H_2O, CH_3CN, $C_6H_5CH_2NH_2$, and $C_2H_5NH_2$ on this process was traced. According to atomic-absorption spectroscopic data and the results of laser microanalysis, the Zn_3P_2 and Cu_3P specimens contained less than 1% of impurities. The average Zn_3P_2 and Cu_3P particle sizes and the specific surfaces measured with the aid of a Coulter counter were 13–47 μm and 90–850 cm^2 g^{-1} respectively.

As the HCl and H_2O concentrations are varied, the rates of the topochemical reactions pass through a maximum at very low concentrations of the additives. Amines inhibit the topochemical process, while LiCl has only a weak influence on the latter. With increase in the concentrations of Cu(II), ROH, and O_2, as well as temperature, the rate of reaction also increases.[115–122]

$$Cu_3P + (3-n)HCl \rightleftharpoons Cu_nH_{3-n}P + (3-n)CuCl. \quad (126)$$

The state of the copper(II) complexes during the experiment was investigated by magnetic susceptibility (MS) and UV and EPR spectroscopic methods. According to MS and EPR spectroscopic data, copper chlorides exist predominantly in the monomeric state in alcoholic solutions. It follows from the UV spectra that water readily displaces alcohols from the coordination sphere of copper(II). Alcohol-containing copper(II) complexes exist only for the ratio $H_2O/Cu(II) < 20$. In the alcohol, the stability constants of copper(II) chlorides are higher than in water. The chloroalcoholcopper complexes predominate already for the ratio $Cl^-/Cu(II) \sim 2$.[47]

$$Cu_nH_{3-n}P + Cu_2Cl_3(ROH) \rightleftharpoons Cu_nH_{3-n}PCu_2Cl_3(ROH). \quad (127)$$

The ^{31}P NMR spectra contain an intense band corresponding to $(RO)_3PO$ (−1 ppm) and a weak band due to $(RO)_2(HO)PO$ (−0.5 ppm). Data taken from Nifant'ev and Vasyanina[45] were used in the analysis of the spectra.

The results presented above, obtained by physicochemical methods, suggest the following mechanism of the oxidative P−O coupling of alcohols to metal phosphides. The process begins with the stage involving the activation of the metal phosphide surface by the acid (however, the metal atoms are not fully substituted by hydrogen atoms and phosphine is not liberated). Subsequently the metal hydrogen phosphide adsorbs the heterovalent copper(II)–copper(I) chloride dimer, which is present, according to UV spectroscopic data,[47] in alcoholic solutions of $CuCl_2-CuCl$.

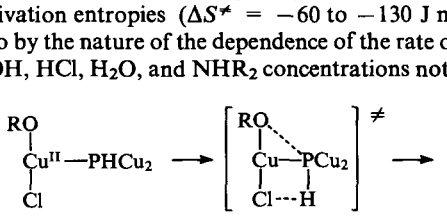
The two-electron redox decomposition of the surface complex, formed in stage (127), leads to the formation of a surface phosphinite and metallic copper.

In the presence of $CuCl_2$, copper dissolves rapidly.

$$Cu + CuCl_2 \rightleftarrows 2CuCl; \qquad K_c = 8 \times 10^6.$$

Thus the oxidative P−O coupling of the metal phosphide to an alcohol includes three main stages: acid hydrolysis of the metal phosphide to the metal hydrogen phosphide, reduction of the chloroalcoholcopper(II) complexes to copper(I) by the metal hydrogen phosphide, and regeneration of the copper(II) ions with oxygen. The acid–base stage (126) is accelerated with increase in the acidity of the medium and the alcohols. The oxidation–reduction stage (128) is retarded as the acidity of the medium increases, which hinders the formation of the alkoxy-ligand. When ROH is displaced from the coordination sphere of copper(II) by the addition of HCl, LiCl, and H_2O, the yield of organic phosphates is seen to fall from 100% to 20%.[115–122]
The oxidation–reduction decomposition reaction (128) takes place as follows:

$$Cu_nH_{3-n}PCu_2Cl_3(ROH) \longrightarrow \longrightarrow Cu + CuCl + Cu_nH_{2-n}P(OR) + 2HCl. \qquad (128)$$



The subsequent stages of the oxidation of $(RO)PCu_2$ to $(RO)_2PCu$, $(RO)_3P$ and $(RO)_3PO$ are rapid.

The oxidation–reduction decomposition of (A) takes place with formation and subsequent reaction of a cyclic transition state.

$$Cu_2X_3(ROH)PCu_3 \underset{-CuX}{\overset{HX}{\rightleftarrows}} Cu_2X_3(ROH)PCu_2 \underset{-HX}{\rightleftarrows} \rightleftarrows Cu_2X_2(RO)PHCu_2 \longrightarrow Cu + CuX + (RO)PCu_2 + HX. \qquad (129)$$

A

The coordination mechanism of reaction (130) is indicated by the low activation energies ($E^{\neq}$ = 50–70 kJ mol^{-1}) and activation entropies ($\Delta S^{\neq}$ = −60 to −130 J mol^{-1} K^{-1}), and also by the nature of the dependence of the rate of reaction on the ROH, HCl, H_2O, and NHR_2 concentrations noted above.

$$\longrightarrow (RO)PCu_2 + Cu + HCl. \qquad (130)$$

The coordination mechanism of reaction (130) has been investigated by the CNDO method.[120] The molecular model of adsorption was used in the calculation.[64] For this purpose, calculations were made for the surface cluster complexes differing in the numbers of H and Cu atoms in the copper hydrogen phosphide and by the number of molecules (H_2O, ROH) and ions (RO^-, HO^-, Cl^-) in the coordination sphere of copper(II). The surface complexes chosen for the investigation modelled the influence of the number of halide, alkoxide, and hydroxide ions and water and alcohol molecules as well as the degree of substitution of copper atoms by hydrogen atoms in the copper phosphide on the nature of the bond between the atoms of the cluster.[120]

The quantum-chemical study established that the adsorption of chloroaquoalcoholcopper(II) complexes on the hydrogen phosphide is accompanied by the formation of bonds not only between the copper(II) ion and the phosphorus atom but also between the chlorine and copper (in the phosphide) atoms, between phosphorus and the alcohol, between phosphorus and water, and between phosphorus and chlorine. These bonds stimulate the oxidation of phosphorus and the reduction of copper(II).[120] The alkoxide ion forms a stronger bond with the phosphorus atom than do ROH, H_2, and the X^- ions. Hence it follows that the products of the oxidative P−O coupling are obtained as a result of the direct reaction of RO^- with the phosphorus atom. The strength of the bond between phosphorus and the alkoxide ion in the adsorption complex increases as the metal atoms are replaced by hydrogen atoms. The greater the number of hydrogen atoms in the hydrogen phosphide, the greater the tendency of the inner-sphere nucleophiles (X^-, HO^-, RO^-) to interact with the phosphorus atom. However, the complete replacement of the metal atoms in the phosphide by hydrogen atoms is not convenient, since the energy of the bonds between the coordinated bases and the metal atoms is much higher than that of the bonds between such bases and hydrogen atoms. Consequently hydrogen phosphides react with chloroalkoxocopper(II) complexes faster than do metal phosphides and phosphine.[120] Hence the cause of the positive influence of a small amount of added acid (up to 0.6 mol litre^{-1}), leading to only partial replacement of metal atoms by hydrogen atoms in the phosphide, on the rate of the topochemical process can be understood. However, when the ligands Cl^-, OH^-, and RO^- are replaced by O^{2-} ions, which form much stronger bonds with the metal atom of the phosphide, the oxidation process is accelerated. Thus the highest catalytic activity is shown by metal halides in weakly acid media and by metal oxides in alkaline media.[63]

XII. Oxidative P−O coupling of zinc and copper phosphides to alcohols in the presence of chlorine

Dorfman observed for the first time[49] that trialkyl and dialkyl phosphates can be obtained rapidly and in high yield (50%–90%) on chlorination of Zn_3P_2 and Cu_3P in alcoholic solutions.

The unreacted alcohol and the organophosphorus reaction products were separated from the inorganic substances by extraction with heptane and vacuum distillation.[115–122] A Cl_2-Ar gas mixture, supplied directly into the liquid phase, was used in the experiments. The rate of supply of the mixture was regulated in such a way that the potential of the Cl_2/Cl chlorine electrode remained constant during the study, while the Cl_2 concentration in the gas at the outlet from the reactor was close to zero. The rate of the reaction was inferred from the consumption of the phosphide, chlorine, and the alcohol and from the accumulation of the reaction products, which were analysed by gas chromatography and ^{31}P NMR spectroscopy.

The introduction of the phosphide into an alcoholic solution of chlorine at 10–80 ° is accompanied by a rapid cathodic shift of the reaction potential to a value which depends on the Cl_2 concentration in the Cl_2-Ar gas mixture. The potential shifts in the negative direction on lowering the Cl_2 concentration and with increase in the amount of the phosphide. On the other hand, it shifts in the anodic direction with increase in the Cl_2 content in argon and with decrease in the amount of the phosphide. The potentiometric method makes it possible to follow continuously during the experiment the chlorine/phosphide ratio in the reaction system.

$$Zn_3P_2 + 8Cl_2 + 8ROH \longrightarrow 2(RO)_3PO + 3ZnCl_2 + 8HCl + 2RCl. \quad (131)$$

$$2Cu_3P + 11Cl_2 + 8ROH \longrightarrow 2(RO)_3PO + 6CuCl_2 + 2RCl + 8HCl. \quad (132)$$

$$Zn_3P_2 + 8Cl_2 + 8ROH \longrightarrow 2(RO)_2(HO)PO + 3ZnCl_2 + 4RCl + 6HCl. \quad (133)$$

$$2Cu_3P + 11Cl_2 + 8ROH \longrightarrow 2(RO)_2(HO)PO + 6CuCl_2 + 4RCl + 6HCl; \quad (134)$$

R = C_4H_9, *iso*-C_4H_9, C_5H_{11}, *iso*-C_5H_{11}.

The sharp cathodic or anodic shift of the chlorine electrode potential depending on the chlorine/phosphide ratio indicates the high rate of the topochemical reaction of the phosphide with chlorine in the alcohol.

According to ^{31}P NMR data,[45] reactions (131)–(134) proceed relatively selectively. Mainly trialkyl and dialkyl phosphates are formed, their chemical shifts being −1 and −2 ppm respectively. The ^{31}P NMR spectra also contain small peaks due to the tetracoordinate phosphorus derivatives Cl_3PO (0.6 ppm), $(RO)_2ClPO$ (0.5 ppm), and $(RO)_2HPO$ (1 ppm). When phosphine is chlorinated in *iso*-C_3H_7OH the chemical shifts (ppm) are displaced upfield: (*iso*-$RO)_3PO$ (−4 ppm) and (*iso*-$RO)_2(HO)PO$ (−6 ppm). Hence it follows that reactions (131)–(134) proceed via the formation and subsequent reaction of phosphorus pentachloride.

The main feature of the reactions of PCl_5 with ROH and H_2O is the initial formation of phosphoryl chloride [reaction (136)], the rate of the subsequent alcoholysis of which increases with increase in the pH of the medium.[104] Such a sequence of reactions of phosphorus pentachloride with alcohols and water is due to the formation of the stable phosphoryl group P=O.[104] The reactions of phosphoryl chloride with ROH and H_2O proceed as stepwise elimination of HCl.[104] In the reactions of alcohols with phosphoryl chloride, phosphorodichloridates are generated initially. This is followed by the formation of phosphorochloridates and finally trialkyl phosphates. Reactions (136)–(138) are significantly accelerated in the presence of HCl binding agents. Without added pyridine, reaction (137) takes several hours, while in the presence of pyridine it reaches completion after several minutes. Therefore, in order to accelerate the reactions, the sample of the solution is treated with pyridine before chromatographic analysis.

$$Zn_3P_2 + 8Cl_2 \longrightarrow 2PCl_5 + 3ZnCl_2. \quad (135)$$

$$PCl_5 + ROH \longrightarrow Cl_3PO + RCl + HCl. \quad (136)$$

$$Cl_3PO + 2ROH \longrightarrow (RO)_2ClPO + 2HCl. \quad (137)$$

$$(RO)_2ClPO + ROH \longrightarrow (RO)_3PO + HCl. \quad (138)$$

$$(RO)_2ClPO + ROH \longrightarrow (RO)_2(HO)PO + RCl. \quad (139)$$

During the chlorination of Cu_3P, it was observed that the yield of trialkyl phosphate increases significantly when the Cl_2 concentration is reduced (to 10^{-3}–10^{-4} mol litre^{-1}) as fresh portions of Cu_3P are added. The autocatalysis is due to the fact that, following the appearance of $CuCl_2$ in the system as a result of the reaction

$$2Cu_3P + 11Cl_2 \longrightarrow 2PCl_5 + 6CuCl_2, \quad (140)$$

processes begin in which $CuCl_2$ becomes the catalyst and Cl_2 and Cu_3P are the reactants.

$$Cu_3P + 8CuCl_2 + 4ROH \longrightarrow 11CuCl + (RO)_3PO + RCl + 4HCl. \quad (141)$$

$$2CuCl + Cl_2 \longrightarrow 2CuCl_2. \quad (142)$$

Copper phosphide is oxidised to trialkyl phosphates by $CuCl_2$ in alcohols, while CuCl, a product of reaction (141), is reoxidised to $CuCl_2$. When there is a deficiency of Cl_2, copper phosphide reacts with $CuCl_2$ and not with Cl_2.

The catalytic pathway ensures a high selectivity of the reation, since the oxidative alcoholysis of Cu_3P proceeds without the preliminary formation of chloro-derivatives of phosphorus via the direct reaction of Cu_3P with ROH in the coordination sphere of copper(II). Tests showed that, in the absence of Cl_2, the stoichiometric reaction (141) taks place.[120,121]

It follows from the ^{31}P NMR spectra, indicating the presence of $(RO)_2HPO$ in the reaction mixture, that trialkyl phosphate is formed from the dialkyl phosphite produced on dealkylation of trialkyl phosphite.[61,62]

$$Cu_3P + 6CuCl_2 + ROH \longrightarrow (RO)_3P + 9CuCl + 3HCl. \quad (143)$$

$$(RO)_3P + HCl \longrightarrow (RO)_2HPO + RCl. \quad (144)$$

$$(RO)_2HPO + 2CuCl_2 + ROH \longrightarrow (RO)_3PO + 2CuCl + 2HCl. \quad (145)$$

According to Dorfman et al.[53] and Fridman et al.,[54] dialkyl phosphate is readily oxidised by $CuCl_2$ in the alcohol to trialkyl phosphate.

* * *

The studies described above were carried out in the little investigated field of the organic chemistry of phosphorus and phosphides, which, however, is of great practical importance. The principal features of the new reaction involving the oxidative phosphorylation of organic compounds by phosphorus and phosphides were described. Organophosphorus compounds can be obtained by this reaction much more simply than by the existing methods in which metallated organic substances and phosphorus halides or alkali metal phosphides and halo-derivatives of organic compounds are used.[1–6] By virtue of the high rates of the reactions considered, highly toxic waste from phosphorus factories with a low content of the phosphorylating agent (the effluent phosphine- and phosphorus-containing gases, dilute phosphorus sludge, transition metal phosphides, and red phosphorus) can be used as raw materials in these processes.[114,123]

It has been shown that the non-polar tetraphosphorus and the weakly polar phosphine, which tend to undergo homolytic reactions, enter vigorously into heterolytic organic reactions in the presence of metal complexes. The mechanism, rate, and mode of reaction depend on the nature of the ligands. The use of the ligand effect, described in 1972 [46] and applied successfully by Lupi and Chubar,[124] makes it possible to alter significantly the nature of the process by adding simple alkali metal salts.

The mechanisms of the activation of phosphorus and phosphides and of the reactions involving the oxidative O-, N-, and C-coupling of alcohols, amines, aldehydes, carboxylic acids, glycols, and nitriles to phosphine, white and red phosphorus, and transition metal phosphides, described above, can be used to discover new reactions of this type with participation of other organic compounds.

Aminoacids of the cyclobutane series

F Avotins

Contents

I. Introduction 897
II. Aminocyclobutanecarboxylic acids 897
III. Aminocyclobutyl-substituted carboxylic acids 903

Abstract. The literature data on the methods of synthesis, the reactivities, and biological activities of aminoacids of the cyclobutane series and their derivatives are described systematically and discussed. The bibliography includes 112 references.

I. Introduction

Aminoacids of the cyclobutane series (AACB) are compounds which have been relatively little investigated. Until recently AACB were almost the only type of aminoacids (AA) which have not been detected in natural sources. It was not until 1980 that Bell et al.[1] isolated for the first time 1-aminocyclobutane-1,3-dicarboxylic (2,4-methanoglutamic) and 2,4-methanopyrrolidine-2-carboxylic (2,4-methanoproline) acids from the seeds of the plant *Atelia Herbert Smithii* (*Sophoreae*, *Leguminosae*). Austin et al.[2] isolated in 1987 from the same material yet another achiral non-protein aminoacid—*cis*-1-amino-3-hydroxymethylcyclobutane-1-carboxylic acid, while Adlington et al.[3] discovered in 1983 *trans*-2-amino-1-hydrocyclobutylacetic acid in a dipeptide—an antimetabolite of the unidentified microorganism *Streptomyces species X-1092*. Since biologically active substances with antiviral, neurotropic, analgesic, depressant, antimicrobial, and other activities have been found among AACB derivatives,[4–20] these compounds have attracted the attention of investigators during the recent decades.

In the present review, an attempt is made for the first time to give a systematic account of and to survey studies in which the methods of synthesis, reactivities, and biological activities of AACB and their derivatives are considered. In order to achieve an ordered arrangement of the literature data, we subdivided all the AACB into two groups: aminocyclobutanecarboxylic acids and aminocyclobutyl-substituted carboxylic acids. All the acids and their derivatives in which the carboxy-group is linked directly to the four-membered carbocycle were included in the present review among aminocyclobutanecarboxylic acids. Compounds in which the carboxy-group is separated from the carbocycle by one or several carbon atoms were assigned to the class of aminocyclobutyl-substituted carboxylic acids. In our view, this approach facilitates a systematic treatment of these compounds and also makes it possible to compare their properties and to survey the methods of their synthesis.

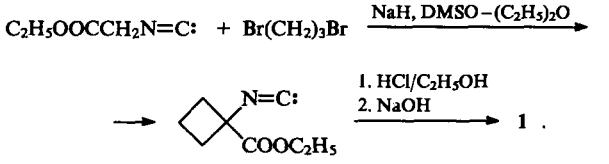
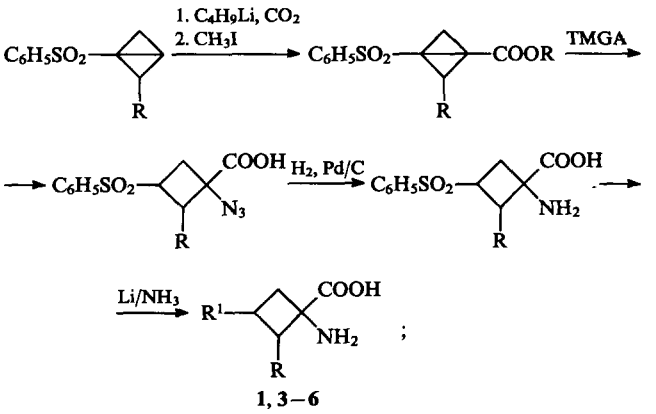
II. Aminocyclobutanecarboxylic acids



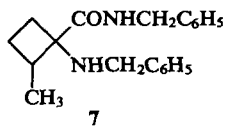
Various methods may be used for the synthesis of aminocyclobutanecarboxylic acids, including both the construction of molecules from individual units containing amino- and carboxy-groups as well as the introduction of the amino-group directly into the cyclobutanecarboxylic molecule.

1. 1-Aminocyclobutane-1-carboxylic acids

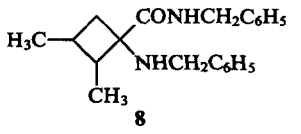


1-Aminocyclobutane-1-carboxylic acid **1** itself is of the greatest interest. Its toxicity is low and it is an inhibitor of the growth of tumours[10, 21] and a selective antagonist of *N*-methyl-D-aspartic acid in relation to the [^{2}H]-receptors of histamine and [^{3}H]-receptors of glycine,[22–25] while its 2-(3-methoxyphenyl) derivative inhibits aminooxidases in rat liver mitochondria.[6] The attempts to obtain compound **1** by the direct ammonolysis of 1-bromo-cyclobutane-1-carboxylic acid **2** (R = H) or its ester **2** (R = CH_3, C_2H_5) by ammonium hydroxide as well as by the reaction of compound **2** with potassium phthalimide (the Gabriel synthesis) or hexamethylenediamine did not yield satisfactory results. The synthesis of compound **1** by this procedure is complicated by the fact that dehydrobromination takes place in the ammonolysis stage, which, according to Connors and Ross[10] and Sudo and Ichihara,[26] leads to the formation of an unsaturated acid with the empirical formula $C_5H_{11}BrN_2O$, the structure of which has not been established. It has also not been possible to obtain compound **1** with the aid of the most often employed two-stage method of synthesis of aliphatic α-aminoacids—by the reaction of α-bromoacids or their esters with sodium azide and the subsequent reduction of the azido-group to the amino-group, since the replacement of the bromine atom in compound **2** by the azido-group was unsuccessful. A more successful preparative method of synthesis of compound **1** is the classical hydantoin synthesis of aminoacids.[10, 11, 27–31] Compound **1** was synthesised by this procedure for the first time as early as 1937,[27] and its yield reached 97%. The initial 5,5-trimethylenehydantoin was obtained by Ingold's method[32] from cyclobutane-1,1-dicarboxylic acid diamide.

The method of synthesis involving the use of ethyl isocyanoacetate and 1,3-dibromopropane has been developed recently for the preparative synthesis of compound **1** (in 95% yield). The reaction was carried out in the presence of sodium hydride in dimethyl sulfoxide/ether or acetone with subsequent stepwise hydrolysis of the intermediate cyclic α-isonitrile.[6, 33–35] Ethyl isocyanoacetate was obtained by dehydrating the ethyl ester of *N*-formylglycine with phosgene[36] or with trichloroacetic acid chloride in the presence of triethylamine.[33]

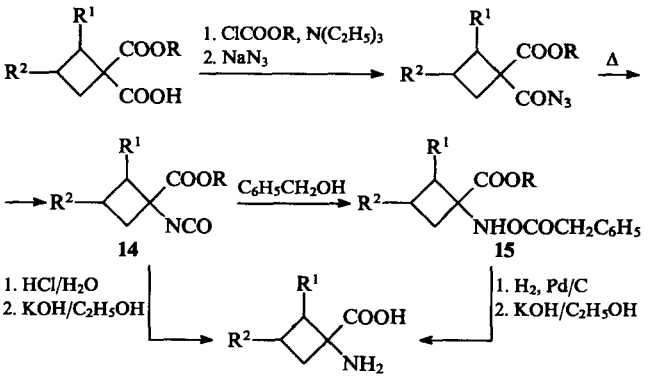


The aminoacid **1** as well as 1-aminocyclobutane-1-carboxylic acids of type **3–6** substituted in the carbocycle and their *N*-derivatives have been synthesised by the regiospecific addition of nitrogen-containing nucleophiles to 1-(arenesulfonyl)-bicyclo-[1.1.0]butane.[37] The synthesis was carried out in four stages: carboxylation of bicyclobutane, introduction of the azido-group by treatment with *N,N,N',N'*-tetramethylguanidinium azide or trimethylsilazide, reduction of the amide, and finally reductive elimination of the arenesulfo-group with lithium in liquid ammonia.

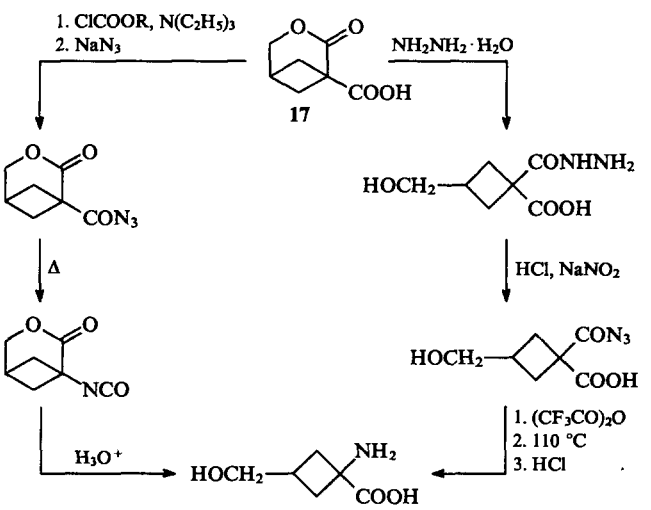


R = R^1 = H (**1**); R = H, R^1 = $C_6H_5SO_2$ (**3**);
R = CH_3, R^1 = $C_6H_5SO_2$ (**4**);
R = CH_3, R^1 = H (**5**); R = R^1 = CH_3 (**6**);
TMGA = *N,N,N',N'*-tetramethylguanidinium azide.

The carboxy-group was introduced into bicyclobutane at −78 °C in solution in hexane or tetrahydrofuran (THF), while the azido-group was introduced in *N*-methyl-2-pyrrolidinone or dimethylformamide (DMF) at 80–90 °C. Although the reaction of bicyclobutane with trimethylsilazide is ten times slower than that with *N,N,N',N'*-tetramethylguanidinium azide, the methoxycarbonyl groups are not solvolysed under these conditions and the corresponding esters are obtained in 92% yield. The aminoacids **1** and **3–6** were isolated on Dowex 50 × 8 ion-exchange resin mainly in the form of the *cis*-isomers. Amides substituted in the amino-group, for example, the benzamide of *N*-benzylmethanovaline **7** and the benzamide of *N*-benzylmethanoisoleucine **8**, were also synthesised in this way.

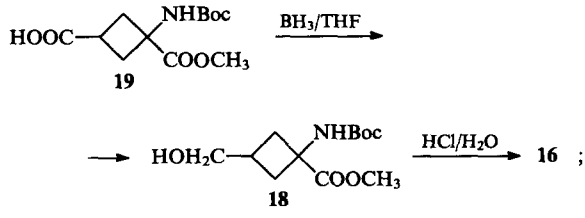


7



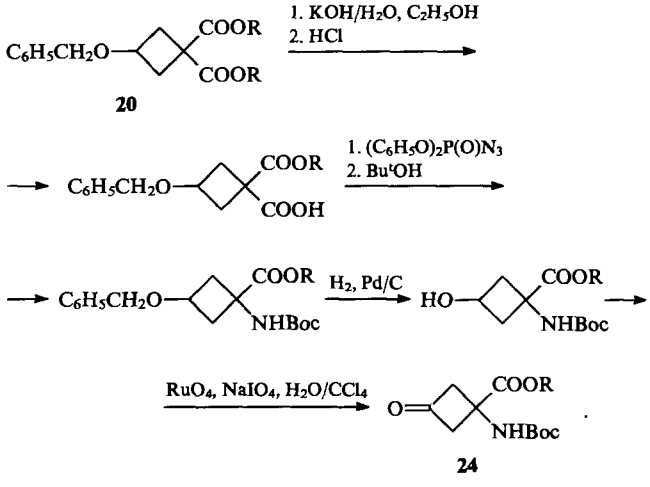
8

The conversion of the carboxy-group into the amino-group by the Curtius method has been used to obtain analogues of compound **1** aryl-substituted in the four-membered carbocycle.[9, 11, 38] A modified Curtius method has been proposed for the synthesis of 1-amino-2-arylcyclobutane-1-carboxylic acids **9** and **10** and 1-amino-3-arylcyclobutane-1-carboxylic acids **11–13**.[39] It is based on the conversion of 2- and 3-arylcyclobutane-1,1-dicarboxylic acids into the corresponding isocyanates of arylcyclobutane-1-carboxylic acids **14**. This was achieved by the successive treatment of the monoesters of cyclobutane-1,1-dicarboxylic acids initially with chlorocarbonic ester in the presence of triethylamine and then with sodium azide and by heating the resulting acyl azide in dry toluene.[38]

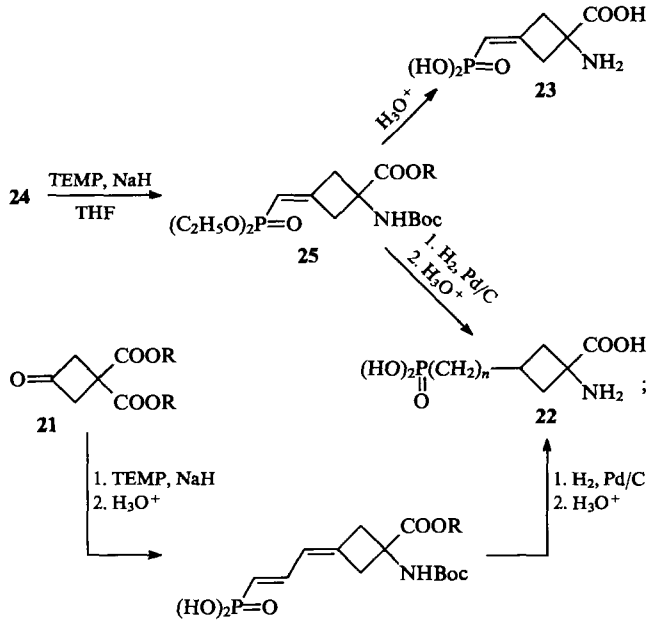


R = CH_3, C_2H_5; R^2 = H; R^1 = C_6H_5 (**9**), 3,4-$CH_2O_2C_6H_3$ (**10**);
R^1 = H; R^2 = C_6H_5 (**11**), 3,4-$(CH_3O)_2C_6H_3$ (**12**), 3,4-$CH_2O_2C_6H_3$ (**13**).

The reaction of the isocyanates **14** with benzyl alcohol made it possible to obtain the aminoacid esters **15** containing the *N*-benzyloxycarbonyl group. The catalytic elimination of the benzyloxycarbonyl group from compound **15** over Pd/C in ethyl acetate and alkaline hydrolysis of the ester group lead to the *trans*-aminoacids **9–13**. The *trans*-aminoacid **13** has been obtained[38] in this way in a yield exceeding 90%. The Curtius reaction has also been used as the key stage in the synthesis of the natural *cis*-1-amino-3-hydroxymethylcyclobutane-1-carboxylic acid(*cis*-**16**)[2] from oxabicyclo[3.1.1]-heptan-2-one-1-carboxylic acid **17**.[40, 41]

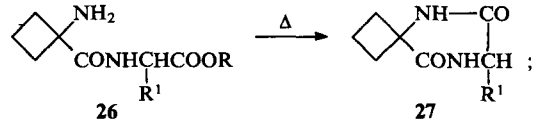


The lactone **17** is converted into the hydrazide, the reaction of which with nitrous acid affords the azide; the rearrangement of the latter in the presence of trifluoroacetic acid anhydride leads to compound *cis*-**16**. The rearrangement of the azide of 3-oxabicyclo[3.1.1]-heptan-2-one-1-carboxylic acid and the subsequent hydrolysis of the resulting isocyanate afforded compound *trans*-**16**, which Hughes and Clardy[42, 43] obtained by acid hydrolysis (yield ~97%) from the methyl ester of *cis*-1-[(*tert*-butoxycarbonyl)amino]-3-(hydroxymethyl)cyclobutanecarboxylic acid **18**, which was synthesised, in its turn, by the selective reduction of the methyl ester of *N*-(*tert*-butoxycarbonyl)-2,4-methanoglutamic acid **19** with borane in THF.



Boc = *tert*-butyloxycarbonyl.

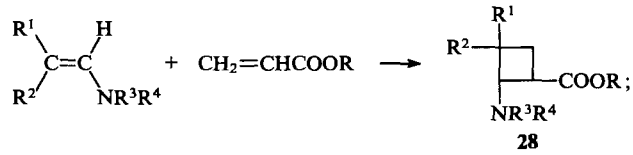
cis- and *trans*-1-Amino-3-phosphonylmethylcyclobutane-1-carboxylic acids **22** (n = 1), 1-amino-3-(3-phosphonylpropyl)cyclobutane-1-carboxylic acid **22** (n = 3), 1-amino-3-phosphonylmethylenecyclobutane-1-carboxylic acid **23**, and their derivatives have been synthesised recently[44] from the esters of 3-benzyloxycyclobutane-1,1-dicarboxylic acid **20** and 3-oxocyclobutane-1,1-dicarboxylic acid **21** in order to investigate them as agonists and antagonists of neurotransmitter aminoacids, in particular *N*-methyl-D-aspartic acid (NMDA). The initial ester of 1-amino-3-oxocyclobutane-1-carboxylic acid **24** was obtained from 3-benzoyloxycyclobutane-1,1-dicarboxylic acid **20** in four stages.[44]



The interaction of the aminoester **24** with tetraethylmethylenebisphosphonate (TEMP) in the presence of sodium hydride leads to the ethyl ester of 1-[(*tert*-butoxycarbonyl)amino]-3-[(diethoxyphosphonyl)methylene]cyclobutane-1-carboxylic acid **25**, the acid hydrolysis of which affords the aminoacid **23** (yield 42%–74%), while the reduction and acid hydrolysis of the unsaturated intermediate ester give rise to a mixture of the *cis*- and *trans*-aminoacids **22** (n = 1) in 33% yield.

cis- and *trans*-1-Amino-3-(3-phosphonylpropyl)cyclobutane-1-carboxylic acids **22** (n = 3) were obtained by a similar procedure in an overall yield of 79% from *cis*- and *trans*-tetraethyl 2-propenylene-1,3-diphosphonate (TEPP) and diethyl 3-oxocyclobutane-1,1-dicarboxylate **21**.

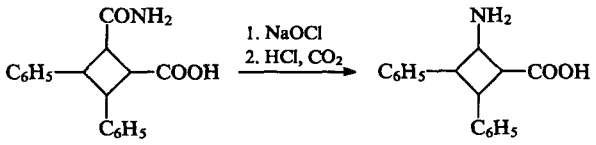
R = C_2H_5; n = 1, 3 .



The stereoisomers were separated on Dowex AG50W ion-exchange resin.[44] L-Aspartyl and D-alanyl dipeptides[45, 46] and D-alanyl tripeptides,[45] the structure of which includes compound **1**, have been obtained. The cyclic dipeptides **27** have been synthesised by cyclising the dipeptides having the general formula **26**. They have been recommended for use in medicine and veterinary science.[46]

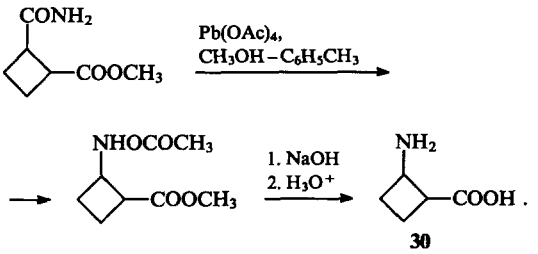
R = CH_3:
R^1 = H, CH_3, $CH_2CH(CH_3)_2$, $CH(CH_3)_2$, CH_2OH, $C_6H_5CH_2$.

2. 2-Aminocyclobutane-1-carboxylic acids



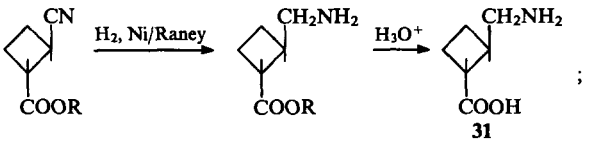
2-Aminocyclobutane-1-carboxylic acids **28** (R = H) are the most numerous among the AACB synthesised and are of interest as biologically active compounds,[7, 17–19, 46–48] antioxidants,[7, 46] and monomers for the synthesis of polyamide resins.[4] Substances with analgesic,[7, 17] anaesthetic,[18] and sedative[7] activities have been discovered among them.

R = CH_3, C_2H_5; R^1 = R^2 = CH_3, C_2H_5;
R^1+R^2 = $(CH_2)_5$; R^3 = R^4 = CH_3, C_2H_5, $CH_3(CH_2)_2CH_2$;
R^3+R^4 = $(CH_2)_5$, $CH_2CH_2OCH_2CH_2$; NR^3R^4 = CN .



The principal method of synthesis of 2-aminocyclobutane-1-carboxylic acids is the cycloaddition of enamines to electrophilic olefins, for example acrylonitrile and acrylic acid esters.[7, 17, 18, 46, 50–56] Enamines without a hydrogen atom in the β-position, in particular enamines based on isobutenyl, have been mainly used. The reaction was carried out at ~85 °C in solution in acetonitrile (yield ~91%) or in an autoclave at 170–175 °C (yield 70%–75%). 2-(*N*,*N*-Dialkylamino)-3,3-dialkylcyclobutane-1-carboxylic acids **28** (R^1–R^4 = alkyl; R = H) and their esters

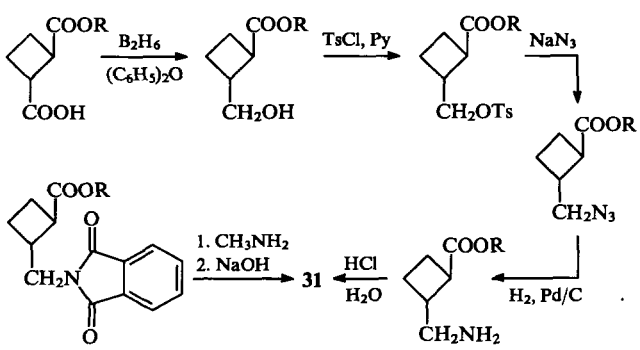
and amides have been obtained in this way. Shoemer and Schenk[57] used the Hofmann rearrangement for the synthesis of 2-amino-3,4-diphenylcyclobutane-1-carboxylic acid **29**. The target acid **29** was obtained from β-truxinic acid by treatment with sodium hypochlorite.



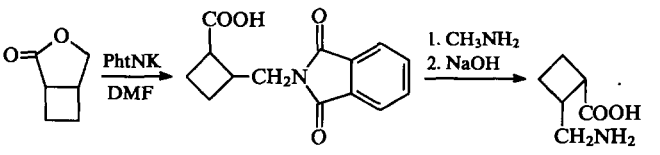
29

Unsubstituted *cis*- and *trans*-2-aminocyclobutane-1-carboxylic acids **30** have been synthesised from the esters of *cis* and *trans*-2-carbamoylcyclobutane-1-carboxylic acids. On treatment with lead tetraacetate, the ester amides were converted into the corresponding esters of *N*-(2-methoxycarbonylcyclobutyl)carbamates, the hydrolysis and decarboxylation of which led to a mixture of *cis*-**30** and *trans*-**30**.[58] The corresponding diastereoisomers were obtained in 56% and 66% yields by resolution on ion-exchange resins.[49]

30



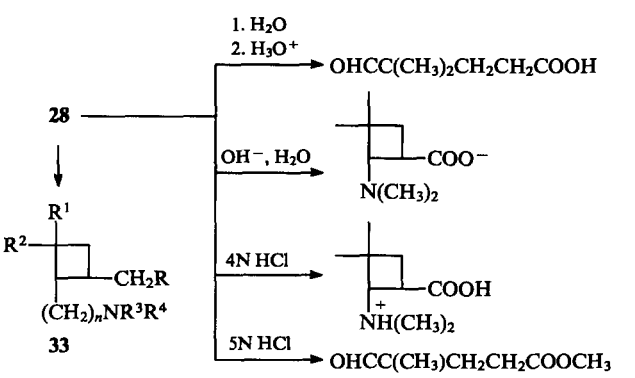
trans-2-Aminomethylcyclobutane-1-carboxylic acid **31** has been synthesised by the catalytic reduction of methyl 2-cyanocyclobutane-1-carboxylic acid and the subsequent acid hydrolysis of the ester. The reduction was carried out over Raney nickel at a pressure of ~14 MPa on heating to 130 °C.



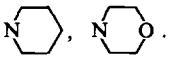
31

R = CH_3, C_2H_5, C_3H_7.

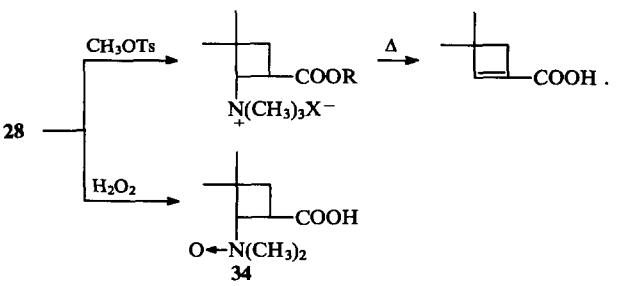
The aminoacid **31** was isolated in ~81% yield by chromatography on ion-exchange resins.[48] Methods in which *trans*-cyclobutane-1,2-dicarboxylic acid and its reaction products were used as the initial compounds have also been proposed for the preparative synthesis of compound **31**.[19, 49, 50] Thus compound **31** has been synthesised from the monoester of *trans*-cyclobutane-1,2-dicarboxylic acid by converting a carboxy-group into an alcoholic group. This was achieved by tosylation and the replacement of the tosyl group (Ts) by the azido-group. After the reduction of the azido-group, the ester of *trans*-2-methylamino-cyclobutane-1-carboxylic acid was obtained in 44% yield. Acid hydrolysis of the ester leads to compound **31** in 72% yield. The aminoacids **31** have also been synthesised by the Gabriel reaction,[50] but in this case the product was obtained in a lower yield (~47%).



A convenient method of synthesis of *cis*-2-aminomethylcyclobutane-1-carboxylic acid **32** is based on the reaction involving the nucleophilic ring opening in *cis*-3-oxabicyclo[3.2.0]heptan-2-one with potassium phthalimide (PhtNK) and subsequent hydrolysis of the resulting phthalimide derivative with methylamine.[49]



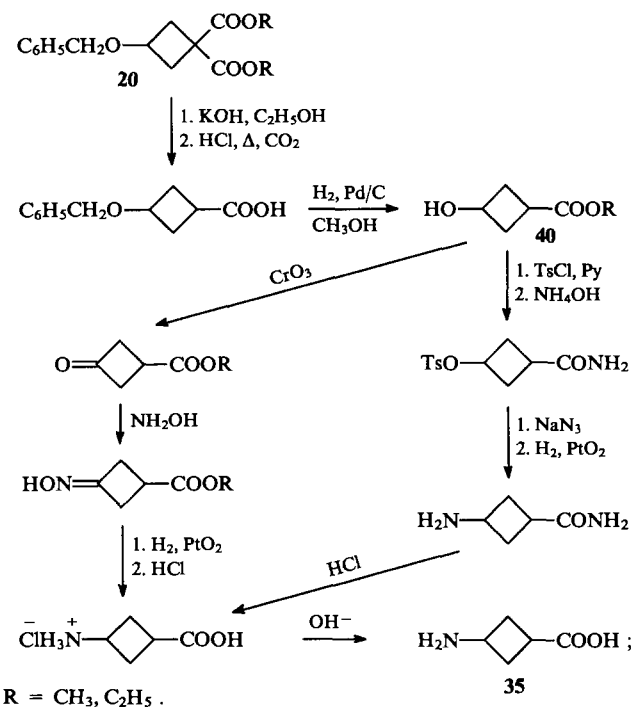
32



The aminoacid **32** was obtained in 67% yield.[50] Biological studies confirmed the hypothesis that the acids **31** and **32** exhibit a neurotropic activity.

The reduction of the esters **28** with metal hydrides leads to the aminoalcohols of the cyclobutane series **33**.[18, 50, 54–56] Substances with anaesthetic, analgesic, and anticholinergic activities have been discovered among the aminoalcohols **33**. They have been recommended also as intermediates for the synthesis of stabilisers of liquid fuels and for the modification of polymers.

n = 0; R = OH;
R^1 = H, CH_3, C_2H_5;
R^2 = H, C_6H_5, CH_3, C_2H_5;
R^3 = R^4 = CH_3, C_2H_5 or NR^3R^4 = 

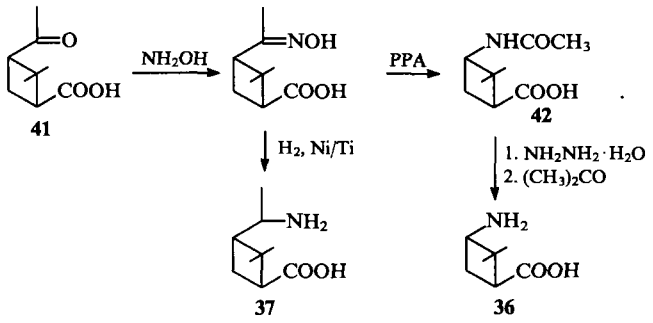


The hydrolysis of the esters **28** ($R-R^4 = CH_3$) in the presence of acids leads to the opening of the cyclobutane ring and the formation of dimethylglutaraldehyde and methyl dimethylglutarate.[52, 54] However, in an alkaline medium the hydrolysis involves only the ester group. The cyclobutane ring is also opened on treatment with Grignard reagents.[54] The quaternisation of the amino-group in compound **28** ($R-R^4 = CH_3$) by methyl tosylate and subsequent elimination of the quaternary amino-group by bases lead to 3,3-dimethylcyclobutene-1-carboxylic acid,[51, 52] whilst oxidation of compound **28** (R = H, $R^1-R^4 = CH_3$) with a H_2O_2 solution affords the *N*-oxide **34**.[52]

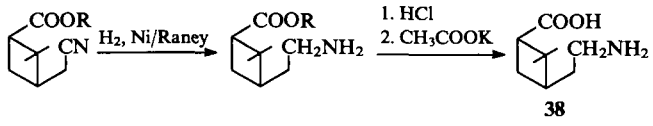
34

3. 3-Aminocyclobutane-1-carboxylic acid

Only the *cis*- and *trans*-3-aminocyclobutane-1-carboxylic acids **35**, *cis*-3-amino-2,2-dimethylcyclobutane-1-carboxylic acid **36**, *cis*-3-(α-aminoethyl)-2,2-dimethylcyclobutane-1-carboxylic acid **37**, 3-(β-aminoethyl)-2,2-dimethylcyclobutane-1-carboxylic acid **38**, and 3-amino-2,4-diphenylcyclobutane-1-carboxylic acid **39** have been synthesised in this group of AACB and described. The *cis*- and *trans*-aminoacids **35** and **36** are of interest as cyclobutyl analogues of γ-aminobutyric acid (GABA).[61] A multistage method has been proposed for the synthesis of compound **35**, in which the diester of 3-benzyloxycyclobutane-1,1-dicarboxylic acid **20** was used as the initial compound.[63] Alkaline hydrolysis and decarboxylation of compound **20** led to 3-benzyloxycyclobutane-1-carboxylic acid, which was converted in the presence of the Adams catalyst into the ester of 3-hydroxycyclobutane-1-carboxylic acid **40**. A mixture of the diastereoisomers of compound **35** was obtained from the latter in an overall yield of 25% (relative to the intial ester **40**).



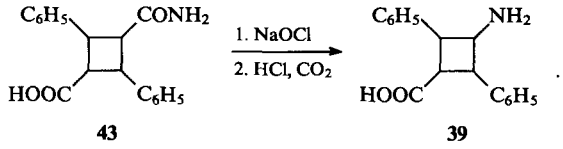
R = CH_3, C_2H_5 .



The *cis* : *trans* isomer ratio in the mixture was 1 : 1.8. The isomers were separated by crystallisation from *tert*-butyl alcohol or by chromatography on Dowex 50 × 8 ion-exchange resin. This method is distinguished by high yields at each stage of the process and by the relative availability of the initial compounds.

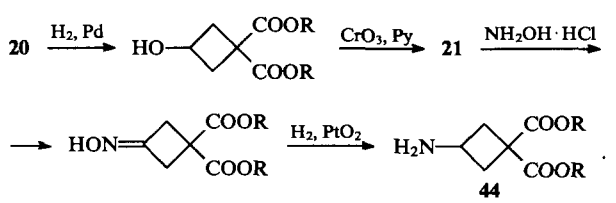
An alternative approach, involving the oxidation of the ester **40** with chromic acid, the conversion of the carbonyl group of 3-oxocyclobutane-1-carboxylic acid into an oxime group, and subsequent catalytic reduction of the oxime group, also affords a mixture of the diastereoisomers of compound **35** (yield ⩽20%), but the isomer ratio has not been established.[63] The aminoacid **35** exhibits a neurochemical activity, the *cis*-isomer proving to be much more active.[61]

cis-3-Amino-2,2-dimethylcyclobutane-1-carboxylic acid **36** has been synthesised from *cis*-3-acetyl-2,2-dimethylcyclobutane-1-carboxylic (pinononic) acid **41**.[64] 3-Acetamido-2,2-dimethylcyclobutane-1-carboxylic acid **42** was obtained from the ketoacid **41** in accordance with the usual scheme for the Beckmann reaction in polyphosphoric acid (PPA). Its hydrazinolysis with hydrazine hydrate leads to the aminoacid **36**. The catalytic hydrogenation of pinononic acid oxime in the presence of the Ni/Ti catalyst (Lyubarskii's catalyst) at atmospheric pressure afforded *cis*-3-(α-amino-ethyl)-2,2-dimethylcyclobutane-1-carboxylic acid **37** in 87.4% yield.[64]



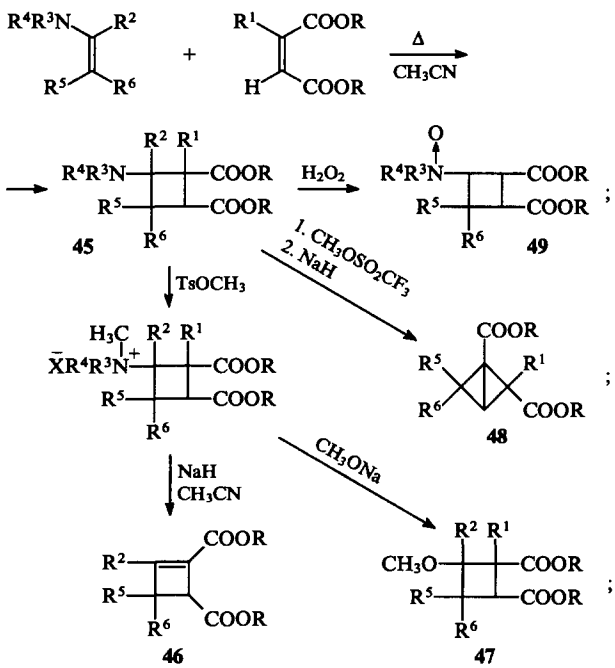
cis-3-(β-Aminoethyl)-2,2-dimethylcyclobutane-1-carboxylic acid **38** has been synthesised under similar conditions form *cis*-(3-ethoxycarbonyl-2,2-dimethyl-1-cyclobutyl)acetonitrile by reduction with hydrogen in the presence of Raney nickel.[65]

R = CH_3, C_2H_5 .



The monoamides of α-, β-, and ε-truxillic acids can be used as the key compounds in the synthesis of 3-amino-2,4-diphenylcyclobutane-1-carboxylic acid **39** by the Hofmann reaction. This was demonstrated in relation to the rearrangement of the monoamide of γ-truxillic acid **43**.[57] The rearrangement was carried out at 30–40 °C in an aqueous solution of sodium hypochlorite. The aminoacid was isolated by neutralising the reaction mixture with HCl and CO_2; the yield of compound **39** was 68% – 80%.

Biological tests showed that aminoacid **37** exerts a weak effect on the vesicular stomatitis virus and inhibits the multiplication of the group A_2 virus in chicken embryos. Among the hydrochlorides of its amides, substances were found with antistaphylococcal and antiviral activities.[64] The aminoacid **36** also exhibits a psychotropic activity, but there is no information concerning more detailed studies of this compound.

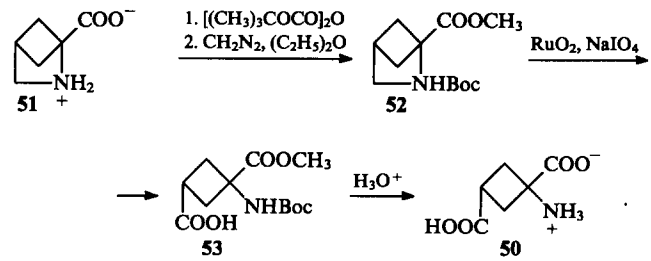


4. Aminocyclobutane-1,1-dicarboxylic and aminocyclobutane-1,2-dicarboxylic acids

Among aminocyclobutane-1,1-dicarboxylic acids, only 3-aminocyclobutane-1,1-dicarboxylic acid **44**, obtained solely as its diethyl ester, is known.[62] Compound **44** has been synthesised from diethyl 3-benzyloxycyclobutane-1,1-dicarboxylate **20** by a procedure similar to that used in the synthesis of compound **35**.[63]

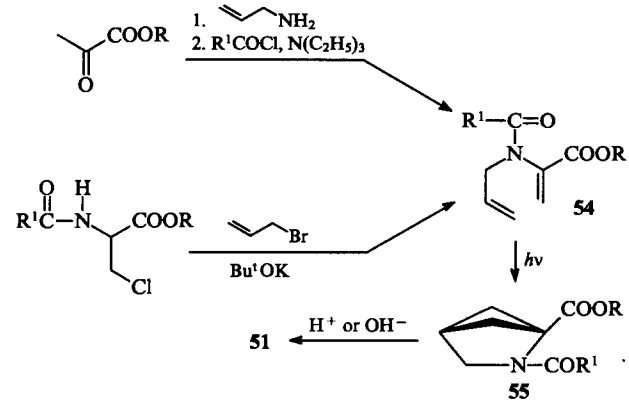
The only examples of aminocyclobutane-1,2-dicarboxylic acids are 3-aminocyclobutane-1,2-dicarboxylic acids **45**, which, like the aminoacid **28**, have been obtained by the cycloaddition of

enamines to electrophilic olefins, in particular to the esters of maleic or fumaric acid.[17, 47, 51, 52, 55, 66] The reaction was carried out at 110–170 °C in solution in acetonitrile. The yields of compounds **45** are 70%–78%. It is noteworthy that the majority of the aminoacids **45** obtained were characterised as the methyl and ethyl esters. Systematic studies of their properties have not been carried out.



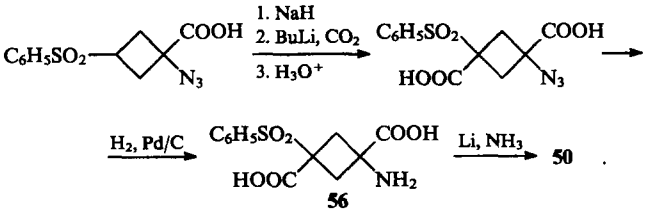
R = R^2 = H, CH_3; R^1 = H, CN, COOMe; R^3 = R^4 = CH_3, C_2H_5; R^5 = R^6 = H, CH_3, C_2H_5; R^6 = H, C_2H_5, $CH_2N(CH_3)_2$;

NR^3R^4 =  .

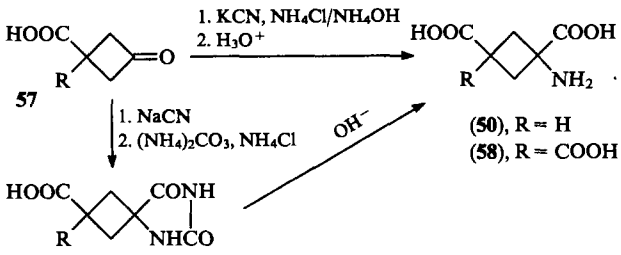


The reduction of the esters **45** (R = CH_3, C_2H_5) with $LiAlH_4$ or $NaBH_3$[55] leads to the corresponding 3-aminocyclobutane-1,2-glycols, which are of interest as intermediates for organic synthesis. As in compound **28**, the amino-group in the aminoacid **45** is quaternised with methyl iodide, methyl tosylate, and methyl trifluoromethane-sulfonate. However, in contrast to compound **28**, the elimination of the quaternary amino-group with sodium hydride, leading to the formation of cyclobutene-1,2-dicarboxylic acids **46**, proceeds only in aprotic solvents (for example, in CH_3CN).[51, 52] On the other hand, on treatment with sodium methoxide in methanol, the quaternary amino-group is replaced by the methoxy-group with formation of the corresponding 3-methoxycyclobutane-1,2-dicarboxylic acid **47**.[66] On quaternisation of 2-methoxycarbonyl-3-(*N*,*N*-dimethylamino)-4,4-dimethylcyclobutane-1,2-dicarboxylic acid **45** (R = CH_3, R^1 = $COOCH_3$, R^2 = H, R^3–R^6 = CH_3) with methyl trifluoromethanesulfonate and the elimination of the quaternary amino-group with sodium hydride, the methyl ester of 4,4-dimethylbicyclo[1.1.0]butane-1,2,2-tricarboxylic acid **48** (R = R^5 = R^6 = CH_3, R^1 = $COOCH_3$, R^2 = H) was obtained.[66] Oxidation of compound **45** with H_2O_2 solution is accompanied by partial hydrolysis and leads to the relatively stable *N*-oxides **49** (R = CH_3; R^1 = R^2 = H; R^3–R^6 = CH_3).

5. Aminocyclobutane-1,3-dicarboxylic acids

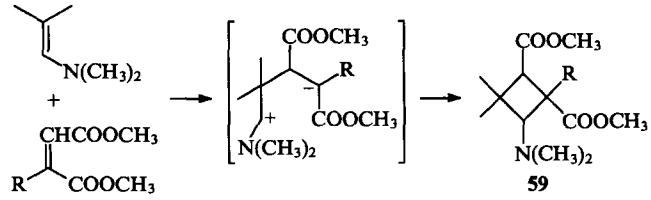


The only known aminocyclobutane-1,3-dicarboxylic acid is *trans*-1-aminocyclobutane-1,3-dicarboxylic(2,4-methanoglutamic) acid **50**, which was isolated form the seeds of *Atelia Herbert Smithii* (*Leguminosae*) together with 2,4-methanopyrrolidine-2-carboxylic acid (2,4-methanoproline) **51**.[1] The stereoisomers of compound **50** are of interest as potential antagonists of the NMDA [*N*-methyl-D-aspartic acid (Translator)] receptors,[44] as therapeutic agents for the treatment of the consequences of ischemia, and as anticonvulsants. They were synthesised by several methods. Hughes and Clardy[41, 42] obtained the achiral aminoacids **50** by oxidising the methyl ester of *N*-(*tert*-butoxycarbonyl)-2,4-methanoproline **52** with sodium metaperiodate and RuO_2 dihydrate in a solvent mixture (H_2O–CH_3CN–CCl_4). The removal of the protecting group by the acid hydrolysis of the intermediate ester of *N*-(*tert*-butoxycarbonyl)-2,4-methanoglutamic acid **53** leads to the aminoacid **50** in ~51% yield (relative to the initial compound **51**).



Pirrung[67] synthesised the initial aminoacid **51** from pyruvic acid and allylamine, but the yield of compound **51** proved unsatisfactory for preparative synthesis (~8.5% relative to the initial ester), since the ester of *N*-alkyl-2-acetamidopropenoic acid **54** (R = C_2H_5, R^1 = CH_3) is formed in a low yield and its photocyclisation is complicated by a side reaction and compound **55** was obtained in a yield of only 17%.

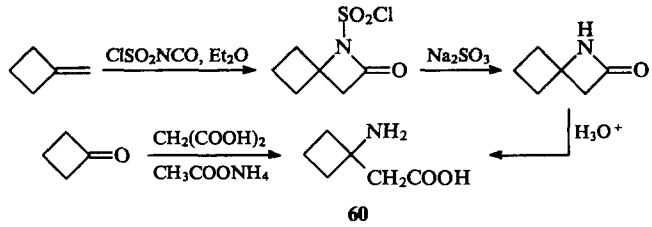
A method of synthesis of compound **51** from serine has been proposed.[42, 43] Serine was converted into 2-benzamido-3-chloropropionate, the condensation of which with allyl bromide under an inert atmosphere in the presence of potassium *tert*-butoxide at −78 °C in THF afforded the ester **54** (R = CH_3, R^1 = C_6H_5) and the photochemical cyclisation of the latter led to the ester of *N*-benzoyl-2-azabicyclo[2.1.1]hexane-1-carboxylic acid **55** in a higher yield (87%). Hydrolysis of compound **55** (R = CH_3, R^1 = C_6H_5) afforded compound **51** in 66.5% yield relative to the initial serine. Gaony[37] proposed a synthesis of a mixture of the stereoisomeric aminoacids **50** from 1-(arenesulfonyl)bicyclo[1.1.0]butane similar to the synthesis of the α-aminoacids **1** and **3**–**6**. 1-(Arenesulfonyl)bicyclo[1.1.0]-butane was converted by a standard method (see above) into the azide and then into 3-arenesulfonyl-1-azidocyclobutane-1,3-dicarboxylic acid. The reduction of the azido-group led to 1-amino-3-arenesulfonylcyclobutane-1,3-dicarboxylic acid **56**, from which the benzenesulfonyl group was removed by reductive elimination and a mixture of the stereoisomeric aminoacids **50** was obtained in 25%–30% yield.



Allan et al.[44] proposed that the stereoisomeric aminoacids **50** be synthesised from 3-oxocyclobutane-1-carboxylic acid by the Strecker reaction. The yield of the aminoacids **50** was ~48% and the ratio of the *cis*- and *trans*-acids in the mixture was 3:2. An alternative synthesis of the aminoacid **50** was achieved by the Bucherer–Bergs reaction.[44] This method gives rise to a better result (overall yield 62%–66%) than the Strecker reaction, but the *cis*:*trans* isomer ratio is in this case 5:1. Pure *cis*- and *trans*-isomers of compound **50** were isolated by chromatography on Dowex AG50W resin in the H^+-form.

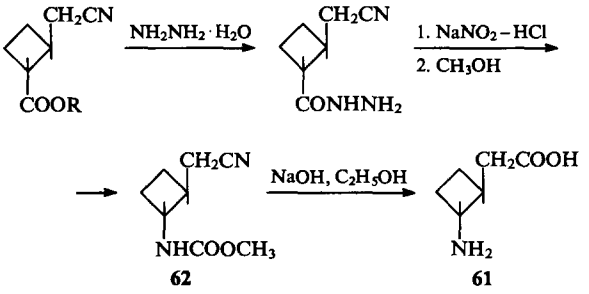
Biological tests showed that *trans*-**50** is 20 times more active as an agonist than NMDA; the *cis*-isomer of compound **50** is a third less active as an agonist, but it proved to be more selective.[44, 68]

6. Aminocyclobutanepolycarboxylic acids



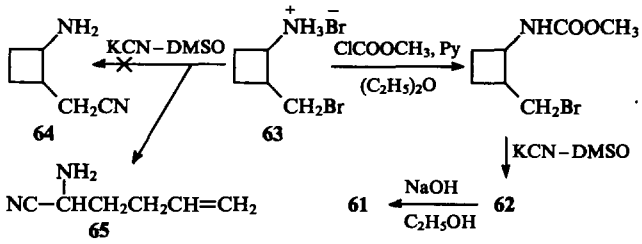
Aminocyclobutanepolycarboxylic acids are little known. 3-Aminocyclobutane-1,1,3-tricarboxylic acid **58** (R = COOH) has been obtained by the Bucherer–Bergs reaction from 3-oxocyclo-butane-1,1-dicarboxylic acid **57** (R = COOH) in solution in methanol.[44] By the cycloaddition of enamines to electron-accepting olefins, in particular by the addition of *N,N*-dimethylisobutenylamine to methyl ethylenetricarboxylate, Hall and Ykman[69] synthesised the trimethyl ester of 4-(*N,N*-dimethylamino)-3,3-dimethylcyclobutane-1,1,2-tricarboxylic acid **59** (R = $COOCH_3$), which was used for the synthesis of bicyclobutane derivatives.

III. Aminocyclobutyl-substituted carboxylic acids

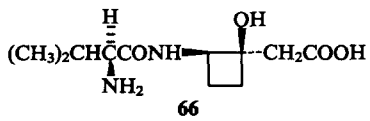


Aminocyclobutyl-substituted carboxylic acids are few in number and have been inadequately studied. Virtually all the known aminoacids of this group have been obtained by the reactions of carboxylic acids, amines, and carbonyl compounds of the cyclobutane series. The classical methods of synthesis of aminoacids have been mainly used to convert the initial compound into aminoacids.

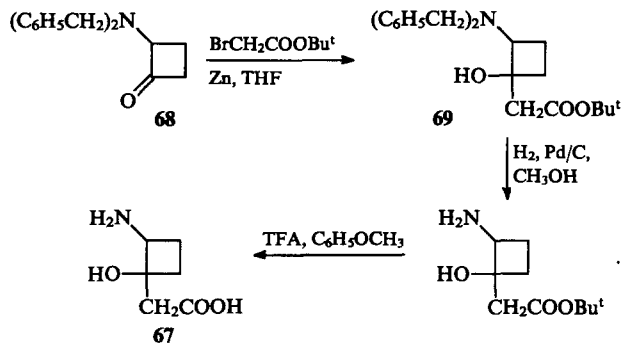
The ability of olefins to form *N*-chlorosulfonyl-β-lactams in their reactions with chlorosulfonyl isocyanate has been used to synthesise the only known compound of this series — 1-amino-cyclobutylacetic acid **60**.[70, 75] The interaction of methylene-cyclobutane with chlorosulfonyl isocyanate led to the synthesis of *N*-chlorosulfonyl-1-azaspiro[3.3]heptan-2-one, the reduction of which with an aqueous solution of sodium sulfite[75] afforded 1-azaspiro[3.3]heptan-2-one.



The opening of the β-lactam ring with the aid of hydrochloric acid leads to the aminoacid **60**. An alternative method of synthesis of compound **60**, from cyclobutanone, under the conditions of the Rodionov reaction has been proposed.[70] It was established that higher yields (60%–70%) of the aminoacid **60** were obtained when the monoammonium salt of malonic acid was used and on heating the reactants in solution in dimethyl sulfoxide (DMSO) or DMF. The acid **60** itself was isolated in the form of the neutral zwitter-ion on Dowex AG50W/H^+ and was used to obtain derivatives of 6-aminopenicillanic acid, which exhibit bactericidal activity.[70]

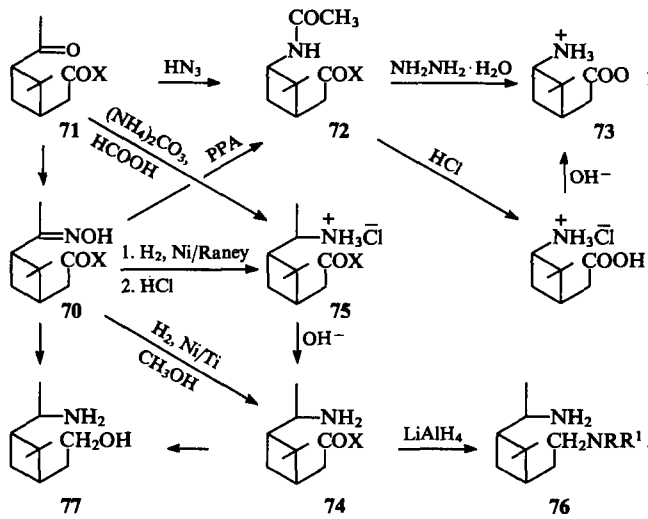


In order to investigate neurotropic activity, *cis*- and *trans*-2-aminocyclobutylacetic acids **61** were synthesised as analogues of GABA with a conformationally limited mobility.[49] *trans* **61** was obtained by a 7-stage synthesis from the diester of *trans*-cyclobutane-1,2-dicarboxylic acid.[19, 49] Using a scheme analogous to the synthesis of compound **31**,[50] the diester was converted into the ester of 2-cyano-methylcyclobutane-1-carboxylic acid.[49] The ester group was replaced by the hydrazide and further by the carbamide group, affording compound **62**. Alkaline hydrolysis of the cyanocarbamate **62** leads to *trans*-**61**.



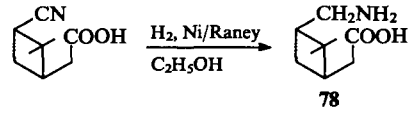
Compound *cis*-**61** was obtained by a similar procedure from the diester of *cis*-cyclobutane-1,2-dicarboxylic acid. The anhydride of *cis*-cyclobutane-1,2-dicarboxylic acid has also been used to synthesise *cis*-**61**.[49] An alternative method of synthesis of *cis*-**61** from the hydrobromide of 2-amino-1-bromomethyl-cyclobutane **63** has been proposed.[49] The conversion of the amino-group of compound **63** into the carbamide group and replacement of bromine by the cyano-group afforded the cyanocarbamate **62**, the hydrolysis of which gives rise to *cis*-**61**. It is noteworthy that the attempts to obtain the aminonitrile **64** by the direct replacement of bromine in compound **63** by the CN group as a result of treatment with potassium cyanide in DMSO at room temperature or on refluxing with sodium cyanide in ethanol led to the opening of the cyclobutane ring and the formation of the nitrile **65**. In the study of the possibility of the binding of *cis*- and *trans*-**61** to the GABA receptor, it was established that *cis*-**61** is a weak inhibitor and *trans*-**61** is a powerful inhibitor of the binding of [^{3}H]muscimol. On the other hand, *cis*- and *trans*-**61** proved to be ineffective as inhibitors of the absorption of [^{3}H]GABA.[49]

The antibiotic X-1092 was isolated from the culture medium of the unidentified microorganisms *Streptomyces species X-1092* under aerobic conditions. It proved to be a dipeptide—(1*S*, 2*S*)-1-hydroxy-2-[(*S*)-valylamino]cyclobutane-1-acetic acid **66**,[3, 72, 73] exhibiting antimicrobial activity on gram-positive and gram-negative microorganisms.



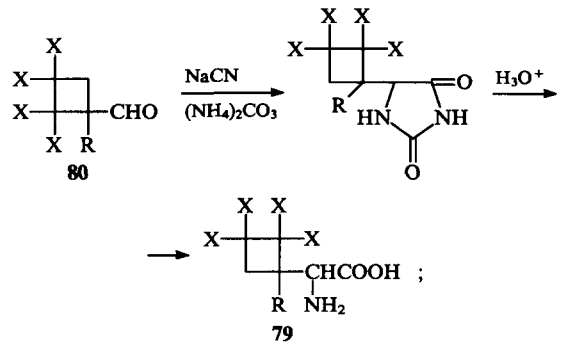
Acid hydrolysis of the dipeptide **66** yielded (1*S*, 2*S*)-2-amino-1-hydroxycyclobutylacetic acid **67**,[3, 72] which also possesses antibacterial activity against gram-positive bacteria. The aminoacid **67** and the dipeptide **66** were synthesised by Baldwin et al.[74], the initial 2-dibenzylaminocyclobutanone **68** being obtained in two stages from diethyl succinate.[76]

The *tert*-butyl acetate group was introduced into the cyclobutanone **68** by the Reformatskii reaction and the resulting mixture of racemic diastereoisomers of the dibenzylamino-alcohols (with a *cis*:*trans* isomer ratio of 8:1) was separated chromatographically on SiO_2, debenzylated, hydrolysed with trifluoroacetic acid (TFA) in anisole, and *cis*- and *trans*-**67** were obtained in 75% and 78% yields respectively (relative to *cis*- and *trans*-**69**) after purification on ion-exchange resins and subsequent high pressure liquid chromatography.



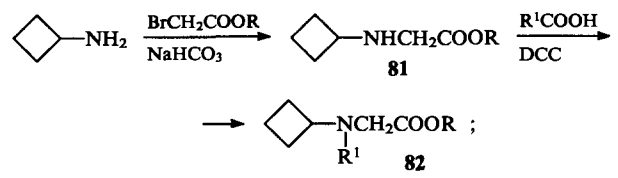
Certain aminocyclobutylacetic acids of the 2,2-dimethylcyclobutane series have been obtained from derivatives of the readily available 3-acetyl- and 3-hydroxycarbonyl-2,2-dimethylcyclobutylacetic (pinonic and pinic) acids.[8, 15, 65, 77–93] The Beckmann rearrangement of the pinonic acid oxime **70** (X = OH)[83, 84] or the interaction of pinonic acid and its esters **71** (X = OH, OR^2) with hydrogen azide (the Schmidt reaction)[15, 78, 81, 82] leads to 3-acetamido-2,2-dimethylcyclobutylacetic acid **72** (X = OH). Hydrazinolysis with hydrazine hydrate or acid hydrolysis of compound **72** affords 3-amino-2,2-dimethylcyclobutylacetic acid **73**.[15, 78, 81, 82, 84] It has been established that the best reagent for the Beckmann rearrangement of the oximes **70** (X = OH, OR^2) is polyphosphoric acid, where the optimum temperature of the rearrangement is 80 to 90 °C, and that the optimum deacylating agent is hydrazine hydrate.[84] The yield of the aminoacid **73** reaches 75.7%.

The amides of 3-acetamido-2,2-dimethylcyclobutylacetic acid **72** (X = NRR^1) have been synthesised under similar conditions from the oximes of pinonic acid amides **70** (X = NRR^1).[84] The amides **75** have been obtained by the reaction of the chloride of 3-amino-2,2-dimethylcyclobutylacetic acid with primary and secondary amines.[84] The aminoacid **73** has been recommended for the synthesis of polymeric materials forming transparent solid coatings.[5] Its esters and ureides are surfactants.[82] The reduction of compound **70** (X = OH) with sodium in isopentyl alcohol[77, 79] or catalytically over platinised nickel, Vavon platinum, Raney nickel,[79, 80, 86–89] and Lyubarskii's catalyst[90, 92, 94–98] leads to 3-(α-aminoethyl)-2,2-dimethylcyclobutylacetic (ε-aminopinanic) acid **74** (X = OH). An alternative method of synthesis of compound **74**—by the rearrangement of compound **71** (X = OH) and its esters **71** (X = OR) in the Leuckart reaction[91]—is less suitable for preparative purposes, since it requires relatively high temperatures (175–190 °C) and the yield of compound **74** (X = OH) does not exceed 33%–45%.

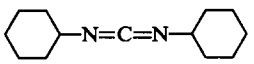


ε-Aminopinanic acid **74** and its esters[99] are of interest as starting materials for the synthesis of biologically active compounds[86–89] and polyamides[90, 91, 93, 100] The aminoacid **74** (X = OH) itself exhibits an antifibrinolytic activity.[8, 16] The hydrochlorides of the amides of ε-aminopinanic acid **75** (X = NRR^1)[95, 97] exhibit an antiviral activity.[101–103] The catalytic reduction or reduction with $LiAlH_4$ of the amides of ε-aminopinanic acid leads to the diamines **76**,[100, 104] while the reduction of the esters **74** (X = OR) leads to the aminoalcohols **77**, which are of interest as biologically active substances[12–14, 18] and as monomers for the synthesis of polymers.[104, 105]

3-Aminomethyl-2,2-dimethylcyclobutylacetic acid **78** has been obtained by the catalytic reduction of 3-cyano-2,2-dimethylcyclobutylacetic acid.[65, 85] The initial nitrile was synthesised in three stages from the monoester of pinanic acid.[65]

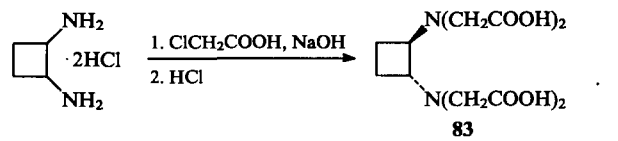


The Bucherer–Bergs method of synthesis of aminoacids has been employed to obtain the cyclobutyl analogue of glycine—α-aminocyclobutylacetic acid **79** (R = X = H) and its derivatives.[20, 106, 107] The unusual aminoacid **79** (R = CH_3, X = F) with the tetrafluorocyclobutyl substituent has also been obtained by this procedure from 2,2,3,3-tetrafluoro-1-methylcyclobutylaldehyde **80** (R = CH_3, X = F).[106]

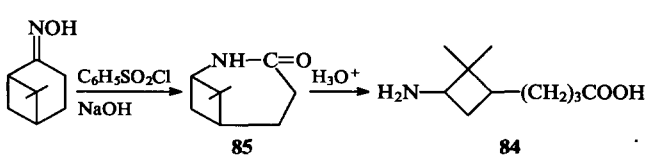


X = H, F;
R = H, CH_3 .

The amide **79** (R = X = H) exhibits a bactericidal activity[20] and certain esters of *N*-aryl-α-cyclobutylglycine exhibit an insecticidal activity.[108] α-Cyclobutylglycine **79** can be used successfully as an alternative substrate for valyl transport RNA-synthetase.[106]



The esters of *N*-cyclobutylaminoacetic acid (*N*-cyclobutylglycine) **81** and the amido-derivatives of the esters **82**, which exhibit a hypotensive activity [antihypertensive (Translator)], have been synthesised by condensing cyclobutylamine with bromoacetic acid esters in the presence of alkaline agents.[109]



R = H, $C(CH_3)_3$;
R^1 = $COCH(CH_3)CH_2SH$, $COCH(CH_3)CH_2SCOCH_3$;

DCC =  .

trans-1,2-Diaminocyclobutane-*N*,*N*,*N*',*N*'-tetraacetic acid **83** has been obtained in the same way from the dihydrochloride of *trans*-1,2-diaminocyclobutane and monochloroacetic acid.[110] The dihydrochloride of *trans*-1,2-diaminocyclobutane was synthesised by the Curtius reaction from the dihydrazide of *trans*-cyclobutane-1,2-dicarboxylic acid.[111] The aminoacid **83** tends to form chelates with metal ions.

Of the higher AACB, only 3-amino-2,2-dimethylcyclobutylpropionic acid **84** has been described in the literature. It was obtained by the acid hydrolysis of 7,7-dimethyl-2-azabicyclo[4.1.1]octan-3-one **85**.[112] The lactam **85** was synthesised by the Beckmann rearrangement of nopinone oxime with benzenesulfonyl chloride.[112] The aminoacid **84** is also used for the synthesis of polyamides.

As can be seen from the literature data examined in this review, many AACB and their derivatives possess biological activity. They are of independent interest and are also of interest as intermediates in the synthesis of physiologically active and other compounds. On the other hand, their reactivity has been investigated relatively little. The majority of AACB can be obtained by the known methods of synthesis of aliphatic aminoacids. However, not all the methods quoted in this review are of preparative value. Therefore AACB still remain compounds which are difficult to obtain, particularly in the form of pure diastereoisomers and enantiomers. One may therefore expect that further studies on the synthesis of AACB will be directed towards the creation of new preparative methods of synthesis of these compounds from available starting materials and to a more detailed investigation of their reactivity, in particular the investigation of their C- and N-substituted analogues.

Abstract. The electrochemical reduction and oxidation of metal ions accompanied by the formation of a film at the electrode–electrolyte boundary is discussed. The formation of a film having a mixed conduction type and consisting of oxide–hydroxide compounds of the metal denotes the presence of a new system: the electrode–film–electrolyte system, called a bifunctional electrochemical system because it can act as an electrolyte and as an electrode simultaneously. The bibliography includes 112 references.

I. Introduction

Interest in the electrochemical reduction and oxidation of transition metals has increased continuously for many decades, in spite of the extensive fundamental studies which have already been reported. This can be attributed to the complexity of the relevant electrochemical reactions, especially in systems containing multivalent metal ions.

When the pH of the cathodic film on an electrode surface differs significantly from its value in the bulk of the electrolyte[3] the intermediate reduction products (compounds of a metal being deposited in lower states of oxidation or compounds of a metal being dissolved in higher states of oxidation) form a cathodic or anodic film whose composition includes compounds able to be discharged directly to the metal.

The formation of this film denotes the presence of a new electrode system (now called a bifunctional system because electrode processes can take place on both sides of the film). The film possesses both electronic and ionic conductivity: the ionic conductivity supports the electrolysis on the side of the electrode and the electronic conductivity supports it on the side of the electrolyte. Hence the film behaves as an electrode towards the electrolyte and as an electrolyte towards the electrode, thus fulfilling two functions simultaneously.

It is therefore of interest to examine electrochemical reduction and oxidation processes from the standpoint of assessing their degree of bifunctionality towards various systems.

II. Formation of a film at the electrode–electrolyte interface

1. Cathodic processes

The presence of a cathodic film was first suggested in the 1920s following a study of one of the most complex of these processes: the electrodeposition of chromium from solutions of chromic acid. The existence of such a film during the electrodeposition of chromium is now generally accepted, and has been confirmed by electrochemical[4–8] and optical methods, by microscopic observations with both still and ciné-film recording,[7–9] and also by an analysis of the zone adjacent to the electrode using special apparatus.[10, 11]

Two types of film (primary and secondary) have been defined, formed on the cathode in a solution of chromic acid in the absence of current and under polarisation respectively.[12, 13] They differ both in their composition and properties and in the mechanism of their formation.

The primary films, formed on the electrode surface before the current is applied, are very thin (~0.02 μm) and almost free from pores; they cover the cathode uniformly and they have an electronic conductivity.[5, 12] The metal atoms of the cathode contribute to their formation, and as a result the primary films formed on different cathodes have different compositions. This explains the effect of the cathode material and of the state of the surface on the nature and structure of the films.[11, 12, 14]

The secondary (truly cathodic) films are formed by the electrochemical reduction of the chromic acid. These films are porous and thicker than the primary films, and they can grow to macroscopic dimensions (~0.1 μm) (0.1 mm? Ed.).[10–12]

Obviously, the properties of the secondary films are independent of the initial state of the electrode surface. It has been suggested[5] that the secondary films have semiconducting properties.

Whereas the presence of a cathodic film is now no longer in doubt there is still a divergence of opinions concerning the influence of foreign ions on the film (and therefore also on the cathodic process). We know[12] that chromium is not deposited from solutions of chromic acid except in the presence of small quantities of H_2SO_4, H_2SiF_6, HF, or HCl. Interest in explaining the role of inorganic acids in the formation of the film was also stimulated by the widely held view[4, 5, 15–18] that chromium is reduced to the metal on the cathode from the film itself.

The direct study of the composition and of the behaviour of the cathodic film during *in situ* electrolysis is a complex problem. Consequently most judgements on the nature of the films have

been based on indirect experimental data.[4, 5] Thus it has been shown[19, 20] that irrespective of the $CrO_3 : H_2SO_4$ ratio in the bulk of the electrolyte this ratio is constant within the film, suggesting the formation of chemical compounds between CrO_3 and H_2SO_4 which are then discharged on the cathode. Possible explanations include the formation[21] of CrO_4^{2-} and Cr^{3+} compounds, complex particles $CrCrO_4^+$ and $CrCrO_4H$, and also the formation of complex compounds of chromium with chromium anions[22-24] and cations, connected through an oxygen bridge: Cr(III)–O–Cr(IV).[19, 22]

Studies of the composition of the cathodic film and of the reduction of chromic acid led many workers to conclude that the layer of liquid adjacent to the cathode may contain Cr^{2+}. This suggestion was first made[25] in the 1930s. In more recent work it has received both indirect and direct confirmation[10, 12]

The presence of bivalent chromium ions in solution denotes their interaction with the chromic acid, which should produce the dimer and hexa-aquo (tervalent) chromium ions (observed experimentally). These results led to the conclusion that the discharge as far as the metallic state is initiated by the bivalent chromium ions, and that the formation of tervalent chromium ions is the result of a secondary chemical reaction.[26]

Since the electrochemical reduction of chromic acid is accompanied by the reduction of H^+ the solution in the layer adjacent to the cathode becomes strongly alkaline, with formation[3, 12, 27] of chromium hydroxides [$Cr(OH)_3$] on the cathode surface by the reaction

$$Cr_2O_7^{2-} + 14H^+ + 6e \longrightarrow 2Cr^{3+} + 7H_2O ,$$

together with a small quantity of $Cr(OH)_2$. Thus the nature of the cathodic film is determined by the character of the interaction of the solid phase of the newly produced hydroxide $Cr(OH)_3$ with the divalent chromium ions and with the ions of the additives (SO_4^{2-}, SiF_6^{2-}, F^-, etc.).[12] The conversion of a finely divided sol into a solution with a molecular degree of dispersion, which has been called[12] a 'phase transformation', is accelerated by a factor of 6–94 in the presence of additive ions, depending on their concentration.

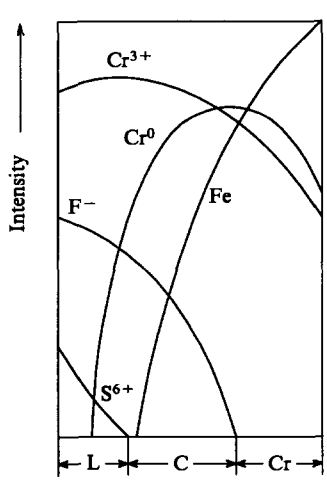

Figure 1. Distribution of the ions in the bulk of the film. Composition of the electrolyte/g dm^{-3}: CrO_3 180; H_2SO_4 0.54; Na_2SiF_6 54; T = 50 °C; i_c = 70 A dm^{-2}; τ = 2 s.

With the aid of recently developed apparatus[10] it was established that the cathodic film formed at the deposition potential of metallic chromium (−1.2 V) consists of two layers (Fig. 1): a dense, sparingly soluble internal layer (the C Layer) and a looser, more soluble external layer (the L layer). The ratio of the L and C layer thicknesses was found[10] to be 10 : 1. In spite of the small thickness of the dense C layer the largest potential drop occurs across this layer because this part of the film has the highest electrical resistance. Some interesting results on the distribution of the ions in the cathodic film have also been reported.[10] Since the electrolyte being studied contained mixed additive ions (SO_4^{2-} and SiF_6^{2-}) the film was found to contain sulfur and F^- ions, but the concentration of F^- decreased sharply on going from the looser to the denser layer, making the interface easily detectable.

A study of the reduction of the CrO_4^{2-} ions in the presence of CH_3COOH by the optical phase contrast method[15] additionally confirmed the presence of at least two layers in the vicinity of the electrode. It was found that if the thickness of the whole film is ~100 μm the main electrode process is confined to a small fraction (~0.01%–0.02%) of the total thickness.

The formation of bivalent chromium compounds which are reduced to the metal during the electrodeposition of chromium in the presence of H_3BO_3 has been established by Auger spectroscopy.[28] It was concluded[28] that the catalytic action of H_3BO_3 consists in the formation of a complex of tetrahydroxy $B(OH)_4^-$ ions with Cr^{3+}, which is then reduced to $Cr(OH)_2$. The latter is dehydrated, forming CrO, which then proceeds to form a complex with the $B(OH)_4^-$ ion, is adsorbed on the cathode surface, and is reduced to the metal. Thus the role of $B(OH)_4^-$ is similar to that of HSO_4^-, but since the hydrolysis constant of H_3BO_3 is small (pK = 9.00) the concentration of $B(OH)_4^-$ ions is also small. This explains the relatively low effect of $B(OH)_4^-$ as compared with that of HSO_4^-.

We may conclude from these observations that the cathodic film formed during the electrochemical reduction of the Cr^{6+} ions consists of lower-valency compounds of chromium formed by an intermediate reduction step.

The products of an intermediate reduction are observed in studies of many cathode processes. Especially interesting in this respect is the electrochemical reduction of the anionic forms of metals, whose deposition takes place with a current yield significantly lower than 100%.

These processes include the electrochemical reduction of the ReO_4^-, MoO_4^{2-}, WO_4^{2-}, and VO_4^{3-} ions. Detailed studies of these systems have established[29] the electrolysis conditions leading to the formation of products of the intermediate reduction of the transition metal ions (in the form of sparingly soluble, often powdery deposits), and also the composition and properties of these compounds. From the totality of the available information it was concluded that the composition of the compounds is described by the general formula $A_2O \cdot xMO_n \cdot yMO_{n-q} \cdot zH_2O$, where A is an alkali metal, ammonium, or hydrogen. The presence of water and of hydroxyl groups connected by hydrogen bonds of various strengths has been demonstrated.[29] The fraction of the current taken up by the formation of these oxygen compounds can be determined from the electrodeposition parameters.[30, 31] For the reduction of the ReO_4^- ions it was shown that the finely divided black deposits are rhenium compounds of various valencies. Since the average of the observed valencies of rhenium was close to 4 it was concluded that both more oxidised and more reduced forms must be present. In the electrochemical reduction of ReO_4^- ions from electrolytes with pH 1–2 the average valency of the rhenium is less than 4: this is attributed[29] to the presence of metallic rhenium in the cathodic deposit.

The formation of rhenium oxide from an aqueous electrolyte of pH ~1.65 has been reported.[32] Polarisation and X-ray diffraction studies have shown that the reduction process takes place in two steps. The first steps produces a film of partially reduced rhenium oxide, whereas in the second step the reduction proceeds to the metallic state. The composition of the oxide is determined by the cathode potential: shifting the potential towards more positive values produces black deposits of rhenium oxides in a higher state of oxidation. The deposition of metallic rhenium (with hydrogen evolution) takes place at potentials below −0.4 V.

Under ordinary conditions metals such as Mo, W, V, Zr and Nb are not deposited from aqueous electrolytes. The products of the incomplete reduction of molybdenum and tungsten have been studied in the greatest detail: the intermediates in the reduction of the MoO_4^{2-} ions are formed sequentially through a series of steps (giving quinque-, quadri-, and tervalent ions respectively), depending on the potential of the electrode, on the composition and temperature of the electrolyte, and on other factors.[33]

In the electrolysis of neutral and of weakly acid solutions of alkali metal molybdates or of ammonium molybdate a black deposit of composition $Mo_2O_3 \cdot 3H_2O$ is formed on the cathode.[29] The kinetics of the deposition and composition of the cathodic films formed in the reduction of MoO_4^{2-} ions have been studied in detail.[29, 34] The average valency of the molybdenum (4.96) was determined by chemical analysis, and the formula $xMoO_{2.4+z} \cdot yH_2O$ was assigned[29] to the compound deposited on the cathode (where $x:y = 1$ and $z = 0.1$). Similar results were obtained in studies of the reduction of molybdates from aqueous chloride solutions. Molybdenum blue, formed on a cathode, was given the formula[35] $MoO_{2.89} \cdot xH_2O$. This nonstoichiometric compound is a semiconductor,[36] and its conductivity is determined by the degree of dehydration.

The formation of a film of insoluble molybdenum oxides and hydroxides in a lower valency state on a cathode has been noted also in studies of the reduction in the presence of metals of the iron subgroup.[37] Experimental data lead to the conclusion that a film consisting of molybdenum compounds in a lower valency state [for example, Mo(III)] is permeable to Fe^{2+} and Ni^{2+} ions even if relatively thick. Introducing these into the film alters its structure and composition: the Mo–O bonds become weaker, bonds between the molybdenum, the iron, and the nickel are formed, and as a result the molybdenum is reduced to the metal with formation of an alloy. The reduction of the iron and of the nickel is also stepwise,[37] and increasing their concentration in the electrolyte increases the rate of reduction of the film.

Molybdenum oxides in a lower state of oxidation formed on a cathode are easily identified and can be used in practice. Thus molybdenum oxide prepared electrochemically has been used as a catalyst[38] and as a functional coating.[38, 39]

The reduction of the WO_4^{2-} ion from acid and from alkaline electrolytes takes place with deposition on the cathode of the lower oxides of tungsten or of a mixture of the oxide and the metal.[40] The composition $Na_2O \cdot nW_2O_5 \cdot mWO_3 \cdot qH_2O$ has been assigned[29] to the cathodic deposit obtained from a solution of Na_2WO_4.

The formation of intermediate reduction products takes place also in the electrochemical reduction of cationic forms of the metal. Thus, in the electrochemical reduction of copper from sulfate[41] and diphosphate[42] electrolytes† on a cathode, sparingly soluble copper compounds have been detected. In the sulfate electrolyte Cu_2O was detected on the cathode[41] in amounts increasing as the current density was decreased. In diphosphate electrolytes also a cathode film was detected:[42, 43] it was formed at all values of the electrode polarisation, and the film itself consisted entirely of univalent copper compounds. In these compounds copper can be reduced to the metallic state during cathodic polarisation in a supporting electrolyte not containing copper.

The presence of a film containing Cu_2O has been observed in a diphosphate electrolyte during a study of the interface by the electroreflectance method.[44] In this case the film was detected, as in a later patent,[45] only at relatively low polarisations (up to -0.1 V). At higher values of the cathodic polarisation the electroreflectance spectra had the characteristic shape of the spectra for metallic copper.

The formation of copper oxides has been established also in sulfate electrolytes at pH > 3 by measurements of the photoelectrochemical effect.[46, 47] It was assumed that the film with *n*-type conduction on the surface of a copper electrode consists of copper oxide. The change in the conductivity type at a well defined potential was attributed to the reduction of CuO to Cu_2O.

The formation of sparingly soluble compounds of the oxide-hydroxide type has been noted[48, 49] in studies of the fluorosilicate copper-plating electrolytes. The role of the concentration of hydrogen ions in the formation of these compounds has been studied by electrochemical reduction methods and by electron-diffraction studies of their composition. As a result it was established that Cu_2O, CuO, and $Cu(OH)_2$ are formed on the copper electrode surface. The relative amounts of these compounds are determined by the pH of the electrolyte: the content of $Cu(OH)_2$ increases with the pH of the solution, and in electrolytes with a low pH value no oxygen compounds are formed (as a rule) on the surface of the copper electrode.

At low current densities $Cu(OH)_2$ is formed in these electrolytes, but the fraction of the current used in this process is small.[48] The most significant process is the reduction of the Cu^{2+} ions. It has been suggested that the increase in the cathodic polarisation is caused by the blocking of the electrode surface by these compounds.[49]

The formation of sparingly soluble copper compounds on the cathode surface increases the cathodic polarisation also in fluoroborate electrolytes.[50]

A solid phase (black zinc) is formed in the electrochemical reduction zinc from a sulfate electrolyte under certain conditions.[51] X-ray diffraction analysis has shown that black zinc consists of finely divided metallic zinc, ZnO, and a small amount of inorganic salt absorbed from the electrolyte. The formation of oxides during the deposition of zinc has also been reported very recently.[52]

Studies of the mechanism of the cathodic deposition of nickel[53] and cadmium[54] have also led to the conclusion that a solid phase is formed on the cathode surface.

The electrolysis of solutions containing $FeCl_2$, $NiCl_2$, $CuCl_2$, $ZnCl_2$, and $PbCl_2$ has produced loose black deposits of composition α–FeOOH, $Ni(OH)_2$, Cu_2O, ZnO, and $PbO \cdot 0.5H_2O$ respectively on the cathode.[55]

The presence of a film of hydroxide on the electrode surface has been established also in the deposition of cobalt from diphosphate electrolytes.[56] In this case the reaction is not the discharge of the unstable diphosphate complex anions $[Co(P_2O_7)_2]^{6-}$ or $[Co(P_2O_7)]^{2-}$, but their dissociation in the cathode layer as a result of the increase in the pH, with formation of a substantial amount of $Co(OH)_2$. Thus, in the electrochemical reduction of cobalt ions the formation of a relatively thick film can be visually observed. The formation of a finely divided sol of composition $\{x[Co(OH)_2] \cdot z[Co(OH)^+]\}$ during the dissociation of the diphosphate cobalt complexes passivates the electrode surface and strongly influences the cathodic process even when the formation of a film cannot be detected visually.[57] A study of the electrocrystallisation of cobalt by the impedance method has shown[58] that the discharge process involves several steps, ultimately leading to the formation of partially reduced cobalt compounds of the $Co(OH)_{ads}$ type, as in the reduction of the Cu^{2+} and Ag^+ ions. This effect is responsible for the inductive component of the Faraday impedance in the low frequency region. On the other hand the composition of the film is determined by the electrolysis conditions.[59]

A study of the polarisation during the electrodeposition of antimony from fluoride electrolytes led to the conclusion[60] that a partially hydrolysed atom of the metal, not containing F^- ions, is contributing to the cathodic process. The retardation of the process at low current densities is attributed to passivation of the surface by oxides, which makes a multistage mechanism possible.[61]

† The term pyrophosphate for these compounds is now obsolete.

Black deposits containing oxides have been observed[62] in the deposition of manganese at potentials up to −0.88 V. The total metal content of these compounds is not more than 70%–80%.

A passivating layer has also been detected on the surface of a gold electrode in weakly acid or in alkaline solutions of $KAu(CN)_2$ by using ellipsometry, Auger spectroscopy, and spectroscopy in the UV and the visible region.[63, 64]

A cathodic film obtained during the deposition of gold from a weakly acid electrolyte consists of $Au(OH)_3$ or Au_2O_3, adsorbed $KAu(CN)_2$, and metallic gold. As reported,[64] the formation of compounds of tervalent gold is due to a disproportionation reaction, involving an unstable compound of univalent gold, induced by the development of alkalinity in the layer of solution adjacent to the cathode. The element composition of the surface layers formed at potentials of −0.33 and −0.88 V, which characterise the initial step of the chemical and the electrochemical gold-plating process respectively, has been determined by Auger spectroscopy. The surface layer formed at −0.88 V is richer in gold than the layer formed at −0.38 V. Under these conditions the total concentration of impurity elements cannot account for complete compound formation by the surface gold, thus showing that metallic gold must be present in the film. After the beginning of the electrolysis the pH of the layer of solution adjacent to the cathode increases from 5.5 to 9.0, thus producing conditions favourable to the formation of insoluble $Au(OH)_3$ on the cathode surface. The compound is initially formed by the oxidation of a univalent gold surface ion by adsorbed and by chemisorbed oxygen. These unstable compounds of univalent gold are subsequently disproportionated to give tervalent gold.

During the initial stage of the electrodeposition of gold from alkaline cyanide solutions the electrode reaction is retarded by the formation of a sparingly soluble film of overall composition $Au_x(OH)_y(CN)_z$ on the cathode. It has been shown by ellipsometric measurements[65] that the thickness of this film of poorly conducting material increases with the concentration of $KAu(CN)_2$. Under these conditions not only the concentration of CN^- ions but also the pH of the electrolyte can strongly influence the coverage of the electrode surface by a film. The maximum coverage is 0.9 monolayer, reached at pH 13.6 and a potential of −0.2 V.

The formation of oxides has been suggested also in the electrodeposition of uranium from an ammonium fluoride solution.[66, 67] The uranium oxide UO_2 is formed on the cathode as a result of the discharge and dissociation of the complex species $UO_2(L)^{n+}$ formed in solution, which migrate to the cathode

$$UO_2(L)^{n+} + ne \rightleftharpoons UO_2 + L ,$$

where L is the ligand of a complexing agent. Since hydrogen evolution takes place simultaneously with metal deposition it is reasonable to assume that the oxide can be reduced by atomic hydrogen:

$$H^+ + e \longrightarrow H^\cdot ,$$

$$UO_2 + 4H^\cdot = U + 2H_2O .$$

Under these conditions (and at low current densities) the metal is deposited together with oxygen-deficient oxides because of the low rate of discharge of H^+. Increasing the current density increases the rate of discharge of hydrogen and of reduction of UO_2 to the metal.

A study of the kinetics and mechanism of the passivation of the electrode during the electrodeposition of gallium from chloride electrolytes[68] has shown that the passivation is due mainly to the formation on the gallium surface of a film of sparingly soluble compounds, described by the general formula $Ga_x O_y H_z Cl_m$.

The cathodic reduction of the TcO_4^- ion has been shown[69–71] to be a multistage process leading to the formation of both compounds of technetium in a lower valence state and metallic technetium. The cathodic processes (deposition of technetium and formation of partial reduction products) take place in parallel, but there is no clear correspondence between changes in their rates.[71]

2. Anodic processes

Films are formed at the electrode–electrolyte interface also during the oxidation of metals, the preparation of oxides, anodic etching, electropolishing, and the chemical machining of metals. In these operations (as in cathodic processes) the film consists of products of variable composition of the oxide-hydroxide type.

A typical example is the oxidation of manganese in alkaline media. The compounds MnO, $Mn(OH)_2$, and MnOOH can be formed on the electrode surface, depending on the pH of the solution and on the polarisation of the electrode.[72] The oxidation process takes place in the solid phase through the interconversion of the different oxide phases:

$$MnO \longrightarrow Mn(OH)_2 \longrightarrow MnOOH \longrightarrow MnO_2 .$$

According to the results[73] of impedance measurements, of the analysis of chronoamperograms, and of measurements with a rotating disk electrode the mechanism of the electrochemical deposition of MnO_2 form solutions of bivalent manganese compounds consists in the formation of intermediate compounds such as MnOOH, Mn_2O_3, and $Mn(OH)_4$, and finally MnO_2. If the rate of conversion of these compounds into MnO_2 is smaller than their rate of formation a layer of intermediates is seen to grow on the outer surface. This layer hinders the transport of the Mn^{2+} ions from the bulk of the electrolyte to the electrode–electrolyte interface. As the thickness of the layer increases, the rate of diffusion of the Mn^{2+} ions changes towards a value comparable to the rate of transformation of the MnOOH and Mn_2O_3 intermediates into MnO_2. This creates a dynamic equilibrium in the electrode–film–electrolyte system.

Film formation takes place also during metal polishing. The electropolishing process depends on the ratio of the rates of formation of the oxide film (on the metal side) and of dissolution of the film (on the electrolyte side). The predominance of either reaction controls the character of the process, i.e. it determines whether etching or polishing is achieved. The highest surface brightness is obtained when he oxide film is as thin as possible (though thick enough to suppress the etching action of the electrolyte). This situation is found under conditions of dynamic equilibrium in the system, when the rates of the electrochemical formation of the film and of its chemical dissolution are equal.[74]

Studies of the capacitance and of the polarisation resistance at the metal–solution boundary during the polishing of steel have shown that under the optimum conditions a capacity minimum is obtained together with a large increase in resistance. This suggests the formation of an oxide film on the metal, since the presence of a salt film could not account for such large changes in the parameters of the electrode–electrolyte boundary.[74] The polishing process is usually carried out in relatively aggressive media, and therefore the ligand composition plays an important role in the dissolution of the film formed on the anode.

The electrochemical treatment of nickel also produces an oxide film (*p*-type) of nonstoichiometric composition on the metal surface. An analysis of the polarisation measurements and of activation energy data has indicated[75] anodic dissolution of the metal within the surface film, and therefore it is reasonable to interpret the role of the formation of films at the electrode–electrolyte boundary as rate-determining in the dissolution.

A similar picture of film formation applies to the polishing and electrochemical machining of metal surfaces. Thus, on the potentiostatic anodic dissolution curves of titanium in alkaline

solutions we observe a decrease in the rate of the process at potentials between −0.5 and −0.7 V, due to the saturation of the anodic layer by the reaction products and to the formation of a porous film of complex composition on the electrode surface.[76]

The oscillations in the electrode potential observed in various cathodic or anodic processes are a consequence of the formation and dissolution of the film. It should be noted that the best polishing results are obtained in the self-oscillatory regime.[77]

III. Modelling of bifunctional electrochemical systems

As was pointed out above, the first step in any electrochemical reduction involving aquo ions of metals (or their complexes with various ligands) or in the electrochemical oxidation of metals is the formation of a film at the electrode–electrolyte interface. The film is a dynamic multilayer system,[78] containing reducible or oxidisable substances in intermediate states of oxidation. The application of a range of research methods to the layer adjacent to the electrode has demonstrated the formation of a film at the phase boundary and its existence for finite times during electrode processes in aqueous and in molten media.

The fundamental property of the films formed at the electrode–electrolyte phase boundary is the presence of a well defined quantitative relationship between the amounts of ionic and of electronic conductivity, which determines the character and the features of the electron transfer process in the electrode–electrolyte system. On the external side of the film (towards the electrolyte) we observe parallel reactions of partial electrochemical reduction of the metal ions being discharged, or their oxidation to the highest oxidation state allowed in the given conditions, or the chemical dissolution of the film by interaction with the components of the solution. On the inner side of the film (towards the electrode) a topochemical process[79] takes place: the further electrochemical reduction to the metal or the electrochemical oxidation of the metal (Fig. 2).

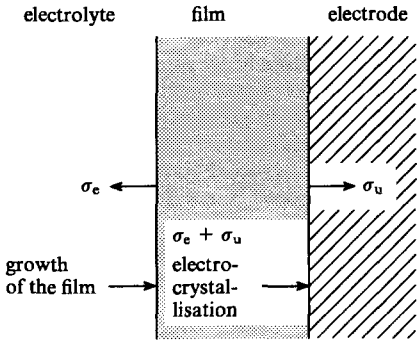

Figure 2. Model of the bifunctional electrochemical system.

The film formed on the electrode surface contributes directly to the electrochemical reactions, which are determined by the physicochemical properties of the film, including its chemical stability towards the reaction medium. A film is formed if the rate of its electrochemical production is greater than the rate of the heterogeneous chemical dissolution process.[80, 81]

The difficulties met in direct studies of the film during its formation and operation stimulated attempts to develop suitable models on the basis of the suggested similarity criteria.[82]

1. Phenomenological description of a model of the bifunctional electrochemical system

Along the normal to the electrode the film is characterised by the nonuniformity of its composition and of its physicochemical properties. We should stress that it is not easy to establish whether a given nonuniformity leads to the formation of discrete phases or whether it merely causes gradual changes in properties. In the former case the model should describe the formation of a sequence of bifunctional systems having a mixed conductivity type. Under these conditions each interface can be associated with one of the successive steps of the electrochemical reduction or oxidation process.

In general the electrochemical step of a cathodic process can be described by the reaction

$$M^{(z-q_{j-1})+} + p_j e \xrightarrow{k_j} M^{(z-q_{j-1}-p_j)+}, \quad (1)$$

where

$$q_{j-1} = \sum_{i=1}^{j-1} p_i$$

is the total number of electrons transferred to an ion during the previous $j-1$ steps of the process; p_j is the number of electrons taking part in the jth step; k_j is the rate constant of the electrochemical process. The reaction products formed under these conditions as a result of the chemical process dissolve on the side of the electrolyte at a constant rate k_j'.

Each of the intermediate phases (from $j = 1$ to $j = m-1$, Fig. 3) is characterised by the average concentration c_j of the partially reduced multivalent metal $M^{(z-q_j)+}$, which is included in the composition of the compounds forming this phase. The electrochemical process leading to the partial solid-phase reduction of the multivalent ions (and to their full reduction at

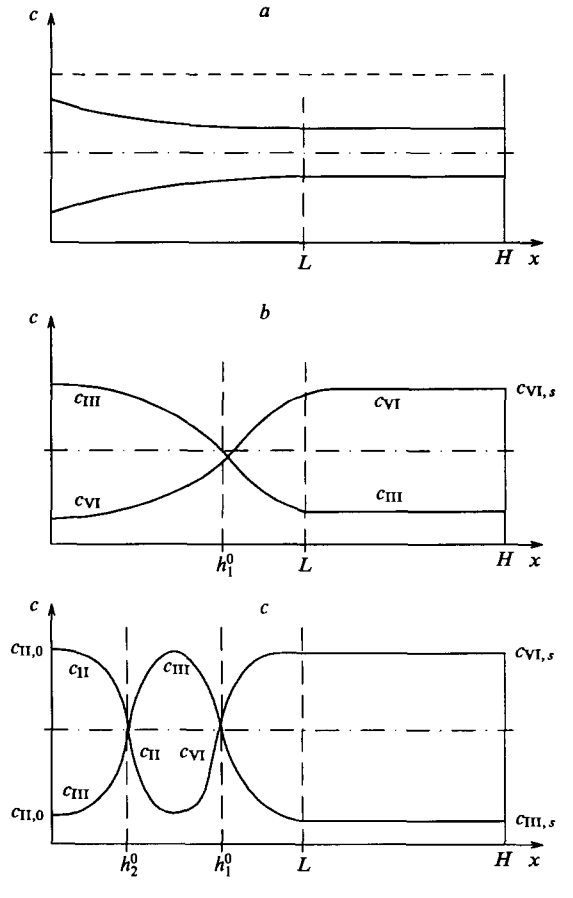

Figure 3. Concentration profile of the partial reduction products in a bifunctional electrochemical system. (*a*) smooth distribution; (*b*) with one boundary ($h_1^0 < L$); (*c*) with two boundaries ($h_2^0 < h_1^0 < L$).

the electrode–film boundary) takes place at increasingly negative potentials of each successive step in the process. The dynamical behaviour of this multilayer structure has recently been described.[78]

The reactions (1), which take place at the interfaces, can lead to changes in the volume of the intermediate phases. For a constant concentration of multivalent metal ions in each layer of thickness h_j the process can be described as follows:

$$c_j \frac{\partial h_j(t)}{\partial t} = Q_{j-1,j} - Q_{j,j+1}\,; \quad j = 1,2,\ldots,(m-1)\,. \tag{2}$$

Here

$$Q_{j,j'} = k_{j,j'} c_j n_{j,j'}^{p_j} - k'_{j,j'} c_j\,; \quad h_j(t)|_{t=0} = 0\,, \tag{3}$$

where $Q_{j,j'}$ is the flux, defined by the total number of multivalent $M^{(z-q_j)^+}$ ions formed in one second as a result of the electrochemical and the chemical processes per unit area of the boundary between phases j and j'; $n_{j,j'}$ is the concentration of conduction electrons in the jth phase near the boundary with phase j'. According to the Tafel equation the rate constant of the electrochemical reaction at the phase boundary is

$$k_{j,j'} = \tilde{k}_{j,j'} \exp(\alpha_{j,j'} e\beta\delta E_{j,j'})\,, \tag{4}$$

where $\alpha_{j,j'}$ is the transfer coefficient; $\beta^{-1} = k_B T$, where k_B is Boltzmann's constant; δ is the average distance between the charge localisation centres; $E_{j,j'}$ is the strength of the electric field at the phase boundary.

Increasing the current I_0 (in the galvanostatic regime) increases the field E_0 at the electrode–electrolyte boundary. When the potential reaches the value corresponding to the electrochemical reduction (1) (which is the first step of the discharge of the metal ions) the ions are reduced to the first intermediate state $M^{(z-p_1)^+}$.

A space charge layer is formed at the metal–semiconductor interface during the growth of the film: the presence of uncompensated charge affects the intensity of the electric field in a volume defined by the space charge region, whose size (in the case of semiconductors) is 10^{-5} to 10^{-4} cm.

The dependence of the electric field intensity on the distance to the cathode surface (where $x = 0$) produces a dependence on x of the rate constant of the electrochemical process, which determines the separation of the phases in space in the bifunctional system for the multistage discharge of multivalent metal ions. The space charge region at the metal–semiconductor interface (bifunctional films usually have semiconductor properties) has been described[80] in terms of the Schottky model on the assumption that the space charge is due mainly to the charge of uniformly distributed ionised donors with a concentration n_0. In this case when the film thickness H is greater than the thickness of the Schottky layer L the field strength in the space charge region ($x < L$) is given by the expression

$$E(x) = E_0 - \frac{en_0}{\varepsilon}(L-x)\,\mathrm{H}(L-x)\,, \tag{5}$$

where

$$L = \left(\frac{2\varepsilon\Delta\varphi}{e^2 n_0}\right)^{1/2}.$$

Here E_0 is the uniform field strength; H is the Heaviside function; ε is the permittivity of the semiconductor; $\Delta\varphi$ is the height of the barrier at the metal–semiconductor interface.

In the region of $0 < x < L$ the concentration of electrons $c_e(x)$ is also dependent on the x coordinate:[83]

$$c_e(x) = n_0 \exp[-\beta\varphi(x)]\,,$$

where

$$\varphi(x) = eE_0(x-L) + \frac{e^2 n_0}{2\varepsilon}(L-x)\,\mathrm{H}(L-x)\,. \tag{6}$$

The presence of a strong electric field $E(x)$ [Eqn (5)] allows the reduction of the multivalent metal ions to proceed in the bulk of the film. The steady state of the film corresponds to equality of the fluxes at the electrolyte–film and electrode–film phase boundaries ($Q_S = Q_0$). The intermediate reduction products are formed when $Q_0 > Q_S$ and the growth rate of the film is

$$V = Q_0 - Q_S\,. \tag{7}$$

When the chemical processes play a dominant role in comparison with the charge transfer process the film is not formed, and therefore the metal deposition is suppressed. This system can be dynamically unstable. The region giving a stable state is determined by the ratio of the rate of the electrochemical process (which depends on the current density) to the rate of the chemical dissolution process (which depends on concentration of the ligand, its nature, the electrolyte temperature, and other parameters).

The mechanism of formation of the bifunctional structure has been examined[80] for the case of the most widely studied of these processes: the electrochemical reduction of the CrO_4^{2-} ions. In this case the kinetic equations which describe processes of type (1) can be written as the following system of equations:

$$\begin{aligned} \frac{dc_{III}(x)}{dt} &= k_1(x)\,c_{VI}(x)\,c_e^3(x) - k'_1 c_{III}(x)\,,\\ \frac{dc_{II}(x)}{dt} &= k_2(x)\,c_{III}(x)\,c_e(x) - k'_2 c_{II}(x)\,,\\ c_{III}(x,t)|_{t=0} &= c_{II}(x,t)|_{t=0} = 0\,, \end{aligned} \tag{8}$$

where k_i, $k_{j'}$ are the rate constants of the reaction, describing the ith process in the discharge of the chromium ions; $k_i(x) = k_i \exp[\alpha_i\beta\delta E(x)]$; $c_{VI}(x,t)$, $c_{III}(x,t)$, $c_{II}(x,t)$ are the concentrations of the chromium ions with a valency of six, three, and two respectively.

The operating regime of the electrochemical system depends on the current flowing through the system. Depending on $E(x)$, i.e. on the current in the system, on the parameters of the Schottky layer, etc., and also on the concentration of the multivalent metal ions at the surface of the film (determined by the rate of the electrochemical processes at the electrolyte–film and the electrode–film boundary), the system of equations (8) can have two solutions, one solution, or no solution.

In the case of large currents, when the field E_0 created by the polarisation of the electrode exceeds the internal field of the Schottky layer, the ion distributions c_{III} and c_{VI} in the film are only slightly dependent on the distance to the electrode (Fig. 3*a*). Decreasing the current brings the field E_0 closer to the field of the electrical double layer, and the system of equations gives successively one solution (Fig. 3*b*) and two solutions (Fig. 3*c*), i.e. an internal multilayer structure is formed in the film under the influence of the field. A further decrease in the current lowers the rate of the electrochemical reaction on the outer surface of the film, and the dissolution of the film becomes the dominant process. The following are the existence criteria of a multilayer structure in the stationary state: for $\tilde{k}_1 c_e < k'$ and $k_2 c_e < k'_2$ the chemical process is dominant in comparison with the electrochemical reduction, and the film is not formed. When the system reaches the $V = 0$ state we observe periodic variations in the rates of growth and dissolution of the film,[84] which leads to oscillations in the potential with a frequency ω_{cr}. In this regime no metal is deposited, as has been observed[82] experimentally. The parameters h_1^0, h_2^0, ω_{cr}, and others, which determine the dynamical behaviour of the bifunctional system, are strongly dependent on the dissolution constants k'_1 and k'_2. In

its turn the parameter k_1' is determined by the nature and concentration c_L of the ligand in the electrolyte and in the bulk of the film, so that the operation of the system can be controlled fairly easily by varying c_L.

The most suitable model of a bifunctional electrochemical system, which allows as fully as possible for all its properties and special features, is provided by the compounds formed on the electrode when the charge transfer process is fixed at an intermediate stage during electrochemical reduction or oxidation. These compounds form a complex electrically conducting heterogeneous system containing the oxides and hydroxides of the appropriate metal in a lower or a higher state of oxidation than in the bulk of the electrolyte, and therefore able to undergo reduction or oxidation. Thus the following similarity criteria between the experimental model and the films actually present on the electrode can be adopted:[85] the presence of low-valency compounds of a mixed conductivity type, and the ability to undergo electrochemical reduction in the solid phase.

2. The presence of low-valency compounds

Let us examine fluorine-containing electrolytes. The rate of formation of partial reduction compounds is determined mainly by the concentration of the F^- ion in the electrolyte and also (to a much lesser degree) by the electrolysis parameters.[86-90] For chromium, nickel, and manganese, which are fairly easily deposited from aqueous solutions, we can define an optimum concentration of the ligand in the electrolyte, offering the maximum rate of formation of the solid phase on the cathode. For molybdenum and zirconium, whose electrode position from aqueous solutions is more difficult, we note a gradual decrease in the rate of deposition of the intermediate reduction products, depending on the concentration of the ligand.

The extent of reduction of the ion being discharged, quantitatively expressed as the total concentration of metal in the solid phase, depends on the concentration of ligand in the electrolyte. In the case of chromium and rhenium it has been shown[91] that this parameter is affected also by changes in the temperature of the electrolyte. An increase in the amount of metal in the deposit produces changes in its properties (colour, microhardness, corrosion resistance). In all the systems which have been examined, including molybdenum and zirconium, a ligand concentration which gives complete reduction to the metal can be identified.

Table 1. Formation conditions and composition of lower-valency oxides.

Metal being discharged	Content of F^- ions in the electrolyte (%)	Total concentration of metal in compound (%)	Phase composition (%)					
			M^0	M^+	M^{2+}	M^{3+}	OH^-	H_2O

VI	65–80	7–25	10–20	20–60	0.5–1

The composition of the partial reduction products of various metals is shown in Table 1. We may conclude from these data that the concentration of ligand in the electrolyte determines the amount of metal in the deposit. Thus, for chromium the concentration of metal in the deposits obtained from an electrolyte containing six-valent chromium is higher than in the deposits from tervalent and bivalent chromium electrolytes (Table 2). This effect is produced by a change in the ratio of the rates of (1) the electrochemical formation of lower-valency metal compounds and (2) their further reduction to the metal. The higher the rate of formation of these compounds as compared with the rate of the electrochemical reaction leading to their further reduction, the lower must be the metal content of the deposit. Under these conditions we observe the electrochemical deposition of partially reduced compounds, as indicated by the data in Table 1. Thus the products of the partial reduction of rhenium and molybdenum ions are characterised by the presence of compounds in which the average valency of rhenium is 3 and that of molybdenum is 4.

The metal deposition takes place under conditions of dynamic equilibrium between the processes leading to the formation and to the further reduction of the substances in the cathode film. The presence of low-valency compounds in the solid phase suggests that these compounds exist in the layer adjacent to the cathode and act as a barrier between the bulk of the electrolyte and the reaction zone. At high concentrations of the ligand in solution the lower-valency compounds in the film are electrochemically reduced to the metal, and at low concentrations of the ligand some partial reduction products are formed. By varying the ligand concentration in the electrolyte we can easily control the cathodic process at the partial or the complete reduction stage.

The identical structures and compositions of the intermediate reduction compounds of the chromium, rhenium, manganese, molybdenum, zirconium, copper, nickel, and zinc ions suggest that their reduction processes from aqueous solutions have identical mechanisms irrespective of the form in which the ions exist in the bulk of the electrolyte.

3. Conductivity of the partial reduction products of the metal ions

According to our model of the bifunctional electrochemical system the film should have a mixed (ionic and electronic) conductivity. A quantitative assessment of the relative contributions from the ionic and the electronic conductivity has been made[92] by the pulse method (Table 3).

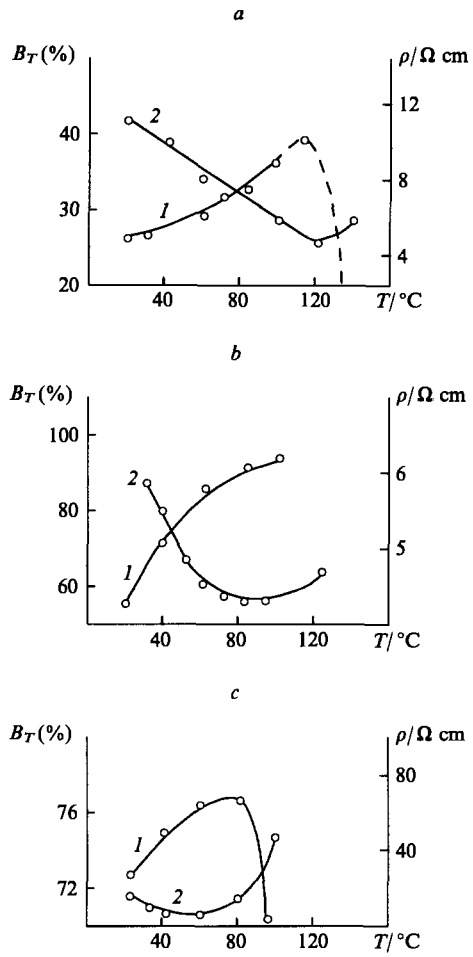

Figure 4. Temperature dependences of the current yield of metal (*1*) and of the resistivity (*2*) of the partial reduction products of chromium (*a*), nickel (*b*), and manganese (*c*).

The results of a study of the temperature dependence of the conductivity by alternating current methods are summarised in Fig. 4. The curves show either a maximum or a minimum, depending on the nature of the system. The systems in which the ionic component makes the larger contribution to the total conductivity (molybdenum, tungsten) show a minimum on the $\ln\sigma = f(T)$ curves, whereas systems in which the ionic conductivity plays a minor role have a maximum (manganese, chromium, nickel) or tend towards a maximum (copper).

A thermogravimetric analysis of these systems at 120 to 160 °C (the upper limit being set by the onset of substantial structural changes in these materials at higher temperatures) revealed the presence of an endothermic effect at 80–120 °C. These effects have only a small influence on the overall conductivity, since an extremum in one of the types of electrical

Table 3. Electrophysical parameters of the cathodic film.

Metal in the system	Temperature of change in slope of the $\ln\sigma-(1/T)$ dependence	Thermogravimetric analysis results: temperature of effects/°C	Total conductivity/Ω^{-1} cm^{-1}		Fraction of ionic conductivity (%)
			alternating current	direct current	
Copper	140	130–140	$2.9\cdot10^{-6}$	$2.6\cdot10^{-6}$	4
Nickel	80–90	80–90	0.22	0.18	8
Manganese	60	60–80	$0.9\cdot10^{-5}$	$0.2\cdot10^{-5}$	10
Chromium	120	120–130	0.25	0.80	11
Molybdenum	90–100	100–120	$1.3\cdot10^{-6}$	$2.4\cdot10^{-6}$	17
Tungsten	110–120	110–130	$0.3\cdot10^{-4}$	$1.5\cdot10^{-4}$	22

conductivity would have been produced if the influence had been large.

The temperature dependence of the conductivity is due to the structural changes associated with the removal of the water of crystallisation and of the OH^- groups, as shown by the correlation with the thermogravimetric analysis results (see Table 3).

Comparing the temperature dependences of the current yield of metal (B_T) deposited under normal conditions and of the resistivity (ρ) of the incompletely reduced compounds also showed a correlation[92] from which it is clear that the higher the electrical conductivity of the system, the higher is the current yield of the metal. This is evidence of a direct dependence of the technological parameters of the electrolysis (rate of deposition of the metals, and current yield) on the physicochemical properties of the cathode film.

4. Electrochemical reduction in the solid phase

An important contribution to the study of cathodic reduction was made by Gorbunova et al.,[93-97] who used a range of electrochemical and structural methods to establish the mechanism of the solid-phase reduction of sparingly soluble compounds (oxides and salts) in protic electrolytes. By applying the Avrami–Erofeev heterogeneous kinetics equation[98] they were able to characterise the process quantitatively. The same approach was used successfully by other workers.[99, 100]

Studies of solid-phase reduction processes have identified diffusional limitations in the solid phase, and also a dependence of the rate of the process on the concentration gradient of oxygen in the phase. Structural studies have established that the process begins at the solution interface and gradually spreads throughout the bulk of the oxide. Under these conditions the composition of the compounds deviates from stoichiometry.[97] Electric fields are formed in the region of the boundary[101, 102] as a result of the changes in concentration and structure.

The process leading to the formation of a metallic phase is localised in the bulk of the compounds of intermediate composition.[103-105]

The possibility of electrochemically reducing compounds of the partial reduction of metals in the anionic (chromium) and the cationic form (copper) in supporting electrolytes not containing ions in common with the solid phase has been demonstrated.[106-108]

The electrochemical reduction[106-108] and the chemical dissolution[109] of these compounds in a supporting electrolyte can be described by the Avrami–Erofeev heterogeneous kinetics equation. The kinetic parameters of these processes for various systems are summarised in Table 4. The rate constants of the electrochemical reduction and of the dissolution of all the compounds used to model the cathodic film are higher in hydrofluoric acid than in sulfuric acid. These data explain the formation of lower-valency compounds only at low concentrations in a hydrofluoric acid electrolyte[82] and the decrease in the rate of the process caused by increasing the concentration of ligand in the electrolyte.

Comparing the rate constants for the heterogeneous dissolution of the lower-valency oxides of chromium and copper in hydrofluoric and in sulfuric acid with the constants of the topochemical electro-reduction of these compounds in the same supporting electrolytes[109] allows us to calculate the role of the chemical processes in the control of bifunctional electrochemical systems.[110, 111]

In the electrodeposition of chromium the contribution of the chemical dissolution reactions of the cathodic film is small, as shown by the small value of the formal rate constant of this process. This accounts for the marked accumulation of film material on the electrode, which can be easily detected, even visually: not surprisingly, cathodic films were first detected in the electroplating of chromium. An entirely different situation is found in the electroplating of copper, because the rates of the chemical dissolution of the cathodic film and of the electrochemical reduction of the film material to the metal are comparable. Evidently, in this case the presence of a film can be detected only under conditions which make the rate of the formation reaction greater than the rates of both the above processes. It is clear that in the electrodeposition of copper film material is difficult to identify and to collect in all electrolytes except those containing fluorine,[112] since the required redistribution of the reaction rates can be achieved only in the latter electrolytes.

Thus the reduction mechanism is determined by the physicochemical properties of the compound: its electrical conductivity and its chemical stability towards the medium chosen for the process. The direct reduction of sparingly soluble compounds in the solid phase is achieved when the electrical conductivity of the substance is reasonably high. In cases of low electrical conductivity reduction takes place only at the points of direct contact between the compound to be reduced and the surface of the current lead. Whether a solid-phase or a liquid-phase mechanism is established depends on the rate of the chemical reaction in the chosen electrolyte: the higher the rate, the greater is the probability of controlling the process through a preliminary dissolution stage.

At a well defined ratio of the rates of the chemical and the electrochemical process the electrochemical reduction becomes possible by both mechanisms. Their relative contributions are determined by the properties of the substance itself and by the composition of the solution, and especially by the nature of the ligand.

IV. Principles of the control of the electrochemical reduction of transition metals

The concept of a bifunctional electrochemical system and the theoretical description of the special features of processes taking place in these systems have allowed us to formulate a set of principles for controlling the electrochemical reduction of transition metals.

Basically the control of electrochemical processes consists in regulating the composition (and therefore also the properties) of the bifunctional electrochemical system by controlled changes in the external factors such as the composition of the electrolyte, the nature and concentration of the ligand, the temperature of the electrolyte, and the current density. These parameters allow us to vary the rate of the electrochemical and of the chemical processes at the electrode–film and electrolyte–film interfaces, and the rates of deposition or of dissolution of the metals (as well as their current yield).

Table 4. Rates of the chemical and of the electrochemical processes in a bifunctional electrochemical system.

System	HF			H_2SO_4		
	K_{chem}/ cm s^{-1}	K_{ec}/ cm s^{-1}	$\lg\beta$	K_{chem}/ cm s^{-1}	K_{ec}/ cm s^{-1}	$\lg\beta$
Copper	$4.41 \cdot 10^{-2}$	$5.8 \cdot 10^{-2}$	0.85	$2.75 \cdot 10^{-2}$	$4.3 \cdot 10^{-2}$	0.50
Molybdenum	$5.07 \cdot 10^{-2}$	–	3.90	$5.01 \cdot 10^{-3}$	–	2.16
Manganese	$5.31 \cdot 10^{-2}$	–	5.48	$3.02 \cdot 10^{-2}$	–	2.30
Chromium	$8.10 \cdot 10^{-6}$	$3.22 \cdot 10^{-1}$	4.4	$1.20 \cdot 10^{-6}$	$9.1 \cdot 10^{-2}$	1.76

Nature and concentration of the ligand. The rates of the electrochemical and of the chemical reactions at the electrode–film and electrolyte–film interfaces are determined by the nature of the ligand and by its concentration, since the stability of the resulting complexes and the rate of dissolution of the partial reduction products are strongly dependent on these factors. We can define an optimum concentration of the ligand in the electrolyte ($c_{L,opt}$) which offers the appropriate ratio of the rates of the electrochemical and the chemical processes.

According to Eqn (7) at concentrations $c_L < c_{L,opt}$ the rate of the electrochemical processes exceeds the rate of the chemical processes. Partial reduction products are formed near the electrode, and are accumulated there. At concentrations $c_L \gg c_{L,opt}$ the rate of the chemical reactions becomes much greater than the rate of the electrochemical reactions, the film cannot be formed, and the new phase is not detected.

Electrodeposition of the metal is observed only for ligand concentrations close to the optimum, i.e. under conditions such that a dynamic equilibrium between the film formation processes and the further reduction of the film material to the metal can be established, i.e. when the equality $Q_S = Q_0$ is obeyed.

On the whole, however, and all other conditions being equal, departures (on either side) of the ligand concentration from the optimum value allow us to vary the composition of the compound formed on the electrode and to create conditions favouring either the electrodeposition or the dissolution of the metal or of its intermediate valency compounds. By varying the metal content of the partial reduction products we can control the ratio of the ionic and the electronic contributions to the electrical conductivity.

Current density. The rate of the electrochemical reactions at the electrode-film and at the electrolyte-film interfaces and within the film itself is determined by the current density. By varying this easily controllable parameter we can impose the required operating regime on the bifunctional electrochemical system. At any given concentration of the ligand we can identify an optimum value of the current density.

For $c_L < c_{L,opt}$ the rate of formation of a new phase on the electrode can be markedly increased by increasing the current density. Because of the relatively small rate of the chemical process at the electrolyte–film interface we can expect the formation of partial reduction products containing a higher proportion of low-valency compounds and a lower proportion of metallic phase. Under these conditions the contribution of the ionic component of the conductivity in the resulting oxides is increased.

For $c_L > c_{L,opt}$ the rate of the chemical process is high, and in order to suppress it (so as to obtain a new phase) we must increase the rate of the electrochemical process, i.e. we must increase the current density.

Electrolyte temperature. Other conditions being equal this factor affects the electrode process less markedly than does the concentration and nature of the ligand, or the current density.

For $c_L < c_{L,opt}$ the rate of the chemical reactions is usually small. Increasing the temperature of the electrolyte increases the rate of the electrochemical reduction processes. The result is an increase in the rate of formation of intermediate-valency compounds on the electrode, and an increase in their content of metallic phase.

For $c_L \gg c_{L,opt}$ increasing the temperature of the electrolyte usually produces predominance of the chemical processes over the electrochemical. As a result a large increase in the current density is needed to bring the bifunctional electrochemical system into dynamic equilibrium. Therefore the temperature dependence of the critical parameters of the process is qualitatively similar to their dependence on concentrations of the ligand.

V. Conclusions

It follows from our discussion that the necessary condition for the electrodeposition or the electrodissolution of the transition metals is the formation of a bifunctional electrochemical system consisting of compounds of the metal ion having a high or a low valency state and a mixed conductivity type. At the electrolyte–film interface the film is formed by the reduction of the metal ions being discharged or by the dissolution of the metal to an intermediate state of oxidation, and at the electrode–film interface the material of the film is consumed by being further reduced to the metal or oxidised to higher valency forms. As a result of the simultaneous occurrence of these processes the film remains continuously in a state of dynamic equilibrium.

Our ability to vary controllably the rate of the processes taking place at the two phase separation boundaries allows the bifunctional electrochemical system to be accurately controlled.

IV. The influence of the interaction through σ-bonds on the reactivity of organic compounds	930

Abstract. The present state of one of the comparatively new theoretical concepts in organic chemistry—the interaction of two heteroatoms having a lone electron pair or of groups incorporating a π-bond through the system of σ-bonds separating them—is considered. Two mechanisms of such interactions are discussed—through space and through the σ-bonds. These interactions are assessed in terms of UV, photoelectron, and electronic transmission spectroscopic and quantum-chemical data. The influence of the above interactions on the reactivity of the molecules is illustrated. The bibliography includes 139 references.

I. Introduction

For a qualitative and quantitative assessment of the mutual influence of substituents in an organic or organoelement molecule, a wide range of various electronic effects are used: the α-effect—interaction of two directly linked heteroatoms having lone electron pairs (LEP);[1,2] geminal interaction (also referred to as the α-effect)—interaction of two substituents separated by one carbon atom or an atom of another element;[3] orbital interaction through space or through σ-bonds—interaction of substituents separated by σ-bonds; the anomeric effect;[4–7] the 'rabbit-ear' or 'hockey sticks' effect;[8,9] vicinal interaction (the β-effect)—interaction of substituents separated by two carbon atoms;[10–12] the alternation effect (the field effect);[13] the inductive effect;[14] hyperconjugation;[15–17] various types of conjugation[18,19] etc.

In 1968–1971, Hoffmann[20,21] examined the interaction between σ-bond-separated heteroatoms having lone pairs or [groups having?] π-electron systems. In relation to biradical systems, he analysed two types of orbital interactions—through space and through σ-bonds. The splitting of the energy levels (ΔE) serves as a measure of the orbital interactions: thus, in the presence of such inte.actions, the energy levels should be [non-?] degenerate, whilst in their absence they should have similar energies. The present state of this problem is considered below. Several reviews on this topic have been published abroad,[17,18,22–28] but these are largely based on the consideration of only individual classes of compounds and differ in the theoretical approach used. Unfortunately, this problem has not been duly considered in Russian literature.

II. Interactions between equivalent substituents having lone electron pairs or π-electron systems

1. Model ideas

According to perturbation theory, in the interaction of two degenerate electronic levels n_1 and n_2 of a molecule (n_1 and n_2 are the LEP orbitals of identical heteroatoms or the π orbitals of unsaturated groups) through space, two new electronic levels are generated—a low-energy level corresponding to the bonding combination ($n_1 + n_2$) and a high-energy level corresponding to the antibonding combination ($n_1 - n_2$). For a biradical system (for which the initial study was performed) with three separating σ-bonds, the $n_1 + n_2$ combination is symmetrical (S or n^+) while the $n_1 - n_2$ combination is antisymmetrical (A or n^-) relative to the symmetry axis perpendicular to the C(2)–C(3) bond (Fig. 1). The interaction through space reduces the energy of the level S relative to A ($E_S < E_A$). When interactions through σ-bonds are considered, it is assumed that the bonding σ orbital of the C(2)–C(3) bond is symmetrical, while the antibonding σ* orbital is antisymmetrical relative to the symmetry axis. When account is taken of the possibility of

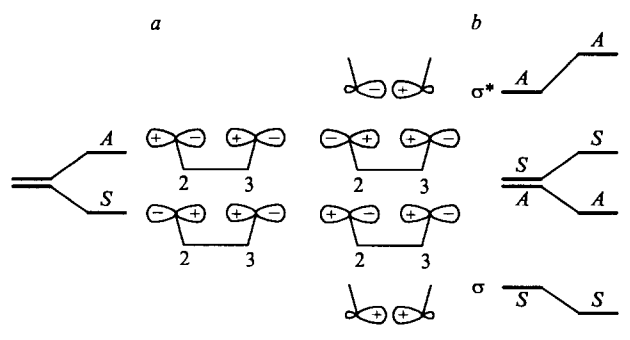

Figure 1. Schematic illustration of the interaction of the orbitals through space (*a*) and through σ-bonds (*b*).[20]

the mixing of only orbitals of similar symmetry, the $n_1 + n_2$ orbital interacts with the σ orbital, while the $n_1 - n_2$ orbital interacts with the σ* orbital. The energy of the level S then increases and that of the level A diminishes. 'Repulsion' of the levels leads to a lower energy of the level A compared with S ($E_S > E_A$). Their splitting ΔE is a function of the overlap of the above orbitals. The influence of the C(1)–C(2), C(3)–C(4), and C–H bonds on the relative positions of E_S and E_A is insignificant.[20,21]

In the general case, the interaction through σ-bonds depends only on the overlap of the LEP of the heteroatoms with the σ and σ* orbitals of the central C(2)–C(3) bond. The degree of overlap is independent of the rotation about this bond but does depend significantly on the rotation about the C–X bonds, since the symmetry is then infringed. On the basis of perturbation theory, displacements of the levels S and A (ΔE_S and ΔE_A) can be calculated by the formula[21]

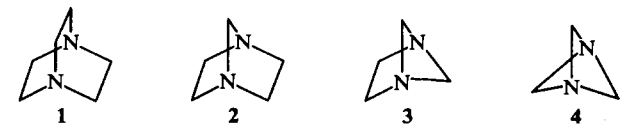
$$\Delta E_i = \frac{|H_{ij}|^2}{E_i - E_j},$$

where $H_{ij} = \int \psi i_i^* H \psi_j \, d\tau$ is the perturbation matrix element and E_i and E_j are the energies of the interacting levels. Hoffmann did not discuss the influence of the energy difference $E_i - E_j$ on ΔE_S and ΔE_A. One can only note that, if E_j is the energy of an occupied σ orbital, then $|E_i - E_j| \approx 0.3$ eV and, if E_j is the energy of an unoccupied σ orbital, then $|E_i - E_j| \approx 10$ eV.[20] If the terminal substituents in the molecule are close to one another, the interaction through space predominates, but when they are separated by a distance greater than 3 Å the interaction through σ-bonds predominates.

Model calculations carried out by semiempirical methods led to certain important conclusions concerning the orbital interactions through a system of m intervening σ-bonds.[20,21,29–32]

1. The sequence of the energy levels generated on interaction through m intervening σ-bonds depends on their number: $E_S < E_A$ for even values of m and $E_S > E_A$ for odd values of m. It follows from this parity rule that the interactions through space and through m σ-bonds intensify one another in the case of even values of m and weaken one another for odd values of m (when these interactions are opposed).

2. For a given value of m, the orbital interactions through m σ-bonds depend on the geometry of the σ-skeleton and their extent is a maximum for the *trans*-structure of the σ-skeleton. Thus the manifestation of orbital interactions through four σ-bonds weakens in the following sequence of molecular conformations: *trans, trans* > *cis, trans* > *cis,cis*.

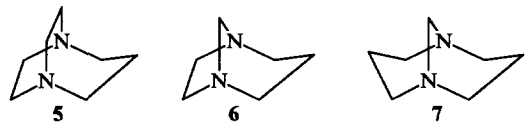


3. The interaction through σ-bonds on the whole stabilises the molecule, but the C–C σ-bond in the X–C–C–X fragment is then weakened.

The principal experimental methods for the investigation of orbital interactions through space or σ-bonds are photoelectron,[33] electronic transmission (electron capture),[34] and UV spectroscopy.

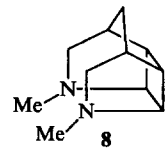
2. Diazabicycloalkanes

The interactions through space and through σ-bonds in diazabicyclic systems have been investigated by photoelectron spectroscopy and quantum chemically.[20,21,35–41] Quantum-chemical calculations by the extended Hückel[20] and MINDO/2 [36] methods for the 1,4-diazabicyclo[2.2.2]octane **1** molecule confirmed that the n^+ level is higher than the n^- level by 1.57 and 1.36 eV respectively. Photoelectron spectroscopy yields 2.13 eV.[35] Analysis of the vibrational structure of the bands in the photoelectron spectrum of compound **1** also confirms that $n^+ > n^-$.[37]



Quantum-chemical calculations for the diazabicycloalkanes **1–4** demonstrated the influence of the intervening σ-bonds on the relative disposition of the levels.[20]

1 **2** **3** **4**



In the series of compounds **1–4**, the number of methylene bridges containing two intervening σ-bonds diminishes, which weakens the interaction through σ-bonds and intensifies those through space as a result of the mutual approach of the nitrogen atoms. The order of the levels S and A is then changed: for compound **1**, the $a_2''(A)$ level lies below $a_1'(S)$ ($\Delta E = 1.573$ eV); for compound **2**, $\Delta E = 0.371$ eV for the levels arranged in the same order; for compound **3**, the opposite order of the levels obtains, i.e. $S < A$ ($\Delta E = -0.605$ eV); for compound **4**, the level S is appreciably below the level A ($\Delta E = -2.878$ eV).

The photoelectron spectra of 1,5-diazabicyclo[3.2.2]nonane **5**, 1,5-diazabicyclo[3.2.1]octane **6**, 1,5-diazabicyclo[3.3.1]-nonane **7**, and various piperazine and hydroxypyrimidine derivatives show that the splitting ΔE for 1,3- and 1,4-diamines depends on the spatial orientation of the LEP of the nitrogen atoms[38] (Fig. 2). The influence of ring strain on the ionisation energies of the bicyclic diamines has been described.[39]

5 **6** **7**

The low ionisation potentials (7.29 and 8.24 eV) of *N,N*-dimethyl-2,7-diazatetracyclo[3.3.3.$0^{4,9}0^{8,11}$]undecane **8** and the appreciable splitting ΔE of the energy levels of the LEP of the nitrogen atoms (0.95 eV) were interpreted in terms of the interaction of the LEP of the nitrogen atoms through space ($n^- > n^+$) (the lone pairs are oriented at an angle of 70° within the undecane skeleton).[41]

8

Non-empirical calculations in terms of the STO-3G basis set for 1,4-diazabicyclooctane **1** and two model molecules containing respectively one and two C–C bonds between the two nitrogen atoms indicate that two types of interaction are mainly responsible for the splitting of the two LEP orbitals—the first

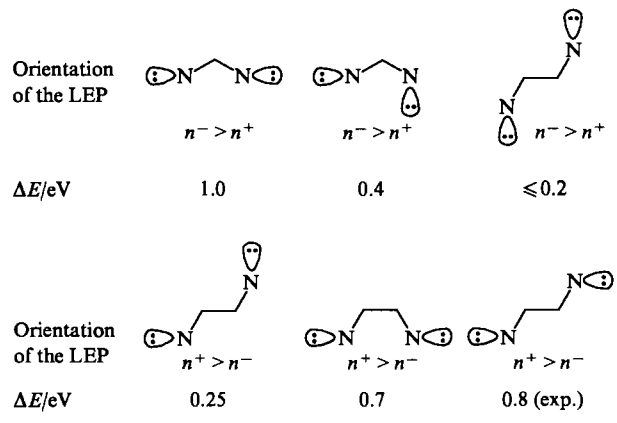


Figure 2. The splittings of the energy levels of the lone pairs in 1,3- and 1,4-diamines.[38]

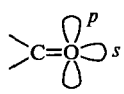
type involves the interaction between the LEP nitrogen and the central C–C bond in the same N–C–C–N fragment, while the second involves the interaction between the neighbouring N–C bonds in different fragments.[40]

3. Oxygen- and sulfur-containing heterocycles

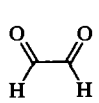
According to the symmetry of the immediate environment of the oxygen or sulfur atoms in saturated ethers and sulfides, their highest occupied nonbonding MO have a π-type symmetry (p_z-orbitals) (Table 1). A number of studies have been devoted to interaction through space and through σ-bonds in heterocyclic compounds containing at least two oxygen and sulfur atoms.[24,42–47]

Table 1. Vertical ionisation potentials of the LEP of oxygen- and sulfur-containing heterocycles.[42]



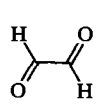
Compound	IP (*n*)/eV		ΔIP(*n*)/eV
1,3-Dioxolan **9**	10.10	10.65	0.55
2,2-Dimethyl-1,3-dioxolan **10**	9.71	10.20	0.49
Tetrahydropyran **11**	9.50		
1,3-Dioxane **12**	10.10	10.35	0.25
1,4-Dioxane **13**	9.43	10.65	1.22
Thiane **14**	8.45		
1,3-Dithiane **15**	8.54	8.95	0.41
1,4-Dithiane **16**	8.58	9.03	0.45
1,4-Thioxane **17**	8.67 (S)	10.0 (O)	

It follows from the analysis of the photoelectron spectra of 1,4-dioxane **13** and 1,4-dithiane **14** that the splitting of the highest occupied levels due to the interaction of the LEP of the oxygen and sulfur atoms is 1.22 and 0.45 eV respectively. The direct overlap of the p_z orbitals of the LEP in these molecules is impossible as they have the chair conformation, so that the interaction through σ-bonds is the main one. The greater splitting for 1,4-dioxane compared with 1,4-dithiane may be a consequence of the better energy correspondence between the LEP orbitals and the σ orbitals of the C–C bonds.



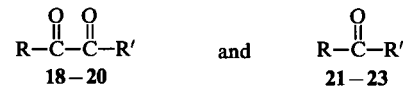
In 1,3-dioxane **12** and 1,3-dithiane **15**, which also have the chair conformation, there is a possibility of the direct overlap of the LEP of the heteroatoms, which is more effective in the case of 1,3-dithiane.[42] Calculations by the MNDO method confirmed that the interaction of the LEP of the sulfur atoms in the 1,3-dithiane is through space, whilst that in 1,4-dithiane is through σ-bonds.[47]

4. Dicarbonyl compounds



In dicarbonyl compounds, there is also a possibility of both types of interactions of the nonbonding *n* orbitals of the oxygen atoms.[17,33,48–60] In the description of the MO of the carbonyl group, taking into account its symmetry, two nonequivalent orbitals of the *p* and *s* types[48] or *p* and *sp* types[19,61] correspond to the LEP of oxygen (the energy of the *p*-type orbital is higher).

In the molecules containing two carbonyl groups, the interaction of the nonbonding *p*-type orbitals results in the splitting of the energy levels. Their order $n_A < n_S$ follows from quantum-chemical calculations for the *s-cis*- and *s-trans*-conformers of glyoxal on the assumption of ideal geometry.



s-cis

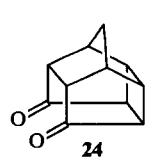
s-trans

The splitting ΔE for *s-cis*-glyoxal is 1.46 eV (EHM) or 2.96 eV (CNDO), whilst for *s-trans*-glyoxal it is 1.46 eV (EHM) or 3.27 eV (CNDO).[48] The experimental splitting ΔE is 1.46 eV.[33] The interaction through space in *s-cis*-glyoxal is insignificant as a consequence of the low value of the overlap integral (0.011) of the two *p*-type orbitals (EHM calculations). However, with decrease in the CCO bond angle, binding through space increases. The energy of the level *A* then increases and that of the level *S* hardly changes.

Similar effects have been discovered[50] in the analysis of the photoelectron spectra of the 1,2-diketones **18–20** and the corresponding ketones **21–23**.

18–20 and **21–23**

18, 21: R = R′ = cyclo-C_3H_5;
19, 22: R = cyclo-C_3H_5, R′ = Me;
20, 23: R = R′ = Me.



The intense low-energy peaks in the vibrational structure of the spectra of the three monocarbonyl compounds **21–23** are largely determined by the liberation of an electron from the localised *p* orbital of the oxygen LEP. Diffuse bands with higher energies are observed in the spectra of the 1,2-diketones **18–20**. The interaction of the nonbonding *n* orbitals of the oxygen atoms through σ-bonds leads to the splitting of the n_S and n_A levels amounting to ~2 eV (Table 2).

Table 2. Ionisation potentials of carbonyl compounds.[50]

Compound	IP/ eV		Assignment[a]
1,2-Dicyclopropylethane-1,2-dione **18**	9.09		n_S
	10.40	11–12	e_A, e_S and n_A
1-Cyclopropylpropane-1,2-dione **19**	9.33		n_S
	10.78	11.35	e_A, e_S and n_A
Diacetyl **20**	9.57		n_S
	11.41		n_A
Dicyclopropyl ketone **21**	9.28		n_O
	10.43	11.50	e_A, e_S
Cyclopropyl methyl ketone **22**	9.50		n_O
	10.62	11.40	e_A, e_S
Acetone **23**	9.71		n_O

[a] n_O is the nonbonding orbital of the oxygen LEP, e_S and e_A are the symmetrical and antisymmetrical orbitals of cyclopropane, and n_S and n_A are the symmetrical and antisymmetrical combinations of the nonbonding *p* orbitals of the oxygen atoms.

The photoelectron spectrum of pentacyclo-[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{5,9}$]undecane-8,11-dione **24** indicates an appreciable splitting of the *n* levels of the oxygen LEP (0.55 eV).[60] The contribution to this splitting by the interaction of the two oxygen atoms through space is very low, since they are quite far apart (4.05 Å).[62,63] The interaction of the *n* orbitals of the oxygen LEP with the σ orbitals of the skeleton becomes more intense if the C–C bonds separating the carbonyl groups form part of a strained system (a three- or four-membered ring).[55,57]

24

Analysis of the first two ionisation bands in the photoelectron spectra of cyclohexane-1,4-dione and its derivatives **25**–**32** indicates an increase in the splitting between the n^+ and n^- combinations of the orbitals from 0.2 eV in the spectra of compound **25** to 0.6 eV in those of compounds **29** and **30** and to 0.9 eV in those of compound **26** (Fig. 3). This can be explained by the intensification of the n^-,σ-interaction on passing from compound **25** to compounds **29** and **30** and further to compound **26**, whereas the n^+,σ-interaction in these molecules remains almost constant.[57]

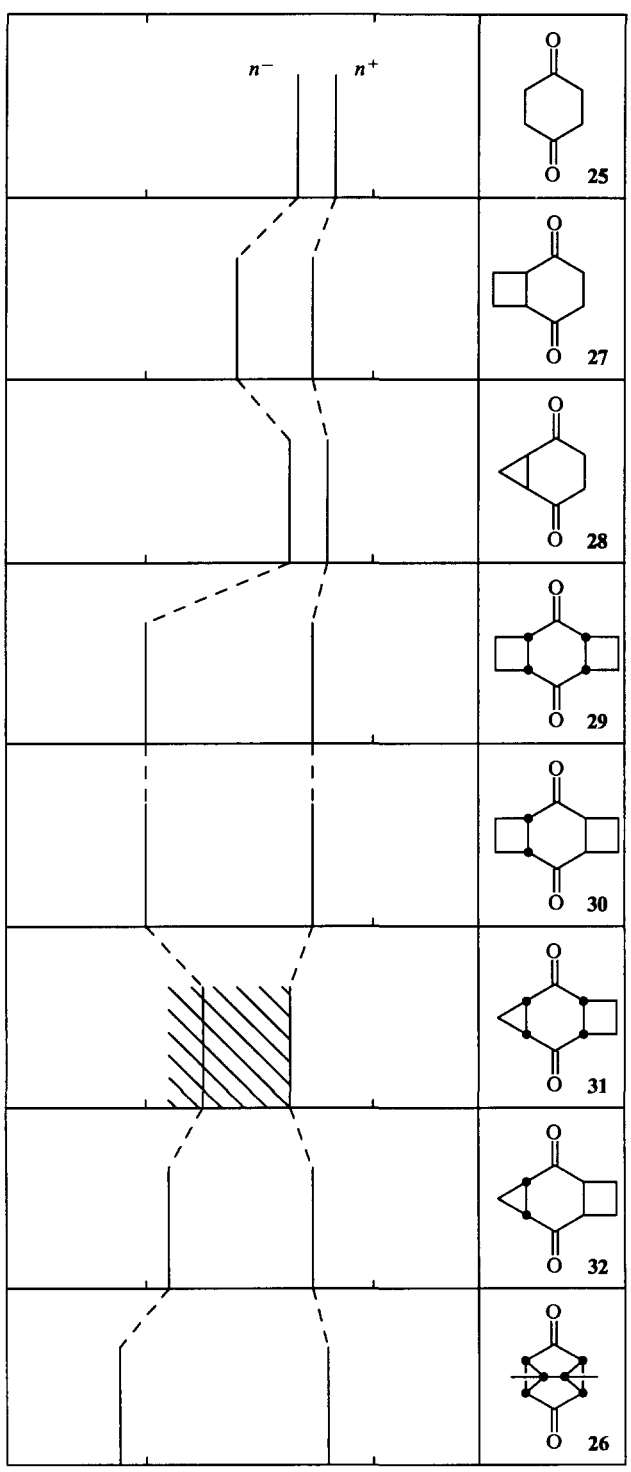


Figure 3. Diagram of the first two bands in the photoelectron spectra of compounds **25**–**32**.[57]

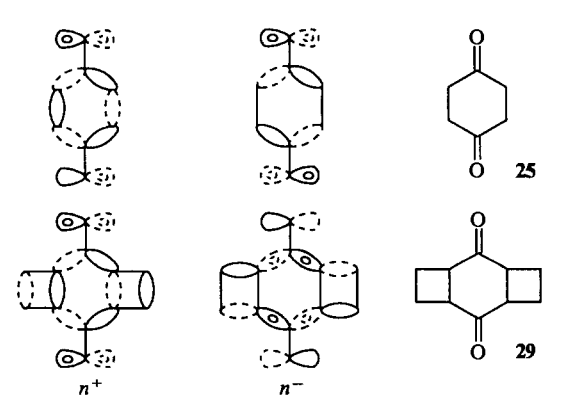
The study of the photoelectron spectra of a large series of α-, β-, γ-, and δ-dicarbonyl compounds demonstrated (the n^+ and n^- ionisation energies were calculated by the CNDO/S and CNDO/2 methods) that the most intense interaction through σ-bonds is observed in the α-dicarbonyl compounds ($\Delta IP = 1.5-3.1$ eV).[23] The extent of this interaction is independent of the dihedral angle between the planes of the carbonyl groups,[49] but diminishes rapidly with increase in the number of intervening CH_2 groups between the two carbonyl groups. The sequence of the energies of the nonbonding MO is determined by the assignment of the dicarbonyl compounds to two classes: compounds with coaxial carbonyl groups are assigned to the first class, whilst those with the noncoaxial groups are assigned to the second. Thus the parity rule, which holds for acyclic dicarbonyl compounds with noncoaxial carbonyl groups, breaks down for the cyclic compounds in which the carbonyl groups are coaxial (the C=O bonds are located on a single axis).[23] For example, the order of the levels is $n^+ > n^-$ for 2,2,4,4-tetramethylcyclobutane-1,3-dione **33** in which the LEP of the oxygen atoms interact through the four σ-bonds, whereas for tetramethyl-1,4-benzoquinone **34**, in which the LEP interaction is effected through five σ-bonds, the order of the levels is $n^- > n^+$, although, according to the parity rule, it should have been the opposite for these compounds. The opposite bond order, namely $n^- > n^+$, is also observed for derivatives of cyclohexane-1,4-dione. Since the carbonyl groups in all the symmetrical four- and six-membered cycloalkanediones are located in virtually one plane and are coaxial, their molecules have a centre of symmetry (Fig. 4).[57] In such compounds, the *p* orbital of the oxygen LEP interacts with the group σ orbital incorporating the two C–C bonds formed by the carbon atom of the carbonyl group. In contrast to the model proposed by Hoffmann,[20,21] in which the overlap of mainly the first lobe of the *p* orbital of the LEP of the heteroatom with one σ orbital of the C–C bond was considered, in this case the overlap of two lobes of the *p* orbital with the σ orbitals localised in two C–C bonds is postulated. Here the n^+ combination is antisymmetrical and the n^- combination is symmetrical relative to the centre of symmetry (in contrast to the plane of symmetry). Therefore the parity rule does not hold for compounds with coaxial carbonyl groups.



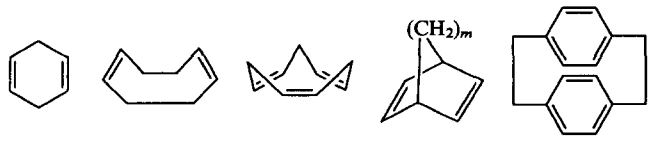


Figure 4. Schematic representation of the highest occupied MO (n^-, n^+) of compounds **25** and **29**. The double contour lines designate a higher electron density.[57]

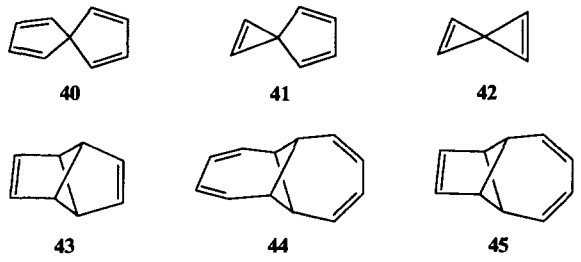
Four singlet *n*, π* transitions are observed in the polarised UV spectrum of a single crystal of 2,2,4,4-tetramethylcyclobutane-1,3-dione **33** at a low temperature.[51,52] Theoretical analysis (EHM, CNDO/2, CNDO/S) confirmed that the interaction through σ-bonds is in fact the main cause of the greater splitting of the *n* orbitals of the oxygen LEP and of the occurrence of *n*, π* transitions.

5. Nonconjugated π-electron systems

In molecules containing π-electron systems (double or triple bonds, aromatic or heteroaromatic fragments) separated by a system of σ-bonds, both types of interactions considered are also manifested — through space and through σ-bonds.[22,25,27] The interactions through space in compounds of this type are divided into two types — homoconjugation[17,64] and spiroconjugation.[65]



The homoconjugation effect can be demonstrated in relation to cyclohexa-1,4-diene **35**, cycloocta-1,5-diene **36**, cyclonona-1,4,7-triene **37**, [2.2.*m*]bicyclanes **38**, and [2.2]paracyclophane **39**.[22,27,66,67]

35 **36** **37** **38** **39**

The interaction through space predominates in norbornadiene **38** (*m* = 1).[66] In view of the presence of two symmetry planes (Fig. 5), the energy level corresponding to the symmetrical combination of the occupied π orbitals (*SS*) has a lower energy, while the energy level corresponding to the antisymmetrical combination (*SA*) has a higher energy. Similarly a level with a lower energy corresponds to the symmetrical combination of the unoccupied π* orbitals (*AS*) and one with a higher energy corresponds to the antisymmetrical combination (*AA*).

The spiroconjugation effect is manifested in molecules where the rings linked to one another contain unsaturated fragments located in mutually perpendicular planes (compounds **40–42**).[65,68–70]

40 **41** **42**

43 **44** **45**

Owing to the specific symmetry of these molecules, the interaction of the occupied (π) and unoccupied (π*) orbitals of the unsaturated fragments through space is mainly manifested. The group orbitals constituting a combination of the π(π*) orbitals of two unsaturated fragments have the a_2 and b_1 symmetries.[68] For compounds **40–42** having a spiro-centre, the interaction through σ-bonds is insignificant and the level b_1 lies below the level a_2. For compounds **43–45**, the interaction through the σ-bonds of the intervening four-membered ring is more significant and the opposite order of the energy levels obtains ($b_1 > a_2$).[68,70] These differences determine the characteristic features of the photoelectron and UV spectra of the spiro-compounds.[65,69,70] Thus the splitting of the above levels of the spiro[4.4]nonatetraene **40** is 1.23 eV according to photoelectron and UV spectroscopic data.[65]

In order to estimate the relative contributions of the interactions through space and through σ-bonds, Table 3 presents the experimental π-ionisation energies $IP_{v,1}$ and $IP_{v,2}$ of the bicyclic dienes **38** as a function of the number of methylene groups (*m*): Dewar benzene (*m* = 0), norbornadiene (*m* = 1), bicyclco[2.2.2]octadiene (*m* = 2), bicyclo[3.2.2]nona-6,8-diene (*m* = 3), bicyclo[4.2.2]deca-7,9-diene (*m* = 4), and the hypothetical hydrocarbon with *m* = ∞. The last system is modelled by the planar cyclohexa-1,4-diene **35**. The splitting ΔIP_v should decrease monotonically with increase in the dihedral angle between the planes of the double bonds. However, it passes through a minimum in the case of compound **38** (*m* = 3) and then again increases to 1.0 eV for the hypothetical hydrocarbon (*m* = ∞). This indicates the mutual cancelling of the interactions through space and through σ-bonds. In compounds with *m* = 1 and 2, the interaction through space between the π_a and π_b orbitals predominates, whereas in compounds with *m* = 3, 4, or ∞ the interaction through σ-bonds predominates.

The effective unit connecting the two π-electron systems in a structure of the type $\pi_1-CH_2-\pi_2$ is a single methylene group. For interaction to occur, it is approached by the π-symmetrical combinations of the σ and σ* orbitals (pseudo-π orbitals) localised on the C–H bonds. The interaction diagram[21] illustrates the result of the mixing of the σ and σ* orbitals with the two *p* orbitals of the trimethylene radical (Fig. 6). The antisymmetrical combination of the *p* orbitals cannot then become mixed with the pseudo-π orbitals of the CH_2 group for symmetry reasons. In four-membered cyclic systems, the interaction between the endocyclic n_0 or π orbitals also takes place via the pseudo-π orbitals.[26,71,72]

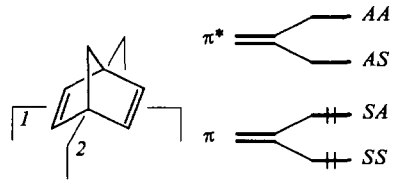


Figure 5. The electronic levels of norbornadiene **38** (*m* = 1) before and after interaction through space (the designations *S* and *A* refer to the mirror planes *1* and *2* shown on the left).[66]

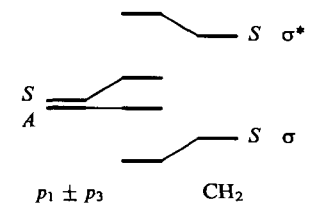

Figure 6. Diagram of the orbital interactions for the trimethylene radical.[21]

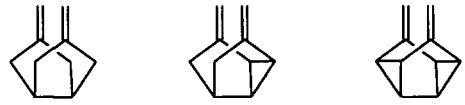

Table 3. Ionisation potentials (eV) of the bicyclic dienes **38** and cyclohexa-1,4-diene **35**.[22]

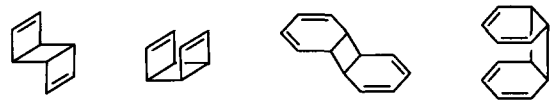
Ionisation band	Ionisation energy	*m*						**35**
		0	1	2	3	4	∞	
1	$IP_{v,1}$	9.4	8.7	8.8	9.0	8.9	8.6	8.8
2	$IP_{v,2}$	9.7	9.5	9.4	9.2	9.3	9.6	9.8
	ΔIP	0.3	0.8	0.6	0.2	0.3	1.0	1.0

The interaction through σ-bonds is manifested most strikingly in the planar cyclohexa-1,4-diene.[66] In this compound, the π orbitals of the two double bonds overlap with the group σ orbitals (incorporating the two C–H bonds of the methylene groups), which are suitable on symmetry grounds. As a result of the interaction of the π orbitals of the double bonds through the two methylene groups, the opposite order of the splitting of the *SS* and *SA* levels is observed (*SS* > *SA*) compared with that in norbornadiene, where there is interaction through space (*SS* < *SA*, Fig. 5). Quantum-chemical calculations (EHM) for the planar model of cyclohexa-1,4-diene confirmed this order of the levels with a splitting of 0.65 eV (the experimental value is 1.0 eV).[66]

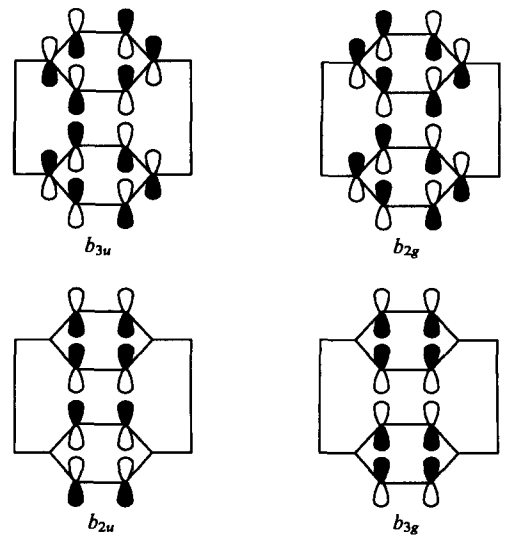


The dependence of the interaction through space and through σ-bonds on distance and the mutual orientation of the basis orbitals has been examined[22] for the model compound **35**. In the boat conformer of cycloocta-1,5-diene **36**, the interaction through space should be considerable. However, the experimental difference between the two π-bonds is only 0.2 eV;[66] on the other hand, the calculated splitting is 1.67 eV with the levels arranged in the order *SS* < *SA*. This is caused by the superposition on the interaction through space in compound **36** of a further interaction of the π orbitals with the *SS* combination of the C(3)–C(4) and C(7)–C(8) σ-bonds which are ideally oriented for the interaction of the two π-electron systems through σ-bonds. This destabilises the π-*SS* combination. When account is taken of this fact, the calculated splitting diminishes to 0.48 eV. In compound **36** in the chair conformation, there is no interaction through space and the interaction through σ-bonds predominates.

According to photoelectron and transmission electronic spectroscopic data, which have been confirmed by quantum-chemical calculations, the interaction of two double bonds separated by a σ-skeleton becomes more marked in the series of compounds **46**–**48**.[54,55] The splitting of the energies of the π^+ and π^- orbitals increases on passing from compound **46** to compounds **47** and **48** (0.2 < 0.4 < 1.26 eV respectively). The interaction through σ-bonds, which intensifies with increase in the rigidity of the σ-skeleton, predominates in these compounds[58,59] and leads to the inverted order of the π orbitals ($\pi^- < \pi^+$).

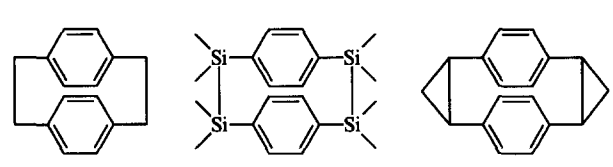
46 **47** **48**

In the series of cyclic hydrocarbons **49**–**52**, the splitting (0.6–1.0 eV) between the π-bonds is greater for the *anti*-isomers of compounds **49** and **51**, which indicates the predominance of the interaction through σ-bonds.[27]



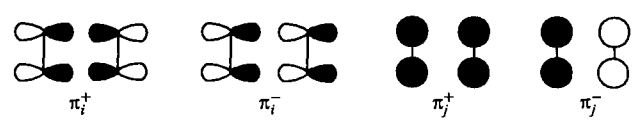
49 **50** **51** **52**

Compound	**49**	**50**	**51**	**52**
ΔIP/eV	1.0	0.3	0.67	0.46



According to electronic, spectroscopic, and Penning ionisation data as well as the results of non-empirical calculations, the differences between the symmetrical and antisymmetrical π orbitals in the molecules of norbornadiene **38** (*m* = 1) and 1,4-diazabicyclo[2.2.2]octane **1** are due to the interaction through space or through σ-bonds.[73] In norbornadiene, where the interaction through space is manifested, the π_S MO is looser than π_A and is characterised by a greater probability of ionisation on electrophilic attack by helium atoms in the metastable excited state. On the other hand, in the case of 1,4-diazabicyclo[2.2.2]octane the n_A MO is looser than n_S owing to the strong interaction through σ-bonds and is distinguished by a greater probability of ionisation.

Orbital interactions have been examined in [2.2]paracyclophane **39** and its analogues, in which two parallel aromatic rings interact through space and through the system of σ-bonds.[67,74] The four $e_{1g}(\pi)$-orbitals of the two benzene rings in compound **39** form the four linear combinations b_{3u}, b_{2g}, b_{2u}, and b_{3g}.



The b_{2g} and b_{3g} combinations, which are antisymmetrical relative to the plane separating the parallel rings, cannot interact with the σ orbitals of the bridging CH_2-CH_2 fragments. The overlap integral between the b_{2u} combinations and the σ orbitals is in fact zero. Their splitting (~1.5 eV) is caused by the interactions through space.[22] Only the linear b_{3u} combination can be effectively mixed with the above σ orbitals (interaction through σ-bonds). Its energy depends significantly on the nature of the bridging fragment.

On passing from the cyclophane **39** to its analogues **53** and **54**, the energy of the σ orbitals of the bridge connecting the benzene rings increases.[73,74] The b_{3u} ionisation energy therefore shifts towards lower values. The opposite shift is observed in *exo*-octafluoro[2.2]paracyclophane as a consequence of the decrease in the energy of the CF_2-CF_2 fragment.[22,27]

39 **53** **54**

As a consequence of the cylindrical symmetry of the π-system of the triple bond, in alka-α,ω-diynes and their analogues, the interaction through space can occur for different orientations of the ethynyl groups.[27] When the two triple bonds are in the same plane, two sets of bonding and antibonding linear combinations of the two in-plane (π_i) and the two out-of-plane (π_j) π orbitals are formed.

For distances between the C≡C bonds ranging from 2.5 to 3.5 Å, small and large splittings may be expected for linear combinations of π_j and π_i respectively. Photoelectron spectroscopic data for the cycloalkanediynes **55–59** indicate a strong dependence of the splitting of the energy levels corresponding to the π_i combinations (Fig. 7) on the distance between the triple bonds.[76]

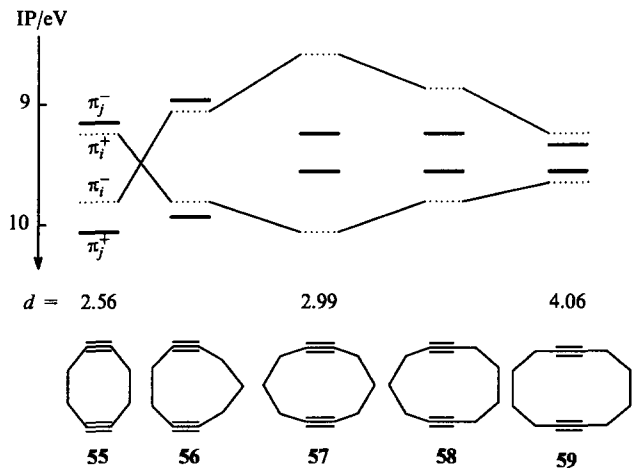


Figure 7. The ionisation potentials in the photoelectron spectra of compounds **55–59** as a function of the average distance (d) between the triple bonds. The continuous lines indicate the out-of-plane π_j MO and the dashed lines indicate the in-plane π_i MO.

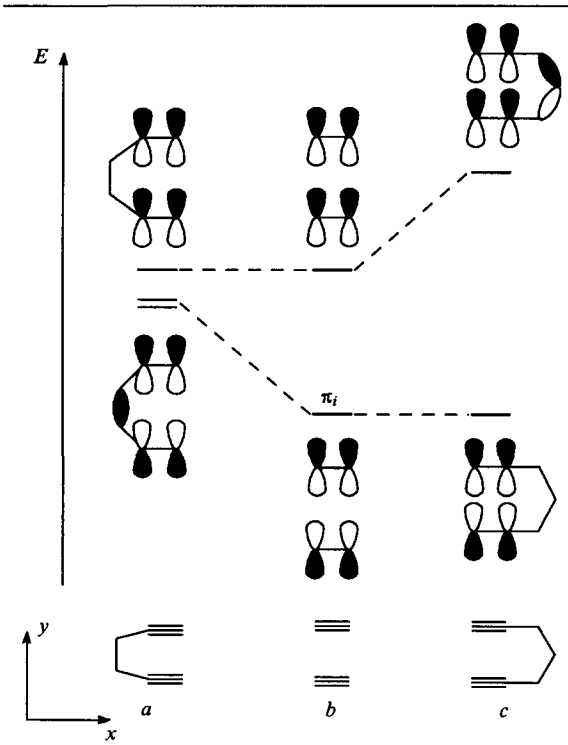
In the case of the in-plane π MO of the two C≡C groups, separated by several σ-bonds, the interaction through space in compounds **55–59** stabilises the bonding (π_i^+) and destabilises the antibonding (π_i^-) linear combinations which have different symmetries relative to the xz planes (Fig. 8*b*). The interaction of the π-system of hexa-1,5-diyne **60** with the σ orbital of the CH_2-CH_2 fragment, symmetrical relative to the xz plane, destabilises the π_i^+ energy level but does not alter the energy of the π_i^- orbital (Fig. 8*a*). The splitting of the levels caused by the interaction through space diminishes correspondingly.



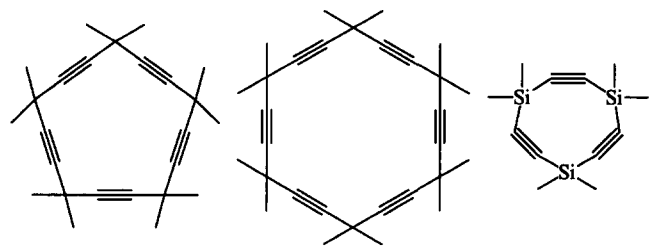


Figure 8. Interaction of the in-plane π MO of the two acetylene fragments in hexa-1,5-diyne **60** (*a*) and hepta-1,6-diyne **61** (*c*) with the σ-skeleton.[27]

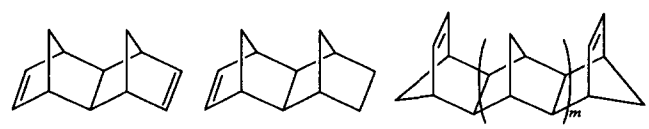

The antisymmetrical σ orbital of the trimethylene chain in hepta-1,6-diyne **61** interacts mainly with the π_i^- orbital, increasing its energy (Fig. 8*c*). In this case, the interactions through space and through σ-bonds increase the splitting of the levels. Thus the interaction of the π_i^+ and π_i^- combinations with the σ-skeleton of the methylene chain depends on the number of CH_2 groups: an even number diminishes the splitting caused by the interaction through space, while an odd number increases it.

The relative contributions of the interactions through space and through σ-bonds depend also on the energy of the σ-skeleton. Thus, in the study of the orbital interactions in compounds **62–64**, stronger interactions were observed for hexamethylcyclotrisilethyne **64**, which has higher [energy] σ orbitals than the carbon analogues **62** and **63**. In perfluorocycloalkadiynes with lower energy σ orbitals, the contribution of the π,σ interaction is not high.[27] Thus the homoconjugation of the triple bonds predominates in the pericyclynes **62–64**.[27,77] Photoelectron and transmission electroscopic data indicate a weak homoconjugation in compounds **62** and **63** in the cationic and anionic states. A similar effect has also been observed for compound **64**.[77]

62 **63** **64**

Hoffmann's model, considered above, has been applied mainly to the analysis of the electronic structures of compounds containing three or less intervening σ-bonds.[21,29] Paddon-Row[25,32,78–85] investigated in detail the dependence of the interaction of the π and n orbitals through m σ-bonds on the value of m for compounds with $m \geqslant 3$ and on the mutual orientation of the σ-bonds. In contrast to Hoffmann's model, in his initial approach, Paddon-Row examined the interactions of the π or n orbitals only with occupied σ orbitals. Here account was taken of the increase in the energies of both the $\pi^+(n^+)$ and $\pi^-(n^-)$ orbital combinations and the initial $\pi(n)$ orbitals relative to model compounds in interactions with σ orbitals. For an even number m, the energy of the $\pi^-(n^-)$ combination increases by a significantly greater amount than for $\pi^+(n^+)$.[25,32] The application of this model to the description of the orbital interactions through four σ-bonds is demonstrated in Fig. 9. An increase in the energy of the basis π orbital in the hex-1-ene molecule by an amount x takes place as a result of its mixing with the highest occupied σ MO (here there are no limitations as regards symmetry). Since the highest of the occupied σ orbitals in antisymmetrical, it interacts with the π^- combination, while the symmetrical σ orbital, having a lower energy, interacts with the π^+ combination.

65 **66** **67**

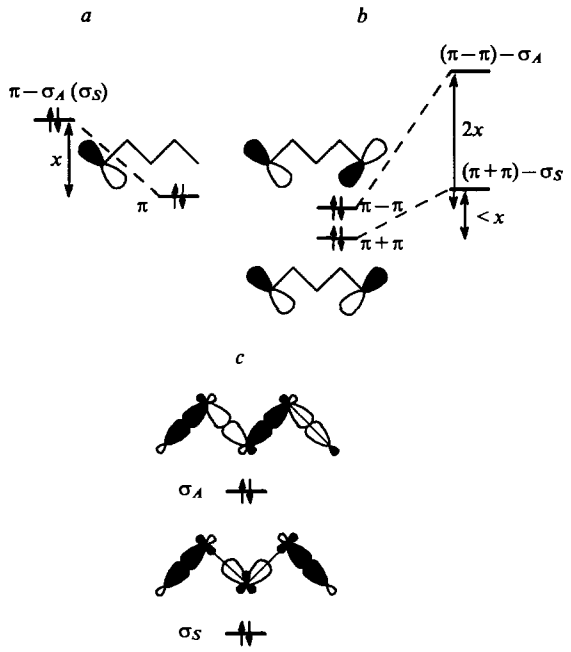

Figure 9. Schematic representation of the σ,π mixing in the molecules of compounds **65** and **66**:[32] (*a*) mixing of the π and highest σ MO: (*b*) mixing of the $\pi^+ - \pi$ combinations with the highest σ MO; (*c*) the π orbital and the two highest σ-type orbitals (*S* and *A*).

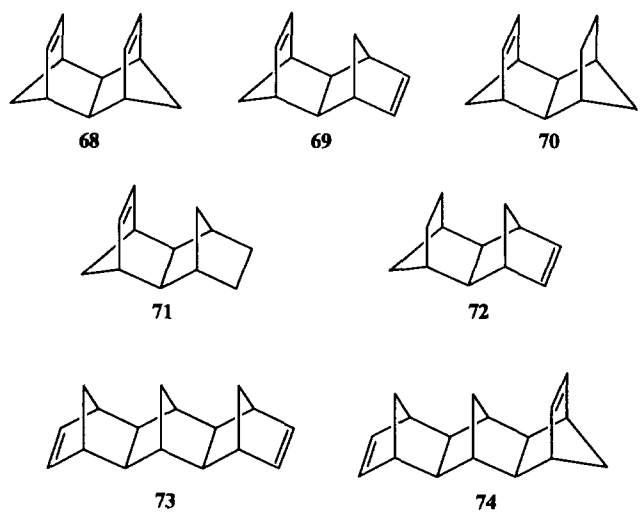


In compounds **67** (*m* = 1), the energy of the π^- combination increases by an amount 2*x* on mixing with the antisymmetrical highest occupied σ MO. In contrast to this, the energy of the π^+ combination increases only slightly ($\Delta E < x$) on mixing with the symmetrical occupied σ MO having a lower energy. This difference is due to two factors: the energies of the π^- and σ_A orbitals are closer and their overlap is greater than in the interaction of the π^+ and σ_S orbitals.

Analysis of the photoelectron spectrum of the hydrocarbon **67** (*m* = 1) confirmed the above scheme. The first ionisation π band is wide, which indicates σ,π-mixing. The fairly sharp second band indicates the ionisation of an electron from the more localised π MO.

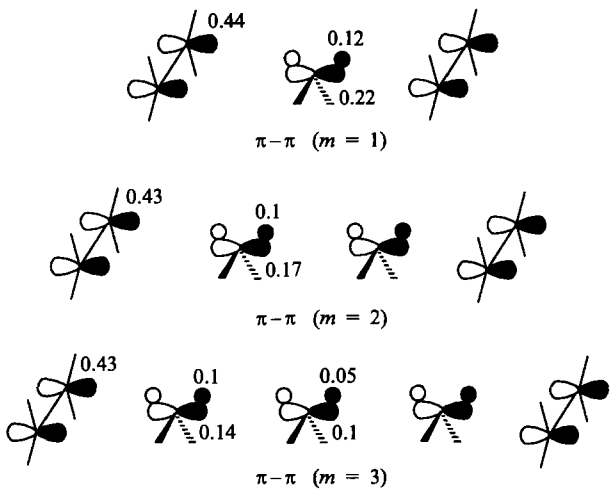
The orbital interactions through space and through four and more σ-bonds have been examined in relation to the photoelectron spectra of the hydrocarbons **65**, **66**, and **68–72**, the ionisation potentials of which are presented in Table 4. The higher value of ΔIP(π) for compound **65** (0.87 eV) is a consequence of the interactions through four σ-bonds,[32] while the higher values of ΔIP for compound **68** (1.26 eV) is caused by the overall contribution of the interactions through space and through σ-bonds. The value of ΔIP(π) for compound **73** (0.32 eV) demonstrates the appreciable manifestation of the interactions through six σ-bonds.[25]

Table 4. Vertical ionisation potentials (eV) of dimethanonaphthalenes.[25]

Compound	IP(π)	ΔIP	Assignment
65	8.48	0.87	π^-
	9.35		π^+
66	8.85		π
68	8.08	1.26	π^-
	9.34		π^+
69	8.46	0.44	π^-
	8.90		π^+
70	8.60		π
71	8.65		π
72	8.78		π
73	8.58	0.32	π^-
	8.90		π^+

The decrease in the extent of the π-orbital interactions through four bonds in the series **65** (0.87 eV), **69** (0.44 eV) agrees with the rule governing the dependence of the orbital interactions on the geometry of the σ-skeleton: for the same values of *m*, the interaction in the molecule with a *trans*-orientation of the σ-bonds is a maximum (the *trans*-rule). Indeed the σ-bonds in compound **65** are in the *trans*, *trans*-positions, whilst in compound **69** they are in the *cis*, *trans*-positions. However, the *trans*-rule clearly breaks down on passing to compounds where there is interaction through six σ-bonds. ΔIP for compounds **73**, **74**, and **67** (*m* = 1) increases in the sequence 0.32 < 0.38 < 0.52 eV.[79] This trend has been confirmed by quantum-chemical calculations and indicates the occurrence of an additional orbital interaction, which is manifested to the maximum extent in compound **67**, to a lesser extent in compound **74**, and is virtually absent in compound **73**. In the presence of such additional interaction, called the laticyclic hyperconjugation, the π MO of the two vinyl groups are mixed with the group orbital of the central CH_2 bridge, which embraces the two C–H bonds.[81,83,86,87] In contrast to the pericyclic hyperconjugation of the planar cyclohexa-1,4-diene mentioned earlier, in these compounds the pseudo-π orbital indicated and the orbitals of the double bonds are located virtually in one plane (Fig. 9). (In the planar cyclohexa-1,4-diene, the pseudo-π orbital and the π orbitals of the vinyl groups are located at right angles to the molecular plane.[21]) A direct estimate of the extent of the π-interaction in compound **67** via the intervening CH_2 group has been obtained from the results of non-empirical calculations.[81]

In subsequent studies,[80,82] similar interactions were also examined taking into account the involvement of aromatic rings in them. Laticyclic hyperconjugation—interaction through the so called 'ribbons'—is also observed in the series of polycyclic hydrocarbons with increase in the number of intermediate cyclic units containing CH_2 groups with the orientation indicated (the orbital schemes are illustrated in Fig. 10).[81,86,87] This results in effective delocalisation of the positively charged 'holes' in the radical-cation of the nonconjugated diene containing two double bonds at a distance of 6 Å.[88]



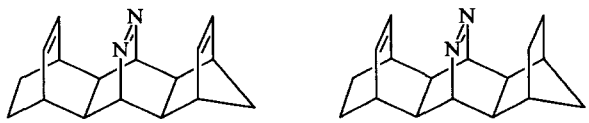


Figure 10. The forms of the orbitals and the coefficients of the π,π interaction calculated by the non-empirical STO-3G method for compound **67** (m = 1–3).[81]

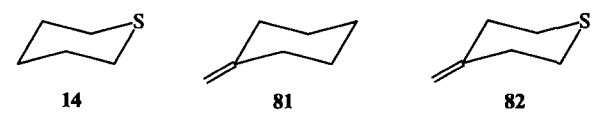
In an experimental study of the electron affinities of compounds **75** and **76**, it was observed that laticyclic conjugation involving the π* orbitals takes place in compound **75**.[78] As the inductive effect and the interaction through σ-bonds in the norbornene fragments of compounds **75** and **76** are identical, the appreciable difference between the ionisation energies (9.02 and 8.40 eV in compounds **76** and **75** respectively) indicates the existence of laticyclic [2 + 2 + 2]-conjugation in compound **75**, which contains three parallel π-bonds.[89,90]

75 **76**

The mechanisms of the interactions under discussion have been analysed[30] on the basis of data derived from semiempirical quantum-chemical calculations in which localised MO were used. With the aid of nonempirical quantum-chemical calculations in terms of different basis sets, a study has been made of the dependence of the splitting of occupied (π^+,π^-) and unoccupied (π^{+*},π^{-*}) orbitals of the vinyl fragments (ΔE) on the number of intervening σ-bonds (m) and their mutual orientation.[91–93] The exponential dependence obtained of $(\Delta E)^2$ on m permits a quantitative prediction of the experimental splittings of the levels and of the rates of electron transfer. The contributions of individual fragments in the transmission of the interaction between π(π*) orbitals have been calculated for similar structures in the analysis of orbitals localised on individual bonds (nature bond orbitals). A more effective transmission of interaction through intervening C–Si bonds has been predicted.



III. Interactions between nonequivalent substituents

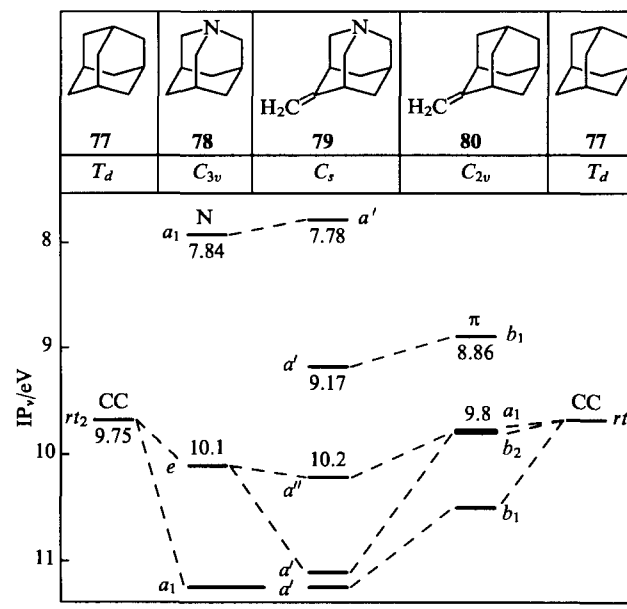
Interactions through space and through σ-bonds between nonequivalent substituents are divided into two main types: interaction of occupied π(n) orbitals of two substituents and interaction of occupied n(π) orbitals of a donor (D) with the unoccupied π* or σ* orbitals of the acceptor (A). Interactions of the first type are most strikingly manifested in the analysis of the photoelectron spectra and those of the second type in the analysis of the electronic absorption and emission spectra. In the second case, there is a possibility not only of a change in the energies of the electronic transitions characteristic of the donor and acceptor but also of the manifestation of new transitions accompanied by a significant intramolecular charge transfer (ICT) from the donor to the acceptor.

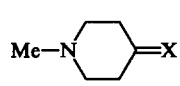
1. Photoelectron spectra

In the photoelectron spectra of aza-, methyleneaza-, thia-, and methylenethia-cycloalkanones as well as oxygen derivatives, the interaction of the occupied π(n) orbitals of two substituents gives rise to changes in the ionisation potentials referring to the LEP of the heteroatoms (n_S, n_N, n_O) and the π orbitals of the unsaturated fragment. This leads to an increase in the distance between the corresponding energy levels.[94–101]

The increase in the energy splitting of the levels assigned to the n and π orbitals, relative to the difference between their energies in the corresponding monofunctional cyclic compounds (for example, 0.06, 0.29, and 0.35 eV for compounds **14**, **81**, and **82** respectively[96]) is a characteristic feature of the interactions indicated (Fig. 11).

14 **81** **82**





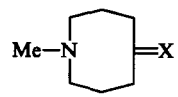


Figure 11. The highest occupied energy levels of compounds **77–80** according to photoelectron spectroscopic data.[95]

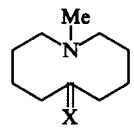
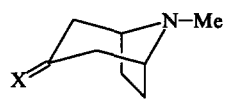
The energy splitting of the levels (ΔE = 0.47 eV) in the case of compound **79** is much smaller than in 1,4-diazabicyclooctane (ΔE = 2.1 eV [35]) as a consequence of the greater symmetry of the latter (D_{3h}). For adamantane **79** and thiacyclohexane **81** derivatives, containing an exocyclic double bond or a carbonyl group and having the chair conformation, the interaction through σ-bonds predominates.[94–96] For the analogous derivatives of thiaperhydronaphthalene, a weak interaction through σ-bonds takes place for the *trans,trans*-orientation of the five σ-bonds, such interaction being absent for the *trans,cis*-orientation,[96] which is consistent with Hoffmann's ideas.[20,21]



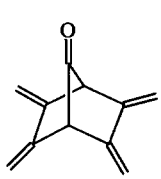
In the azacycloalkanones **83–86** or methyleneazacycloalkanones **87–90**, the increase in the splitting of the levels of the n_N nitrogen orbital and the π orbital of the carbonyl group or the double bond compared with that in the cyclic monofunctional compounds is due to the transannular interaction.[97]



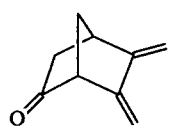
83, 87

84, 88

85, 89

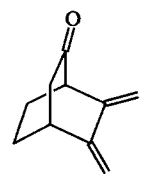


86, 90

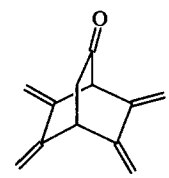


83–86: X = O;
87–90: X = CH_2.

The manifestation of the appreciable n,π interactions in the eight-membered rings of compounds **84** and **88** has been explained by the mutual approach in space of the corresponding structural groups. In 1-azacyclodecan-6-one **85**, n,π interaction also occurs, whereas in 6-methylene-1-azacyclodecane **89** it is not observed, which can be accounted for by the difference between the conformations of these molecules.[97] Furthermore, interactions of the n orbitals of the nitrogen atom and the oxygen atom of the carbonyl group have been observed for compounds **83–86**.[97]

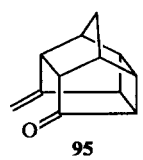


Comparison of the photoelectron spectroscopic data for 2,3,5,6-tetramethylidenebicyclo[2.2.1]heptan-7-one **91**, 5,6-dimethylidenebicyclo[2.2.1]heptan-2-one **92**, 5,6-dimethylidenebicyclo[2.2.2]octan-2-one **93**, and 5,6,7,8-tetramethylidenebicyclo-[2.2.2]octan-2-one **94** with the spectra of other β,γ-unsubstituted ketones and related alkenes as well as the results of nonempirical calculations (STO-3G) for compounds **91–94** confirmed that the appreciable interactions of the n_O orbital of the oxygen LEP and the π orbitals of the double bonds are largely effected through σ-bonds.[98]

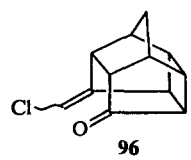


91

92



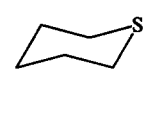
93



94

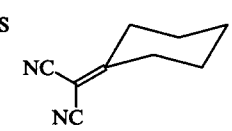
In the photoelectron spectra of paracyclophanes containing π-donor and π-acceptor substituents in the aromatic rings, the splitting of the first ionisation bands (~0.3 eV) as a consequence of the interaction of the π orbitals through space is observed.[98] In the study of the photoelectron spectra of 8,11-disubstituted pentacycloundecanes **95** and **96**, the splitting of the peaks (0.4–0.6 eV), caused by the interaction of the two unsaturated fragments through space, has also been observed.[56]

95



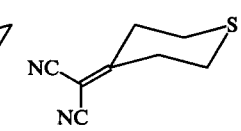
96

In the molecules of ethanolamine and its derivatives containing the O–C–C–N group, there is a possibility of interaction of the LEP of the nitrogen and oxygen atoms with the neighbouring σ-bonds of the skeleton or their interaction through σ-bonds is possible for certain conformations.[100,101] This entails the transfer of electron density from the less electronegative nitrogen atom to the more electronegative oxygen atom. The same effect has been observed in the study of acyclic and cyclic organosilicon compounds containing the Si–O–C–C–N fragment. In these compounds, the basicity of the nitrogen atom is appreciably reduced regardless of the presence or absence of the transannular Si ← N.[102]



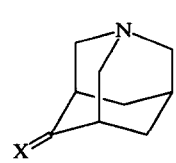
Similar phenomena have been observed also in other X–C–C–Y systems, for example in N–C–C–Cl and S–C–C–Cl, in which the chlorine atom is distinguished by a high mobility (in the O–C–C–Cl system, the chlorine atom is chemically inert), whereas in the X–C–Y systems (for example, in α-chloroethers) electron density is transferred from the more electronegative heteroatom (oxygen) to the less electronegative heteroatom (chlorine).

2. Absorption and emission spectra



UV spectroscopy has been used widely in the study of interactions through space and through σ-bonds in molecules containing an explicit donor and acceptor separated by σ-bonds.[95,103–108] A new UV band (the ICT band) appears in the absorption spectra of bifunctional compounds with fixed geometries in which the donor and acceptor are separated by three or five σ-bonds. The band is due to charge transfer from an occupied orbital of the donor (nitrogen, sulfur, etc.) to the unoccupied π^* orbital of the acceptor [C=C, C=O, $C=C(CN)_2$, $C=CHCO_2R$, $C=C(CN)CO_2R$].[107]

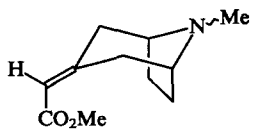
14 (λ = 228 nm)



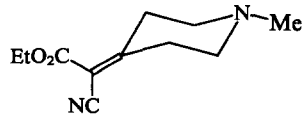
97 (λ = 235 nm)

98 (λ = 230 and 294 nm)

In our view, this transition can take place with a fairly high probability both on partial overlap of the above two orbitals in space and when they are mixed with the occupied (σ) and unoccupied (σ*) orbitals of the intervening system. The charge transfer between the structural groups (D and A) separated in space has been confirmed by the higher dipole moments of these molecules in the excited state (10.5–23.0 D).[104,108]



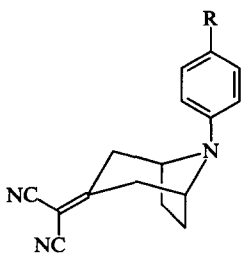
As a consequence of the large distance between the nitrogen atom and the electron-accepting substituent ($C=CH_2$, C=O) and also the unfavourable mutual orientation of the LEP of nitrogen and the π^* orbital of the acceptor, in rigid bicyclic systems (derivatives of azaadamantane) direct overlap (through space) is impossible.[94,95,104,106,108] An ICT band has been observed in the UV absorption and emission spectra of compounds **79** and **99** in solutions (at 220 and 241 nm for compounds **79** and **99** respectively); it has a very weak vibrational structure (even in the gas phase).[95,104] It was assigned to the transition from the orbital embracing mainly the nitrogen LEP to the antibonding π^* orbital of the $C=CH_2$ or C=O group. Similar ICT bands in the range 280–330 nm ($\varepsilon \simeq 4500$) have been observed for the derivatives of azaadamantane containing the electron-accepting groups $C=CHCO_2R$ (λ = 275 nm), $C=C(CN)CO_2R$ (λ = 316 nm), and $C=C(CN)_2$ (λ = 317 nm). Similar effects have been noted also in the analysis of the UV spectra of nitroazaadamantanes.[109]

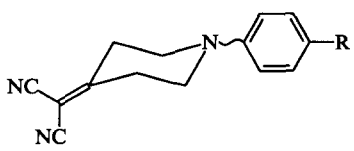


X = CH_2 (**79**), X = O (**99**)

The spectrum of compound **100**, in which the nitrogen atom is separated from the $MeO_2CCH=C$ group by three σ-bonds, also contains an ICT band (at 250 nm).[108] This molecule has a

geometry which is consistent with all the necessary conditions for the mutual orientation of the nitrogen LEP and the σ-bonds suitable for the occurrence of the interactions under consideration.[20,21,30,31] An ICT band is absent from the spectrum of compound **101**, the conformation of which is inconsistent with the above conditions.





100

101

The influence of the conformation on the extent of the interaction through σ-bonds has been studied in relation to compounds **102**–**105** containing donor and acceptor centres.[110]

102 (R = H), **103** (R = OMe) **104** (R = H), **105** (R = OMe)

In compound **102**, the phenyl group occupies an axial position relative to the piperidine rings, which leads to an antiparallel orientation of the nitrogen LEP and of the central C–C bond. This conformation is retained also in solution in the solid phase (according to X-ray diffraction data). The spectrum of compound **102** contains an ICT band, the intensity of which hardly changes with decrease in temperature (Table 5).

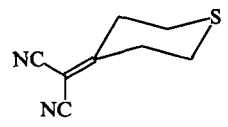


Table 5. The ICT bands in the spectra of compounds **102**–**105** (293 K, solvent — CH_2Cl_2).[110]

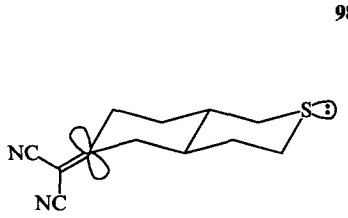
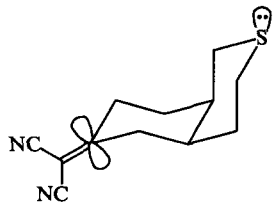
Compound	λ_{CT}/ nm	ε/litre mol^{-1} cm^{-1}
102	360	6100
103	378	5100
104	352	3065
105	368	2130



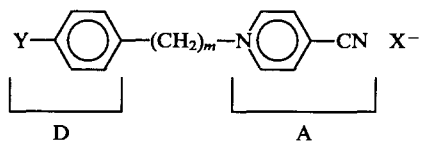
Similar results were also obtained in the study of the structural and spectroscopic characteristics of compound **103**. The spectrum of compound **104** likewise contains an ICT band, but its intensity is appreciably lower, increasing significantly with decrease in temperature. This feature of the compound can be explained by the existence in solution of an equilibrium between conformers with axial and equatorial disposition of the phenyl group, although in the solid phase compound **104** has only one (axial) conformation.[110] In the spectrum of compound **105**, the intensity of the ICT band is lowest and equilibrium between the conformers is observed, but the relative content of the axial conformer is low (in the crystalline state, this compound exists in the equatorial conformation). According to X-ray diffraction data, the length of the central C–C bond in compound **102** is much greater (1.559 Å) than in compound **105** (1.526–1.529 Å).

In compound **98**, having the chair conformation, the mutual orientation of the LEP of the sulfur atom and the C–C π-bonds is favourable for their interaction. An ICT band is observed in the spectrum of compound **98** at 294 nm (ε = 2860).[107]



For the fixed *trans*-orientation of the bicyclic compound **106a**, an ICT band is also observed in the spectrum of the latter (at 270 nm), indicating the interaction of the sulfur LEP with the π-acceptor through five σ-bonds. For the *cis*-orientation in compound **106b**,[107,108] there is no such interaction, in conformity with Hoffmann's requirement that the σ-bonds must have the *trans,trans*-orientation.

98



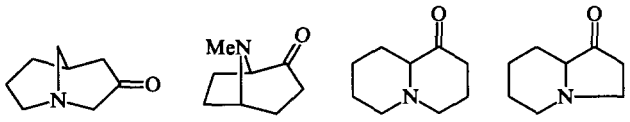
106a

106b

The band due to the intramolecular charge transfer between the aromatic fragment (the donor D) and the pyridinium cation (the acceptor A) is observed in the electronic spectra of compounds **107** having the general formula.[111–113]

107

m = 1–4, Y — electron-donor substituents.



The transition energy is determined by the difference between the π and π* energy levels of the donor and acceptor. Accordingly the length of the methylene chain has little influence on the position of the band but does have a significant effect on its intensity.[111] For certain conformations of compound **107** (m = 1), there is a possibility of a direct overlap of the π orbitals of the donor and the acceptor.

The *trans*- and *gauche*-conformations are believed to be the main ones in compound **107** (m = 2). They are described by the angle φ (rotation about the central C–C bond). For $\varphi > 60°$, only the interaction through σ-bonds takes place, whilst for $\varphi < 60°$ there is in addition also direct π,π overlap due to the interaction through space. The interaction through σ-bonds depends on the overlap of the π orbitals of the donor and the π* orbitals of the acceptor with the σ and σ* orbitals of the intervening C–C bond. The intensity of the ICT band is then determined by their mutual orientation and varies from 225 litre mol^{-1} cm^{-1} ($\varphi \sim 60°$) to 1715 litre mol^{-1} cm^{-1} ($\varphi \sim 144°$).

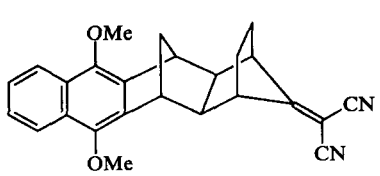
Quantum-chemical calculations have made it possible to estimate the extent of the interaction of the LEP of the nitrogen atom and the carbonyl oxygen atom with the occupied and unoccupied σ and σ* orbitals of the intervening C–C bond and also with the π orbitals of the carbonyl group in α-aminoketones containing the N–CH_2–C=O group.[105,114,115] It was established at the same time that the interactions under consideration depend on the mutual orientation of the functional groups. The conformations of the molecules of these compounds are specified by the angles φ and θ ($\varphi = 0$, if the C–N bond eclipses C=O and $\theta = 0$ if the nitrogen LEP eclipses the C–C bond).[105]

The interaction through σ-bonds is a maximum in the (φ, 0) and (φ, 180) conformations, whereupon there is maximum overlap between the orbitals of the nitrogen and oxygen LEP and of the adjoining σ-bond. As a consequence of the manifestation of the above interactions, the band due to the $n \rightarrow \pi^*$ transition at 290 nm in the UV absorption spectra of unsaturated cyclic ketones shifts to the region 300–335 nm in the spectra of the cyclic α-aminocarbonyl compounds **108–111** (Table 6).[105]

108 **109** **110** **111**

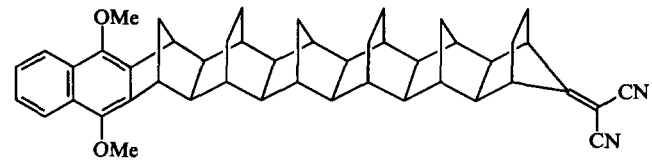
Table 6. Spectroscopic parameters for certain α-aminoketones with a fixed conformation.[105]

Compound[a]	φ/deg	θ/deg	Solvent	λ/nm (ε)
108	160	165	Hexane	330 (55)
109	180	330	Ethanol	314 (68)
110	150	300	Isooctane	314 (48)
111	170	270	Isooctane	293 (29)



[a] The compounds are quoted in order of increasing deviation of n_O and n_N from coplanarity.

The angle φ for these compounds is close to 180° and the interaction through space is hardly manifested. The energy of the $n \rightarrow \pi^*$ transition depends mainly on the angle θ. When the orbital of the nitrogen LEP is oriented at right angles to the N–C–C=O plane (θ = 90°), the interaction through σ-bonds is ruled out and the energy of the $n \rightarrow \pi^*$ transition is the same as in saturated ketones.



Appreciable changes are observed in the circular dichroism spectra of azacyclohexanones containing the $N-CH_2-C=O$ group when the nitrogen LEP is antiperiplanar relative to the $C_\alpha-C(O)$ bond. Such effects are absent when the nitrogen LEP is in the *gauche*-conformation relative to this bond.[114,115] This demonstrates the influence of the conformations on the interaction through σ-bonds and shows how the interaction with charge transfer differs in stereoisomers containing donor and acceptor fragments with different orientations.

The characteristics of the ICT bands are more sensitive to the interaction through the σ-bonds of nonequivalent groups than photoelectron spectroscopic data.[96]

Studies by pulse radiolysis and photoinduced electron transfer methods of the interactions between the donor and acceptor separated by saturated σ-bridges in rigidly fixed systems containing between 4 and 13 intervening σ-bonds (for example, in compounds **112** and **113**) confirmed the theoretical ideas concerning the mechanism of the interaction through σ-bonds.[28,116] The very rapid intramolecular electron transfer between the donor and the acceptor separated by distances ranging from 7 to 14.9 Å is due to the interaction of their π and π* orbitals with the σ and σ* orbitals of the hydrocarbon bridge.

112

113

The experimental rate constant for the intramolecular electron transfer depends on the number of intervening σ-bonds (m). A similar dependence has been obtained with the aid of nonempirical calculations in the analysis of the interaction through σ-bonds in model compounds.[28] The intramolecular electron transfer rate constant is also determined by the geometry of the intervening bridge. It decreases by a factor of approximately five on passing from the *trans,trans*- to the *trans,cis*-conformation (m = 8) and diminishes from 10^{11} s^{-1} to 4×10^8 s^{-1} on passing from compound **112** to **113**. The high electron transfer rate constants have been explained by the interaction through σ-bonds, including the σ,π interaction.[28,116] Electron transfer processes between equivalent and nonequivalent groups joined by different hydrocarbon bridges have been investigated by the luminescence and EPR methods and by electronic spectroscopy.[117–121]

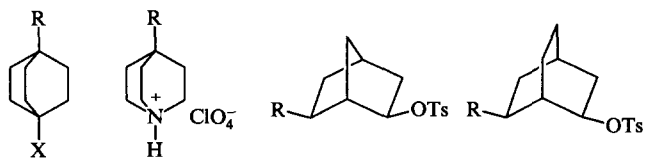
IV. The influence of the interaction through σ-bonds on the reactivity of organic compounds

Electronic interactions cannot fail to influence the reactivity of organic compounds. We shall consider this influence in relation to several examples.

The heterolytic fragmentation

is a very common reaction in organic chemistry and has been studied in detail by Grob.[103,122] The fragmentation of 1-amino-3-halopropanes to ethylene and the corresponding iminium salt can also serve as an example.

Reaction may occur either via a concerted mechanism or as a two-stage process. In the former case, the C^1-C^2 and C^3-X bonds are ruptured simultaneously, while in the latter the cation



is formed initially. Analysis of the experimental and theoretical results led Grob to the conclusion that the concerted fragmentation occurs if the nitrogen LEP and the C^1-C^2 and C^3-X σ-bonds lie in the same plane and are oriented approximately parallel to one another. Such orientation of the fragments presupposes their interaction through σ-bonds. As a result, the C^1-C^2 bond is weakened, which leads to fragmentation.

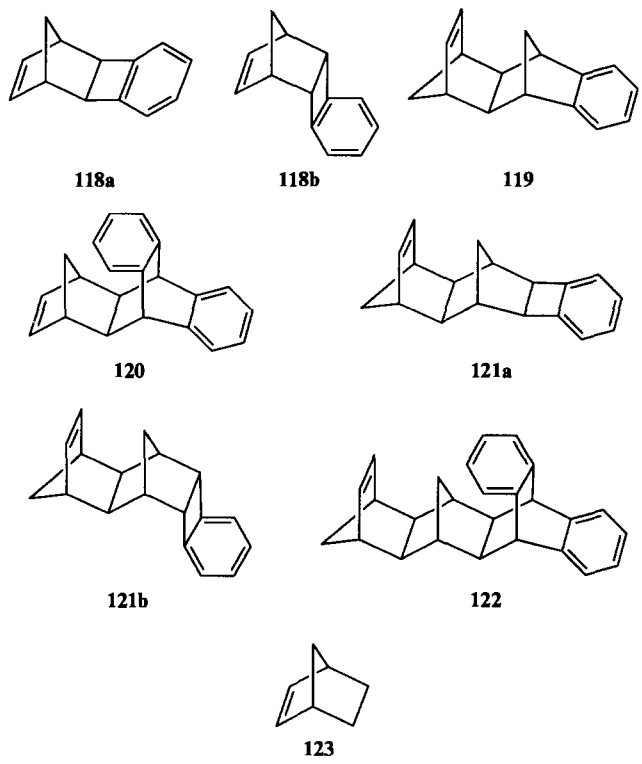
For the antiperiplanar orientation of the nitrogen LEP, the C^1-C^2 σ-bond, and the free p orbital of the C^3 atom, the interaction in the cation through σ-bonds likewise induces a weakening of the C^1-C^2 bond; the following order in the arrangement of the levels has been established: A(HOMO) < S(LUMO). Thus both mechanisms presuppose a definite role of the interaction through σ-bonds in the fragmentation reaction.

It has been established that, in the solvolysis of 4-substituted bicyclo[2.2.2]oct-1-yl *p*-nitrobenzenesulfonates **114**, 4-substituted quinuclidinium perchlorates **115**, and the 2-substituted norbornyl tosylate **116** and bicyclo[2.2.2]octyl tosylate **117**, the

influence of the substituents R on the reaction centre X is largely determined by their inductive effect.[123-125] However, for R = $HOCH_2$, CH_3OCH_2, H_2NCH_2, $AcOCH_2$, $ClCH_2$, $TsOCH_2$, and H_2NCO, the rate of reaction increases by a factor of 2–8 compared with the rate calculated from the inductive constant of the substituent R. The increase in the rate of reaction has been explained by the interaction through σ-bonds. For the same reason, the solvolysis of compound **114** with R = $Sn(CH_3)_3$ is 3000 times faster than for R = Alk.[126]

114 **115** **116** **117**

X = p-$NO_2C_6H_4SO_3$



According to quantum-chemical calculations (EHM), the interaction through σ-bonds between the lowest unoccupied MO of aryl cations, localised on a positively charged centre, and the occupied $n(\pi)$ orbitals of the substituents leads to their stabilisation compared with the unsubstituted phenyl cation.[29,127] Similarly, electron-accepting substituents stabilise the aromatic carbanion $XC_6H_4^-$.[29] The photolysis of cyclobutanones entails ring expansion with formation of the corresponding tetrahydrofurans. This has been explained by the interaction through σ-bonds in the intermediate radical.[128]

The high stereospecificity of the cycloaddition of tetracyanoethylene to alkyl propenyl ethers with the intermediate formation of the 1,4-dipoles has also been explained by the predominance in the latter of the interaction through σ-bonds.[29,129]

A striking example of the influence of the interaction through σ-bonds on the reactivity of unsaturated organic compounds is provided by their Birch reduction with a solution of an alkali metal in liquid ammonia.[25,130,131] Isolated double bonds are usually not reduced by this method. However, when they approach one another or an aromatic ring, the rate of hydrogenation increases sharply, which is largely due to the interaction through space. Thus norbornadiene **38** (m = 1) and the related compounds **118–122** are reduced 10^5 times faster than norbornene **123** (Table 7).

Table 7. The coefficients (k_D^E) of the increase in the rate of the Birch reduction of double bonds[25] (*tert*-butyl alcohol served as the proton donor).

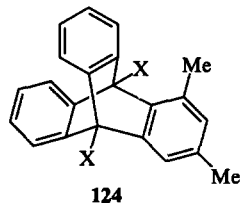
Substrate	Standard	Metal	k_D^E
38 (m = 1)	**123**	Li	10^5
118a	**123**	Li	140
	123	Na	169
	123	Na/cryptand[2.2.2]	206
118b	**123**	Li	78
69	**71**	Li	26
65	**66**	Li	18
119	**71**	Li	96
120	**66**	Li	2900
121a	**71**	Li	3
121b	**71**	Li	3.5
122	**71**	Li	5
71	**123**	Li	5.8
66	**123**	Li	0.6

118a **118b** **119**

120 **121a**

121b **122**

123



In the Birch reduction of the polycyclic unsaturated hydrocarbons **65**, **69**, and **118–122**, in which the unsaturated fragments are separated by three (compounds **118a, b**), four (compounds **65**, **69**, **119**, and **120**), five (**121a, b**), or six (compound **122**) σ-bonds, the rates of reduction of the double bonds (k_D^E) reflect the interaction of these fragments through σ-bonds (Table. 7).[25] Thus the double bond in the *exo*-compound **118a** is reduced 140 times faster than in norbornene **123**. The lower value of k_D^E for the *endo*-compound **118b** compared with the *exo*-compound **118a** can be explained very successfully by the competition in this system of the interaction of the π orbitals through space and through σ-bonds.[131] An example of the chemical manifestation of the interactions through four σ-bonds is provided by the Birch reduction of the hydrocarbons **119** and **120**, in which the rate constants k_D^E are 96 and 2900 respectively.[132] In terms of the mechanism adopted for this reaction, the interaction between the π* levels of the double bonds and the aromatic ring diminishes the energy of the lowest unoccupied MO and increases the probability of the formation of a radical-anion.[25,131] This has been confirmed by quantum-chemical calculations (EHM, INDO) for compound **118a**, indicating an appreciable mixing of the π* MO of the double bond and the aromatic ring.

The interaction through space and through σ-bonds of the vinyl groups in hexa-1,5-diene and hepta-1,6-diene determines their capacity for photochemical [2 + 2]-cyclisation.[133,134]

The change in reactivity in many intramolecular reactions proceeding with formation of intermediate radicals or biradicals can be explained by the effects of the interaction through space or through σ-bonds of two p orbitals with unpaired electrons (a biradical) or of p orbitals with an unpaired electron and an occupied π orbital (a radical).[135] The stability of the cyclic transition state depends on the number of intervening σ-bonds, the state incorporating ($4m$ + 2) σ-electrons being energetically more favourable. This concept of the 'σ-cooperation' indicates the preferential formation in the transition state of odd-membered rings on biradical cyclisation and of even-membered rings on intramolecular hydrogen or hydride migration.[136]

Analysis of the unoccupied π* orbitals and reactivities of triptycene derivatives **124** showed that the deprotonation of compound **124a** (X = H) takes place preferentially with

participation of the methyl group in the 1(C_α)-position, whereas the corresponding reaction of compound **124b** (X = Cl) takes place with participation of the methyl group in the 3(C_β)-position.[137]

124

X = H (**124a**), Cl (**124b**)

By virtue of the interaction of the π* orbitals of the benzene rings of triptycene through σ-bonds, the relative energies of the degenerate unoccupied levels are $e' < e''$. In interaction through space, this relation is reversed. On passing from X = H ($e' < e''$) to an electronegative substituent (X = Cl), the interaction through σ-bonds is weakened and the order in the arrangement of the levels changes ($e' > e''$). The reactivity agrees with the nature of the lowest unoccupied orbitals e' and e''.

Yet another example of the chemical effect of orbital reactions through σ-bonds and through space on the reactivity of molecules may be provided by the reactions of unsaturated cyclic sulfones with ethyl azidoformate and peracids, which is accompanied by the formation of the corresponding aziridine and oxiran derivatives.[138] There is a correlation between the reactivity of the double bond and its π-ionisation potential, which is higher in the compounds investigated compared with olefins. This increase is caused by the orbital interaction through σ-bonds and/or through space between the sulfone group and the double bond.[138] Similar effects have been noted in the interaction of a series of bicyclic olefins with nitrenes.[139]

Reactions of cyclopropene derivatives with electrophiles

V R Kartashov, E V Skorobogatova, N S Zefirov

Contents

I. Introduction 935
II. The influence of the nature of the reagent on the reactions of cyclopropene derivatives 935
III. The mechanisms of the interaction of cyclopropene derivatives with electrophiles 947

Abstract. A systematic account is given of data on the reactions of cyclopropene derivatives with acids, halogen- and sulfur-containing electrophiles, and mercury salts. The influence of the nature of the electrophile and of the structure of the cyclopropenes on processes with retention and opening of the ring, on the stereochemistry of the addition of reactants to the cyclopropene bond, and on the stereochemistry of the formation of the ring opening products is examined. The reaction mechanisms are discussed. The bibliography includes 120 references.

I. Introduction

Cyclopropene derivatives as highly strained systems[1–11] have aroused much scientific interest. For a long time, the study of the physicochemical properties and reactivities of cyclopropene derivatives was held back by the difficulty of their synthesis. However, since the appearance in the 1960s of new methods of synthesis which have made these compounds entirely available, such studies have developed vigorously. The chemical properties of cyclopropenes in the diene synthesis,[3,4,12–15] dipolar addition,[3,4,16–20] and cyclodimerisation[21–23] reactions as well as reactions with electrophiles have been investigated systematically. Cyclopropene derivatives have proved convenient substances for the synthesis of a wide variety of heterocyclic and polycyclic systems.[3,4,12–23] Numerous studies have been devoted to the molecular and orbital structures of cyclopropenes, the main results of which may be found in the relevant publications[1,2,7–9,24–26] and in the literature quoted therein.

A large number of studies have led to the need for a systematic arrangement of the literature data. However, there have been very few review publications[3,4,27,28] and none whatever exist for reactions of cyclopropenes with electrophiles.

The aim of the present review is to survey the experimental data on the reactions of cyclopropene derivatives with electrophiles. Some information about these reactions has been published in review articles[3,4,27] and where necessary it is considered in the context of the data discussed in the present communication.

Although in the description of the literature data the probable reaction mechanisms are also considered, we thought it desirable to describe in a separate section of the review, on the basis of the data presented, the most general mechanisms of these reactions and also to consider in greater detail the publications devoted specifically to these problems. The review reflects the state of the problem at the end of 1992.

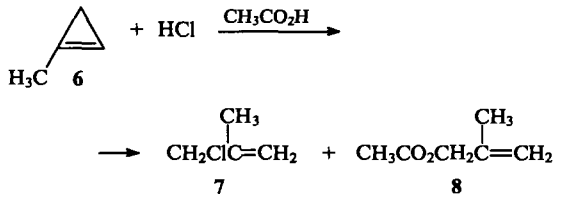
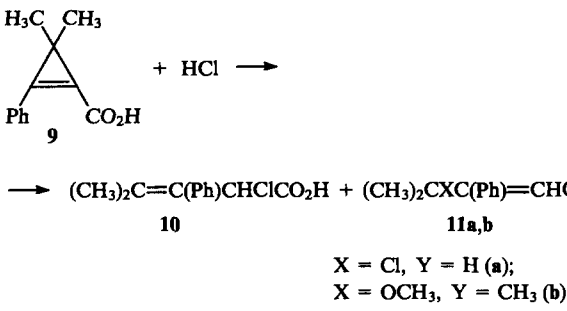
II. The influence of the nature of the reagent on the reactions of cyclopropene derivatives

1. Reactions of cyclopropenes with protic and Lewis acids



The reactions of propenes with protic acids usually lead to ring opening products. Thus the reaction of 1,3,3-trimethylcyclopropene with dry hydrogen chloride at –50 °C leads to the formation of 1-chloro-2,3-dimethylbut-2-ene **1** and 3-chloro-2,3-dimethylbut-1-ene **2** with compound **1** predominating.[3]

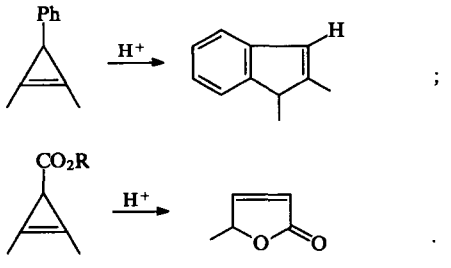
The reaction of 3,3-dimethylcyclopropene **3** with hydrogen chloride in acetic acid takes place similarly to the preceding reaction and involves the formation of 3-chloro-3-methylbut-1-ene **4** and 4-chloro-2-methylbut-2-ene **5**, the product ratio **4**:**5** varying during the course of reaction and amounting to 42 : 58 on extrapolation to zero time.[29]



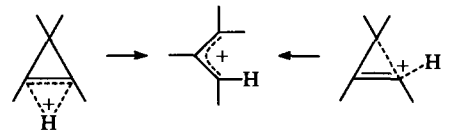
Under the same conditions, the interaction of 1-methylcyclopropene **6** with hydrogen chloride leads to a mixture of methylallyl chloride **7** and methylallyl acetate **8**.[29]

The formation of compound **8** with participation of the solvent indicates the cationoid nature of the intermediate, while the presence of the isomeric products of types **4** and **5** is evidence for its allylic structure.[29]

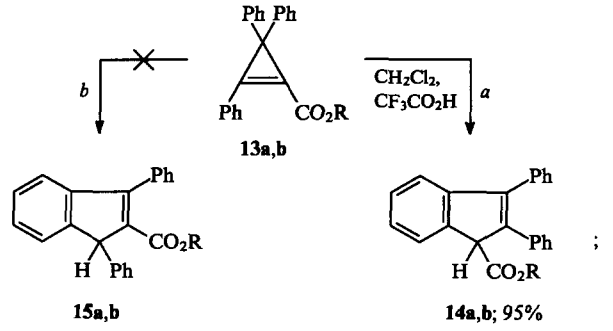
The reactions involving cyclopropene derivatives containing an electron-accepting substituent at the double bond, which hinders the formation of an allylic intermediate, proceed with formation of a cationoid intermediate. Thus 3,3-dimethyl-2-phenylcyclopropene-1-carboxylic acid **9** is converted into 2-chloro-4-methyl-3-phenylpent-3-enoic acid **10** and 4-chloro-4-methyl-3-phenylpent-2-enoic acid **11a** on treatment with hydrogen chloride.[30]



At 40–80 °C, compound **10** is formed preferentially (**10**:**11a** = 4:1, overall yield 60%), whilst at 20 °C the main product is compound **11a** (**10**:**11a** = 3:7).[30] The reaction of hydrogen chloride with the cyclopropene derivative **9** in methanol affords methyl 4-methoxy-4-methyl-3-phenylpropene-2-carboxylate **11b**.[31]

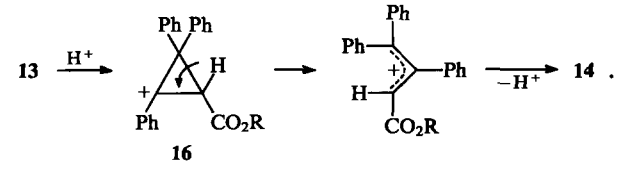


On treatment with toluene-4-sulfonic acid in boiling toluene, compound **9** is converted into 4-methyl-3-phenylpenta-2,4-dienoic acid **12**.[30]

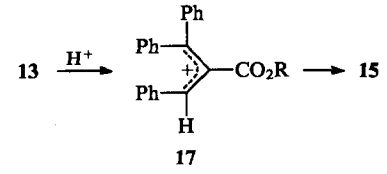


In the presence of a nucleophilic substituent at the methylene fragment of the cyclopropene derivative, treatment with acid leads to the isomerisation of the substrate.[3,27]

It has been suggested that this is a result of the protonation of the double bond or electrophilic attack on the C–C bond.[3,27]

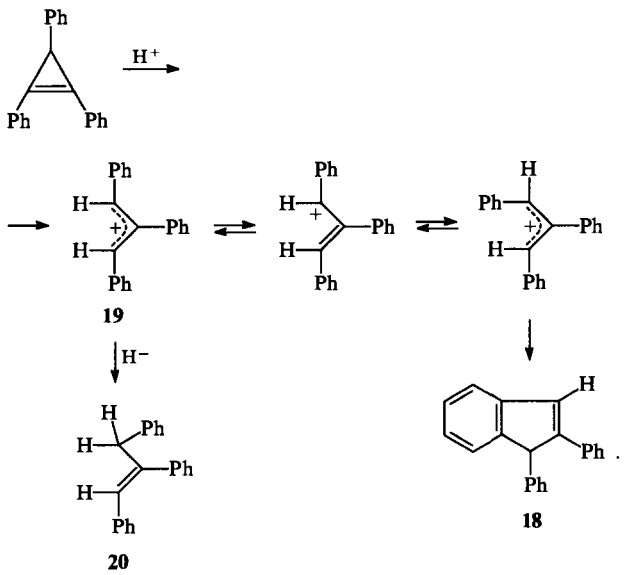


The occurrence of the reaction via the first mechanism is apparently more likely. This is indicated, for example, by the isomerisation of the esters of 2,3,3-triphenylcyclopropene-1-carboxylic acid **13**, which results in the exclusive formation of the indenes **14**.[32,33]

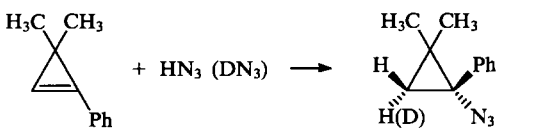


R = CH_3 (**a**), C_2H_5 (**b**).

The authors propose the following mechanism for the formation of the indenes **14**:

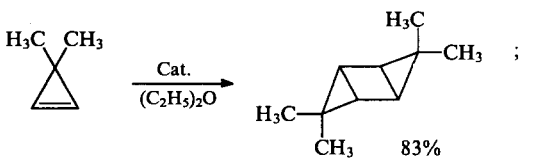


In the alternative version, one should expect the formation of the intermediate **17** and hence of the indenes **15**.



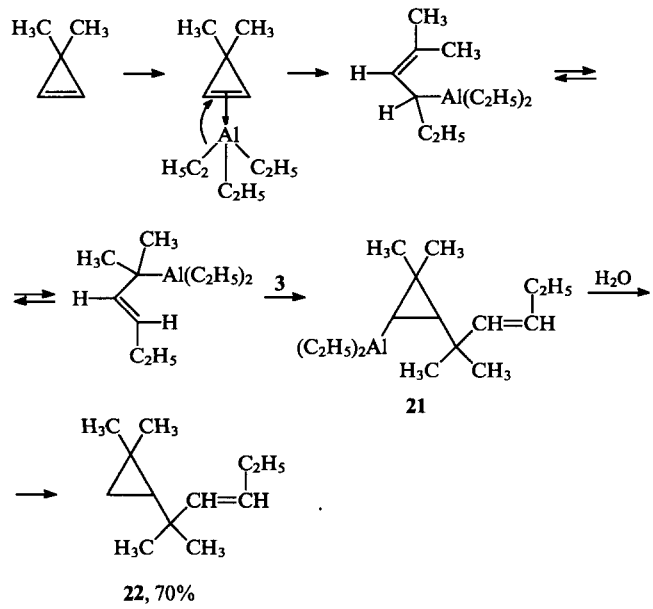
The question of the involvement in the reaction of the cyclopropyl type intermediate **16** is extremely controversial.[3] It is more probable that the allylic intermediate is formed directly as a result of the interaction of the electrophilic hydrogen with the double bond. This mechanism will be analysed in detail in the subsequent sections.

Kudryavtseva and Nesmeyanova[34] attempted to obtain data confirming the formation of the allylic intermediate in the reactions of cyclopropene derivatives with protic acids. For this purpose, a study was made of the isomerisation of 1,2,3-triphenylcyclopropene catalysed by trifluoroacetic acid in methylene chloride using triethylsilane as the donor of a hydride ion. Under the usual conditions, 1,2,3-triphenylcyclopropene is converted on

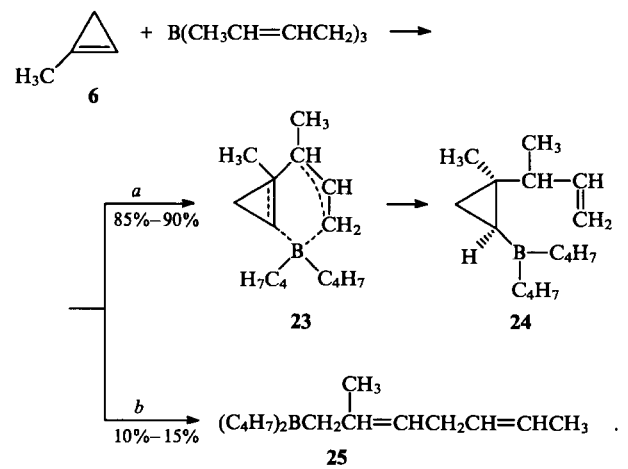


treatment with acid into 1,2-diphenylindene **18**. On the other hand, in the presence of triethylsilane, *cis*-1,2,3-triphenylpropene **20** is formed in a quantitative yield, which indicates the involvement of the allylic intermediate **19** in the reaction.

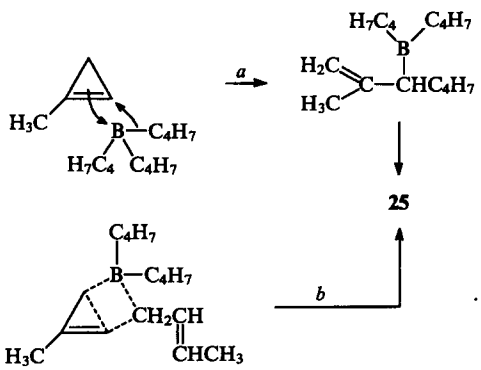
In the light of the data described above, the results of the reaction of 3,3-dimethyl-1-phenylcyclopropene with hydrazoic acid and deuterium azide were unexpected. Only adducts having the *cis*-configuration are formed in 60% and 38% yields respectively.[35]



Extensive studies have been carried out on the reactions of cyclopropenes on treatment with Lewis acids. A characteristic feature of these processes is the wide variety of products and modes of reaction, which are determined mainly by the nature of the Lewis acid. For example, the cyclodimerisation of 3,3-dimethylcyclopropene[36] takes place smoothly on treatment with a number of Lewis acids and leads to the formation of *trans*-3,3,6,6-tetramethyltricyclo[3.1.0.$0^{2,4}$]hexane.

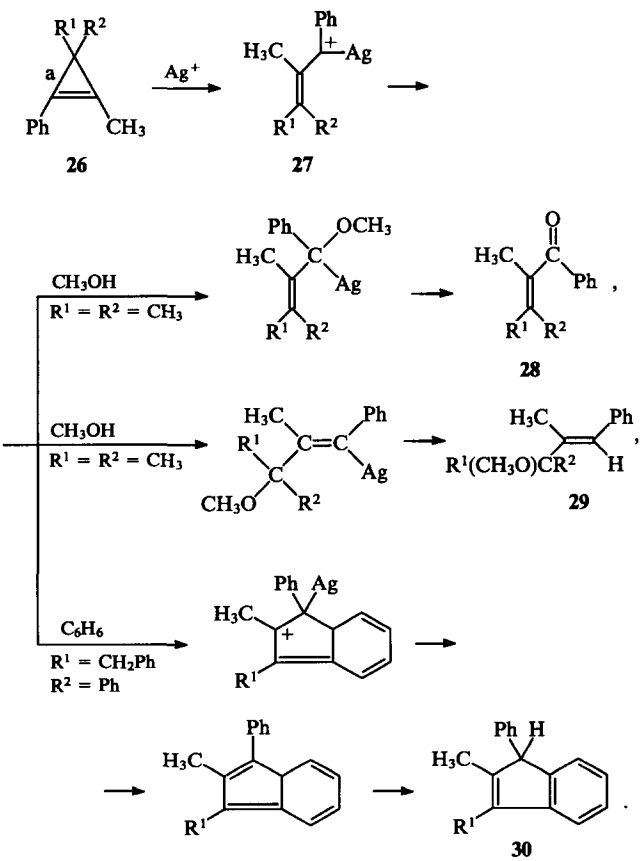


Cat. — $BF_3O(C_2H_5)_2$, $AlCl_3O(C_2H_5)_2$, $B(C_2H_5)_3$, $Al(C_2H_5)_3O(C_2H_5)_2$.

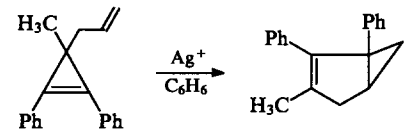


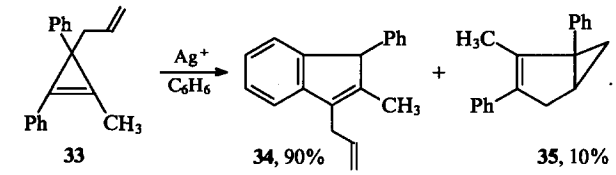
If the triethylaluminium dimer is used as the catalyst, then the process takes place differently and involves the formation of the product **21**, which affords *trans*-2-methyl-2-(2′,2′-dimethylcyclopropyl)hex-3-ene **22** after hydrolysis.

1-Methylcyclopropene **6** cyclodimerises in the reaction with boron trifluoride diethyl etherate,[36] but, when it is treated with triethylborane,[37] triallylborane,[38] and tricrotylborane,[39] the reagent adds to the cyclopropene with retention or opening of the ring. Thus, in the last case the products are *cis*-2-(but-3-en-2-yl)di(but-2-enyl)(2-methyl-1-cyclopropyl)borane **24** and di(but-2-enyl)(2-methylhepta-2,5-dien-1-yl)borane **25**.



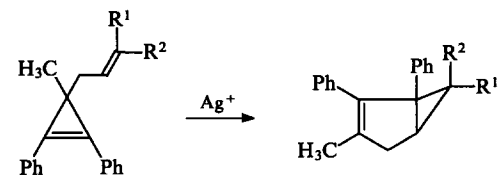
According to Bubnov et al.,[39] the formation of compound **24** shows that the addition of allylboranes to the double bond in cyclopropene derivatives is accompanied by the allyl rearrangement, apparently via the six-centred transition complex **23** with cyclic electron transfer. The formation of compound **25** can be represented by alternative schemes, according to which tricrotylborane attacks the double bond of the cyclopropene (pathway *a*) or the single C3 – C2 σ-bond (pathway *b*). The latter scheme appears less likely according to the authors,[39] as the location of the boron atom at the trigonal rather than the tetragonal carbon atom in the transition state is energetically more favourable.



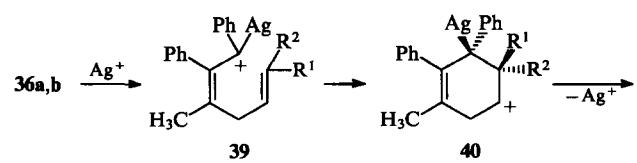


On treatment with silver perchlorate in benzene and methanol, the regio-selective opening of the ring compound **26** takes place with rupture of the single bond 'a'.[40] The structure of the product depends on the nature of the substituents. Thus 2,3,3-trimethyl-1-phenylcyclopropene **26** ($R^1 = R^2 = CH_3$) affords a mixture of 2,3-dimethyl-1-phenylbut-2-en-1-one **28** (65%) and 3-methoxy-2,3-dimethyl-1-phenylbut-1-ene **29** (45%). On the other hand, 3-benzyl-2-methyl-1,3-diphenylcyclopropene **26** ($R^1 = CH_2Ph$, R^2 = Ph) in benzene is converted into 3-benzyl-2-methyl-1-phenylindene **30** in a quantitative yield.

It is believed[40] that the silver ion, which is a strong Lewis acid, attacks the cyclopropene ring, forming the intermediate **27**, the stabilisation of which by the phenyl group determines the selectivity of the ring opening at the bond 'a'.

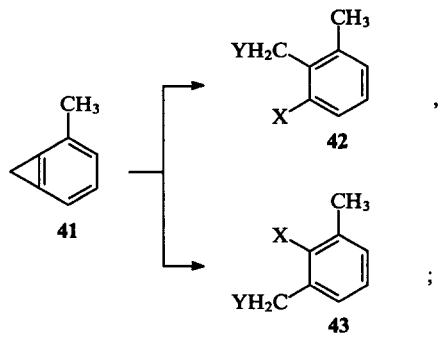


3-Allyl-3-methyl-1,2-diphenylcyclopropene **31** is converted into 3-methyl-1,2-diphenyl-bicyclo[3.1.0]hex-2-ene **32** in the presence of silver ions in benzene, while its analogue 3-allyl-2-methyl-1,3-diphenylcyclopropene **33** affords 3-allyl-2-methyl-1-phenylindene **34** and 2-methyl-1,3-diphenylbicyclo[3.1.0]hex-2-ene **35**.



The isomerisation of (*E*)- and (*Z*)-1-(1-methyl-2,3-diphenyl-2-cyclopropen-1-yl)-but-2-enes **36a, b** takes place stereoselectively under these conditions with formation of *exo* and *endo*-3,6-dimethyl-1,2-diphenylbicyclo[3.1.0]hex-2-enes **37** and **38** respectively.[40]

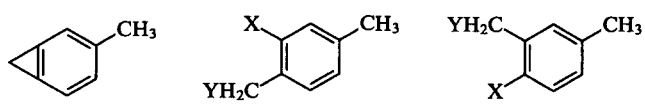
$R^1 = CH_3$; R^2 = H (**a**)
R^1 = H; $R^2 = CH_3$ (**b**)



37: $R^1 = CH_3$; R^2 = H; 96%
38: R^1 = H; $R^2 = CH_3$; 97%

The authors[40] explain the stereoselectivity of the latter reaction within the framework of the mechanism of the formation of the argentocarbonium ion **39** and the subsequent interaction of the terminal double bond with the carbonium ion centre. The intermediate **40** formed under these conditions is converted into the products **37** and **38** after the elimination of silver.

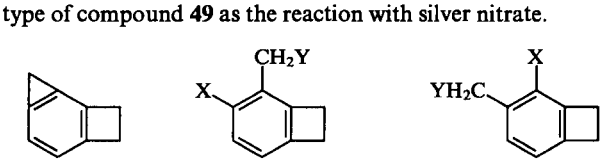
The way in which the cyclopropene ring is opened in the reactions of methylbenzocyclopropenes depends on the nature of the electrophiles.[41] On reaction with silver nitrate in ethanol or



aniline, 2-methylbenzocyclopropene **41** affords compounds **42e, f** as the main products, whereas the reactions with bromine, iodine, and hydrogen chloride give rise to compounds **43a, c, d** as the main products. The overall yield of the products **42** and **43** in these reactions ranges from 54% to 70%.

41 **42** **43**

X = Y = Br (**a**); X = Br, Y = H (**b**); X = Y = I (**c**);
X = H, Y = Cl (**d**); X = H, Y = OC_2H_5 (**e**); X = H, Y = NHPh (**f**)

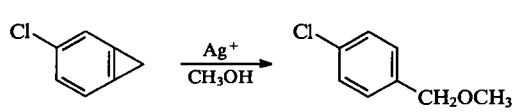


Similarly 3-methylbenzocyclopropene **44** reacts with silver nitrate to form mainly the *p*-xylenes **45**, while the reactions with the halogens and hydrogen chloride afford compounds **46**.

44 **45** **46**

X = H, Y = OC_2H_5, NHPh

Cyclopropa-3,4-benzocyclobutene **47** also affords various products on reaction with silver nitrate and the halogens, but in this case the reaction with hydrogen chloride leads to the same type of compound **49** as the reaction with silver nitrate.



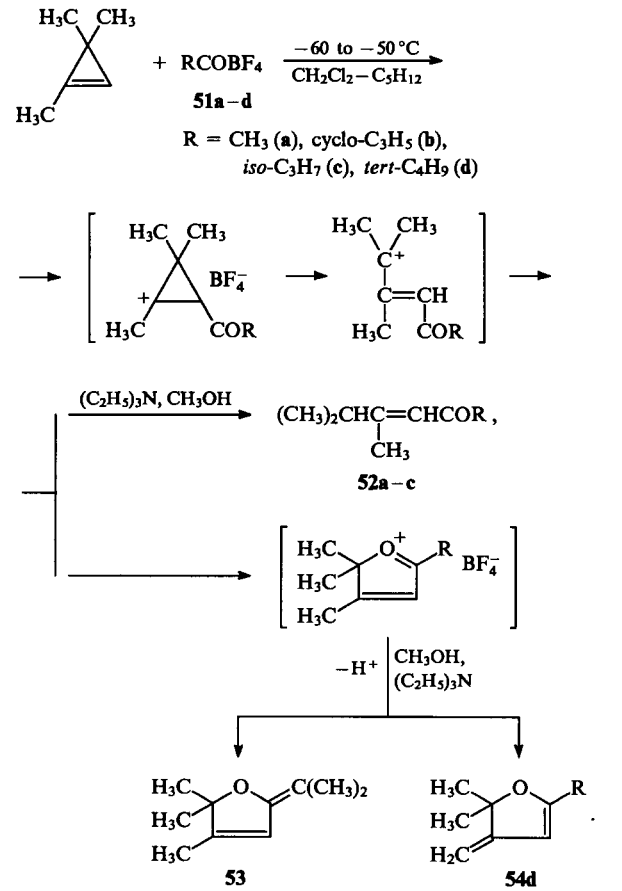
47 **48** **49**

X = Y = I (**a**)
X = Y = Br (**b**)
X = Y = H (**c**)

X = Y = I (**a**)
X = H, Y = Cl (**b**)
X = H, Y = OC_2H_5 (**c**)
X = Y = H (**d**)

The different behaviour of compounds **41**, **44**, and **47** in relation to two types of electrophiles has been explained[41] as due to the attack by silver ions (and the proton in the case of the reaction of compound **47**) on the σ-electrons of the cyclopropene ring, while other electrophiles attack the π-system of the benzene ring.

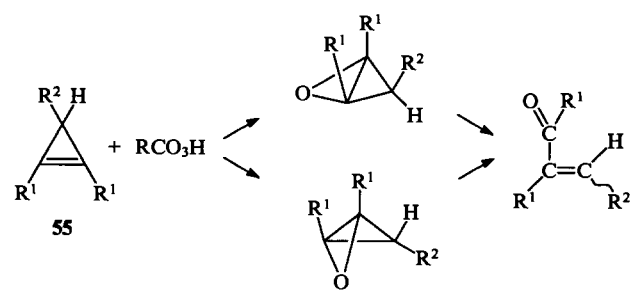
In the silver ion-catalysed reaction of 3-chlorobenzocyclopropene **50** with methanol, only one product is formed.[42]



50

A reaction with ring opening is characteristic also of other electrophiles.

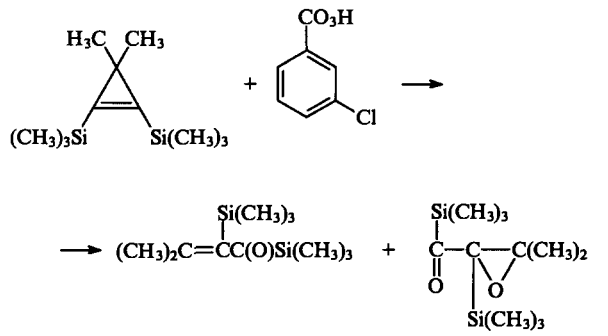
The acyl tetrafluoroborates **51a–d** react with 1,3,3-trimethylcyclopropene to form the acyclic ketones **52a–c** and the products **53** and **54** (Scheme 1).[43]



Scheme 1

R = CH_3 (**a**), cyclo-C_3H_5 (**b**), *iso*-C_3H_7 (**c**), *tert*-C_4H_9 (**d**)

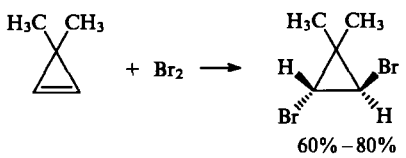
52a–c **53** **54d**



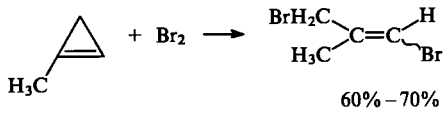
The opening of the cyclopropene ring has also been observed in the epoxidation reactions.[44–47] On treatment with peracids, compounds **55** are converted into acyclic ketones.[47]

55

R^1 = R^2 = Ph (Ref. 44); R^1 = Ph, R^2 = CH_2OH, CH_2OCH_3 (Ref.45);
R^1 = CH_2CH_3, R^2 = $CO_2C_2H_5$, CH_2OH (Ref. 46).

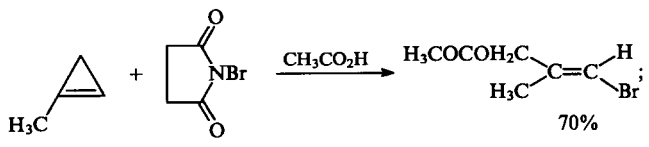


3,3-Dimethyl-1,2-bis(trimethylsilyl)-cyclopropene undergoes a similar reaction on treatment with *m*-chloroperbenzoic acid (reactant ratio 1 : 1, overall yield 65%).[47]

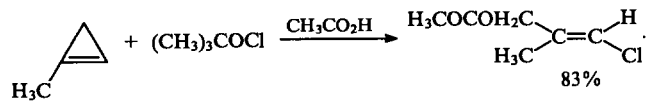


2. Reactions with the halogens and halogen-containing reagents

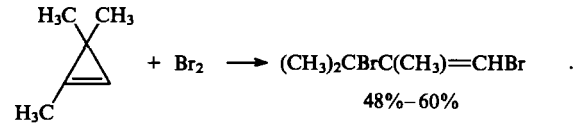
Cyclopropene combines with bromine and iodine in carbon tetrachloride with retention of the ring.[48] On bromination, a *trans*-adduct with a small admixture of the *cis*-isomer is formed in 57% yield.



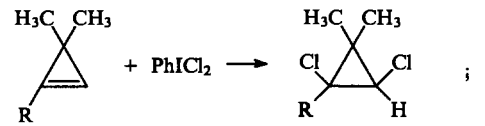
The bromination of 3,3-dimethylcyclopropene **3** in methylene chloride (−50 °C),[49] carbon tetrachloride, acetonitrile, and nitromethane[50] leads to *trans*-1,2-dibromo-3,3-dimethylcyclopropane.



On passing from compound **3** to 1-methylcyclopropene **6**, the mode of addition changes. In this case, the reaction with bromine in carbon tetrachloride,[50] chloroform,[51] or methylene chloride[52] results in the formation of 1,3-dibromo-2-methyl-1-propenes as a mixture of the (*Z*) and (*E*)-isomers (*E* : *Z* = 1 : 2 in CCl_4 and 3 : 1 in $CHCl_3$ and CH_2Cl_2).

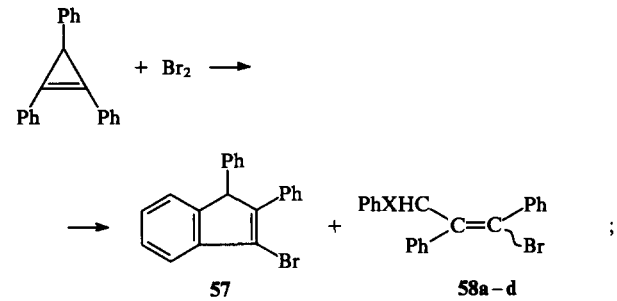


Complete ring opening is observed also in the reactions of 1-methylcyclopropene with *N*-bromosuccinimide (NBS)[51,52] and *tert*-butyl hypochlorite[52] in acetic acid, which results in the formation of the corresponding haloacetates with the (*E*)-configuration.



1,3,3-Trimethylcyclopropene reacts similarly with bromine (CCl_4, CH_2Cl_2, C_5H_{12}, T = 30 to −110 °C).[53]

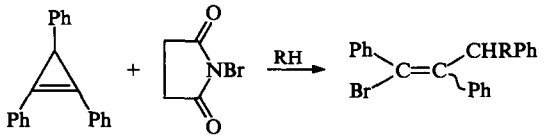
In the reaction with chlorine under the same conditions, it affords a complex and a virtually unidentified mixture of acyclic products,[53] whereas treatment with dichlorophenyliodine resulted in the formation of 1,2-dichloro-1,3,3-trimethylcyclopropane **56a** in 50% − 70% yield. The reaction with 3,3-dimethylcyclopropene also takes place similarly (the yield of compound **56b** is 50%).



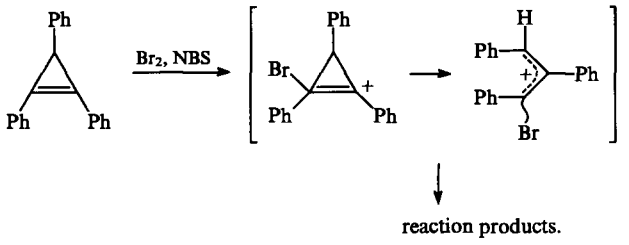
R = CH_3 (**a**), H (**b**). **56a,b**

It has been suggested[53] that the reaction of dichlorophenyliodine takes place in one stage, possibly via a concerted mechanism, whereas chlorination with free chlorine results in the formation of cationoid or radical intermediates.

The data presented show that the presence of a methyl substituent at the double bond of cyclopropene intensifies the tendency towards the formation of products with ring opening.

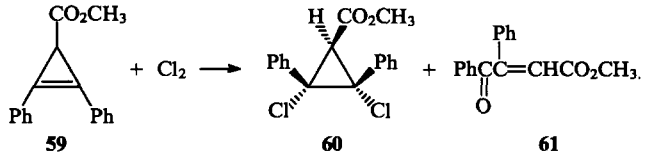


On interaction of 1,2,3-triphenylcyclopropene with bromine in acetic acid or nitromethane, virtually one product of intramolecular alkylation is formed — 3-bromo-1,2-diphenylindene **57**, whereas the reaction in methanol and aqueous acetic acid led to the isolation, together with compound **57**, of the acyclic solvatoadducts **58a − c** and that in acetonitrile led to the dibromo-derivative **58d**.[54]



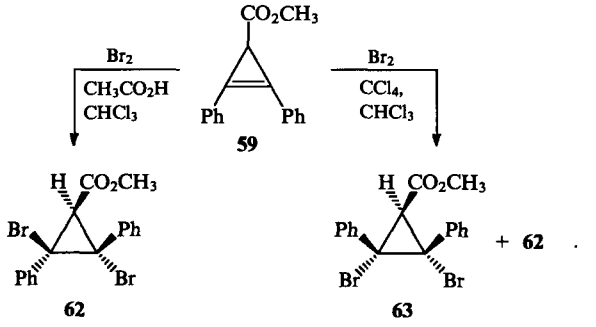
X = OCH_3 (**a**), $OCOCH_3$ (**b**), OH (**c**), Br (**d**).

Solvent	Yield of products (%)				
	57	**58a**	**58b**	**58c**	**58d**
CH_3OH	30	45	–	–	25
80% CH_3CO_2H	30	–	40	30	–
CH_3CO_2H	100	–	–	–	–
CH_3CN	90	–	–	–	10
CH_3NO_2	100	–	–	–	–



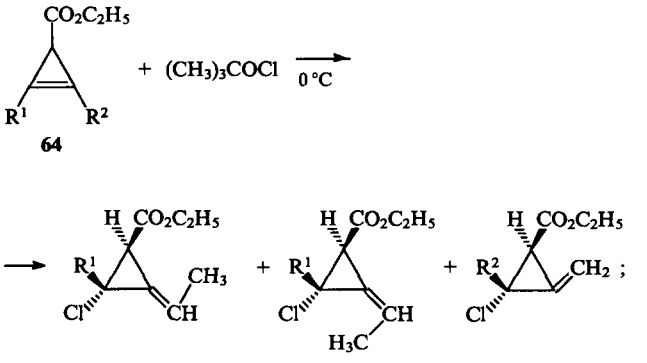
Bromination of 1,2,3-triphenylcyclopropene with *N*-bromosuccinimide in polar solvents affords a mixture of acyclic stereoisomeric products with the (*E*)-isomer predominating.[55]

The authors[54,55] proposed the following mechanism for the above reactions of triphenylcyclopropene with bromine and NBS. As will be shown below, this mechanism is consistent with the nonstereoselectivity of the process:



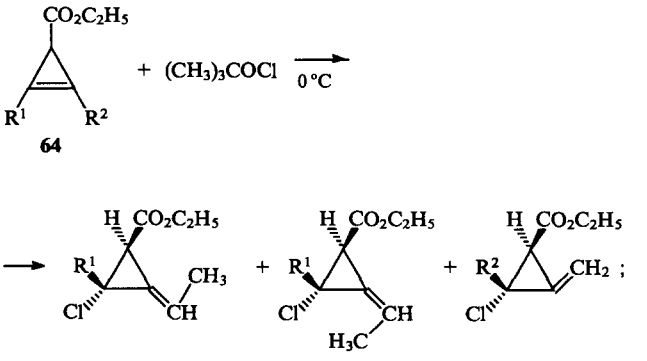
The tendency towards ring opening decreases sharply after the introduction of a carboxylate substituent into the cyclopropene ring. Thus the main pathway in the reaction of chlorine with methyl 2,3-diphenylcyclopropene-2-carboxylate **59** is its addition, which takes place stereoselectively in the *cis*-position regardless of the conditions (acetic acid or carbon tetrachloride in scattered light and under irradiation) with formation of methyl 2,3-dichloro-*cis*-*cis*-2,3-diphenylcyclopropanecarboxylate **60**.[56] Methyl 3,4-diphenylbut-2-en-4-oate **61** is formed at the same time, but the mechanism of its formation was not established.[56]

Reaction conditions	Yield of **60** (%)	Yield of **61** (%)
CCl_4, dispersed light, 0 °C	41	22
CH_3CO_2H, −12 to 13 °C	35	25
CCl_4, light irradiation (500 W electric lamp)	71	8



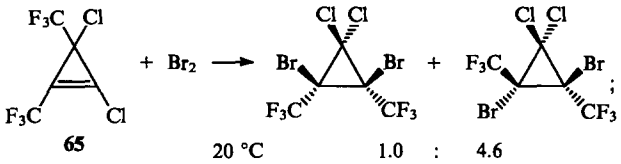
The following features are noteworthy: (a) the addition reaction proceeds not only stereoselectively but also regioselectively—the attack on the double bond takes place from the sterically less hindered side in the *anti*-position relative to the carboxylate group; (b) in acetic acid, where an electrophilic mechanism is most probable, the contribution of the pathway with retention of the ring diminishes compared with the reactions which probably proceed via a radical mechanism (CCl_4, irradiation). According to Grigorova and Komendantov,[56] this may be evidence for the greater stability of the intermediate cyclopropyl radical compared with the cationic species of the cyclopropyl type.

The stereochemistry of the bromination of the ester **59** depends on the reaction conditions.[57] In chloroform or acetic acid in the dark or in the light, bromine adds in accordance with a *trans*-mechanism to form methyl *cis*, *trans*-2,3-dibromo-2,3-diphenylcyclopropanecarboxylate **62** in 30%–39% yield. The rest of the mixture was not identified. On irradiation with light in carbon tetrachloride, bromine adds to the ester **59** mainly with formation of methyl 2,3-dibromo-*cis*,*cis*-2,3-diphenylcyclopropanecarboxylate **63**. The *trans*-adduct **62** is obtained under these conditions in insignificant amounts (5%). As in chlorination, the double bond is attacked from the sterically less hindered side.



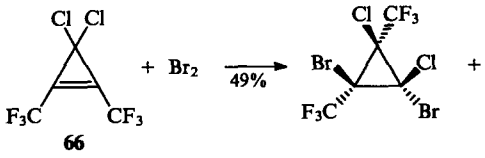
The halogenation of the esters of cyclopropene-2-carboxylic acid **64** by *tert*-butyl hypochlorite leads to isomerisation and the formation of a mixture of the products of the *cis*- and *trans*-addition of chlorine.[58,59]

At temperatures below 0 °C, the first pathway predominates (overall yield 50%), whereas at 60 °C the yield of the adducts increases (overall yield 85%).



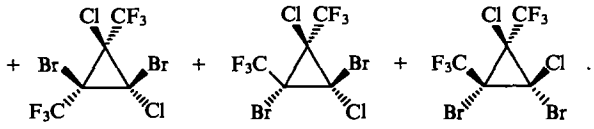
$R^1 = CH_3, C_2H_5$; $R^2 = C_2H_5$.

$R^1 = CH_3, C_2H_5$; $R^2 = C_2H_5$.



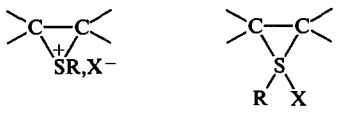
Choubani and coworkers[58,59] considered these results from the standpoint of a radical mechanism. There is no doubt that the cyclopropene derivatives **65** and **66** are brominated in the gas phase via a radical mechanism,[60] which results in the formation of

a mixture of *cis*- and *trans*-adducts. For compound **66**, the ratios of the reaction products are 4.0 : 2.2 : 1.1 : 1.0 with an overall yield of 49%.



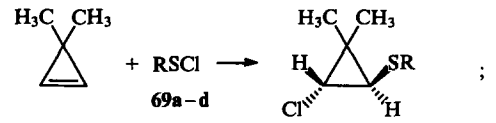
65

20 °C 1.0 : 4.6
70 °C 1.0 : 3.0



66

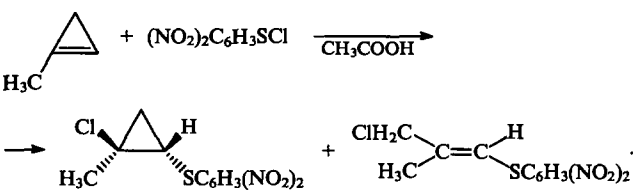
3. Reactions with sulfur-containing electrophiles



The reaction of sulfenyl halides with alkenes is one of the most thoroughly investigated reactions of the Ad_E type. It is characterised by a high *trans*-selectivity of the addition with a low tendency towards molecular rearrangement under the usual conditions. When the reaction is carried out in nucleophilic solvents, the products of the addition of the reagent are obtained as a rule as a mixture of regioisomers. The formation of mixed adducts with participation of the solvents, which is characteristic of the vast majority of electrophiles, is not observed in this case.[61-65] Salt additives exert an effective influence on this reaction (the phenomenon of the doping effect).[66-72] Under the conditions of the doping effect, there is a possibility of a series of unusual pathways in the reaction, which greatly extends its synthetic potential.[72] It has now been established that the above features are due to the formation in the sulfenyl halogenation of alkenes of a cyclic intermediate, the cationoid component of which is the highly symmetrical and relatively stable episulfonium ion **67**, which reacts selectively with the counterion. In weakly polar media, one cannot rule out the possibility of the formation of the species **68**, having the sulfurane structure, as intermediates.

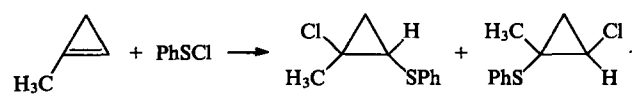
67 **68**

A salt-like compound of type **67** was isolated in a stable form and its structure was determined by X-ray diffraction.[73] It is of interest to discover the extent to which the above rules hold for unusual systems such as cyclopropene derivatives.



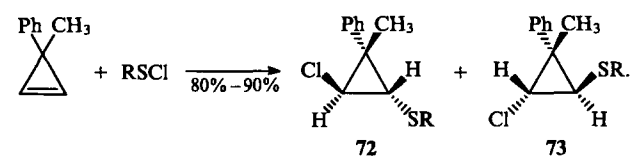
It has been established[74-76] that 3,3-dimethylcyclopropene reacts with benzene- and 2,4-dinitrobenzene-sulfenyl chlorides in acetic acid[74] and with sulfenyl halides **69a-d** in other solvents [$(C_2H_5)_2O$, CCl_4, $CHCl_3$],[75,76] forming *trans*-1-aryl(alkyl)thio-2-chloro-3,3-dimethylcyclopropanes in high yields (80% - 90%).

69a-d



R = CH_3 (**a**), C_2H_5 (**b**), C_6H_5 (**c**), 2,4-$(NO_2)_2C_6H_3$ (**d**).

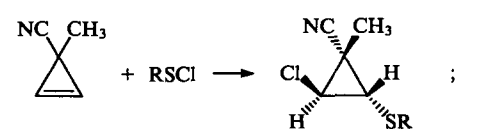
The same stereochemistry of the addition reaction has been observed in the reaction of 1-methylcyclopropene with 2,4-dinitrobenzenesulfenyl chloride. The structure of *trans*-1-chloro-2-(2′,4′-dinitrophenyl) thio-1-methylcyclopropane **70** was determined by X-ray diffraction.[52] It is noteworthy that the addition of the reagent takes place in accordance with the Markovnikov rule (overall yield 90%).[52]



70 **71**

In contrast to this reaction, the addition of benzenesulfenyl chloride leads to a mixture of regioisomers in proportions which depend on the nature of the solvent.[29]

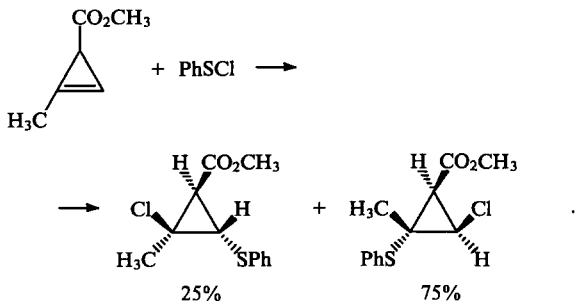
The reaction of 3-methyl-3-phenylcyclopropene with sulfenyl halides results in the formation of a mixture of isomers,[75,76] each of which was obtained from the *trans*-addition of the reagent.



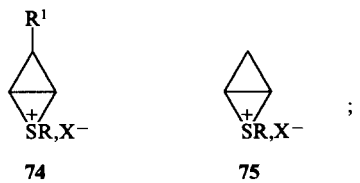
72 **73**

R	Solvent	72 : 73 Ratio
CH_3	$(C_2H_5)_2O$	1.0 : 1.5
	CH_3CN	2.5 : 1.0
C_2H_5	$(C_2H_5)_2O$	1.0 : 1.8
	CH_3CN	1.7 : 1.0
Ph	CCl_4	1.0 : 2.0
	CH_3CN	3.0 : 1.0

The product ratio depends on the polarity of the solvent: in weakly polar solvents (ether, CCl_4), the isomers **73** predominate, whereas in the appreciably more polar acetonitrile mainly the isomers **72** are formed.



The data presented show that the general principle of *trans*-addition of the reagent holds in the sulfenyl halogenation of cyclopropenes. This postulate remains valid also for the substrates where there is a strongly electronegative group in the methylene unit. Thus 3-cyano-3-methylcyclopropene reacts smoothly with methane- and benzene-sulfenyl chlorides, forming *trans*-adducts, the nitrile and sulfide groups being in the *syn*-positions.[75,76]

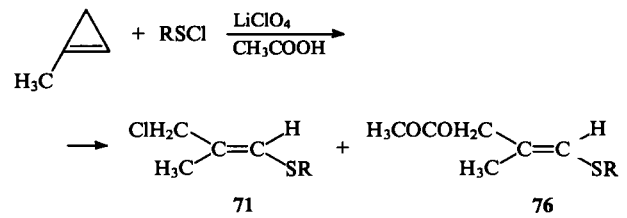


R = CH_3 (93%), Ph (94%).

The authors explain this mode of addition[75,76] by the attractive interaction in the transition state between the electrophile and the cyano-group.

The occurrence of *trans*-addition has also been established in the reaction of methyl 1-methylcyclopropene-3-carboxylate with benzenesulfenyl chloride, which results in the formation of a mixture of regioisomers in an overall yield of 85%–90%.[77] It is interesting to note that in this case the electrophile attacks the double bond from the *anti*-side relative to the ester group, in contrast to the preceding reaction.

The results demonstrate that, for the sulfenyl halogenation of cyclopropenes, the *trans*-addition principle is just as fundamental as for the unstrained systems. The introduction of highly negative groups undoubtedly renders the intermediate **74** less stable compared with its unsubstituted analogue **75**, but the sulfenyl halogenation of cyclopropenes, even when the latter contain electronegative substituents, is nevertheless exclusively *trans*-stereoselective.



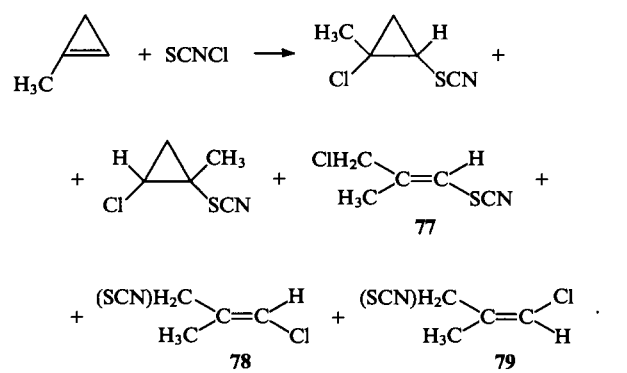
74 **75**

R^1 = electronegative group.

As can be seen from the data presented, the dominant pathway in the reaction of benzene- and alkane-sulfenyl halides with cyclopropenes involves the formation of cyclic adducts. However, the specific properties of the substrate can be manifested in this reaction too.

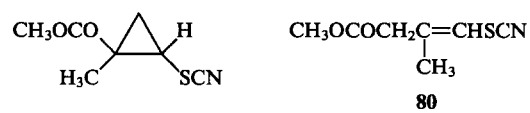
The introduction of electronegative substituents into the reagent and the presence of an electron-donating group at the cyclopropene double bond promote the occurrence of a reaction with ring opening. Thus the ring opening product (*E*)-3-chloro-1-(2,4-dinitrophenyl)thio-2-methyl-1-propene **71** is formed together with the cyclic adduct in the reaction of 1-methylcyclopropene with 2,4-dinitrobenzenesulfenyl chloride.[52] The amount of the acyclic compound **71** increases with increasing polarity of the medium and in solvents such as nitromethane and acetonitrile its yield reaches 50%. The (*E*)-configuration of compound **71** was established on the basis of ^{13}C and ^1H NMR spectroscopic data.[52]

The reaction of sulfenyl halides with cyclopropenes proved to be extremely sensitive to the addition of lithium perchlorate. In solution in acetic acid, the yield of compound **71** does not exceed 13%. If the reaction is carried out in the presence of a fivefold excess of $LiClO_4$ relative to RSCl, it takes place entirely with ring opening, which results in the formation of compound **71** and the product of the reaction with participation of the solvent—(*E*)-3-(2,4-dinitrophenyl)thio-2-methyl-propene-2-acetate **76**.[69]



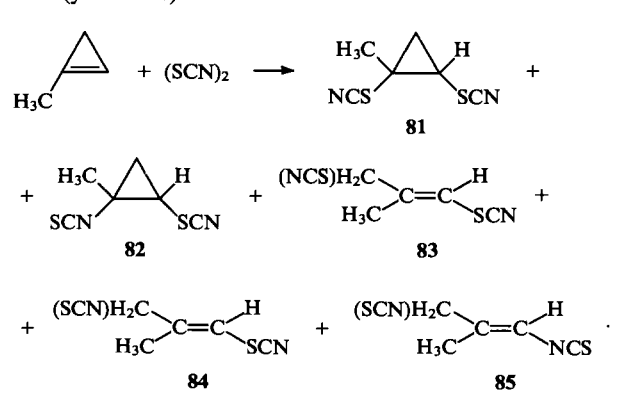
71 **76**

R = 2,4-$(NO_2)_2C_6H_3$.



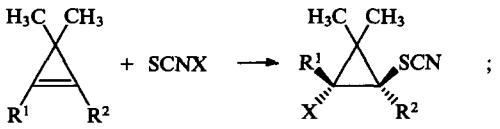
Thiocyanato-reagents interact with cyclopropenes in a more complex manner than sulfenyl halides, although both types of reagents have the same electrophilic centre. The main difference between these reactions consists in the fact that, in the substitution of thiocyanato-groups into cyclopropenes, the contribution of the pathway with ring opening is greater.

1-Methylcyclopropene reacts with thiocyanogen chloride in chloroform, affording up to 50% of acyclic products.[78,79]



Chloro-2-methylpropen-1-yl thiocyanate **77** has the (*E*)-configuration, while 3-chloro-2-methylpropen-2-yl isothiocyanates **78** and **79** consist of a mixture of the isomers (*E*)-**78** and (*Z*)-**79** in proportions of 9 : 1.[79]

When the reaction is carried out in acetic acid, the products of solvo-addition are formed together with those indicated above:[79] 2-acetoxy-2-methyl-cyclopropyl thiocyanate and 3-acetoxy-2-methylpropen-1-yl thiocyanate **80** (overall yield 85%–90%).

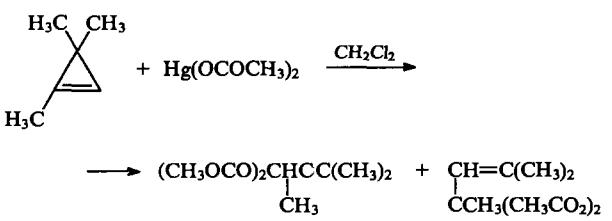


The reaction of 1-methylcyclopropene with thiocyanogen in chloroform and acetic acid results in the formation of the products **81**–**85** (yield 85%).[79,80]

The fraction of the acyclic products is in this case 42% – 43%. Ring opening takes place fully stereoselectively with formation of products having the (*E*)-configuration.[79]

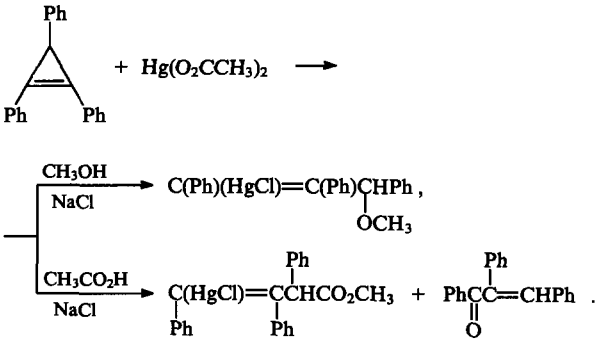
It is striking that in the reactions indicated fundamentally different pathways leading to the synthesis of the acyclic products are observed. The formation of compounds **77** and **80**, (*E*)-2-methyl-1,3-dithiocyanato-1-propene **83**, and (*E*)-3-isothiocyanato-2-methylpropen-1-yl thiocyanate **84** is presumably induced by the electrophilic attack on the double bond in 1-methylcyclopropene by the sulfur atom, whereas compounds **78** and **79** are obtained in the reaction with thiocyanogen chloride as a result of the attack on this bond by the chlorine atom and (*E*)-1,3-diisothiocyanato-2-methyl-1-propene **85** is formed in the reaction with thiocyanogen as a result of the attack by the nitrogen atom on the double bond. One cannot rule out the possibility that thiocyanogen chloride and thiocyanogen exhibit the properties of an ambident electrophile in these reactions.[49,79]

As in the reactions with other electrophiles, substitution of the thiocyanato-group into 3,3-dimethylcyclopropene results in the formation of only the *trans*-adducts.[78]



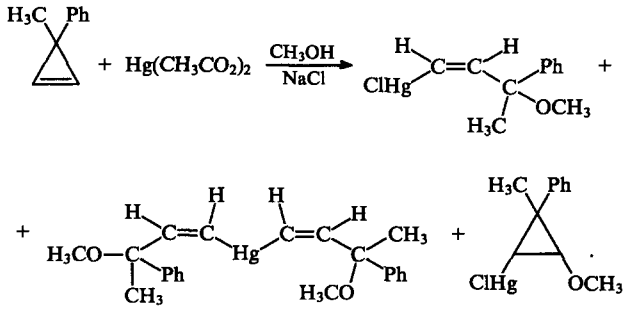
X = Cl, SCN;
$R^1 = R^2 = H$ (96%); $R^1 = H$, $R^2 = CH_3$ (81%);
$R^1 = R^2 = CH_3$ (100%); $R^1 = Ph$, $R^2 = CH_3$ (87%).

4. Reactions with mercury salts

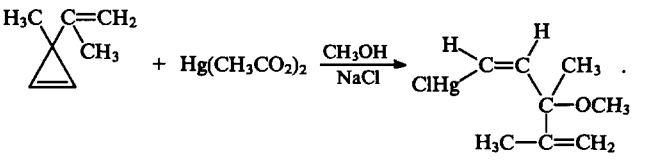


The reaction of mercury salts with cyclopropenes has aroused special interest for a long time. It follows from a large number of studies that a characteristic feature of the mercuration of unsaturated compounds, which distinguishes this reaction from others of the Ad_E type, is its high sensitivity to the structure of the substrate. Whereas mercury salts react with unstrained systems in accordance with the general *trans*-addition mechanism, the mercuration of strained unsaturated compounds, particularly those having a bridged structure, proceeds as a *cis*-process, frequently simultaneously with *trans*-addition.[81,82] Although the claim that the strain in the structure is the main cause of the 'anomalous' stereochemistry is not open to doubt, the specific mechanism of its influence on the *cis*-addition is very complex.[81,82] This is clearly manifested, for example, by the fact that in certain cases opposite stereochemical results are obtained for the same substrate depending on the reaction conditions.[81–85] However, it is noteworthy that quantum-chemical calculations have led to the conclusion that the *cis*-addition is determined not by the structural strain but by the unusual structure of the intermediate.[86]

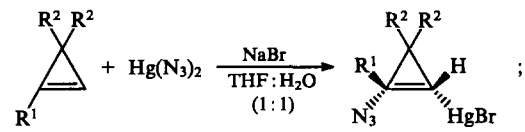
Cyclopropene derivatives constitute a good model for testing the relationship between the process stereochemistry and the structure of the substrate because steric factors do not play a significant role in these systems, in contrast to bridged systems.



First attempts to elucidate the stereochemistry of the mercuration of cyclopropene derivatives were not successful, as mercury salts react with the simplest cyclopropenes to form acyclic compounds which do not contain mercury.[82,87,88] A characteristic example of reactions of this type is that between 1,3,3-trimethylcyclopropene and mercury acetate in methylene chloride.[87,88]



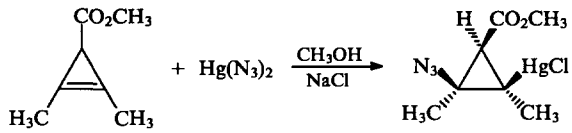
1,2,3-Triphenylcyclopropene interacts with mercury acetate in methanol and acetic acid with ring opening.[89]



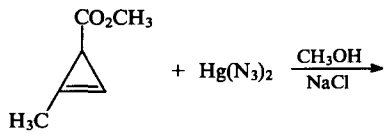
It has been shown in relation to the mercuration of 3-methyl-3-phenylcyclopropene that the acyclic products obtained in the reaction have the (*Z*)-configuration.[90]

A similar stereochemical result was obtained in the reaction with 3-isopropenyl-3-methylcyclopropene (yield of reaction product 10%).[90]

The results of the study of Galle and Hassner[35] constituted an important step in the investigation of the stereochemistry of the addition of mercury salts to cyclopropenes. It was established that mercury azide adds to a number of cyclopropenes with formation of *cis*-adducts.

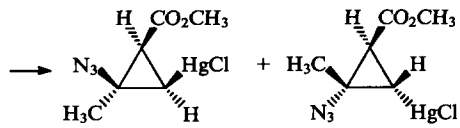


$R^1 = R^2 = H$; $R^1 = H$, $R^2 = CH_3$;
$R^1 = R^2 = CH_3$; $R^1 = Ph$, $R^2 = CH_3$.



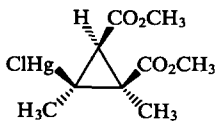
The esters of cyclopropene-2-carboxylic acids are a convenient model for the study of the stereochemistry of the mercuration of cyclopropenes as well as certain other aspects of this reaction. They react smoothly with mercury salts, affording products containing a three-membered ring, the nature of the reaction remaining unchanged on variation over a wide range of the electronic properties of the substituents at the double bond.

The azidomercuration of methyl 2,3-dimethylcyclopropene-2-carboxylate **86** and methyl 2-methylcyclopropene-2-carboxylate **87**, like that of cyclopropene hydrocarbons, proceeds in accordance with the *cis*-mechanism. In the reaction of

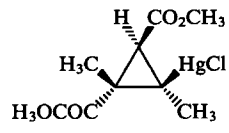


mercury azide with the ester **87**, a mixture of *cis*-2-azido-*cis*-3-chloromercurio-*trans*-2-methyl- and *trans*-2-azido-*trans*-3-chloromercurio-*cis*-2-methylcyclopropanecarboxylic acids was obtained after the exchange reaction with NaCl (**88**:**89** = 1:1).[91]

86 52%

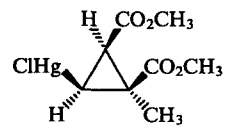


87

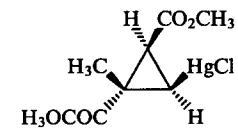


88 **89**

The use of mercury azide as the reagent made it possible to discover, in relation to monocyclic unsaturated compounds, a clear relationship between the strain in the substrate and the probability of the *cis*-addition. In contrast to the reactions with cyclopropenes, the azidomercuration of the less strained cyclobutene affords a mixture of the *cis*- and *trans*-azidomercurio-derivatives in proportions of 60:40,[92] while the reaction with cyclohexene results in the formation of only the *trans*-adduct.[85]

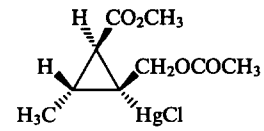


It follows from the data presented that mercury azide is a specific *cis*-azidomercurating agent for cyclopropene derivatives. The reactions with other mercury salts are nonstereoselective. The interaction of the esters **86** and **87** with mercury acetate in acetic acid results in the formation of mixtures of the methyl esters of *trans,trans*- and *trans,cis*-2,3-dimethyl-*cis*-3-chloromercurio-2-acetoxycyclopropanecarboxylic acids (compounds **90** and **91**) and the methyl esters of *trans*- and *cis*-2-methyl-*cis*-2-chloromercurio-2-acetoxycyclopropanecarboxylic acids (compounds **92** and **93**) in the proportions **90**:**91** = 31:46 and **92**:**93** = 4:1.[91]



90

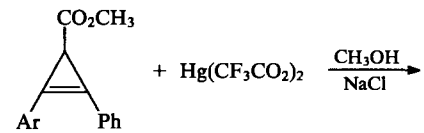
91



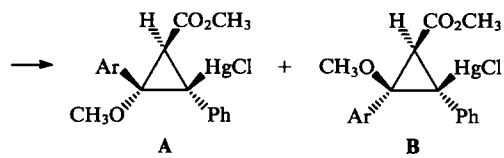
92

93

Furthermore, the methyl ester of *trans*-3-chloromercurio-*trans*-2-methyl-3-acetoxymethylcyclopropanecarboxylic acid **94** was isolated after the reaction with compound **87**. The mechanism of the formation of compound **94** has not been investigated (the overall yield of the products of the reactions indicated was 85%–90%).[91]



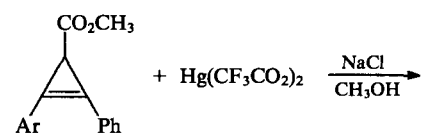
94



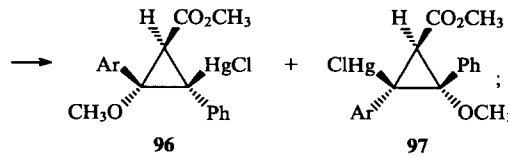
Although mercuration with mercury acetate takes place nonstereoselectively, nevertheless in this case too there is a tendency towards a decrease in the amount of *cis*-adducts with decrease in the substrate strain energy. For example, in the reaction of mercury acetate with cyclobutene in methanol, the amount of the *cis*-adduct does not exceed 7%, while in solution in acetic acid it is not formed at all.[92]

It follows from the data considered that the influence of strain on the degree of *cis*-addition of mercury salts depends radically on the nature of the reagent and the solvent. A convincing argument confirming this postulate is provided by the results of the mercuration of the methyl esters of 2-aryl-3-phenylcyclopropene-2-carboxylic acids. In this case, the influence of the reaction conditions on the process stereochemistry is so great that the strain factor is almost completely abolished.

Thus the interaction of the cyclopropenes **95a–c** with mercury trifluoroacetate in methanol affords a mixture of the *cis*- and *trans*-adducts.[93–96]



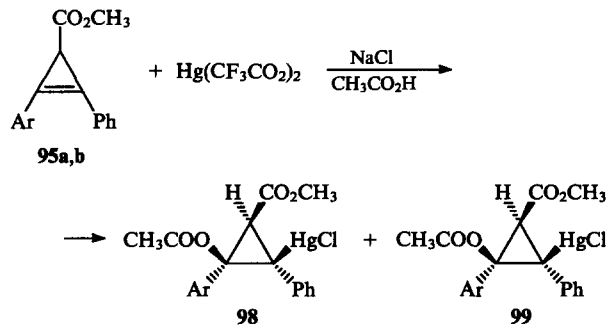
95a–c



A **B**

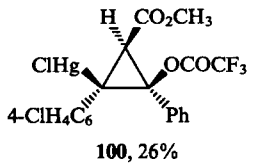
Ar	Yield of A (%)	Yield of B (%)
4-$CH_3OC_6H_4$ (**a**)	42	16
4-$CH_3C_6H_4$ (**b**)	30	19
Ph (**c**)	54	4

The amount of the *trans*-adduct increases as the electron-donating properties of the aryl substituent in the substrate are weakened and the reaction of compound **95d** (Ar = 4-ClC_6H_4) proceeds mainly in accordance with the *trans*-mechanism with formation of two regioisomeric methyl esters of *cis*-2-chloromercurio-*trans*-3-methoxy-3-(4-chlorophenyl)-2-phenyl- and *cis*-2-chloromercurio-*trans*-3-methoxy-2-(4-chlorophenyl)-3-phenylcyclopropanecarboxylic acids (**96**:**97** = 33:67, overall yield 40%).[90]



95d

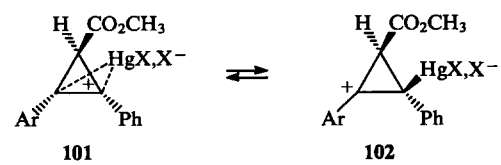
96 **97**



Ar = 4-ClC_6H_4.

The replacement of methanol by acetic acid makes the process *cis*-stereoselective[95-98] with formation of the adducts **98** and the solvatoadducts **99**.

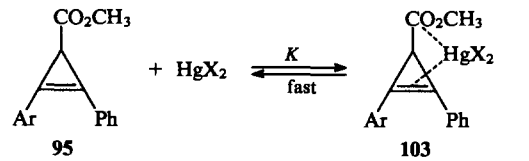
Ar	Yield of **98** (%)	Yield of **99** (%)
4-$CH_3C_6H_4$ (**a**)	50	–
Ph (**b**)	30	8



In the mercuration of compound **95d**, the change of solvent not only leads to the inversion of the stereochemistry of the process but also renders the reaction strictly regioselective with formation of methyl *cis*-2-chloromercurio-*cis*-3-trifluoroacetoxy-2-(4-chlorophenyl)-3-phenylcyclopropanecarboxylate **100**.[96]

100, 26%

As can be seen from the data presented above, in the mercuration of the esters of cyclopropene-2-carboxylic acids the carboxylate group exhibits a pronounced directing effect, as a consequence of which the substituent and the chloromercurio-group are in the *syn*-positions. The manifestation of the directing effect by functional groups in the mercuration of other unsaturated systems has been discussed.[99-102] Examination of the nature of the influence of the substituent on the course of solvatomercuration led to the conclusion that one of the causes of this phenomenon may be conformational effects.[102] Since these effects are absent for cyclopropene derivatives, the *syn*-regioselectivity indicates the interaction of the functional group and the mercury atom of the reagent.[103]



It is believed[96] that the reaction of the cyclopropene derivatives **95** with mercury trifluoroacetate in methanol leads to the formation of the mercurinium intermediate **101** (the *trans*-adduct), which is in equilibrium with the intermediate open-chain structure **102** (the *cis*-adduct).

In acetic acid, the reaction proceeds via a different mechanism. In this case, the close ion pair **102** is apparently formed as an intermediate species, which is converted into the reaction products as a result of the *cis*-addition of counterions from the solvent. The regioselectivity of the addition of the solvent to the ester **95d** is an argument in support of this hypothesis. Another no less important fact confirming the above hypothesis is that the solvatomercuration products **99** are formed as a result of the *cis*-addition of acetic acid from the sterically hindered side, i.e. the side from which the reagent attacks the double bond. This result is feasible if the solvent molecule completing the reaction is part of the solvation shell while the cation of the intermediate has an open-chain structure.

It was noted above that the regioselectivity of the mercuration of cyclopropenecarboxylic acid esters indicates the manifestation of the 'reagent–substrate' coordination. The occurrence of coordination of this type is indicated by the results of kinetic studies on the reactions of esters of cyclopropene-2-carboxylic acid **95** with mercury trifluoroacetate in methanol and acetic acid.[96]

The reaction in methanol is described by the kinetic scheme including the stage involving the formation of the pre-reaction complex **103**.

;

103 $\xrightarrow[k_1,\ \text{slow}]{CH_3OH}$ reaction products .

Under the conditions of a large excess of the mercury salt, the observed second-order rate constant depends on the initial reagent concentration $[HgX_2]_0$ in conformity with Eqn. (1), which made it possible to determine the equilibrium constant K from kinetic data.

$$\frac{1}{k_{II}} = \frac{1}{k_1}\left(\frac{1}{K} + [HgX_2]_0\right), \qquad (1)$$

where k_{II} is the observed second-order rate constant.

The equilibrium constant increases with enhancement of the electron-donating properties of the aryl substituent, which shows that not only the functional groups but also the cyclopropene double bond participates in the complex formation reaction.

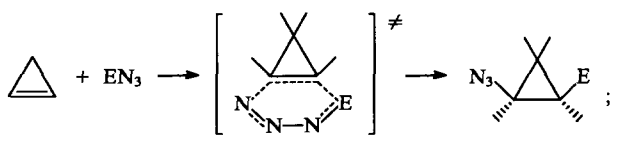
The reaction in acetic acid proceeds in a more complex manner, but in this case too the kinetic data lead to the conclusion that there is a coordination interaction between the ester group and the reagent. The kinetic data are described by the equation

$$\frac{1}{k_{II}} = \frac{1}{k_1} + \frac{1}{k_1 K [HgX_2]_0}, \qquad (2)$$

which corresponds to the scheme

95 + HgX_2 $\underset{\text{fast}}{\overset{K}{\rightleftharpoons}}$ **103** ;

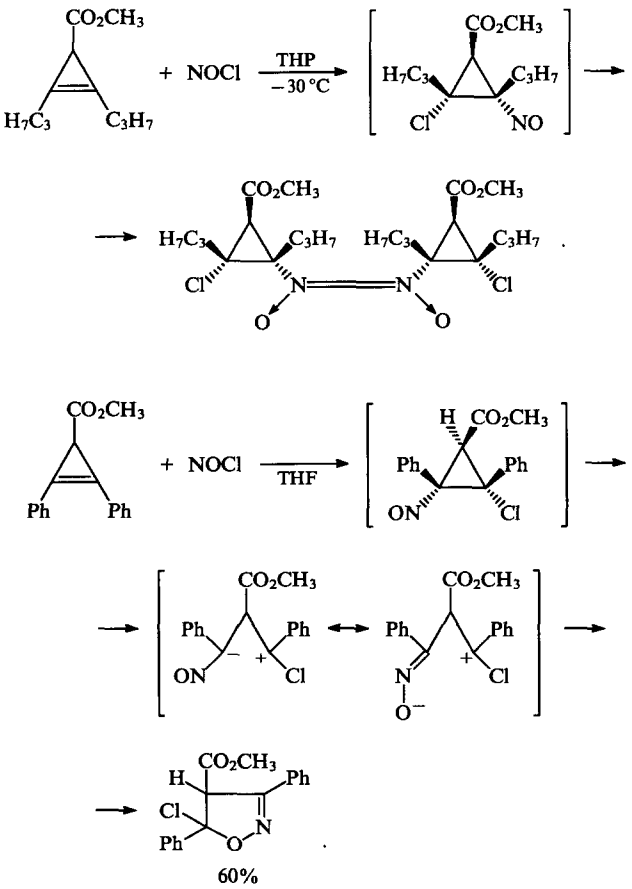
103 + HgX_2 $\xrightarrow[\text{slow}]{k_1}$ reaction product .



III. Mechanisms of the interaction of cyclopropene derivatives with electrophiles

It follows from the data presented that the main pathway in the reactions of cyclopropenes with electrophiles is the competitive formation of products with both retention of the ring and with its opening. The same data have shown that development of the competing pathways is influenced significantly by the substrate structure factors. Cyclopropenes with electron-donating substituents at the double bond tend more to form products with ring opening.[50-55] Conversely, electron-accepting substituents favour the formation of the products of addition to the double bond.[56,57]

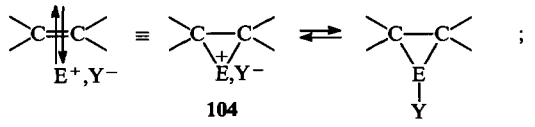
Together with substrate structure factors, the nature of the electrophiles plays a major role in the development of the competing pathways. In terms of the increasing amount of acyclic products formed in the reaction, the reagents can be arranged in the sequence



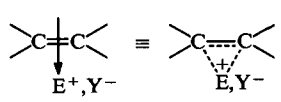
$$RS^+, I^- < SCN^+ < Br^+ \approx Cl^+ \ll H^+.$$

The view exists that the products of the addition to the double bond in cyclopropenes are formed in certain reactions via a concerted mechanism.[35,53] Indeed, a concerted mechanism is apparently most preferred for a series of reagents. Thus *cis*-adducts are probably formed via this mechanism in the reactions of cyclopropenes with hydrazoic acid[35] and mercury azide.[35,91] It may be that the high nucleophilicity of the azide group is in this case the decisive factor which determines the reaction pathway.

E = H, HgN_3 .



The interaction of the esters of cyclopropene-2-carboxylic acids with nitrosyl chloride, which results in the formation of either dimerisation or ring-opening products, is considered from these standpoints.[104,105]



60%

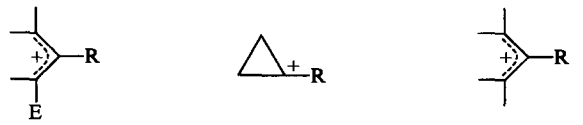
It follows from stereochemical,[52,57,74-78] kinetic,[69,106] and other studies[29,52,69] that a stepwise mechanism operates for the remaining reagents of the series quoted above. As in the reactions with unstrained systems,[61,81,107] the structure of the intermediate species depends on the nature of the reagent. For reagents with a considerable tendency towards the reverse coordination, the formation of cyclic intermediates is most likely. According to Dewar's views,[109] the reverse coordination takes place as a result of the interaction of the occupied *p* or σ orbital of the electrophilic atom with the unoccupied antibonding π MO of the alkene. If the electronegativity of the electrophilic atom is comparable with that of the carbon atom, then the energies of the AO and MO are comparable and the interaction is strong. The linkage between the electrophilic atom E and the carbon atoms of the double bond is produced as a result of the formation of two usual two-electron bonds, while the intermediate has the structure of the onium species **104**.

For a highly electronegative electrophilic atom, the energy of the occupied AO is appreciably lower than that of the antibonding π MO and the reverse coordination is insignificant. For such electrophiles, the cyclic intermediate constitutes in essence the 'classical' Dewar π-complex **105** with a three-centre two-electron bond.[108,109]

104

105

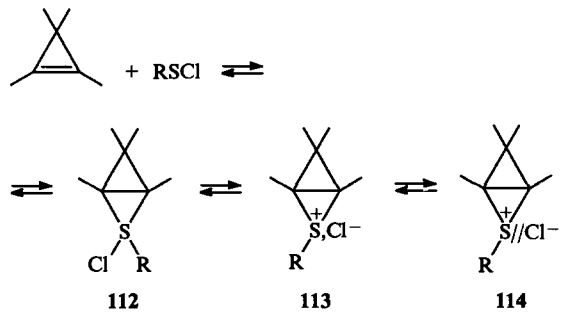
Within the framework of this concept of the dependence of the reaction mechanism on the electronegativity of the electrophilic atom of the reagent, there should exist a continuum of cyclic species with different degrees of reverse coordination, the intermediates **104** and **105** being the extreme members of this series.



The stability of the cyclic species **104** and **105** and the reactions leading to their conversion into the final products are greatly influenced by the nature of the interaction of the electrophilic centre E^+ with the counterion Y^-. This problem has been recently investigated both experimentally and theoretically. The main results of these studies may be found in Refs 108–111.

Although the orbital structure of the cyclopropenes is more complex than that of the usual alkenes,[1,2,24-26,112] nevertheless they have an antibonding orbital similar to the π MO of the unstrained alkenes.[8] For this reason, the approach developed by Dewar is apparently valid also for the electrophilic reactions of cyclopropenes. In this case, the structures of the cyclic intermediates can be represented as **106** and **107**.

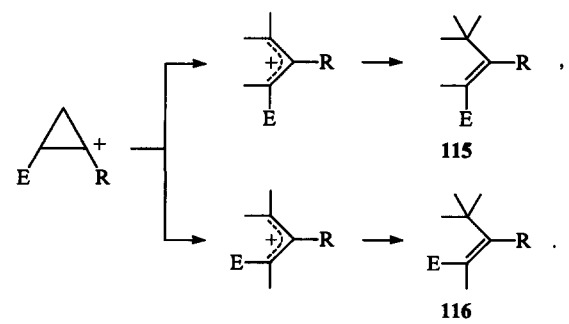
Considerations indicating that the reactions of cyclopropenes, especially with reagents having an electrophilic hydrogen atom, can proceed with participation of cyclopropyl ions **108** and the corresponding allyl ions **109** have been frequently proposed in the literature. Taking this into account, one may assume that in a multi-stage reaction of cyclopropene systems with electrophiles, the formation of the species **106**–**109** is most probable.[3,32,34,54,55]



106 **107** **108**

109 **110** **111**

As mentioned above, a high *trans*-stereoselectivity of the addition to the double bond in cyclopropenes is character-istic of sulfenyl halides. Stereochemical as well as kinetic data[52,69,74,77,106] provide grounds for the assumption that, as in the sulfenyl halogenation of unstrained alkenes, this reaction results in the formation of either cyclic intermediates having the sulfurane structure **112** or the ion pairs **113** and **114** with the episulfonium cation.

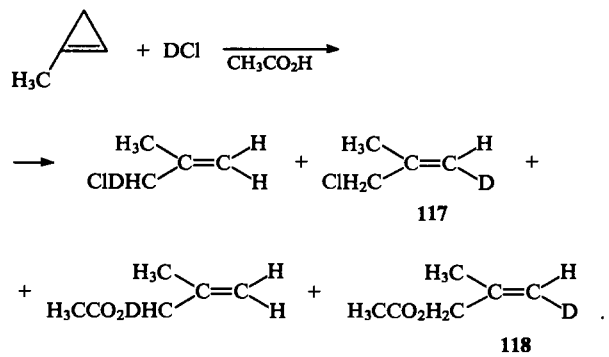


112 **113** **114**

In the reactions of cyclopropene derivatives with benzenesulfenyl chloride, only adducts are formed.[29,74-76] In contrast to this, in the interaction of 1-methylcyclopropene with 2,4-dinitrobenzenesulfenyl halides, the pathway leading to the formation of acyclic products may become the main one.[69] The electronegativity of the sulfur atom in 2,4-dinitrobenzenesulfenyl chloride is enhanced whilst the reverse coordination is diminished. This increases the electron deficiency on the carbon atoms of the three-membered skeleton in the intermediate **114**, which is in fact the reason for the occurrence of the reaction pathway involving the formation of acyclic adducts.

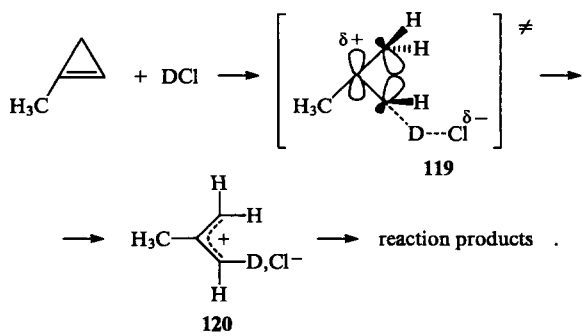
The sulfur atom in reagents containing the thiocyanato-group (thiocyanogen, thiocyanogen halides) is even more electronegative. For this reason, one may assume that the intermediates formed in the substitution of the thiocyanato-group into cyclopropenes have the character of π-complexes to an even greater extent and the reaction pathway involving the opening of the three-membered carbon ring becomes one of the main ones. An intermediate of type **107**, having a similar structure, is probably formed in the reactions of cyclopropenes with the halogens (Cl_2, Br_2) and their electrophilic analogues (*tert*-butyl hypochlorite, *N*-bromosuccinimide, etc.) in protic solvents.[52]

Quantum-chemical calculations have shown[113,114] that the total energy of the 1-R-cyclopropyl cations **110** is appreciably higher than the energy of the 2-R-allyl cations **111**. The relatively unstable high-energy intermediates are as a rule converted into the products or other intermediates with an insignificant activation energy. Consequently, if the formation of the ion **108** is possible in the electrophilic reactions of cyclopropenes, one should expect its conversion into the allyl cation **109** and further into acyclic products. There is also a possibility of another reaction pathway where the allyl cation **109** is obtained directly by electrophilic attack on the double bond of the cyclopropene,[3,52] by-passing the stage involving the formation of the cation **108**. However, if the substituents at the double bond are strong electron donors, the reaction can include only the stage involving the formation of a β-substituted cyclopropyl cation, which is subsequently converted into cyclic adducts. The most convincing data concerning the possibility of such a mechanism have been obtained in the reactions of esters of cyclopropene-2-carboxylic acids with mercury trifluoroacetate in acetic acid,[96,98] which were considered above.



The stereochemistry of the opening of the cyclopropene ring is very important for the elucidation of the mechanism of the electrophilic reactions of cyclopropenes. In particular, it makes it possible to establish, in principle, whether the reaction proceeds via the stage involving the formation of the cyclopropyl cation **108**, which subsequently isomerises to the allyl cation **109**, or whether the latter is formed directly on electrophilic attack on the double bond of the cyclopropene. The Woodward–Hoffmann rules[115] and quantum-chemical calculations[116-119] predict a disrotatory reaction pathway **108**→**109**. There are two such procedures; if the electrophilic group E cannot make a decisive contribution to the stereochemistry of the ring opening for steric reasons, the isomeric products **115** and **116** will result. The formation reaction of the acyclic products is on the whole nonstereoselective.

115 **116**



Stereoselective ring opening implies that the cyclopropyl cation of type **108** is not formed in the reaction.

It has been established[52] that the interaction of 1-methylcyclopropene with deuterium chloride entails the stereoselective opening of the cyclopropene ring and that the products of the reaction of 1-deuterio-3-chloro-2-methyl-1-propene **117** and 1-deuterio-3-acetoxy-2-methyl-1-propene **118** have the (*Z*)-configuration.

117 **118**

Within the limits of experimental error, a uniform distribution of the deuterium label is observed. This means that the reaction products are formed from the allylic intermediate **120**. The observed stereochemical result indicates a single-stage synchronous pathway leading to its formation. As the C–D bond is formed and a deficiency of electron density arises on the β-carbon atom disrotatory ring opening takes place in the transition state **119** in conformity with the stereoelectronic requirements, similarly to the behaviour manifested in the reactions involving the solvolysis of cyclopropane derivatives.[120]

119 **120**

The stereoselective formation of the product having the (*Z*)-configuration has also been observed in the isomerisation of 1,2,3-triphenylcyclopropene on treatment with trifluoroacetic acid.[34]

The reactions of 1-methylcyclopropene with 2,4-dinitrobenzenesulfenyl chloride, thiocyanogen, thiocyanogen chloride, and *tert*-butyl hypochlorite in acetic acid are likewise stereoselective, but the ring opening products have the (*E*)-configuration.[52] These data show that an intermediate with a fundamentally different structure is formed in the latter reactions. As mentioned above, it most probably has a cyclic structure.

One may conclude from the data presented that the (*Z*)-stereoselective ring opening is evidence for a single-stage formation of an allylic intermediate. If the reaction is (*E*)-stereoselective, the intermediate has a cyclic structure. More intensive stereochemical studies and theoretical calculations should show the extent to which this postulate is general and rigorous.

Abstract. The influence of catalytic amounts of organic compounds of Group III – V elements on the initiation stage and chain propagation in the (co)polymerisation of vinyl and certain other monomers is discussed. The question concerning the formation of complexes by the monomers and growth radicals with organoelement additives are examined. Examples of the practical application of the coordination-radical (co)polymerisation with participation of organic compounds of Group III – V elements, including peroxides, in the synthesis of high-molecular-mass substances, including the copolymers of vinyl monomers and olefins as well as alternating copolymers based on acrylates, are presented. The bibliography includes 105 references.

I. Introduction

The use of modifying additives, which alter the reactivity of monomers and macroradicals as well as the kinetic parameters of the process, and of novel initiators, ensuring the effective generation of radicals under energetically favourable conditions and the regulation of chain propagation and termination, leads to promising ways of solving the problem of the synthesis of polymers with specified properties. The first procedure (using protic and aprotic acids as additives) has already led to the creation of a new aspect of polymer chemistry — the complex-radical polymerisation.[1-3] The effectiveness of the second procedure depends on the use, together with azo-compounds and peroxides, of radical initiators based on organoelement compounds (OEC), subdivided into oxygen-reduction systems based on organic derivatives of non-transition metals and oxidants (oxygen, peroxide) and Ziegler-Natta catalysts.[4-7] The latter are used predominantly for the synthesis of the (co)polymers of olefins and dienes and are used for the polymerisation of vinyl monomers to a limited extent.

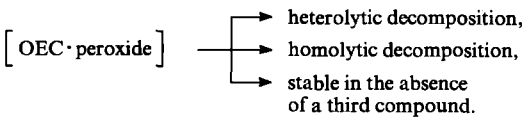
II. Characteristics of radical formation in organoelement compound – peroxide systems

The oxidation – reduction systems based on OEC and oxygen as well as OEC and hydroperoxides have been investigated in fair detail.[4, 5, 7-9]

The study of the products of the reactions of OEC with organic and then organoelement peroxides was begun as early as the 1960s. Such studies have been performed by a number of schools of organic chemists, including the school directed by Academician G A Razuvaev (see, for example, Refs 10 and 11).



As a result of the vigorous application of physicochemical methods to the study of the above reactions, the use of kinetic approaches, and allowance for the influence of electron-donating and electron-accepting additives on the radical generation stage, a series of new data have appeared in recent years concerning the application of the systems in (co)polymerisation processes, which permitted certain generalisations.

It has now been reliably established that one of the initial stages in the interaction of organometallic compounds with peroxides is the formation of a complex of the donor – acceptor type:[12-14]

$$R_nM + R'OOR'' \rightleftharpoons \left[R_nM \cdot R'OOR''\right]. \qquad (1)$$

The majority of organoelement peroxides (OEP) of Group IV and V metals are fairly stable compounds, the thermal stability of which is likewise high and which undergo homolytic or heterolytic decomposition only at temperatures not below 80 – 100 °C.[5] As a result of the formation of the peroxide – OEC complex, the electron density in the peroxide molecule is redistributed, which leads to the loosening of the oxygen – oxygen bond and appreciably facilitates thereby its dissociation.

The OEC – peroxide complex can decompose both heterolytically with formation of ethers and homolytically with generation of radicals, or can dissociate reversibly into the initial components.

The complex formation constants in the OEC–peroxide system have been estimated in a series of studies[14–16] in relation to organoboron compounds (Table 1). Donor–acceptor complexes involving boron compounds have been investigated in greatest detail. The is because trialkylboranes are fairly convenient in practical use, are synthesised under industrial conditions, and are most promising as radical polymerisation coinitiators.

Table 1. The complex formation constants (litre mol^{-1}) in the OEC–peroxide system (T = 293 K).

OEC	Bu^tOOBu^t	$(C_6H_5)_3SiOOBu^t$	$(CH_3)_3SiOOBu^t$
$Bu^n_2BC_6H_5$	–	–	0.33
Bu^i_3B	–	–	0.64
Bu^n_3B	0.37	0.46	1.16
Bu^n_2BOBu	–	–	1.42
Bu^n_2BCl	–	–	2.78

The stability of the OEC–peroxide complex as well as the mode of its decomposition are determined by the structure of the peroxide and the OEC as well as the nature of the metal atom. Thus, whereas the complexes of organoboron compounds with *tert*-butyl peroxide (TBP) and its organosilicon and organogermanium analogues (*tert*-butylperoxytrimethylsilicon, *tert*-butylperoxytriethylgermanium) are stable in the temperature range up to 300 K and decompose reversibly to the initial components, the complexes involving *tert*-butylperoxytriethyltin, *tert*-butylperoxytetraphenylantimony, and di-*tert*-butylperoxytriphenylantimony undergo spontaneous homolytic decomposition at room temperature with formation of alkyl and alkoxyl radicals.[16]

$$R_3B + Bu^tOOER'_n \longrightarrow \left[R_3B \cdot Bu^tOOER'_n\right] \longrightarrow \begin{cases} \longrightarrow R^\cdot + R_2BOBu^t + {}^\cdot OER'_n , \\ \longrightarrow R^\cdot + R_2BOER'_n + Bu^tO^\cdot ; \end{cases} \quad (2)$$

E = Sn, Sb; n = 3, 4 .

The complexes of OEP with organic derivatives of aluminium, gallium, indium, and thallium undergo similar reactions. However, in this case there is both homolytic and heterolytic decomposition of the complexes.[17, 18]

$$\left[R_3Al \cdot R'OOR'\right] \begin{cases} \longrightarrow R_2AlOR' + R^\cdot + {}^\cdot OR' , \\ \longrightarrow R_2AlOR' + ROR' . \end{cases} \quad (3)$$

It has been shown in relation to the ethyl, butyl, and isobutyl derivatives of these metals with the aid of EPR[17, 18] and by analysing the reaction products that the ratio of the components in the complex is 1 : 1.

The methyl derivatives of Group III elements react with acyl peroxides, affording 1 : 2 complexes. The complex decomposes homolytically and the oxygen-centred radicals do not emerge into the solution under these conditions.

$$(CH_3)_3E + (C_6H_5COO)_2 \longrightarrow \left[\begin{array}{l} E(CH_3)_3 \\ \vdots \\ O \\ \| \\ C_6H_5C-O-O-CC_6H_5 \\ \| \\ O \\ \vdots \\ E(CH_3)_3 \end{array}\right] \longrightarrow 2C_6H_5COOE(CH_3)_2 + 2CH_3^\cdot . \quad (4)$$

The existence of the homolytic and heterolytic pathways in the decomposition of the OEC–peroxide complex makes it possible to postulate a one-electron transfer between the components of the complex as one of the probable stages of the process.

$$R_nE + R'OOR' \rightleftharpoons \left[R_nE \cdot R'OOR'\right], \quad (5)$$

$$\left[R_nE \overset{e}{\cdots} R'OOR'\right] \longleftrightarrow \left[R_nE^{\cdot+} \cdots {}^{\cdot-}R'OOR'\right], \quad (6)$$

$$\left[R_nE^{\cdot+} \cdots {}^{\cdot-}R'OOR'\right] \longrightarrow \left[\begin{array}{ll} R^\cdot & {}^+ER_{n-1} \\ R'O^\cdot & {}^-OR' \end{array}\right] \longrightarrow \begin{cases} \longrightarrow ROR' + R'OER_{n-1} \\ \longrightarrow R^\cdot + R'O^\cdot + R'OER_{n-1} . \end{cases} \quad (7)$$

The hypothesis of the one-electron transfer in the reactions of the OEC of nontransition elements with peroxides has been put forward in a number of studies[4, 19, 20] and has been demonstrated unambiguously by the EPR method in relation to organic compounds of iron and chromium and the peroxides of Group IV elements.[21]

$$Cr(C_6H_5C_2H_5)_2 + R'OOR' \longrightarrow \left[(C_6H_5C_2H_5)_2Cr^{\cdot+} \cdots {}^{\cdot-}R'OOR'\right] . \quad (8)$$

The complex formed decomposes via a radical mechanism and the alkoxyl radicals, obtained in the reaction, are not released into the surrounding volume but remain coordinated to the metal atom. This is followed by the abstraction of a hydrogen atom from the alkyl fragment of the OEC.

$$\left[(C_6H_5C_2H_5)_2Cr^{\cdot+} \cdots {}^{\cdot-}R'OOR'\right] \xrightarrow{-R'OH} \left[C_2H_5C_6H_5CrC_6H_5\dot{C}HCH_3\right]^+O\bar{R}' \longrightarrow Cr(OR')_4 + C_6H_5CH_2CH_3 + C_6H_5\dot{C}HCH_3 . \quad (9)$$

Organometallic compounds of Group V also react with OEP via a radical mechanism but without the liberation of alkoxyl radicals into the surrounding volume.[22]

$$R_3Bi + Bu^tOOER'_3 \longrightarrow \left[R_3Bi \cdot (Bu^tO)OER'_3\right] \longrightarrow 2R^\cdot + RBi(OBu^t)OER'_3 . \quad (10)$$

Oxygen-containing radicals remain in the coordination sphere of the metal atom. For example, evidence for the existence of radicals in the coordination sphere of the bismuth atom has been obtained in an EPR study of the interaction of triphenylbismuth with alcohols and alkoxides.[23]

A free-radical mechanism has been proposed for the interaction of TBP and acyl peroxides with organomercury and organotin compounds. It is believed[24] that the donor–acceptor complexes of the above OEC with peroxides are convenient sources of free radicals and that the addition of organomercury and organotin compounds greatly increases the initiating capacity of the organic peroxides.

Radicals (alkyl and alkoxyl) are formed in the reactions of virtually all the alkyl derivatives of Group II, III, and V elements with peroxides. Despite this, it is organoboron and organoaluminium compounds[12, 25] as well as alkyl derivatives of bismuth,[22] tin, and mercury[24] that have found the greatest application as initiators.

Initiating systems based on organoboron compounds occupy a special position. They make it possible to polymerise vinyl chloride and acrylates with a conversion close to 100% over a wide temperature range and to obtain polymers with effective physicochemical properties. Compositions based on trialkylboranes and peroxides are capable of glueing together Teflon, polyethylene, and a number of other 'nongluable' thermoplastic materials without a preliminary treatment of the surface.[10, 11, 25]

As stated above,[14, 15, 18] the complexes of trialkylboranes with TBP and its organosilicon and organogermanium analogues are stable at room temperature and dissociate reversibly into the initial components. The complexes decompose into radicals in the presence of a third compound — an electron-accepting additive, for example the polar vinyl monomer.[6, 26]

$$\left[R_3B\cdot(CH_3)_3SiOOBu^t\right] + M \longrightarrow \begin{cases} \longrightarrow R-M^{\cdot} + (CH_3)_3SiO^{\cdot} + R_2BOBu^t, \\ \longrightarrow R-M^{\cdot} + Bu^tO^{\cdot} + R_2BOSi(CH_3)_3; \end{cases} \quad (11)$$

(M = monomer).

Thus the monomer is directly involved in the radical generation stage.

The structure of the ternary OEC–OEP–monomer complex has not been established experimentally. It has been demonstrated by IR[27] and ^{1}H NMR[28] spectroscopy and by calorimetry[29] that the unsaturated compound may be coordinated both to the element in the peroxide and to the oxygen bridge.

$$R_nEOOR' + CH_2{=}CH{-}X \longrightarrow \begin{cases} \left[\begin{array}{c} CH_2{=}CH{-}X \\ \vdots \\ R_nEOOR' \end{array}\right], \\ \left[\begin{array}{c} CH_2{=}CH{-}X \\ \vdots \\ R_nE{-}O{-}OR' \end{array}\right]. \end{cases} \quad (12)$$

Like organoaluminium compounds,[30] trialkylborane can be bound to the monomer also via an unoccupied *p* orbital.

$$R_3B + CH_2{=}CH{-}X \rightleftharpoons \left[R_3B\cdots\begin{array}{c} CH_2 \\ \| \\ CH{-}X \end{array}\right]. \quad (13)$$

Ternary systems involving organoaluminium compounds have been investigated in detail by Milovskaya and coworkers.[12] According to Milovskaya,[12] an OEC–monomer complex is formed initially in the trialkylaluminium–peroxide–monomer complex and then reacts with the peroxide, affording radicals.

$$R_3Al + M \rightleftharpoons \left[R_3Al\cdot M\right], \quad (14)$$

$$\left[R_3Al\cdot M\right] + R'OOR' \rightleftharpoons \left[R_3Al\cdot M\cdot R'OOR'\right], \quad (15)$$

$$\left[R_3Al\cdot M\cdot R'OOR'\right] \longrightarrow R_2AlOR' + R^{\cdot} + R'OM^{\cdot}. \quad (16)$$

Aleksandrov and coworkers[31] put forward a general mechanism taking into account virtually all the principal coordination interactions in the three-component system:

$$MMA + A \rightleftharpoons \left[MMA\cdots A\right], \quad (17)$$

$$MMA + P \rightleftharpoons \left[MMA\cdots P\right], \quad (18)$$

$$P + A \rightleftharpoons \left[P\cdots A\right], \quad (19)$$

$$\left[MMA\cdots A\right] + P \rightleftharpoons \left[MMA\cdots A\cdots P\right], \quad (20)$$

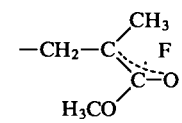
$$MMA + \left[P\cdots A\right] \rightleftharpoons \left[MMA\cdots P\cdots A\right], \quad (21)$$

$$\left[P\cdots MMA\right] + A \rightleftharpoons \left[P\cdots MMA\cdots A\right], \quad (22)$$

where MMA = methyl methacrylate, P = peroxide, and A = Lewis acid.

The mechanism of the generation of radicals in such systems has not been established, but one can postulate that the monomer is capable of combining with the components of the complex [the organometallic compound (OMC) and the OEP]. Such interaction alters the reactivity of the monomers, which is characteristic of the so called complex-radical polymerisation.[3] The study of the characteristics of the (co)polymerisation of vinyl monomers and olefins has confirmed the above hypothesis.

III. Accelerating influence of organoelement compounds on the homo- and copolymerisation of vinyl monomers



As stated above, organoelement initiating systems based on the OEC of Group III elements and OEP have a number of advantages compared with the traditional radical initiators,[10, 11, 25] in particular they are more effective than azo-compounds and percarbonates and make it possible to obtain a large amount of the polymer per unit time.[25, 32, 33]

The rapid chain propagation and certain features of the physicochemical properties suggest that the components of the organoelement initiator participate not only in the radical generation stage but also in the chain propagation and termination processes. As mentioned above, unsaturated compounds, including monomers, are capable of coordinating to the OEC of non-transition elements and OEP [Eqns (12) and (13)]. In these complexes, the monomers function as electron donors. On the one hand, such complex formation facilitates the decomposition of the peroxide into radicals and hence increases the rate of initiation[27] and, on the other, it promotes a redistribution of electron density to the π-bonds of the monomer and thereby alters its reactivity.

Complexes of vinyl monomers with Lewis acids (metal halides) have long been known and have been studied in detail by a number of investigators.[3] It has been established by IR[35–38] and NMR[39] spectroscopy that metal halides are coordinated to the carbonyl group of the monomer.[35] The constants for the complex formation reactions of organic compounds of Group III elements with MMA and acrylonitrile (AN) have been estimated in relation to organoaluminium compounds.[30]

Together with the formation of complexes with the monomers, organometallic compounds are capable of forming complexes with radicals,[40] including polymeric ones.[35]

It has been established by the EPR method that the components of the organoelement initiator trialkylborane(TAB)-di-*tert*-butylperoxytriphenylantimony (DPA), containing boron and antimony atoms with unoccupied *p* and *d* orbitals, are coordinated during the chain propagation process to the growing MMA macroradical.[41, 42]

F — fragment of the organoelement initiator

The formation of similar complexes of the macroradical with Group II and III metal halides as Lewis acids has been noted.[35]

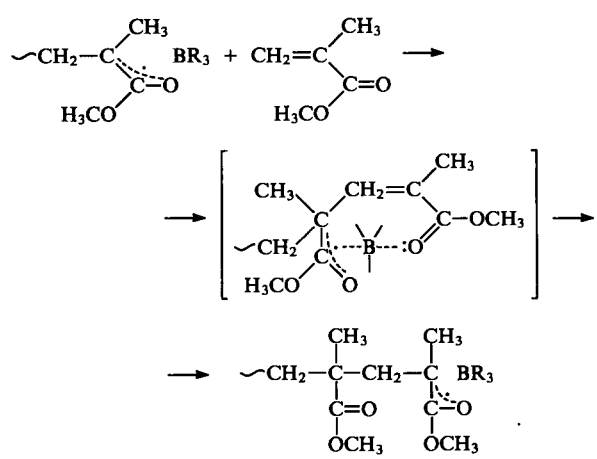
Such interaction enhances the electron-accepting properties (electrophilicity) of the growing macroradical and increases its reactivity relative to the double bond of the monomer. This increases the propagation rate constant. Thus the rate of polymerisation of MMA in the presence of typical radical initiators — dicyclohexyl peroxydicarbonate (DCC) and azoisobutyronitrile (AIBN) — increases significantly after the introduction of triisobutylborane in amounts comparable to the initiator concentration.[43] Boron alkyls have no catalytic effects on the decomposition of the above initiators.

Rate of polymerisation/ 10^4 mol litre^{-1} s^{-1}	0.74	1.08	1.48
Triisobutylborane concentration (mol.%)	0	0.2	0.4

The polymerisation of acrylonitrile in the presence of AIBN is also accelerated by trialkylboranes. The rate of the process increases synchronously with increase in the content of the OEC in the mixture. Similar data have been obtained in studies of the copolymerisation of MMA with styrene[44] and allyl chloride[45] in

the presence of organoelement initiators. Other OEC of Group III elements, in particular dibutylbutoxyborane and triethylaluminium, also have an accelerating effect on the polymerisation of MMA (Table 2). Being a stronger Lewis acid than trialkylboranes, dibutylbutoxyborane exhibits an increased coordinating capacity and has an appreciably greater influence on the rate of polymerisation.

Table 2. The influence of certain OEC of Group III elements and phenolic inhibitors (1 mol.%) on the rate of polymerisation of MMA ($10^3 v$/mol litre^{-1} s^{-1}).



OEC	Without inhibitor	Hydroquinone	Di(hydroxyphenyl)propane	Ionol	Benzoquinone
–	0.08	0.01	–	–	–
Bu^i_3B	0.22	0.40	0.24	0.17	0.04
Bu^i_2BOBu	0.43	–	0.50	0.15	0.02
$(C_2H_5)_3Al$	0.11	0.16	0.20	0.12	0.01

Note. In all cases, the initiator was AIBN (0.1 mol.%). T = 313 K.

Certain metal halides have a similar activating effect on chain propagation in the polymerisation of acrylic monomers.[3] Thus, according to the data of Bamford et al.,[46] the propagation rate constant in the polymerisation of acrylonitrile in the presence of lithium chloride increases by a factor of two, while the termination rate constant remains unaltered. The accelerating effect is due to the formation of complexes between lithium ions and the acrylonitrile growth radical. It was shown subsequently in a series of studies[47–56] that the activating effect of the coordinatively unsaturated metal salts on the polymerisation of acrylic monomers is a common phenomenon, which has been discussed in detail in a monograph.[3]

In contrast to metal halides (Lewis acids), organometallic additives have a catalytic effect on chain propagation when they are introduced into the system in amounts comparable to the initiator concentration (0.01–0.1 mol.% relative to the monomers). This fact definitely shows that the formation of a complex between the OEC and the macroradical and not the monomer is responsible for the increase in the rate of (co)polymerisation in the presence of the Lewis acid indicator, particularly since the complex between the electron acceptor and the growth radical is somewhat more stable than the analogous complex with the monomer.[35]

Taking into account the foregoing, one may postulate that the same OEC molecule, functioning as a complex forming agent, can participate in several consecutive chain propagation stages, permanently retaining the growing macroradical in its coordination sphere. Chain propagation then occurs in a six-membered reaction complex, which includes the growing macroradical, the monomer, and the complex forming agent.

(23)

By retaining in its coordination sphere the growing macroradical, the atom of the element orients the monomer molecule and creates conditions for chain propagation which are most favourable from the energetic and steric standpoints.

A similar mechanism, except for the fact that it incorporates an eight-membered reaction complex, has been proposed by Kabanov[57] to explain the increase in the chain propagation rate constant in the polymerisation of MMA in the presence of metal halides and also by Semchikov and coworkers[58, 59] in studies of the copolymerisation of acrylic acid with vinyl acetate in the presence of germanium salts. However, the six-membered complex presented above, which includes a delocalised allylic macroradical, is thermodynamically most stable.[60]

The concept of the cyclic transition state has been frequently used in coordination chemistry to account for the characteristics of the chain propagation.[61] Precisely this analogy probably enabled Kabanov et al.[3] to introduce the term 'coordination-radical polymerisation' for polymer formation processes occurring in the presence of metal compounds as electron acceptors. However, the term 'complex-radical polymerisation' is used more frequently to describe the above reactions in both Russian and foreign literature. However, when organoelement compounds are used as chain propagation regulators the term 'coordination-radical polymerisation' appears more apt, since, firstly, it emphasises the interrelation and common features of the mechanisms in coordination and radical polymerisation with participation of OEC and, secondly, the coordination interaction between the monomer and the OEC and between the macroradical and the OEC is fairly weak, as stated above, and the formation of stable complexes should not be considered.

IV. Specific effects of hydroquinone, benzoquinone, and other phenolic inhibitors on the (co)polymerisation of acrylates in the presence of organoelement compounds

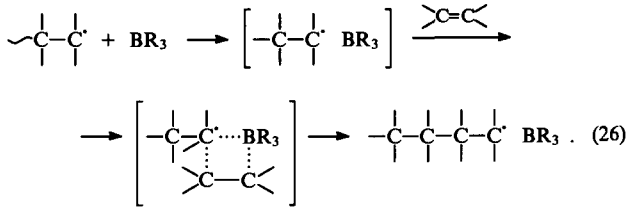
Hydroquinone, ionol, and certain other phenols are familiar inhibitors of the radical polymerisation of vinyl monomers and are used traditionally as stabilisers. The effectiveness of the inhibition increases significantly in the presence of oxygen, which, according to Dolgoplosk and Tinyakova,[62] is associated with the oxidation of phenols to quinones, which exert a stronger retarding effect on chain propagation.

According to the most common point of view,[62, 63] the inhibiting effect of hydroquinone is based on the ready abstraction by the radical of the mobile hydrogen atom from the phenol molecule with formation of a phenoxyl radical.

$$R^{\cdot} + ArOH \longrightarrow RH + ArO^{\cdot} . \qquad (24)$$

As a consequence of its low reactivity relative to the multiple bond in the monomer, the phenoxyl radical cannot initiate the radical process (polymerisation).

As early as the 1960s, it was noted[64–67] that the addition of certain OEC of Group III elements makes it possible to carry out the polymerisation of MMA with a high conversion in the presence of benzoyl peroxide (BP) or AIBN despite the presence of comparable amounts of hydroquinone.



In the presence of OEC, the phenoxyl radicals probably enter into a S_N2 substitution reaction at a high rate.[68]

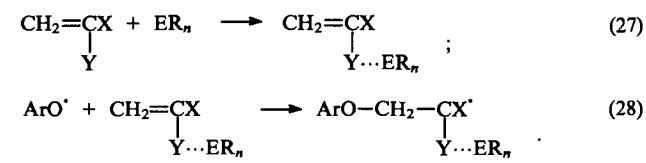
$$ArO^{\cdot} + R_3E \longrightarrow R^{\cdot} + ArOER_2 . \qquad (25)$$

The alkyl radicals formed in this reaction can again initiate the polymerisation. This means that organoboron compounds can function as chain transfer agents in the polymerisation of acrylates. The chain transfer rate constant in the polymerisation of MMA initiated by peroxides is 1.5×10^{-2} for tri-n-butylborane and 1.0×10^{-2} for triisobutylborane.[69]

A somewhat different point of view on the causes of the lack of the inhibiting effect of phenols in polymerisation in the

presence of organometallic compounds has been expressed by Arimoto,[65] who suggested that the OEC is coordinated to the growing macroradical via the unpaired electron of the latter.

(26)



This results in the blocking of the reaction centre of the radical and its interaction with the phenol becomes impossible. It is essential to note that the experimental results obtained by Arimoto have been questioned.[64]

It has been shown in a number of studies published in the 1990s[43, 70–72] that hydroquinone and di(hydroxyphenyl)propane not only do not inhibit the radical polymerisation of acrylates but actually accelerate it (Table 3). Thus the rate of polymerisation of MMA and acrylonitrile increases significantly in the presence of the OEC of Group III elements and increases synchronously with increase in the content of the OEC and of the inhibitor. Such an unusual accelerating effect is associated with reactions involving chain transfer to the OEC [Eqn (25)]. However, the absence of the inhibiting effect in the polymerisation of MMA, acrylonitrile, and methyl acrylate in the presence of large amounts (an order of magnitude higher than the initiator concentration) of hydroquinone and di(hydroxyphenyl)propane as well as a significant weakening of the inhibiting effect when Lewis acids (metal halides) are introduced into the polymerising system cannot be accounted for solely by this factor.[73–75] Such nontraditional behaviour of phenols can be caused by the coordination-radical nature of the (co)polymerisation of acrylic monomers in the presence of organoelement initiators. In the presence of Lewis acids as electron acceptors, the macroradical and the monomer are coordinated (see above) to the components of the initiator. The formation of a complex between the OEC and the monomer activates the latter, as a result of which the initiation of the polymerisation by phenoxyl radicals becomes possible.

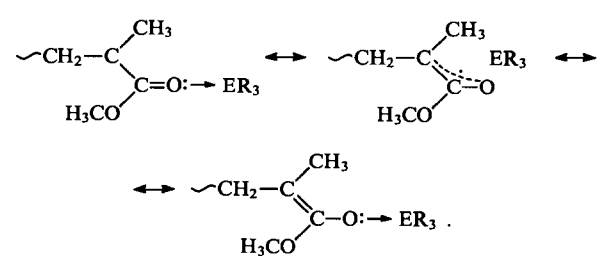
Table 3. The influence of hydroquinone, di(hydroxyphenyl)propane, and ionol on the rate of polymerisation of acrylic monomers.

Monomer	Inhibitor concentration (%)	Rate of polymerisation ($10^3 v$/ mol litre^{-1} s^{-1}) in the presence of different inhibitors		
		hydro-quinone	di(hydroxy-phenyl)propane	ionol
MMA	0	1.20	1.20	1.20
	0.5	1.40	1.31	0.78
	1.0	1.67	1.40	0.63
	5.0	–	1.59	0.28
AN	0	4.50	–	4.50
	0.5	6.10	–	1.31
	1.0	7.70	–	0.51
VA*	0	9.10	9.10	9.10
	0.1	4.30	–	–
	0.5	–	2.50	0.17
	1.0	0.05	0.75	0.04
	5.0	–	0.38	–

Note. In all cases, the initiator was triisobutylborane–di-*tert*-butylperoxytriphenylantimony (the content of triisobutylborane was 0.4 mol.%). T = 293 K.
* VA = vinyl acetate.

(27)

(28)



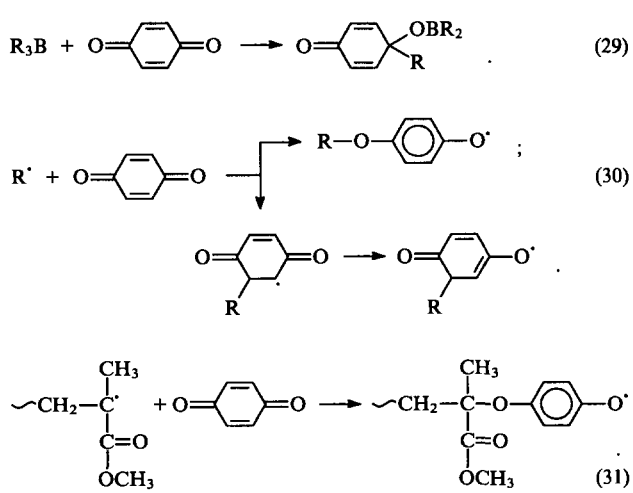
The hypothesis of the activation of the monomer by the complex-forming agent has been confirmed by the data of Bamford et al.,[53] who demonstrated a threefold increase (compared with the monomer) in the reactivity of the complex of MMA with zinc dichloride in the chain propagation stage. This permits the hypothesis that phenoxyl radicals can initiate the polymerisation of the monomer bound in a complex.

The occurrence of reaction (28) has been confirmed also by the detection of phenoxy-groups in poly(methyl methacrylate) by UV[70] and IR[72] spectroscopy. An indirect confirmation of the validity of the proposed approach to the consideration of the kinetic features of the polymerisation of acrylates in the presence of OEC and inhibitors is provided by the absence or weakening of the inhibiting effect in the polymerisation of MMA with added Group III metal halides. In this case, the occurrence of the S_R2 substitution reaction [Eqn (25)] is in principle impossible and an explanation of the observed effect can be found either in terms of Arimoto's mechanism [Eqn (26)] or in terms of the approach put forward above [Eqns (27) and (28)].

Reactions (25)–(28) lead to the observed increase in the rate of polymerisation of acrylates in the presence of OEC of Group III elements and phenols such as hydroquinone and di(hydroxyphenyl)propane. However, in the case of ionol—a sterically hindered phenol—some decrease in the rate of polymerisation of the monomers investigated has been observed.[70, 72] This is probably associated with the fact that, owing to steric factors, reactions (25) and (28) involving ionol proceed much less effectively than those involving hydroquinone and di(hydroxyphenyl)propane.

In contrast to acrylates, the polymerisation of vinyl acetate in the presence of OEC is effectively inhibited by phenols (Table 3) and, after the introduction of hydroquinone in amounts exceeding the concentration of trialkylborane, ceases completely.[71] The above inhibitors retard significantly also the polymerisation of vinyl chloride in the presence of organoelement initiators, but the process cannot be fully inhibited because of the low solubility of hydroquinone in vinyl chloride.

Trialkylborane is incapable of activating vinyl chloride and vinyl acetate owing to the characteristic features of their structure as electron-donating monomers.[76] As a consequence of the remoteness of the oxygen atom of the carbonyl group from the carbon–carbon double bond, in the coordination of the Lewis acid to vinyl acetate the activation of the π-bond of the latter is not quite so marked as in the case of acrylate and reaction (28) does not take place. Furthermore, whereas an appreciable delocalisation of the unpaired electron in the growing macroradical on coordination to the OEC (π-e conjugation[71]) is characteristic of acrylonitrile and (meth)acrylates, this is not possible in the poly(vinyl acetate) radical for steric reasons—as a consequence of a different disposition of the carboxy-group and the unpaired electron.[76]



It is quite likely that, on transfer of electron density to the unoccupied orbitals of the trialkylborane as a result of coordination to the macroradical, the borane increases the electrophilicity of the coordinated poly(methyl methacrylate) radical or the polyacrylonitrile radical. This makes them inert to phenols [see Eqn (24)]. In this case, chain propagation takes place in a cyclic reaction complex incorporating the monomer, the growing macroradical, and the OEC, directly in the coordination sphere of the metal, which hinders the reaction of the macroradical with the mobile hydrogen atom of the phenol. Because of this, the polymerisation of MMA continues up to a high degree of conversion in the presence of a tenfold excess of the inhibitor relative to the OEC.[70]

Phenolic inhibitors exert a definite influence also on the molecular mass of the polymer:[70-72] thus the molecular mass of poly(methyl methacrylate) diminishes synchronously with increase in the content of the inhibitor in the monomer mixture. However, this change is insignificant compared with the analogous influence of the above inhibitors in the absence of OEC or when traditional chain transfer agents are introduced.

A significant role is attributed to oxygen in the mechanism of the inhibition of radical polymerisation by various phenols. According to Dolgoplosk, the influence of oxygen reduces to the oxidation of the phenol to the corresponding stable radicals or quinones. In the presence of organic compounds of boron and aluminium[64-67, 70] as well as benzoquinone (BQ), there is no induction period in the polymerisation of MMA. The inhibiting effect of benzoquinone in the presence of added trialkylborane depends on the molar ratio [TAB]:[BQ]. If the amount of benzoquinone is smaller than that of trialkylborane, the inhibiting effect hardly influences the polymerisation kinetics. The process proceeds up to a high degree of conversion and the molecular mass changes insignificantly.[72] Under similar conditions in the absence of trialkylborane, benzoquinone effectively inhibits the polymerisation of acrylates: the rate of polymerisation is initially close to zero and the limiting degree of conversion does not exceed 0.5%.[71, 72]

With increase in the concentration of benzoquinone, the rate of polymerisation diminishes. However, even in the presence of a twofold excess of benzoquinone relative to trialkylborane, it is significantly higher than in the absence of the latter. Analysis of the literature as well as data on the reactivities of organoboron compounds relative to benzoquinone indicates the effective involvement of trialkylborane and benzoquinone in the processes.[70-72, 77, 78]

The phenoxyl radicals formed by reactions (30) and (31) enter into the S_R2 substitution reaction with generation of alkyl radicals which are capable of again initiating the polymerisation [Eqn (25)]. The average chain length indicates that there are two chain transfers to the trialkylborane molecule.[66]

Organoaluminium compounds exert a no less effective influence on the polymerisation of acrylates in the presence of quinones.[67, 72] The rate of polymerisation increases with increase in the ratio [trialkylaluminium]:[BQ], reaches a maximum, and then falls again. Grotewold and Hirschler[67] explained this by the operation of two initiation mechanisms: the first is associated with the decomposition of the initiator into radicals and the second with the generation of radical centres as a result of the decomposition of the complex between triethylaluminium and the quinone. Analysis of the products of the reactions of organoaluminium compounds with quinones[79, 80] showed that the latter mechanism appears extremely controversial.

As in the case of trialkylboranes, a heterolytic reaction [Eqns (29)-(31)] and homolytic transfer of the reaction centre to the metal atom [Eqn (25)] probably take place in the given instance. Whereas the reaction involving trialkylborane can involve two alkyl groups, in the case of triethylaluminium only one such group is involved[67] (the chain transfer rate constant is 89 litre mol^{-1} s^{-1}; we may note for comparison that the chain propagation rate constant is 576 mol $litre^{-1}$ s^{-1}).[81]

V. The influence of organoelement additives on the composition of the copolymer and on the kinetics of the copolymerisation of vinyl monomers

Copolymerisation is at present the main method of synthesis of polymers with the required set of chemical and physical properties. This can be explained by the fact that in most cases it is difficult to regulate the properties of homopolymers while the need for such regulation in order to obtain polymers for different purposes does exist.[2, 3, 6]

Copolymerisation usually leads to the formation of statistical copolymers the composition and properties of which are determined both by the initial content of the monomers in the mixture and by the reactivity of the monomers and growth radicals. However, there exist monomer pairs in the copolymerisation of which a regular alternation of units in the monomer takes place. As a rule, a strict alternation of the monomer units is observed when one of the monomers is a distinct donor of electron density while the other is an electron acceptor. Since the number of monomers with pronounced electron-accepting properties is small (for example, maleic anhydride and its derivatives, sulfur dioxide), the number of monomer pairs forming alternating copolymers is likewise small.

For this reason, methods based on the introduction of special additives into the system, as a rule protic or aprotic acids, have been developed for the regulation of the composition of the copolymers.[2] As shown above, the acids are coordinated to the monomers or growth radicals, enhancing thereby their electron-accepting properties and permitting the synthesis of alternating copolymers.[1, 2] The main disadvantage of this procedure is the need for a large excess of the regulating additive (by 1-3 orders of magnitude) relative to the initiator. This leads to the contamination of the polymeric product and precludes the industrial application of this method for the regulation of the composition.

The use of initiators based on organometallic compounds of Group III elements and peroxides makes it possible to eliminate the above disadvantage because the regulating effect of these compounds on chain propagation is manifested, as stated above, when catalytic amounts of the initiator (0.1-1.0 mol.%) are used.

The effects of complex formation in radical copolymerisation in the presence of Lewis acids are determined to a large extent by the electronic structure of the monomer. The limiting systems are those in which only one of the monomers interacts with the complex-forming agent and also those in which both monomers interact with it. Both versions are analysed below.

It has been established unambiguously for the copolymerisation of acrylonitrile with a series of vinyl monomers[82, 83] that the organoelement initiator exerts a significant influence on the dependence of the composition of the copolymer on that of the monomer mixture.

Thus, in the case of the classical radical initiator—azoisobutyronitrile, the acrylonitrile–vinyl acetate (VA) copolymer is enriched in acrylonitrile as the more active monomer whatever the composition of the monomer mixture (the coefficients of the relative reactivities of the monomers are r_{AN} = 4.05 and r_{VA} = 0.06). When the trialkylborane–OEP organoelement initiator is used, the composition curve is S-shaped (Fig. 1). The section of the curve where the composition of the copolymer is virtually independent of that of the monomer mixture can be clearly seen, which suggests that there is a tendency towards the alternation of monomer units in the copolymer and indicates that the copolymerisation is of the complex-radical type. This is also indicated by the equalisation of the relative reactivities of the monomers [r_{AN} = 0.35 and r_{VA} = 0.42; for comparison, we may note that r_1 and r_2 calculated in accordance with the $Q-e$ scheme (the Alfrey–Price scheme)[6] are respectively 4.27 and 0.06] and by the deviation from linearity in the calculation of the copolymerisation constants by the Kelen–Tüdös method.

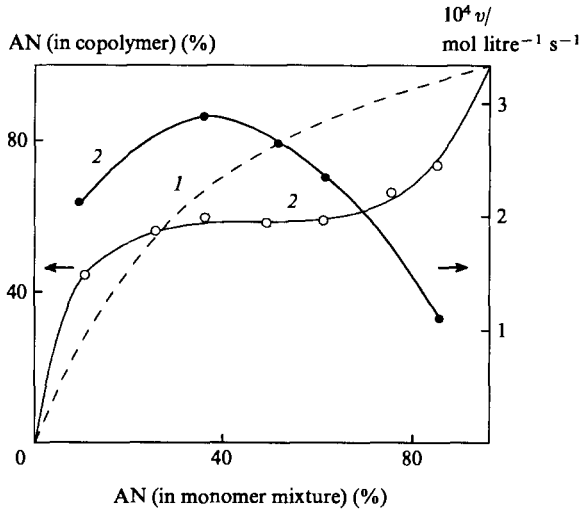


Figure 1. Dependence of the composition of the acrylonitrile–vinyl acetate copolymer and of the rate of copolymerisation on the composition of the monomer mixture. Initiator: (*1*) AIBN; (*2*) triisobutylborane–di-*tert*-butylperoxytriphenylantimony.

Note. The following abbreviations have been adopted: TBB = triisobutylborane, DPA = di-*tert*-butylperoxytriphenylantimony, TBPA = *tert*-butylperoxytetraphenylantimony, TBPS = *tert*-butylperoxytrimethylsilicon, TBPG = *tert*-butylperoxytriethylgermanium, TBPT = *tert*-butylperoxytriethyltin, VPD = *N*-vinylpyrrolidinone, VC = vinyl chloride, ST = styrene, VDC = vinylidene chloride, and CPC = dicyclohexylperoxy carbonate.

Such an appreciable influence of low concentrations of the initiator {[TAB] = $(2-8) \times 10^{-3}$ mol/mol of the monomer mixture, [OEP] = 10^{-3} mol/mol of the monomer mixture} is due to the coordination of the growing macroradical to the components of the initiating system. The trialkylborane, which has an unoccupied orbital in the boron atom, should then play the most active role. Its coordination to the growing acrylonitrile radical leads to a redistribution of electron density and enhances the electron-accepting properties of the polyacrylonitrile radical. The dependence of the rate of copolymerisation on the composition of the monomer mixture has a distinct maximum (Fig. 1). This suggests that the monomers form a reaction complex in the chain propagation stage.[1, 3]

Similar features have been observed also in the copolymerisation of acrylonitrile with acrylic and methacrylic acids and also with MMA.[83] Thus the composition curve for the acrylonitrile–vinyl acetate monomer pair contains a section where the composition of the copolymer is virtually independent of that of the monomer mixture. The relative reactivities (Table 4) in the case of an organoelement initiator differ appreciably from the values calculated in accordance with the $Q-e$ scheme and literature data.[63] The observed equalisation of the copolymerisation constants should lead to the synthesis of a polymer with a uniform composition.

Organoelement compounds exert a no less powerful influence on the dependence of the composition of the copolymer on that of the monomer mixture in the case of the methyl methacrylate–methacrylic acid pair as well.[41, 44] In the copolymerisation of the above monomers without the addition of organoelement compounds (with AIBN as the initiator, Table 4), the copolymer is enriched in methacrylic acid (MAA) whatever the composition of the monomer mixture. In the presence of the trialkylborane–OEP binary organoelement initiator, the composition curve is S-shaped and the relative reactivities of both monomers are significantly less than unity (Table 4). The product of the copolymerisation constants ($r_{MMA} \cdot r_{MAA}$) tends to zero, which indicates the alternation of the monomer units in the copolymer.[3]

The study of the separate influences of the components of the binary organoelement initiator on the chain propagation showed that the addition of 0.2 mol.% of triisobutylborane at a AIBN initiator concentration of 0.1% leads to an appreciable equalisation of the relative reactivities of the monomers. The introduction of an organoantimony peroxide together with AIBN also exerts a fairly strong influence on the reactivity of the monomers and growth radicals—the copolymer is enriched in MMA along all the sections of the composition curve. *tert*-Butylperoxytrimethylsilicon, which is used as a fairly effective coinitiator in relation to trialkylboranes, has a similar influence on the effective constants for the copolymerisation of MMA and methacrylic acid.[25, 32] Thus both components of the organoelement initiator (trialkylborane and OEP) have a regulating effect on the composition of the copolymer in the copolymerisation of acrylic monomers.

The rate of copolymerisation and the degree of conversion depend significantly on the nature of the heteroatom in the peroxide. Thus, in the copolymerisation of acrylonitrile with vinyl acetate, organoantimony and organotin peroxides are the most active as coinitiators in relation to trialkylborane (Table 5), while the composition with *tert*-butyl peroxide is least active: after 3 h, the degree of conversion does not exceed 5%. These data agree with the available information about the homopolymerisation of vinyl monomers in the presence of organoelement initiators[11, 25, 32, 33] and indicate a direct influence of the nature of the heteroatom in the peroxide on the rate of generation of radicals and on the chain propagation stage.

The last conclusion has been confirmed by a study of the dependence of the composition of the acrylonitrile–vinyl acetate copolymer on the composition of the monomer mixture when various OEP (Fig. 2) and *tert*-butyl peroxides are used. The form of the composition curves as well as the dependences

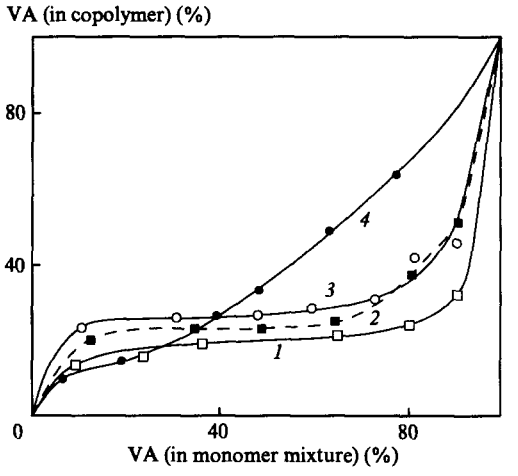

Figure 2. The influence of the nature of the heteroatom in the organoelement peroxide on the dependence of the composition of the vinyl acetate–acrylonitrile copolymer on the composition of the monomer mixture (T = 293 K) in the presence of the triisobutylborane–peroxide initiator; peroxide: (*1*) *tert*-butylperoxytriethylgermanium; (*2*) *tert*-butylperoxytriethyltin; (*3*) *tert*-butylperoxytetraphenylantimony; (*4*) *tert*-butyl peroxide.

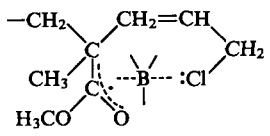
of the rate of copolymerisation on the composition of the monomer mixture differ significantly in the case of *tert*-butyl peroxide and its organoelement analogues. When germanium, tin, and antimony OEP are used, a section is observed on the composition curve where the composition of the copolymer is virtually independent of the composition of the monomer mixture. For the composition involving *tert*-butyl peroxide, the composition curve is also S-shaped, but there is no linear section.

Similar relations have been observed also in the case of the acrylonitrile–MMA monomer pair.[83] When organoelement peroxides are used, the reactivities of the monomers are equalised, whereas in the presence of *tert*-butyl peroxide as the coinitiator, the composition curve is close to the analogous curve for AIBN as the initiator.[63] When OEP are used for the copolymerisation of MMA with acrylonitrile, the copolymerisation constants of the monomer are similar and less than unity in all cases (Table 4), differing from the analogous constants for *tert*-butyl peroxide and AIBN.

Organosilicon peroxides exert a regulating effect on the copolymerisation of acrylates in the presence of sulfuryl chloride and phosphorus trichloride,[84, 85] but it is not quite so explicit as in the case of organic compounds of Group III elements, which can be accounted for by the difference between the electron-accepting properties of the modifying agents.



In the copolymerisation of two structurally related monomers, for example MMA–methacrylic acid, the differences between the coordination capacities of the heteroatoms in the peroxides do not exert a significant influence on the composition of the copolymer (Table 5),[41, 44] although on the whole a binary organoelement initiator exerts a regulating effect manifested by the equalisation of the relative reactivities of the monomer and by the S-shape of the composition curves. Similar features have

Table 5. Dependence of the rate of copolymerisation of acrylonitrile with vinyl acetate and methyl methacrylate in the presence of the triisobutylborane–peroxide binary initiator on the nature of the peroxide component (T = 293 K).

Comonomer (mol.%)	$10^4 v$ / mol litre^{-1} s^{-1}			
	TBP	TBPG	TBPT	DPA
VA, 49	0.05	0.86	1.40	2.02
MMA, 45	0.05	0.76	0.81	2.32

been observed also for the acrylonitrile–MMA, acrylonitrile–methacrylic acid, and acrylonitrile–acrylic acid monomer pairs.[41, 83] In all these pairs, two electron-accepting monomers are copolymerised, each of them being capable of coordination interaction with the OEC via its functional groups.

In the copolymerisation of electron-donating and electron-accepting monomers, for example MMA–styrene,[86] MMA–allyl chloride,[45] acrylonitrile–styrene,[83] and acrylonitrile–vinyl acetate, the regulating effect of the organoelement initiators is most explicit. The initiator influences not only the dependence of the composition of the copolymer on that of the monomer mixture but also the dependence of the rate of copolymerisation on the initial contents of the monomers in the mixture. For the monomer pairs indicated, the dependence of the rate of copolymerisation on composition passes through a maximum in the vicinity of a nearly equimolar monomer ratio (Fig. 1). This yet again constitutes evidence in support of the complex-radical nature of the copolymerisation and also suggests that the monomers and macroradicals can form a complex in the chain propagation stage.[45]

^{1}H NMR study of the MMA–styrene copolymer obtained in the presence of dicyclohexyl peroxydicarbonate (DCC) and an organoelement initiator has shown that the microstructures of the specimens differ significantly.[86] A satisfactory agreement between the calculated and experimental fractions of the triads has been observed for the copolymer synthesised using DCC. For the specimens obtained in the presence of organoelement compounds, the discrepancy between the experimental and calculated data is significant (Table 6), which demonstrates the inapplicability of the Mayo–Lewis scheme under these conditions. The triad ratio calculated from the relative reactivities in conformity with the penultimate unit model showed that the Mertz–Alfrey–Goldfinger equation describes the copolymerisation process much better. However, it is seen from the data presented that the influence of the penultimate unit is not the only factor which alters the composition of the copolymer. These data indicate yet again that the complex formation reaction between the monomer and the initiator and also between the initiator and the macroradical makes an appreciable contribution to the change in the relative reactivities of the monomers.

Table 6. The triad ratios (1–3) in the ^{1}H NMR spectra of the MMA–styrene copolymer (mole fraction of MMA in the copolymer 0.6)[86]

Triad*	DCC		Bu^i_3B–$Ph_4SbOOBu^t$		
	1	2	1	2	3
AAA	0.42	0.38	0.13	0.24	0.17
BAA	0.37	0.33	0.62	0.33	0.43
BAB	0.21	0.29	0.25	0.43	0.50

Note. 1–experimental fraction; 2–fraction calculated for the terminal model; 3–fraction calculated for the penultimate model.
* In the triads, A = MMA and B = styrene.

Data concerning the dependence of the instantaneous and overall compositions of the MMA–styrene copolymer on the degree of conversion show that, in copolymerisation in the presence of DCC, the copolymer is enriched in MMA at high degrees of conversion. This indicates the nonuniformity of the product. Initiation by the tetraalkylborane–OEP system leads to the formation of a copolymer with a narrower distribution of the fractions with respect to composition.[86]

In the copolymerisation of acrylates with alkenes, the regulating effect of organoelement compounds is not quite so explicit as in the examples examined above. The rate of copolymerisation of acrylonitrile with hex-1-ene and cyclohexene, of MMA with ethylene, and of vinyl acetate with ethylene diminishes linearly with increase in the content of the olefin in the mixture.[87] Although the relative reactivities of the monomers do differ somewhat from those for the classical radical initiators the difference is less than for the copolymerisation of two vinyl monomers (Table 4). This is associated with the fact that olefins and especially the growth radicals associated with them show a smaller tendency towards complex formation than the monomers containing functional groups or atoms with lone electron pairs.

An organoelement initiator exerts a modifying influence also on both copolymerising monomers or electron donors, for example *N*-vinylpyrrolidinone (VPD)–vinyl acetate.[33, 88] For this pair, the composition of the copolymer is constant within a certain range of monomer compositions, which indicates the alternation of the monomer units in the copolymer. This is also indicated by the equalisation of the relative reactivities of the monomers (Table 4) and also by the deviation from the linear variation of the calculated parameters in the determination of the copolymerisation constants by the Kelen–Tüdös method. The dependence of the rate of copolymerisation on the composition of the monomer mixture passes through an extremum in the region of the equimolar composition of the monomer mixture (Fig. 3). One cannot rule out the possibility that the monomers form a 1 : 1 reaction complex during chain propagation.[1]

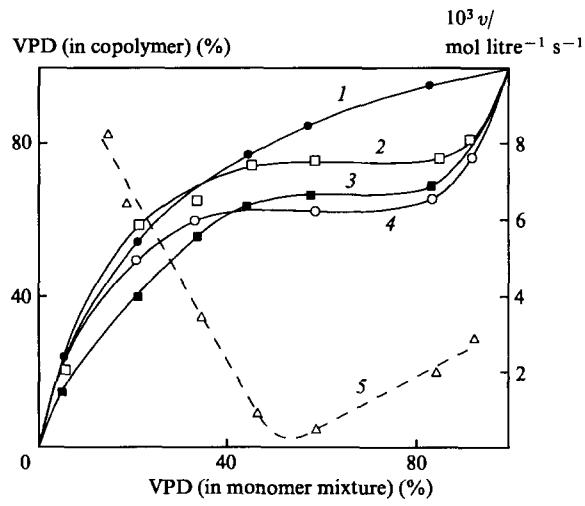


Figure 3. Composition curves (curves *1–4*) and the rates of copolymerisation (curve *5*) of *N*-vinylpyrrolidinone with vinyl acetate. Initiator: (*1*) AIBN; (*2*) triisobutylborane–*tert*-butyl peroxide; (*3*) and (*5*) triisobutylborane–di-*tert*-butylperoxytriphenylantimony; (*4*) triisobutylborane–*tert*-butylperoxytriethylgermanium.

The organoelement exerts a significant influence also on the copolymerisation of *N*-vinylpyrrolidinone with vinylidene chloride (*N*-vinylpyrrolidinone and vinylidene chloride are 'naturally alternating' comonomers).[33] The composition curve is S-shaped when DCC is used as the initiator. In the copolymerisation of the above pair of monomers in the presence of the trialkylborane–OEP initiator, a unilateral enrichment of the copolymer in vinylidene chloride is observed.

Thus catalytic amounts of organic compounds of Group III–V elements not only effectively initiate the low-temperature (co)polymerisation of vinyl monomers but also exhibit a regulating activity on the rate of (co)polymerisation and the composition of the copolymers.

VI. Copolymerisation of vinyl chloride with ethylene and α-olefins in the presence of organometallic compound–peroxide initiating systems

Vinyl chloride and α-olefins are known to polymerise effectively at a low pressure via different mechanisms: vinyl chloride via a radical mechanism and ethylene and its homologues via a coordination mechanism in the presence of Ziegler–Natta catalysts.[6, 7] The copolymers of vinyl chloride with olefins cannot be synthesised with a high degree of conversion under technologically convenient conditions in the presence of the usual radical initiators:[89] the maximum degree of conversion is 17% in the presence of AIBN,[90] 24% in the presence of Ziegler–Natta catalysts,[91] and 30% in the presence of electron-donating additives.[92] The lack of effective initiators has held back the industrial production in our country of the above copolymers, which are extremely promising as plastics: they can be easily worked, have a larger elongation on rupture than poly(vinyl chloride), have an enhanced impact strength, etc. Furthermore, the introduction of even 5%–10% of ethylene into poly(vinyl chloride) appreciably lowers the cost of the monomer.

The coordination-radical initiators based on organic compounds of Group III elements and organic peroxides of Group IV elements occupy an intermediate position between the traditional radical initiators and Ziegler–Natta catalysts by virtue of their structural characteristics. They make it possible to copolymerise vinyl chloride with ethylene and α-olefins at a high rate and with a high conversion under energetically convenient conditions.[93, 94]

After 5 h, the limiting conversion for the vinyl chloride–ethylene copolymer in the presence of the trialkylborane–OEP organoelement initiator reaches 90%. With increase in the length of the alkyl group in the olefin, the rate of polymerisation and the conversion fall and in the case of oct-1-ene the yield of the copolymer does not exceed 20%. The additional introduction of the initiator into the system leads merely to a slight increase in the yield of the copolymer. The reason for the decrease in conversion is probably associated with chain termination due to the mobile hydrogen atoms in the olefin in the α-position relative to the double bond.

The structure of the peroxide and the composition of the monomer mixture exert direct influence on the process kinetics. It has been shown in relation to hex-1-ene that, with increase in the content of vinyl chloride in the monomer mixture from 6% to 89%, the limiting conversion rises from 3% to 49%, which agrees well with the reactivity of the copolymerising monomers. It has been found that the olefins themselves are incapable of homopolymerisation in the presence of the systems indicated.[25, 94] Organoantimony peroxides are more active as coinitiators than their organogermanium and organosilicon analogues, which is probably associated with the characteristic features of the radical formation in the OEC–peroxide systems[27] and also agrees with data on the homopolymerisation of vinyl chloride in the presence of organoelement initiators.[95]

When traditional radical initiators as well as Ziegler–Natta catalysts are used for the copolymerisation of vinyl chloride with olefins, the possibilities for the variation of the composition of the copolymer are extremely limited. The form of the composition curves and the relative reactivities of the monomers (Table 4) show that the copolymer is enriched in one of the monomers. This is associated with the significant difference between the reactivities of vinyl chloride and olefins. The use of trialkylborane–OEP systems leads to an appreciable equalisation of the copolymerisation constants. For a series of systems, the composition of the copolymer is almost independent of the composition of the monomer mixture and is nearly equimolecular over a wide range of [mixture] compositions.[87, 94]

Calculations of the relative reactivities of the monomers by the Kelen–Tüdös and Fineman–Rossi methods reveal a deviation of the calculated parameters from the linear relation. This indicates the system does not obey the classical Mayo–Lewis equation and can be explained within the framework of the coordination-radical copolymerisation mechanism: the boron atom in trialkylborane and the element in the peroxide may be coordinated both to the monomers and to the growing macroradicals, altering their reactivity and hence the relative reactivities of the monomers.

Analysis of the physicochemical properties of the copolymers of vinyl chloride with olefins showed that, when olefin units are introduced, the Fikentscher constant is reduced. This facilitates the processing of the polymeric product and improves its plasticity.[96]

When oxidation-reduction systems based on triethylborane and organic oxidants (oxygen, *tert*-butyl hydroperoxide) are used, the regulating activity is manifested to a lesser extent[92, 97, 98] than in the case of the trialkylborane–OEP binary initiator. It is quite evident that the heteroatom in the OEP also participates in the propagation stage by virtue of its unoccupied *d* orbitals. The possibility of the formation of complexes between the peroxides of Group IV elements and the monomers, including olefins, has been demonstrated in a series of studies.[9, 28, 29]

The regulating activity of the OEC–peroxide initiator is manifested not only in the presence of organoboron compounds but also in the presence of alkyl derivatives of aluminium and bismuth.[99]

The trialkylborane–OEP binary initiator also made it possible to achieve the single-stage synthesis of terpolymers containing vinyl chloride, vinyl acetate, and olefin units.[100] The above terpolymers can be used as elastomers, effective adhesives, and constructional materials, including materials for the medical industry. A series of such copolymers, obtained in recent years by foreign companies, can be processed without the introduction of plasticisers. They have been called third generation polymers with internal plasticisation.

As for the ethylene–divinyl chloride copolymers, the main complication in the synthesis of the above terpolymers consists in the fact that under mild conditions (room temperature, low pressure) olefins and vinyl monomers in the presence of traditional radical initiators copolymerise ineffectively and as a rule graft polymerisation is used for their synthesis.[101, 102] The trialkylborane–OEP binary initiator makes it possible to obtain the above polymers with conversions up to 70% over a period of 5–6 h within a wide range of compositions. It is of interest that, along the initial sections, the copolymer is enriched in ethylene although its relative reactivity constant is somewhat lower than for vinyl acetate and vinyl chloride. On the other hand, for the limiting conversion the copolymer contains more vinyl chloride. The above features demonstrate yet again that the components of the initiator are capable of coordinating to the growing macroradicals and monomers and of altering their reactivity. In ter- and tetra-polymerisation in the presence of complex forming agents, the overall proportions of the monomer-donor and monomer-acceptor units which have entered into the polymer are known to be similar.[103–105]

VII. Conclusion

The set of data presented indicates the development of a promising aspect of the synthetic chemistry of polymers involving the application of catalytic amounts of organometallic compounds as modifying agents for the homo- and co-polymerisation of vinyl monomers and olefins. Small amounts of added organoelement compounds make it possible to influence the reactivity of the monomers and the macroradicals and to regulate thereby the kinetic process parameters in the initiation, chain propagation, and chain termination stages as well as the composition, structure, and properties of the (co)polymers.

The use of catalytic amounts of the modifying agent eliminates the problem of its removal from the final product and leads to the prospect of the industrial application of the above approach to the synthesis of (co)polymers with specified properties without the preliminary elimination of stabilisers.

III. Conclusion 978

Abstract. Data on the synthesis, steric structures, and photochemical properties of molecular diad systems based on porphyrins as synthetic models of the reaction centre in photosynthesis are considered and treated systematically. The bibliography includes 102 references.

I. Introduction

The conversion of light energy into chemical energy has at present aroused much interest among investigators. Molecular photosynthetic systems, reproducing at a simpler level the individual stages of natural photosynthesis, are being created for the solution of this problem. The donor–acceptor systems based on porphyrin structures may serve as an example of such models.[1–3]

The most important stage in the transformation of light energy into chemical energy is the photochemical charge separation in the photosynthesis system. In nature, this problem has been solved by the creation during the evolutionary process of photosynthetic reaction centres in which charge separation takes place at a record speed. Studies in recent years have shown that synthetic molecular systems of the type D–P–Q, i.e. models containing a photosensitive pigment (P), an electron donor (D), and an electron acceptor (Q), are also capable of giving rise to the structure D^+-P-Q^- with separated charges simulating the primary charge separation in photosynthesis, where the singlet-excited porphyrin reduces the acceptor and is itself reduced by the donor. Such model systems make it possible to investigate in detail the dependence of the process itself on the distance between the donor and the acceptor, on their mutual orientation, on the free energy of the reaction, on the electronic interaction, and on the rates of electron transfer.[4–6]

All the compounds described, containing bound chromophores, are based on systems of two types: molecular diads and multicomponent structures—triads, tetrads, and pentads.

The synthetic methods for the creation of molecular assemblies[7] are discussed in the present review and the possibility of investigating the energy transfer and the primary charge separation in the photosynthesis on diad models is considered. Such models are the simplest systems for the photosynthetetic electron transfer, consisting of chromophores bound covalently to a donor or acceptor.

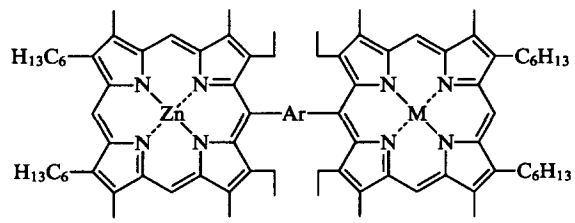
II. Methods of synthesis and photochemical properties of the model compounds

1. Porphyrin dimers

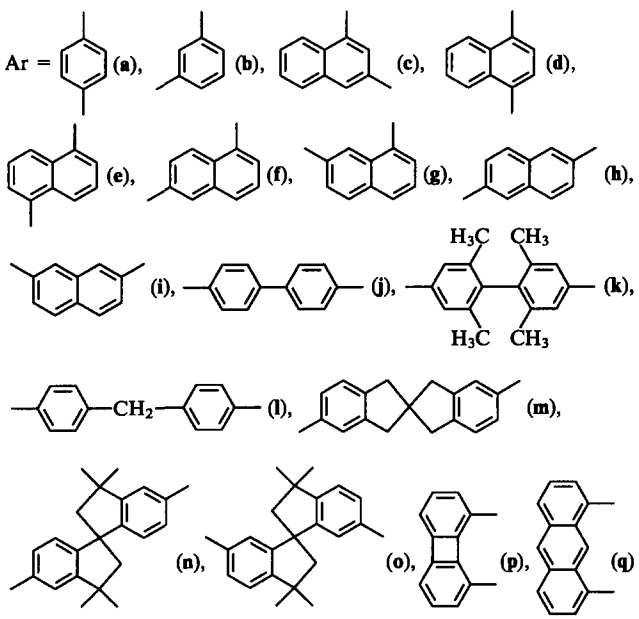
Studies on the structure of the reaction centres in photosynthetic bacteria and of the mechanism of the electron transfer have shown that the reaction centre consists of six interacting tetrapyrrole pigments. It has also been established that the primary electron donor is a 'special pair' consisting of two aggregated chlorophyll molecules. The problem of current interest in the study of the primary photosynthetic process is therefore that of the creation of covalently bound conformationally-restricted structures containing two and more porphyrin units, i.e. molecular assemblies capable of participating very effectively in specific energy and electron transfer reactions.[4,8–10]

a. Methods of synthesis of porphyrin dimers

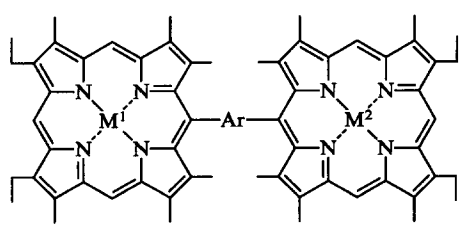


The synthesis of primary porphyrin dimers was described as early as the 1970s.[1] Since then, various multicomponent tetrapyrrole compounds have been obtained and investigated.[11–14]

It was shown that octaalkylporphyrin dimers **1a–q**,[8,9,15] **2a–o**,[16] **3a–i**,[17] and **4a–h**,[18] linked by aromatic spacers, are interesting models.

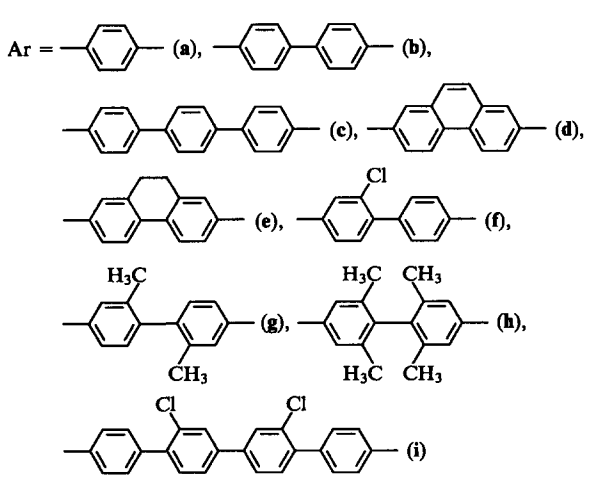


In these dimers, two porphyrin rings are held rigidly in a definite conformation as a result of steric hindrance. The aromatic spacer is perpendicular to the mean plane of the porphyrin, reducing to a minimum the direct $\pi-\pi$ interaction between the porphyrin and the connecting bridge.

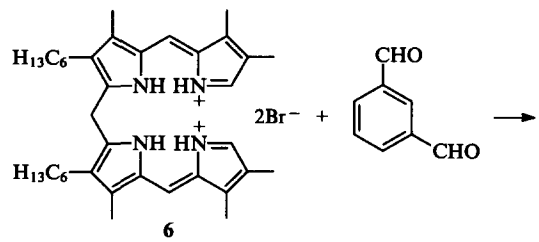


The spacer used in compounds **1m** and **1n** simulates the chromophores with a 'twist' type of conformation such as the haems and chlorophylls in natural systems, while compound **1o** serves as a model of the chromophore with the 'twist' conformation, which has partly the same geometry as the 'special pair' in the bacterial photosynthetic reaction centre. All these symmetrical porphyrins **1a–q**, **2a–o**, **3a–i**, and **4a–h** have been synthesised from the corresponding arenedialdehyde by Chang's method.[19,20]

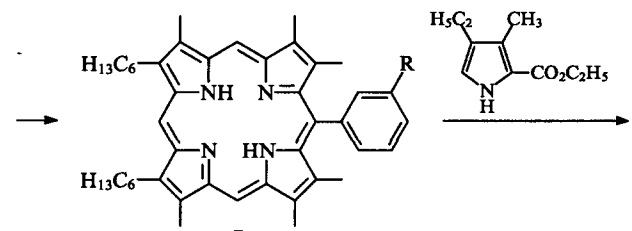
An alternative approach has been used to synthesise the asymmetric dimer **5** (Scheme 1). Condensation of 1,19-dideoxybiladiene-ac dihydrobromide **6** with isophthalic aldehyde afforded the porphyrin **7a** with a formyl group, which was converted by the reaction with ethyl 4-ethyl-3-methyl-pyrrole-



1a–q: M = 2H
2a–o: M = Fe^{III}



3a–i: $M^1 = M^2 = 2H$
4a–h: M^1 = Zn; $M^2 = Fe^{III}$



2-carboxylate into the porphyrin-dipyrrolylmethane **8a**. The latter was initially converted into the zinc complex **8b** and was then treated with $LiAlH_4$ in order to obtain the corresponding diol **9**, the interaction of which with 5,5′-unsubstituted dipyrrolmethane **10** afforded the dimer **5** in 9% yield.[9]

The principal task solved in relation to the given structures was the elucidation of the nature and degree of the interaction of the porphyrin components of these assemblies.

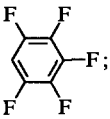
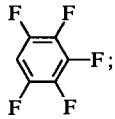
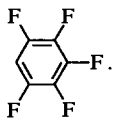
8: M = 2H, X = $CO_2C_2H_5$ (**a**); M = Zn, X = $CO_2C_2H_5$ (**b**)
9: M = Zn, X = CH_2OH

10



5

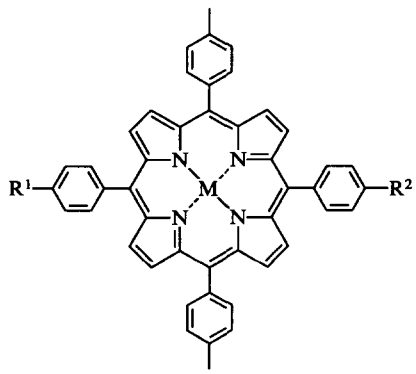




11-15

11: M = 2H; R^1 = $NHCOCH_3$;
R^2 =  ; R^3 =  ;

12: M = Zn; R^1 = $NHCOCH_3$;
R^2 =  ; R^3 =  ;



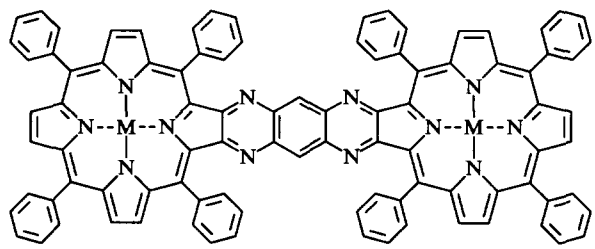
13: M = 2H; R^1 = $NHCOCH_3$; R^2 = R^3 =  ;

14: M = 2H; R^1 = CH_3; R^2 = R^3 =  ;

15: M = Zn; R^1 = CH_3; R^2 = R^3 =  .

The porphyrin dimers **11**–**15** were used to investigate the photoinduced electron transfer and the transfer of the energy of the excited state between the porphyrins.[21]

As an example, the synthesis of the porphyrin dimer **11** is described below. The diester **16** was hydrolysed to the corresponding monoester, from which the acid chloride was obtained by treatment with thionyl chloride. The condensation of the latter with 15-(4-acetamidophenyl)-5-(4-aminophenyl)-10,20-bis(4-methylphenyl)porphyrin, which had been obtained in its turn by the partial hydrolysis of compound **17**, leads to the amide **11** in 93% yield.



16, 17

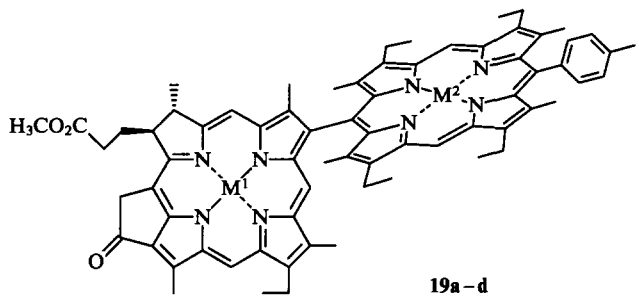
16: R^1 = R^2 = $COOCH_3$; M = 2H;
17: R^1 = R^2 = $NHCOCH_3$; M = 2H.

The porphyrin dimer **12** was synthesised similarly in 63% yield. In this case, the acid chloride of the monocarboxyporphyrin was condensed with the zinc complex of 15-(4-acetamidophenyl)-5-(4-aminophenyl)-10,20-bis(4-methylphenyl)porphyrin.

5-(4-Methoxycarbonylphenyl)-10,15,20-tris(pentafluorophenyl)porphyrin was obtained by Lindsay's method involving the condensation of pyrrole, pentafluorobenzaldehyde, and methyl 4-formylbenzoate with trifluoroacetic acid and subsequent oxidation of the resulting product with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, after which the ester was hydrolysed and the acid made to react with thionyl chloride. Interaction of the resulting porphyrin acid chloride with an excess of 5,15-bis(4-aminophenyl)-10,20-bis(4-methylphenyl)-porphyrin led to the diad **13**. The dimers **14** and **15** were synthesised via the same mechanism in 95% and 54% yields respectively.[21]

The steric disposition of the porphyrins in the system **18** and the distance between them (7.5 Å) are very similar to those for the central haems in the cytochrome units of the photosynthetic reaction centre of the bacterium *Rhodopseudomonas viridis*,[22] where the tetrapyrrole macrocycles are almost coplanar and are linked in such a way that the distance between the porphyrins is 7.5–8.5 Å.

18a, b



M = 2H (**a**), Zn (**b**)

The strategy used in the synthesis of such a rigidly linked bisporphyrin system involves the condensation of the α-dione (17,18-dioxo-5,10,15,20-tetraphenylchlorin) with the tetrahydrochloride of 1,2,4,5-benzotetraamine, taken in proportions of 2 : 1, in pyridine. The yield of the dimer **18** was 71%.

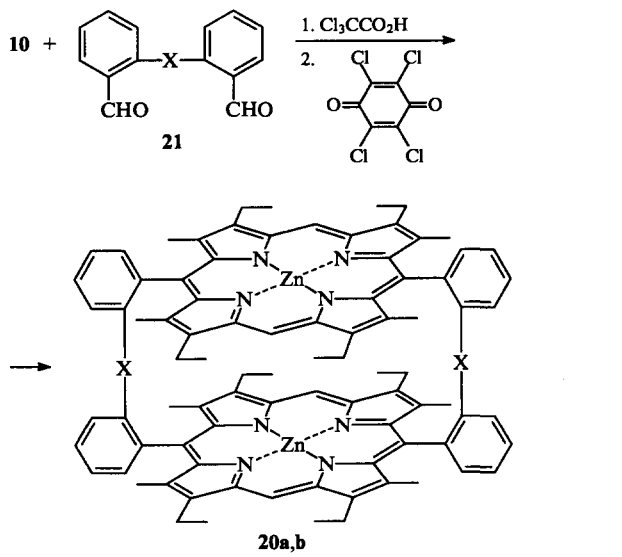
As already stated above, the electron donors and acceptors in the photosynthetic reaction centres are located at a fixed separation with a definite orientation relative to one another, which ensures an effective photoinduced separation of the charges and retards their recombination. However, it is believed that the intervening component located between the donor and acceptor exerts a major influence on the rate of electron transfer.

For example, in the bacterial photosynthetic reaction centre, the bacteriochlorophyll (BChl) molecule is located between the dimeric bacteriochlorophyll donor ($BChl_2$) and the bacteriopheophytin acceptor (BPh). It is believed that the 'super exchange' process, which involves the mixing of the low-energy ionic and virtual states of the intervening bacteriochlorophyll and of the selectivity excited donor, may lead to an appreciable increase in the rate of charge separation.[24]

For a better understanding of the influence of the low-energy states, formed during charge transfer, on the photophysical characteristics of the donor–acceptor systems, a series of chlorophyll-porphyrin molecules with a fixed distance between these two macrocycles were synthesised.[24]

19a–d

$M^1 = M^2 = 2H$(**a**);
$M^1 = M^2 = Zn$ (**b**);
$M^1 = Zn$; $M^2 = 2H$ (**c**);
$M^1 = 2H$; $M^2 = Zn$ (**d**).



The dimer **19a** was obtained from methylpyropheophorbide *d* and *p*-toluic aldehyde by their condensation with the corresponding dipyrrolylmethane and subsequent oxidation of the resulting porphyrinogen with chloranil.

It was found that[24] the reaction of the dimer **19a** with zinc acetate at room temperature leads to the product **19d**, while compound **19b** is obtained on refluxing. After treatment of compound **19b** with a small amount of dichloroacetic acid, it loses the zinc atom more readily than the chlorin macrocycle, so that compound **19c** can be more effectively obtained from compound **19b**.

The structures of compounds **19a–d** contain a chlorophyll molecule bound rigidly to the porphyrin and the π-systems of the two macrocycles, restricted by steric interactions, are perpendicular to one another. Such orientation is preferred for the simulation of the geometrical relation between the bacteriochlorophyll donor and the spacer ($BChl_2$ and BChl) in the photosynthetic reaction centres.[23,24]

The porphyrin dimers, the macrocycles of which are in the 'face-to-face' configuration, are of interest. Compounds **20a,b** of this type have been synthesised from 3,3′-diethyl-4,4′-dimethyl-2,2′-dipyrrolylmethane **10** and the dialdehyde **21** (Scheme 2).[25,26]

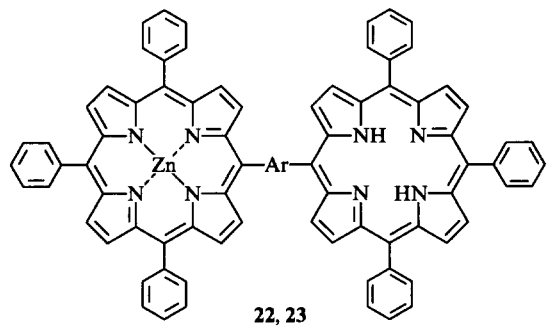
Scheme 2

20a,b

X = $O(CH_2)_4O$ (**a**), $O(CH_2)_3O$ (**b**).

Although the yields of compounds **20a,b** are low (5% and 2% respectively), the reaction merits attention from the standpoint of its simplicity and the ease with which the starting materials can be obtained.[26]

The chemistry of porphyrin dimers and their metal complexes is at present in the stage of its establishment and a wide range of problems in this field still await solution. However, the accumulated experimental data indicate the importance of this field.[12]



b. Photochemistry of porphyrin dimers

Considerable advances have been achieved hitherto in the study of the photochemical properties of the model compounds. Among the questions arising in the investigation of the photochemistry of such molecular structures, the most important involves the discovery of the characteristic features of the organisation of the photosynthetic apparatus ensuring a high efficiency of the charge separation.

In spectroscopic studies on the system **1a–q**, it was shown that the rates of the direct electron transfer diminish with increase in the 'centre-to-centre' distance between two porphyrins, whereas the rates of the reverse electron transfer remain almost constant [the rate constant is k = (4 to 6) × 10^8 s^{-1}] for a series of 'centre-to-centre' distances from 8 to 22 Å and are independent of the orientation and structure of the spacer.[15]

It has also been noted that the intensity of the fluorescence of the metal-containing porphyrin is appreciably weakened, whereas the intensity of the fluorescence of the second porphyrin component is intensified, which indicates an effective transfer of excitation energy from the singlet state.[27]

Results agreeing with the data described by Osuka et al.[27] have been obtained for the dimers **22** and **23**.[28] Although Rempel et al.[28] used other porphyrin subunits, the models which they presented are similar to compounds **1b** and **1l** in terms of geometrical parameters.

22, 23

22: Ar =

23: Ar =

The role of the intermediate linker in determining the electronic bonding between the electron donor and acceptor, which makes the electron transfer reaction possible, has attracted the attention of investigators in recent years. It has been found that, when the donor and acceptor are covalently bound via a rigid spacer, the rates of electron transfer increase. It has also been noted that, when aromatic spacers are employed, the rate constant depends on the distance between the chromophores to a much lesser extent than in the case where aliphatic linkers are used. Thus an increase in the length of the aromatic spacer by 4 Å leads to a decrease in the rate by a factor of 20, while in the case of an aliphatic bridge the rate falls by a factor of 100. Such an enormous difference can be explained by the fact that the electron transfer in the case of an aromatic linker proceeds via a 'super exchange' mechanism. Furthermore, it has been found that the rate constant for electron transfer depends on the electronic structure of the spacer.

All these data show that the electron transfer reactions between the spacer-bound chromophores are determined by the donor–acceptor interaction.[17]

Osuka et al.[16] described diporphyrins consisting of the hybrid metal complexes **2a–o** with different mutual orientations and a series of aromatic spacers including benzene, naphthalene, and spirobiindan fragments.

It has been demonstrated for these rigidly bound compounds that the reactions involving the separation and recombination of charges exhibit different dependences on distance. The rate constant for charge separation is related mainly to the distance and does not exhibit any dependence on orientation, whereas the rate constant for the recombination of charges is hardly influenced by either the distance or the mutual orientation.

In contrast to the well established dependence on distance, the data concerning the relation between the rate of electron transfer and the angle between the donor and acceptor are virtually lacking,[18] although Osuka et al.[16] believe that the recent studies have a bearing on precisely this problem.

The first results indicating the dependence on orientation were obtained using a series of bisporphyrins **4a–h**, in which the angle between the donor and acceptor varies systematically.

In these molecules the rate of intramolecular electron transfer changes by an order of magnitude when the angle between the porphyrin units is varied.[17,18]

In the dimers **4a–c**, the 'edge-to-edge' distances were measured and were found to be respectively 5.8, 10.1, and 14.4 Å. Studies showed that, with increase in the length of the spacer, the electron transfer rate constant diminishes: $(4 \pm 1) \times 10^{10}$, $(7 \pm 1) \times 10^{9}$, and $(1.1 \pm 1) \times 10^{9}$ s^{-1} for compounds **4a–c** respectively. However, Helms et al.[17] attribute this decrease in the rate not to the increase in the distance between the chromophores but to the break in the conjugation of the spacer owing to the biphenyl 'twist' angle (50°) for each junction between two benzene rings. The inadequate overlap of the chromophores for this value of the angle leads to an approximately sixfold decrease in the rate of electron transfer to the benzene ring, which is confirmed by the results.[17]

Much work has been done in the study of the photochemical characteristics of the dimers **11–15**.[21] The results clearly demonstrated the occurrence of the singlet–singlet energy transfer between the porphyrin components of the dimers **11–13** and **15**. The photoinduced electron transfer in compounds **13** and **15** was also observed, confirming the occurrence of electronic exchange interactions in these compounds, which probably lead to an increase in the rate constant for the singlet–singlet energy transfer. The fact that the quenching of the fluorescence is observed only in the diads where the charge-separated state is located at a lower energy level than the primary excited singlet state confirms the assignment of the fluorescence quenching process to electron transfer and not to other photophysical or photochemical processes.[21,24]

The photophysical properties of compounds **19b** and **19c** can be compared directly with the characteristics of the dimer $BChl_2$ in natural reaction centres. Spectroscopic studies of the natural reaction centre did not yield evidence for the formation of the ion pair $BChl^{+}-BChl^{-}$ in the bacteriochlorophyll dimer but made it possible to postulate that the low-energy state of the dimer with separated charges overlaps the singlet state of the dimer located at an even lower energy level. The results of the study of compound **19b** showed that the low-lying charge-separated state is located 0.1 eV above the excited singlet state and this influences strongly the rate of decomposition of compound **19b** without the formation of an ion pair. It may be that the dimer $BChl_2$ in the natural reaction centres also decomposes rapidly, like compound **19b**.

The considerable similarity of the photophysical characteristics of the dimers of the reaction centre and the heterodimers **19b,c** suggests that further studies should be carried out on these lines.[24]

2. Porphyrin-carotenoid compounds

Studies on the synthesis and properties of molecular diads consisting of a porphyrin or a chlorophyll derivative and a carotenoid polyene are of considerable interest.

Carotenoids (Car) simulate the functions of an antenna, absorbing light in the region of the solar spectrum where chlorophyll is ineffective, and transfer the energy of the excited singlet state to chlorophyll.[1,6,29–35]

$$\mathrm{Car} + h\nu \longrightarrow {}^{1}\mathrm{Car}^{*},$$

$${}^{1}\mathrm{Car}^{*} + \mathrm{Chl\,(BChl)} \longrightarrow \mathrm{Car} + {}^{1}\mathrm{Chl}^{*},$$

$${}^{1}\mathrm{Chl}^{*} \longrightarrow \mathrm{Chl} + h\nu\,\mathrm{(fluorescence)}.$$

Furthermore, they play the role of photoprotectors. On irradiation of chlorophylls, long-lived excited triplet states are generated. The chlorophyll triplets react with oxygen, forming singlet oxygen ($O_2^{*1}\Delta_g$), which is very reactive and is therefore dangerous to plant tissues.

$$\mathrm{Chl\,(BChl)} + h\nu \longrightarrow {}^{1}\mathrm{Chl}^{*},$$

$${}^{1}\mathrm{Chl}^{*} \longrightarrow {}^{3}\mathrm{Chl}^{*},$$

$${}^{3}\mathrm{Chl}^{*} + \mathrm{O_2} \longrightarrow \mathrm{Chl} + O_2^{*1}\Delta_g.$$

Carotenoid polyenes prevent the decomposition of plant tissues by singlet oxygen by 'extinguishing' the triplet state of chlorophyll before its interaction with oxygen. This energy transfer from the triplet state of chlorophyll leads to the triplet carotenoid (a harmless state) and the initial state of chlorophyll.

$$\mathrm{Chl\,(BChl)} + h\nu \longrightarrow {}^{1}\mathrm{Chl}^{*},$$

$${}^{1}\mathrm{Chl}^{*} \longrightarrow {}^{3}\mathrm{Chl}^{*},$$

$${}^{3}\mathrm{Chl}^{*} + \mathrm{Car} \longrightarrow \mathrm{Chl} + {}^{3}\mathrm{Car}^{*},$$

$${}^{3}\mathrm{Car}^{*} \longrightarrow \mathrm{Car} + Q.$$

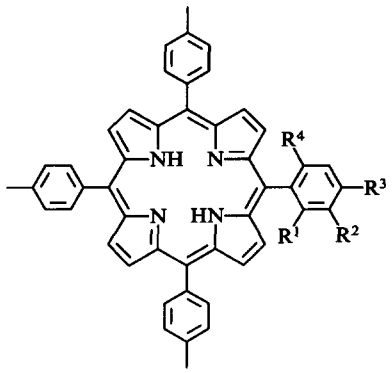
Carotenoids can also fulfil the function of photoprotectors by 'extinguishing' singlet oxygen.

$$O_2^{*1}\Delta_g + \mathrm{Car} \longrightarrow {}^{3}\mathrm{Car}^{*} + {}^{3}\mathrm{O_2},$$

$${}^{3}\mathrm{Car}^{*} \longrightarrow \mathrm{Car} + Q.$$

It has been established that under certain conditions carotenoid polyenes can act as electron donors in photosynthetic systems, although their importance as electron donors is not known.[1,6,29–35]

In order to investigate the photochemical characteristics of carotenoids, namely their functions as photoprotectors and antennae, a series of porphyrin-polyene compounds **24–37** were synthesised.[36–41] (see over)

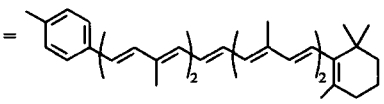


a. Methods of synthesis of porphyrin-carotenoid compounds

Compounds **24–36** have been obtained by condensing the corresponding 5-aminophenyl-10,15,20-tris(4-methylphenyl)porphyrins with the acid chloride of 7′-apo-7′-(4-carboxyphenyl)-β-carotene.

Compounds **27** and **28** were synthesised using 7′-apo-7′-(4-aminophenyl)-β-carotene and the acid chloride of the porphyrin obtained by treating 5-carboxyphenyl-10,15,20-tris(4-methylphenyl)porphyrin with oxalyl chloride.[36]

The reaction of 5-hydroxyphenyl-10,15,20-tris(4-methylphenyl)porphyrins with 7′-apo-7′-(4-iodomethylphenyl)-β-carotene leads to the model systems **29–31**.



The porphyrin-carotenoid compounds **32** and **33** were obtained respectively by the interaction of dihydroxyphenyl derivatives of tetraphenylporphyrin with 7′-apo-7′-(4-iodomethylphenyl)-β-carotene.

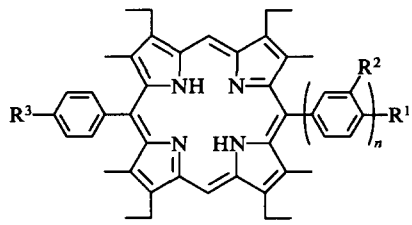
X =

Compound **34** was synthesised using the phosphonium salt of 5-[4-(3-hydroxypropoxy)phenyl]-10,15,20-tris(4-methylphenyl)-porphyrin and β-apo-8′-carotenal, while compound **35** was obtained in its turn by condensing 5-[5-(2-hydroxyethoxy)-phenyl]-10,15,20-tris(4-methylphenyl)porphyrin with 7′-apo-7′-(4-carboxyphenyl)-β-carotene in the presence of *N*,*N*-dicyclohexylcarbodiimide (DCC).[37–39]

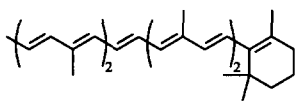
Carotenal, which is necessary for the synthesis of compounds **36** and **37**, was itself synthesised from α-bromo-*p*-toluic aldehyde with the aid of the corresponding phosphonium salt. The aldehyde group was protected in the form of an acetal by means of ethylene glycol. The Wittig reaction of this salt and β-apo-8′-carotenal was accompanied by the hydrolysis of the protecting group with formation of an aromatic aldehyde, which was converted into an alcohol by reduction with KBH_4. Condensation of the polyene alcohol with the acid chloride of the corresponding porphyrin afforded the molecular systems **36** and **37**.



38

The synthesis of the diad **38**, in which the cartenoid is bound to a chlorophyll precursor—pyropheophorbide *a*, has been described.[42] Compound **38** was obtained from derivatives of the aminocarotenoid and pyropheophorbide *a* by the acid chloride method.

Compounds **24–38** described above are porphyrin-carotenoids with a flexible covalent bond. The appreciable conformational mobility of such systems gives rise to certain complications in photochemical studies and investigators have therefore endeavoured to create rigidly bound structures.



Model compounds in which the carotenoid is bound to the porphyrin by a rigid aromatic spacer have been described.[43,44]

39–42

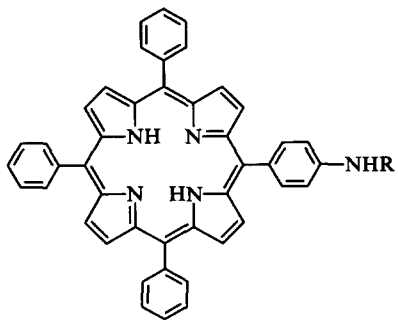
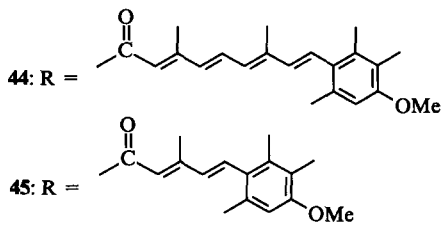
42: $R^1 = R^3 = X$; $R^2 = H$; $n = 1$.

X =

Compounds **39–42** have been synthesised in accordance with Scheme 3. Condensation of 3,3′-diethyl-4,4′-dimethyl-2,2′-dipyrrolylmethane **10**, 7′-apo-7′-(4-formylphenyl)-β-carotene **43**, and 4-methylbenzaldehyde with dichloroacetic acid and subsequent oxidation of the reaction mass with *p*-chloranil led to the porphyrin-carotenoid **39** in 95% yield.



Scheme 3



Compounds **40** and **41** were synthesised similarly in 50% and 15% yields respectively. The biscarotene-porphyrin **42** was obtained in 67% yield by condensing compounds **10** and **43**.[43]

The study of the properties of porphyrin-carotenoids has been continued[45] using the aromatic derivatives of retinoic acid, differing in the length of the conjugated bonds, as the polyenes.

The porphyrin-carotenoids **44** and **45** (see following page) were synthesised in 51% and 68% yields respectively from 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin and aromatic derivatives of retenoic acid by the mixed anhydride method using ethyl chloroformate as the activating agent.[45]

44, 45

b. Photochemical studies

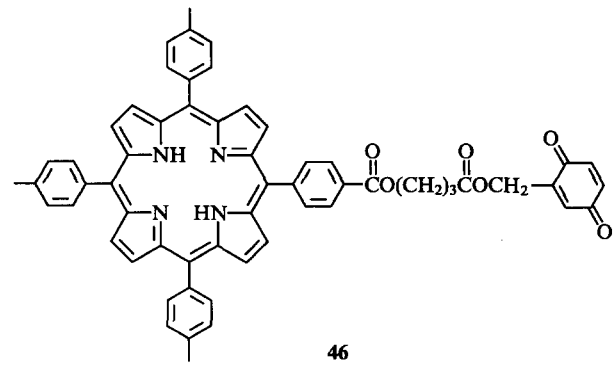
Not only the porphyrin but also the carotenoid is excited by light. One of the functions of the carotenoid—that of an antenna—consists in the absorption of light and the singlet–singlet energy transfer to the porphyrin.

Such intramolecular energy transfer has been detected[43] for compounds **39** and **40** from fluorescence spectra. It was noted that in tetrahydrofuran (THF) ~30% of the excitation energy absorbed by the carotenoid is transferred to the porphyrin. In the porphyrin-carotenoid diad, the fluorescence lifetime (840 ps) is appreciably reduced compared with the porphyrin H_2P (10^4 ps), indicating the existence of an additional path to the decomposition of the singlet-excited state (^1P_e) in the carotenoid-containing system. A possible explanation of this effect may be electron transfer from the carotenoid to the excited state of the porphyrin with the appearance of a short-lived charge-separated state in the form $Car^{\cdot+}-P^{\cdot-}$. If this is so, then the charge-separated state should return very rapidly to the initial state, since the spectrum of the carotenoid radical-cation is not observed even over a time interval ranging from several picoseconds to several nanoseconds.[43,46,47]

A similar phenomenon has been noted in the covalently bound porphyrin-carotenoid compounds **24**–**37**. Thus the main manifestation of the decomposition of compound **24** accompanied by fluorescence is a decrease in the fluorescence lifetime to 3.4 ns. The study of compound **24** showed that the transfer of the energy of the singlet state takes place within the limits of 10%. This relatively small amount of energy is indeed quite appreciable, since the lifetime of the excited singlet state of the carotenoid is usually several picoseconds owing to the rapid internal conversion. The successful simulation of the function of the carotenoid antenna in compound **24** is due to the interaction between the chromophores as a result of the partial overlap of the π-electron systems of the carotenoid and the porphyrin through the amide bond and the aromatic ring. In other carotenoid-porphyrin systems, a high efficiency of the energy transfer was found. For example, in compound **37** the efficiency of the singlet–singlet energy transfer is about 25%. Such high efficiency is due to the disposition of the carotenoid chain over the porphyrin in such a way that the two π-electron systems can interact with one another (within the limits of ~4 Å).[6]

The reaction centre in the photosynthetic process may be protected against decomposition by singlet oxygen, which is generated by the triplet states of chlorophylls or porphyrins. The energy transfer from the triplet state may be investigated with the aid of laser flash spectroscopy: the maximum of the porphyrin triplet absorption is at ~440 nm, whereas the absorption maximum for the carotenoid is in the region of ~540 nm. The rapid and effective transfer of the energy of the triplet state from the porphyrin to the carotenoid requires an electron exchange mechanism. In the case of compound **24** the transfer is facilitated further by the partial conjugation between the chromophores. In the porphyrin-carotenoid systems, where there is a deficiency of such conjugations, a rapid triplet transfer can nevertheless occur through a series of conformations where the π-electron systems are in contact (compound **37**).[6]

There exist two different paths for the triplet–triplet energy transfer, which probably occurs via an electron exchange mechanism: a static transfer which does not require appreciable intramolecular motion, and dynamic transfer associated with intra-molecular changes. The relative importance of the triplet energy transfer via these pathways depends on the molecular structure. The photochemical and photophysical conditions for the protection of the reaction centre against damage by singlet oxygen both in photosynthetic systems and biological organisms are determined by them.[37]



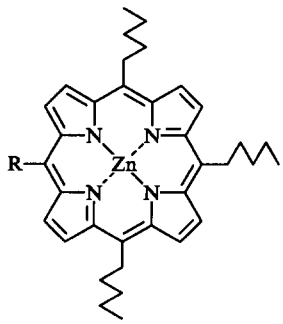
The energy transfer process has also been detected in the model compounds **44** and **45**. It was noted that the efficiency of the energy transfer increases with the length of the polyene chain from 33% to 55% on passing from system **45** to system **44**.[48,49]

Finally, most of the molecular diads obtained to simulate the photosynthesis electron transfer process are covalently bound porphyrin-quinone systems.

3. Porphyrin-quinone systems

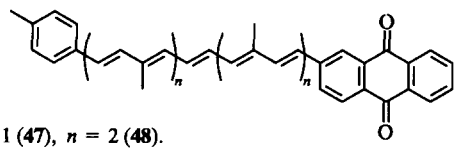
a. Methods of synthesis

One of the first compounds of this type described was the porphyrin-quinone **46** obtained by condensing *meso*-(*p*-carboxylphenyl)tritolylporphyrin with substituted dimethoxybenzene and subsequent dimethylation and oxidation of the hydroquinone.[50]



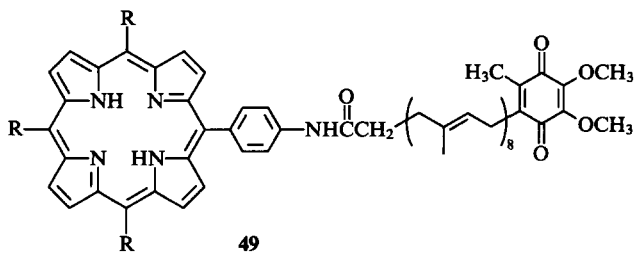
46

Data obtained by laser flash photolysis and EPR spectroscopy showed this compound can assume a conformation in which electron transfer from the porphyrin to the quinone occurs.[1,50]



Data have been published[51] concerning two zinc complexes of the porphyrin-polyene-anthraquinone compounds **47** and **48** having five and nine double bonds between the donor and the acceptor (see over). The 'centre-to-centre' distance between the porphyrin and the quinone in these molecules is 25 Å for compound **47** and 35 Å for compound **48**.

Recent experiments have shown[6] that carotenoids usually act only as energy transfer agents in photosynthesis, although under unusual conditions there may be electron transfer from the carotenoids. However, it is believed[51] that the low electronic energy state of the polyenes can be used to create artificial photosynthetic systems which use the polyene as molecular 'conductors' to facilitate the electron transfer between the donor and the acceptor.



Compound **49**, containing a ubiquinone derivative, has been synthesised from 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin in order to study the photoinduced electron transfer.[52]

47, 48

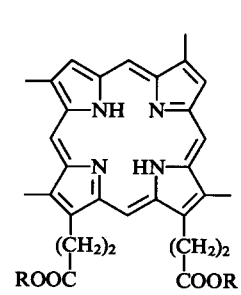
R = 

n = 1 (47), n = 2 (48).

49

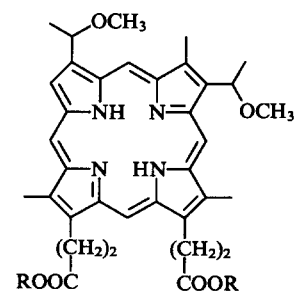
R = C_6H_5.

Ubiquinones — 2,3-dimethoxy-5-methyl-6-polyprenylbenzoquinones — are most important factors in cell metabolism; they play a significant role in the cell bioenergetics and also in the photosynthetic process.[4, 53, 54]



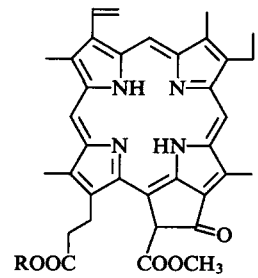
The addition of 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin to the ubiquinone acid Q_8 has been achieved by the mixed anhydride method using ethyl chloroformate (yield 5%).[52]

The natural porphyrins **50–52** — deuterioporphyrin IX, haematoporphyrin IX, and pheophorbide *a* linked to a quinone by an ester bond — have been used to synthesise porphyrin-quinone compounds.[55–57] An interesting feature of these systems consists in the fact that the quinone structure in them is linked directly to the heteroatom (nitrogen and sulfur). This is due to the strategy used in the synthesis. At the same time, there is a possibility of elucidating the influence of the heteroatom on the photochemical electron transfer reaction and the dark charge recombination.

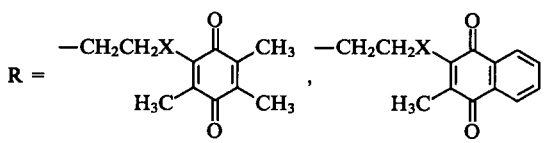


The length of the covalent chain between the quinone and porphyrin components corresponds to 5 or 7 atoms. The change in the distance between the chromophores makes it possible to determine the dependence of the degree of interaction between donor and acceptor and of the efficiency of the photoinduced charge separation on the distance: an increase in the length of the covalent chain under these conditions increases the lifetime of the separated charges, hindering their recombination.[6, 58]

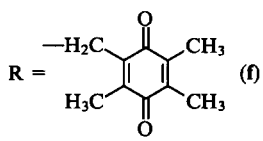
Hydroxylated quinone derivatives have been obtained by adding 2-mercaptoethanol, 2-aminoethanol, and 3-aminopropanol to 2-methylnaphthoquinone and 2,3,5-trimethylbenzoquinone.



An advantage of this method of synthesis lies in the fact that the conditions in the modification of the quinone component and in its condensation with the porphyrin structure make it possible to employ unsubstituted quinones, reducing the total number of stages and simplifying the synthesis of the porphyrin-quinone derivatives.



50



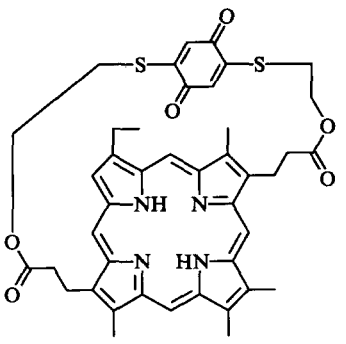
51

52

R = 

X = CH_2 (a), S (b), NH (c). X = S (d), NH (e).

R =  (f)



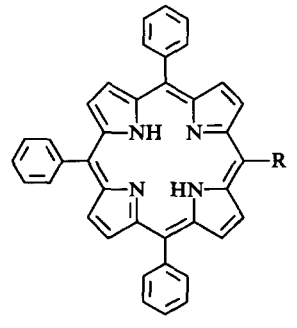
Condensation of hydroxylated quinones with porphyrins using di-*tert*-butyl pyrocarbonate (Boc_2O) and 4-dimethylaminopyridine (4-DMAP) leads to the formation of the diquinone derivatives **50–52** in satisfactory yields.[55–57]

However, the presence of a flexible covalent bridge in compounds **50–52** is responsible for their considerable conformational lability on exposure to external factors, which makes it difficult to explain the experimental data on electron phototransfer in such systems. The creation and study of model structures with a molecular geometry known beforehand therefore becomes important.[7, 59, 60]

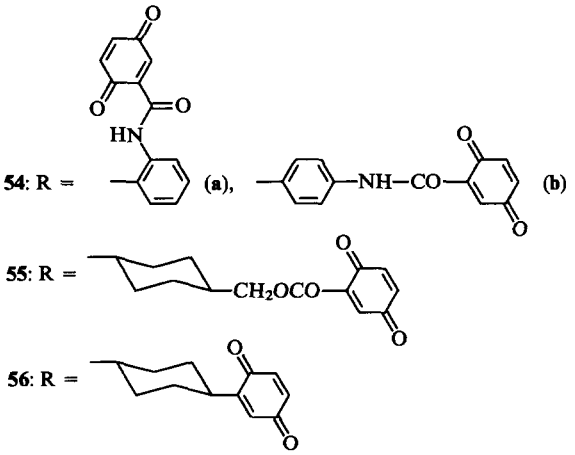
One of the aspects of studies in this field involved the construction of models in which the quinone was strictly oriented over the centre of the porphyrin ring — the so called 'covered' porphyrins. The advantage of such model compounds arises from the possibility of monitoring during the synthetic process the relative oxidation-reduction potentials of the fragments, the distance between them, and their mutual orientation.[7]

Such a 'covered' porphyrin-quinone has been obtained from the symmetrical mesoporphyrin II and a quinone with two hydroxy-groups.[61]

In order to synthesise the 'covered' porphyrin-quinone **53**, a method was developed to obtain the bifunctional sulfur-containing electron-accepting component – 2,5-di-(2-hydroxyethylthio)-1,4-benzoquinone (DHEP). Condensation of the acid chloride formed when the mesoporphyrin II is treated with oxalyl chloride with DHEP affords the required compound **53**.



53

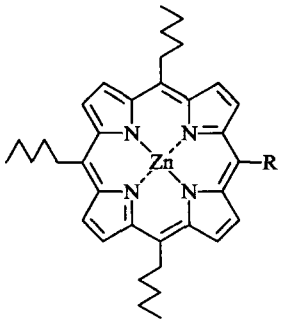


Compound **53** differs from the porphyrin-quinones known in the literature[7,59,60,62–65] by the presence of a sulfur atom linked directly to the quinone structure, which influences significantly the efficiency of the photoinduced transfer process.[61]

Another aspect ensuring the rigidity of the structure is the creation of models with a fixed distance between the porphyrin and the quinone. The synthesis of a compound meeting this requirement has been described.[66]

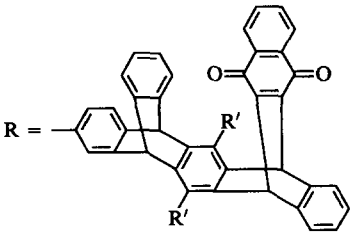
The mono-*o*-aminotetraphenylporphyrin, obtained by the Rothenmund reaction using pyrrole, benzaldehyde, and *o*-nitrobenzaldehyde with subsequent reduction of the nitro-group to the amino-group, was condensed with the chloride of 2,5-diethoxybenzoic acid. After selective hydrolysis and oxidation of the hydroquinone to the quinone with lead dioxide, the porphyrin-quinone **54a** was isolated.

54–56



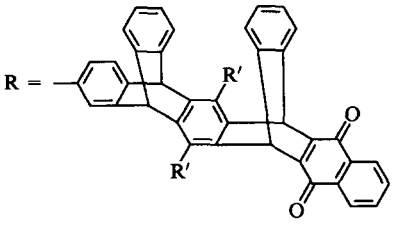
Another approach to the synthesis of a similar compound **54b** has been proposed.[67,68] Mono-*p*-aminotetraphenylporphyrin was made to react with acetylated gentisic acid in the presence of the ethyl ester of 2-ethoxy-1,2-dihydroxyquinoline. The protecting groups were then removed in a methanol solution of hydrochloric acid and the hydroquinone system was oxidised with lead dioxide to the quinone system (compound **54b**).

The porphyrin-quinone model compounds **55** and **56** have also been described.[67]



The Rothenmund condensation of pyrrole, benzaldehyde, and *trans*-4-(hydroxymethyl)cyclohexanaldehyde affords a hydroxylated porphyrin, the esterification of which with acetylated gentisyl chloride and subsequent removal of the protecting groups from the quinone component and oxidation of the hydroquinone system with lead dioxide lead to compound **55**.

In the synthesis of the porphyrin-quinone **56**, the monoester of cyclohexane-1,4-dicarboxylic acid was bound to *p*-benzoquinone by oxidative decarboxylation. After the substitution of the corresponding hydroquinone by treatment with sodium dithionite and reduction of the ester group with diisobutylaluminium hydride, the aldehyde was obtained. The latter reacts with pyrrole and benzaldehyde in the presence of atmospheric oxygen to form the required compound **56**, in which the porphyrin and quinone halves of the compound are connected by a rigid spacer.

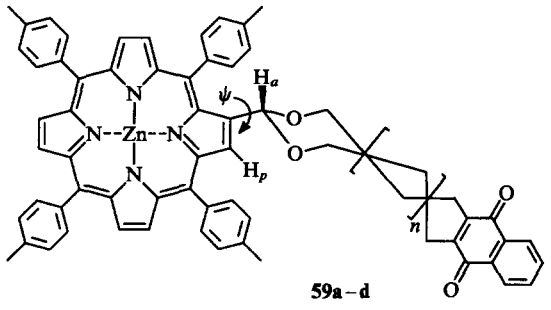


The four porphyrin-quinone compounds *syn*- and *anti*-**57** and *syn*- and *anti*-**58** with a fixed distance between the donor and the acceptor were synthesised to obtain information about the dependence of the electron transfer between the chromophores on the orientation of the quinone component.[69]

57, 58

R′ = H (*anti*-**57**), OCH_3 (*anti*-**58**).

R′ = H (*syn*-**57**), OCH_3 (*syn*-**58**).



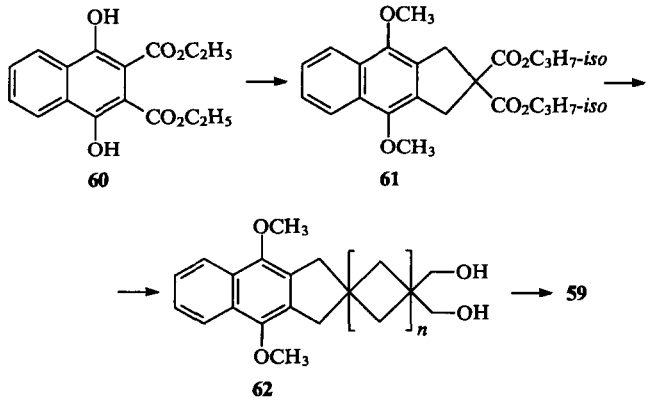
A hydrocarbon spacer—pentiptycene—was used to maintain a fixed distance and to restrict the spatial mobility between the porphyrin and the quinone in compounds **57** and **58**. The reasons for using this rigid system as a spacer are as follows: firstly, it is related to the thoroughly investigated triptycene spacer;[60,70,71] secondly, the presence of two

positional isomers, in which the porphyrin and the quinone are in the '*syn*'- or '*anti*'-positions relative to one another, makes it possible to investigate the dependence of the photoinduced electron transfer over a fixed distance on the orientation; thirdly, the presence of the central benzene ring, rigidly bound to two triptycene bridges, makes it possible to introduce substituents into the remaining free positions in this ring and to alter the influence of the ionic states of the spacer on the 'superexchange' electron transfer process.[69]

The Diels-Alder condensation of the reduced anthraquinone with the quinone and formylation of the naphthoquinone-pentiptycene derivative obtained afford a mixture of '*syn*'- and '*anti*'-aldehydes, which enter into the Lindsay reaction with 1-hexanal and pyrrole to form *syn*- and *anti*-**57** in an overall yield of 2.9%.

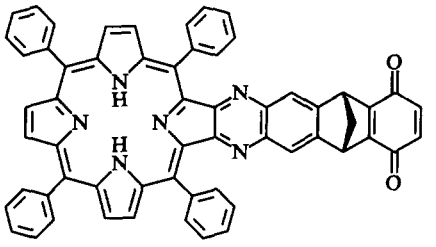
In order to obtain *syn*- and *anti*-**58**, anthracene was made to undergo the diene condensation with *p*-benzoquinone followed by hydrogenation of the diketone, the reaction of which with *o*-phthalaldehyde afforded 1,4-anthraquinone. The subsequent stages in the reduction of 1,4-anthraquinone to the hydroquinone and treatment with an excess of dimethyl sulfate led to the formation of the 1,4-dimethoxyanthracene derivative in 75% yield. Condensation of the latter with naphthoquinone and subsequent formylation gave rise to a mixture of the corresponding aldehydes required for the synthesis of *syn*- and *anti*-**58**. The yield of the isomers is 4.8%. The *syn*- and *anti*-isomers were separated as the corresponding zinc complexes by preparative thin-layer chromatography on silica gel.[69]

The rigid spirocyclic spacer[72] in the models **59a–d** controls the 'edge-to-edge' distance between the porphyrin and the quinone and reduces to a minimum the complications in the interpretation of the experimental data induced by the rotational degree of freedom of the porphyrin-acetal linkage (the angle ψ).



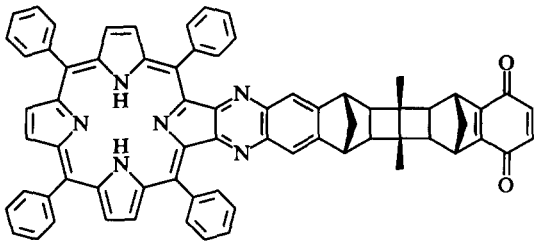
59a–d

n = 0 (**a**), 1 (**b**), 2 (**c**), 3 (**d**).



Compounds **59a–d** were synthesised in accordance with Scheme 4.

Scheme 4

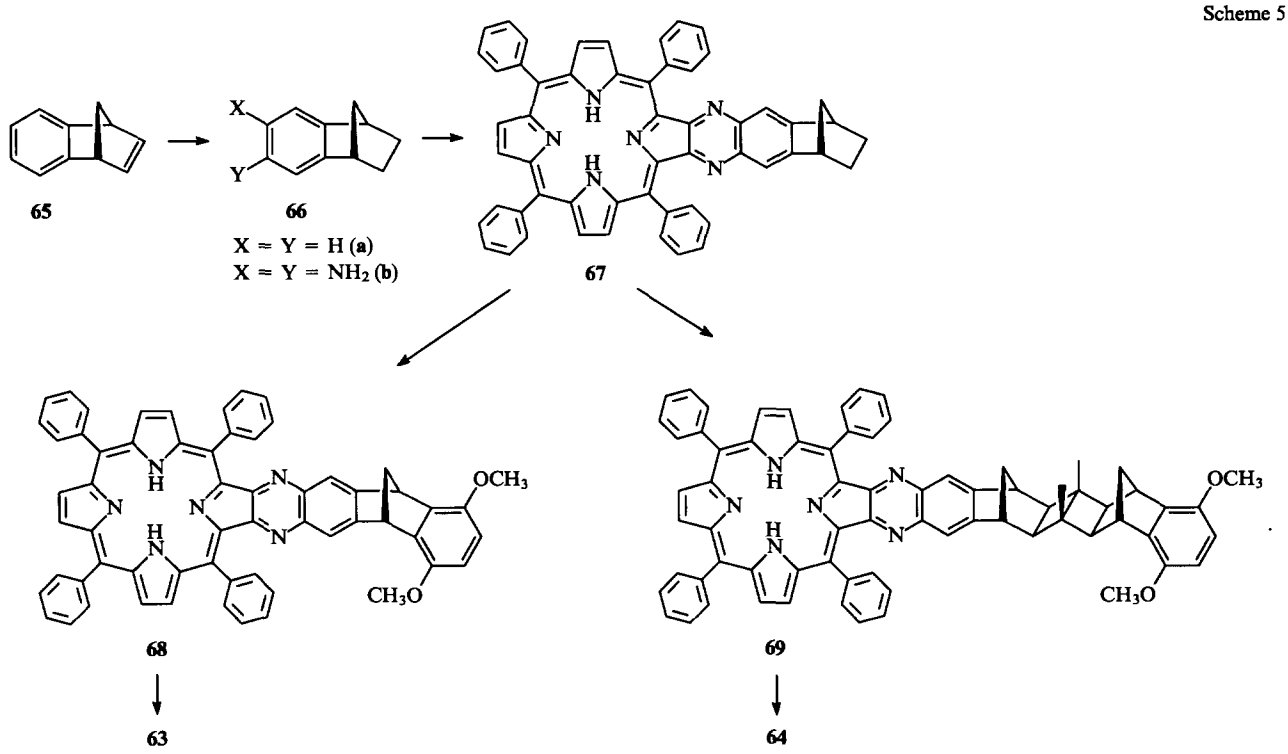


The diester **60** was treated with methyl iodide, reduced to the diol, and converted into the dichloro-derivative, which was cyclised and the resulting diisopropyl diester **61** was converted into compound **62**. The 1,4-dimethoxynaphthalene derivative **62** was oxidised to the corresponding naphthoquinone diol and condensation of the latter with 1-(dimethoxymethyl)tetra-tolylporphyrin afforded compound **59**.

The porphyrin-quinones **63** and **64**, in which the connecting bridge not only fixes rigidly the 'centre-to-centre' distance between the chromophores, amounting to 11.6 Å for compound **63** and 16.2 Å for compound **64**, but also, in contrast to other spacers, excludes the rotational degree of freedom of the quinone component, have been described.[73]

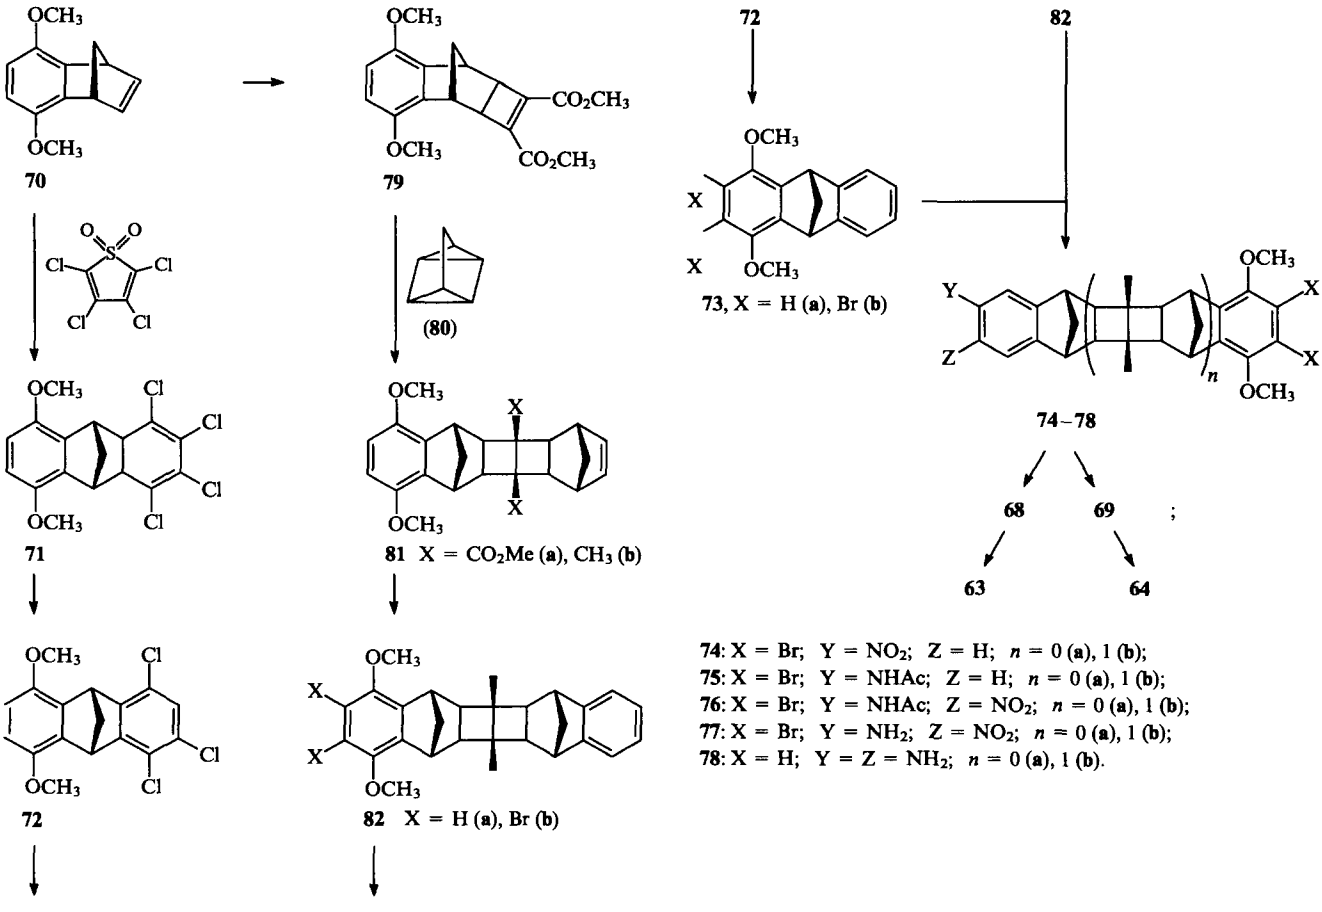
63

64



Two methods of synthesis of compounds **63** and **64**, differing in the sequence of operations, have been developed.[74]

The synthesis was begun with benzonorbornadiene **65** to which the porphyrin group was attached through the series of stages presented in Scheme 5.



Compound **65** was initially reduced to compound **66a**, the nitration and subsequent reduction of which afforded the unstable diamino-compound **66b**. The latter was immediately treated with 17,18-dihydroxy-5,10,15,20-tetraphenylchlorin and compound **67** was obtained. The subsequent transformation of compound **67** led to the dimethoxybenzene derivatives **68** and **69**, from which the required porphyrin-quinones **63** and **64** were synthesised.

The other approach to the synthesis of such porphyrin-quinones is illustrated in Scheme 6. The key compound in this synthesis is 5,8-dimethoxybenzonorbornadiene **70**, the treatment of which with tetrachlorothiophene dioxide led to compound **71**. The dehydrohalogenation of the latter under standard conditions afforded compound **72**, the subsequent reductive dechlorination of which gave rise to the product **73a**. The protecting groups were introduced into the dimethoxybenzene ring of compound **73a** by bromination, which yielded compound **73b**. The subsequent synthetic stages presented no problems. Nitration of compound **73b** with copper nitrate led to compound **74a**, the reduction of which with zinc acetate afforded compound **75a**. The latter was subjected in its turn to nitration ($HNO_3-AcOH-Ac_2O$) with formation of compound **76a**, the treatment of which with hydrazine hydrate yielded compound **77a**. Compound **77a** was converted into compound **78a** in one stage using hydrazine hydrate and Pd/C in ethanol. The reaction of compound **78a** with the α-dione (17,18-dioxo-5,10,15,20-tetraphenylchlorin) led to compound **68** in 82% yield.

Scheme 5

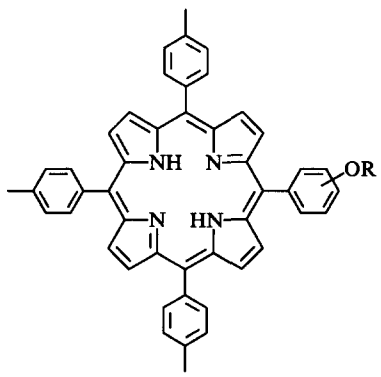
Scheme 6

The following synthetic transformations were carried out in order to obtain compound **82a** from compound **70**. The ruthenium-catalysed cyclisation reaction between compound **70** and dimethyl acetylenedicarboxylate (DMAD) afforded the adduct **79**, which was subjected to a further cyclisation reaction with the quadricyclane **80**. The product **81a** was subsequently converted into compound **81b**. Further transformations were similar to those described above for the synthesis of compound **78a**. In the concluding stage, the dimethoxy-derivative **69**, synthesised from compound **78b**, was converted into the required porphyrin-quinone **64** in 62% yield.[74]

During the subsequent several years, it was shown that the rigidly bound polynorbornylenebicyclo[2.2.0]hexyl systems have a series of exceptional advantages over other hydrocarbon bridges usually employed. Firstly, the norbornyl spacer is extremely effective, which was demonstrated by numerous photoelectron and picosecond absorption spectroscopic studies. It was predicted that the intramolecular electron transfer in these systems should be especially rapid. This was subsequently confirmed. Secondly, the overall rigidity of the polynorbornylenebicyclo[2.2.0]hexyl spacers completely rules out any conformational uncertainties between the chromophores. Consequently, these spacers make it possible to achieve specific orientations and distances between the porphyrin and the quinone. Thirdly, and this is the most important advantage, there is a possibility of adding a series of chromophore rings, including benzenes, naphthalenes, anthracenes, pyrimidines, and pyrazoles, to both ends of the spacers.[73]

As already mentioned above, much attention is being devoted nowadays to the study of the role of the spacer connecting the donor and the acceptor.[23,24,69] It has been shown[73–75] that saturated hydrocarbon spacers effect electron transfer at a high rate between the oxidation-reduction sections similar to those found in the photosynthetic unit.

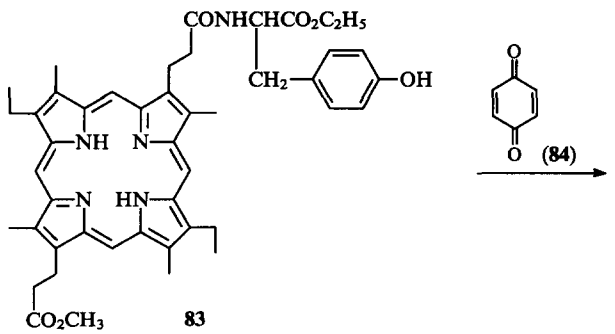
It has been suggested[69] that aromatic aminoacids, such as tyrosine, phenylalanine, and tryptophan, located between the electron donor and acceptor in proteins, can also accelerate the electron transfer reactions.



Osuka and Maruyama's study[76] is part of a research program designed to investigate the role of the aminoacid residues in biological electron transfer reactions in model compounds incorporating a porphyrin. Tyrosine was chosen among the aminoacids because it has been postulated that it performs the functions of both an electron and a proton donor.

The porphyrin-tyrosine **83** was obtained by condensing the acid chloride of the monomethyl ester of mesoporphyrin II with the ethyl ester of L-tyrosine (yield 96%). Irradiation of the porphyrin-tyrosine **83** in the presence of benzoquinone **84** in benzene by light at a wavelength > 590 nm under an argon atmosphere led to the formation of the adduct **85** in 75% yield (Scheme 7).[76]

Quinone-substituted porphyrins have been generally recognised recently as models of the primary electron transfer in the photosynthetic process. However, despite the vigorous investigation of the photoinduced electron transfer reactions between the porphyrin and the quinone, there have been only a few studies of synthetic interest.[77]



A highly effective synthesis of porphyrin-quinones, based on the self-photosensitisation of the porphyrin, has been reported.[64,76,77] The proposed method of synthesis has a number of advantages: firstly, it does not require the protection of the quinone groups and, secondly, different quinones, with a wide range of electrochemical and stereochemical properties, may be used.

Irradiation of hydroxyphenylporphyrin in the presence of benzoquinone or naphthoquinone (λ > 590 nm, Ar) in chloroform affords the quinone-substituted porphyrins **86a,b** or **87a,b** respectively.[77] The wavelength λ > 590 nm and the absence of air in the reaction solution are decisive factors for the high yield of the porphyrin-quinone compounds. Compounds **88a–c** and **89a–c** have been obtained similarly.[64]

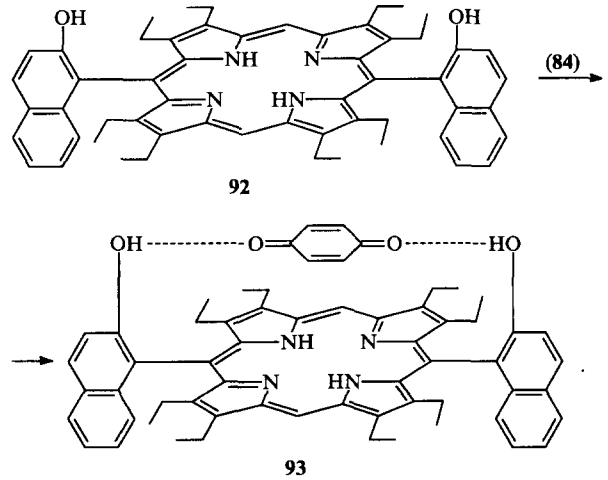
A multiplicity of covalently bound porphyrin-quinone derivatives have been synthesised to be used as models of the photoinduced electron transfer.

An alternative approach to the photosynthetic modelling includes the synthesis of supermolecular aggregates which are not covalently bound. The multichromophore structures of the photosynthetic reaction centres or light-absorbing antenna aggregates may serve as examples of such non-covalent binding in natural systems.



This new approach to the construction of photochemically active systems is simpler than that described above and based on the formation of covalent bonds between the chromophores.[78] The synthesis of the new noncovalently bound photosynthetic system **90**–**91** has been described recently.[79]

When the guanine and cytosine derivatives are mixed in methylene chloride, the formation of hydrogen bonds between the complementary bases is observed. The subunits of the assemblies formed in this way assume different conformations and the 'edge-to-edge' distance between them does not exceed 20 Å.

The rate constants for the binding of the guanine and cytosine derivatives in methylene chloride have been determined by ^{1}H NMR spectroscopy (k = 3100 ± 470 mol^{-1}). The 'coated' porphyrin-quinones, obtained as a result of the non-covalent binding, have been described by Aoyama et al.[80]

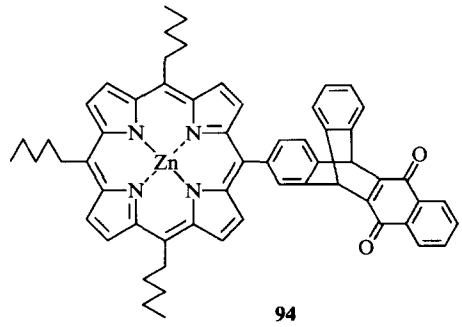
5,15-*cis*-Bis-(2-hydroxy-1-naphthyl)octaethylporphyrin **92** in chloroform binds selectively benzoquinone **84** with formation of the symmetrical adduct **93** of the 'face-to-face' type via hydrogen bonds (Scheme 8).

Scheme 8

92 93

The noncovalent binding used to construct porphyrin-quinones of the 'face-to-face' type is free from synthetic difficulties and the yield of complex **93** can reach 100% when a large excess of the quinone and a low temperature are used. It is noteworthy that the four free positions in the initial benzoquinone make it possible to obtain a whole series of derivatives with functional group substituents, which permits the modification of the electronic and steric structures of the quinones.[80]

Scheme 8 constitutes an extremely simple procedure for the synthesis of porphyrin-quinone compounds. On the basis of these results, one can postulate that the combination of the individual components into a single system via hydrogen bonds constitute a new and important strategy for the construction of biologically important structures[78] and in general of molecular aggregates with functional group substituents.[79,80]



b. Photochemistry of the porphyrin-quinone compounds

In the first studies on the synthesis of porphyrin-quinone compounds, attempts were made to investigate their photochemical properties.

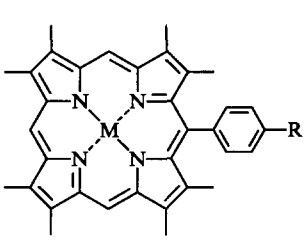
In the system **46** described, tetraphenylporphyrin plays the role of chlorophyll (an electron donor), while the quinone plays the role of the electron acceptor.

Important information about the photochemical processes occuring in porphyrin-quinone compounds can be obtained from the emission spectra. The fluorescence spectra of the derivatives **50a**–**f** and **51a**–**f** do not differ from the spectra of the initial porphyrins, but in their case an intense quenching of the fluorescence of the porphyrin is observed. The relative fluorescence quantum yield of the diquinone derivatives is 4%–5%. Such quenching of the fluorescence, which is characteristic of covalently bound porphyrin-quinone compounds, is a consequence of the photoinduced electron transfer from the porphyrin to the quinone.[55,56]

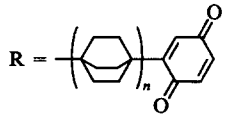
The introduction of the pentiptycene spacer between the porphyrin and the quinone in compounds **57** and **58** diminishes both the charge separation and charge recombination rate constants by a factor of ~10 compared with those observed for compound **94**.

94

The 'edge-to-edge' distance between the π-systems of the porphyrin and the naphthoquinone in compounds **57** and **58** is ~6 Å, while the corresponding distance in the porphyrin-quinone **94** is ~2.4 Å and, although the donor–acceptor distance has increased by 3.6 Å on passing from compounds **94** to compounds **57** and **58**, the presence of the benzene ring and of the unsaturated carbon atoms in the peptiptycene spacer in compounds **57** and **58** reduces the rate of electron transfer in these systems by more than an order of magnitude, which was in



fact expected on passing from the spacer with one saturated carbon atom (compound **94**) to a spacer with two such atoms (compounds **57** and **58**).



The electron transfer reactions involving the excited state and the recombination of the ion pair in the porphyrin-quinone compounds **57** and **58** exhibit an appreciable dependence on the orientation: the ion pair recombines twice as fast in the *anti*-isomers as in the *syn*-isomers. Such dependence on the orientation has also been observed for the fluorescence lifetimes of these compounds. Taking into account the nature of these dependences, one can postulate that the electron transfer is effected through the bonds of the rigid hydrocarbon spacer.[69]

A similar conclusion has also been reached by Antolovich et al.[73] The observed and theoretically predicted ability of the spacers to promote the electron transfer diminishes in the sequence spirocycles > bicyclo[2.2.2]octanes > alkanes. This result confirms the fact that the electron transfer over large distances in the porphyrin-quinone systems takes place through the hydrocarbon bonds of the spacer.[60,72]

As already stated above, the natural chromophores participating in the main stages of the photosynthetic electron transfer are represented by the special pair $BChl_2$, the excited electronic state of which transfers an electron to pheophytin in the first stage of the process at a rate of $\sim 3 \times 10^{11}$ s^{-1}, while in the second stage the charge is transferred from pheophytin to the quinone at a rate of $\sim 4 \times 10^9$ s^{-1}. It is assumed that this natural donor–acceptor pair is simulated in the second stage of the photosynthesis process by the porphyrin-quinone molecules connected by the spacer.[73] However, in only a few of the model compounds are the distance between the chromophores and the orientation of the latter similar to those in the natural photosynthetic unit.

One of the model compounds in which the spacer ensures a suitable 'centre-to-centre' distance is system **95**.[75]

95, 96

n = 1 (**95**), 2 (**96**)
M = 2H (**a**), Zn (**b**)

Compounds **95a,b** with a strong octaalkylporphyrin donor exhibit[73] high rates of charge separation in different solvents, reaching 1.25×10^{10} s^{-1}.

It is of interest to note that the rates of the photoinduced intramolecular electron transfer in the model system **95b** can exceed the rate of electron transfer from pheophytin to the quinone (4×10^9 s^{-1}) in the photosynthetic unit. Investigators attribute this to the fact that the spacer in compound **95** contains the *p*-phenylene π-system conjugated with the porphyrin. The degree of this conjugation is compensated by the marked rotation about the bond connecting these halves, which hinders the determination of the 'edge-to-edge' distance between the donor and the acceptor systems.[73] The increase in this distance and in the 'centre-to-centre' distance in compound **95** as a result of the introduction of a second bicyclooctane unit into the spacer[75] led to compound **96** in which the rate of electron transfer was found to be $< 10^7$ s^{-1}.

The results of a study of the porphyrin-quinone systems **63** and **64** have been reported.[73] This is yet another part of the studies of electron transfer over long distances. The distance (16.2 Å) between the chromophores attained in compound **64** and its zinc complex greatly exceeds the 'centre-to-centre' distances in compound **95** and **96** and in the photosynthetic BChl unit between the pheophytin and quinone halves (13–14 Å), whereas the angle between the normals to the chromophores is 40°–45° (established from extrapolated crystal structure data), which is comparable to the values for the natural systems (35° ± 6°). The rates of electron transfer in compound **95** are comparable with those obtained for compound **64** despite the greater number of saturated bonds and the greater distance in space between the chromophores, which is probably associated with the structures and configurations of the hydrocarbon spacers employed.[73] Thus the rate of charge separation in system **95** was found to be 3.7×10^7 s^{-1} in propionitrile,[75] which is comparable with the rate 3.6×10^7 s^{-1} for compound **64** in acetonitrile.[73]

The results obtained by Antolovich et al.[73], confirm and expand the data of Joran et al.,[75] who demonstrated the possibility of attaining high rates of charge separation ($> 10^9$ s^{-1}) between the porphyrin and quinone components with the aid of saturated bonds.

The system **90–91**, in which the effective specific electron transfer over long distances takes place through hydrogen bonds, has been considered.[79] In methylene chloride, the fluorescence of the porphyrin **90** is quenched following the addition of large amounts of compound **91**. The fluorescence quantum yield of compound **90** falls with increase in the concentration of compound **91** to 35%.

The binding constant for compounds **90** and **91** is 1290 ± 230 mol^{-1}, while the electron transfer rate constant is $k = (4.2 \pm 0.7) \times 10^8$ s^{-1}. These values correspond to electron transfer through bonds over a distance of 12 Å, which follows from the interpolation of data for porphyrin-quinone compounds bound covalently via a spacer.[74]

The porphyrin-quinone compound **93**, described by Harriman et al.,[79] has a 3 Å separation of the 'face-to-face' type and, as shown by UV spectroscopy, exhibits the porphyrin-quinone π–π-interaction. It was found that the fluorescence of the porphyrin-quinone **93** is fully quenched by effective electron transfer with the complex. The authors concluded that the ability of quinones to quench the fluorescence of the porphyrin **92** is determined not by their oxidation-reduction properties but by the degree of binding of the quinone to compound **92**.

4. Porphyrin compounds bound covalently to aminoacid residues — tyrosine and tryptophan

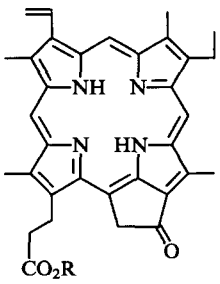
Much attention is being devoted nowadays to the study of the role of aromatic aminoacids, especially tyrosine (Tyr) and tryptophan (Trp), in the photosynthetic process. It was established previously that, together with other aromatic aminoacids, tyrosine influences the conformation of the protein component of the photosynthetic pigment,[81,82] but tyrosine began to be considered as an electron donor only in recent years.[34,82–86]

It has been shown that in the case of the photosystem II a further two cofactors, called Z* and D*, participate in the photosynthetic process in addition to chlorophyll. A series of studies[83,84,87,88] showed that the tyrosine radicals participating in electron transfer from the water-cleaving manganese-protein complex to the photochemically oxidised radical-cation P_{680}^+ are the Z* and D* cofactors. The spectroscopic characteristics of the tyrosine radicals Z* and D* of the photosystem II are being widely investigated at the present time.[89–94]

The study of the tyrosine radicals helped to discover the location of L-Tyr[162] in *Rhodopseudomonas viridis* and *Rhodobacter sphaeroides* — it was found to be located between the special pair and the nearest cytochrome subunit.[84,85,87,95]

As already mentioned above,[69,76] aromatic aminoacids such as Tyr and Trp accelerate the electron transfer reaction between the donor and the acceptor separated by a fairly long distance — via electron binding through the corresponding orbitals.[84]

The study of the mechanism of the photocatalytic decomposition of water made it possible to discover the



participation in this process of the manganese ion[96] located in the proteins of the photosystem II.

It is believed that tyrosine is an electron transfer agent between clusters made up of four manganese atoms in the oxygen complex formed and in the chlorophyll radical-cation P_{680}^{+} of the photosystem II of the green bacteria.[87,88,97,98] Furthermore, tyrosine-containing porphyrins exhibit a biological activity—they have a carcinostatic effect.[85,99]

The zinc complexes of pyrochlorophyllide *a* and bacteriochlorophyllide *a*, containing the methyl esters of the aminoacids Trp and Tyr in the side chain of the macrocycle and capable of being coordinated to the metal and of π–π interaction with the macrocycle, have been synthesised in order to investigate the chlorophyll–protein interactions. It was shown by ^{1}H NMR spectroscopy that, as a result of the above interactions, the aminoacid residues participate in the formation of the dimeric compounds in which the methoxycarbonyl group of the aminoacid is coordinated to the metal. The planes of the macrocycles are parallel and overlap in the rings IV.[82]

Such compounds can also serve as models of the reaction centre of the chlorophyll molecule.[82,100]

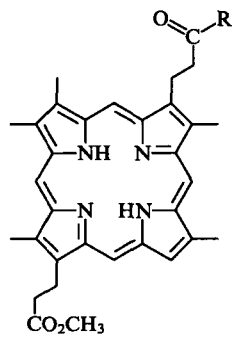
The condensation of the activated ester of pyropheophorbide *a* with a fivefold excess of the methyl esters of L-Tyr or L-Trp leads to the formation of the covalently bound complexes **97a** and **98** containing aminoacid residues (2-chloro-*N*-methylpyridinium iodide in a mixture of methylene chloride and triethylamine was used as the activating agent in the synthesis of the activated ester of pyropheophorbide *a*).[82]

97–99

97: R = NH–CH(CH$_2$–C$_6$H$_4$–OH)–CO$_2$X

X = CH_3 (**a**), C_2H_5 (**b**)

98: R = NH–CH(CH$_2$–3-indolyl)–CO$_2$CH$_3$



99: R = NH–CH(CH$_2$–C$_6$H$_4$–O–C$_6$H$_3$(=O)$_2$)–CO$_2$C$_2$H$_5$

Compounds **97b** and **98** were synthesised by the method described[83] (59% and 55% yields respectively) in order to carry out further investigations.[87,101]

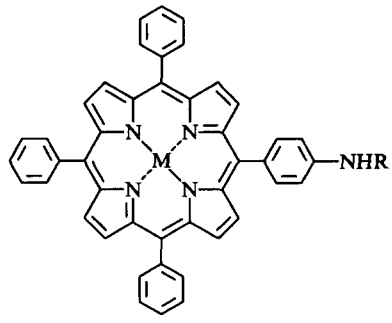
Irradiation of compound **97b** in the benzene–acetonitrile solvent mixture in the presence of benzoquinone by light at a wavelength in excess of 590 nm under an inert gas atmosphere affords compound **99** in 56% yield, the yield depending on the quinone concentration. This concentration dependence clearly indicates that compound **99** is formed as a result of the quenching of the triplet state of pyropheophorbide-tyrosine **97b** by benzoquinone **84**. This reaction is similar to the photochemical reaction of tyrosine-mesoporphyrin II **83** with benzoquinone.[76,87,95]

Irradiation of compounds **98** and **84** under identical conditions did not yield a photochemical product.[87]

On the other hand, pulsed irradiation (0.3 s) of a solution of compounds **100a** and **84** in deuteriobenzene at 514 nm from an argon laser in the tube of a ^{1}H NMR spectrometer (400 MHz) under an inert gas atmosphere affords compound **100b** in 8% yield.[101]

100

R = NH–CH(CH$_2$–3-indolyl)–CO$_2$CH$_3$



X = H (**a**), 1,4-benzoquinone (**b**)

Tyrosine-containing porphyrins have been synthesised from 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin and di-(*tert*-butoxycarbonyl)-protected tyrosine in order to create subsequently photosynthetic model systems and to investigate their biological activity.[102]

In this case tyrosine adds to the amino-group of the porphyrin and not to the carboxy-group, as described in other studies.[76,82,87,95,101]

Two methods were used to synthesise compound **101**. The mixed anhydride method using isobutyl chloroformate as the anhydride-forming agent (the yield of tyrosylporphyrin was 26.6%) and the *N,N'*-dicyclohexylcarbodiimide method (yield 80%).

Trifluoroacetic acid was used to remove the protecting groups from tyrosylporphyrin **101** and compound **102a** was obtained in 92.5% yield.

101, 102

101: R = NH–CH(CH$_2$–C$_6$H$_4$–OBoc)–CO–NH–Boc

M = 2H

102: R = NH$_2$–CH(CH$_2$–C$_6$H$_4$–OH)–CO–

M = 2H (**a**), Mn (**b**)

Manganese ions were introduced by heating the porphyrin **102a** with manganese acetate and the yield of compound **102b** was 42.8%.[102]

It follows from the foregoing that the porphyrins bound to tyrosine can serve as model compounds for the investigation of the photosynthetic process and, in particular, of the mechanism of the catalytic decomposition of water and also for the elucidation of the role of tyrosine in the natural photosynthetic process, which is at present the subject of scientific discussions.

III. Conclusion

The model compounds presented above have found extensive application in the study of the primary photosynthetic process. Furthermore, they are ideal models for the determination of the main principles of the photoinduced electron transfer.[1,4,7]

Only a small proportion of the enormous amount of work carried out on the study of the natural photosynthetic process is described in the present review. Such research has become possible as a result of the development of methods for the synthesis of complex molecules, for the determination of their structures, and for the investigation of their spectroscopic, photochemical, and photoelectric properties.

IV. Gas-phase thermal stability of yttrium, barium, copper, calcium, and bismuth β-diketonates, used in CVD technology 984
V. Use of CVD technology in the synthesis of high-temperature superconducting films 984

Abstract. We shall examine the fundamental aspects of the chemistry of volatile β-diketonates: the dependence of their volatility on the coordination unsaturation of the complexes, on the structure of the ligands, and on the nature of the metals. The gas-phase thermal stability of the β-diketonates and the structural changes which take place when these compounds are transferred to the gas phase are discussed. The most important results on the synthesis of Y–Ba–Cu–O, Bi–Sr–Ca–Cu–O, and Tl–Ba–Ca–Cu–O by chemical vapour deposition from the gas phase are reported. The bibliography contains 106 references.

I. Methods of preparing epitaxial high-temperature superconducting films

According to recent reports[1] high-temperature superconductors (HTSC) are finding practical applications in thin film form, mainly for the following reason. The best samples of high-temperature superconducting films now being produced have surprisingly high critical current densities. The use of HTSC in thin film form can solve several problems in cryoelectronics. In particular, in devices based on the Josephson effect the required current density (10^2–10^3 A cm^{-2}) can be obtained even with polycrystalline films. Many studies (in particular those based on tunnel spectroscopy, optical methods, etc.) aimed at establishing the physical characteristics of the material and the mechanism of the superconductivity in HTSC have had to be carried out with thin film samples.

The anisotropy of the physical characteristics of the materials is being studied with monocrystalline (epitaxial) HTSC films, of which the best samples have properties closer to those of an ideal crystal than is found in most of the monocrystals now being prepared.[2] Studies of the stability (ageing) of HTSC are also most conveniently carried out with films because chemical or physical instability effects are easily detected in film samples (for example, in studies of the effect of irradiation with high-energy particles on the properties of HTSC). Films are also widely used in the search for new superconductors: in particular, the high-temperature metastable phases NbGe and Nb_3Si have been prepared as thin films.

Uspekhi Khimii **62** (10) 1037–1046 (1993); translated by J I Carasso

Various chemical (as well as physical) methods have been used to prepare HTSC films. According to Schieber[3] the most promising of these is the CVD method (chemical vapour deposition from the vapour phase). The basis of the method is to transport the components of the film to the substrate in the form of the vapours of volatile compounds: the vapours are decomposed on the substrate to give a film of the required composition. Halides, hydrides, or organometallic compounds are used as the volatile compounds; this variant of the method is called MOCVD. The CVD method offers a number of advantages over the PVD (physical vapour deposition) method.

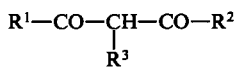
1. The possibility of depositing films of uniform composition and thickness on component parts having a complex configuration. This feature is specially important for HTSC films because it makes possible the production of large current-carrying structures in film form, of magnetic screens, and of other 'nonplanar' components.

2. The possibility of achieving high rates of deposition (up to several micrometres per hour) while maintaining a high-quality product (i. e. while controlling its epitaxial character, density, and crystallinity). In contrast to the physical evaporation methods, in which the need for a high growth rate is met by providing a high-energy flux of particles of the substance to be evaporated, with the consequent danger of decomposing the substrate surface (or the already deposited film), in the CVD method a high production rate is achieved by using a high pressure of the transporting vapour or a high flow rate of the carrier gas.

3. A high reproducibility of the properties of the coatings prepared with constant process parameters.

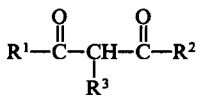
4. Easy control of the process and flexibility in the choice of the technological regime (especially in changes of the chemical composition of the deposit).

5. The possibility of changing from high-vacuum apparatus to assemblies giving a vacuum of 10 Pa or to flow assemblies operating at pressures of 10^2–10^5 Pa.



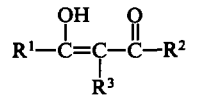
The development of the CVD technology has been fastest in Japan and in the USA. The best samples of HTSC film[4,5] prepared by CVD have been reported from those countries. It should be noted that this type of work is now being carried out, in preference to sustained studies of evaporation in a vacuum by physical methods, in the laboratories of the largest firms active in this field, such as Riken, Nissan Motors, Ori Electronics, Westinghouse, and others. This confirms the favourable prospects of the adoption of the CVD technology in the industrial production of HTSC films.

II. Volatile metal β-diketonates used in CVD technology



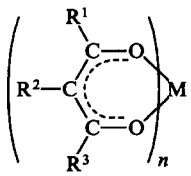
The first and most fundamental problem in the development of the CVD technology is the choice of volatile compounds which satisfy at least the following two requirements: they should have a technologically acceptable vapour pressure and they should pass into the vapour phase (by evaporation or by sublimation) without decomposition, since decomposition of the compound could affect its volatility and thus perturb the constancy of the rate of deposition and of the composition of the film.

In a study of the synthesis of $YBa_2Cu_3O_{7-x}$ the components were transferred through the gas phase as β-diketonates [organometallic chelated complexes having a high volatility at relatively low temperatures (100–300 °C)].



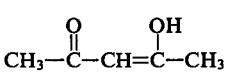
β-Diketones of the general formula

are liquid or solid colourless compounds which exist in two tautomeric forms:



keto form

enol form

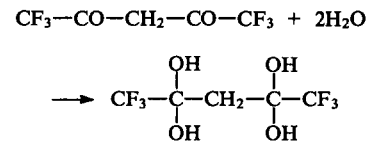


In aqueous solutions β-diketones have weakly acidic properties and react with many metals to give compounds of the chelate type:

where n is the charge on the metal ion. The double bond in the metal ring is delocalised, and the two O–M bonds are equivalent.

Extensive studies of the chemistry of β-diketonates have established quite unambiguously the fundamental principles which determine the relationship between the volatility of these compounds and their composition and structure.[6–8] Since the molecules must overcome the intermolecular interaction forces during evaporation or sublimation, the highest volatility is found in the coordinationally saturated complexes, which do not tend to form oligomers or hydrogen bonds.

Let us examine for example the metal acetylacetonates. When in the enol form



these compounds interact with many metals to give stable uncharged inner complexes (chelates) in which the bond between the metal and the ligands is often covalent. The complexes of acetylacetone with beryllium(II), aluminium(III), and chromium(III) are coordinationally saturated and have a high volatility. On the other hand the acetylacetonates of lithium, sodium, and magnesium are almost completely involatile, probably because of the ionic character of their bond, and also as a result of polymerisation in the condensed phase.

The complexes of the rare-earth elements (REE) with acetylacetone are coordinationally unsaturated, since their c.n. is 8–11, but the β-diketones occupy only six coordination sites in the inner coordination sphere of the metal. Therefore many REE β-diketonates are hydrated and usually contain two or three water molecules. The hydrated metal chelates undergo hydrolytic dissociation when heated, with formation of involatile hydroxy compounds. Furthermore the coordinationally unsaturated β-diketonates of many metals are often oligomerised or polymerised. These compounds have a low volatility and are thermally dissociated when heated.[9]

The replacement of the end methyl groups in acetylacetone by heavier unbranched hydrocarbon radicals (ethyl, n-propyl, n-butyl, phenyl, etc.) produces a change in the volatility of the corresponding complexes. This can be attributed to the increase in the molecular mass, and also to the strengthening of the intermolecular interaction. The latter factor plays a substantial role, because the volatility of the β-diketonates is strongly dependent on the degree of branching of the hydrocarbon end groups. These chelates are less readily hydrated or polymerised. In recent years a strong research effort has been aimed at the β-diketonato complexes of metals with the end methyl groups replaced by *tert*-butyl groups (dipivaloylmethane, DPM).[10–17]

Another indicator of the dependence of the volatility of chelates on the form of the molecule is the fact that the volatility of the REE β-diketonates increases rather than decreases in the series from lanthanum to lutetium, in spite of the increase in molecular mass. Sicre et al.[18] have attributed this effect to the decrease in the ionic radius of the metal (the lanthanide contraction). The result is either a decrease in the intramolecular local dipoles or a better screening from the neighbouring molecules, which weakens the intermolecular interaction forces.

Replacing the hydrogen in the end methyl groups of acetylacetone (AA) by fluorine greatly increases the volatility of the corresponding β-diketonates, evidently (again) as a result of the decrease in the intermolecular interaction forces and of the increased covalency of the metal–ligand bond.[19,20] The coordinationally saturated chelates of hexafluoroacetylacetone (HFA) $CF_3-CO-CH_2-CO-CF_3$ are the most volatile of all the known metal β-diketonates. However, hexafluoroacetylacetone has a serious disadvantage: it reacts with water to give a tetrahydroxy compound:[19]

Therefore the most 'popular' ligand is trifluoroacetylacetone (TFA) $CF_3-CO-CH_2-CO-CH_3$. The volatility of most of its chelates is slightly lower than that of the HFA chelates, but much higher than that of the corresponding acetylacetonates. However, it reacts with water at a negligible rate, and this allows the chelates to be synthesised by extraction of aqueous solutions of the metals with solutions of TFA in organic solvents. The trifluoroacetylacetonates do not tend to form adducts as readily as the hexafluoroacetylacetonates.[8]

Thus the replacement of hydrogen by fluorine increases the volatility of the β-diketonates, but it lowers the thermal stability of the complexes. Therefore some workers[8,21,22] concluded that the most effective complexes are those with β-diketones containing not only a fluorinated radical (which increases the volatility) but also a *tert*-butyl radical (which contributes additional thermal stability). These include pivaloyltrifluoroacetone (PTFA) and 2,2-dimethyl-6,6,7,7,8,8,8-heptafluoro-octan-3,5-dione (FOD), which contain the CF_3 and C_3F_7 radicals respectively. The rare-earth metals form monohydrates with FOD, which are readily dehydrated without decomposition when dried in a vacuum over P_2O_5. The chelates of REE with PTFA can react with uncharged donors with formation of thermally stable complexes.[23]

The volatility of the β-diketonates depends on the nature of the complex-forming metal. For example, films of HTSC can be produced by using complexes of copper with various ligands,

including the complex with acetylacetone, $Cu(AA)_2$, since they all have an adequate vapour pressure and thermal stability (see Table 1).[24–26]

Table 1. *Volatile chelated compounds used in the preparation of HTSC films from the vapour phase.*

Metal	Ligand		Designation of chelates
	R	R′	
Cu	CH_3	CH_3	$Cu(AA)_2$
Cu, Y, Ba, Sr, Ca	$(CH_3)_3C$	$(CH_3)_3C$	$M(DPM)_n$
Cu, Ba	CF_3	CF_3	$M(HFA)_2$
Ba, Y	C_3F_7	$(CH_3)_3C$	$M(FOD)_n$
Cu	$CH_3-C(=NH)-CH_2-CO-CH_3$		$Cu(Acim)_2$ [a]

[a] Acim is acetylacetoneimine.

The ions of the alkaline earth metals (the components of the HTSC, Sr^{2+} and especially Ba^{2+}) form involatile oligomeric complexes with β-diketones. The freshly prepared complexes of these metals are monomeric and contain between two (the magnesium, calcium, and barium β-diketonates) and four water molecules (the strontium β-diketonates). However, after dehydrating and heating the complexes additional lines are observed in the IR and Raman spectra[27] in the metal–ligand vibration region (400, 650 cm^{-1}) and in the bending region of the chelate ring (600–900 cm^{-1}). Under these conditions the chelates are characterised by a total involatility, and the mass spectra of the complexes indicate the formation of species with a molecular mass well in excess of the molecular mass of the monomeric compound. The appearance of new bands in the IR and Raman spectra after dehydration and heat treatment of the complexes may be associated with polymerisation during dehydration, which is the mechanism most likely to oppose the transfer of compounds to the gas phase. The degree of oligomerisation is strongly dependent on the nature of the central atom and increases with the atomic number of the metal. It has been established that the volatility of the alkaline-earth metal chelates is markedly affected by the method of dehydrating the prepared compounds, and also by the method of storage.[28] The sublimation characteristics of even the most suitable of these complexes for CVD technology (barium dipivaloylmethanate, $BaL_2 \cdot 2H_2O$) are markedly degraded during storage. The results of photoelectron spectroscopy in the gas phase and of thermal analysis have shown that barium dipivaloylmethanate is hydrolysed as follows during storage:

$$BaL_2 \cdot 2H_2O \longrightarrow Ba(OH)L + HL + H_2O .$$

The additional hydration of $BaL_2 \cdot 2H_2O$ during storage favours more extensive hydrolysis. It should be noted that storage over P_2O_5 is also undesirable because this drying agent appears to enhance the hydrolysis by shifting the equilibrium as a result of its interaction with the vapour of the acid (HL) evolved by the hydrolysis of $BaL_2 \cdot 2H_2O$. Large changes in the sublimation properties during the storage of the preparations over P_2O_5 are observed also in the β-diketonates of other metals (for example the REE).[29]

Thus the hydrolysis of $BaL_2 \cdot 2H_2O$ during the storage and subsequent sublimation processes is one of the main causes of instability of this compound. However, an equally important cause may be the slow oligomerisation of the anhydrous barium dipivaloylmethanate. It has been reported[28] that reproducible results on the sublimation of barium dipivaloylmethanate can be obtained by eliminating all the factors which favour polymerisation. One way of solving this problem is to add the BaL_2 in the form of compounds with additional uncharged ligands, $BaL_2 \cdot nQ$ whose inclusion in the composition of the complex suppresses the hydrolysis and favours the depolymerisation of $(BaL_2)_n$ by saturating the coordination sphere of the Ba^{2+} ion with the donor molecules of the additional ligand Q. The complex of the pivaloyltrifluoroacetonate of barium(II) with dimethylformamide has been discussed as an example.[27]

It would seem that the vapour pressure of the barium chelates could be increased by increasing the temperature. However, this method is limited by considerations of the thermal stability of the β-diketonates. The competition between the sublimation and the thermal decomposition of the barium complexes is one of the main problems in the CVD technology for the production of $Y(Ln)Ba_2Cu_3O_{7-x}$. As has already been pointed out[1] this problem can be solved by a careful choice of the sublimation regime and of the method of synthesis of the chelates, aimed at minimising the possibilities of oligomerisation.

III. Structural changes of metal β-diketonates during their transfer to the gas phase

The metal cation is usually attached to the β-diketonate anion through two oxygen atoms belonging to the hydroxyl and the carbonyl group, forming the chelate. However, recent physicochemical studies have shown that other methods of coordinating the β-diketone ligands are possible: in particular, the monodentate coordination of the metal by an oxygen atom. Compounds of this type include the complexes Cu(HFA)(MeNHCH$_3$NHMe), $Cu(AA)_2En_2 \cdot 2H_2O$, $(CH_3)Si(AA)$, and $(CH_3)_3Hg(AA)$, where Me is methylene and En is ethylenediamine.[30–34]

A similar method of coordination is possible also at temperatures close to the thermal dissociation temperature. ESR studies and studies by electronic and IR spectroscopy have shown that during the transfer to the gas phase at high temperatures the c. n. of the complex decreases as a result of the opening of the chelate ring. This effect is most clearly seen in compounds containing an additional electron donor molecule, for example $M(HFA)_2 \cdot 2TBPO$, where M = Co, Ni, Cu and TBPO is tributylphosphine oxide.[35,36] From the standpoint of thermodynamics this means that at least in the gaseous state the metal β-diketonates can exist as an equilibrium of two isomeric forms: a chelate and an open ring. The quantitative relationship between the bidentate and the monodentate form depends both on the temperature and on the energy of the M–O bond in the complex. Because of their structure the metal β-diketonates with a monodentate coordination should be chemically more active towards addition and exchange reactions.

It has been shown[37] that the vapour formation process is accompanied by exchange reactions induced by three

$$ML_n \rightleftharpoons ML_{n-1} + L^{\cdot} , \quad (1)$$

$$M'L'_n \rightleftharpoons ML'_{n-1} + L'^{\cdot} , \quad (2)$$

$$ML_n + L'^{\cdot} \rightleftharpoons ML_{n-1}L' + L^{\cdot} , \quad (3)$$

$$M'L'_n + L^{\cdot} \rightleftharpoons M'L'_{n-1}L + L'^{\cdot} \text{ etc.} \quad (4)$$

mechanisms. The first is the radical–chain mechanism:

The second mechanism is the formation of polymeric species in the condensed or the gaseous phase followed by dissociation

$$kML_n(\text{sol., gas}) + lM'L'_n(\text{sol., gas}) \rightleftharpoons (MM'L_nL'_n)_{k+l}(\text{sol., gas}), \quad (5)$$

$$(MM'L_nL'_n)_{k+l}(\text{sol., gas}) \begin{cases} \longrightarrow lML_{n-1}L'(\text{gas}) + kM'L'_{n-1}L(\text{gas}) \\ \longrightarrow lML'_n(\text{gas}) + kM'L_n(\text{gas}) . \end{cases} \quad (6)$$

into monomeric molecules during vapourization:
This mechanism probably applies to the exchange reactions between the β-diketonates which can either have an oligomeric structure in the condensed state or form dimeric molecules in the gas phase.

The third ligand exchange mechanism is possible when the β-diketonates exist in an open form. Under these conditions unstable polymeric molecules exist on the surface of the condensed phase, where they can subsequently dissociate into the initial complex and a mixed complex:

$$ML_n \rightleftharpoons ML_{n-1}L^* , \quad (7)$$

$$M'L'_n \rightleftharpoons M'L'_{n-1}L'^* , \quad (8)$$

$$ML_{n-1}L^* + M'L'_{n-1}L'^* \rightleftharpoons \{MM'L_nL'_n\} \rightleftharpoons ML_{n-1}L'^* + M'L'_{n-1}L , \quad (9)$$

where L* (L'*) is a ligand with monodentate coordination.

The possible occurrence of all the above mechanisms must be borne in mind when superconducting films are synthesised from the gas phase by the pyrolysis of organometallic compounds. Thus, it has been shown[38] by IR spectroscopy that when a mixture of gaseous $Cu(AA)_2$ and $Ba(DPM)_2$ is heated in an argon atmosphere at 200 °C a redistribution of the ligands is observed, leading to the formation of the involatile complexes $Ba(AA)_2$ and Ba(AA)L which perturb the stoichiometric relationship between Ba and Cu. In order to avoid uncontrolled changes in stoichiometry during the deposition of BaO and CuO/Cu_2O on an oriented Si(100) face the use of copper dipivaloylmethanate has been recommended as the source of the Cu phase.

IV. Gas-phase thermal stability of yttrium, barium, copper, calcium, and bismuth β-diketonates, used in CVD technology

The β-diketonates of elements such as yttrium, barium, copper, bismuth, etc. are used as the initial components for the synthesis of HTSC thin films by chemical deposition from the vapour phase. Data on the thermal stability of these compounds and on the effect of oxygen on the thermolysis process have been reported,[39-46] and the mutual effects of the β-diketonates during thermolysis have been discussed.

According to mass spectrometric results the main gaseous products of the thermal decomposition of the yttrium, copper, and barium acetylacetonates are acetone and ethylene. Passing from copper to barium increases the ethylene content of the thermolysis products from 22 to 87 mol%. By combining kinetic data with an analysis of the product we may conclude[39] that the thermolysis of $M(AA)_n$ takes place by an intramolecular process in the coordination sphere of the metal. The first step of this process is the opening of the chelate ring, followed by the breaking of the M–O and C=C bonds in the case of $Cu(AA)_2$ and of the C=C bond in the case of yttrium and barium chelates.

Changing to fluorine-substituted β-diketones gives thermolysis products with a more complex composition.[40] Thus the products of the thermal dissociation of the calcium, strontium, barium, and yttrium, trifluoroacetylacetonates are trifluoroacetone, trifluoromethanol, trifluoroethane, trifluoromethane, acetone, ethanol, carbon dioxide and monoxide, ethylene, hydrogen fluoride, and methane. The relative amounts of these products are determined by the nature of the metal. In the case of trifluoroacetylacetone (TFA) the main thermal decomposition product was trifluoroacetone, whereas for the derivatives of strontium, barium, and yttrium the main products were carbon dioxide and monoxide. Replacing the actylacetonato ligand by its fluorine-substituted analogue lowers the thermal stability of the calcium derivatives five-fold. The β-diketonates can be arranged in the following series of decreasing thermal stability:[41]

$$(AA)_2Ca > (TFA)_2Ca \approx (PTFA)_2Ca > (TFA)_2Sr.$$

In a study[42,43] of the sublimation of yttrium and barium dipivaloylmethanates it was established that $Y(DPM)_3$ sublimes in two steps at 130 and 160 °C. Evidently this effect is due to the formation of dimers. The ratio of dimers to monomers is 1 : 3. Barium dipivaloylmethanate sublimes at 300 °C. A mass spectrometric study has shown that the sublimed product is a trimer in the gas phase, and according to a thermal study of the vapour of the chelate complex the thermolysis is preceded by a depolymerisation process. A combination of mass spectrometric and DTA methods has been used[44] to study the thermal decomposition of the vapours and of the solid phase for bismuth chelates of general formula $Bi(R-CO-CH_2-CO-R')_3$, where $R = CF_3$, $R' = CH_3$, CF_3, $C(CH_3)_3$, $C(CH_3)_2OCH_3$. From an analysis of the mass spectra it was concluded that the vapour of these compounds consists of BiL_3 monomers. The volatility of the complexes with respect to the form of the substituent R' decreases in the sequence $C(CH_3)_2OCH_3 > C(CH_3)_3 > CH_3 > CF_3$. In the thermolysis of the chelate vapours the gaseous products are β-diketones and their fragments.

In a study of the thermal decomposition of the solid phase of the bismuth β-diketonates it was noted that in a flow of helium and oxygen the β-diketonates containing trifluoroacetylacetone and hexafluoroacetylacetone as ligands decompose at 100–150 °C. The thermal stability of the complexes containing *tert*-butyl groups rises to 300 °C, and these complexes are less likely to form oligomers because of the steric factors associated with the bulky substituents of the ligands in the octahedral bismuth complex. The increase in the steric factor produced by the replacement of the $C(CH_3)_3$ substituent by $C(CH_3)_2OCH_3$ suppresses the dimerisation of the molecules almost totally and thus allows the sample to be sublimed repeatedly with a yield of 90%–95%.

The thermal stability of the β-diketonates in the gas phase is strongly influenced by the presence of oxygen, which is added to the reaction volume, and of other volatile β-diketones (the initial complexes for the synthesis of the HTSC).[45,46] Thus the thermal stability threshold of the vapour of copper dipivaloylmethanate *in vacuo* is 330 ± 10 °C, whereas in the presence of oxygen it falls to 280 ± 10 °C. For the vapour of yttrium dipivaloylmethanate the stability threshold is 490 ± 10 °C. Oxygen lowers this threshold to 395 ± 5 °C. It was shown that the vapour of copper dipivaloylmethanate affects the thermolysis of yttrium dipivaloylmethanate in oxygen. Since the vapour of the $Cu(DPM)_2$ complex has a lower thermal stability than the vapour of $Y(DPM)_3$ a shortage of oxygen is produced in the reaction region during the thermolysis of the vapour of the yttrium complex. This raises the decomposition threshold to the temperature level observed in the absence of added oxygen.

A study of the thermal stability of the yttrium, barium, and copper β-diketonates with various ligands allowed Bykov et al.[46] to choose the optimum conditions for the deposition of layers at pressures of 1–5 torr on substrates of monocrystalline silicon and of sodium silicate glass in a reactor of the bell-jar type with heated walls, three heated evaporators, and an oxygen admission tube. The organometallic compound was introduced in a stream of argon.

The maximum growth rate of the copper, barium, and yttrium oxides obtained from the corresponding dipivaloylmethanates was found to occur at 530–550, 600–620, and 550–560 °C respectively. The rate of growth of the films of copper oxide from the acetylacetonate decreased at temperatures above 550 °C, probably as a result of the partial decomposition of the organometallic compound in the reactor volume. The optimum temperatures of the evaporators of the β-diketonates for the synthesis of films at suitable rates have been determined. For $Cu(AA)_2$, $Cu(DPM)_2$, $Y(DPM)_3$, $Ba(DPM)_2$ they are 110–140, 90–120, 60–120, and 210–260 °C respectively.

V. Use of CVD technology in the synthesis of high-temperature superconducting films

1. Y–Ba–Cu–O films

The volatility of β-diketonates under equilibrium conditions is determined by the temperature dependence of the saturated vapour pressure. The vapour pressures of the β-diketonates used in the synthesis of $YBa_2Cu_3O_{7-x}$ have been reported.[6,18,47,48] However, under real conditions these results are not always reproducible because non-equilibrium conditions tend to be established in flow-through reactors, which must be used because of the low volatility of the chelate compounds of barium and also because of the need to reconcile the sublimation and vapour transport conditions with the conditions for the oxidative thermal decomposition of the volatile compounds near the substrate surface.

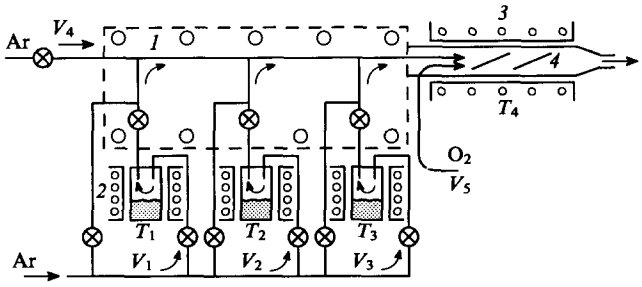


Figure 1. Apparatus for depositing coatings from the gas phase. T_1-T_3 are the temperatures of the evaporators (bubbler type); T_4, temperature of the substrate; V_1-V_3, flow rates of the inert gas (Ar) passing through the evaporators; V_4, flow rate of the inert gas (Ar) passing through the gas collector; V_5 flow rate of the oxygen; the arrows denote the directions of the gas flows; *1* gas collector, *2* evaporators, *3* heaters, *4* substrate.

A typical CVD apparatus[49,50] for the preparation of $YBa_2Cu_3O_{7-x}$ thin films is shown in Fig. 1. In these assemblies the independently variable parameters are the temperatures of the substrate and of three evaporators of the bubbler type, the rates of five gas flows (the flows of inert gas through the three bubblers and through the gas collector, and the flow of oxygen over the substrate), and the total pressure in the reactor. We know that the homogeneity region for the cations in the $YBa_2Cu_3O_{7-x}$ phase is very narrow, and therefore even small departures from stoichiometry induce the formation of a second phase. To avoid this danger a very precise control must be applied to the flow rates of the inert gas (~1%) and to the evaporator temperatures (~0.1 K).

Difficulties are also met in the construction of the 'hot' flow controllers at the outlet of the evaporators and of the hot collector, whose temperatures must not fall below the temperature of the evaporators (in order to avoid condensing the sublimed vapours). The vapours of the β-diketonates and of their thermal decomposition products can interact with the material of the reactor walls. Therefore the reactor must be constructed with an inert material or with materials coated with silver, which does not form stable β-diketonates. Quartz cannot be used because at high temperatures the hot quartz walls could absorb barium from the vapour (forming the stable barium silicate).

Let us examine the results of some studies of the synthesis of $YBa_2Cu_3O_{7-x}$ by the CVD technology,[51-56] using as the initial components the dipivaloylmethanates of yttrium, barium, and copper. The total flow of carrier gas in the three evaporators was 0.3 $dm^3\ min^{-1}$; the pressure in the horizontal quartz reactor was 660–1300 Pa. Depositing the condensate at a rate of 0.8–1.0 μm h^{-1} on a polycrystalline substrate of $ZrO_2(Y_2O_3)$ heated to 800 °C produced film with zero resistance at 45 K with inclusions of textureless[51,52] $BaCuO_2$ and CuO. Raising the temperature of the substrate to 900 °C improved the quality of the films: at a thickness of 0.8–1.0 μm they consisted of preferentially oriented crystallites (with the *c* axis perpendicular to the plane of the substrate, the so-called type 001 texture), and they began to enter the superconducting state at $T_c^H = 89$ K, $T_c(\rho = 0) = 80$ K. The best transition into the superconducting state was obtained by slowly cooling the films in a stream of oxygen ($p_{O_2} = 10^5$ Pa).[53,54] Textured films 2 μm thick with zero resistance at 84 K and a critical current density of 2×10^4 A cm^{-2} (at 77 K and the zero magnetic field *H*)[55] were obtained at 900 °C on a monocrystalline $SrTiO_3$ substrate cut in the (100) plane.

By lowering the substrate temperature to 850 °C (thus suppressing the chemical interaction at the film–substrate interface) Yamane [56] obtained the film with the best transport properties, having the following parameters at 77 K:

H/T	27	8	1	0
J/ A cm^{-2}	6×10^4	2.2×10^5	4.8×10^5	10^6.

In this case the total flow rate of the carrier gas (argon) was 0.45 $dm^3\ min^{-1}$, the flow rate of oxygen was 0.25 $dm^3\ min^{-1}$, and the pressure in the reactor was 130 Pa. The sublimation of $Cu(DPM)_2$, $Y(DPM)_3$, and $Ba(DPM)_2$ was carried out at 136, 145, and 253 °C respectively. The rate of growth of the film was 1–6 μm h^{-1}. By using masking techniques Muto[57] and Watanabe [58] obtained superconducting films 1 μm thick having $T_c = 92$ K and a high value of J_c ($10^5 - 10^6$ A cm^{-2} at 77 K in a magnetic field of up to 30 T).

Superconducting films have been obtained[5,59] on monocrystalline MgO by separating in time the condensation of the oxides and the solid-phase formation reaction of the superconducting phase. The dark brown condensate obtained at 400–600 °C was roasted in oxygen at 800–920 °C and was then slowly cooled. The $YBa_2Cu_3O_{7-x}$ films were converted into the superconducting state over a wide range of temperatures: 80–20 K (Berry[5]) and 76–60 K (Nakamori[59]).

Zhang et al.[60] have claimed slightly better characteristics for their superconducting films. The temperature of the onset of superconductivity was $T_c^H = 93$ K, and zero electrical resistance of the Y–Ba–Cu–O film was observed at 84 K. Good results have been obtained by using the two-stage technology.[61-63] Thus, Noh et al.[61] synthesised semitransparent films which had a resistance of >10 MΩ at a thickness of 1 μm on substrates of $SrTiO_3$ [oriented (100)] in a rotating high-speed disk reactor. After heat treatment at 860–980 °C the $YBa_2Cu_3O_{7-x}$ films became superconducting, some of the samples having $T_c = 90$ K and a transition width $\Delta T_c < 2$ K. Schmaderer et al.[62] used yttrium, barium, and copper 2,2,6,6-tetramethylheptan-3,5-dionates (TMHD), having evaporation temperatures of 112, 208, and 117 °C respectively, to prepare $YBa_2Cu_3O_{7-x}$ thin films on polycrystalline substrates of stabilised ZrO_2 and on monocrystalline $SrTiO_3$ (100) substrates, which were roasted at temperature ≥850°C. On these films the authors found $T_c > 90$ K, $\Delta T_c = 0.2-0.5$ K. The maximum critical current density J_c on a ZrO_2 substrate was 6×10^3 A cm^{-2} at 77 K, whereas on an $SrTiO_3$ substrate the films had $J_c \approx 10^6$ A cm^{-2} in a zero magnetic field and 10^5 A cm^{-2} in a field of 5.5 T. By using the same β-diketonates films of Y–Ba–Cu–O have been obtained[63] on substrates of stabilised $ZrO_2+Y_2O_3$ and BaF_2+ZrO_2/Y_2O_3. After being heat treated at high temperatures the best films on the BaF_2-ZrO_2/Y_2O_3 substrate had $T_c^H \approx 100$ K and $T_c(\rho = 0) = 80$ K.

The low volatility of the barium β-diketonates (including its dipivaloylmethanate) has been repeatedly pointed out.[5,21,50,59] Therefore even at high flow rates through the bubbler (0.5 $dm^3\ min^{-1}$ for a bubbler temperature of 253 °C) the growth rate of the films is unacceptably slow.[5] Raising the temperature of the bubbler to 300 °C does not usefully improve the growth rate

because it lowers the effectiveness of the barium source.[21,50] To increase the volatility some workers[21,22,49] have used fluorinated β-diketonates, but high rates of deposition of the films were not invariably achieved. Thus, when using barium hexafluoroacetylacetonate[49] with an evaporator temperature of 220 °C the rate of deposition was only 0.3 μm h^{-1}. The use of barium 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctan-4,6-dionate increased the rate of deposition of the film to 1.6 μm h^{-1} in a stream of argon (0.3 dm^3 min^{-1}) for an evaporator temperature of 170 °C. For a rate of supply of argon of 1 dm^3 min^{-1} and an evaporator temperature of 350 °C the growth rate of the film rose[22] to 4.6 μm h^{-1}.

The use of fluorinated β-diketones introduces serious complications into the phase transition process during the synthesis of $YBa_2Cu_3O_{7-x}$ by the CVD method. Even in an oxygen atmosphere the decomposition of the fluoro-organic complexes of barium at 400–1000 °C leads to the formation of the thermally stable BaF_2. This is confirmed by a study[64] in which copper acetylacetonate and yttrium dipivaloylmethanate were mixed with barium hexafluoroacetylacetonate. After heat treatment in an oxygen atmosphere at 900 °C a mixture of Cu_2O, CuO, Y_2O_3, $Cu_2Y_2O_5$, and BaF_2 was formed.

To convert BaF_2 into an oxide phase some workers have used a mixture of oxygen and water vapour.[21,22,65] As has been pointed out,[65,66] in order to shift the equilibrium of the reaction

$$BaF_2 + H_2O \longrightarrow BaO + 2HF \qquad (10)$$

towards the right we need a large excess of water vapour in comparison with the HF. Thus, at 830 °C $\Delta G < 0$ if $p_{H_2O}/p_{HF} > 10^5$, and at 1200 °C $\Delta G < 0$ if $p_{H_2O}/p_{HF} > 10^3$.

In practice the process takes place under nonequilibrium conditions: the inert gas or the oxygen, saturated with water vapour, removes the HF from the reaction volume, which corresponds to conversion, and the resulting BaO reacts with the CuO and Y_2O_3. In a gas stream saturated with H_2O at 23 °C reaction (10) begins[22] at 550 °C. But BaF_2 can be incorporated in the film in substantial amounts even at high temperatures. The inclusion of the BaF_2 conversion stage into the kinetics of the solid-phase formation reaction of $YBa_2Cu_3O_{7-x}$ and the presence of water vapour (which assists the mass transfer in oxide systems) alter the morphology of the films as compared with those prepared from compounds not containing fluorine. The predominance of crystallites with their *a* axis oriented perpendicular to the substrate in these films has been pointed out.[22] However, it is also accepted[1] that the effect of residual fluorine on the properties of the film is still not understood.

Reaction (10) proceeds more smoothly if the evolved HF is trapped as SiF_4 by interacting with SiO_2. This requires the use of quartz reactor walls or alternatively the addition of a special charge of SiO_2. It has been shown[66] that films prepared in the presence of SiO_2 have a zero resistance at 89 K whereas in the absence of SiO_2 the superconducting state is reached only at 50 K. The best films of $YBa_2Cu_3O_{7-x}$, prepared by using fluorinated yttrium, barium, and copper β-diketonates, are characterised[22,67,68] by a temperature of transition to the superconducting state in the region of 70–90 K.

Some of the published work deals with the effect of various factors on the processes of deposition from the vapour phase and with the preparation of superconducting Y–Ba–Cu–O films of high quality (i.e. with high values of T_c and J_c). Thus, several workers[69–71] have determined the effect of the substrate material on the parameters of the superconducting film. The β-diketonates were deposited on different substrates, including MgO(100), $SrTiO_3$(100), ZrO_2(100), sapphire (1102), pure metals, and metals covered with a buffer layer of polycrystalline $SrTiO_3$. The best results (T_c = 90 K and ΔT_c = 2 K) were obtained[71] on $SrTiO_3$(100) substrates. These workers introduced the metal chelates into the reaction chamber in a stream of N_2 at temperatures above 100 °C. The residual pressure in the chamber was 1.01 × 10^4 Pa, and the oxygen partial pressure was 5.06 × 10^3 Pa. Singh et al.[72] tried to increase the stability of the film towards atmospheric degradation by depositing on the substrate a preliminary buffer layer of BaF_2. By chemically depositing $Y(TMHD)_3$, $Ba(TMHD)_2$, and $Cu(TMHD)_2$ from sources at temperatures of 150–250 °C on to a silicon substrate heated to 700 °C they obtained superconducting films with parameters T_c^H = 90 K and $T_c(\rho = 0)$ = 73 K.

Sugii et al.[73] studied the effect of the heat treatment temperature of the substrate on the properties of films prepared by the deposition of yttrium, barium, and copper 2,2,6,6-tetramethylheptan-3,5-dione complexes at temperatures in the range of 600–700 °C on monocrystalline $SrTiO_3$(100). It was established that the crystallinity, which was degraded by lowering the substrate temperature (T_c = 71 and 10 K for substrate heating temperatures of 650 and 600 °C respectively), could be restored by lowering the rate of addition of oxygen during the deposition process.

Attempts to lower the working temperature of the substrate by using a modified plasma method of chemical deposition from the vapour phase have been reported.[74–77] The presence of a plasma substantially alters the mechanism of film formation: the atomic mechanism is replaced by an atomic–ionic (or purely ionic) mechanism, which offers a large energy gain during compound formation. The Y–Ba–Cu–O films prepared at 580 °C had T_c = 82 K and $J_c = 10^6$ A cm^{-2} (at 50 K).[77] The effect of the vapour pressure of the organometallic compounds on the quality of the films has been studied.[78,79] It was found[78] that lowering the vapour pressure increases the $T_c(\rho = 0)$ temperature of the superconducting transition from 66 to 83 K. At the same time by lowering the pressure from 1.33 × 10^3 to 6.67 × 10^2 Pa the volatility of the yttrium and copper chelates was increased while that of the barium chelate remained unchanged, causing a depeltion of barium in the film. In order to obtain films of stoichiometric composition Kim et al.[79] increased the amount of the charge of barium 2,2,6,6-tetramethylheptan-3,5-dione in the reactor: this allowed them to prepare films of stoichiometric composition on an MgO substrate with T_c = 91 K (ΔT_c = 2 K), whereas on a substrate of $SrTiO_3$ they produced films with a critical current density of 10^5 A cm^{-2} in a zero magnetic field at 77 K.

The effect of the oxygen source (O_2, H_2O, O_2 + H_2O or N_2O) on the chemical deposition from the vapour phase of Y–Ba–Cu–O films by using metal β-diketonates containing (or not containing) fluorine atoms has been discussed.[80] The best conditions for the deposition of chelates without fluorine are found at low pressures and by using N_2O as the source of oxygen. With chelates containing fluorine better results are obtained by using O_2 and H_2O, but in this case the region of deposition of the required phase is narrowed. In a study[81] of the dependence of J_c and T_c on the thickness of $YBa_2Cu_3O_{7-x}$ films (0.2–2.4 μm), produced by coevaporation and heat treatment in O_2 and water vapour at 850 °C for 3.5 h on $SrTiO_3$(100) substrates it was found that J_c decreases exponentially from 1 × 10^6 to 4 × 10^3 A cm^{-2} as the film thickness is increased, whereas T_c falls from 90 to 85 K.

Khoroshun et al. [82] have proposed a new and apparently simpler aerosol method of chemical deposition of organometallic compounds from the gas phase. The main feature of this method is that predetermined amounts of the initial materials are introduced as aerosols into the reaction volume. Very thin monocrystalline $YBa_2Cu_3O_{7-x}$ films were prepared in this way. Films of thickness $d \geqslant 80$ nm had $T_c(\rho = 0)$ = 78–80 K and $\Delta T_c \approx 2$ K. The critical current density was 10^7 A cm^{-2} at 4.2 K in a magnetic field of 5 T. Thinner films (d = 10 nm) had $T_c(\rho = 0)$ = 50 K, $\Delta T_c \approx 13$ K.

2. Bi–Sr–Ca–Cu–O films

The preparation of Bi–Sr–Ca–Cu–O films is complicated by the existence of many cuprates of bismuth and of the alkaline

earths in this system, with similar thermodynamic characteristics.[83] The problem of the volatility of the initial components, which created the main difficulties in the synthesis of the Y–Ba–Cu–O films, is now of secondary importance because the β-diketonates of strontium and calcium are much more volatile than the corresponding barium compounds.[8] Bismuth is usually introduced as one of the volatile alcoholates or as a BiR_3 compound with various alkyl or aromatic radicals, because the β-diketonates of bismuth have not been adequately studied. A description of the synthesis and properties of the bismuth β-diketonates has been published very recently.[84]

Films of Bi–Sr–Ca–Cu–O have been synthesised[85,86] by using bismuth ethoxide and calcium, strontium, and copper dipivaloylmethanates. The deposits were produced on $ZrO_2(Y_2O_3)$ and MgO substrates at 800 and 900 °C respectively. Using a deposition rate of 8 μm h^{-1} gave superconducting films with T_c = 70–80 K and a tetragonal (or pseudotetragonal) lattice.

Several workers[87–93] used triphenylbismuth $Bi(C_6H_5)_3$ as the initial component for the deposition of Bi–Sr–Ca–Cu–O films. Some of these,[87,88] by combining this reactant with the β-diketonates of calcium, strontium, and copper, working at 550 °C, and heat treating the deposit in a stream of oxygen at 600–865 °C, obtained a superconducting film with T_c = 78.8 and ΔT_c = 7.7 K on an MgO(100) substrate (with some CuO phase as an impurity). An X-ray phase analysis of this system[88] detected the presence of a $Bi_2(Ca, Sr)_3Cu_2O_x$ phase with T_c = 85 K, and traces of phases with the lattice parameter c = 24.4 or 37 Å and T_c = 110 K. Bi–Sr–Ca–Cu–O films have been grown[89,90] on substrates of monocrystalline $SrTiO_3$(100) by using as the initial components triphenylbismuth, and also calcium, strontium, and copper 2,2,6,6-tetramethylheptan-3,5-dionates[89] and the fluorocarbon chelates of the same metals.[90] The use of lower pressures and a plasma gave[89] a single-phase film with its crystallographic c axis in a preferential orientation normal to the substrate surface. Nemoto and Yamana[90] used a horizontal quartz reactor with a residual pressure of ~1 Pa, and after heat treatment of the product they obtained films with T_c = 80 K and a zero resistance at 50 K.

Zhang et al.[91] described the synthesis of Bi–Sr–Ca–Cu–O films by the deposition of triphenylbismuth, copper acetylacetonate, and strontium and calcium dipivaloylmethanates on a polycrystalline silver substrate at 625–700 °C. Their films are a mixture of the $Bi_2(Sr, Ca)_2CuO_x$ and $Bi_2(Sr, Ca)_2Cu_3O_x$ phase, the proportion of the phase with T_c = 110 K increasing with the decomposition temperature. A study of these films by scanning electron microscopy showed that the deposition on polycrystalline silver greatly improves the texture and the morphology of the films as compared with those prepared on a magnesium oxide substrate. This effect was attributed to the nucleating properties of silver for films of the 2212 phase. The critical current density of these films was ~3.9×10^5 A cm^{-2} at 5.5 K.

The Bi-containing films were doped with lead in order to stabilise the high-temperature phase.[92] Bi–Pb–Sr–Ca–Cu–O films were prepared by two methods. In the first method the lead was introduced by depositing (alternately) Bi–Sr–Ca–Cu–O and PbO_x layers, using the volatile organometallic compounds $Cu[(CH_3)_2CHCOCOCH_3]_2$, $Sr[CH_2(COC(CH_3)_3)_2]_2$, $Ca[CH_2(COC(CH_3)_3)_2]_2$, $Bi(C_6H_5)_3$, and $Pb(C_6H_5)_4$. In the second method the lead was introduced in the initial deposition of the Bi–Sr–Ca–Cu–O film by using PbO as the source. The addition of lead greatly improves the crystal orientation and morphology of the films. On MgO(100) substrates films consisting mainly of the $Bi_2(Sr, Ca)_3Cu_2O_x$ phase were obtained, with T_c^H and $T_c(\rho = 0)$ equal to 110 and 80 K respectively. The formation of HTSC on MgO substrates at 850 °C has been monitored[93] by electron microscopy and X-ray phase analysis. It was established that the 2212 phase (with the lower critical temperature) is deposited during the early stages of the process. The 2223 phase is formed from the low-temperature phase after 30 min. Films 8 nm thick begin to be converted into the superconducting state at 110 K, and zero resistance is reached at 21 K.

Thus it follows from the results considered above that all the following modifications contribute to the stabilisation of the high-temperature $Bi_2SrCa_2Cu_3O_{10}$ with T_c = 110 °C: heating the substrate, plasma treatment during the growth of the film (followed by heat treatment), partial replacement (up to 30%) of the bismuth by lead, and a lengthy final heat treatment.

Volatile halides ($BiCl_3$, CuI_2, CaI_2, SrI_2), heated together in a single stream of inert gas, have been used[94–97] as the initial components for the synthesis of the films. In one method[94] the halides were placed in the tubular quartz reactor of a horizontal gradient furnace, each compound being located in a different temperature region: 150–250 °C for $BiCl_3$, 450–600 °C for CuI_2, 750–850 °C for CaI_2 and 800–850 °C for SrI_2. At the same time the substrate (heated to 800–850 °C) was placed in the region where the halide vapours came into contact with the water vapour entering the reactor with the external stream of inert gas, giving a pyrohydrolysis reaction. The film thus produced had the composition $BiSr_{0.8}CaCu_{3.7}O_x$, T_c = 70–80 K, and a critical current density of ~10^4 A cm^{-2} at 10 K. Films of a better quality were obtained[95] by omitting the additional heat treatment in oxygen. The films were deposited on an MgO(001) substrate at 700–850 °C from a gaseous mixture of halides which had reacted with oxidising agents (O_2 and H_2O). The films, of average thickness 0.1 μm, consisted of a mixture of phases with low or high critical temperatures (~80 and ~110 K). The films deposited at 850 °C had a zero resistance at 98 K. Their critical current density was ~1.7×10^4 A cm^{-2} at 4.2 K. The authors point out that the characteristics of the films depend both on the concentration of oxygen and on the deposition temperature. The structure of Bi–Sr–Ca–Cu–O, thin films deposited on MgO(001) from their chlorides or iodides with helium as the carrier gas and oxygen as the oxidising agent has been studied[97] by transmission electron microscopy. The best films, having a superconducting transition temperature of ~100 K, were oriented along their c axis, and consisted of large domains with an average size of 15–100 μm. Five types of layer were identified in the structure of the Bi–Sr–Ca–Cu–O films along the c axis, with crystal structures of the perovskite type and different thicknesses. It was pointed out that the phase with T_c = 80 K is predominant in these films, whereas the phase with T_c = 110 K is present in much smaller quantities.

3. Tl–Ca–Ba–Cu–O films

In the synthesis of films of high-temperature superconductors in the Tl–Ca–Ba–Cu–O system we again meet the problem of many possible phases. However, there are also other difficulties. Because of the high toxicity of thallium conventional evaporators cannot be used. To avoid contaminating the surface of the apparatus the toxic thallium compounds have to be kept in traps cooled in liquid nitrogen.[98] Because of the high volatility of the oxide Tl_2O_3 the heat treatment temperature of the thallium films must be very accurately controlled. However, the high volatility of thallium oxide can be exploited in the technological process for saturating the Ba–Ca–Cu–O film with the vapour of this compound.[99–102]

Lin and Wu[99] placed a Ba–Ca–Cu–O film prepared by magnetron evaporation in an Al_2O_3 boat at the centre of a tube furnace which also contained a crucible filled with powdered thallium oxide. After holding the charge for 15–60 min at 925 °C a film with $T_c^H \approx$ 120 K and zero resistance at 78 K was obtained. The main superconducting phase was the 2122 phase, which was found to contain large quantities of $BaCuO_2$, $CaCuO_2$, CuO, and other impurities. Other workers[100] used both pure thallium oxide and a mixture of powdered Tl_2O_3, BaO_2, CaO_2, and CuO heated at 895 °C to impregnate a film of Ba–Ca–Cu–O prepared by the pyrolysis of the salts of organic acids. This method gave thick films with T_c^H = 126 K and zero

resistance at 108 K, the high-temperature 2223 phase being dominant in the second case.

The use of massive ceramic samples as sources of thallium oxide allows films of stoichiometric composition to be synthesised, because the reaction takes place under thermodynamic equilibrium conditions.[83] The best film samples, containing mainly the highly oriented $Tl_2Ca_2Ba_2Cu_3O_{10+y}$ phase and traces of the $Tl_2CaBa_2Cu_2O_{8+y}$ phase were obtained[102] at 895–900 °C (in the region of the Ba–Ca–Cu–O film sample) and 810–805 °C (in the region of the Tl_2O_3 boat). These films had $T_c(\rho = 0) = 95-105$ K and a critical current density of 28 800 A cm^{-2} at 77 K in a zero magnetic field. It is pointed out that the films with the highest critical current densities have a highly textured structure consisting of platelet crystallites.

The preparation of high-temperature superconductor films in the Tl–Ba–Ca–Cu–O system by the direct CVD method has been reported.[103–106] Ba–Ca–Cu–O films were synthesised[103] on $ZrO_2(Y_2O_3)$ substrates using barium heptafluorodimethyloctandionate, calcium dipivaloyldimethanate, and copper acetylacetonate as the initial components. The thallium was introduced by two methods: as the gas phase from a solid source containing Tl, Ba, Ca, and Cu, and as the organometallic compound cyclopentadienylthallium. The films thus obtained consisted mainly of the $TlBa_2Ca_2Cu_3O_x$ phase with T_c = 100 K. Highly oriented epitaxial films of the 2122 phase with T_c > 105 K were synthesised[104] by decomposing organic compounds of thallium, calcium, barium, and copper on the surface of an MgO(100) crystal. By doubly annealing $Tl_2CaBa_2Cu_2O_y$ on sapphire substrates at 850 and 500 °C (the first anneal being in the presence of $Tl_2CaBa_2Cu_2O_y$ wafers for 40 min) Zhang et al.[105] increased $T_c(\rho = 0)$ from 87.5 to 94 K, but the films were contaminated by traces of the $BaCO_3$ and Ca_2Cu_3O phase. The best samples of thallium films were synthesised by Hamaguchi et al.,[106] who prepared oriented films of $Tl_2Ba_2Ca_{1.4}Cu_2O_x$ and $Tl_2Ba_2Ca_{2.3}Cu_3O_x$ by chemical deposition in the gas phase on monocrystalline MgO(100) substrates. The stoichiometry of the films was preserved by annealing them in dry oxygen in the presence of Tl_2O_3 vapour at 850–900 °C. These films had T_c^H and $T_c(\rho = 0)$ equal to 125 and 109 K respectively, and their critical current density was 10^4 A cm^{-2} at 90 K

* * *

This analysis of published results in the chemistry of volatile β-diketonates has shown that because of their high volatility at relatively low temperatures and of their thermal stability these materials have been widely applied in the synthesis of thin films of high-temperature superconductors containing yttrium, bismuth, and thallium.

The volatility of the β-diketonates is determined by their composition and structure, and depends on the nature of the complex-forming metal, on the coordinational saturation of the complexes, and on the degree of branching of the hydrocarbon end groups. The highest volatility is found in the coordinationally saturated complexes, which do not readily form oligomers or hydrogen bonds. Replacing the hydrogen in the end methyl groups by fluorine causes a large increase in the volatility. In order to improve the thermal stability we can use complexes containing a *tert*-butyl radical as well a a fluorinated radical.

In the gaseous state the metal β-diketonates exist as two isomeric forms in equilibrium: the chelate and the open ring. The quantitative relationship between the bidentate and the monodentate coordinated forms depends both on the temperature and on the energy of the M–O bond in the complex. The possible mechanisms of the exchange reactions in the vapour formation process discussed above should be allowed for when thin films are synthesised from the gas phase. The thermal stability of the β-diketonates in the gas phase is strongly influenced by oxygen, and also by the presence of other volatile β-diketonates, used as the initial components for the synthesis of the thin films. The high quality and the characteristics of the high-temperature superconducting films prepared in many laboratories by CVD confirm that this method offers very attractive prospects.

Abstract. The formation of a space charge in dielectrics under the influence of ionising radiation (one of the fundamental effects stimulated by the irradiation of solids) is discussed. An increasing interest in this problem has been generated by the wide use of powerful sources of ionising radiation in both science and technology. Radioactive dielectrics, i.e. highly resistive solids of various natures (glasses, crystalline compounds, ceramics, etc) containing a permanent source of ionising radiation (radionuclides) occupy a special place in this field of study. These materials are used, for example, for the treatment and consolidation of nuclear waste in atomic technology. It has been experimentally established that the properties of irradiated dielectrics are affected not only by the presence of space charge resulting from the permanent self-irradiation but also by the form of the charge distribution in the volume of the dielectric. Examples of the relationship between the volume charging of radioactive and of irradiated dielectrics and the characteristics of the materials such as their dissolution kinetics, mechanical and electrophysical properties, redistribution of the energy absorbed from the ionising radiation, etc, are discussed. The bibliography includes 42 references.

I. Introduction

The formation of substantial space charges in solids during their interaction with ionising radiation (radiation charging) was first recognised as an independent physical phenomenon during studies of radioactive salts. In 1900 Pierre and Marie Curie published the results of their study of the formation of space charge in radioactive preparations of $Ba(Ra)Cl_2$.[1] The chosen experimental method allowed them to establish the sign but not the magnitude of the stationary space charge†, since only the current of ionising species from the sample was monitored. Unfortunately, no other studies of the charging of radioactive samples were published at the time.

Almost the whole of the later work in this field was aimed at solving the fundamental technical problem of creating 'radioactive current sources' (atomic batteries). Some current sources of this type operate on the principle of collecting the charges on a collector separated from the radioactive preparation by an insulating layer.[2] Their operation is very closely associated with the accumulation and redistribution of charges in a heterogeneous medium consisting of a source of radiation, a dielectric interlayer, and a collector.

Similar effects have been noted in the interaction of accelerated electrons, γ quanta, and other ionising species with various solid materials. Even the irradiation with electrons having an energy of 50 – 100 keV, in an electron microscope, stimulates the explosive breakdown[3] of crystals such as $BaSO_4$ and KCl as a result of the accumulation of electric charges in the bulk of the crystals. Explosions due to the internal charging of the lead walls of protective chambers used in operations with a ^{60}Co γ source (several hundreds of curies) have had disastrous consequences.[4]

'Radiation charging' can also affect the properties of solids.[5] The catalytic activity of solids, their dissolution and vaporisation kinetics, and their electrochemical and other properties are all extremely sensitive to radiation charging. Thus, any solid having an electric resistivity greater than 10^{12} Ω m passes into the 'electret state' after lengthy irradiation.[6] For example, in ordinary window glass the space charge produced by electron irradiation decreases two-fold[7] after ~100 h.

In general the following changes take place in all dielectrics exposed to ionising radiation: the formation of primary and secondary radiation-induced defects (excited and ionised particles, localised holes and electrons, displaced atoms, etc); local disordering of the dielectric structure (thermal cracks, recrystallisation); radiation-chemical decomposition (degradation) of the material, characteristic of complex organic

† The term stationary space charge denotes the maximum charge (in equilibrium under the stated conditions) found in the sample during irradiation.

molecules, followed by the evolution of volatile radiolysis products; strong local heat evolution (especially during irradiation with powerful beams of accelerated electrons), accompanied by the formation of large thermal stresses in a region of radius equal to one-third the penetration (range) of electrons in the substance, possibly leading to the evaporation of the substance by a microexplosion; the accumulation of electric space charge, often up to levels where spontaneous electric discharges can take place, leading to the breakdown of the material.

All these processes affect the properties of dielectrics, and in particular they degrade the radiation stability of electric insulators, enhance their electric conductivity, lower their mechanical strength, etc.

Irrespective of the formation conditions of the electric space charge (external irradiation, or self-irradiation in the case of radioactive materials) the formation mechanisms of the radiation-induced charge exploit the following basic processes: the retardation of the charged particles in the bulk of the irradiated uniform material (for example, in a heterogeneous system) and the appearance of electric charging as a result of the gradient (in space) of the flow density of ionising radiation.

In all these systems we observe a macroscopically nonuniform distribution of charge density over the volume of the solid, which in the case of radioactive dielectrics (ceramics, glasses, salts) is retained almost indefinitely as long as radionuclides remain in the sample. Because of the accumulation of space charge, conditions favourable to local electric discharges may be produced. This phenomenon, together with the formation of radiation-induced damage, should be interpreted as one of the fundamental effects associated with the action of ionising radiation on solid dielectrics. Under these conditions the energy needed to break down the material radiation-electrically is very much smaller than the energy needed for the purely radiation-mechanical degradation.

II. Analysis of the space charging process. Microscopic approach. Irradiation with electrons

The most thorough analysis of the models that have been proposed for the dynamics and the kinetics of the formation of space charge can be found in the work of Tyutnev et al.[8] and Evdokimov.[9] The following are the main propositions underlying the general approach to the solution of this problem: the dielectric contains both free and trapped charge carriers of different signs (electrons and holes); the action of the ionising radiation on the medium produces, in addition to excess (thermalised) electrons, also carriers of each sign, in equal amounts, as a result of the ionisation of the medium; a loss of carriers is produced by their recombination and drift towards the sample surface under the influence of the space-charge field; the irradiation acts on the trapping centres, i.e. the degree of filling of the traps by carriers may depend on the radiation dose; carriers of both signs contribute to the charge transfer; the diffusion component of the current of carriers is ignored; the charge transfer obeys Ohm's law. The polarisation of the dielectric under the influence of the space charge is indirectly allowed for in the analysis of the charge dynamics by postulating the presence of deep as well as of shallow traps. Furthermore it is assumed that the dielectric is isotropic in its properties, though this stipulation is valid only for amorphous materials. However, the assumption allows us to write the kinetic equations in a one-dimensional variant, which simplifies the solution:

$$\frac{\partial n}{\partial t} - \mu_n \frac{\partial (En_0)}{\partial x} = G + G_n - k_1 n_0 p - k_2 n p_0 , \tag{1}$$

$$\frac{\partial p}{\partial t} - \mu_p \frac{\partial (Ep_0)}{\partial x} = G - k_1 n_0 p - k_2 n p_0 , \tag{2}$$

$$\frac{\partial n_T}{\partial t} = k_{3,n} n_0 [M_n(\xi) - n_T] - \nu_{0,n} \exp\left(-\frac{\xi}{kT}\right) n_T - k_2 p_0 n_T , \tag{3}$$

$$\frac{\partial p_T}{\partial t} = k_{3,p} p_0 [M_p(\xi) - p_T] - \nu_{0,p} \exp\left(-\frac{\xi}{kT}\right) p_T - k_1 n_0 p_T , \tag{4}$$

$$n = n_0 + \int_0^\infty n_T \, d\xi ; \qquad p = p_0 + \int_0^\infty p_T \, d\xi ; \tag{5}$$

$$\frac{dE}{dx} = e \frac{p - n}{\varepsilon \varepsilon_0} , \tag{6}$$

where e is the electronic charge; n is the total concentration of electrons in the dielectric, equal to the concentration of holes; n_0 is the concentration of mobile quasi-free electrons having a mobility μ_n; G is the rate of injection of free electrons and holes into the volume during the irradiation of the dielectric; k_1 and k_2 are the rate constants of the bimolecular recombination of the carriers; k_3 is the rate constant for the capture of the quasi-free carriers; n_T and p_T are the densities of trapped (thermalised) electrons and holes respectively for the trap energy range $\xi \to (\xi + d\xi)$; ξ is the energy depth of the traps, measured from the bottom of the conduction band; $M_n(\xi)$ is the energy density of the distribution of electron traps; ν_0 is the frequency factor; G_n is the rate of the volume injection of electrons; the symbol p refers to holes (everywhere); E is the field generated by the space charge; k is Boltzmann's constant.

The functions of the carrier sources $G(x,t)$ and $G_n(x,t)$ depend on the irradiation conditions, on the type of radiation, on the thickness of the sample, and on the strength of the electric field produced by the space charge (i.e. they depend also on the local absorbed dose rate). The latter dependence makes the system of equations (1)–(6) strongly nonlinear. Therefore special cases of the solution are usually considered separately.

To make the discussion specific we shall examine only one variant, very often met in practice: the irradiation of a plate having end faces covered with a conducting layer, i.e. a short-circuited flat dielectric of thickness h. The system of equations (1)–(6) must now be supplemented by

$$\int_0^h E(x,t) dx = 0 . \tag{7}$$

The most difficult step in the solution of this problem is the evaluation of the source functions $G(x,t)$ and $G_n(x,t)$. It is often convenient to use the Monte Carlo method in the continuous retardation of the injected electrons approximation, to rely on semiempirical dependences, or to determine these functions by direct measurements.[8-11]

Case 1. The dielectric is irradiated with fast electrons whose depth of penetration exceeds the thickness of the sample. These conditions produce a uniform distribution of the absorbed dose and of the sources of thermalised electrons over the sample volume, i.e. they give a uniform primary distribution of space charge. Furthermore it is assumed that only the electrons behave as mobile charge carriers. Under these conditions the solution of the system of equations (1)–(7) takes the form

$$\bar{n}_0 = \left[\frac{(G + G_n) \sin \alpha\pi}{k_1 M_0 \alpha\pi}\right]^{\Delta} \left(\frac{\nu_0}{k_{3,n}}\right)^{\alpha/(1+\alpha)} , \tag{8}$$

where $\bar{n}_0$ is the stationary concentration of electrons; M_0 is the stationary distribution of the trap energy density; $\Delta = (1 + \alpha)^{-1}$; α is the dispersion parameter, equal to T/T_1 [where T is the temperature of the sample and T_1 is the distribution parameter of $M(\xi)$].

For the distribution of the electric field strength we can write

$$E(x) = -\frac{G_n}{\mu_n \bar{n}_0} x , \tag{9}$$

and the maximum value of the field is $G_0 h / 2\mu_n \bar{n}_0$. It follows from Eqn (9) that the field created by the space charge is proportional to the rate of injection of the carriers and inversely proportional to their loss rate. The conditions of space charge accumulation for

which $n \gg p$ are called the 'space charge current regime', whereas with $n \approx p$ we are in the 'plasma injection regime'. Thus, in this regime of space-charge accumulation the charge distribution is determined mainly by functions of the carrier sources in the bulk of the given sample, i.e. $G(x,t)$ and $G_n(x,t)$.

Case 2. The conditions specified above are supplemented by the assumption that both electrons and holes are mobile in the dielectric, and furthermore that $\mu_n = \mu_p$, $v_{0,n} = v_{0,p}$. For the stationary regime the space charge ($\bar{n}_0$) can be calculated by the equation

$$\bar{n} = \frac{\bar{n}_0}{(\bar{p} + \gamma_i \bar{n}_0)^{1-\alpha}} \left(\frac{k_3}{v_{0,n}}\right)^{\alpha} \frac{\alpha\pi}{\sin \alpha\pi} M_n \gamma_i^{1-\alpha}, \tag{10}$$

where γ_i is the radiation-induced electric conductivity of the dielectric. The stationary concentration of holes is

$$\bar{p}_0 = \left(\frac{G \sin \alpha\pi}{2M_p k_2 \alpha\pi}\right)^{A} \left(\frac{v_{0,p}}{k_3}\right)^{\alpha/(1+\alpha)} (1 + \gamma_i)^{(1-\alpha)/(1+\alpha)}. \tag{11}$$

An important aspect of this approach to the solution of the problem of space charge formation is that the final expressions contain microscopic characteristics of the dielectric such as $M(\xi)$, μ_n, μ_p, and α. Therefore it should be possible to find the microscopic parameters of the carrier migration from the experimentally determined macroscopic parameters which characterise the space charge.

III. Formation of an electric space charge. Total current model

In the present approach to the analysis of the formation of a space charge only the macroscopic (averaged) characteristics of the dielectric are taken into account: its electric conductivity (γ_0); its dielectric permittivity (ε), and the effective mobility of its carriers (μ), treated as a phenomenological quantity.[6-12] The most important component of the electric conductivity of a dielectric being irradiated (or previously irradiated) is its radiational component γ_i, which cannot be calculated by existing theoretical methods. Therefore it is usually determined either experimentally or from empirical relationships.

In the analysis of the formation of space charge in terms of the macroscopic approach an expression for the total current can be obtained in the one-dimensional variant. It is often called the total current integral:

$$J = \varepsilon\varepsilon_0 \frac{\partial E(x,t)}{\partial t} + \gamma_i(x,t)E(x,t) + j(x,t), \tag{12}$$

where all the currents are assumed to be calculated for unit area of the irradiated surface; ε_0 is the dielectric permittivity of a vacuum (equal to 8.85×10^{-14} F cm^{-1}); γ_i is the radiation-induced electric conductivity, depending on the local dose rate during irradiation (and in general on the density of the majority carriers, i.e. on the distribution of the space charge). Furthermore, in dielectrics $\gamma_i \gg \gamma_0$; $j(x,t)$ is the current density of the injected carriers. The first term in Eqn (12) corresponds to the displacement current, the second to the 'leakage' (or conduction) current; $E(x, t)$ is the field generated by the space charge. As before, the diffusion component of the conduction current is assumed to be negligibly small. Let us use Eqn (12) to examine different cases of the formation of space charge.

By adopting the total current model it is relatively simple to find the time dependence of the space charge density, i.e. $\rho(t)$. Thus by assuming that in the stationary regime (charge accumulation $\leftrightarrow$ leakage) discharge takes place mainly through the irradiated part of the dielectric we arrive at the following expression from Eqn (12)

$$\rho(x,t) = \frac{j(x,t)\varepsilon\varepsilon_0}{S\gamma_i}\left[1 - \exp\left(-\frac{t}{\tau_i}\right)\right], \tag{13}$$

where $\tau_i = \varepsilon\varepsilon_0/\gamma_i$; S is the surface area of the sample. This expression clearly shows the change in space charge with irradiation time for a material having purely electronic conduction. It was first obtained empirically.[6] It should not be forgotten that under our irradiation conditions the stationary space charge ρ_{st} (for $t \to \infty$) is given, according to (13), by

$$\rho_{st} = \frac{j_i(x)\tau_i}{S}, \tag{14}$$

i.e. it is limited only by the values of j_i and τ_i. With large injection currents j_i electric breakdowns can take place in the dielectric even before the formation of a space charge ρ_{st}. This suggests that the accumulation of space charge is limited by the dielectric strength of the material. Therefore electric breakdown occurs under the condition

$$j_i > j_l, \tag{15}$$

where j_l is the leakage current in the given sample during the irradiation, and the time changes of the space-charge field (at every point of the dielectric being irradiated) are described by an expression analogous to formula (13).

IV. Charging processes during the irradiation of dielectrics by γ quanta

In contrast to the widely investigated aspects of the formation of a stationary charge as a result of the action of fast electrons on dielectric materials the charging of highly insulating solid samples in a field of γ radiation has been poorly investigated, even though the first publications in both these fields appeared at about the same time. This state of affairs probably arose because the use of accelerated electrons to inject electric space charge into a dielectric is experimentally more convenient than the use of γ rays.

γ Quanta are not electric charge carriers, and in this case the charging is a secondary process induced by the ionisation of the irradiated material and by the redistribution of the resulting carriers (mainly Compton electrons) over the volume of the dielectric. From this standpoint there is a great deal in common between charging by the interaction of electrons with the material and charging by γ radiation.

Even the earliest experiments with γ-irradiated dielectric materials detected undeniable charge effects. Thus, it was shown that a substantial amount of electric charge can accumulate in borosilicate glasses under the influence of γ quanta.[13] The following experimental technique was used. After being irradiated in a cobalt source [absorbed dose 4×10^4 Gy (4 Mrad)] the glass samples in the form of disks fitted with pressure ohmic contacts were heated at 300 °C while maintaining a temperature difference of 30–50 K between the contacts. As a result of the heat treatment the injected charge leaked to the external circuit, producing a current of 10^{-12} A. The charge leaking to the contact which was held at the higher temperature was always negative, denoting a correlation between the direction of the thermal current through the irradiated glass and the direction of the temperature gradient. As the heating and discharge proceeded, the current in the external circuit gradually decreased, and the dark yellow colour produced by the irradiation disappeared. A small current could be detected even after the complete bleaching of the glasses.

In the qualitative experiments described above the accumulated charge could not be calculated even approximately. Nevertheless the presence of a space charge following γ irradiation was established beyond doubt.

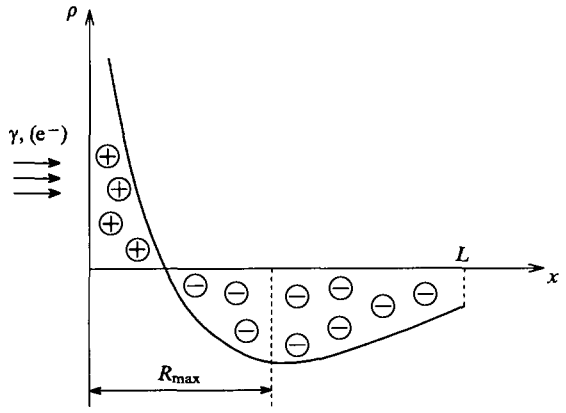

Figure 1. Charge distribution in a γ-irradiated dielectric with linear dimension L.[14] The ordinate axis coincides with the surface of the sample; ρ is the bulk density of the charge; the abscissa axis coincides with the direction of the γ quanta; the maximum penetration of the Compton electrons is R_{max}.

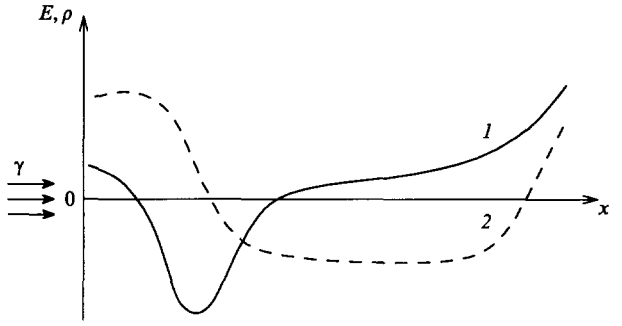

Figure 2. Distribution of space charge density (ρ) and of internal field (E) in a lead glass irradiated with γ quanta.[16] The abscissa axis coincides with the flow direction of the γ quanta: (*1*) charge; (*2*) field.

The magnitude, sign, and distribution of the charge are strongly affected by the irradiation conditions. For example, when the sample is not in electronic equilibrium and the Compton electrons leave the surface layer and move in the direction of the primary γ quanta the surface layer is positively charged, and the charge vanishes at a given depth (Fig. 1). If secondary electrons from the surroundings fall on the sample with the stream of γ quanta the charge can be negative as a whole and reside mainly near the irradiated surface. Experiments with irradiated paraffin wax[14] and Lucite‡[15] were satisfactorily consistent with these concepts.

The formation of large electric space charges by exposure to γ radiation leads to spontaneous internal discharges, as in the case of electron irradiation. The phenomenon was observed in experiments with large ^{60}Co sources in chambers shielded by thick lead walls,[7,16] the glasses being gradually broken down by spontaneous electric discharges. In some types of lead glass discharge formation was noted for doses of radiation higher than 5×10^5 Gy (5×10^7 rad).

It was established experimentally that a perturbation of the electronic equilibrium in the system is a necessary condition for the generation of radiation-induced charge by γ quanta. In other words, the number of electrons dislodged from the dielectric should be markedly different from the number of electrons arriving from the surroundings with the flux of γ quanta. If electronic equilibrium is established an excess of electric charge is not formed in the bulk of the dielectric during the irradiation: of course, this conclusion is valid only for isotropic solids.

The flux of γ quanta passing through the substance generates a flux of Compton electrons almost parallel to the γ flux. This is because the electrons are struck off mainly in the direction of motion of the γ quanta. For example, in Plexiglas exposed to a flow of γ radiation of 25 Jm^2s the average density of the accompanying electron flow was found[17] to be 1.37×10 A m^{-2}. A space charge is generated by the trapping of the Compton electrons as they travel through the material.

An empirical formula has been proposed[17] for the amount of charge accumulated in lead glass:

$$\rho = 4.4 \times 10^{-5} S\left[1 - \exp\left(-\frac{t}{\tau}\right)\right], \qquad (16)$$

where t is time (h), and τ is the relaxation time, equal to 64.1 h.

‡Lucite, Mylar, and Plexiglas are trade names of the same product: poly(methyl methacrylate) (PMMA).

If the dielectric experiences only the action of γ quanta, not accompanied by a flow of electrons from the surroundings, the charge distribution in the medium will be similar to that shown schematically in Fig. 2. If secondary electrons enter the medium simultaneously with the flow of γ quanta the distribution of charge in the depth of the sample can have an entirely different form. The absence of charge effects is certainly not guaranteed by the presence of an electronic equilibrium in the interaction of the γ quanta. Thus, even with an initially uniform distribution of positive and of negative carriers in the sample we can find a gradual separation of charges of opposite sign caused by the difference in their mobility in the solid matrix.

A simplified variant of the analysis of the accumulation of charge during the γ irradiation of dielectrics gives the following expression for the dependence of the total stored charge on the parameters of the sample and on the irradiation conditions:[6]

$$\bar{\rho} = S\frac{j_k(0)\varepsilon}{\mu_\gamma h\bar{\gamma}}\left[1 - (1 + \mu_\gamma h)\exp(-\mu_\gamma h)\right], \qquad (17)$$

where S is the surface area of the sample; h is its length; $\bar{\gamma}$ is the average electric conductivity; μ_γ is the linear absorption coefficient of the γ radiation; $j_k(0)$ is the current of Compton electrons near the sample surface. It is assumed that an equilibrium between the charge accumulation and the leakage currents was established during the γ irradiation.

To describe the charging process more correctly we need to allow for the appearance of a radiational component of the electric conductivity. A stricter derivation of formula (17) has been obtained[17] in the light of these considerations. In fact, the theory has been tested only for the region of linear charge accumulation, i.e. for the early stage of the irradiation. In lead glasses the charge accumulation in the initial stage has been shown to be satisfactorily described by these formulae.

In spite of this satisfactory agreement with experiment the above model of the charging of dielectrics in a field of γ radiation is not free from defects. In particular, many workers consider that the Compton electrons are trapped in the sample almost completely, and that their scattering can be ignored (thus ignoring the effect of the field from the charge on the path followed by the electrons and the spatial change in polarisation).

A commonly found case (the irradiation of an isotropic dielectric by a collimated monoenergetic beam of γ quanta) has been examined theoretically.[18] Under these conditions the charge becomes localised along the boundary between the irradiated and the nonirradiated part of the sample (Fig. 3). Charge formation is determined by the scattering of the Compton electrons. To simplify the treatment it was assumed (as in the work of Gross[17]) that the ratio of the dielectric permittivity to the conductivity is invariant during the exposure of the sample to γ quanta. It was

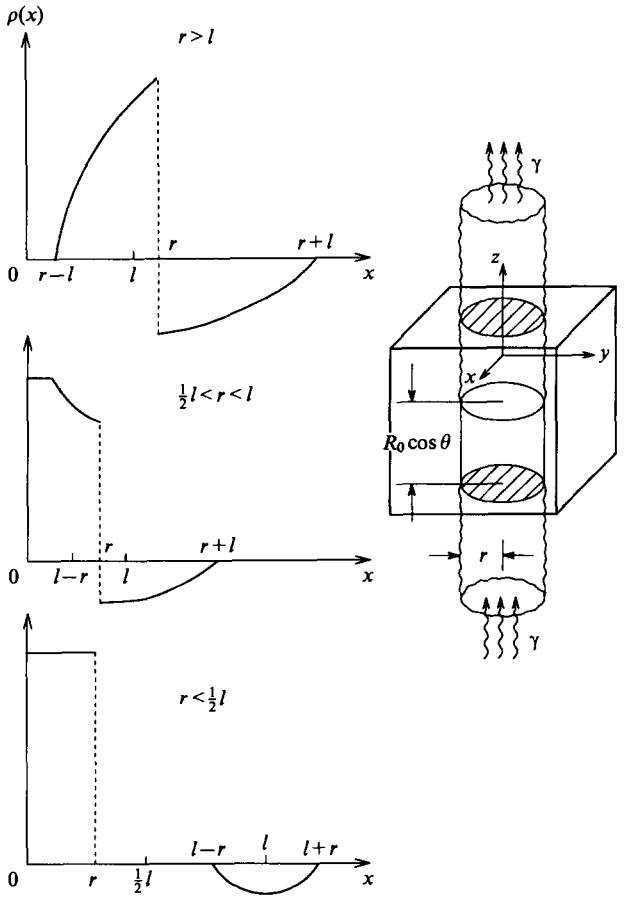

Figure 3. Distribution of charge density during the irradiation of a dielectric with a cylindrical stream of γ quanta for various ratios between the radius of the beam r and the deviation l of the Compton electrons from the direction of the γ quanta.[18] The orientation of the beam and of the sample relative to the chosen system of coordinates is shown on the right: θ is the average divergence angle, R_0 is the average path of the Compton electrons.

also assumed that the flux of particles incident on the surface consists only of γ radiation without any secondary Compton electrons from the surroundings, and that the suppression of the flux of electromagnetic radiation can be ignored.

If a cylindrical beam of γ quanta of radius r is used the charge distribution under stationary conditions is defined by the function f:

$$\rho(x) = ebf = ebj_\gamma \frac{1}{\pi} \arccos\left(\frac{x^2 - r^2 + l^2}{2lx - 1}\right), \qquad (18)$$

where l is the distance by which the Compton electron deviates from the direction of motion of the γ quanta; b is a coefficient which defines the link between the flux densities of the γ quanta (j_γ) and of the Compton electrons (with $r > l$). If $x > r$ the law for the dependence of $\rho(x)$ on x becomes

$$\rho(x) = ebj_\gamma \frac{1}{\pi} \arccos\left(\frac{x^2 - r^2 + l^2}{2lx}\right). \qquad (19)$$

The orientation of the sample and of the beam of γ quanta relative to the system of coordinates is shown in Fig. 3. The charge distribution is given for the xy plane.

A calculation shows that three special cases are possible.

1. $r > l$. In the region of $0 \leqslant x < r-l$ the sample does not become charged, since $f = 0$, and in the region of $r-l < x < r$ the charge density is proportional to f [see formula (18)]. Thus the centre of the irradiated cylindrical region is not charged. The density of positive charge to the left of the $x = r$ boundary is greater than the absolute density of negative charge outside the cylinder of radius r.

2. $\frac{1}{2}l < r < l$. Under these conditions the irradiated part of the sample is charged positively in the region of $0 < x < l-r$. For $l-r < x < r$ the charge is determined by the value of the function f according to formula (18), and for $x > r$ according to formula (19).

3. $r < \frac{1}{2}l$. In this case the whole of the dielectric enclosed in the cylinder of radius r is positively charged, and the charge density is proportional to $f = -ebj_\gamma$; the region between r and $l-r$ is uncharged, and in the region of $x > l-r$ the negative charge varies according to the expression (19).

We also note that on the side of the irradiated surface the region $r > l$ shown in Fig. 3 (a cylinder of radius r and height $R_0 \cos\theta$) becomes positively charged, as is also found in practice (compare with Fig. 2).

Under practical conditions the charge distribution is a superposition of all the cases which we have discussed. Therefore a discontinuity in the function f at the point $x = r$ should probably not be expected. However, the region outside the beam ($r < x < l-r$) should always be negatively charged.

In conclusion we should dwell briefly on the mechanism of the electrification of dielectrics by γ radiation. The effect is based on the difference between the rates of retardation and of generation of Compton electrons upon passing from one medium into the other, i.e. it can be realised in heterogeneous media in which the components have different absorption coefficients for the ionising radiation and different cross-sections for the formation of Compton electrons. A general discussion of this problem for systems composed of two media has been given by Lenchenko.[19]

V. Electric charge of radioactive substances

Radiation-induced charges were first observed, and then studied and used under practical conditions, in radioactive materials.[1,2,5] However, a reasonably complete theory of this phenomenon was developed only by abandoning to some extent the requirement of direct practical application and the existing theory of charging from external sources of ionising radiation. Unfortunately, even the present stage of development of the theoretical study of charge formation in radioactive materials cannot be taken as conclusive. Nevertheless, we now have some reasonably good theoretical models which can be used to establish an unambiguous relationship between the experimental results on the charging of radioactive materials and the properties of these materials.

One of the simplest and most effective methods of studying the electric properties of the surface of ionic crystals is to decorate the samples with charged particles of metallic sols.[20] The basis of the method is the fixing of the charged particles of the metallic sol on the appropriately charged regions when deposited on the surface. Experiments of this type have been carried out[5] with radioactive crystals of K_2SO_4* (containing ^{35}S, a β^- emitter).

It was established that individual sol particles are deposited, irrespectively of their charge, on elements of the surface topography (hillocks, growth steps, etc.). Thus, the negatively charged particles of a silver sol in methanol covered almost uniformly the whole surface of cleavage faces in radioactive crystals of potassium sulfate, which must obviously carry a positive charge. On the other hand, if the radioactive crystal was decorated with a nickel salt the metal particles were deposited only on surface nonuniformities. This is a direct proof that a stationary positive charge exists on the surface of β^- emitters.

One of the most characteristic features of radioactive dielectrics is the formation of a charged surface layer with a thickness equal to the maximum path length of the charged particles emitted by the radionuclide (if the linear dimensions of the sample are $L > R_{max}$), as was first reported by the present writer.[21]

In high-resistance radioactive materials the space charge can be so large that the electric field in the near-surface layer reaches the breakdown level. This assumption was tested by special experiments with a radioactive glass.[22]

The resistivity of the prepared glass blocks was $\sim 10^{22}$ Ω m. After solidification the samples began to darken and became opaque in a few minutes owing to the strong self-irradiation. According to tentative calculations the electric field intensity in the charged near-surface region of these glasses reached breakdown values ($\sim 10^8$ V m^{-1}). However, in order to stimulate electric discharges we need to create mechanical stresses by pressing a glass or a metallic rod on the surface of the radioactive glass block. A spark was seen in the charged layer beneath the pressure point. In most cases the discharges took place at the beginning of the experiment. The sparking then ceased, showing that the charge in the near-surface layer had become exhausted. After several days' storage of the blocks a new charge had accumulated, and the experiments on spark formation could easily be reproduced.

In contrast to irradiated materials a charge is always present in radioactive dielectrics: this is one of their most characteristic properties. The field generated by this charge can also extend beyond the dielectric, unless the charge is compensated by that of carriers drifting towards the surface of the radioactive sample from the surroundings. The charge accumulated in radioactive materials is most clearly detected in 'hot' aerosol particles, i.e. in solid formations whose specific radioactivity reaches ~ 10 Ci g^{-1} (3.7×10^{11} Bq g^{-1}) in particles of about micrometre size, so that the radioactivity of each aerosol particle is $\sim 10^{-8}$ Ci (or 200 Bq).[23]

VI. The charging of radioactive samples

The general theory of the formation of charge in radioactive solids has now been fully developed.[5,6,21,24] Two basic assumptions are made in the analysis of this phenomenon: Ohm's law is obeyed in the solid sample and the properties of the material are isotropic. In this case we can easily obtain a general expression which describes the dynamics of the charging both of radioactive materials (in which the radiation sources are located within the sample) and of materials irradiated from external radiation sources. Under these conditions the electrophysical properties of the system are characterised by macroscopic parameters such as γ (electric conductance) and ε (dielectric permittivity). It is also stipulated that charge neutralisation processes between charges of opposite sign can take place only on the surface. By allowing for these conditions we arrive at the following expression:

$$\rho(x,t) = \exp\left(-\frac{\gamma}{\varepsilon\varepsilon_0}t\right)\left[\int_0^t f(x,t)\exp\left(\frac{\gamma}{\varepsilon\varepsilon_0}t\right)\mathrm{d}t\right], \qquad (20)$$

where x is the coordinate of the reference point; $f(x,t)$ is the function of the charge sources (whose physical significance is to define the change in the charge density per unit time); γ is the electric conductance of the dielectric.

If the source of charged particles acts for a finite time (short-lived radionuclide) we can see from formula (20) that after the 'switching off' of the source the space charge density relaxes to zero with a time constant $\tau = \varepsilon\varepsilon_0/\gamma$. When the source of radiation acts for a long time with constant intensity (long-lived nuclide), i.e when f is independent of time, the solution of Eqn (20) takes the form

$$\rho(x,t) = \frac{\varepsilon\varepsilon_0}{\gamma}\left[1 - \exp\left(-\frac{\gamma}{\varepsilon\varepsilon_0}t\right)\right]f(x). \qquad (21)$$

Two special solutions of Eqn (21) are of interest.

1. Small electric conductance (dielectrics). By expanding the exponent into a Taylor series in powers of γ we obtain

$$\rho(x,t) = f(x)t.$$

Therefore, up to time t,

$$t \ll \frac{\varepsilon\varepsilon_0}{\gamma},$$

the charging will take place by a linear law, and at long times the charge ρ will tend towards the stationary value

$$\rho_{st} = \frac{\varepsilon\varepsilon_0}{\gamma}f(x). \qquad (22)$$

2. Large electric conductance (conductors), small relaxation time. Under these conditions the charge ρ immediately reaches the value ρ_{st} defined by Eqn (22), from which it follows that ρ depends only on the intensity of the sources of charged particles and on the electrophysical properties of the material.

At this stage of the solution the expressions obtained still retain their generality: they are valid also for an external source of radiation acting on the dielectric. The whole of the 'significance content', which allows ρ to be obtained in an explicit form for different particular conditions, is included in the 'source function' $f(x)$.

A strict derivation of the general form of the charge sources function for a uniform distribution of the radionuclide over the sample volume (when the specific radioactivity Q is independent of x) has been reported,[24] and also partial expressions for $f(x)$, which can be used to calculate the $\rho(x)$ values at various points in the radioactive sample. For example, for a radioactive preparation in the form of a sphere of radius r under stationary conditions we can write

$$\rho_{st} = b_n\int_0^x F_w(b_nR+1)\,\mathrm{d}R + \frac{b_n}{2}\int_x^{R_{max}} F_w\left(1+\frac{2Rx-x^2-R^2}{2R(r-x)}\right)\left(b_nR+1\right)\mathrm{d}R - 1, \qquad (23)$$

where ρ_{st} is expressed in relative units and is equal to

$$\rho_{st} = \frac{f(x)}{Q_0 e}$$

or

$$\rho_{st} = \rho\left(Q_0\frac{\varepsilon\varepsilon_0}{\gamma}\right)^{-1};$$

b_n is a constant, proportional to the concentration of electrons in the sample; Q_0 is the initial specific radioactivity; R is the range of β^- particles in the given material; x is the coordinate; F_w is a function which defines the form of the β^- spectrum. For a monoenergetic spectrum of β^- particles Eqn (23) simplifies to

$$\rho_{st} = 1 - \frac{1}{2}\left[1+\frac{2rx-x^2-R^2}{2R(r-x)}\right]. \qquad (24)$$

The results of a calculation of the charge distribution by using formula (23) for β-radioactive samples in the form of a plate or a sphere are shown in Fig. 4. As can be seen, in the radioactive samples the charge is accumulated in a near-surface layer of thickness R_{max}. Depending on the geometry of the sample the following cases are possible (for a sphere):

1. $r > R_{max}$; the central region of the sphere $(r-R)$ is uncharged.

2. $r < R_{max}$; the whole sphere is charged, but its near-surface layers have a charge density higher than in the central part.

3. $r \ll R_{max}$; the whole sphere is uniformly charged. This variant corresponds to hot aerosol particles.

Calculations by formula (24) give a qualitatively similar charge distribution, though some details of the changes in charge density over the volume of the radioactive sample are lost.

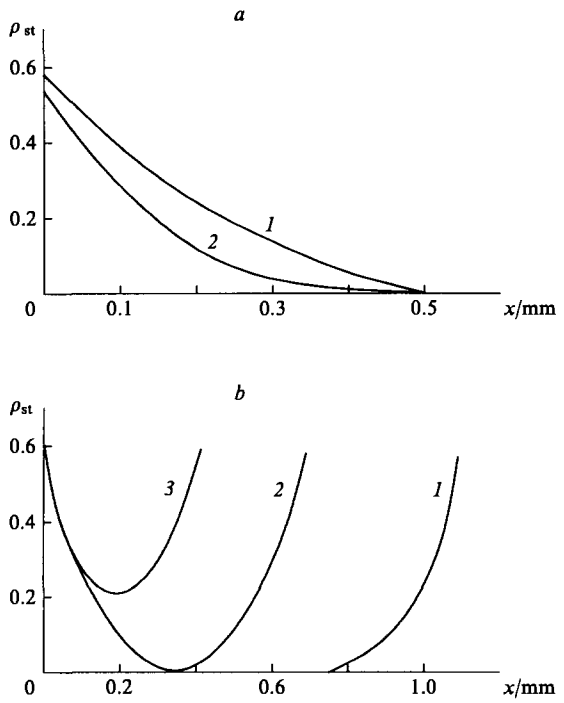

Figure 4. Changes in the charge density $\rho(+)$ of β^--radioactive samples of different size and shape. Maximum energy of β^- particles assumed to be 3 MeV, with a continuous emission spectrum; range R_{max} = 0.5 cm; (*a*) radioactive sphere, the ordinate axis coincides with the surface of the sphere, curves *1* and *2* correspond to sphere radii of 1 and 0.5 cm; (*b*) flat infinite layer, the ordinate axis coincides with the coordinate of one of its surfaces, layer thickness (cm): *1*, 1.1; *2*, 0.7; *3*, 0.4.

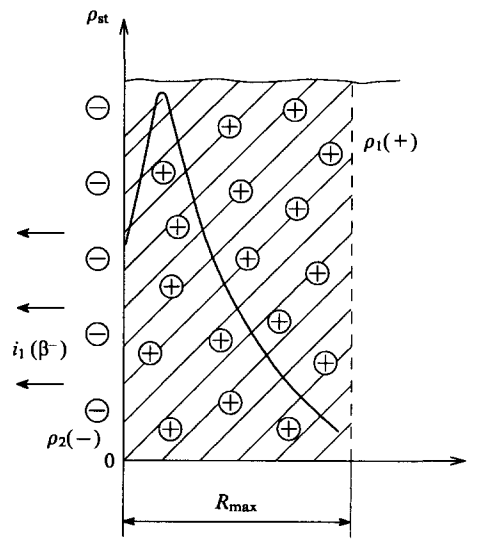

Figure 5. Charge distribution in a dielectric containing a β^- emitter and surrounded by a conducting medium (the ordinate axis coincides with the coordinate of the dielectric surface). i_1 is the flow of β^- particles emitted from the surface of the sample.

These calculations can account for the distribution of the charge expressed in relative units. To obtain the absolute values of ρ we must know the relationship between the change in γ and the dose rate of the ionising radiation, but at present only empirical formulae are available. This is one of the weaknesses of the theory in its present state of development.

Depending on the values and on the ratio of the conductivities of the radioactive material and of the surrounding medium, we may find different distributions of charge in the radioactive sample. For a β^- emitter in a conducting medium the distribution is shown in Fig. 5. The cross-hatched region corresponds to a positively charged near-surface region. Negative charge $\rho(-)$, created by ions from the surroundings, is localised on the surface. As can be seen from the figure, it is useful to distinguish between the total (positive) charge $\rho_1(+)$, distributed in a volume limited by a layer of thickness R_{max}, and the charge ρ_2, equal to the difference between $\rho_1(+)$ and the absolute value of $|\rho(-)|$.

The values of ρ_1 and ρ_2 can be calculated fairly accurately if the electrophysical parameters and the geometry of the radioactive sample and of the surrounding medium are known. By treating the formation of ρ_2 as a competition between the accumulation of charge ρ_1 (formed by the emission of β^- particles from the surface, which determines the current i_1) and the discharges in the surface layer resulting from the recombination with carriers of the opposite sign, i.e. by solving in a simplified variant the system of equations

$$\frac{d\rho}{dt} = i_1 - \frac{\rho_1}{\tau_{ef}}, \qquad \frac{di_1}{dt} = -\lambda t, \tag{25}$$

where λ is the disintegration constant and τ_{ef} is the effective relaxation time of the charge in the given system, we arrive at the expression

$$\rho_{t(2)} = \rho_{st\ (2)}\left[1 - \exp\left(\lambda t - \frac{t}{\tau_{ef}}\right)\right]\exp(-\lambda t)\,. \tag{26}$$

In the case of a time-invariant source intensity (i.e. for $\lambda = 0$) Eqn (26) simplifies to

$$\rho_{t(2)} = \rho_{st\ (2)}\left[1 - \exp\left(-\frac{t}{\tau_{ef}}\right)\right], \tag{27}$$

where $\rho_{st(2)} = i_1\tau_{ef}$. However, formula (27) gives no information on the distribution of charge in the bulk of the dielectric.

For practical purposes it is important to know not only the magnitude of the uncompensated (residual) charge of the radioactive sample ρ_2, but also the total charge ρ_1 distributed in the surface region. In the case of a spherical sample[5] these calculations can easily be made by using the following formula:

$$\rho_1 = \frac{b_1 emQ\varepsilon\varepsilon_0 f(\mu, r)}{4\pi r\gamma_1}, \tag{28}$$

where b_1 is a constant§; γ_1 is the electric conductivity of the sample (allowing for the radiational component). The function $f(\mu, r)$, which defines the fraction of the β^- particles leaving a sphere of radius r, is given in the form

$$f(\mu, r) = \frac{3}{4\mu r}\left[\frac{(2\mu r + 1)\exp(-2\mu r) - 1}{2\mu^2 r^2} + 1\right], \tag{29}$$

where μ is the linear absorption coefficient of the β^- particles in the given substance.

Thus, calculations for crystals of radioactive strontium sulfate containing ^{35}S ($\gamma \approx 10^{-16}$ S m^{-1}, r = 0.1 cm, ε = 5, μ = 840 cm^{-1}), showed that the charge averaged over the volume of a near-surface layer 8×10^{-3} cm thick for Q = 1 Ci g^{-1} (3.7×10^{10} Bq g^{-1}) is 3×10^{-3} C cm^{-1}, and the internal field in the charged layer is $10^3 - 10^4$ V cm^{-1}, $\tau \approx 5 \times 10^2$ s.

§ If the sample is an α emitter, the constant b_1 should include a factor for calculating the yield of δ electrons defining the magnitude and sign of the stationary charge.

These results agree tolerably well with experimental determinations, and they show convincingly that a fairly large charge with a corresponding electric field gradient exists in the near-surface layer of radioactive dielectrics, even if electrically neutral overall (the space charge is compensated though not neutralised).

A stationary distribution of electric charge should be established also at the boundary between two media (a radioactive and a nonradioactive solid dielectric).[25] Let us examine these cases.

Case 1. In a nonradioactive isotropic material we have a region containing a uniformly distributed β^- emitter. If this region is a sphere of radius r the volume density of electric charge at the point x can be found from the expression

$$\rho = \frac{eQ\varepsilon\varepsilon_0}{\gamma_0 - \varepsilon\varepsilon_0\lambda}\left(\frac{r^2 - R^2 - x^2}{4xR} \pm \frac{1}{2}\right)B(t)\,, \qquad (30)$$

where Q is the specific radioactivity; ε is the dielectric permittivity of the medium; λ is the disintegration constant; R is the range of the electrons emitted by the given radionuclide (it is assumed that all the β^- particles have the same energy, i.e. that the spectrum of the radiation is monoenergetic); γ_0 is the electric conductivity;

$$B(t) = \exp(-\lambda t) - \exp\left(-t\frac{\gamma_0}{\varepsilon\varepsilon_0}\right).$$

Eqn (30) defines the dependence of the bulk charge density upon the radioactivity of the dielectric, its electrical parameters, and the coordinate and time. In the region of $x \leqslant r$ (β^- emitting sphere) the term 1/2 of Eqn (30) takes the plus sign, and in the region of $x > r$ (nonradioactive dielectric) it takes the minus sign. Fig. 6 shows the 'coordinate part' of the dependence of the bulk charge density G:

$$G = \frac{r^2 - R^2 - x^2}{4xR} \pm \frac{1}{2}$$

for the case of $R < r$.

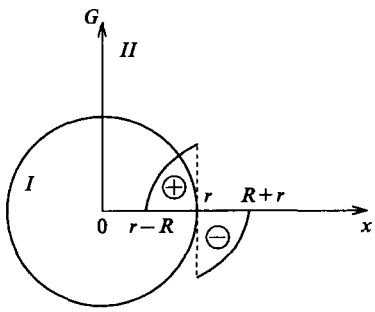

Figure 6. Plot of the 'coordinate part' of the charge density (G) for dielectric half-spaces with different radioactivities. R is the range of electrons in regions I and II; the plus and minus signs correspond to the sign of the space charge.

It should be noted that in every case the whole of the radioactive region (or part of it) becomes positively charged while the nonradioactive region is negatively charged; the $x = r$ boundary defines the charge separation zone. Furthermore 'radiative' electric charging does not take place at any point within the radioactive dielectric at a distance equal to or greater than R from the zone boundary (where $\rho = 0$).

A similar result is seen at the flat interface between the radioactive and the nonradioactive region of a dielectric: the near-surface region of the radioactive dielectric is charged positively, and that of the nonradioactive dielectric is charged negatively.

Case 2. In dielectric materials containing a uniformly distributed β^- emitter with a monoenergetic spectrum we can distinguish regions with different physical properties (i.e. two radioactive materials of different nature but with identical and uniformly distributed radionuclides, which produce an interface). Calculations have shown that the region with the higher electron density becomes negatively charged, and that with the lower electron density positively charged. For example, for a radioactivity of 10^{13} Bq m^{-3} and a conductivity of approximately 10^{-13} $(\Omega\,\mathrm{m})^{-1}$ the charge at the phase boundary is ~ 1 C m^{-3}, which corresponds to electric fields of flashover magnitude ($\sim 10^8$ V m^{-1}).

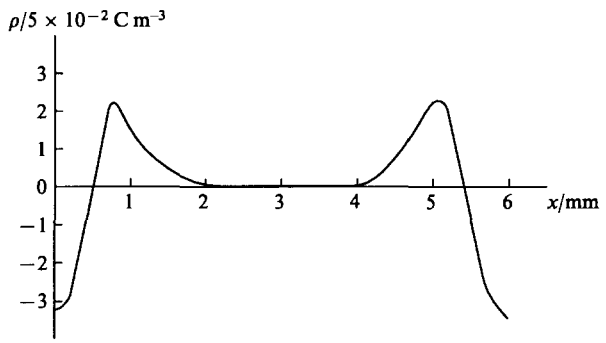

Figure 7. Distribution of electric charge in monocrystals of $Y_3Al_5O_{12}$ (yttrium-90 specific radioactivity 4×10^8 Bq g^{-1}).

The most correct experimental test of the theory of the distribution of space charge in the bulk of radioactive dielectrics was carried out by the acoustic probing method.[26] Thus, in the case of yttrium aluminium garnet ($Y_3Al_5O_{12}$) crystals irradiated with neutrons it was shown that the charge is not uniformly distributed on the surface of flat specimens (Fig. 7). Neutron irradiation of garnet crystals produces the β^- emitter yttrium-90.

It is clear from Fig. 7 that at the centre of the sample with $R < h$ (where h is the thickness of the sample and R the range of the β^- particles from yttrium-90) the charge is zero, whereas in the near-surface regions of thickness R we find an accumulation of positive charge. Narrow negatively charged layers are formed on the surface by the drift of carriers of opposite signs from the surroundings.[26,27]

VII. Charge and properties of solids

Many workers have noted the appearance of spontaneous electrical discharges during the irradiation of dielectrics, leading to the mechanical breakdown of the samples. For example, borosilicate glasses distintegrated when exposed to a flux of 10^{13} electrons cm^{-2} and a current density of $\sim 10^{11}$ electrons cm^{-2} s^{-1} (electron energy 1 – 2 MeV).[28] Discharges can occur in glasses even during lengthy storage (two weeks or more).

Some workers[29] associate the mechanical properties of irradiated glasses with the presence in those glasses of space charges, responsible for the production of internal mechanical stresses. It was pointed out[30] that the mechanical strength of a dielectric is decreased by charging. This effect can probably be attributed to an increase in the ponderomotive forces in a charged dielectric, since their bulk density increases linearly as charge is accumulated in the material.

The internal electric field of the space charge can also have a marked influence on the bleaching of the colour centres in transparent dielectric materials. For example, in glasses of composition $6B_2O_3.Na_2O$ the application of an external electric field of 7×10^7 V m^{-1} was found to break down the

radiation-induced colour centres. It was suggested that the internal 'cold' emission of trapped electrons into the conduction band is responsible for this process.[31]

According to both a theoretical analysis[32-35] and experimental determinations radiation-induced charging strongly decreases the penetration of electrons. The effect was observed visually[32] as a change in thickness of the luminescent layer in poly(methyl methacrylate) which had been irradiated with accelerated electrons with an energy of 1.3–1.7 MeV. This surface layer is a region of electron retardation and accumulation of space charge. The results of these studies are shown in Fig. 8.

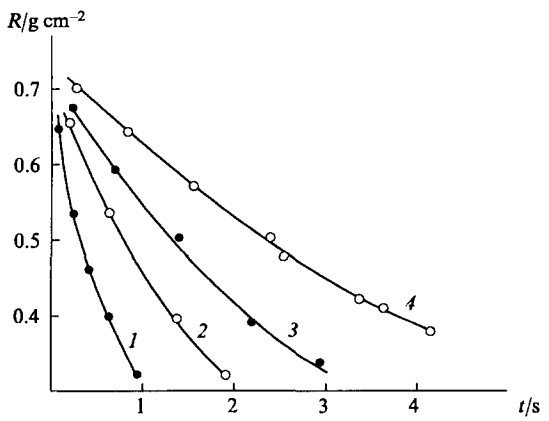

Figure 8. Plots of the range of electrons in poly(methyl methacrylate) against the time of irradiation.[32] Current density of electrons with an energy of 1.7 MeV in the beam (μA cm^{-2}): (*1*) 2.7; (*2*) 1.0; (*3*) 0.8; (*4*) 0.5.

It can be seen that the depth of penetration decreases with time (i.e. it decreases as space charge accumulates). Furthermore R tends towards a limiting value from which the maximum strength of the electric field generated by the space charge can be determined. According to the theory which has been proposed for this phenomenon the energy U_e of the electrons which reach the boundaries of the luminescence region is given by the nonlinear equation

$$\frac{dU_e}{dx} = -w(U_e) - eE(x), \tag{31}$$

where x is the coordinate of the motion of electrons in the materials; $w(U_e)$ is the stopping power of the material; $eE(x)$ is the force acting on an electron at a depth x from the field created by the space charge. Numerical solution of Eqn (31) for an initial electron energy of 1.3 MeV gives the maximum value of $eE(x)$ in poly(methyl methacrylate) as 3.4 MeV cm^{-1}.

Th existence of a relationship between the space charge field and the range of the electrons in irradiated dielectrics produces another interesting effect: the redistribution of absorbed energy.[36,37] In calculations of the profile of absorbed energy (which is very difficult to determine experimentally) it is assumed that some fixed distribution of electric field exists in the bulk of the dielectric. Therefore we need additional experimental definitions of the $E(x)$ or $\rho(x)$ dependences, which complicates the solution of the problem. However, at least when the thickness of the dielectric exceeds the range of the electrons, the required information on the distribution of absorbed dose can be obtained if a family of distributions calculated for a uniform electric field is available.[36] The method of calculation relies on a kinetic equation which describes the transport of electrons on the assumption of continuous retardation. The calculations were carried out for uniform dielectrics with $z_{ef} = 6$ and 14 (where z is the atomic number of the element). Some results of these calculations for a uniform field within the dielectric are shown in Fig. 9.

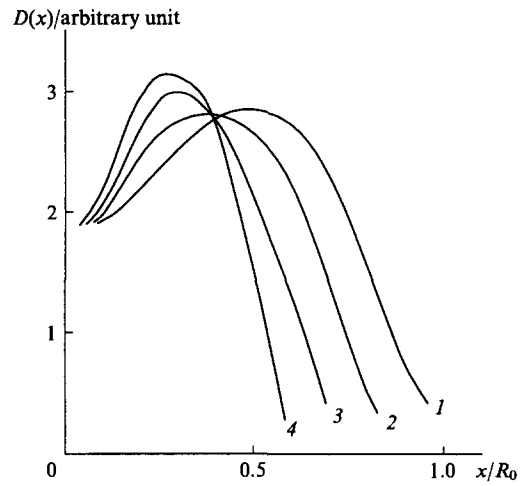

Figure 9. Distribution of the absorbed energy D for different values of the force $eE(x)$ acting on the electrons of energy 1 MeV injected into a dielectric ($z = 6$) from the side of the space charge field (MeV cm^2 g^{-1}): (1) 0; (*2*) 0.5; (*3*) 0.8; (*4*) 1.1.

The calculations show that as the interaction of the space-charge field with the electrons injected into the sample is increased the absorbed energy maximum moves towards the surface of the irradiated dielectric. This conclusion is of direct relevance to the study of the mechanical and optical properties of dielectrics exposed to a flux of charged particles. Allowance for this phenomenon should probably also be made in the measurement of radiation-chemical yield, which must also be varying over the thickness of the sample. Estimates[43] of the local values of the density of radiation-induced defects allowing for the space-charge field have confirmed this assumption.

The presence of large electric fields in irradiated dielectrics and semiconductors affects the yield of Compton electrons.[33] The change is characterised by the quantity δ, defined as the difference between the quantum yield in the electric field and without the field, and depending on the field intensity as follows:

$$\bar{\delta} = \int_0^R E(x) f(x) dx, \tag{32}$$

where $f(x)$ is the sensitivity function [$f(x) = \alpha x$], α is a constant, and R is the range. Integrating Eqn (32) by parts, and assuming that the electric potential is $V(x) = 0$ at $x = R$, we obtain

$$\bar{\delta} = 2\frac{\bar{\delta}_0}{ER}\int_0^R V(x)dx,$$

where $\bar{\delta}_0$ is the change in the quantum yield in a uniform electric field E. This result is strict in relatively weak fields. As the experiments show, $\bar{\delta}$ increases as E decreases. For example, in poly(methyl methacrylate) $\bar{\delta}$ increases almost 5-fold as the field strength is increased from 0.2 to 1.2 MV cm^{-1}.

Some published results[37] describe the formation of a powerful (explosive) emission from the free surface of dielectrics irradiated with strong beams of accelerated electrons in a pulsed regime. Unlike the previously known explosive emission from metallic samples this process is initiated by an internal (not by an external) electric field. It is observed in many dielectric materials —organic compounds, dielectric glasses, ionic crystals, and ceramic materials. It has been established that as soon as the intensity of the beam of bombarding electrons exceeds the threshold value characteristic of the particular material a powerful emission is produced, leading to a vacuum discharge [the experiments were carried out at a pressure of $10^{-6}-10^{-3}$ Torr, electron energy 0.35 MeV, pulse length $(2-30)\times 10^{-9}$ s, current density $(0.01-1.5)\times 10^3$ A cm^{-2}].

Threshold electron beam densities for various materials are shown below (10^{-5} cm^{-2} pulse^{-1}):

LiF	3
NaF	4
NaCl	6
KCl	7
Polyethylene	1
Teflon	3
Quartz glass	8

The strong explosive emission carries away from the dielectric, together with the ejected ion plasma, a charge ~100 times greater than the charge injected by the electron beam. This phenomenon could find practical applications in connection with the use of dielectrics excited by powerful electron beams as cut-off cathodes and commutators for high-current beams.

VIII. Dissolution kinetics of charged crystalline substances

The electrification of solids and the formation of electrical space charge in solids exposed to an ionising radiation have been studied reasonably widely, as has also the effect of the space charge on various physicochemical processes.[6]

We shall examine some examples in which the relationship between changes in the rates of dissolution and of electrification of the irradiated compounds can be monitored. We should point out first of all that the space charging of the dielectric is accompanied by its polarisation. Therefore when the substance is dissolved the transfer of ions (or of dipolar molecules) from the solid to the liquid phase takes place in an electric field.

In the dissolution of irradiated salts it is very difficult to separate the effects of one among several factors, such as charging, radiation-induced defects of the electronic type, displaced atoms, or structural surface changes. We shall discuss the changes in the dissolution rate constant k_v of irradiated crystals which may be attributed to radiation charging.

In crystals of $SrSO_4$ exposed to γ radiation or to accelerated electrons defects such as SO_4^- and SO_3^- ion radicals are produced, as well as e_{st}^- and others. At temperatures below −100 °C in the case of interaction with γ radiation (or at room temperature in the case of irradiation with electrons having energies of 1–3.5 MeV) only ion radicals and trapped electrons are formed. In Fig. 10 we show the changes in the rate of dissolution of crystals of natural celestine ($SrSO_4$) irradiated with fast electrons.

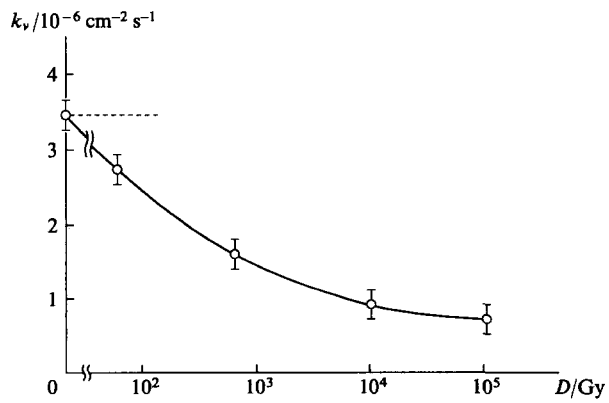

Figure 10. Dependence of the rate constant for the dissolution of a monocrystalline substance in water at 298 K on the dose of radiation. Crystals irradiated with accelerated electrons; energy 3.5 MeV; the broken line shows the value of k_v for nonirradiated crystals.

The experiments were carried out as follows. The crystals were irradiated at 20–30 °C (which produced only SO_4^- radicals and e_{st}^-) and immediately after the irradiation they were dissolved in distilled water at 20 °C. The outer layer of the crystals, damaged by the radiation, was removed by partial dissolution. Under these conditions a change in k_v could be attributed only to the radiation charging and to the formation of electronic defects. As can be seen from Fig. 10 the crystals of celestine freshly irradiated with 3.5 MeV electrons dissolve more slowly than the nonirradiated samples. In this effect the dominant role is played by the radiation charging, which nullifies the action of the radiation-induced defects.

When the crystals were stored (for several months) the charge produced by the irradiation decayed to some extent, and k_v increased, approaching the rate constant of the dissolution of the nonirradiated sample. We note that the concentration of SO_4^- fell slightly during storage, and SO_3^- ion radicals were formed instead. After heat treatment, which removed all the defects, the properties of irradiated and nonirradiated crystals became identical. This is confirmed by the results of experiments with polarised samples of $SrSO_4$ (Fig. 11). In this case the k_v value also gradually decreased as the polarisation field strength was increased.

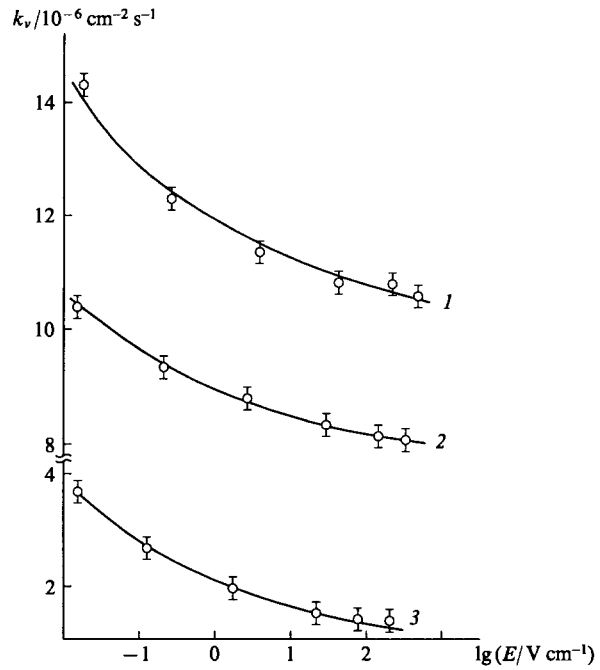

Figure 11. Changes in the rate constant for the dissolution in water for different values of the electric field strength (crystal polarisation). (*1*) NaF; (*2*) LiF; (*3*) $SrSO_4$.

In experiments on the action of fast electrons on LiF crystals[38] the thickness of the plates was chosen so that almost all the electrons with an energy of ~3.5 MeV were absorbed by the sample. After the irradiation the plates darkened, and a visual inspection showed that all the electrons had been absorbed near the irradiated surface. According to the experimental results the excess space charge was negative. Some of the irradiated crystals were placed in an electric field in a direction which increased the radiational polarisation, others were placed in a depolarising field (see Table 1). The lowest value of the dissolution rate constant was observed for the crystals in which the radiational polarisation was increased by the electric field. Decreasing the polarisation in the stimulated discharge of the irradiated LiF increases the rate of dissolution.

Table 1. Changes in the dissolution rate constant of LiF crystals irradiated with electrons and polarised in an external electric field[38] with a strength of 1500 V cm^{-1}.

Application conditions of electric field	$k_v/10^{-6}$ cm^{-2} s^{-1}	Notes
No field, crystal not irradiated	12.4	–
No field, crystal irradiated	11.2	Dose absorbed during irradiation 5×10^2 Gy
Field depolarisation used	10.4	Polarisation (depolarisation) time 48 h
Field polarisation used	9.4	–

The radiation-induced charging is often masked, and even counteracted, by the action of the radiation-induced defects. Obviously, opposing factors are developed simultaneously in the irradiated compounds: the dissolution is retarded by the radiational polarisation and the transfer of ions from the solid into the solution is accelerated by the formation of radiation defects. Similar effects are also seen in the dissolution of radioactive crystalline compounds, in which a stationary electric charge is permanently maintained during the disintegration of the radionuclides.[5, 38, 39]

A relationship between the charge in the crystals and their rate of dissolution was first established in studies of the dissolution of radioactive $SrSO_4$ crystals in water. It was then shown that NaCl, $SrSO_4$, and other salts dissolve more slowly than the nonpolarised compounds. The polarisation of the solvents also has an effect, and therefore the change in k_v is strongly dependent on the ratio of the dielectric constants of the solid and the liquid phase.[38, 39] Furthermore, the solubilities of the components of the system also play an important part.

Thus, according to the data in Fig. 11, the dependence of the change in the dissolution rate constant (in water) on the intensity of the electric field shows that as the field E is increased the k_v value decreases most markedly in $SrSO_4$, which has the lowest solubility. The decrease in k_v in a series of salts of the same type (NaCl, LiF, NaF) is strongest in the least soluble compound (LiF), which has the highest dielectric permittivity. The slower dissolution of ionic crystals after irradiation may to some extent be associated with their radiation-induced charging.

Let us examine the relationship between k_v and the strength of the field in the crystal. We shall express k_v in terms of two factors, one dependent and one independent of the polarisation of the crystal, and we shall discuss the elementary act of the dissolution of the crystal from the standpoint of the change in energy of the molecule during its transfer to the liquid phase. It will be assumed that the dissolution process obeys the Brønsted relation

$$\Delta Q_a = b\Delta Q_h , \tag{33}$$

where ΔQ_a is the activation energy of the dissolution; ΔQ_h is the heat of dissolution; b is an empirical constant ($0 \leqslant b \leqslant 1$). We can then write the following expression for the dissolution rate constant;

$$k_v = k_v^0 \exp\left(-\frac{b\Delta Q_h}{kT}\right) , \tag{34}$$

where k_v^0 is a temperature-independent quantity. Formula (34) can be rewritten

$$k_v = k_v^* \exp\left(-\frac{b\Delta F_{el}}{kT}\right) , \tag{35}$$

where ΔF_{el} is the change in the 'electric' component of the free energy (the Helmholtz free energy) of the molecules of the ionic crystal during the dissolution, and k_v^* includes both the entropy term and a term which characterises the free energy in terms of the strength of the electric field applied to the crystal. The parameter ΔF_{el} is $U_2 - U_1$ (the difference between the 'electric' free energies of the dissolution of the molecule in the solution and in the crystal respectively).

The dependence of the rate constant for the dissolution on the external electric field can be influenced only by that part of the free energy of the molecule in the crystal which is contributed to by the polarisability of the molecule. Therefore we can write the following expression for U_1:

$$U_1 = -\alpha|E|^2 , \tag{36}$$

where α is the total polarisation of one molecule; E is the strength of the electric field within the crystal. In the case of crystals with a uniform charge of anions and cations the energy U_2 (in the Gouy–Chapman approximation) is given as

$$U_2 = -16C_0K_D\pi r_0^2kT\sinh^2\frac{ez\phi}{4kT} , \tag{37}$$

where C_0 is the average equilibrium concentration of ions in the bulk of the solution; $K_D = (8\pi e^2z^2C_0/\varepsilon_2kT)^{1/2}$ is the reciprocal Debye length; z is the charge of the ions in the crystal; r_0 is the corresponding radius of the ion in solution; ϕ is the average potential of the outer Helmholtz plane (in which the centres of the ions in solution nearest to the crystal surface are localised); ε_2 is the average dielectric permittivity of the solution.

The total polarisability of the molecule in the solid phase α can be calculated by the Clausius–Mosotti relation

$$\alpha = 3M\frac{\varepsilon_1 - 1}{4\pi dN_A(\varepsilon_1 + 2)} , \tag{38}$$

where ε_1 is the static dielectric permittivity of the crystal; M is the molecular mass; d is the density; N_A is the Avogadro number.

In order to calculate E and ϕ we need to solve the problem of the distribution of potential in a system consisting of a polarised crystal with Helmholtz layers at its boundaries with the solution, and surrounded by the diffuse parts of the electrical double layer. If we adopt the Gouy–Chapman model to describe the distribution of charge in the diffuse part of the double layer the problem of the distribution of the ϕ potential (even only in the plane separating the crystal from the solution) reduces to the simultaneous solution of a system of two Poisson–Boltzmann equations (for the diffuse parts of the double layer) and three one-dimensional Laplace equations (for the Helmholtz part of the double layers and for the polarised crystal). The boundary conditions should ensure the continuity of the potential and of the electric induction at the interface between the crystal and the solution. After some algebra we arrive at the expressions

$$|E| = -\frac{4\pi}{\varepsilon_1}\left[|P| - \frac{4ezC_0}{K_D}\sinh\left(\frac{ez\phi}{2kT}\right)\right] , \tag{39}$$

$$\phi = \frac{4\pi e}{\varepsilon_1}\left[|P| - \frac{4ezC_0}{K_D}\sinh\left(\frac{ez\phi}{2kT}\right)\right] , \tag{40}$$

where $|P|$ is the polarisation of the crystal.

By combining the well known relationship between $|P|$ and the strength of the field applied to the crystal with Eqns (35)–(40) we obtain the dependence of the rate constant for the dissolution of the crystals upon their polarisation:

$$\ln\frac{k_v^*}{k_v} = 16b\left\{\sinh^2\left(\frac{ez\phi}{4kT}\right) - \frac{\alpha\pi^2}{\varepsilon_1^2kT}\left[|P| - \frac{4ezC_0}{K_D}\sinh\left(\frac{ez\phi}{2kT}\right)\right]^2\right\} . \tag{41}$$

The parameter P is related to the intensity E_1 of the electric field applied to the crystal by the expression

$$P = \frac{(\varepsilon_1 - 1)E_1}{4\pi\varepsilon_1}. \quad (42)$$

We may conclude from (39)–(42) that for sufficiently large values of α and not too small bulk concentrations of the solution k_v decreases with increase in E_1 (or P). However, it should not be forgotten that in strong fields ($ez|\phi| \gg kT$) the polarisability α is itself dependent on the field strength, decreasing as $|\phi|$ increases. Therefore an increase in the potential difference applied to the crystal should suppress the dependence of the rate constant of the dissolution on E_1, as is found in practice.

The theoretical prediction of an increase in the rate of dissolution of polarised crystals has been confirmed by observations of the dissolution of crystals of tartaric acid in solvents having different dielectric permittivities (Fig. 12).

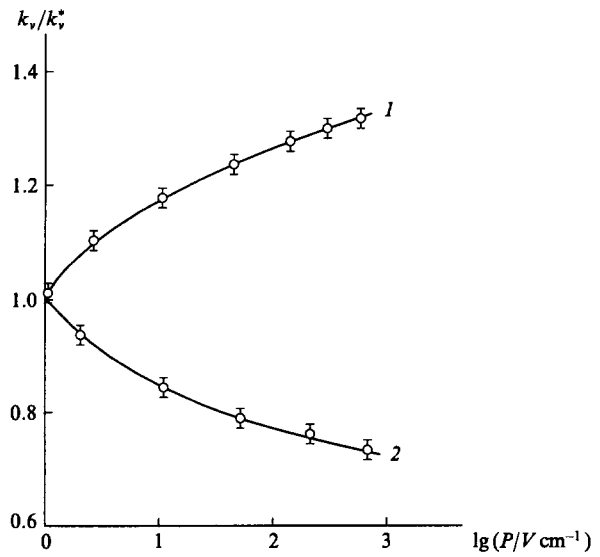

Figure 12. Changes in the rate of dissolution in water of crystals of tartaric acid as a function of the polarisation of the solid phase P ($\varepsilon_1 = 35.9$) in ethanol ($\varepsilon_2 = 20$) (*1*) and in water ($\varepsilon_2 = 80$) (*2*).

The physical significance of the slower dissolution of charged crystals is that the polarised dipole–molecule being transferred to the liquid phase must perform additional work against the force of the electric field. However, if the solvent also is polarised, it becomes more difficult for the dipole–molecule to return to the solid surface for $\varepsilon_{sol} \gg \varepsilon_{liq}$, i.e. the rate of dissolution increases and the molecule is 'pulled' into the liquid phase by the electric forces.

Similar effects have been observed[40] in a study of the rate of growth of etch pits at the emergence of dislocations on the surface of polarised LiF crystals.

Brief mention should be made of another possible way of suppressing the dissolution of crystalline dielectrics, in which the liquid phase is subjected to the orienting effect of an electric field. Thus, the polarisation of the solvent molecules in the boundary layer at the interface can stabilise the layer of liquid adjacent to the surface of the dissolving crystal.[41] In the present model the calculated strengths of the electric field produced by polarisation can vary between wide limits (from 0 to 10^3 V cm^{-1} or more). In actual systems the polarisation can strongly influence the viscosity and the perviousness of the surface layers. This is consistent with the views of a dependence of the viscosity of polar liquids on electric field effects. The dissolution of polarised crystals can also be retarded by the condensation (accumulation) of reaction products and other dissolved substances in the boundary layer under the influence of an electric field, and by the formation of crystal nuclei or polymer chains (for example, in P_2O_5 or SiO_2) able to interact with each other and with the molecules of the liquid medium. The new formations 'armour' the system and can induce the formation of a gel-like metastable state at the interface between the solid and the liquid phase. Therefore in some cases the polarisation of molecules on the surface of dissolving compounds can lead to the formation of protective gel-like films.

IX. Conclusions

The experimental work shows that the accumulation of electric charge in irradiated and in radioactive solid dielectrics is one of the most fundamental phenomena accompanying the action of ionising radiation on high-resistance materials. The developments in this field of study have been stimulated not only by their purely scientific interest but also by specific practical needs. Thus, the prediction of the service life of various electrical insulators and articles in fields of ionising radiation is impossible without a knowledge of the special features of the growth and relaxation processes which control the 'radiational' electric charging. This may ultimately determine the reliability of the operation of nuclear energy converters and apparatus used in cosmic flights when continuously exposed to ionising radiation, and other similar problems. Therefore further progress in this area is impossible without studies in depth of the mechanism of reversible and of irreversible processes initiated by ionising radiation in dielectrics.

At present the following promising fields of study in this area can be identified:

1. The development of a theory of the distribution of electric field in dielectric materials (or articles) in various configurations exposed to ionising radiation.

2. Improvements in the theory and methods of calculating the distribution of electric space charge (and its corresponding electric field) in heterogeneous structures (mixtures of solid substances, solid systems containing inclusions of various solid phases).

3. The acquisition of experimental information on the effect of external factors on the formation of an electric charge and on the 'freeing' of this charge from the given material (for example, in the form of electric discharges).

4. The study of the mechanism of radiation-chemical and radiation-physical processes in charged dielectrics: this should lead to the development of new methods of controlling the properties of these materials and of the physicochemical processes carried out by using them.

5. The modelling of actual operating conditions encountered by various materials in a field of ionising radiation, i.e. allowing for the combined effects on the dielectric of the charging, defect formation, temperature fields, mechanical interactions, and other factors.

The importance of this type of study arises because in many cases the formation of charge and the subsequent electric breakdown (which can even lead to the mechanical fracture of the dielectric) are the precursors of irreversible (and even, on occasions, reversible) radiation-chemical or radiation-physical changes in the material. For example, it has been shown[42] that at low temperatures (~77 K) the effectiveness of the charge accumulation in glasses irradiated by accelerated electrons increases, so that conditions conducive to electric discharges are produced even in a flow of 10^{12} electrons cm^{-2} (electron energy ~2 MeV). Heat treatment after irradiation merely accelerated this process. Similar effects are found in composite materials and polymers.

The solution of these problems should stimulate the development of reliable methods of increasing the radiation stability of various dielectric materials.

VI. Conclusion	1023

Abstract. The literature data on the methods of synthesis and the properties of naphthacenequinones and related compounds are surveyed. The tautomeric and photochromic transformations of naphthacenequinone derivatives are examined. The bibliography includes 158 references.

I. Introduction

The chemistry of polycyclic quinones is a promising and vigorously developing field of modern organic chemistry. This is associated with the fact that they have been finding increasingly wide application in many branches of science and engineering.

The first and so far the main application of quinones involves their use as organic dyes. In particular, naphthacenequinones—linear benzologues of anthraquinone—have been patented as dyes for synthetic fibres and polymeric resins.[1-10]

The study and synthesis of organic conducting materials based on certain naphthacenequinone derivatives has developed vigorously to the present time.[11-18]

Certain polycyclic quinones have found applications as pharmaceutical preparations. Thus anthracyclines, which are based on the naphthacenequinone carbon skeleton, constitute an important group of antibiotics.[19,20] Studies in the field of anthracyclines have developed vigorously in connection with the search for an alternative biochemical method of synthesis of compounds of this type in the preparation of new antitumour agents.[21-33]

It has been proposed that certain derivatives of naphthacenequinone be used in the manufacture of photochromic materials for the optical recording of information.[34]

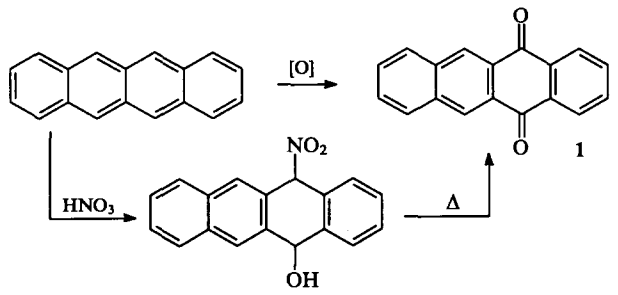
This review surveys the literature data on the methods of synthesis and the chemical and spectroscopic properties of naphthacenequinones and presents the results of studies on the tautomeric transformations of these compounds.

II. Methods of synthesis of naphthacenequinones and their derivatives

Depending on the position of the carbonyl groups in the naphthacene nucleus, naphthacenequinones are known to include three monoquinones—5,12-naphthacenequinone (*p*-naphthacenequinone), 5,11-naphthacenequinone (*ana*-naphthacenequinone), and 1,4-naphthacenequinone:



5,12-Naphthacenequinones have been most thoroughly investigated among these compounds.

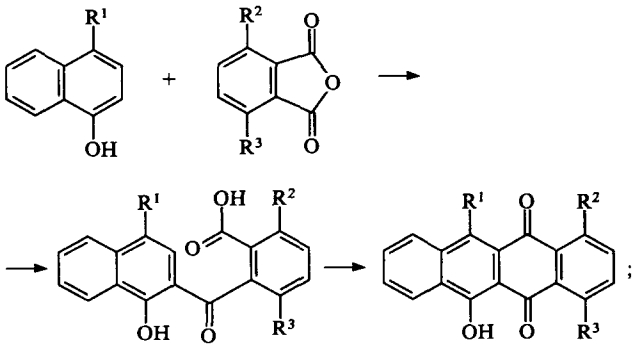
1. Methods of synthesis of 5,12-naphthacenequinone and its derivatives

The existing methods of synthesis of 5,12-naphthacenequinones can be divided into two groups depending on whether they are based on the use of compounds already having the napthacene carbon skeleton or whether they involve its construction.

The first group includes the oxidation reactions of naphthacene and its derivatives. Chromium trioxide in acetic acid,[35-38] chromic acid,[39] ozone,[40] perbenzoic acid,[41] nitric acid,[42] etc. are used as oxidants.

The unsubstituted 5,12-naphthacenequinone **1** was first obtained by oxidising naphthacene with chromium trioxide in acetic acid.[43]

Substituted derivatives of 5,12-naphthacenequinone were synthesised by a similar procedure: 2-isopropyl-, 2,8-dimethyl-, and 2,9-dimethyl-naphthacenequinones.[35,36] When naphthacene is oxidised with nitric acid, an adduct is first formed, being converted on heating into 5,12-naphthacenequinone **1**.[42]

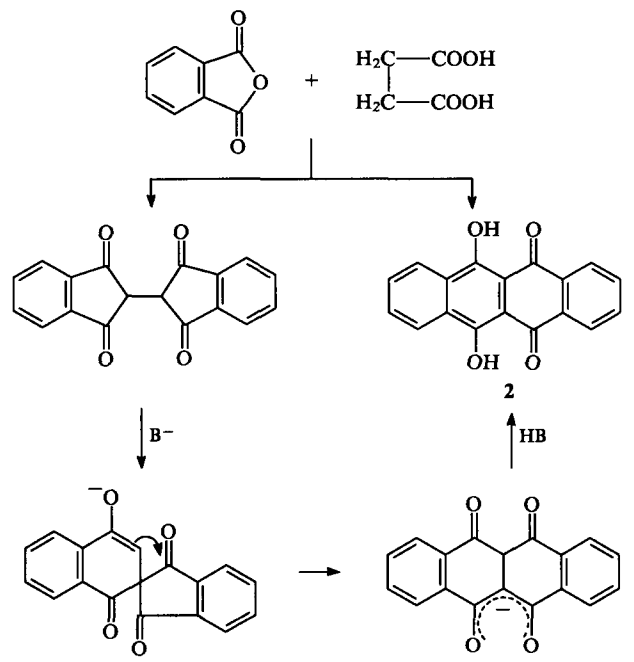


Compound **1** can also be obtained by oxidising naphthacen-5-one.[44,45]

The oxidation of 1,4-dichloronaphthacene leads to 7,10-dichloro-5,12-naphthacenequinone.[39] 6-Chloro- and 6-bromo-5,12-naphthacenequinones have been obtained from 5,11-dihalonaphthacenes.[38]

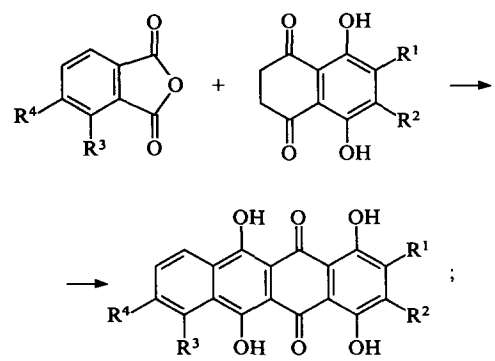
There exist data indicating the formation of 6,11-dihydroxy-5,12-naphthacenequinone in the vapour-phase oxidation of napthalene.[46,47] A method for the isolation of 6,11-dihydroxy-5,12-naphthacenequinone from the still residues remaining after the distillation of phthalic anhydride by codistillation with liquid paraffin has been proposed.[48]

The second group of methods of synthesis of 5,12-naphthacenequinone derivatives is based on cyclisation reactions, the main ones involving intramolecular acylation and diene synthesis.



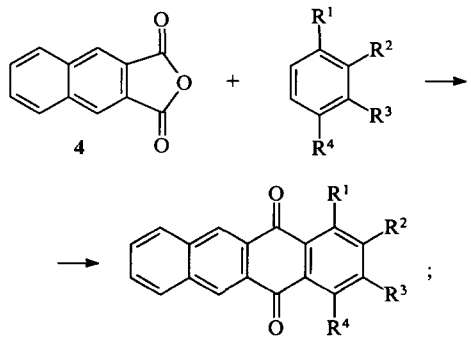
The intramolecular acylation reaction, widely used in the synthesis of anthraquinone derivatives, is also applicable to the synthesis of naphthacenequinones. Unsubstituted 5,12-naphthacenequinone **1** and many of its derivatives have been obtained by acylating naphthalene (or benzene) derivatives with phthalic anhydride (or the anhydride of naphthalene-2,3-dicarboxylic acid) by the Friedel–Crafts reaction in the presence of $AlCl_3$ or boron trioxide followed by the cyclisation of the resulting 2-(β-naphthoyl)benzoic (or 3-benzoyl-2-naphthoic) acid by a mixture of sulfuric and boric acids or in the $AlCl_3$–NaCl melt.[49,50]

R^1 = H, OH; R^2 = H, OH, NO_2, NH_2, NHAc, NMe_2, Cl; R^3 = H, OH, Cl.



The synthesis of 6-chloro-5,12-naphthacenequinone by the cyclisation of the corresponding naphthoylbenzoic acid on treatment with P_2O_5 has been described.[57]

Condensation of phthalic anhydride with succinic acid leads[58] to diphthalideneethane, which can be readily converted into naphthacenequinone **2**, but 40% of bis-1,3-indandionyl **3** is then formed as a side product. Prolonged refluxing of compound **3** in aqueous ammonia or 10% sodium acetate solution leads to naphthacenequinone **2** in a low yield.[59] When compound **3** is fused with a mixture of sodium and potassium acetates, naphthacenequinone **2** is obtained in 50%–60% yield. A mechanism of this reaction has been proposed.[60]

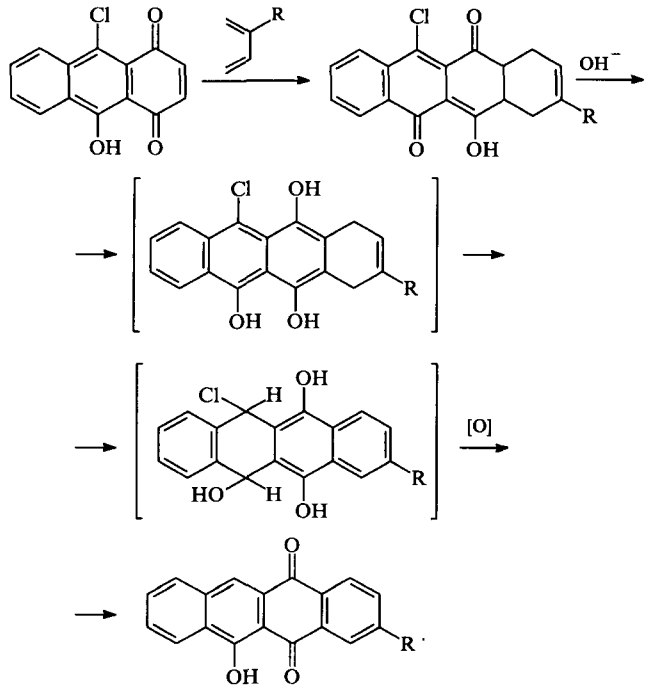


As in the case of the analogous anthraquinone derivatives, in the syntheses of a series of derivatives of 5,12-naphthacenequinone it is possible to carry out the acylation with phthalic anhydride and cyclisation of the resulting acids in a single stage in the presence of strong electron-donating substituents in the molecule to be acylated. The interaction of 1,4-dihydroxynaphthalene and 4,5-difluorophthalic anhydride with phthalic anhydride in the presence of boron trioxide afforded 6,11-dihydroxy-5,12-naphthacenequinone[52] and 2,3-difluoro-5,12-naphthacenequinone[61] respectively.

A whole series of 5,12-naphthacenequinones have been synthesised by the reactions of 3,4-disubstituted phthalic anhydride with derivatives of 2,3-dihydronaphthazarin in a melt of aluminium and sodium chlorides.[62,63]

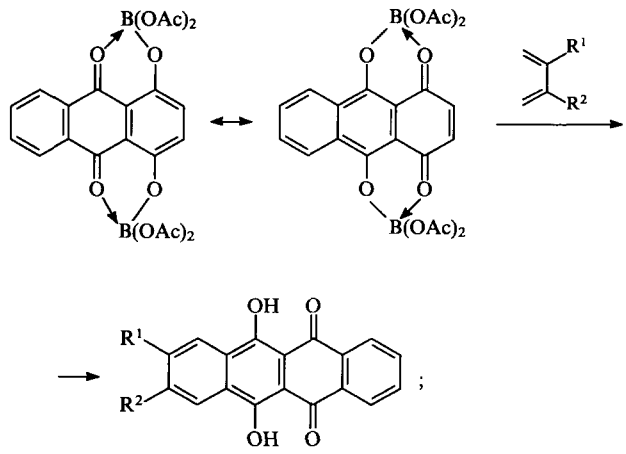
R^1 = H, OH; R^2 = H; R^3 = OH; R^4 = Et.

A series of substituted 5,12-naphthacenequinones has been synthesised by the reaction of the anhydride of naphthalene-2,3-dicarboxylic acid **4** with substituted benzene derivatives in the presence of aluminium chloride.[49,64]



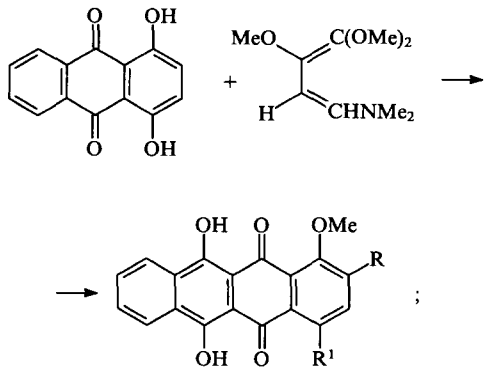
R^1 = Cl, NH_2, Me, OH; R^2 = H, Cl, Me, OH, OAlk, OPh; R^3 = OH; R^4 = H, Hal, OH, OAlk, SAlk, OPh, SPh, NH_2.

Condensation of compound **4** with substituted aminophenols in 80% – 100% sulfuric acid in the presence of boric acid at 100 – 200 °C afforded[65] disperse dyes which dye polyester fibres, giving rise to bright yellowish-red shades.



In the synthesis of 5,12-naphthacenequinones by the Diels – Alder reaction, anthraquinone derivatives, which combine with 1,3-dienes, are used as dienophiles. The adducts formed are then oxidised (Scheme 1).[66–70]

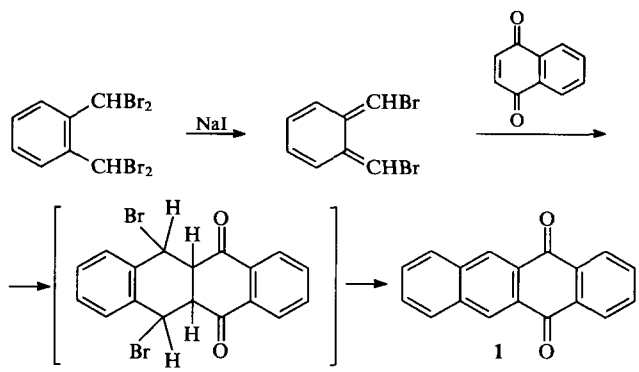
Scheme 1



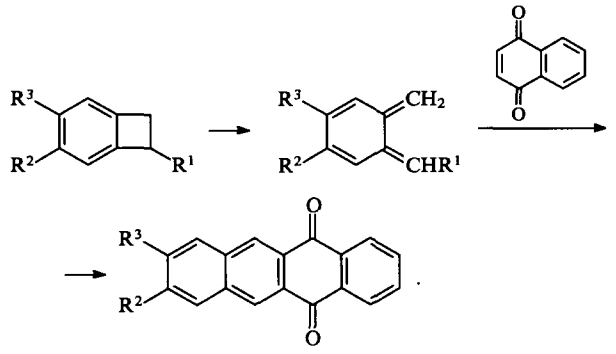
Analogues of natural antibiotics of the tetracycline series have been synthesised in this way.[71–73] There exists convincing evidence[74,75] that the dienophile enters into the reaction as a 1,4-anthraquinone.

The Diels – Alder reaction can be carried out also for the boron complexes of 1,4-dihydroxy- and 1,4-diamino-anthraquinones.[76]

R^1 = R^2 = H, Me.

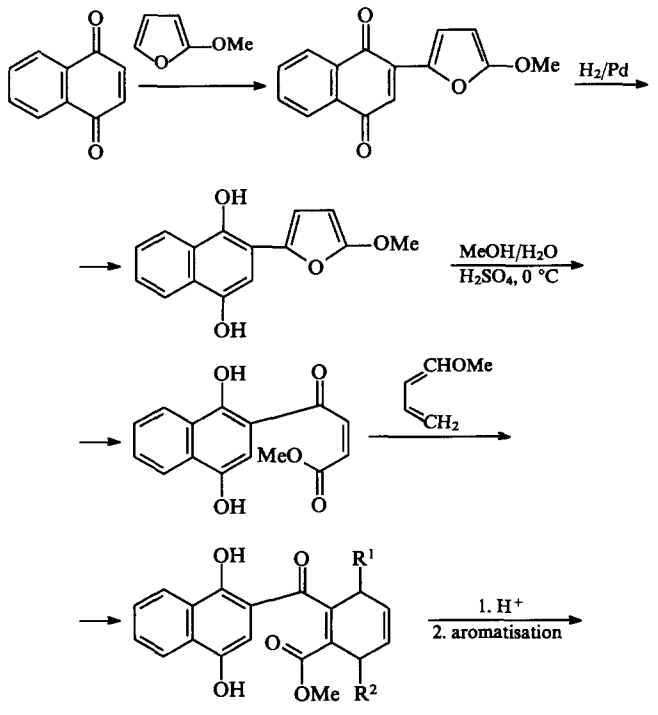


A mixture of naphthacenequinones **5a** and **5b** has been obtained from quinizarin and 4-dimethylamino-1,1,2-trimethoxybuta-1,3-diene.[77]



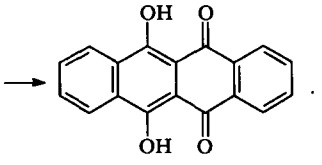
5a,b

5a: R = OMe, R^1 = H; **5b**: R = H, R^1 = NMe_2.

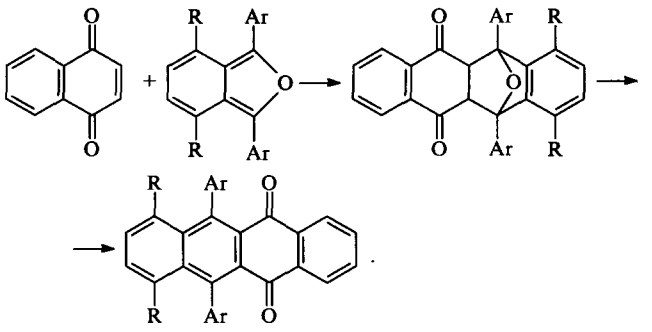


The addition of a dienophile such as dibromo-*o*-benzoquinodimethane to 1,4-naphthaquinone leads to 5,12-naphthacenequinone **1**. Dibromo-*o*-benzoquinodimethane is obtained by treating 1,2-bis(dibromomethyl)benzene with sodium iodide.[78]

The cycloaddition of benzocyclobutenes to 1,4-naphthaquinone apparently also involves the initial formation of the corresponding *o*-quinodimethanes.[79]

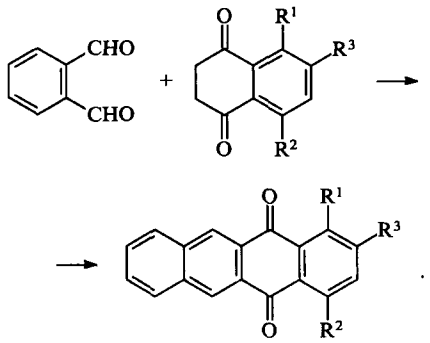


6,11-Dihydroxy-5,12-naphthacenequinone can be obtained in a low yield (13%) from 2-(5-methoxyfuryl)-1,4-naphthaquinone.[80]



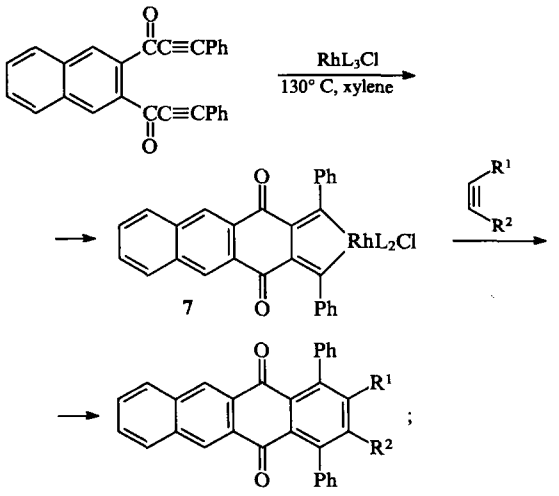
6a,b

6a: R^1 = H, R^2 = OMe; **6b**: R^1 = OMe, R^2 = H



6a : **6b** = 2 : 3

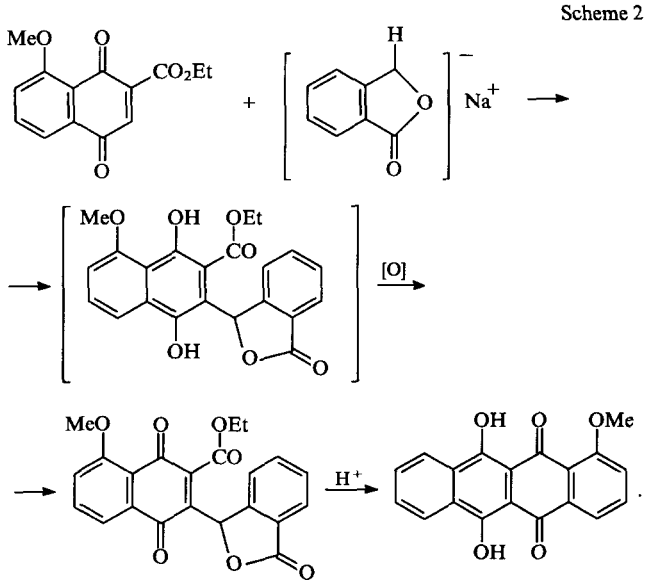
The use of benzofurans in the reaction with 1,4-naphthaquinone permits the synthesis of 5,12-naphthacenequinone derivatives.[81-83]



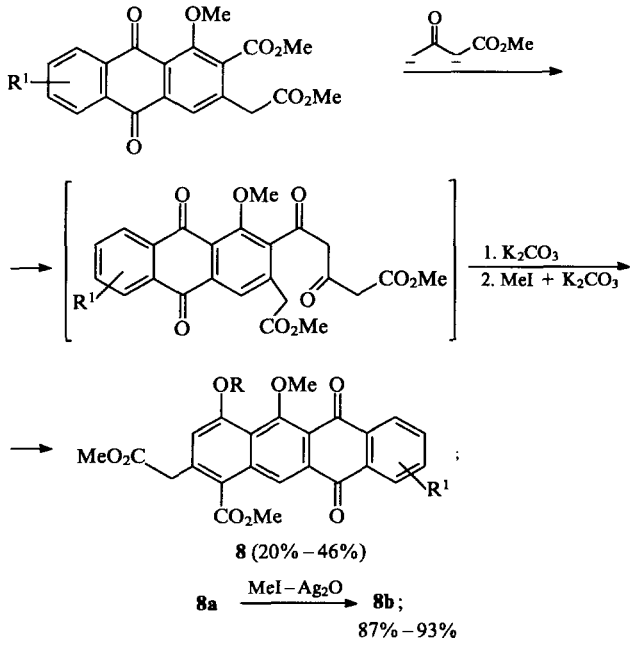
Derivatives of 5,12-naphthacenequinone have also been obtained by condensing aromatic *ortho*-dialdehydes with cyclic γ-diketones.[84-86]

1,4-Dihydroxy-5,12-naphthacenequinones can be obtained similarly from 1,2-diacylbenzenes and 2,3-dihydronaphthazarin in an acid medium.[87]

A method has been proposed for the synthesis of derivatives of 5,12-naphthacenequinone via the rhodium[88-91] and nickel[92] complexes obtained in the reaction of 1,2-bis(1-oxo-3-phenylprop-2-ynyl)naphthalene with ML_3Cl. Thus, when the rhodium complexes **7** are heated with disubstituted acetylenes, cycloaddition takes place with formation of tetrasubstituted naphthacenequinones:



L = PPh_3; R^1 = Me, OEt, COOEt, NEt_2; R^2 = H, Me.

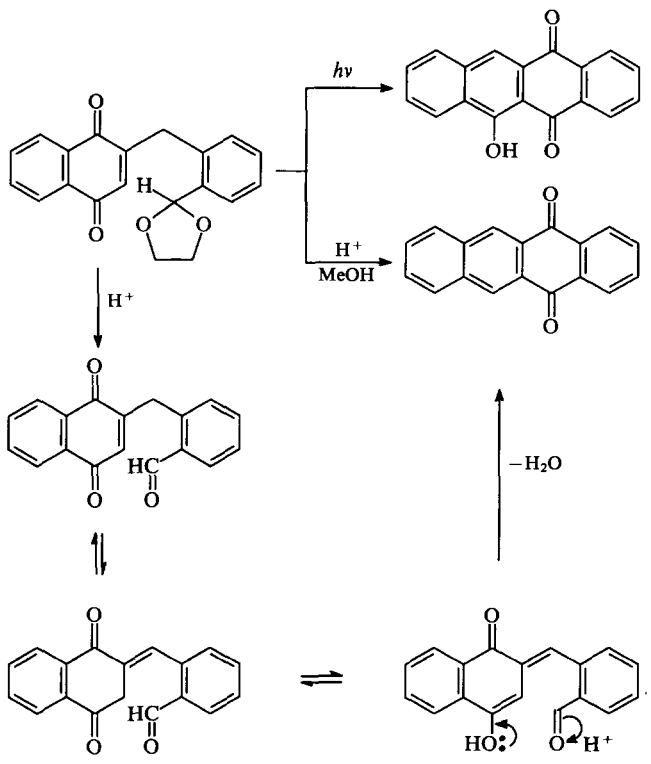


1,2-bis(1-oxo-3-phenylprop-2-ynyl)benzene isomerises to 6-phenyl-5,12-naphthacenequinone on heating or irradiation with UV light.[93]

The synthesis of 6,11-dihydroxy-1-methoxy-5,12-naphthacenequinone, the first stage of which is the addition of the phthalide ion to a substituted naphthaquinone, has been described. The adduct formed undergoes an acid-catalysed cyclisation with simultaneous decarboxylation, affording a substituted naphthacenequinone (Scheme 2).[94]

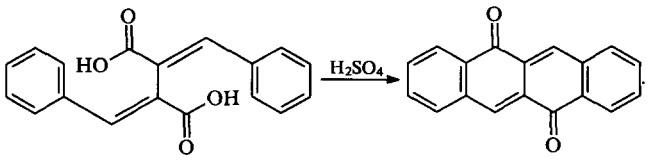
Scheme 2

Naphthacenequinone derivatives can be obtained by the Claisen condensation of substituted anthraquinones with the dianion of methyl acetoacetate and subsequent cyclisation on treatment with potassium carbonate.[95]



8 (20%–46%)

8a $\xrightarrow{MeI-Ag_2O}$ **8b**; 87%–93%

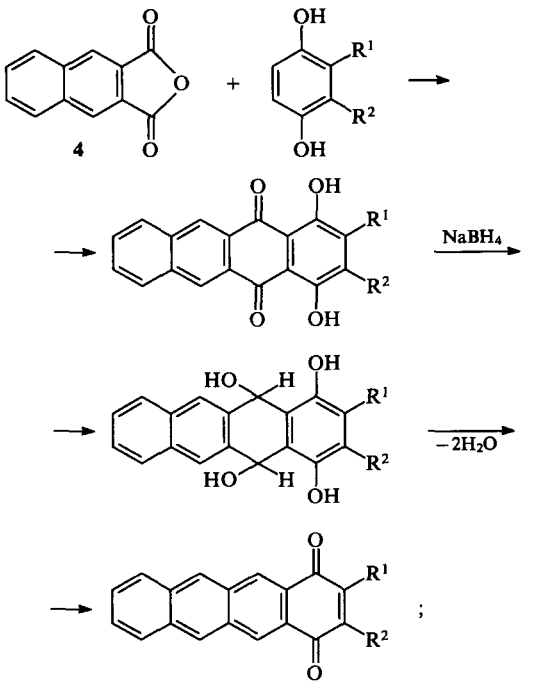


8a: R = H; **8b**: R = Me.

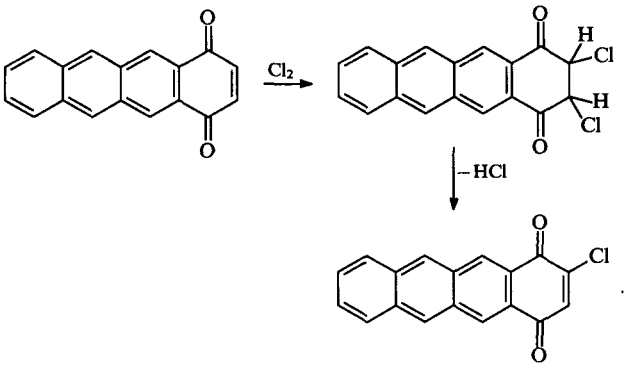
Irradiation of 2-[2-(1,3-dioxolan-2-yl)benzyl]-1,4-naphthaquinone in methanol (in a neutral, acid, or alkaline solution) affords a low yield of 6-hydroxy-5,12-naphthacenequinone. Hydrolysis of 1,4-naphthaquinone in sulfuric acid and methanol leads to naphthacenequinone (a mechanism is proposed for this reaction).[96]

2. Methods of synthesis of 5,11- and 1,4-naphthacenequinones

5,11-Naphthacenequinone (*ana*-naphthacenequinone), an isomer of 5,12-naphthacenequinone, was first obtained by cyclising 1,4-diphenylbuta-1,4-diene-2,3-dicarboxylic acid in concentrated sulfuric acid.[97]



ana-Naphthacenequinone is also formed on hydrolysis of 5,11-dibromonaphthacene.[38] The synthesis of derivatives of 5,11-naphthacenequinone is described below in the section on the properties of 5,11-naphthacenequinone.

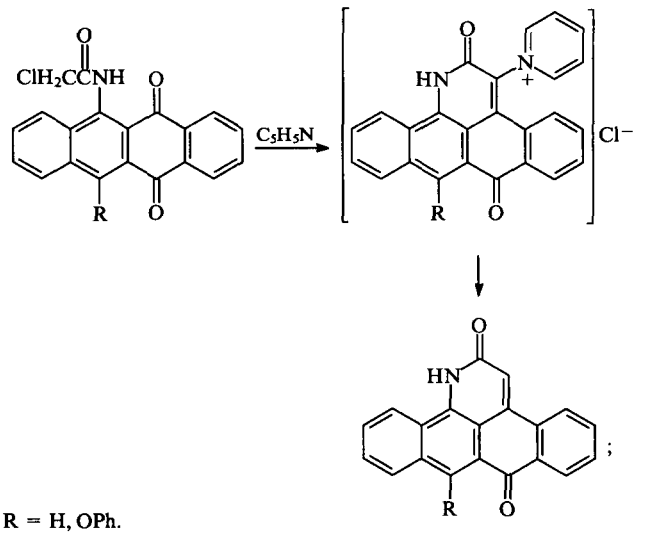


1,4-Naphthacenequinone and its derivatives have been obtained by condensing the anhydride of naphthalene-2,3-dicarboxylic acid **4** with derivatives of hydroquinones containing substituents in the 2- and 3-positions followed by the reduction of the resulting substituted 1,4-dihydroxy-5,12-naphthacenequinones with sodium tetrahydroborate and dehydration.[87,98,99]

1,4-Naphthacenequinone has many of the properties of the so called 'true' quinones having an isolated double bond, such as 1,4-naphthaquinone and 1,4-anthraquinone. Thus, 1,4-naphthacenequinone combines fairly readily with a chlorine molecule at the double bond, giving rise to 2,3-dichloro-2,3-dihydro-1,4-naphthacenequinone,[98,99] which readily splits off hydrogen chloride and is converted into the true monochloroquinone.[99]

The relatively unstable adduct was characterised in terms of the intense IR absorption band at 1721 cm^{-1} due to the carbonyl stretching vibration.

R^1 = H, Me, Cl, Br; R^2 = H, Cl, Me.



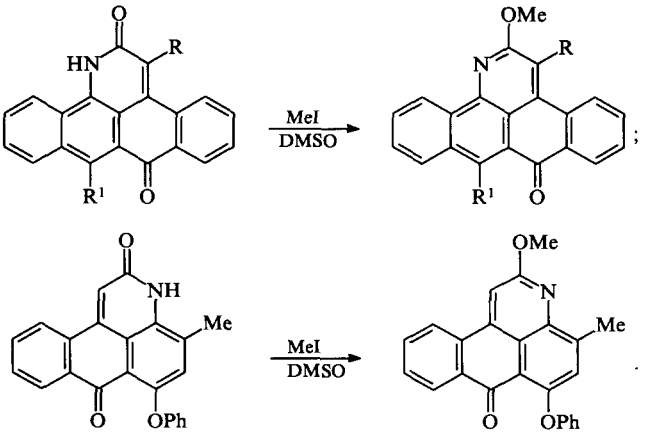
3. Methods of synthesis of heterocyclic *peri*-condensed derivatives of naphthacenequinone

In the series of naphthacenequinones, an important place is assumed by its heterocyclic *peri*-condensed derivatives. In terms of the site where the heterocycle has been added, 1,12- and 11,12-substituted derivatives are known.

As in the case of anthraquinone derivatives, the interaction of a heteroatom or functional group in the *peri*-position relative to one of the carbonyl groups of 5,12-naphthaquinone with this carbonyl group leads to the closure of a new ring beween these positions. The cyclisation reaction, leading to the formation of a new bond involving the carbon atom of the carbonyl group of naphthacenequinone, constitutes an intramolecular nucleophilic addition reaction with subsequent dehydration. The addition of a C-nucleophile and dehydration are accompanied by the replacement of a C=O bond by a C=C bond in 5,12-naphthacenequinone derivatives and the formation of a new ring.

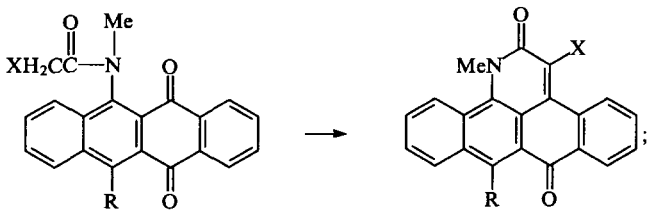
Thus in 6-aminonaphthacenequinone the C-nucleophile bound to the nitrogen atom attacks the carbonyl group in the 5-position, which results in the closure of a six-membered nitrogen-containing ring with formation of a new heterocyclic derivative of naphthacenequinone—2*H*,8*H*-naphtho[1,2,3-*de*]-benzo[*h*]quinoline-2,8-dione (naphthacenopyridone).

Naphthacenopyridones are formed as a result of the cyclisation of 6-(*N*-chloroacetyl)amino-5,12-naphthacenequinones in pyridine to the corresponding naphthaceno(2-oxo-3-pyridyl)pyridinium chlorides[100,101] and subsequent reductive elimination of the pyridinium residue.



R = H, OPh.

When 6-acetamido-5,12-naphthacenequinone and its 11-chloro-derivative are heated in phenol in the presence of sodium carbonate, the elimination of the acetyl group results in the formation, together with naphthacenopyridone and its 9-phenoxy-derivative, of an appreciable amount of 6-amino- and 6-amino-11-phenoxy-5,12-naphthacenequinones.[101]

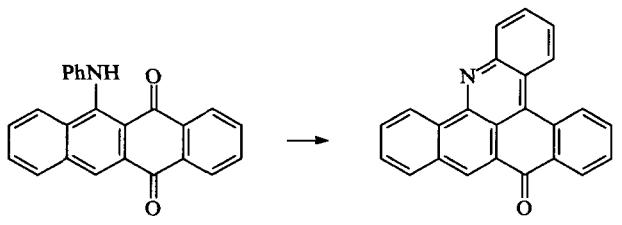


The 3-acetyl derivative of naphthacenopyridone has been obtained by the reaction of 6-amino-11-chloro-5,12-naphthacenequinone with acetoacetic ester in phenol in the presence of potassium carbonate.[101] The conditions in this reaction are the same as those used for the synthesis of anthrapyridones.[102]

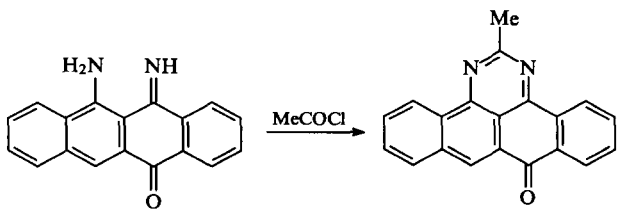
Methylation of naphthacenopyridones with methyl iodide in dimethyl sulfoxide leads to 2-methoxynaphthacenopyridines (*O*-methyl derivatives), whereas methylation of anthrapyridone under the same conditions affords its *N*-methyl derivative.

This difference in the behaviour of similar structures under identical conditions is apparently associated with steric hindrance to alkylation at the nitrogen atom in the case of naphthacenopyridones. Indeed, the sterically hindered 4-methyl-6-phenoxyanthrapyridone forms on methylation 2-methoxy-4-methyl-6-phenoxyanthrapyridine (the *O*-methyl derivative), in contrast to 6-phenoxyanthrapyridone.[101]

2*H*,8*H*-Methylnaphtho[1,2,3-*de*]benzo[*h*]quinoline-2,8-diones (*N*-methylnaphthacenopyridones) are obtained by heating 6-(*N*-acetyl)methylamino-5,12-naphthacenequinone in 3% aqueous[104] or alcoholic[105] sodium hydroxide solution. 6-(*N*-Acetyl)methylamino-11-chloro- and 6-(*N*-acetyl)methylamino-11-phenoxy-5,12-naphthacenequinones are converted under these conditions into 9-hydroxy-*N*-methylnaphthacenopyridones. A convenient method of synthesis of *N*-methyl-9-phenoxynaphthacenopyridone involves heating 6-(*N*-acetylmethylamino-11-phenoxy-5,12-naphthacenequinone in phenol in the presence of potassium carbonate.[103]

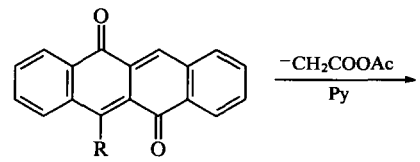


X = H: R = H, OPh, OH;
X = Cl: R = OPh.

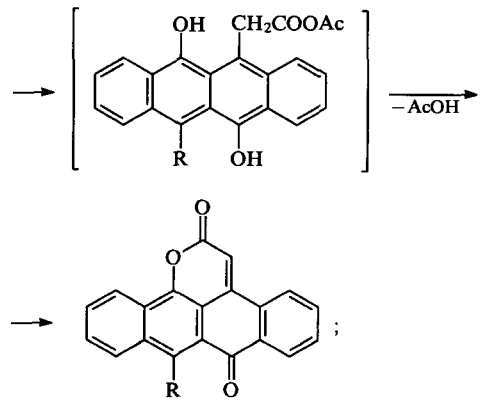


Heating of 6-(*N*-chloroacetyl)methylamino-11-phenoxy-5,12-naphthacenequinone in phenol leads to 3,9-diphenoxy-*N*-methylnaphthacenopyridone, i.e. cyclisation with simultaneous substitution in the resulting napthacenepyridone of the chlorine atom in the 3-position by a phenoxy-group takes place under these conditions.

A widely known method of synthesis of anthrapyridones, involving the cyclisation of chloroacetamidoanthraquinones in pyridine, proved to be applicable also to the synthesis of 3-chloro-*N*-methyl-9-phenoxynaphthacenopyridone.[100] 1-Methyl-9-phenoxynaphthaceno(2-oxo-3-pyridyl)pyridinium chloride, formed on heating the chloroacetamido-derivative of naphthacenequinone in pyridine, is converted into naphthacenopyridone on subsequent refluxing in nitrobenzene.[103]



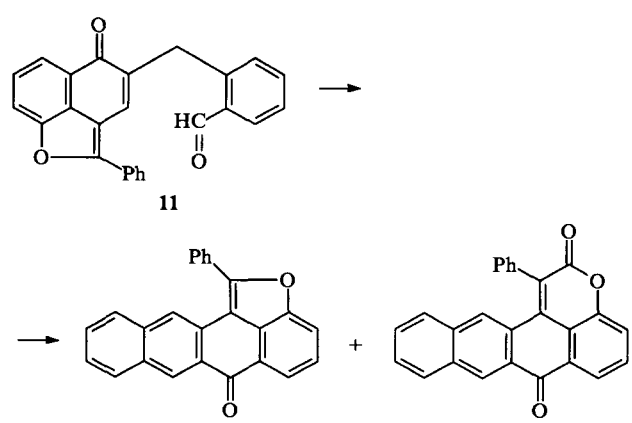
Cyclisation of 6-phenylamino-5,12-naphthacenequinone under the conditions used for the synthesis of ceramidonines, namely treatment with aluminium chloride or 75% sulfuric acid, leads to naphthacenoceramidonine[106] — 10*H*-naphtho-[*m*,*n*]benzo[*c*]-10-acridone.



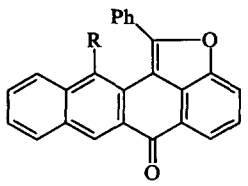
A naphthacenopyrimidine — 8*H*-dibenzo[*e*,*j*]pyrimidin-8-one — has been obtained by the reaction of 6-amino-5,12-naphthacenequinone imine with acetyl chloride in pyridine.[107]

Heterocyclic derivatives of naphthacenequinone with an oxygen-containing six-membered heterocycle — 2*H*,8*H*-naphtho[1,2,3-*de*]benzo[*h*]-1,2-chromene-2,8-diones (naphthacenopyrones) — are formed on reaction of 5,11-naphthacenequinones with acetic anhydride in pyridine or triethylamine.[108,109]

R = NAcPh (**9**), H, OPh.



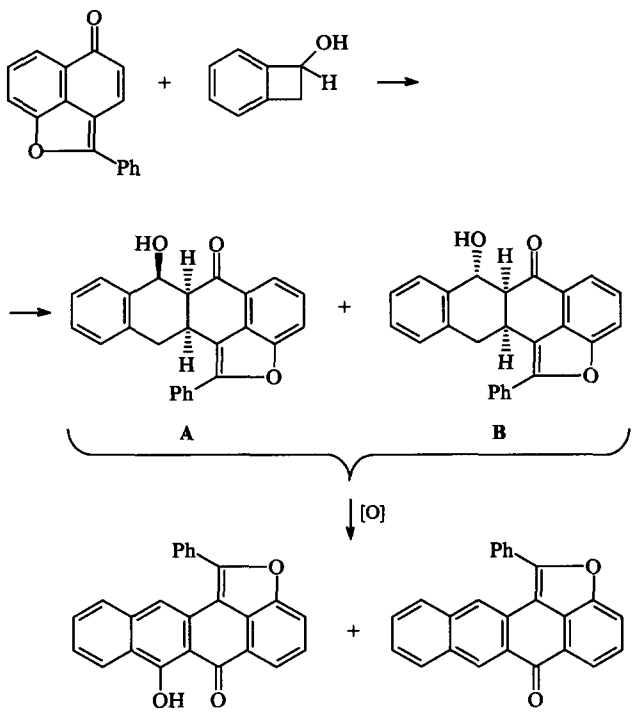
R = NAcPh, NHPh (**10**), H, OPh.



6-(*N*-Acetyl)phenylamino-5,11-naphthacenequinone interacts even more readily with malonic ester in pyridine to form 3-ethoxycarbonylnaphthacenopyrone.[108] In all the reactions enumerated above, the carbanion generated from acetic anhydride in the presence of pyridine apparently adds (via a Michael reaction) to the carbon atom in the 12-position with subsequent oxidation of the dihydro-derivative and the formation of the corresponding pyrone.

Refluxing of compound **9** (R = NAcPh) in a mixture of acetic and hydrochloric acids leads to the pyrone **10** (R = NHPh).[108]

Among the heterocyclic 1,12-*peri*-condensed derivatives of naphthacenequinone, compounds containing furan and pyrone rings are known. Treatment of the aldehyde **11** with sodium cyanide leads to a mixture of 1-phenylnaphtho[2,3-*e*]-benzo-[*h*,*i*]isobenzofuran-6-one (a naphthacenofuran) and 1-phenyl-7*H*,2*H*-benzo[*cd*]naphtho[2,3-*g*]-1,2-chromene-2,7-dione (a naphthacenopyrone). The naphthacenopyrone is formed on interaction of the naphthacenofuran with sodium cyanide.[110]



Treatment of the cyanohydrin of the aldehyde **11** with sodium hydride leads to cyano- and hydroxy-naphthacenofurans.[110]

R = OH, CN.

Thermal condensation of derivatives of naphthofuran with benzocyclobutenol in the dark results in the formation of a mixture of the stereoisomers **A** and **B**, the oxidation of which affords a mixture of naphthacenofurans (Scheme 3).[111]

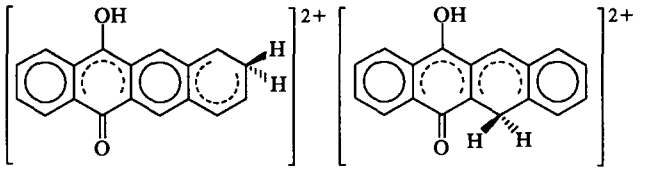
Scheme 3

Treatment of the isomers **A** and **B** with a solution of alkali leads to a single naphthacenofuran.

III. Chemical properties of naphthacenequinones

1. Properties of 5,12-naphthacenequinone and its derivatives

On treatment with an alkaline solution of sodium hydrogen sulfite, 5,12-naphthacenequinone is converted into the unstable green 5,12-dihydroxynaphthacene. The latter is readily oxidised to 5,12-naphthacenequinone and also enters readily into disproportionation and ketone formation reactions.[113] The reduction potential of 5,12-naphthacenequinone has not been measured owing to the instability of the corresponding hydroquinone (the calculated value is −0.3146 V).[114] The reduction of 5,12-naphthacenequinone with tin in acetic acid leads to the stable naphthacene-5-one; refluxing with zinc dust in an alkaline alcoholic solution affords 5,12-dihydronaphthacene.[113]



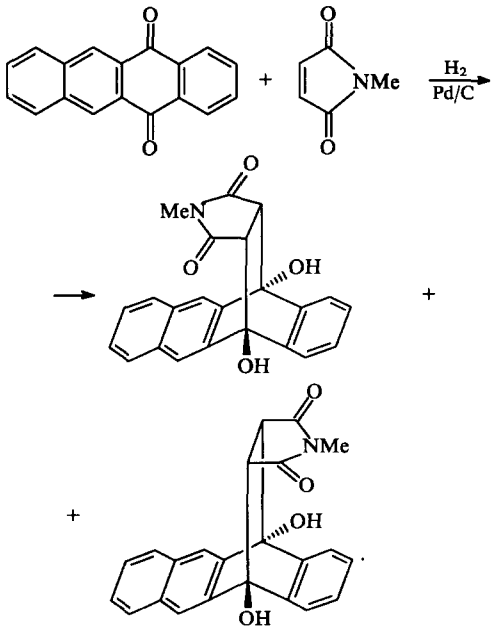
The reduction of alkylhydroxynaphthacenequinone with a cyclohexanol–aluminium cyclohexanolate mixture leads to alkylnaphthacenes.[115,116]

The polarographic behaviour of 5,12- and 5,11-naphthacenequinones in water–pyridine buffer mixtures of different composition has been investigated.[117] The reversible two-electron wave observed in acid solutions corresponds to the process[117]

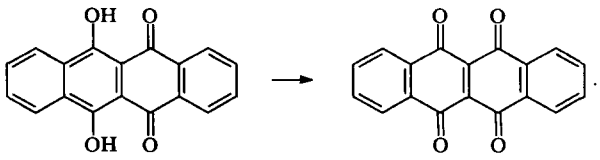
$$Q + 2e^- + 2H^+ \rightleftharpoons QH_2,$$

where Q is the naphthacenequinone.

5,12-Naphthacenequinone is protonated twice in sulfuric acid. The pK_a for the first and second protonations have been determined[118] as −8.20 and −8.66 respectively. It has been suggested[118] that the second proton adds to the carbon atom of the terminal aromatic ring. Quantum-chemical calculation and ^1H NMR data indicate the formation of structures **A** and **B** on protonation.[119]

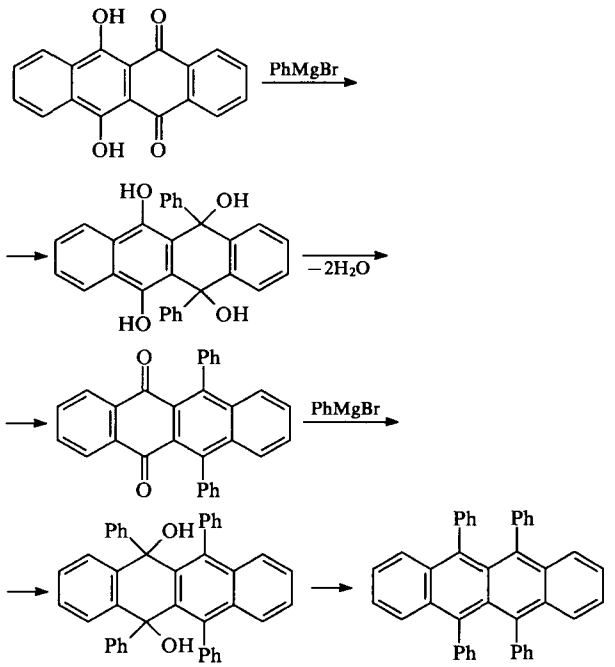


A **B**



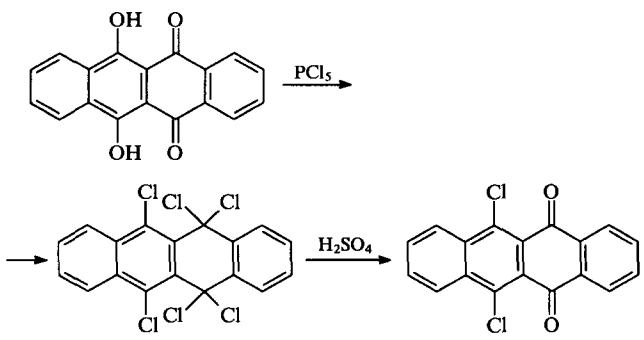
The mechanism of the electrochemical reduction in dimethylformamide of 6,11-dihydroxy-5,12-naphthacenequinone, which is reduced reversibly to 5,6,11,12-tetrahydroxynaphthacene, has been investigated by polarographic and cyclic voltammetric methods.[120]

The reduction half-wave potential of 5,12-naphthacenequinone in dimethylformamide in the presence of lithium perchlorate increases with increasing concentration of lithium ions, which has been explained by the formation of 1 : 1 and 1 : 2 ionic associated species.[121]



The catalytic reduction of a mixture of 5,12-naphthacenequinone and *N*-methylmaleimide in pyridine affords two products, which have been identified as the *endo*- and *exo*-adducts.[122]

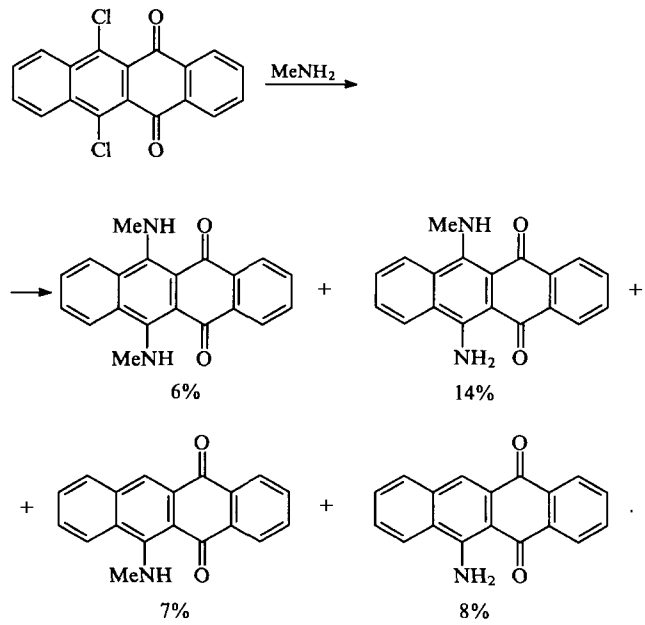
Oxidation of 6,11-dihydroxy-5,12-naphthacenequinone with nitric acid leads to the formation of 5,12;6,11-naphthacenediquinone.[43]



The interaction of naphthacenequinones with phenylmagnesium bromide leads to diols.

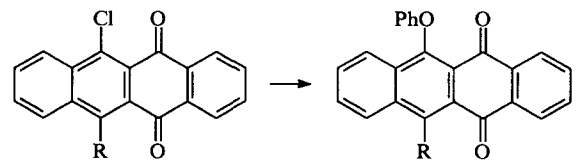
This reaction has been used in one of the syntheses demonstrating the structure of rubrene.[123]

The interaction of PCl_5 with 6-hydroxy-5,12-naphthacenequinone in nitrobenzene results in the formation of 6-chloro-5,12-naphthacenequinone,[38,57,124] while the reaction with 6,11-dihydroxy-5,12-naphthacenequinone affords 5,5,6,11,12,12-hexachlorodihydronaphthacene, the hydrolysis of which in sulfuric acid leads to 6,11-dichloro-5,12-naphthacenequinone.



The reaction of 6,11-dihydroxy-5,12-naphthacenequinone with PCl_5 is carried out either in tetrachloroethane[125] or without a solvent in a sealed tube.[126] An improved method of synthesis of 6,11-dichloro-5,12-naphthacenequinone in a PCl_5—quinone melt has been proposed.[127]

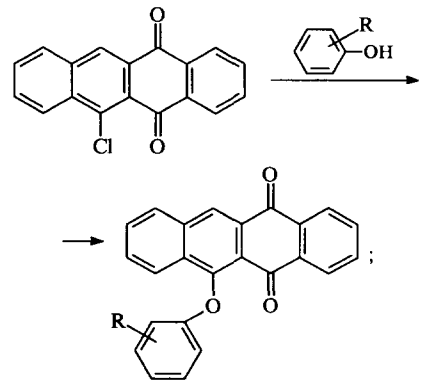
6,11-Dichloro-5,12-naphthacenequinone is also formed on heating 5,12-naphthacenequinone with sulfuryl chloride in a sealed tube.[38,124] On reaction with thionyl chloride, 5,12-naphthacenequinone affords 11-chloro-6-hydroxy-5,12-naphthacenequinone.[128]



Like 1-halo- and 1,4-dihaloanthraquinones, 6-halo- and 6,11-dihalo-5,12-naphthacenequinones enter into nucleophilic substitution reactions. The mobilities of the halogen atoms in these compounds are similar.

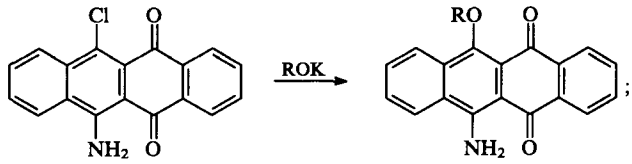
6-Amino- and 6,11-amino-5,12-naphthacenequinones have been obtained by treating chloronaphthacenequinones with toluene-*p*-sulfonamide or benzamide in the presence of copper salts and subsequent hydrolysis of the resulting tosylamino-derivatives.[49,57] 6-Amino-5,12-naphthacenequinone can also be synthesised from 6-chloro-5,12-naphthacenequinone and ammonia under pressure.[129] The interaction of 6,11-dichloro-5,12-naphthacenequinone with one mole of toluene-*p*-sulfonamide in nitrobenzene in the presence of copper salts and subsequent hydrolysis in sulfuric acid lead to 6-amino-11-chloro-5,12-naphthacenequinone.[127]

Treatment of 6,11-dichloro-5,12-naphthacenequinone with methylamine led to the formation of a mixture of amines.[130]



The interaction of halonaphthacenequinones with potassium phenoxide in phenol results in the formation of derivatives of 11-phenoxynaphthacenequinone.[127,129]

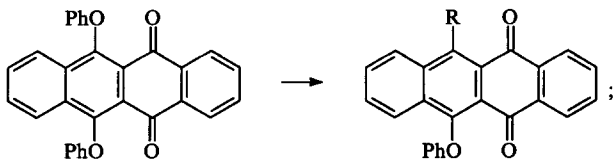
R = NH_2, H, NHTs, OPh.



A series of 6-aryloxy-5,12-naphthacenequinones has been synthesised by the reactions of 6-chloro-5,12-naphthacenequinone with substituted phenols.

R = *p*-Br, *p*-OH, *p*-OMe, *p*-NHPh, 2,4,6-Me_3, *p*-MeCO, *p*-NO_2, *p*-NH_2.

6-(4-Aminophenoxy)-5,12-naphthacenequinone has been obtained by reducing 6-(4-nitrophenoxy)-5,12-naphthacenequinone on palladised charcoal in formic acid.[131]

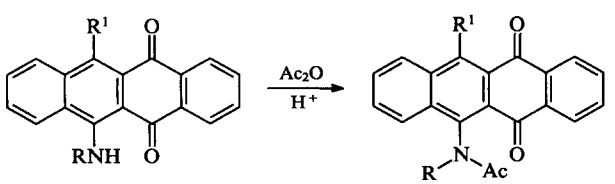


When 6-amino-11-chloro-5,12-naphthacenequinone and a substituted phenol were heated in an ArOH–ArO$^-$ melt in the presence of copper(I) chloride, 6-amino-11-aryloxy-5,12-naphthacenequinones were synthesised.[132]

R = *p*-MeC_6H_4, *p*-EtC_6H_4, *p*-$MeOC_6H_4$, *p*-$HPhNC_6H_4$, *p*-HOC_6H_4, *m*-ClC_6H_4, *p*-$O_2NC_6H_4$, α-$C_{10}H_7$.

The attempt to synthesise 6-amino-11-(4-hydroxyphenoxy)-5,12-naphthacenequinone by heating 6-amino-1-chloro-5,12-naphthacenequinone in an excess of the hydroquinone led only to the dehalogenation of the initial compound. 6-Amino-11-(4-hydroxyphenoxy)- and 6-amino-11-(4-phenylamino)-5,12-naphthacenequinones have been obtained by the reaction of 6-amino-11-chloro-5,12-naphthacenequinone with the corresponding substituted potassium phenoxide in dimethyl sulfoxide in the presence of copper(I) chloride.[132]

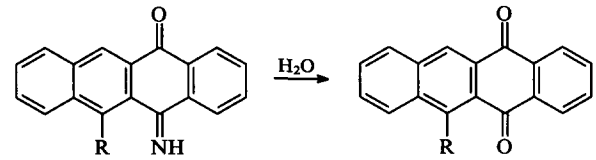
The interaction of 6,11-diphenoxy-5,12-naphthacenequinone with aliphatic and aromatic amines leads to 6-R-11-phenoxy-5,12-naphthacenequinone.[127]



R = NHMe, NMe_2, NHPh.

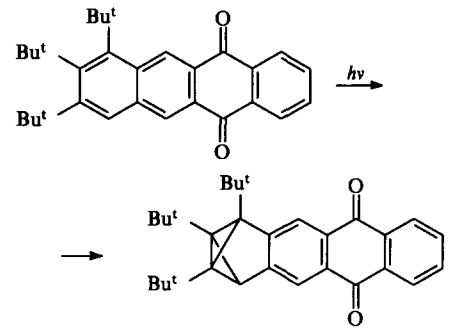
6-Methoxy-11-phenoxy-5,12-naphthacenequinone has been obtained by the transesterification of diphenoxynaphthacenequinone with methanol in benzene.[127]

6-Acetoxy-11-phenoxy-5,12-naphthacenequinone has been synthesised from 6-hydroxy-11-phenoxy-5,12-naphthacenequinone and acetic anhydride in the presence of pyridine.[127]



Acetoxy- and benzoyloxy-groups located in the *peri*-positions relative to the carbonyl group of naphthacenequinone are converted into hydroxy-groups on treatment with trifluoroacetic acid containing a small amount of water. With increase in the water content, the rate of the first-order reaction falls.[132]

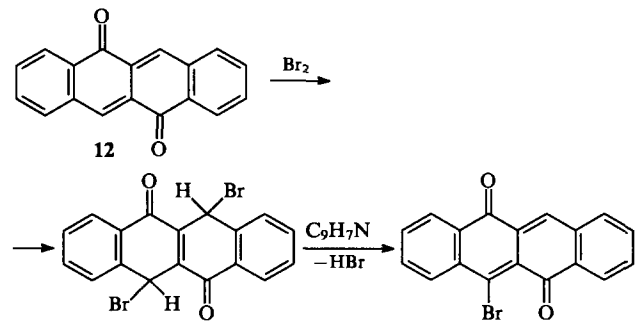
Acetylation of aminonaphthacenequinones with acetic anhydride in the presence of sulfuric acid leads to *N*-acetyl derivatives.[127]



6-Nitro-11-phenoxy-5,12-naphthacenequinone has been synthesised by oxidising 6-amino-11-phenoxy-5,12-naphthacenequinone with peracetic acid.[127]

Hydrolysis of 5-iminonaphthacen-12-one leads to 5,12-naphthacenequinone.[44,45,107]

R = H, Ph, NH_2.

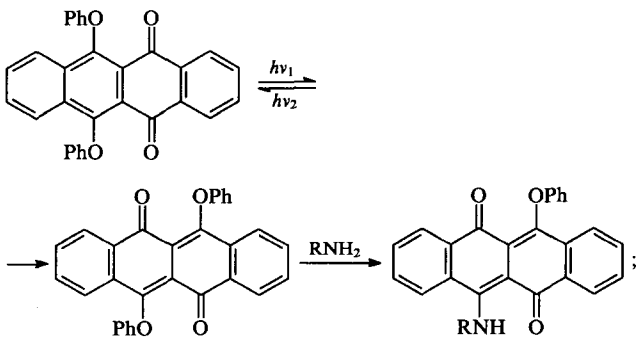


8,9,10-Tri(*tert*-butyl)naphthacenequinones have been synthesised. Under the influence of light, they undergo photovalent isomerisation with formation of a kinetically stable bicyclobutane derivative in a quantum yield of 0.09.[134]

2. Properties of 5,11-naphthacenequinones

The reduction of 5,11-naphthacenequinone **12** with zinc leads to the formation of naphthacene,[97] whilst its fusion with alkali in air gives rise to 6,11-dihydroxy-5,12-naphthacenequinone.[97]

5,11-Naphthacenequinone readily combines with bromine in the 6- and 12-positions with formation of a dibromodihydro-derivative, which on treatment with quinoline is converted into 6-bromo-5,11-naphthacenequinone.[39]

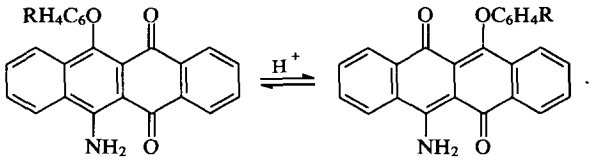


The reaction of 6-bromo-5,11-naphthacenequinone with aniline leads to 6-phenylamino-5,12-naphthacenequinone.[39]

When 5,11-naphthacenequinone is heated with sulfuryl chloride in nitrobenzene at 120–150 °C 6-chloro-5,12-naphthacenequinone is formed.[38,124] This reaction is an example of the conversion of an *ana*-quinonoid structure into a *p*-quinonoid structure. If the reaction is carried out with an excess of sulfuryl chloride in a sealed tube, 6,11-dichloro-5,12-naphthacenequinone is obtained.[38,124]

It follows from the foregoing that the 6- and 12-positions in the 5,11-naphthacenequinone molecule are reactive in relation to nucleophiles. Thus heating of 5,11-naphthacenequinone in aniline leads to 6-phenylamino-5,11-naphthacenequinone.[39]

Reactions involving the nucleophilic substitution of the halogen atom in 6-halo-5,11-naphthacenequinones proceed under much milder conditions[39] than the analogous reactions in the series of 5,12-naphthacenequinones and anthraquinones. 6-Bromo-5,11-naphthacenequinone interacts readily with primary amines at room temperature with formation of 6-amino-5,11-naphthacenequinones in quantitative yields.[39]



The phenoxy-group in 6-phenoxy-5,11-naphthacenequinones is extremely readily substituted by an amino-group.[135] 6-Amino-12-phenoxy-5,11-naphthacenequinones have been obtained by treating 6,12-diphenoxy-5,11-naphthacenequinone with an amine RNH_2; 6,12-diphenoxy-5,11-naphthacenequinone is formed as a result of a photorearrangement of the *p*-quinone.[127]

R = H, Me, Ph.

Treatment of 6-bromo- and 6-phenoxy-5,11-naphthacenequinones with secondary amines does not lead to tertiary amines but to 6-hydroxy-5,12-naphthacenequinone, which is probably associated with the impossibility of the existence of such tertiary amines in a stable *p*-quinone imine form.[108]

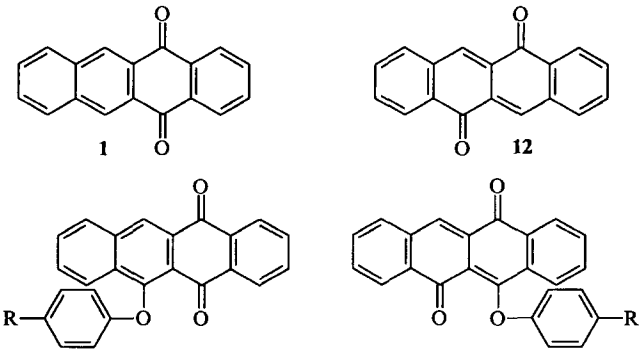
6-Amino-12-aryloxy-5,11-naphthacenequinones have been obtained by the acid rearrangement of the corresponding *p*-quinones.[132,136]

Acetylation of amino-derivatives of *ana*-naphthacenequinone with acetic anhydride leads to *N*-acetamido-5,11-naphthacenequinones.[108,127]

The interaction of 6-hydroxy- and 6,12-dihydroxy-5,11-naphthacenequinones with aniline in the presence of boric acid will be examined in the section devoted to the tautomeric transformations of naphthacenequinones.

IV. Spectroscopic properties

The IR spectra in the 1665–1678 cm^{-1} range of 5,12-naphthacenequinones contain absorption bands due to the C=O bond stretching vibrations characteristic of *p*-quinones with integral intensities $A_{C=O}$ of 2.0 for each C=O group. The presence of intramolecular hydrogen bonds lowers $\nu_{C=O}$ (the amino-group exerts a particularly strong influence). The intense absorption bands due to the stretching vibrations of the bonds of the quinonoid ring O=C–C=C–C=O in the region of 1280 cm^{-1}, which are typical of quinones, are observed in the range 1275–1290 cm^{-1} in the case of *p*-naphthacenequinones.



The IR spectra of 5,11-naphthacenequinones differ markedly[137] from those of 5,12-naphthacenequinones. The frequency of the stretching vibrations of the C=O bonds diminishes to 1650–1655 cm^{-1}, while the integral intensity $A_{C=O}$ falls to 1.3. In the absorption region of C=C bonds, there is only one absorption band at 1595 cm^{-1} with an enhanced intensity in the spectra of 5,11-naphthacenequinones, in contrast to 5,12-naphthacenequinones. The absorption bands due to the quinonoid ring bonds of the *ana*-isomers are displaced to 1320 cm^{-1} with retention of their intensity. The results indicate an increase in the degree of delocalisation of the π-electron density in the *ana*-isomers compared with the *para*-isomers, as suggested by Nurmukhametov et al.[138] This is confirmed both by the decrease in $\nu_{C=O}$ and $A_{C=O}$ (since the bond dipole moments, characterised by the integral intensities of the absorption bands, are reduced on delocalisation) and by the increase in the intensity of the absorption bands due to the C=C bonds in the region of 1595 cm^{-1}.

A two-dimensional electron-gas model has been used to calculate the π-electron density and spectral transition energies in naphthacenequinones; the transition energies obtained agree well with the experimental data.[139]

The localisation energies of different types have been calculated by the MO method for 5,12- and 5,11-naphthacenequinones.[140]

The main chromophore in the *p*-naphthacenequinone molecule is the naphthalene ring with two-carbonyl groups in the β-positions, while in the *ana*-naphthacenequinone molecule it is the diphenylbutadiene component with two carbonyl groups.[138,141]

The absorption spectrum of 5,12-naphthacenequinone **1** in hexane is characterised by the long-wavelength absorption band due to the $\pi \rightarrow \pi^*$ transition with vibrational structure and a relatively weak shoulder corresponding to the $n\pi^*$ absorption.[142] The validity of this interpretation is confirmed by the hypsochromic shift of the $n\pi^*$ absorption band with increase in the number of rings in the series benzoquinone → naphthaquinone → anthraquinone. On passing from anthraquinone to naphthaquinone, there are no further changes in the system of conjugated bonds, including the carbonyl group, and hence there are no reasons for a further hypsochromic displacement of the absorption band despite the increase in the number of rings in the molecule. Therefore the lowest singlet state in naphthacenequinone is the $n\pi^*$ state, as in the quinones with a smaller number of rings.[143]

R = H, NO_2, Ac.

The introduction of a phenoxy-group or of more complex substituents in the 6-position in the naphthacenequinone molecule does not induce any significant change in the position of the long-wavelength $\pi\pi^*$ band. The $n\pi^*$ band in the absorption spectra of these compounds is not observed explicitly, possibly owing to the electron-donor effect of the phenoxy-group which induces an increase in the energy of the $n\pi^*$ transition.

The bathochromic shift of the long-wavelength absorption band after the introduction of hydroxy- and amino-groups in the 6-position in naphthacenequinone can be readily accounted for

in terms of the molecular orbital theory concerning the influence of electron-donating substituents on the electronic spectra of aromatic molecules. When electron-donating substituents are introduced, a higher occupied π orbital appears, which induces a decrease in the $S_1 - S_0$ transition energy. In the case of a strong electron-donating substituent (the amino-group is of this kind), this orbital corresponds to a large extent to the heteroatom and can be designated as a π_{ED} orbital, whereas in the presence of a weaker substituent (the hydroxy-group) it is the perturbed highest occupied π_{Ar} orbital. In conformity with the foregoing, the long-wavelength absorption band of 6-aminonaphthacenequinone can be assigned to the $\pi_{ED} \rightarrow \pi^*_{EA}$ transition, while the band in the range 25 000–28 000 cm^{-1} can be assigned to the $\pi_{Ar} \rightarrow \pi^*_{EA}$ transition.[138]

The long-wavelength band of 5,11-naphthacenequinone **12** is of the $\pi\pi^*$ type. The introduction of substituents in the *para*-position of the phenoxy-group in 6-phenoxy-5,11-naphthacenequinone hardly affects the energy of the $^1\pi\pi^*$ transition, as in the corresponding *p*-naphthacenequinones.

The absorption of the $n\pi^*$ type is clearly not observed in the spectra of *ana*-naphthacenequinones. According to the results,[3] one may expect that the $n\pi^*$ absorption band in the spectra of *ana*-naphthacenequinones is in the immediate vicinity of the $n\pi^*$ levels of 1,4-naphthaquinone and benzylideneindandione. It is then found that the energy of the $n\pi^*$ level of the naphthacenequinone is very close to the energy of the $^1\pi\pi^*$ level, exceeding the latter somewhat.[143]

5,12-Naphthacenequinone does not fluoresce either at room temperature or at 77 K. At 77 K prolonged green phosphorescence of 5,12-naphthacenequinone in methylpentane has been noted.[145] In hexane, the phosphorescence spectrum has a well-resolved structure[147] with an intense peak at 1940 cm^{-1}. The appreciable gap between the absorption and phosphorescence bands (6000 cm^{-1}) and the long duration of the phosphorescence ($\tau_{ps} \simeq 0.3$ s) [145] make it possible to assign the phosphorescence to the $\pi\pi^*$ state. A similar picture has been observed also for substituted *p*-naphthacenequinone. 6-Phenoxy-5,12-naphthacenequinone does not exhibit an intrinsic fluoresence (Fig. 1).[143]

Solutions of 5,11-naphthacenequinone do not exhibit an intrinsic luminescence either at room temperature or at 77 K. A weak fluoresence, intensifying as a function of time, has been attributed to the appearance of 6-hydroxy-5,12-naphthacenequinone — the 5,11-naphthacenequinone conversion product.

In acetic acid, which quenches the fluorescence of 6-hydroxy-5,12-naphthacenequinone, the bright green fluorescence of 5,11-naphthacenequinone was observed at 77 K. The 'activation' of the fluorescence of 5,11-naphthacenequinone by a polar solvent shows that the $^3n\pi^*$ level, located below the $^1\pi\pi^*$ level in non-polar solvents, lies above the $^1\pi\pi^*$ level in the polar acetic acid and does not participate in the non-radiative deactivation of the latter.[143]

An intrinsic fluoresence has not been observed for 6-phenoxy-5,11-naphthacenequinone in acetic acid. The introduction of substituents in the phenoxy-group does not alter appreciably the luminescence properties of the molecule. This difference in the behaviour of 5,11-naphthacenequinone and that of its 6-phenoxy-substituted derivatives is probably associated with the occurrence of the competing photoisomerisation process in the phenoxy-derivative. Fig. 2 illustrates the energy state diagram and the most probable paths leading to the degradation of the excitation energy of 5,12- and 5,11-naphthacenequinones.[143]

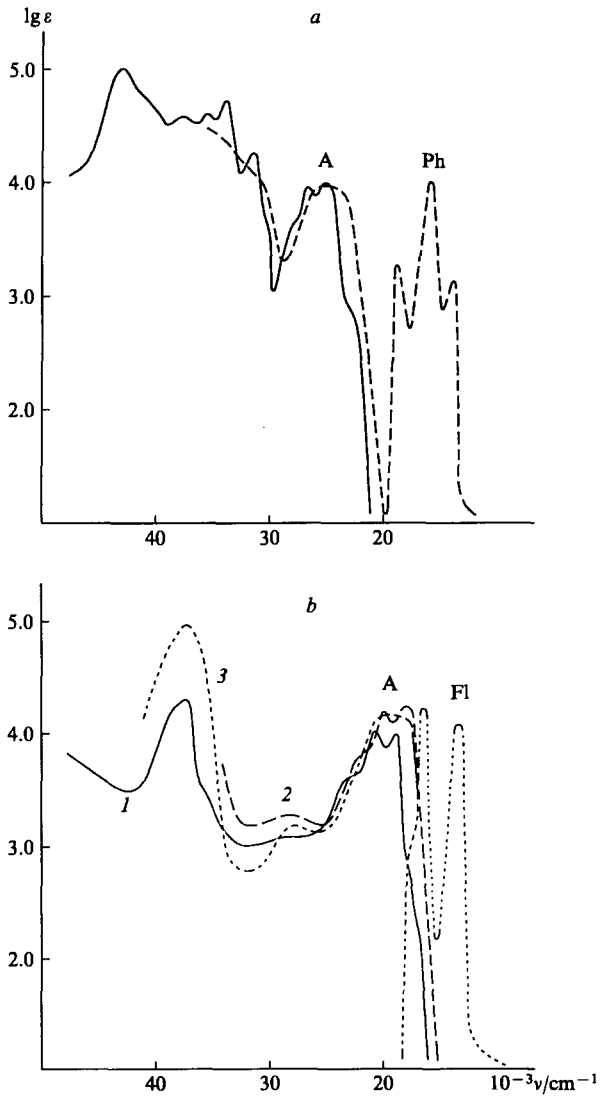


Figure 1. Absorption (A), phosphorescence (Ph), and fluorescence (Fl) spectra of the naphthacenequinones **1** (*a*) and **12** (*b*) in hexane (curve *1*), toluene (curve *2*), and acetic acid (curve *3*).[143]

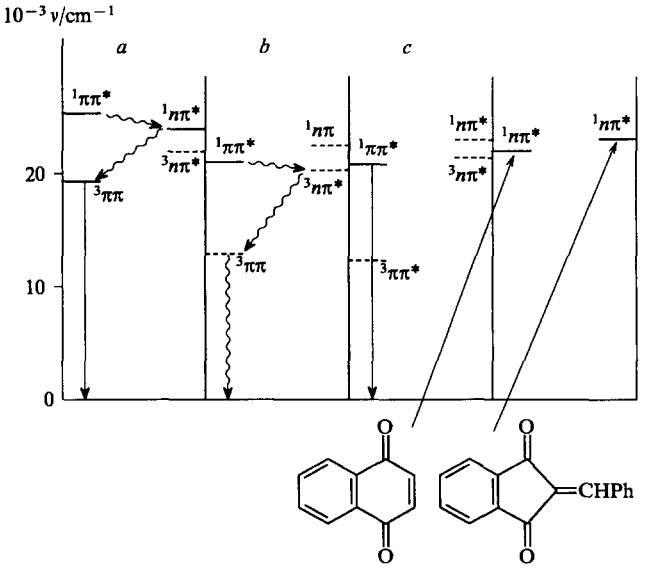

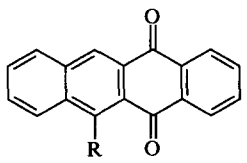

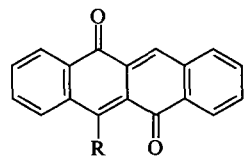

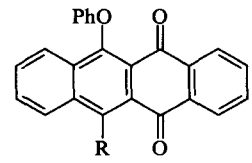

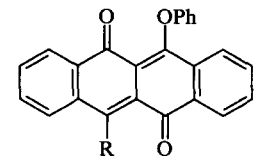

Figure 2. Electronic level diagram. The phosphorescence (Ph) (*a*, *b*) τ = 0.3 s and fluorescence (Fl) (*c*) of *p*-naphthacenequinone **1** and *ana*-naphthacenequinone **12** in hexane (*a*, *b*) and acetic acid (*c*); the dashed lines indicate the levels which are not manifested in the optical transitions.

Table 1. Electronic absorption spectra of 5,12- and 5,11-naphthacenequinones and the 6-derivatives of 11-phenoxy-5,12- and 12-phenoxy-5,11-naphthacenequinones in toluene.

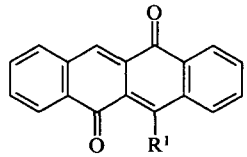
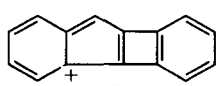
The electronic absorption spectra of 6-substituted naphthacenequinones[129] are very similar (as regards the position of λ_{max}) to the analogous spectra of the 6-derivatives of 11-phenoxynaphthacenequinone.[127] A definite analogy in the influence of the substituents in the 6-position in naphthacenequinone and in the 1-position in anthraquinone on the colour of these compounds can be traced.



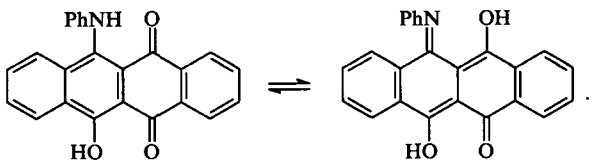
The nature of the substituents in the arene nucleus of 6-aryloxy-5,12-,[131] 6-amino-11-aryloxy-5,12-,[132] 6-aryloxy-5,11-naphthacenequinone[131] exerts little influence on the positions of the long-wavelength absorption maxima and the molar absorption coefficient (Table 1).

Comparison of the long-wavelength absorption band maxima of 6-R-11-phenoxy-5,12- and 6-R-11-phenoxy-5,11-naphthacenequinones by the proportional response method indicates the existence of a linear correlation (r = 0.992), which may apparently indicate that the nature of the bands is identical.[127]



The study of the mass spectra of compounds **13–18** showed[146] that the main process involving the dissociative ionisation of compounds **13** and **16** is the consecutive removal of

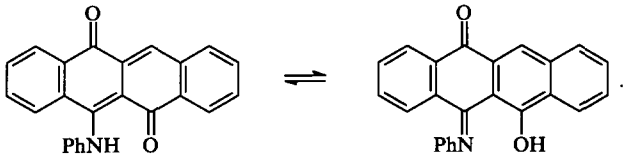
13–15



9, 16–18

19

R = H (**13**); NHPh (**14**); NAcMe (**15**); R^1 = NH_2 (**16**); NHPh (**17**); NAcPh (**9**); MeNCPh (**18**).
‖
O

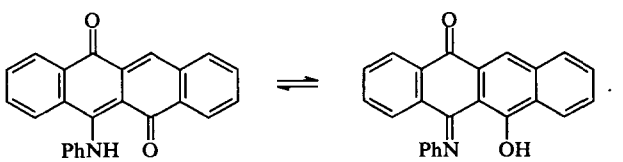


the two carbonyl groups, i.e. an anthraquinone type of decomposition leading to the formation of the stable structure **19**. The similar type of fragmentation of compounds **13** and **16** constitutes indirect evidence for the existence of 6-amino-5,11-naphthacenequinone **16** in an excited state following ionisation by electron impact in the *p*-quinonoid form. Together with the fragments characterising the *p*-quinonoid form **14a**, the mass spectrum of compound **14** contains a fairly large number of specific fragments corresponding to the *ana*-quinone imine form **14b**.

14a **14b**

The disporportionation of compound **15** after the removal of the acetyl group probably takes place in the *ana*-quinone imine form.

The successive elimination of the two carbonyl groups, characteristic of compounds with the *p*-quinonoid structure **13–15** is not observed in the dissociative ionisation of the *ana*-quinones **16–18**. The specific fragmentation processes are in all probability due to the fact that in the excited state, arising on ionisation by electron impact, 6-phenylamino-5,11-naphthacenequinone exists predominantly in the *p*-quinone imine form **17b**.



17a **17b**

Analysis of the mass spectra of compounds **17** and **18** also confirm this decomposition pathway for *ana*-phenylaminonaphthacenequinones.[147]

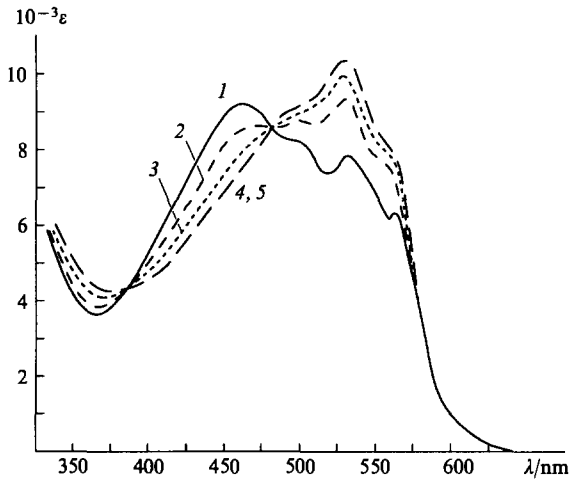
V. Tautomerism of naphthacenequinone derivatives

1. Prototropic and acylotropic rearrangements

The electronic absorption spectra of 6-phenylamino-5,11-naphthacenequinone **17** vary as a function of the polarity of the solvent employed. The family of spectral curves in CCl_4–EtOH mixtures of different composition is characterised by the presence of an isosbestic point, which indicates the presence of two coloured forms in solution (Fig. 3). The characteristic features of the spectroscopic properties of compound **17** can be explained[131] by the tautomerism due to the migration of a proton between the O and N atoms in the *peri*-positions.

17a **17b**

Bearing in mind the similarity of the absorption characteristics of the isoelectronic molecules, one might expect that the spectrum of the *p*-quinone imine tautomer would be similar to that of 6-hydroxy-5,12-naphthacenequinone and for this reason the shorter-wavelength absorption band, appearing in non-polar solvents, was assigned to 6-hydroxy-5-phenyliminonaphthacen-12-one **17b**, while the longer-wavelength band was assigned to the amino-derivative of *ana*-naphthacenequinone **17a**.



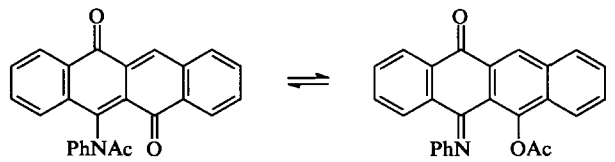


Figure 3. Electronic absorption spectra of 6-phenylamino-5,11-naphthacenequinone in CCl_4 (curve *1*), in C_2H_5OH (curve *5*), and in CCl_4–C_2H_5OH mixtures in different proportions: (*2*) 4 : 1; (*3*) 1 : 1; and (*4*) 1 : 4.

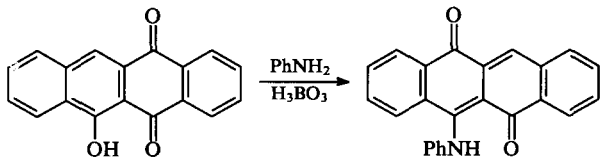
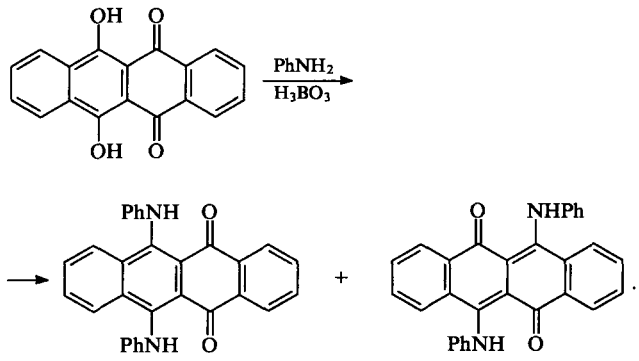
Similar prototropic transformations are characteristic also of 6-phenylamino-12-phenoxy-5,11-naphthacenequinone. 6-Amino- and 6-alkylamino-5,11-naphthacenequinones exist predominantly in the *ana*-quinonoid form in solvents of different polarity.[131]

A capacity for N,O-acylotropism has been observed for certain derivatives of 6-phenylamino-5,11-naphthacenequinone. Depending on the solvent used for recrystallisation, 6-(*N*-acetyl)-phenylamino-5,11-naphthacenequinone **9** can be isolated in two forms differing in the colour of the crystals. Analysis of the IR spectroscopic data led to the structure of the *ana*-quinone **9a** being attributed to the 'red' form, while the structure of the *p*-quinone imine **9b** was assigned to the 'yellow' form.

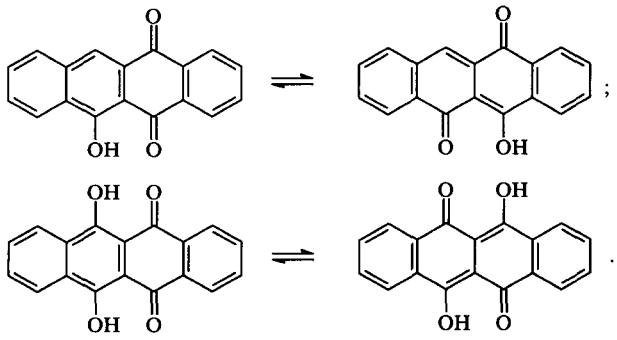


9a **9b**

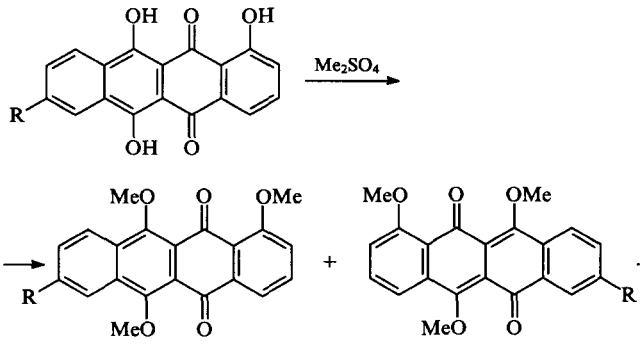


The electronic absorption spectra of compounds **9a** and **9b** in the same solvents are identical. The family of spectral curves of both compound **9a** and compound **9b** in decane–ethanol mixtures with different proportions of the individual solvents show isosbestic points, a consequence of the acylotropic equilibrium **9a** ⇄ **9b**. The tautomeric equilibrium constants were estimated approximately by the method of model compounds as 2.0 in ethanol and 0.4 in decane.[108]

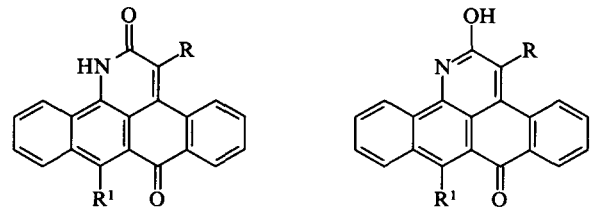
6-Benzoylphenylamino-5,11-naphthacenequinone also exists in solution in two forms, but, in contrast to the acetyl derivative, the *p*-quinone imine form predominates in both polar and non-polar solvents.[108] 6-(*N*-Acetyl)methylamino-5,11-naphthacenequinone does not exhibit acylotropic properties.[108]



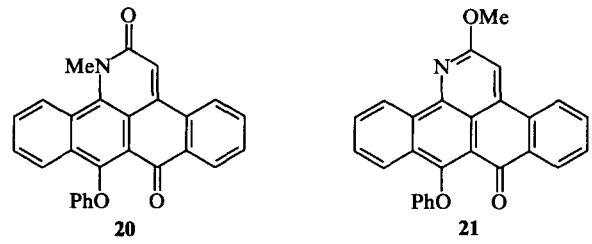
Instead of the expected 6-phenylamino-5,12-naphthacenequinone, its isomer 6-phenylamino-5,11-naphthacenequinone is formed on refluxing 6-hydroxy-5,12-naphthacenequinone with aniline in the presence of boric acid.[39]



The analogous reaction of 6,11-dihydroxy-5,12-naphthacenequinone leads to a mixture of two isomers.[124,125]



These facts suggested the existence of a tautomeric equilibrium.[39,124]



Methylation of derivatives of trihydroxynaphthacenequinone afforded isomeric compounds with *para*- and *ana*-quinonoid structures.[148]

Lactim–lactam tautomerism of naphthacenopyridones has been observed[101] for heterocyclic *peri*-condensed derivatives of naphthacenequinone, in contrast to the analogous derivatives of anthrapyridones which are incapable of this type of prototropism.

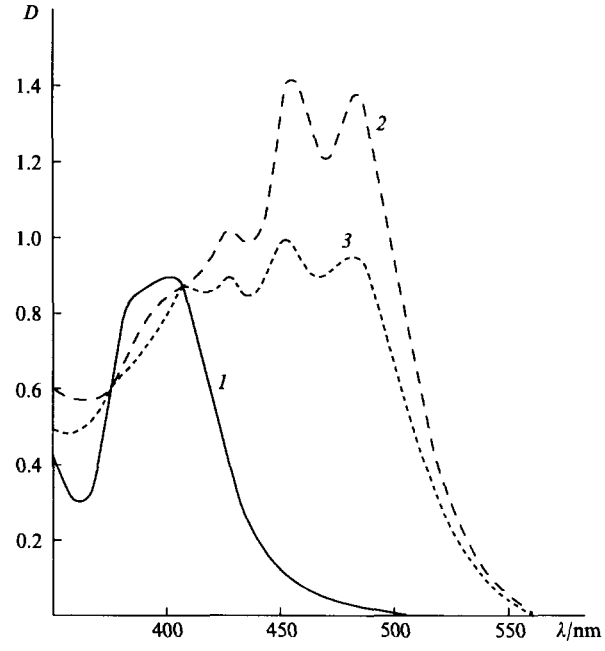
R = R¹ = H; R = H, R¹ = OPh; R = Ac, R¹ = OPh

20 **21**

It follows from the analysis of spectroscopic data for naphthacenopyridone and its fixed lactam (compound **20**) and lactim (compound **21**) forms that in polar solvents (*N*-methylpyrrolidone, hexamethylphosphoramide, dimethyl sulfoxide) pyridones exist mainly in the lactim form. The approximate constant of the lactam ⇄ lactim tautomerism for the unsubstituted naphthacenopyridone in *N*-methylpyrrolidinone is 0.4 at 25 °C.[101]

2. Arylotropic rearrangement of *peri*-aryloxynaphthacenequinones

One of the most interesting properties of derivatives of naphthacenequinone is the capacity of the *peri*-aryloxy-substituted 5,12-naphthacenequinones to undergo a reversible colour change in their solutions on exposure to light at different wavelengths, i.e. a capacity for photochromic transformations (Fig. 4).[135,149]



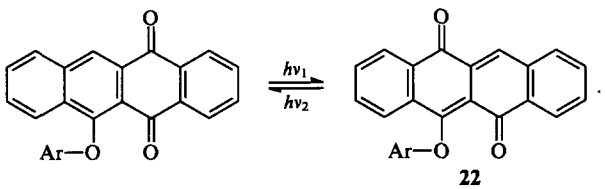


Figure 4. Electronic absorption spectra of 6-(β-naphthoxy)-5,12-naphthacenequinone in toluene ($c = 7.6 \times 10^{-5}$ M, $l = 2$ cm). (*1*) Initial solution prepared in the dark; (*2*) solution *1* irradiated for 2 min through a UFS-1 light filter; (*3*) solution *2* irradiated for 5 min through a ZhS-16 light filter. Source of radiation — DRK-120 mercury lamp.

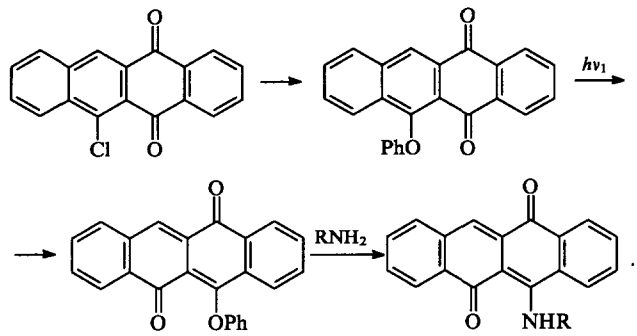
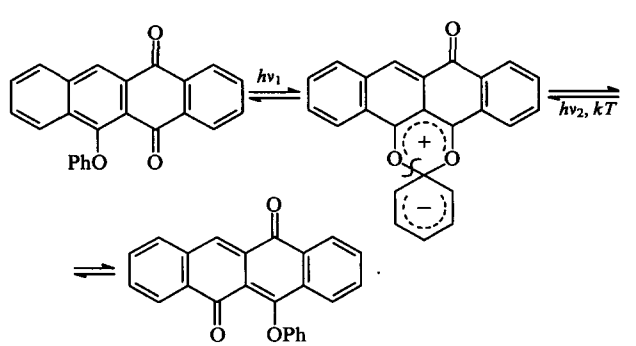


The photochromism of *peri*-aryloxynaphthacenequinones is due to the photoisomerisation of the *p*-quinonoid structure to the *ana*-quinonoid structure on exposure to light as a result of the migration of the arene nucleus to the oxygen atom of the carbonyl group in the *peri*-position relative to the ArO group.[149]

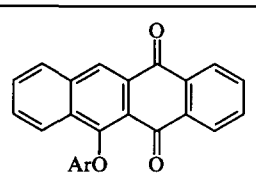
22

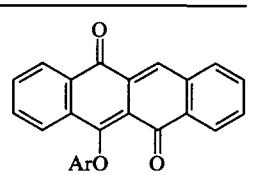


The formation of the *ana*-quinonoid structure as a result of the photorearrangement of 6-phenoxy-5,12-naphthacenequinone is confirmed by the similarity of the electronic absorption spectra of the photoinduced form **22** and those of 5,11-naphthacenequinone and 6-bromo-5,11-naphthacenequinone.[135] Furthermore, the intensities of the C=O stretching vibration bands (1685 and 1682 cm^{-1}) of 6-phenoxy-5,12-naphthacenequinone diminish after irradiation and new C=O absorption bands (1635 and 1660 cm^{-1}), characteristic of *ana*-naphthacenequinones, appear.[150]

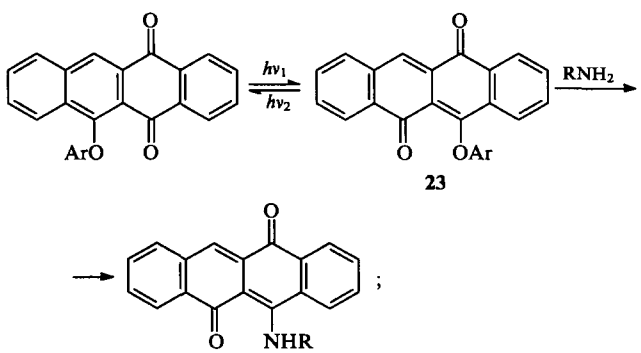
The photoinduced form of 6-phenoxy-5,12-naphthacenequinone is stable under the usual conditions and is readily converted on treatment with ammonia and aniline into the nitrogen-containing derivatives **16** and **17** of *ana*-naphthacenequinone.[135]

16, 17





The unambiguous synthesis of compounds **16** and **17** from bromo-5,11-naphthacenequinone has been achieved.[39,97,151] It has been suggested that the intramolecular photoarylotropic rearrangement of naphthacenequinone most probably proceeds via an associative mechanism, although one cannot fully rule out the possibility of a dissociative mechanism with the intermediate formation of a contact ion or radical pair. The absence of radicals on irradiation of the *p*-quinone ⇄ *ana*-quinone system constitutes indirect evidence (obtained by the EPR method) for the heterolytic dissociation of the C=O bond. The dissociation of the C=O bond is preceded by the formation of a σ-complex, the stabilisation of which may lead to either the *p*- or *ana*-quinonoid structure.[149]



A mechanism of the isomerisation of 6-phenoxy-5,12-naphthacenequinone in solutions in organic solvents at room temperature has been proposed based on a comparative analysis of the spectral-kinetic behaviour of the intermediates and T-states of the nonphotochromic *p*- and *ana*-naphthacenequinones arising on laser photoexcitation. The photoexcitation of the initial form of 6-phenoxy-5,12-naphthacenequinone by radiation at a wavelength of 347 nm induces a transition of the molecule to a coloured form via an intermediate triplet photoproduct. The photoexcitation of the coloured form leads to the population of the T-state of this form, its deactivation not being accompanied by a transition of the molecule to the initial form.[152]

The nature of the substituent in the arene ring has little influence on the positions of the long-wavelength absorption maxima and the molar absorption coefficient but it does affect significantly the quantum yields of the forward and reverse reactions of aryloxynaphthacenequinones. However, a dependence of the quantum yields on the electronic structure of the substituent has not been observed (Table 2).[131]

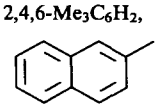


Table 2. Molar absorption coefficients and quantum yields of the forward (φ_B) and reverse (φ_A) photoisomerisation of 6-aryloxy-5,12- and 6-aryloxy-5,11-naphthacenequinones in toluene (λ_{act} = 366 nm).

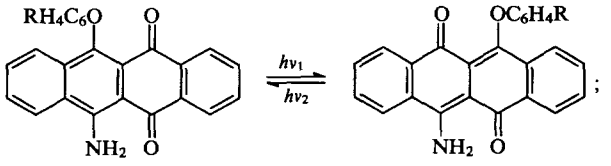
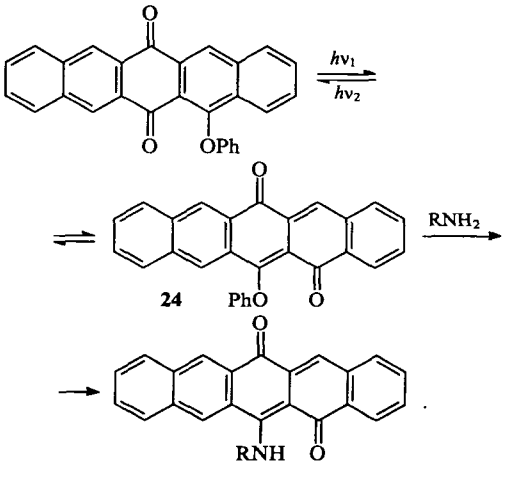
The ability of the photoinduced form of aryloxynaphthacenequinones to react with amines at room temperature has been used to determine the molar absorption coefficients ε of *ana*-aryloxynaphthacenequinones **23** without their isolation in a pure form.[153]



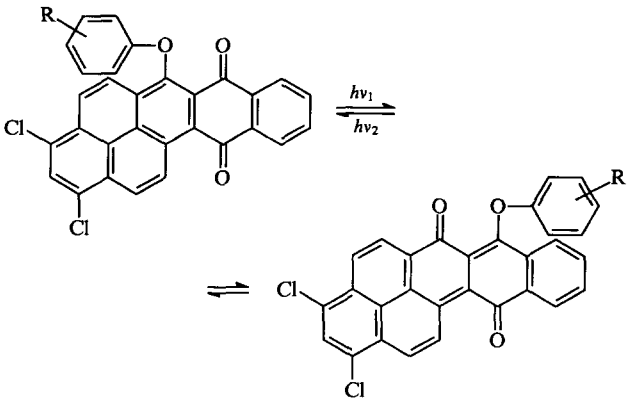
23

Ar = Ph, *p*-HOC_6H_4, *p*-$MeOC_6H_4$, *p*-$PhHNC_6H_4$, 2,4,6-$Me_3C_6H_2$, *p*-$MeCOC_6H_4$, *p*-$NO_2C_6H_4$, *p*-$NH_2C_6H_4$, *p*-PhC_6H_4,  .

Solutions of 11-phenoxy-5,12-naphthacenequinones containing substituents of different electronic nature (Cl, NO_2, OMe, NH_2, NHTs, NHAc, NAcMe), in the 6-position in the naphthalene nucleus exhibit photochromic properties in polar and non-polar solvents. 6-Dimethylamino-, 6-phenylamino-, 6-hydroxy-, and 6-acetoxy-11-phenoxynaphthacenequinones proved to be non-photochromic. In the series of 6-(*N*-acetyl)-methylamino-, 6-amino-, and 6-methylamino-11-phenoxy-5,12-naphthacenequinones, the photosensitivity of the compounds diminishes with enhancement of the electronic-donating properties of the substituent. 6-(*N*-Acetyl)methylamino-11-phenoxy-5,12-naphthacenequinone is photochromic, in contrast to the 6-methylamino-derivative, the photoinduced form of which is hardly observable spectroscopically after prolonged irradiation, while the reverse photochemical reaction does not occur. Substituents such as NO_2 and MeO, which exert very different electronic influences, also diminish the stability of the photoinduced form, which cannot be isolated in an analytically pure form owing to its degradation on contact with silica gel.[127]

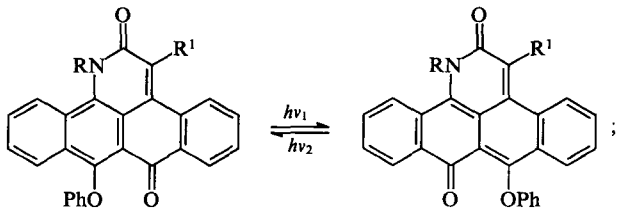


The presence of electron-donating substituents in the migrating group of 6-amino-11-aryloxy-5,12-naphthacenequinones promotes the occurrence of the photorearrangement in these compounds, in contrast to 6-amino-5,12-naphthacenequinone. 6-Amino-11-aryloxy-5,12-naphthacenequinones, containing electron-accepting substituents in the arene nucleus, isomerise under the influence of light less effectively than the unsubstituted 6-amino-11-phenoxy-5,12-naphthacenequinone.[132]



R = *p*-Me, *p*-Et, *p*-OMe, *p*-NHPh, *p*-OH, *p*-NO_2, *m*-Cl.

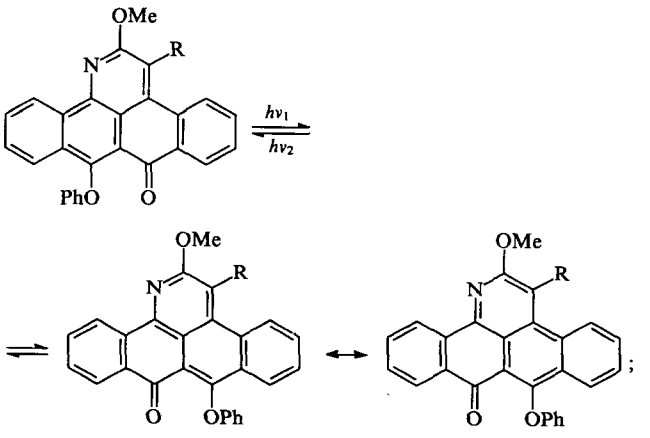
These data are consistent with experimental findings on substituent effects in photonucleophilic substitution and do not conflict with the hypothesis according to which the photoarylotropic rearrangement of *peri*-aryloxynaphthacenequinones is regarded as intramolecular photonucleophilic substitution.[149]



Derivatives of 5,12-naphthacenequinone with a linearly condensed benzene ring—5-phenoxy-6,13-pentacenequinone—isomerise reversibly under the influence of UV radiation to 6-phenoxy-5,13-pentacenequinone **24**. The photoinduced form was isolated in a pure form by virtue of the low rate of the dark isomerisation of the *ana*-quinone to the *p*-quinone. The high reactivity of the photoinduced form made it possible to obtain the first, previously unavailable, amino-derivatives of 5,13-pentacenequinone.[154]

Aryloxy-derivatives of a more complex polycyclic quinone—6,8-dichloro-2,3-phthaloylpyrene (structurally similar to 5,12-naphthacenequinone) are capable of arylotropism.[155,156]

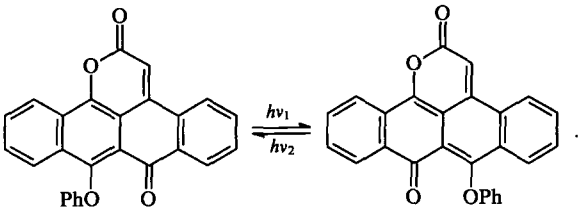
peri-Phenoxy-substituted *N*-methylnaphthacenopyridones are photochromic, like their anthrone analogues—*N*-methylanthrapyridones.[103]



R = Me, R^1 = H, Cl, OPh,  ; R = H, R^1 = H, MeCO.

Naphthacenopyridones, which have no methyl group attached to the nitrogen atom of the heterocyclic fragment of the molecule, undergo in chloroform photochromic transformations similar to those of phenoxyanthrapyridones,[157] but, together with the photochromic transformations, the decomposition of the photoinduced form under the influence of light is also observed.[101]

In contrast to *N*-methylnaphthacenopyridones,[103] alcoholic solutions of *NH*-naphthacenopyridones are not photochromic, which may be associated with the occurrence in alcohol of the photoinduced prototropic transformation of the *NH*-naphthacenopyridone into the lactim form, which rapidly isomerises to the initial pyridone.[101]

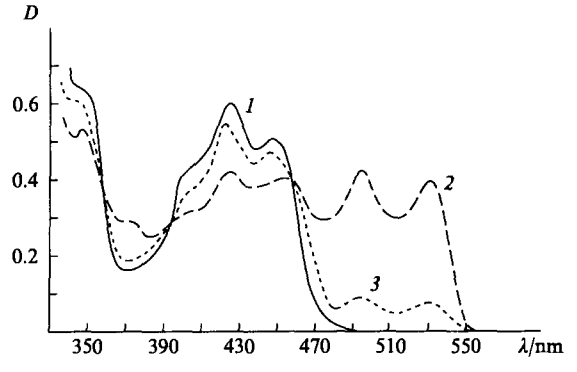


The ability to undergo the photophenyltropic rearrangement has been observed also in toluene solutions of naphthacenopyridones.[101]

R = H, COMe.

The photoinduced forms of naphthacenopyridines exist in solutions probably in the *p*-quinone imine forms, since the absorption band of the photoinduced form of naphthacenopyridines has undergone a hypsochromic shift relative to the band of the photoinduced form of naphthacenopyridones.[101]

9-Phenoxynaphthacenopyridone undergoes a reversible arylotropic rearrangement on exposure to light (Fig. 5).[109]



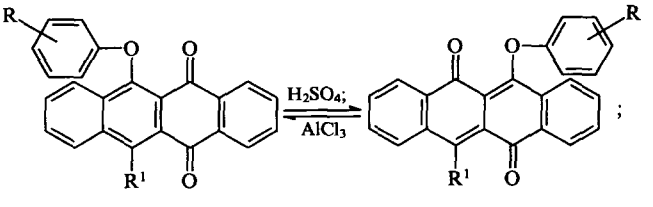


Figure 5. Electronic absorption spectra of 9-phenoxynaphthacenopyrone in toluene ($c = 6.97 \times 10^{-5}$ mol litre^{-1}). (*1*) Initial solution prepared in the dark; (*2*) solution *1* irradiated for 3 min through a SS-8 light filter; (*3*) solution *2* irradiated for 5 min through a ZhS-16 light filter. Source of radiation—DRK-120 mercury lamp.

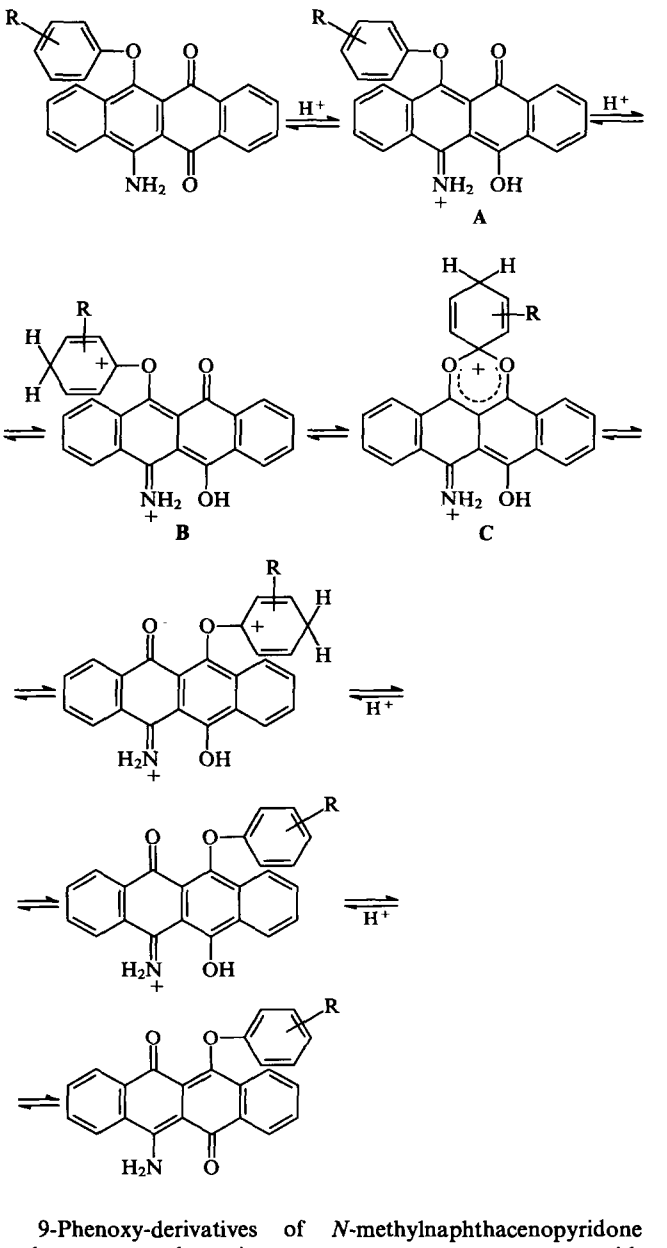
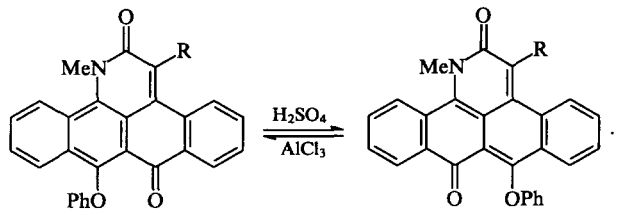
The arylotropic rearrangement in the series of *peri*-phenoxynaphthacenequinones takes place not only under the influence of light but also in the dark. Treatment of *peri*-phenoxynaphthacenequinones with sulfuric acid or aluminium chloride leads to the corresponding *ana*-naphthacenequinones.[136]



R^1 = NH_2, NHMe, NHPh, NHAc, H, OPh, OMe, Cl.

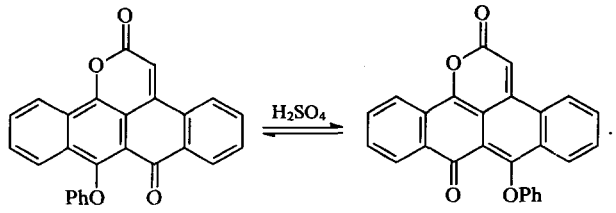
When naphthacenequinones containing an amino- or a substituted amino-group in the 6-position isomerise, the *ana*-isomer predominates in the equilibrium mixture; in the case of the remaining derivatives, the *p*-isomer predominates.[136]



6-Amino-11-aryloxy-5,12-naphthacenequinones, containing electron-accepting substituents in the migrating group, isomerise in sulfuric acid with a higher yield than derivatives having electron-donating substituents.[132]

The *p*-quinone ⇄ *ana*-quinone rearrangement in sulfuric acid proceeds intramolecularly, which is indicated by the results of the cross-experiment: treatment of a mixture of 6-amino-11-(4′-ethylphenoxy)-5,12-naphthacenequinone and 6-phenylamino-11-phenoxy-5,12-naphthacenequinone with sulfuric acid at room temperature leads to the corresponding *ana*-isomers without admixture of intermolecular reaction products. The isomerisation of *peri*-aryloxynaphthacenequinones under the influence of sulfuric acid can apparently be represented as intramolecular nucleophilic substitution (Scheme 4). Protonation of the amino-group of *peri*-phenoxynaphthacenequinone and the appearance of the cation **A** with the *ana*-quinone imine structure in the equilibrium mixture apparently constitute an essential condition for the rearrangement. *peri*-Phenoxynaphthacenequinones, for which such protonation is impossible, for example 6-nitro-11-phenoxy-5,12-naphthacenequinone, do not isomerise under these conditions. In concentrated sulfuric acid, a second proton adds to the phenoxy-group of the monocation **A** with formation of the cation **B**. The latter is stabilised in the form of the spiro-complex **C**. Depending on which oxygen–carbon bond dissociation predominates in the spiro-complex **C**, both the *ana*-isomer and the initial quinone may be formed.[132]

Scheme 4



9-Phenoxy-derivatives of *N*-methylnaphthacenopyridone undergo an arylotropic rearrangement on treatment with sulfuric acid or aluminium chloride. The *para*-isomer predominates in the equilibrium mixture. The isomerisation is accompanied by degradation processes.

Phenoxynaphthacenopyridones without a methyl group at the nitrogen atom of the heterocyclic fragment as well as phenoxy-derivatives of *N*-methylanthrapyridones, anthrapyridines, and naphthacenopyridines do not isomerise under these conditions. 8-Phenoxy-derivatives of *N*-methylnaphthacenopyridones with the *ana*-quinonoid bond distribution have been obtained in a pure form by acid isomerisation.[158]

The acid arylotropic rearrangement is also characteristic of 9-phenoxynaphthacenopyrone.[109]

VI. Conclusion

The present review constitutes the first attempt to survey the literature data on the methods of synthesis and properties of naphthacenequinones and their derivatives. The observation of photochromism of a new type, involving the reversible photoarylotropic rearrangement of 6-phenoxy-5,12-naphthacenequinone to 6-phenoxy-5,11-naphthacenequinone, is especially interesting. The undoubted value of these data lies in the fact that the photochromism discovered for 6-phenoxy-5,12-naphthacenequinone proved to be general for the whole series of aryloxy-derivatives of polycyclic quinones (anthraquinone, pentacenequinone, and phthaloylpyrene) and also for heterocyclic derivatives based on them.

A high photostability and pronounced cyclic behaviour are characteristic of this class of photochromic materials. The photochromic materials obtained after the introduction of 6-phenoxy-5,12-naphthacenequinone into poly(methyl methacrylate) and other polymers can be used to record holograms with the aid of a helium-cadmium laser (λ = 441.6 nm) and for the non-disruptive recovery of the image from the holograms by means of the radiation from a helium-neon laser (λ = 632.8 nm).

Photochromism of this type can be used as a photochromic method of synthesis of compounds with the *ana*-quinoid structure, the synthesis of which by traditional methods is extremely difficult or impossible.

Data concerning the ability of 11-substituted derivatives of 6-phenoxy-5,12-naphthacenequinones to undergo the phenylotropic rearrangement under the influence of Lewis acids are extremely interesting.

It is noteworthy that the widely known reactions leading to the formation of heterocyclic derivatives based on 9,10-anthraquinone are also applicable to the synthesis of the analogous derivatives based on 5,12-naphthacenequinone, which makes it possible to synthesise a whole series of new heterocyclic derivatives with interesting properties.

Thus it may be hoped that the data presented in this review will attract the attention of investigators and that the chemistry of naphthacenequinones will undergo a new development.

Abstract. The advances in the synthesis and study of derivatives of cyclopentadienyltricarbonylmanganese (cymantrene) are considered. The bibliography includes 356 references.

I. Introduction

The cyclopentadienyl complexes of metals constitute one of the classes of organic transition metal complexes which have been studied in greatest detail. In terms of the number of experimental studies, cyclopentadienyltricarbonylmanganese (cymantrene, CTM) occupies the second place after ferrocene. Two stages may be distinguished in the studies on cymantrene. The synthetic aspect, based on the analogy with the electrophilic substitution reactions in benzene and ferrocene, was characteristic of the first stage in the chemistry of cymantrene. Other reactions involving the substitution of hydrogen in the Cp ring are known for cymantrene although their number is somewhat smaller than in the case of ferrocene. These are the acylation, alkylation, and phosphorylation reactions under Friedel – Crafts conditions, sulfonation, chloromethylation, metallation with butyllithium, mercuration with mercury(II) salts, and hydrogen isotope exchange with acids and bases. A multiplicity of cymantrene derivatives with a wide variety of substituents in the Cp ring have been obtained by means of the reactions listed above (for the literature data up to 1972, see the references in a review[1]).

On the other hand, reactions involving the substitution of CO by other ligands as well as processes occurring with a change in the ligand environment of the metal are extremely characteristic of cymantrene, as for all metal carbonyl complexes.

The second stage in the development of studies on cymantrene was associated with the synthesis of its derivatives both with 'classical' ligands, coordinated to manganese via the electron-donating atoms of Group IV – VI elements, and with ligands of a new type such as complexes with molecular hydrogen, free – radical complexes, complexes with 'indene' ligands, etc.

The combination of the reactions involving substitution of hydrogen in the Cp ligand and CO substitution reactions made it possible to obtain a large number of a wide variety of derivatives with C_5H_5Mn, C_5H_4RMn, C_5R_5Mn (R = alkyl, halogen, etc.) fragments. A unique feature of cymantrene is a combination of a varied reactivity with thermal and oxidative stabilities, which are unusually high for π-complexes.

On average, 30 – 40 studies devoted to the chemistry of cymantrene are published each year. However, despite very extensive experimental data, review information on the recent chemistry of cymantrene is virtually lacking. The reviews[1-3] and monographs[4] published previously are to a greater or lesser extent obsolete. A review[5] dealing with the structural aspects of manganese carbonyl complexes was published comparatively recently. The present review presents a compilation in one article of extremely extensive and comprehensive data for the last 10 – 12 years on the chemistry of compounds containing one or several cymantrene residues [the cymantrenyl radical $(CO)_3MnC_5H_4$ is designated below in the text by (**Mn**)]. The limited space available in the review precluded the consideration of data concerning the synthesis and properties of numerous complexes of the type $CpMn(CO)(LL')$, where L and L' are two-electron ligands. Studies in which the key role was assumed by various physicochemical and computational studies (optical and microwave spectroscopy, kinetic and electrochemical methods, gas-phase chemistry of cymantrene, mass-spectrometric studies, and quantum-chemical calculations) are also not considered.

Cymantrene, the isoelectronic cation $CpMn(NO)(CO)_2^+$, and their derivatives are diamagnetic 18-electron complexes which contain an Mn atom with the d^6 configuration and a formal +1 oxidation state. Cymantrene and its derivatives can be regarded as pseudooctahedral complexes in which the Cp ligand occupies three coordination sites. This follows from X-ray diffraction (XRD) data, according to which the OC – Mn – CO bond angles are 87° – 93° in virtually all structurally characterised cymantrene derivatives. However, in stereochemical studies it has become unusual to consider cymantrene and analogous molecules with the geometry of the 'piano stool with three legs' type as pseudotetrahedral assuming that the Cp ligand occupies one coordination site.

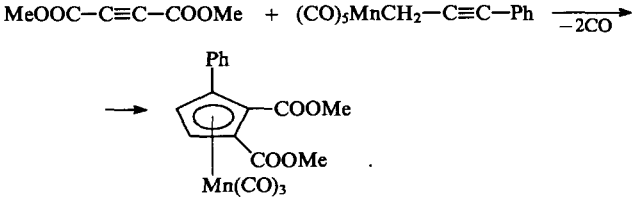
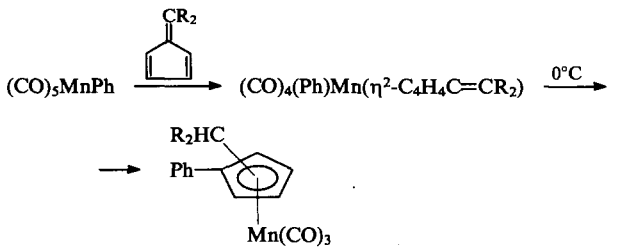
II. The formation and cleavage of the cymantrene system

Detailed X-ray diffraction data for cymantrene have been obtained by Fitzpatrick et al.[6] and Cowie et al.[7] A difference between the C–C bond lengths in the Cp ring was observed in the above investigations. They vary in the ranges 1.400–1.439 Å [6] and 1.399–1.426 Å.[7] The study of cymantrene by vibrational spectroscopic methods also indicated slight deviations from the C_{5v} symmetry for the Cp ligand, which may be induced by crystal packing effects.[6] The heat capacities of cymantrene and of its π-pyrrole analogue[8] as well as the heat of formation of cymantrene[9] have been measured.



In addition to the procedures known earlier (see the relevant review[1]), a number of new methods of synthesis of cymantrene have been proposed. On reduction[10,11] of a mixture of anhydrous $MnCl_2$ and cyclopentadiene by metallic magnesium or manganese in the presence of $TiCl_4$ or $Ti(OBu)_3$ followed by carbonylation with CO (180 °C, 80 atm), the yield of cymantrene reaches 70%–75%. The interaction of anhydrous $MnCl_2$ and $Me_3SiC_5H_4^-Na^+$ and subsequent carbonylation afford $Me_3Si(\mathbf{Mn})$.[12] Cymantrene exhibits a high thermodynamic stability and its derivatives are formed as a result of thermal or photochemical reactions of manganese carbonyl complexes with olefins and dienes. Thus, in the thermal decomposition of solid cationic complexes of azidobenzene and azidotoluene with $Mn(CO)_3$, nitrogen is evolved even at 130 °C and an intermediate complex of phenylnitrene with $Mn(CO)_3$ is apparently formed. The ring contraction reaction takes place readily in the intermediate and leads to cyano- or 1-methyl-3-cyano-cymantrene.[13]

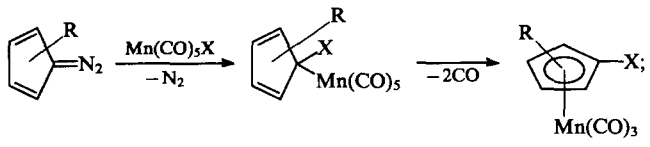


R = H, Me.

After the thermal decomposition of non-coordinated phenyl azide in solution, azobenzene (resulting from the dimerisation of phenylnitrene) and aniline (produced by the abstraction of hydrogen from the solvent) were detected among the reaction products. Thus coordination to $Mn(CO)_3$ alters sharply the mode of thermal decomposition of the coordinated azides.

The [3 + 2]-cycloaddition reaction takes place on interaction of $(CO)_5MnCH_2C{\equiv}CPh$ with dimethylacetylenedicarboxylate and affords a trisubstituted cymantrene derivative.[14]

One of the most general methods of synthesis of cymantrene derivatives is based on the reaction of the carbonyl halides $Mn(CO)_5X$ or $Mn(CO)_3L_2X$ (X = Cl, Br; L = a ligand, for example, amine, pyridine, etc., linked by labile bonds), $Mn(CO)_5Ph$, and $Mn_2(CO)_{10}$ with substituted cyclopentadienes or cyclopentadienylthallium derivatives. The reaction of $H_3Mn_3(CO)_{12}$ with 6-dimethylaminofulvene leads to the formation of dimethylaminomethylcymantrene $(\mathbf{Mn})CH_2NMe_2$.[15] Under the conditions of photchemical activation on irradiation with UV light of 6,6-dimethyl- or 6,6-diphenyl-fulvene in the presence of $Mn(CO)_5Ph$ in hexane at –20 °C, the displacement of CO and coordination of fulvene to one of the double bonds result in the formation of the intermediates $Mn(CO)_4LPh$ (L = η^2-fulvene), which rearrange on heating to 0 °C to disubstituted cymantrenes with insertion of the fulvene double bonds in the Mn–Ph bond.[16]



The phosphine oxide $Ph_2P(O)CH_2C_2H_5$ reacts with $Mn_2(CO)_{10}$ to form the complex $(\mathbf{Mn})CH_2P(O)Ph_2$.[17] Reaction of the bromide $Mn(CO)_5Br$ with the cyclopentadiene derivatives $Me_3SnC_5H_4CH_2CH_2PPh_2$ is accompanied by elimination of two CO molecules and Me_3SnBr and leads to the formation of the complex $(\mathbf{Mn})CH_2CH_2PPh_2$.[18] Phenylcymantrene is formed similarly from phenylcyclopentadiene and $Mn(CO)_5Br$.[19]

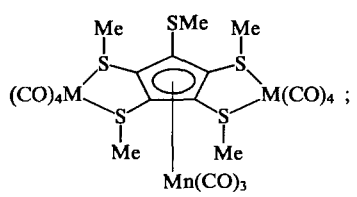
The reaction of $Mn(CO)_5Br$ with cyclopentadienylthallium derivatives containing functional group substituents constitutes a thoroughly developed method of synthesis of substituted cymantrenes.

$$RC_5H_4Tl + Mn(CO)_5Br \longrightarrow (\eta^5\text{-}RC_5H_4)Mn(CO)_3 + 2CO + TlBr\ .$$

Compounds with R = $-C(CN)=C(CN)_2$,[20,21] CF_3,[22] Ph, CH_2Ph,[23] Cl, Br,[24], *m*-, *p*-FC_6H_4,[25,26] CHO, C(O)Me, C(O)OMe, C(O)OEt [27] have been synthesised in this way. This reaction can be extended also to dinuclear complexes. Thus the corresponding biscymantrenyl derivative has been obtained from 1,4-bis(cyclopentadienylthallium)buta-1,4-dione by reaction with $Mn(CO)_5Br$.[28] The reaction of tricyano(ferrocenyl)ethylene $Fc-C(CN)=C(CN)_2$ with 1 equivalent of $Mn(CO)_5Br$ and C_5H_5Tl affords the dinuclear complex $Fc-C[=C(CN)_2](\mathbf{Mn})$.[21]

The simultaneous elimination of nitrogen and two CO molecules results in the ready formation of mono- and polyhalocymantrenes in the reactions of $Mn(CO)_5X$ with diazacyclopentadienes.[29]

X = Cl, Br, I.



Chloro-, bromo-, and iodo-cymantrenes have been obtained in 60%–80% yields from unsubstituted diazacyclopentadiene $C_5H_4=N_2$ in one stage, while the reaction of $C_5Ph_4=N_2$ with $ClMn(CO)_5$ afforded chlorotetraphenylcymantrene.[30] The single-stage syntheses of halocymantrenes via CpTl or diazacyclopentadienes as well as the syntheses via the interaction of mercurio-derivatives of cymantrene with copper(II) salts[31] are much simpler than the previously proposed multistage method of synthesis via aminocymantrene (see the relevant review[1]). Halo-derivatives of indenylmanganese tricarbonyl have been obtained from diazaindene.[32]

The synthesis via diazacyclopentadienes constitutes a convenient path to polyhalocymantrenes. The reaction of tetrachlorodiazacyclopentadiene with $XMn(CO)_5$ leads to a mixture of the monohapto-complexes η^1-$C_5Cl_4XMn(CO)_5$ and to pentahalocymantrenes formed from them as a result of a σ → π

rearrangement and the elimination of CO. The proportions of the above products depend greatly on the reaction conditions. On heating to fusion, the η^1-complexes readily split off CO and are converted into the thermodynamically more stable pentahalocymantrenes in a quantitative yield.[33] The conversion of η^1-$C_5Cl_5Mn(CO)_5$ into η^5-$C_5Cl_5Mn(CO)_3$ can also take place photochemically via the intermediate η^3-$C_5Cl_5Mn(CO)_4$.[34] Pentabromo- and tetrabromoiodo-cymantrenes have been obtained from tetrabromodiazacyclopentadiene and $XMn(CO)_5$ (X = Br or I), while tri-iodocymantrene has been obtained from di-iododiazacyclopentadiene and $IMn(CO)_5$.[35] A preparative synthesis of mono- and poly-halocymantrenes by this procedure has been described.[36] When an attempt was made to obtain dibromocymantrene by the reaction of bis(bromomercurio)-cymantrene with $CuBr_2$ in acetone (by analogy with the synthesis of bromocymantrene[31]), a mixture containing cymantrene, bromocymantrene and all possible di-, tri-, tetra-, and penta-bromocymantrenes, which was separated into its components with the aid of preparative gas–liquid chromatography (GLC), was obtained instead of the expected dibromides.[37]

The chemistry of polychlorocymantrenes and their derivatives has developed vigorously in recent times. In the metallation of bromotetrachlorocymantrene with butyllithium (hexane, −60 °C), a key synthon—the lithio-derivative (η^5-$C_5Cl_4Li)Mn(CO)_3$—is formed as a result of the substitution of bromine by lithium. The reactions of the synthon with various electrophiles yielded a series of tetrachlorocymantrenes [(η^5-$C_5Cl_4R)Mn(CO)_3$, R = H, Me, $SiMe_3$, $SiPh_3$, COOH, COOMe, SMe, and SPh,[38] as well as $SnMe_3$, PPh_2, SePh, and CHO [39]]. The dicymantrenyl sulfide $S[(C_5Cl_4)Mn(CO)_3]_2$ has been obtained by the reaction of the lithio-derivative with SCl_2.[39] The corresponding acid chloride, azide, isocyanate, and amine have been synthesised from tetrachlorocymantrenecarboxylic acid. Haloferrocenes are known to form nitriles on reaction with CuCN. However, the reaction of $(C_5Cl_4Br)Mn(CO)_3$ and CuCN does not afford stable products in pyridine, and the usual procedure was therefore used to obtain the nitrile. The reaction of the acid chloride with ammonia afforded the amide [R = $C(O)NH_2$], while dehydration of the latter by $POCl_3$ afforded the nitrile (R = CN).[39]

A whole series of compounds having the general formula [η^5-$C_5Cl_{5-n}(SMe)_n$]$Mn(CO)_3$, where $n = 1-5$, have been obtained from (η^5-$C_5Cl_4SMe)Mn(CO)_3$ by successive metallation with BuLi and treatment with Me_2S_2.[40] The corresponding compounds containing two or three SPh groups and mixed complexes containing simultaneously the SPh and SBu groups have been obtained similarly from (η^5-$C_5Cl_4SPh)Mn(CO)_3$ by metallation and treatment with Ph_2S_2 or Bu_2S_2.[41] More than three SPh groups cannot be introduced in this way. The complexes $C_5(SMe)_5Mn(CO)_3$,[40] $C_5Cl_2(SPh)_3Mn(CO)_3$, etc.[41] have been characterised by XRD. Compounds containing two or four SMe or SPh groups in the Cp ring readily form a wide variety of dinuclear complexes as a result of the coordination of the metal-containing fragments to the sulfur atoms.[41,42] Trinuclear complexes with two chelate rings, whose structure has been established by the XRD method, are formed in the case of $C_5(SMe)_5Mn(CO)_3$.[42]

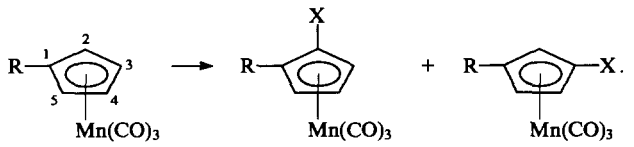
M = Cr, Mo, W.

The reaction of $(C_5Cl_4Li)Mn(CO)_3$ with sulfur leads to the monothiolate derivative $(C_5Cl_4SLi)Mn(CO)_3$, which does not afford the expected thiol on protonation, the disulfide $[(CO)_3MnC_5Cl_4S-]_2$ being formed instead. On the other hand, on repeated metallation of the monothiolate and treatment with sulfur, the dithiolate $C_5Cl_3(SLi)_2Mn(CO)_3$ was obtained. On protonation, the latter was smoothly converted into the dithiol $C_5Cl_3(SB)_2Mn(CO)_3$, which was characterised by XRD.[43]

Apart from the tetra- and penta-halocymantrenes, pentaalkylcymantrenes have also been obtained. Pentaethyl-cymantrene was synthesised as early as 1964 by the successive acylation of cymantrene with $MeC(O)Cl/AlCl_3$ and the reduction of the keto-group to CH_2 on treatment with $LiAlH_4/AlCl_3$ (ten stages altogether).[44] Pentamethylcymantrene is formed as a result of the reaction of pentamethylcyclopentadiene with $MeMn(CO)_5$ or $Mn_2(CO)_{10}$.[45,46] An improved version of this method, involving the interaction of C_5Me_5H with $Mn_2(CO)_{10}$ without a solvent at 180 °C, has been proposed,[47] but it was shown later that a mixture of pentamethyl- and tetramethyl-cymantrenes is formed under these conditions.[48] Pentabenzylcymantrene, the structure of which was confirmed by XRD, has been obtained by the reaction of pentabenzylcyclopentadiene with $Mn_2(CO)_{10}$.[49] A series of pentamethylderivatives of cymantrene have been investigated[50,51] by ^1H, ^{13}C, and ^{17}O NMR spectroscopic methods. The pentasubstituted complex $C_5(SiMe_2H)_5Mn(CO)_3$, characterised by XRD, as well as all the intermediates, each containing from one to four $SiMe_2H$ groups, have been synthesised from $C_5Br_5Mn(CO)_3$ by multistage metallation (2 equiv. of BuLi) and alkylation (2 equiv. of Me_2SiHCl).[52]

Penta(methoxycarbonyl)cymantrene $[C_5(COOMe)_5]Mn(CO)_3$ has been synthesised by the reaction of the anion $C_5(COOMe)_5^-$ with $BrMn(CO)_5$. It reacts with NH_3, affording a mixture of compounds containing simultaneously C(O)OMe and $C(O)NH_2$ groups in the ring. The reaction with butylamine leads to the monoamide derivative, while exhaustive reduction with $LiAlH_4$ results in the formation of $C_5Me_5Mn(CO)_3$.[53]

Apart from the reactions described above, in which the thermodynamically stable cymantrene system is formed, examples of reverse processes occurring with dissociation of the Mn–Cp bond are known. The reduction of cymantrene with sodium in hexamethylphosphoramide leads initially to $NaMn(CO)_5$ and then to $Na_3Mn(CO)_4$.[54]



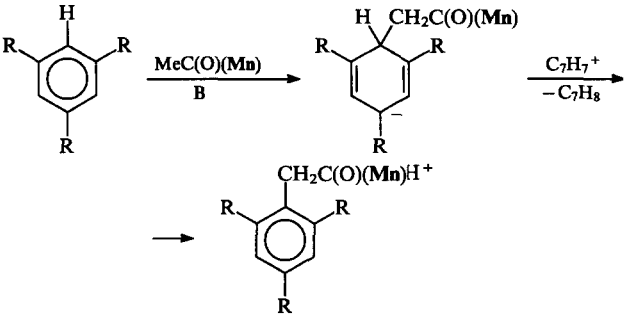
The thermal decomposition of cymantrene at 380–420 °C and a pressure of 10^{-2} Torr gives rise to the cyclopentadiene dimer, metallic manganese, and CO.[55,56] On catalytic hydrogenation in acetic acid in the presence of Pd/C, cymantrene and many of its derivatives are completely cleaved to cyclopentane and cyclopentene.[57] The reaction of ferrocene and cymantrene, adsorbed in the large cavities of zeolites, with phthalonitrile vapour at 100–150 °C *in vacuo* leads to cleavage, induced by the zeolite matrix, and to the formation of iron- and manganese-phthalocyanines. The latter are retained within the zeolite cavity, not as a consequence of chemical bonding with the skeleton, but as a result of the difference between their diameters and the dimensions of the inlet windows of the zeolite.[58]

The interaction of methylcymantrene with bis(1,3-diphenyl-propane-1,3-dionato)tin proceeds with complete cleavage of the molecule and the transfer of propanedionate ligands from tin to manganese. The complex bis(1,3-diphenylpropane-1,3-dionato)manganese$(THF)_2$, in which the manganese atom is surrounded octahedrally by six oxygen atoms, has been isolated from the reaction mixture and characterised by XRD.[59] Treatment of methylcymantrene with the potassium derivative of 18-crown-6 in THF resuts in two-electron reduction accompanied by a profound rearrangement of the molecule with dissociation of the Mn–Cp bond. In the presence of 1 equiv. of naphthalene, the reaction product is the anionic complex (η^4-$C_{10}H_8)Mn(CO)_3^-$, in which the naphthalene molecule is involved in η^4-type of coordination.[60] The Mn–Cp bond dissociates also when an attempt is made to achieve the photochemical substitution of CO by PPh_3 in the complex $Ph_2PC_5H_4Mn(CO)_3$.[61,62]

III. Reactions involving the substitution of hydrogen in the Cp ligand and the syntheses of compounds with the cymantrenyl substituent

Numerous cymantrene derivatives, examined in detail in a review,[1] have been synthesised by a set of substitution reactions. Yet another reaction involving the substitution of hydrogen atoms in the Cp ring was discovered subsequently: direct boryl-ation of the Cp ligand. It was shown that cymantrene, methyl-cymantrene, and ferrocene react with BI_3, BBr_3, $PhBI_2$, and $MeBI_2$ in carbon disulfide in cyclohexane or without a solvent at 80 to 100 °C with substitution of a hydrogen atom in the Cp ring by the BI_2, BBr_2, PhBI, or MeBI group. The resulting compounds enter into reactions with $SnMe_4$, Et_2O, Me_2S_2 and $NHMe_2$ involving the substitution of the halogen by the alkyl, OEt, SMe, and NMe_2 groups respectively.[63,64]

On passing from unsubstituted cymantrene to its mono-substituted derivative $RC_5H_4Mn(CO)_3$, the problem of the site of substitution arises, as in the case of the benzene derivatives RC_6H_5. The newly introduced substituent can replace hydrogen in the 2- and 3-positions. Substitution reactions in cymantrene as a rule proceed nonselectively and mixtures of 1,2- and 1,3-isomers are formed, the proportions of which depend significantly on the nature of the substituent and the type of reaction.



1,2- 1,3-

If the substituent R contains a chiral centre, then the CH groups in the 2,3- and 4,5-positions become nonequivalent (diastereotopic). In this case the substitution reaction may be stereoselective if the substitution proceeds exclusively or predominantly in one of the two nonequivalent positions. The instances of regio- and stereo-selectivity on substitution in cymantrene will be noted below.

A large group of ketones of the cymantrene series have been synthesised by the acylation and benzoylation of cymantrene, alkylcymantrenes, and other cymantrene derivatives (see the relevant review[1]). A series of substituted benzoylcymantrenes having the general formula $[\eta^5\text{-}C_5H_3(Y)C(O)C_6H_4X]Mn(CO)_3$ (X = *o*-, *m*-, and *p*-Me, MeO, Cl, Br, F, etc.; Y = H, 1- and 2-Me) have been obtained by benzoylating cymantrene and methylcymantrene with the acid chlorides $XC_6H_4C(O)Cl/AlCl_3$ in CH_2Cl_2.[19] β-Phenylethyl- and styryl-cymantrenes as well as the carbinol $PhCH_2CH(OH)(\mathbf{Mn})$ have been obtained from benzyl cymantrenyl ketone $PhCH_2C(O)(\mathbf{Mn})$.[19] Refluxing of substituted benzoylcymantrenes with $Cr(CO)_6$ in dibutyl ether leads to a series of benchrotrenyl cymantrenyl ketones having the general formula $(CO)_3Cr[\eta^6\text{-}XC_6H_4C(O)C_5H_3Y\text{-}\eta^5]Mn(CO)_3$ as a result of the coordination of the benzene ring to chromium.[65] On reduction with sodium, these ketones afford the corresponding Na ketyls, in which the radical centre is stabilised simultaneously by the cymantrenyl and benchrotrenyl substituents.[66]

The ω-chloroketones $Cl(CH_2)_nC(O)(\mathbf{Mn})$ have been synthesised by acylating cymantrene with the chlorides of ω-chlorocarboxylic acids. Clemmensen reduction of the ketones affords the ω-cymantrenyl chlorides $Cl(CH_2)_{n+1}(\mathbf{Mn})$, where n = 2 and 3.[67] The interaction of the chlorides with trimethyl-amine leads to the ammonium salts $Me_3N^+(CH_2)_n(\mathbf{Mn})Cl^-$,[68] while their reaction with $(EtO)_2PONa$ leads to the alkylphosphonic acid esters $(EtO)_2P(O)(CH_2)_n(\mathbf{Mn})$.[69] The ketoacid chlorides $PhC(O)(CH_2)_nC(O)Cl$, where n = 4 and 6, afford on acylation of cymantrene the asymmetric diketones $PhC(O)(CH_2)_nC(O)(\mathbf{Mn})$ in a high yield, but the acid chlorides with n = 2 and 3 do not interact with cymantrene under these conditions.[70]

Ketones of the cymantrene series form the corresponding derivatives with functional group substituents (oximes, hydrazones, etc.) and enter into reactions characteristic of ketones. Acetylcymantrene reacts with trinitrobenzene in the presence of bases (triethylamine) with abstraction of a proton and the formation of anionic cyclohexadienyl complexes, which react with the tropylium cation with transfer of a hydride ion, forming cymantrenyl trinitrobenzyl ketone and cycloheptatriene.[71]

R = NO_2.

Cymantrenecarbaldehyde and acetylcymantrene enter readily into the Wittig reaction with the ylide $Ph_3P=CH_2$ and its analogues with formation of the corresponding olefines — vinyl- and alk-2-enyl-cymantrenes.[72,73] Acetylcymantrene also enters into the Reformatskii reaction with ethyl bromoacetate in the presence of zinc dust.[73]

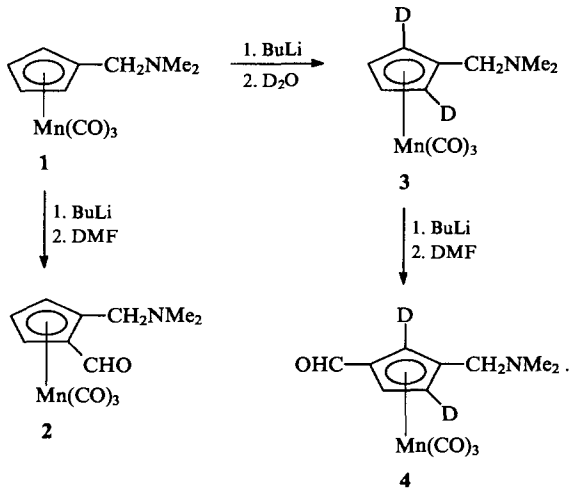
The acylation and benzoylation reactions constitute virtually the only method of synthesis of cymantrenyl ketones. The acyl-ation of cymantrene derivatives is a nonselective reaction. As early as 1970, it was shown that the acylation of alkyl-, halo-, acylamino-, and methoxy-cymantrenes always results in the formation of a mixture of two isomeric ketones.[74–76] The results of the study of the acetylation of methyl(methylthio)cymantrene agree with this finding. The acetylation of both the 1,2- and 1,3-isomers leads to the formation of a mixture of three isomeric ketones containing the Me, MeS, and C(O)Me substituents in different positions in the Cp ring.[77]

The alkylation of cymantrene with $Bu^tCl/AlCl_3$ results in the formation of a complex mixture of alkylation products containing one or two Bu^t and/or C(O)Bu groups in the Cp ring. Reactions involving the succinoylation of *tert*-butylcymantrene, leading to the synthesis of a series of compounds in which the substituted Cp ring has been condensed with the tetramethylene ring, were investigated in the same studies.[78,79]

The mononuclear ketones $(\mathbf{Mn})C(O)CH_2X$, the dinuclear ketones $(\mathbf{Mn})C(O)CH_2XCH_2C(O)(\mathbf{Mn})$, and their ferrocene analogues (X = residues with thiolan and thiolene 1,1-dioxide groups) have been obtained by acylating cymantrene and ferrocene with the acid chlorides $XCH_2C(O)Cl$ and the acid dichlorides $ClC(O)CH_2XCH_2C(O)Cl$.[80]

The reaction involving metallation with butyllithium,[81,82] which proceeds via two pathways depending on the conditions (temperature, solvent), is undoubtedly of greatest importance for the synthetic chemistry of cymantrene. In tetrahydrofuran (THF) or in THF–hexane mixtures at temperatures between −50 °C and −70 °C, the Cp ring is metallated with formation of only the monolithio-derivative.

$$C_5H_5Mn(CO)_3 + BuLi \longrightarrow LiC_5H_4Mn(CO)_3 + BuH.$$

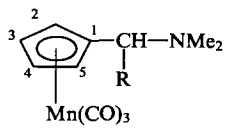


It has been established that, like phenyllithium, cymantrenyl-lithium is unstable in THF: the highest yield of the acid $(\mathbf{Mn})COOH$ (up to 70%–75%) is obtained only when the reaction with CO_2 is carried out 5–15 min after adding butyllithium. On the other hand, if the reaction mass is kept at −60 °C for 1–1.5 h and CO_2 is then added, the yield falls

appreciably.[83] A wide variety of complexes, which are difficult to obtain or are altogether unobtainable by other methods, including compounds with the (**Mn**)—M, (**Mn**)—B, etc. bonds, have been obtained via cymantrenyllithium.[1,83]

Under other conditions (ether, 20 °C), cymantrene reacts with various RLi (R = alkyl, Ph), in which the carbon atom of the carbonyl group is subjected to nucleophilic attack by R^- with formation of oxo-derivatives, the alkylation of which with trialkyloxonium salts leads to carbene complexes (classical Fischer synthesis of carbene complexes).[84]

$$C_5H_5Mn(CO)_3 \xrightarrow{RLi} C_5H_5Mn(CO)_2C(R)O^-Li^+ \xrightarrow{Me_3O^+\,BF_4^-} C_5H_5Mn(CO)_2{=}C(R)OMe\,.$$

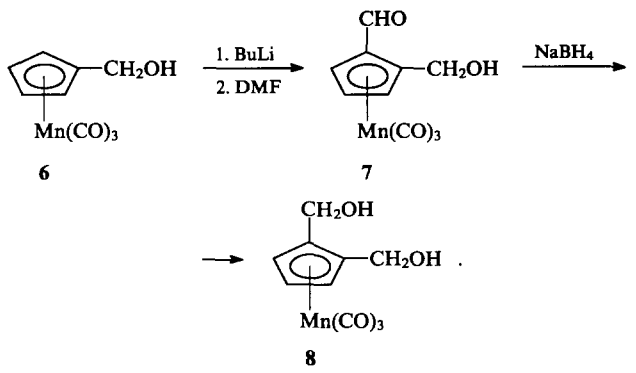


The reaction of cymantrenyllithium (**Mn**)Li with dimethylformamide leads to the formation of cymantrenecarbaldehyde (**Mn**)CHO.[85–87] The oxime (**Mn**)CH=N(OH) has been synthesised from the aldehyde and hydroxylamine in HCOOH. Its dehydration affords the nitrile (**Mn**)CN, which had been obtained previously by other methods.[1] The interaction of the aldehyde (**Mn**)CHO with dimethylformamide (DMF) on refluxing in HCOOH (the Leuckart—Wallach reaction) leads to the formation of dimethylaminomethylcymantrene **1**, the metallation of which with butyllithium takes place stereoselectively, the α-positions being metallated to the extent of 97%.[87]

After the decomposition of the lithio-derivative of the amine **1** with DMF, the 2-aldehyde **2** was obtained and after treatment with D_2O the product was 2,5-dideuteriodimethylaminomethylcymantrene **3**. However, if the amine **3**, where both α-positions contain C—D bonds, is metallated, then a mixture of aldehydes containing 30% of the 2-aldehyde and 70% of the 3-aldehyde **4** is obtained after treatment with DMF. Thus, when hydrogen is replaced by deuterium in the α-position in the amine **1**, the site of attack by butyllithium and the mode of substitution in the Cp ring are altered, i.e. the kinetic isotope effect in the metallation reaction (the ratio of the rates of reaction involving the C—H and C—D bonds) should be very large.[87] The fact that, when an attempt is made to metallate the 2,5-dideuterioamine **3** (with subsequent decomposition of the lithio-derivative with H_2O), deuterium is hardly removed from the α-position in the Cp ring agrees with the above finding.

The regioselectivity of the metallation of the amine **1** (the α-position is metallated exclusively) is apparently associated with the presence of the lone electron pair at the nitrogen atom to which lithium may coordinate. If this electron pair is blocked, as in the complex (**Mn**)$CH_2NMe_2W(CO)_5$, then metallation with butyllithium proceeds nonselectively and virtually to equal extents in the α- and β-positions.[88]

In the metallation of the chiral alkylamines **5** followed by decomposition with D_2O, the insertion of deuterium is also regioselective, and 2- and 5-positions being 75%—80% methylated.



5

R = Me, Et.

Stereochemical induction takes place in the metallation of the amines **5**: substitution in the 2- and 5-positions is unequal, the ratio of the substitution products amounting to 65 : 35 (R = Me) and 95 : 5 (R = Et).[89] The protons and the carbon nuclei in the 2- and 5- (and also 3- and 4-) positions in the amines **5** are diastereotopic and give rise to four different signals in the ^1H and ^{13}C NMR spectra, as in those of the cymantrene derivatives containing a chiral centre in the side chain, which were investigated previously.[90,91]

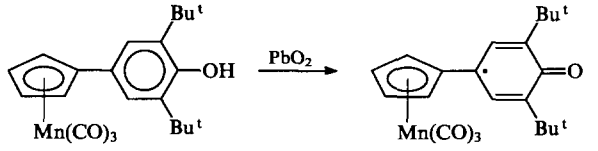
The mode of substitution in the metallation of cymantrene derivatives has been investigated also for several substituents. In the case of R = Me, metallation takes place nonselectively—simultaneously in the α- and β-positions (the product ratio is 1 : 1.5).[92] However, the metallation of the carbinol (**Mn**)CH_2OH, obtained by reducing cymantrenecarbaldehyde with $NaBH_4$,[93] and also of the sulfonamide derivative (**Mn**)SO_2NMe_2 [94] proceeds regioselectively and only in the α-position. On the other hand, the metallation of diphenylphosphinocymantrene (**Mn**)PPh_2 as well as diphenylphosphinomethylcymantrene (**Mn**)CH_2PPh_2 also takes place stereoselectively but only in the β-position.[93,95] Apparently, in the metallation of the carbinol (**Mn**)CH_2OH **6**, the hydrogen atom in the OH group is initially replaced by lithium, and the lithium cation may remain bound to the oligomeric structure of butyllithium, which facilitates the abstraction of a proton, on treatment with a second molecule of butyllithium, and subsequent substitution in the nearest α-position. The directing influence of the amino-groups in the metallation of amines is most probably induced by the coordination of lithium via the nitrogen atom. The direction of the methylation reaction to the α-position in the case of the SO_2NMe_2 substituent may be associated both with the coordination of lithium to the nitrogen of the sulfonamide group and with the pronounced electron-accepting properties of this group, which are manifested more effectively precisely in the α-position adjoining the substituent. The direction of the substitution reaction to the more remote β-position in the case of the bulky substituents PPh_2 and CH_2PPh_2 is most probably associated with steric effects. Thus the metallation of monosubstituted derivatives constitutes a general method of synthesis of 1,2- and 1,3-disubstituted cymantrene derivatives, while methylation of diphenylphosphinocymantrenes represents the only method in the selective synthesis of 1,3-disubstituted compounds among metallocenes.[92–95]

The capacity of the carbinol **6** for selective metallation in the α-position made it possible to achieve the syntheses of a series of 1,2-disubstituted cymantrene derivatives. Carboxylation of the lithio-derivative of the carbinol **6** afforded 2-hydroxymethylcymantrenecarboxylic acid and reduction of the latter by the ionic hydrogenation method gave rise to 2-methylcymantrenecarboxylic acid.[92] Metallation of the carbinol **6** followed by decomposition with DMF affords the aldehydoalcohol **7**, the reduction of which with $NaBH_4$ leads to 1,2-dihydroxymethylcymantrene **8**.

Substitution of the hydroxy-groups in the diol **8** by Cl or Br on treatment with gaseous hydrogen halides leads to the corresponding 1,2-di(chloromethyl)- or 1,2-di(bromomethyl)-cymantrene. Oxidation of the diol **8** with manganese dioxide affords 1,2-diformylcymantrene, which is also obtained on oxidation of compound **7**.[96]

The interaction of (**Mn**)Li with benzopyridines and their *N*-acyl derivatives has been investigated.[97]

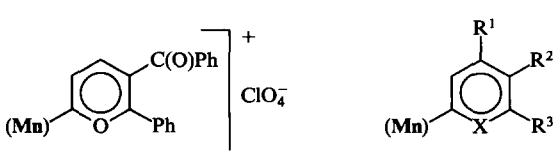
Other substitution reactions, apart from acylation and metallation with butyllithium, have been investigated in lesser detail. After the pioneering work by Cais on the sulfonation of cymantrene,[98] only two studies were published in which it was shown that the sulfonation of methylcymantrene proceeds nonselectively and leads to a mixture of 1,2- and 1,3-isomers.[77,99] Cymantrenesulfonic acids can be conveniently isolated in the form of readily crystallising salts with *p*-toluidine or *p*-chloroaniline. These salts serve as the starting materials for the synthesis of compounds with C_5H_4-S bonds. The sulfonyl chloride (**Mn**)SO_2Cl, obtained on treatment with PCl_5, is reduced with zinc dust to the thiol (**Mn**)SH, which can be extremely readily oxidised to the disulfide (**Mn**)SS(**Mn**).[76,100] Methylcymantrenesulfonic acids react similarly.[77,99] 1,2- and 1,3-Di(methylthiomethyl)cymantrenes were synthesised from 1,2- and 1,3-di(mercaptomethyl)derivatives by methylation with diazomethane.[99] The synthesis of the disulfide $[(CO)_3MnC_5Cl_4S]_2$ has been described.[43]



The mercuration of cymantrene with mercury acetate leads to the substitution of one and to a slight extent also two hydrogen atoms of the Cp ring. Early studies on the synthesis and properties of the mercurio-derivatives of cymantrenes were described in a review.[1] The interaction of cymantrene with mercury trifluoroacetate, a powerful mercurating agent, entails exhaustive mercuration with substitution of all five hydrogen atoms and the formation of $C_5(HgOCOCF_3)_5Mn(CO)_3$.[101] We may note that the reaction involving the cyclopalladation of amines, which has been thoroughly developed for ferrocene, has not been investigated in the cymantrene series.

A large series of studies on the hydrogen isotope exchange (HIE) reactions involving metallocenes (ferrocene, ruthenocene, cymantrene and its rhenium analogue, and benchrotrene) were carried out in the 1960s – 1970s. All these complexes enter into the HIE reactions with both acids and bases. Extensive experimental data on the HIE reactions involving cymantrene and its derivatives have been published in reviews.[102–104] A mechanism involving the protonation of the transition metal atom (Fe, Mn, Re, Cr) and subsequent migration of the proton to the π-linked ligand has been proposed for HIE reactions in the presence of acids.

Isotope exchange in the presence of bases, for example in the alcohol – sodium alkoxide and cyclohexylamine – lithium, sodium, potassium, etc. cyclohexylamide systems, as well as metallation with butyllithium are protophilic substitution reactions in which the rate-determining stage is the abstraction of a proton from the Cp ring by the base. For example, measurements of the kinetic isotope effects in the HIE reactions in basic media agree with this postulate. On the other hand, the mechanism of the isotope exchange with acids cannot be regarded as reliably established. For reactions with electrophiles, a special case of which is the hydrogen isotope exchange with acids, two mechanisms are possible. The first involves the attack by the reagent on the Cp ring, while the second involves the attack on the metal with subsequent migration of the electrophile to the Cp ring (the so called 'ricochet' substitution mechanism proposed at an early stage by A N Nesmeyanov). The hydrogen isotope exchange in the reactions of cymantrenylferrocene with acids has been investigated[105] and the acidity of the C – H bonds in the Cp ring of cymantrene and its derivatives in the HIE in alkaline media has been determined by a kinetic method.[106,107]



In addition to the early studies[1] concerned with the preparation of a wide variety of cymantrene derivatives, mention may be made of syntheses the majority of which have been carried out through cymantrenyllithium. In this connection, we may mention that, in contrast to benzene derivatives, for the syntheses of which both organolithium and organomagnesium compounds are equally widely employed, in the cymantrene chemistry the corresponding Grignard reagent, namely (**Mn**)MgI formed in a moderate yield from (**Mn**)I and magnesium,[76] is used extremely rarely.

The attack on the keto-group in the 4-position in the interaction of (**Mn**)Li with 2,5-di(*tert*-butyl)-1,4-quinone results in the formation of a carbinol, the Clemmensen reduction of which leads to the cymantrenylphenol **9**. The oxidation of the latter with PbO_2 affords the free-radical complex **10**, which has been characterised by EPR spectroscopy.[108]

9 **10**

A series of studies[109–113] have been devoted to the synthesis of pyryllium salts containing cymantrenyl substituents. The reaction of β-chloro-β-cymantrenylacrolein and dibenzoylmethane in $MeCOOH/HClO_4$ with acetic anhydride led to the formation of the cation **11**, the reactions of which with copper and cobalt acetates afford the bimetallic copper and cobalt β-keto-pyranolates.[109] The cyclisation of acetylcymantrene with α,β-unsaturated ketones $R^1CH=CR^2C(O)R^3$ in a mixture of acetic and perchloric acids gives rise to the tetrasubstituted pyryllium salts **12** with R^1-R^3 = Ph, $MeOC_6H_4$, etc. On treatment with ammonia and aniline, they are converted into the corresponding pyridines.[110]

11 **12**

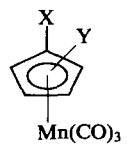
X = O⁺, N.

Cymantrenyllithium (**Mn**)Li and 2,5-disubstituted pyryllium salts afford 4*H*-pyrans, the abstraction of a hydride ion from which on treatment with $Ph_3C^+ClO_4^-$ leads to the formation of pyryllium salts with the cymantrenyl substituent in the 4-position.[111] The reaction of acetylcymantrene with orthoformic ester in the presence of 70% $HClO_4$ affords 2,6-dicymantrenyl-pyryllium perchlorate, which, on refluxing in ethanol, reacts with $PdCl_2$ in the presence of Na_2CO_3 with cleavage of the pyryllium ring and the formation of the bis-η^3-allyl complex of palladium with perchlorate bridges. The reaction of the latter with CpTl in

acetonitrile leads to the rupture of the dimeric structure and the formation of the allyl complex (η^3-RCH···CH···CHR)PdCp, where R = $(CO)_3MnC_5H_4C(O)$.[112] The electrochemical properties of pyryllium salts with cymantrenyl substituents have been described.[113].

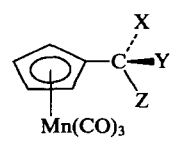
A series of studies have been devoted to the chemistry of thioketones of the cymantrene series. Benzoylcymantrene reacts with P_4S_{10} in CS_2 in the presence of the base $NaHCO_3$ to form the thioketone (**Mn**)C(S)Ph.[114] The latter is readily coordinated by the 16-electron fragments ML_n [ML_n = $W(CO)_5$, $Mn(CO)_2Cp$, etc.], forming dinuclear complexes of the type (**Mn**)(Ph)C=S →ML_n, in which the cymantrenyl thioketone is a two-electron ligand.[115] The structure of the dinuclear complex where ML_n = $Mn(CO)_2Cp$, was established by X-ray diffraction.[116] Reversible temperature variations have been noted in the ^1H and ^{13}C NMR spectra. It follows from them that in solution the complex exists as a mixture of (*E*)- and (*Z*)-isomers with different dispositions of the manganese-containing fragments relative to the C=S bond. The barriers to rotation about his bond, determined from the NMR data, amount to 12.4–13.0 kcal mol^{-1}.[116,117] The thioketone (**Mn**)(Ph)C=S reacts with the anions Cp^- or $CpFe(CO)_2^-$ to form initially phenyl(cymantrenyl)fulvene, which rapidly dimerises under the reaction conditions via a diene synthesis type of reaction or enters into a cycloaddition reaction via the C=S bond.[118] The formation of the dimer is reversible: on interaction of the dimer with $Cr(CO)_6$, it dissociates to the monomer, which affords the complex [η^6-C_4H_4C=C(Ph)(**Mn**)]$Cr(CO)_3$ in which the Cr atom is coordinated to the three C=C bonds of cymantrenylfulvene.[119]

Cymantrenylthioketones are reactive compounds. Thus, on being kept in air (at 25 °C, 20 days), the thioketone (**Mn**)C(S)Me is converted into a complex mixture of products, from which biscymantrenyl derivatives with trithiolan and dithietan rings, characterised by X-ray diffraction, were isolated.[120]



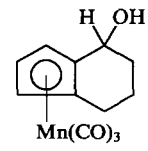
Among the numerous studies on the synthesis of various organic and heterocyclic compounds with a cymantrenyl substituent, one may distinguish the syntheses of cymantrenyl analogues of mandelic acid[121] and alanine[122] as well as cymantrenylthioglycolic acid.[100] Carbinols containing the $SiMe_3$ group have been obtained by the reactions of acetylcymantrene and benzoylcymantrene with the Grignard reagents Me_3SiCH_2MgCl and $Me_3SiC_6H_4MgBr$.[123] The syntheses and reactions of dihydric alcohols in the acetylene series of the type (**Mn**)C(OH)(R)C≡CC(OH)R^1R^2 have been studied.[124–126]

A series of cymantrenyl vinyl ketones (cymantrenyl analogues of chalcones) having the general formula (**Mn**)CH=CHC(O)R, where R = phenyl, cymantrenyl, ferrocenyl, and vinylcymantrene or vinylferrocene residues, have been obtained by condensing formylcymantrene with the ketones MeC(O)R.[127] These compounds readily enter into cyclisation reactions with hydrazine, forming relatively unstable pyrazolines, the acylation of which affords the more stable *N*-acetyl derivatives.[128] Condensation of the pyrazolines with benzaldehydes gives rise to 4-benzylidenepyrazolines.[129,130] Catalytic pyrolysis of cymantrenylpyrazolines results in the formation of cymantrenylcyclopropanes, including dicymantrenylcyclopropanes.[129–132] This reaction is nonselective and gives rise to mixtures of the *cis*- and *trans*-isomers of the substituted cyclopropanes.



In reactions with $Fe_2(CO)_9$ or $Fe_3(CO)_{12}$, cymantrenyl vinyl ketones form mixtures of heterodiene complexes of iron tricarbonyl and olefin derivatives of iron tetracarbonyl in which the diene or olefin ligand contains the cymantrenyl substituent.[133,134] The reaction of ferrocenylideneacetylcymantrene with MeMgI affords a mixture of the substituted allyl alcohol FcCH=C(OH)Me(**Mn**) and the ketone FcCHMeCH$_2$C(O)(**Mn**).[135] Cymantrenyl vinyl ketones and their complexes with $Fe(CO)_3$ are protonated on treatment with CF_3COOH at the oxygen atom of the carbonyl group with formation of cations of the allyl type.[136,137] A reaction involving the addition of dimethyl malonate to cymantrenyl vinyl ketones has been described.[138]

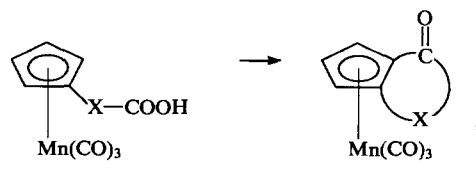
IV. Chiral derivatives of cymantrene



Two types of chiral derivatives of cymantrene are known. The structural characteristics of metallocenes as well as compounds containing one planar cyclic ligand (C_5H_5, C_6H_6, etc.), linked to a $M(CO)_3$ fragment, are such that, when the ring contains two different substituents, these molecules become chiral. Accordingly, disubstituted cymantrene derivatives are planarly chiral (type **A**) regardless of whether the two different substituents occupy the 1,2- or 1,3-positions. The second type of chiral derivatives consists of compounds containing a chiral centre in the α- or more remote position in the side chain (type **B**). Compounds containing simultaneously both elements of chirality, in particular the carbinol **13** and its analogues, have been obtained.

A

B

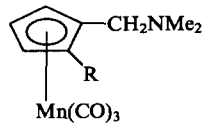


13

The first studies on the stereochemistry of cymantrene derivatives were carried out on compounds with planar chirality, mainly on a series of different derivatives of methylcymantrene. As early as 1961, 2- and 3-methylcymantrenecarboxylic acids, obtained by acylating methylcymantrene and then oxidising with iodine the mixture of ketones (2- and 3-methylacetylcymantrenes), were resolved into the enantiomers.[139] Systematic study of the stereochemistry of the cymantrene derivatives was begun in the middle of the 1960s. Schlögl and his group[140–143] synthesised, resolved into enantiomers, investigated the chirooptical properties, and established the absolute configurations of a series of derivatives of methylcymantrene [C_5H_3(R)Me]$Mn(CO)_3$, where R = COOH, C(O)Cl, $C(O)N_3$, Na_2, Cl, Br, I, NCO, etc.] and also cymantrenylbutyric acids and methylcymantrenylcyclohexa-1,2-dienes, obtained by succinoylating methylcymantrene with succinic anhydride and subsequent cyclisation (see also Schlögl[144,145]).

Studies on the synthesis, resolution into enantiomers, and the determination of the absolute configurations of 1-methyl-2-cymantrenyl- and 1-methyl-3-cymantrenylpropionic and 1-methyl-2-cymantrenyl- and 1-methyl-3-cymantrenyldimethylpropionic acids were carried out at the beginning of the 1970s.[146–149]

All the known planarly chiral derivatives of cymantrene have been obtained in one way — by introducing the second substituent into monosubstituted cymantrenes. Since the acylation reaction is nonselective, mixtures of the 1,2- and 1,3-isomers of different ketones of the cymantrene series are always formed (see the table in the relevant review[1]) with the sterically less hindered 1,3-isomers predominating. In order to separate the mixtures, laborious chromatographic separation procedures have to be resorted to.



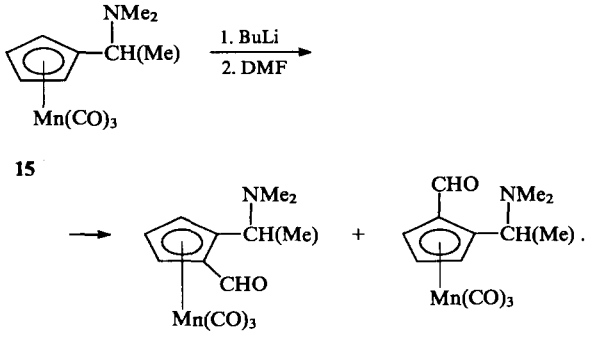
;

X = SCH_2,[76] CH_2CH_2,[150] $CH_2CH_2CH_2$ [151].

One of the methods of selective introduction of the second substituent in the 2-position involves the intramolecular acylation of monosubstituted acids and their chlorides, which leads to the 1,2-isomers of cymantrenyl ketones with a condensed polymethylene ring.[76,150,151]

When the keto-group is reduced to the CH(OH) fragment by $NaBH_4$ or $LiAlH_4$, a chiral centre arises in the α-position and diastereoisomers containing two elements of chirality — the plane and the centre — are formed.[152]

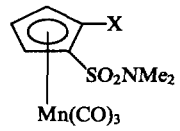
Metallation of monosubstituted derivatives of cymantrene has been used widely in recent times for the synthesis of planarly chiral cymantrene derivatives with substituents in the 1- and 2-positions. This reaction is based on the fact that, for certain substituents containing a heteroatom with a lone electron pair, such as CH_2NMe_2 and CH_2OH, metallation is regioselective and proceeds almost exclusively only in the position adjoining the substituent. Metallation of dimethylaminomethylcymantrene followed by treatment with electrophiles afforded the 1,2-disubstituted cymantrenes **14a–c**.[87,93]



14a–c

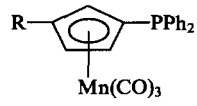
R = D (**a**), CHO (**b**), PPh_2 (**c**).

Stable Cu^{2+} complexes with Schiff bases, obtained from the aminoaldehyde **14b** and chiral dipeptides, have been proposed for the resolution of the racemic aminoaldehyde **14b** into enantiomers. The copper complexes are mixtures of diastereoisomers, which were resolved by extraction and liquid chromatographic methods. Acid hydrolysis of the diastereoisomers affords the optically pure enantiomers of the aldehyde **14b**.[153–156] The absolution configuration of one of them as well as the structure of the copper complex of the dipeptide Ala–Ala have been established by X-ray diffraction.[155,157]



Metallation of α-(*N*,*N*-dimethylamino)ethylcymantrene **15**, containing a chiral centre in the α-position, followed by treatment with dimethylformamide produced a mixture of two diastereoisomers of the aminoaldehyde **16** in proportions of 7:2 (asymmetric induction). The Cu^{2+} complexes obtained from the Schiff bases formed from these aldehydes and a different dipeptide were resolved by liquid chromatography. The enantiomers of the aldehyde **16**, the absolute configuration of one of which was established by X-ray diffraction,[159] were obtained from them by acid hydrolysis.[158]

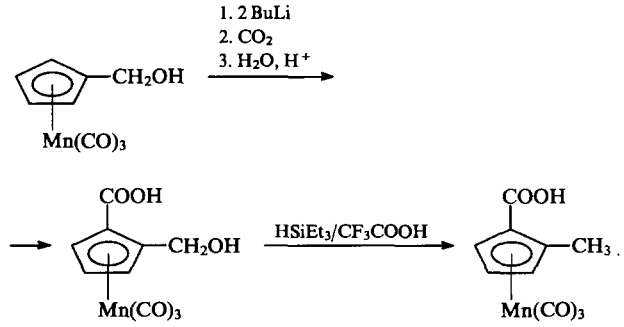
15



16

The regioselective metallation only in the α-position in cymantrene derivatives with the substituents R = CH_2OH [93] and SO_2NMe_2 [94] was noted above. A series of racemic 1,2-disubstituted complexes **17** [X = COOH, COOMe, CMe_2OH, CPh_2OH, CH(Ph)OH, etc.] have been obtained by the reactions of the lithio-derivative containing the sulfonamide group with electrophiles.[94]

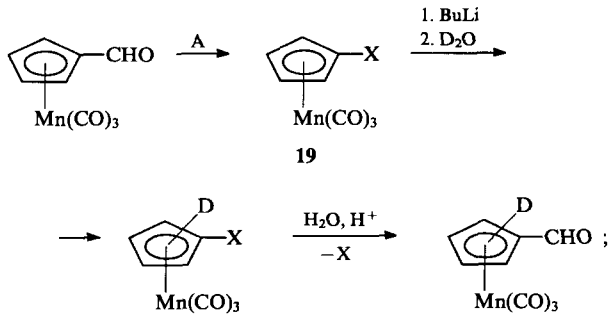
17



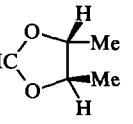
On the other hand, the metallation of the diphenylphosphino-derivative **(Mn)**PPh_2 also proceeds regioselectively but only in the β-position, which is evidently associated with steric factors. The reaction of the lithio-derivative of this phosphine with DMF and Ph_2PCl leads to the phosphinoaldehyde **18a** and 1,3-bis(diphenylphosphino)cymantrene **18b**. The dimethylaminomethyl derivative **18c** was obtained from the aldehyde in the reaction with DMF and HCOOH.[93]

18a–c

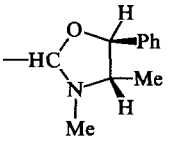
R = CHO (**a**), PPh_2 (**b**), CH_2NMe_2 (**c**).



A method, based on the acylation of methylcymantrene with subsequent oxidation of the mixture of the resulting methylacetyl derivatives by iodine in pyridine and the separation by fractional recrystallisation and chromatography of the mixture of acids or their esters produced, was proposed previously for 2-methylcymantrene-1-carboxylic and 3-methylcymantrene-1-carboxylic acids.[141] As a result of the numerous stages in the synthesis, the yield of 2-methylcymantrene-1-carboxylic acid does not exceed 10%. An improved method of synthesis of 2-methylcymantrenecarboxylic acid, based on the stereoselective metallation of hydroxymethylcymantrene, obtained readily from cymantrenecarbaldehyde by reduction with $NaBH_4$ and EtOH,[93] has been developed recently.[92] The hydroxymethyl group was reduced to the methyl group by ionic hydrogenation in the Bu_2SiH_2/CF_3COOH system. The absolute configuration of 2-methylcymantrenecarboxylic acid was determined by chemical correlation with the aldehyde **14b**, the absolute configuration of which had been obtained earlier by X-ray diffraction.[155]

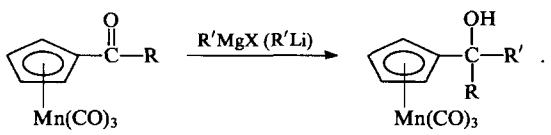


There are at present two methods of synthesis of optically active compounds of the cymantrene series with a planar chirality. The first of these is the classical resolution of racemates via the intermediate formation and separation of diastereoisomers.[141–143,155] The second method is based on the kinetically controlled enzymic reduction of disubstituted chiral and achiral compounds, one example of which has been described.[160] In each specific case, it is essential to select carefully the optimum reactants and resolution conditions.



A new approach to the synthesis of optically active 1,2-disubstituted cymantrene derivatives with a planar chirality, based on the regioselective metallation of a series of new monosubstituted derivatives with butyllithium, has been

developed recently.[161-164] In this method, the initial achiral compound with a functional group substituent—cymantrenecarboxylic acid or cymantrenecarbaldehyde—is converted in a preliminary step into a chiral derivative with the aid of the optically active molecule of the inductor **A**. This is followed by the stage in which the second substituent is introduced—usually metallation with butyllithium and treatment with the appropriate reagents (D_2O, CO_2, etc.). In the third stage, the inductor molecule is removed from the diastereoisomeric product by acid hydrolysis.

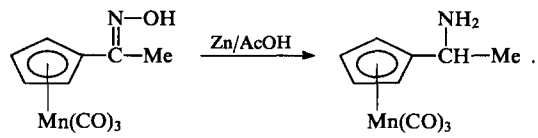


A = $CH(OEt)_3$; X =  ;

A = (2*R*,3*R*)-MeCH(OH)CH(OH)Me; X =  ;

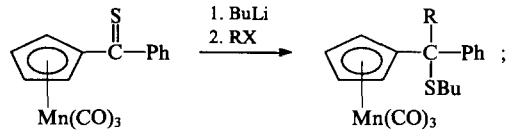
A = (−)-ephedrine; X =  .

Metallation of compounds **19** by treatment with BuLi proceeded exclusively at the CH positions of the Cp ring, whereupon the regioselectivity of the process depends on the nature of the reagent **A**.[161,162] (−)-Norephedrine, (−)-2-aminobutanol, (*R*)-phenylethanediol, and (*S*)-prolinol may be used as the inductor molecules **A**.[162,163] This approach has been used to synthesise the enantiomers of 2-methylcymantrene-1-carboxylic and 3-methylcymantrene-1-carboxylic acids.[161] By virtue of the extensive possibilities of the metallation reaction, this method makes it possible to obtain directly the enantiomers of planarly chiral compounds with a wide set of substituents. Compounds containing two elements of chirality—the chiral centre at the metal atom and the chiral plane—have been obtained by substituting two CO groups in 3-methylcymantrenecarboxylic acid and its esters by various phosphine ligands.[165,166]



Cymantrene derivatives with a chiral centre in the side chain are usually obtained by forming this centre from a prochiral fragment already available. A typical example is provided by the synthesis of secondary and tertiary carbinols from ketones.[167,168]

In the case of cymantrenyl methyl ketones, it has been shown that the reduction of the 1,2-isomers proceeds with a high degree of stereoselectivity, whereas the selectivity for the 1,3-isomers is much lower.[169] The stereoselectivity in organomagnesium synthesis is fairly high, the proportions of the enantiomers depending significantly on the nature of the groups R and R'. Similar reactions for a ketone with a condensed polymethylene ring have been investigated.[152] Chiral carbinols of the cymantrene series can be converted into other chiral derivatives (esters, azides, nitriles, amines, etc.) by esterification and nucleophilic substitution reactions.

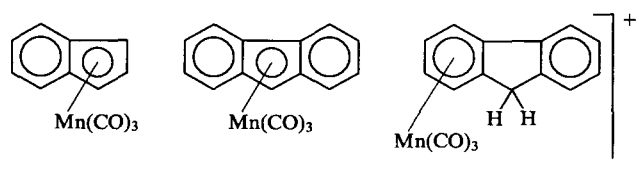


In certain cases, asymmetric synthesis has been used to obtain optically active cymantrene derivatives with a chiral centre. In the reduction of acetyl- and benzoyl-cymantrenes by a complex of lithium tetrahydroaluminate and quinine, the corresponding carbinols are formed, but their optical yield does not exceed 10%−15%.[169]

Yet another example of the formation of a chiral centre involves the reduction of ketone oximes to primary amines.[170]

The racemic α-aminoethylcymantrene synthesised in this way was resolved into enantiomers by crystallising the salts with (+)-*d*-tartaric acid. α-Dimethylaminoethylcymantrene (**Mn**)CH(Me)NMe_2, its methiodide (**Mn**)CH(Me)$^+NMe_3I^-$, and the acetamido-derivative (**Mn**)CH(Me)NHC(O)Me have been obtained from this amine. The absolute configuration of the acetamido-derivative was established by X-ray diffraction.[170] Subsequently 14 optically active derivatives of aminocymantrenes having the general formula (**Mn**)CH(Me)X [X = NH_2, NHCHO, NHMe, $NHCH_2Ph$, $NHCH_2$(**Mn**), N_3] as well as the Schiff bases (**Mn**)CH(Me)N=CHPh, (**Mn**)CH(Me)N=CH(**Mn**), etc. were synthesised and their chirooptical properties were investigated.[171] The reactions of the optically active (+)-α-phenylethylamine with (**Mn**)CH_2Cl, (**Mn**)C(O)Cl, and (**Mn**)CHO, which resulted in the synthesis of the corresponding compounds with a chiral centre in the β-position in the side chain, have been described.[172] As for compounds with the chiral centre in the α-position, the protons and carbon nuclei in the 2,5- and 3,4-positions are diastereotopic and give rise to different signals in the ^1H and ^{13}C NMR spectra.

The reaction of the thioketone (**Mn**)(Ph)C=S with butyllithium follows the so called 'thiophilic' path with metallation of the sulfur atom. Treatment of the reaction product with electrophiles afforded the previously unknown metallocenyl sulfides with the chiral centre in the α-position.[173]



R = H, D, Me.

V. Complexes with polycyclic ligands and polynuclear derivatives of cymantrene

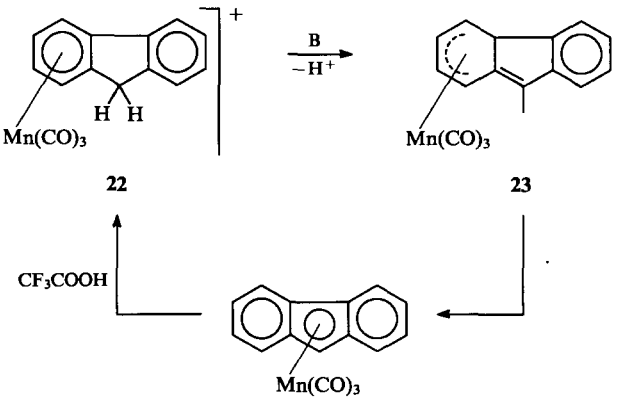
The synthesis and properties of the complexes of $Mn(CO)_3$ with indene, fluorene, and related compounds, in which the Cp ligand is part of a more complex cyclic system, are considered below.

If the ligand contains simultaneously five- and six-membered rings, there is a possibility of two types of coordination of the

20 **21** **22**

$Mn(CO)_3$ fragment. The η^5-type of coordination affords the neutral compounds **20** and **21**, containing the indenyl or fluorenyl ligands. The cationic complex **22**, in which the $Mn(CO)_3$ residue is η^6-linked to the cyclic ligand, is also known.

Metallotropic rearrangements, in which the $Mn(CO)_3$ fragment migrates from the five- to the six-membered ring and conversely, are characteristic of the indenyl and fluorenyl complexes.



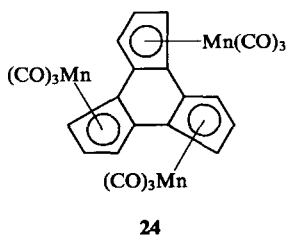
Complexes **20** and **21** were first obtained by the reaction of $Mn(CO)_5Br$ with indenyl- and fluorenyl-sodium (in 56% and 11% yields)[174] or with the $SnMe_3$ derivatives of indene and fluorene (in 62% and 20% yields).[175] An improved method of their synthesis by the reactions of $Mn(CO)_3(MeCN)_2$ with indenyl- or fluorenyl-potassium was developed subsequently.[176] The indenyl complexes of manganese and rhenium can also be obtained by direct synthesis in yields up to 90% on refluxing the decacarbonyls $M_2(CO)_{10}$ in an excess of indene as the solvent.[177]

The CO groups in complexes **20** and **21** undergo photochemical substitution by PPh_3, $AsPh_3$, and $SbPh_3$,[174] but, in contrast to cymantrene, in these compounds there is a possibility of not only photochemical but also of thermal substitution of CO by phosphines and phosphites. In the study of the kinetics of the thermal substitution of CO (decalin, 200 °C), an appreciable increase in the rate of reaction in the sequence $C_5H_5 < C_9H_7 < C_{13}H_9$ was noted.[178,179] These reactions are second order overall and first order with respect to the complex and the ligand; an associative mechanism has been proposed for them with the formation of an η^3-intermediate. In the photochemical substitution of CO by PPh_3, such an effect was not observed, which indicates a dissociative process mechanism.[180] A CO group in complex **20** can be substituted by NO with formation of the cation $(\eta^5\text{-}C_9H_7)Mn(CO)_2(NO)^+$.[176] The cationic complex $(\eta^5\text{-}C_9H_7)Mn(CO)(NO)(PPh_3)^+$, chiral with respect to the Mn atom, has also been obtained.[181] Its interaction with the anions $X^- = Br^-$, I^-, or CN^- involves the ready cleavage of the Mn—C(Cp) bond with the removal of the indenyl ligand and the formation of the complexes $Mn(NO)_2(PPh_3)_2X$.[181]

A series of studies on the hydrogen substitution reactions in the indenyl and fluorenyl ligands were carried out in the 1980s. In the reaction of $(\eta^5\text{-}C_9H_7)Mn(CO)_3$ with an excess of $MeC(O)Cl/AlCl_3$, acetylation takes place simultaneously both in the five- and six-membered rings, the ratio of the isomers depending significantly on the reaction conditions.[182] It has been shown by the competitive acylation method that the reactivity of the indenyl ligand is higher than that of the cyclopentadienyl ligand. In the case of $(\eta^5\text{-}C_{13}H_9)Mn(CO)_3$, acylation takes place only in the six-membered ring and is accompanied by the cleavage of the Mn—η^5-ligand bond.[183] Apart from the 2-acetyl derivative, 2-acetylfluorene and fluorenone were also isolated. The appreciably lower strength of the bond between the η^5-ligand and $Mn(CO)_3$ in $(\eta^5\text{-}C_{13}H_9)Mn(CO)_3$ compared with $(\eta^5\text{-}C_9H_7)Mn(CO)_3$ agrees with the mass-spectrometric data on the strength of the corresponding bonds in the gas phase.[184] The acylation of $(\eta^5\text{-}C_{13}H_9)Mn(CO)_3$ led to the isolation and characterisation by X-ray diffraction also of the products of the partial hydrogenation of one of the six-membered rings.[185]

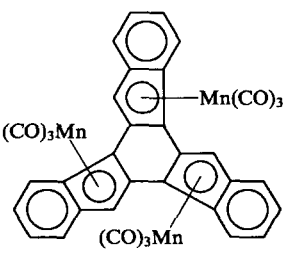
In the isotope exchange of hydrogen in the $CF_3COOD/D_2SO_4/CH_2Cl_2$ system, H is substituted by D in both rings of the $\eta^5\text{-}C_9H_7$ ligand, although the substitution in the five-membered ring predominates.[183] The complex $(\eta^5\text{-}C_9H_7)Mn(CO)_3$ can be metallated by butyllithium in THF at −40 °C, but the reaction proceeds nonselectively and a mixture of the 1- and 2-isomers containing lithium in the five-membered ring is formed.[186] Competitive metallation of a mixture of $(C_9H_7)Mn(CO)_3$ and $(C_{13}H_9)Mn(CO)_3$ has shown that the indenyl ligand is more reactive.[187]

Metallotropic rearrangements are very characteristic of the indenyl and fluorenyl derivatives of manganese and rhenium. The reaction of fluorene with $Mn(CO)_5Br$ (refluxing in hexane) afforded the cationic complex **22**. Its deprotonation by bases (Bu^tOK, MeONa, NEt_3, etc.) gives rise to the neutral complex **23**, which on heating or storage in the solid state is converted into the thermodynamically more stable complex **21** as a result of the $\eta^6 \rightarrow \eta^5$ rearrangement.[188]



22 **23** **21**

It has been established by X-ray diffraction that complex **23** has a structure typical for cyclohexadineyl derivatives.[189] Quantum-chemical calculations for the $\eta^6 \rightarrow \eta^5$ rearrangement of fluorenyl complexes have shown[190] that the η^6-isomer is less stable (by ~7 kcal mol^{-1})† than the η^5-isomer, while the activation energy for the rearrangement via the η^3-intermediate is 25 kcal mol^{-1}. Kinetic studies on $\eta^6 \rightarrow \eta^5$ rearrangements for the fluorenyl complexes $(\eta^6\text{-}C_{13}H_9)Mn(CO)_2L$ (L = CO or PBu_3) confirmed the results of the calculations.[191]



The reverse $\eta^5 \rightarrow \eta^6$ rearrangement has been observed in the study of the protonation of complex **21** in the presence of CF_3COOH.[192] It has been suggested that the acid proton adds directly to the fluorenyl ligand. In the η^5-indenyl complexes of manganese and rhenium, the analogous $\eta^5 \rightarrow \eta^6$ rearrangements take place (according to Ezernitskaya et al.[193]) only in the presence of stronger acids HSO_3F and $AlCl_3$ + HCl. In the complexes with phosphine ligands $(\eta^5\text{-}C_9H_7)Mn(CO)_2PPh_3$ and $(\eta^5\text{-}C_{13}H_9)Mn(CO)_2PPh_3$, the basicity of the central metal atom is greater than the basicity in the tricarbonyl complexes and in the presence of CF_3COOH only protonation at the Mn atom takes place and there is no metallotropic rearrangement..

The $\eta^5 \rightarrow \eta^1$ rearrangement of the fluorenyl ligand has been observed in the reaction of $(\eta^5\text{-}C_{13}H_9)Mn(CO)_3$ with an excess of PBu_3.[179] In a later study,[194] the complex $(\eta^1\text{-}C_{13}H_9)Mn(CO)_3(PEt_3)_2$ was isolated and characterised by a set of spectroscopic methods.

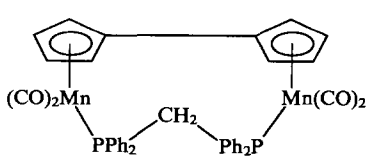
The properties of the indenyl and fluorenyl complexes of manganese and other transition metals have been examined in detail in a review.[195] Communications concerning the study of the metallotropic rearrangements of the manganese tricarbonyl complexes with other polycyclic hydrocarbons, such as fluoradene[196] and 9,10-dihydro-9-methylindeno[1,2-*a*]indene and its analogues,[197,198] have appeared recently. The structure of the dinuclear complex $(\eta^5,\eta^5\text{-}L)Mn_2(CO)_6$, where L = 3,5-dimethylazulene, has been established by X-ray diffraction.[199]

24

25

† 1 kcal = 4.18 kJ.

Bismanganese tricarbonyl complexes of *sym*- and *asym*- indacenes have been obtained[200,201] by the reaction of the corresponding biscyclopentadienyl anions with $Mn(CO)_5Br$ or $Mn(CO)_3Py_2Br$. The trismanganese tricarbonyl complex **24** has also been obtained recently[202] and complexes containing one and two $Mn(CO)_3$ residues as well as the triscomplex **25** have been synthesised from the hydrocarbon truxene.[203,204]



The simplest compound in which the two parts of the ligand are linked by a single C–C bond is the complex bicymantrenyl (**Mn**)–(**Mn**). It was synthesised in 1969 by three groups of investigators simultaneously.[76,205,206] A compilation of different methods of its synthesis is given in Table 1. These methods for the reactions involve the oxidative coupling of two $(CO)_3MnC_5H_4$ fragments, formed when the Grignard reagent (**Mn**)MgI or (**Mn**)Li is acted upon by metal salts, and radical dimerisation reactions in the course of the pyrolysis of cymantrene metallo-derivatives [(**Mn**)Cu, (**Mn**)Ag, $(\mathbf{Mn})_2$Hg]. The optimised yield of bicymantrenyl in the reaction of (**Mn**)Li with carefully dehydrated $CuCl_2$ reaches up to 90%.[212]

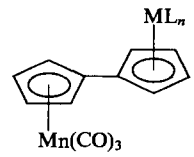
Table 1. Syntheses of bicymantrenyl.

Initial compounds	Yield of cymantrenyl, (%)	Other reaction products	Ref.
(**Mn**)$AuPPh_3$ + Cl_2	72	(**Mn**)Cl	205
(**Mn**)$AuPPh_3$ + Br_2	33	(**Mn**)Br	205
(**Mn**)MgI + $CoCl_2$	30	–	76
	15	–	206
(**Mn**)Li + $CoCl_2$	13	–	206
(**Mn**)I + Cu[a]	21	–	206
$(\mathbf{Mn})_2$Hg + Ag[a]	67	–	206, 207
(**Mn**)Cu + I_2	10	(**Mn**)I	208
(**Mn**)$B(OH)_2$ + $Cu(OAc)_2$	10	cymantrene	209
(**Mn**)Li + $CuBr_2$	52	–	210
(**Mn**)Li + $CuCl_2$	69	–	211
(**Mn**)Li + $CuCl_2$	90	–	212
(**Mn**)Cu + Br_2	50	–	211
(**Mn**)Ag + Br_2	23	–	211
$Mn(CO)_5Br$ + fulvalenedithallium	86	–	213

[a] Pyrolysis in the presence of metal powders.

Although bicymantrenyl has been known for more than 20 years, only one substitution reaction in the Cp ring has been described for this compound: acetylation with the MeC(O)Cl + $AlCl_3$ mixture, which proceeds in the 3-position.[207] Other substitution reactions, including metallation with BuLi, have not been investigated. As in cymantrene, the CO groups in one or simultaneously in two $Mn(CO)_3$ fragments can be substituted by n- and π-donor ligands (triphenylphosphine, ethylene, cyclooctene, dimethylacetylene, and pyridine) with formation of both mono- and di-substituted compounds. After the reaction of bicymantrenyl with the diphosphine $Ph_2PCH_2PPh_2$, complex **26** was isolated and characterised by X-ray diffraction. Because of the presence of the rigid chelate skeleton of the diphosphine, the coplanarity of the two Cp rings in complex **26** is significantly disturbed. Their planes form with one another a dihedral angle of 65°.[212]

26



In the absence of steric hindrance, the similar bifulvalenyl system is known to be planar.

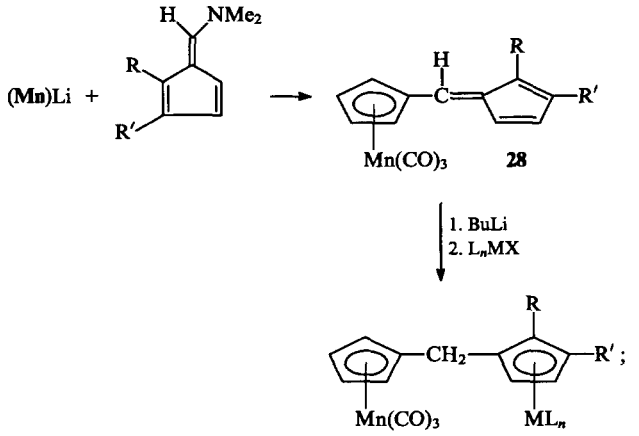
Cymantrenylferrocene[214] and a series of its derivatives[215–217] have been obtained by the thermal reaction of haloferrocenes with (**Mn**)Cu, (**Mn**)Ag, or $(\mathbf{Mn})_2$CuAg.

The properties of cymantrenylferrocene have been investigated in greater detail than those of bicymantrenyl.[217] Depending on the type of reagent, substitution takes place either in the ferrocene or in the cymantrenyl ring. Thus, on acetylation with acetic and anhydride in the presence of H_3PO_4, i.e. under mild conditions, the acetyl substituent enters the unsubstituted ferrocene ring. On the other hand, on treatment with BuLi the Cp ring in the cymantrene nucleus is metallated. The reaction of the lithio-derivative of cymantrenylferrocene with $B(OBu)_3$ affords after hydrolysis (3-ferrocenyl)cymantreneboronic acid, from which complexes with the Br or HgCl substituents in the cymantrenyl fragment were obtained after treatment with $CuBr_2$ or $HgCl_2$. The study of the hydrogen isotope exchange with acid showed that the introduction of the electron-accepting cymentrenyl substituent lowers the rate of exchange in the ferrocenyl nucleus approximately by an order of magnitude compared with the unsubstituted ferrocene.[105]

As a result of the coupling of the two metallocenyl fragments, the thermolysis of a mixture of the Ag derivative of dimethylaminomethylferrocene together with (**Mn**)Cu or (**Mn**)Ag at 120 °C afforded 2-(dimethylaminomethyl)-1-cymantrenylferrocene and a series of its derivatives.[218,219] The same complex is formed also by the oxidative coupling of a mixture of lithio-derivatives of dimethylaminomethylferrocene and cymantrene.[219]

A cymantrenylbenchrotrene complex has been obtained by the reaction of phenylcymantrene with $Cr(CO)_3(MeCN)_3$.[220] The interaction of $H_3Mn_3(CO)_{12}$ with azulene led to the isolation of a complex[221] in which two azulene nuclei are linked by a C–C bond in the 4–4′ positions; its structure was established by X-ray diffraction.[222] The heterodinuclear complexes **27** have been synthesised from the monometallic derivatives of difulvalene.[223]

27



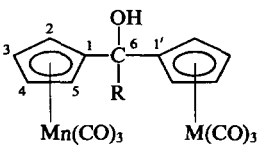
ML_n = $W(CO)_3$, $Mo(CO)(PMe_3)_2Me$.

In the compounds examined above, two identical or different metal-containing fragments are joined by a C–C bond. Together with these, a large number of compounds having the general formula (**Mn**)–X–ML_n, where the cymantrene residue is linked to another organometallic group ML_n via a carbon-containing fragment X [X = CO, CH_2, $C(O)CH_2$, etc.], have also been synthesised. The interaction of benzoylcymantrenes (**Mn**)$C(O)C_6H_4R$ or the ketone (**Mn**)$C(O)CH_2Ph$ and a series of its derivatives with $Cr(CO)_6$ on refluxing in diglyme led to the formation of the dinuclear complexes (**Mn**)–X–$C_6H_4RCr(CO)_3$, where X = CO, CH_2, CH_2CO, CHCH(OH), CH=CH, etc.[224] The dithallio-derivative of dicyclopentadienylmethane is a convenient precursor in the synthesis of various homo- and hetero-dinuclear complexes, including also dicymantrenyl-methane $(\mathbf{Mn})_2CH_2$.[225]

It has been suggested that 6-dimethylaminofulvene be used for the synthesis of heterodinuclear derivatives of cymantrene (Scheme 1).[226]

The comparatively ready availability of the intermediate **28**, the structure of which has been characterised by X-ray diffraction, opens a pathway to the synthesis of various dinuclear complexes

Scheme 1



ML_n = $Co(CO)_2$, $Mo(CO)_3Br$.

with the $(Mn)CH_2$ fragment. The interaction of dimethylaminofulvene with indenyllithium and further with $(CO)_3Py_2Mn(Br)$ (Py = pyridine) led to the formation of cymantrenylbenzofulvene—an analogue of compound **28**, where RR′ = condensed benzene rings.[227] The auration of acetylcymantrene by treatment with the oxonium salt $(Ph_3PAu)_3O^+BF_4^-$ in the presence of NaH led to the formation[228] of the complex $(Mn)C(O)CH_2AuPPh_3$, in which the C—Au bond is readily cleaved on treatment with HCl. A series of dinuclear complexes having the general formula (Mn)—X—ML_n, where X = CH_2,[229] $C(O)CH_2$,[230] or C(O),[231–235] while ML_n = $Fe(CO)_2Cp$, $Mo(CO)_3Cp$, $W(CO)_3Cp$, $Mn(CO)_5$, or $Re(CO)_5$, have been obtained by the reactions of the chlorides $(Mn)CH_2Cl$ and $(Mn)C(O)CH_2Cl$ or the acid chloride (Mn)C(O)Cl with the carbonylate anions Na^+ML_n in THF. The compounds containing the $Fe(CO)_2Cp$ and $W(CO)_3Cp$ fragments were characterised by X-ray diffraction.[236, 237] The reactions involving the photochemical substitution of the CO ligands by PPh_3 at the Fe, Mo, and W atoms were carried out for some of the complexes of this type. A characteristic property of these compounds is the capacity for ready decarbonylation with formation of the corresponding compounds having the C_5H_4—M bonds (see below).

Tungsten hexacarbonyl $W(CO)_6$ reacts in the usual way with (Mn)Li, affording after alkylation with $Et_3O^+BF_4^-$, the carbene complex $(CO)_5W=C(OEt)(Mn)$ with the cymantrenyl substituent at the carbene carbon atom. On treatment with $AlBr_3$, it is readily converted[238] into the carbyne complex $[(CO)_4W\equiv C(Mn)]^+$. Dinuclear complexes of the type $(C_6H_6)Cr(CO)_2(Mn)L$, where L = PPh_2 or CH_2PPh_2, have been obtained by the reactions of $(C_6H_6)Cr(CO)_3$ with cymantrenylphosphines.[239]

Compounds containing two or three cymantrenyl fragments in one molecule have been synthesised in a series of studies. The vast majority of these syntheses were carried out via cymantrenyllithium. The reaction of (Mn)Li with cyanoferrocene in the presence of MeOH gives rise to the ketimine (Mn)—C(NH)—Fc (Fc = ferrocenyl).[240] Hydrolysis of the ketimine leads to the ketone (Mn)C(O)Fc, which is identical with the one obtained previously[241] by acylating ferrocene with the acid chloride $(Mn)C(O)Cl/AlCl_3$. Metallation of methylcymantrene and subsequent treatment with DMF result in the formation of a mixture of isomers of 2- and 3-methylformylcymantrenes,the reduction of which with $NaBH_3(CN)$ in the presence of NH_4OAc in MeOH leads to secondary amines of the type $[(CO)_3MnC_5H_3(Me)CH_2]_2NH$. Layered materials based on acid zirconium phosphate were obtained from the latter compounds.[242] The reaction of the Grignard reagent (Mn)MgI (obtained from iodocymantrene and magnesium in THF) with $N(CH_2Cl)_3$ leads to the tertiary amine $[(Mn)CH_2]_3N$.[243]

A series of studies have been devoted to the synthesis and the properties of polynuclear carbinols of the cymantrene series. The dinuclear carbinols $(Mn)_2C(R)OH$, where R = Me or Ph, have been synthesised by the reactions of (Mn)Li with acetyl- and benzoyl-cymantrenes,[83] while the carbinol $(Mn)_3C(OH)$ has been obtained in the reaction with dicymantrenyl ketones.[244] On treatment with acids, these carbinols are converted into the corresponding stable carbenium ions (see below). The dinuclear carbinols $(Mn)_2C(R)OH$ can be obtained also in one stage as a result of the interaction of 2 equiv. of (Mn)Li with the acid chloride RC(O)Cl. With M = Mn, the plane passing through the O(hydroxy-groups) and C(6) atoms and the neighbouring atom H or C of the group R in the carbinols **29** cannot be a plane of symmetry, because, as shown below, both $(CO)_3MnC_5H_4$ residues occupy different positions relative to it. Therefore, in each C_5H_4 fragment the CH groups in the 2,5- and 3,4-positions are diastereotopic (symmetry elements are absent). This is clearly manifested in the ^1H NMR spectra, where the four protons of the C_5H_4 ligand form the *ABCD* spin system and give rise to four individual signals,[245] and also in the ^{13}C NMR spectra. The study of the reactivities of the carbinols with R = H or Me showed that metallation with BuLi proceeds with a high regio- and stereoselectivity, while in the case where R = CF_3 or Ph the carbinols decompose. When the lithio-derivatives are quenched[245] with D_2O, deuterium is ~90% incorporated in only one of the two α-positions in each C_5H_4 ring. The study of the structures of these carbinols in the crystal by X-ray diffraction and by the method of molecular mechanics (calculation of conformations) showed that the molecules have a chiral conformation with different orientations of the two cymantrenyl residues and that the structure of the carbinols with R = Me differs from that of the carbinols with R = CF_3 or Ph, which makes it possible to explain the observed differences between their reactivities.[246] The structures of the carbinol with R = Me and related compounds have been established by X-ray diffraction.[247, 248]

29

M = Mn, Re; R = H, Me, CF_3, Ph.

A series of communications[249–252] have been devoted to the application of the palladium-catalysed cross-coupling of the organometallic fragments (Mn) in order to synthesise dinuclear complexes. The interaction of iodocymantrene [obtained from (Mn)Li and 1,2-diiodoethane or I_2] with $Bu_3SnC\equiv CSnBu_3$ in the presence of $(MeCN)_2PdCl_2$ in DMF results in the formation of the disubstituted acetylene $(Mn)C\equiv C(Mn)$, the reaction of which with $Co_2(CO)_8$ leads[249] to the tetrahedral cluster $(Mn)C\equiv C(Mn)Co_2(CO)_6$ with the Co_2C_2 skeleton. The initially monosubstituted acetylene $(Mn)C\equiv CH$ was obtained similarly from (Mn)I and $Bu_3SnC\equiv CH$ and its interaction with Et_2NSnR_3 afforded the complex $(Mn)C\equiv CSnR_3$ (R = Me or Bu). The cross-coupling of this acetylene with the iodo-derivatives $IC_5H_4ML_n$ led to the synthesis of the heterodinuclear complexes $(Mn)C\equiv CC_5H_4ML_n$, where ML_n = $Fe(CO)_2Me$, $W(CO)_3Me$, or $Re(CO)_3$.[250] The dinuclear complex $(Mn)C\equiv CC_5H_4Fe(CO)_2CH_2Ph$ was obtained from $(Mn)C\equiv CSnMe_3$ and $IC_5H_4Fe(CO)_2CH_2Ph$, while the reaction with $Co_2(CO)_8$ afforded a cobalt-containing cluster [as a result of the coordination of $Co_2(CO)_6$ to the triple bond]. The structure of the latter complex was demonstrated by X-ray diffraction.[251] Treatment of the acetylene complex $(Mn)C\equiv CH$ with the base KOH in MeOH at 0 °C in the presence of a source of iodine (*N*-iodosuccinimide or 1,2-diiodoethane) afforded the iodo-substituted acetylene $(Mn)C\equiv CI$, which is converted into the

β-vinyl iodide (**Mn**)CH = CHI by the reaction with an excess of the diimide NH = NH as a result of the reduction of the triple bond to a double bond. The cross-coupling of this vinyl iodide with $Me_3SnC{\equiv}CC_5H_4ML_n$ led to the formation of complexes of the type (**Mn**)CH = CH − C = $CC_5H_4ML_n$, where ML_n = $Re(CO)_3$, $W(CO)_3Me$, or $Fe(CO)_2Me$.[252]

The formation of the intermediate $CpMn(CO)_2$ and small amounts of a new dinuclear complex $Cp_2Mn_2(CO)_5$ was noted in a study of the photochemistry of cymantrene in liquid paraffin at 77 K. The new dinuclear compound is formed as a result of the addition of $CpMn(CO)_2$ to cymantrene.[253] The photochemical reactions of dinuclear complexes of manganese and chromium, including (**Mn**) − (**Mn**) and (**Mn**)CH_2(**Mn**), have been investigated in argon matrices at 12 K.[254].

A new organometallic porphyrin — *meso*-tetracymantrenylporphyrin — has been obtained by the reaction of cymantrenecarbaldehyde with pyrrole on refluxing in MeCOOH in the presence of a stream of air.

VI. Compounds with organoelement substituents

A multiplicity of compounds with the $(CO)_3MnC_5H_4$ − E bonds, where E = Group I − VIII elements (Li, Cu, Ag, Au, Mg, Cd, Hg, B, Tl, La, Y, Sm, Sr, Ge, Sn, Pb, P, Sb, Bi,Ti, Mo, W, Mn, Re, Fe, Ni, and Pt) have now been obtained. Their syntheses and properties are considered below.

1. Compounds with Group I − V elements

Syntheses of cymantrene derivatives via (**Mn**)Li have been described in a review[1] and in Sections III − V of the present review. Much attention has been devoted also to the synthesis of cymantrene derivatives containing copper, silver, and gold. The compounds (**Mn**)Cu and (**Mn**)Ag have been obtained by the reaction of cymantreneboronic acid (**Mn**)$B(OH)_2$ or its anhydride with $Cu(OAc)_2$ [208] and $AgNO_3$ [256] respectively. Two types of reactions are characteristic of these compounds: cleavage of the C − Cu and C − Ag σ-bonds on treatment with electrophiles and their use in syntheses as sources of the (**Mn**) fragment. The compounds (**Mn**)Cu and (**Mn**)Ag successfully supplement (**Mn**)Li, the coupling of the cymantrenyl radicals with formation of bicymantrenyl being characteristic of the reactions involving them.[208, 211]

Treatment of (**Mn**)Li with copper(I) halides (in proportions of 1 : 2) in THF at −50 °C leads to the dissolution of CuHal with formation of solutions of cymantrenyl cuprates, $(Mn)_2CuLi$, etc. In contrast to (**Mn**)Li, these solutions are stable both at room and elevated temperatures, which makes it possible to use the compounds for the introduction of the cymantrenyl residue over a wide range of temperatures.[257]

The polymeric or oligomeric derivative $(Mn)_2AgCu$ has been obtained by treating CuI with (**Mn**)Ag.[216] Its structure has not been established, whilst its properties are similar to those of the monometallic derivatives. In particular, the reactions with iodobenzene and bromoferrocene lead to the formation of phenylcymantrene and cymantrenylferrocene respectively.[216]

The complex (**Mn**)$AuPPh_3$, in which one carbonyl group can be replaced photochemically by PPh_3 without dissociation of the C − Au bond, has been obtained by the reaction of (**Mn**)Li with $ClAuPPh_3$.[205] The reaction of (**Mn**)$AuPPh_3$ and its phosphine derivative with HBF_4 or $Ph_3PAu^+BF_4^-$ affords the complex salts $[(CO)_2LMnC_5H_4(AuPPh_3)_2]^+BF_4^-$.[258] Later the same salts were obtained by the reaction of $(Mn)_2Hg$ with $MeAuPPh_3$ in the presence of HBF_4.[259] The C − Au bond in the cymantrenyl derivatives of gold is readily cleaved by electrophiles.[205, 256]

The properties of the mercury derivatives of cymantrene — (**Mn**)HgX (X = Cl, Br, I) and $(Mn)_2Hg$ — were investigated in detail in the 1960s (see the relevant review[1]). The use of $(Mn)_2Hg$ in the synthesis of bicymantrenyl was examined above.[207] Treatment of CdI_2 with (**Mn**)Li gave rise to a mixture of (**Mn**)CdI and $(Mn)_2Cd$.[260] The 1,2-disubstituted cymantrenes $(CO)_3MnC_5H_3(HgR)CH_2NMe_2$ were obtained by metallating the amine (**Mn**)CH_2NMe_2 and treating its lithio-derivative with the mercury compounds RHgX, where R = $Mn(CO)_5$, $Re(CO)_5$, or phenylcarbaboranyl. Depending on the reactant ratio, treatment of $(CO)_3MnC_5H_3(Li)CH_2NMe_2$ with mercury halides HgX_2 (X = Cl, Br, I) led to the isolation of the mercurio-derivatives $(CO)_3MnC_5H_3(HgX)CH_2NMe_2$ (1 : 1) and $[(CO)_3MnC_5H_3CH_2NMe_2]_2Hg$ (2 : 1); the latter was characterised by X-ray diffraction.[261] A weak intramolecular coordination of mercury to the two nitrogen atoms of the dimethylamino-groups was observed in this complex.

The synthesis of cymantreneboronic acid and of its anhydride was first described as early as 1969.[262] The acid (**Mn**)$B(OH)_2$ was used to obtain the copper and silver derivatives of cymantrene.[208, 256] Its reactions with the copper salts $CuCl_2$ and $CuBr_2$ constitute a convenient method of synthesis of chloro- and bromo-cymantrenes (in yields greater than 85%).[209] The synthesis and reactions of ferrocenylcymantrenelboronic acid have been described.[217]

Cymantrenyl derivatives of the lanthanides (Yb, Sm, Eu) have been obtained by treating the iodides $LnI_2.nTHF$ or metallic lanthanide powders with (**Mn**)Li or $(Mn)_2Hg$.[263−266]

$$(Mn)_2Hg + YbI_2{\cdot}nTHF \longrightarrow (Mn)YbI_2{\cdot}nTHF + Hg,$$

$$(Mn)Li + YbI_2{\cdot}nTHF \longrightarrow (Mn)_2Yb{\cdot}nTHF + LiI,$$

$$(Mn)I + Ln \longrightarrow (Mn)LnI{\cdot}nTHF,$$

$$(Mn)_2Hg + Ln \longrightarrow (Mn)_2Ln{\cdot}nTHF.$$

Like (**Mn**)Li, the complex (**Mn**)YbI reacts readily with Me_3SiCl and Ph_3SnCl, forming compounds with the (**Mn**) − Si and (**Mn**) − Sn bonds.[266] Dicymantrenylthallium chloride $(Mn)_2TlCl$ was obtained by the reaction of (**Mn**)Li with $TlCl_3$ (THF, −50 °C). The same compound has been synthesised from $(Mn)_2Hg$ and $TlCl_3$ in ether or in $CHCl_3$ at 25 °C.[267]

The reactions of (**Mn**)Li with the corresponding halides have been used to synthesise compounds with the (**Mn**) − E bonds, where E is a Group IV element (Si, Ge, Sn, Pb). Cymantrenylsilanes (**Mn**)SiR_3, where SiR_3 = $SiPh_3$ [268] or SiRR′R″,[269, 270] have been obtained from chlorosilanes R_3SiCl. The reaction of (**Mn**)SiMePhCl with $LiC{\equiv}CFc$ afforded cymantrenylsilylacetylene (**Mn**)SiMePh − C ≡ CFc.[271] Reactions involving the hydrosilylation of the acetylenes RC ≡ CH (where R = $SiEt_3$, $SiPh_3$, Ph, Fc) with the silane (**Mn**)SiMePhH in the presence of the Speier catalyst based on H_2PtCl_6 proceed nonselectively and give rise to mixtures of products of two types,[272−275] which have been characterised by X-ray diffraction.[276, 277] Tricymantrenylsilane $(Mn)_3SiMe$ has been synthesised by the reaction of (**Mn**)Li with $MeSiCl_3$.[278] The addition of a solution of (**Mn**)Li to the silane Me_2SiHCl (THF, −80 °C) affords (**Mn**)$SiMe_2H$, but when the reactants were introduced in the reverse order, the disubstituted complex $(Mn)_2SiMe_2$ was obtained. The reactions of (**Mn**)$SiMe_2H$ with $Co_2(CO)_8$ or $Ir(CO)(PPh_3)_3H$ are accompanied by the cleavage of the Si − H bond and lead to the synthesis of complexes of the type (**Mn**)$SiMe_2-ML_n$, where ML_n = $Co(CO)_4$ or $Ir(CO)(PPh_3)_2H_2$.[279]

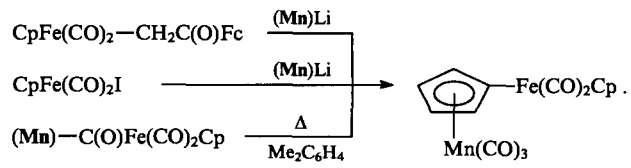
The reactions of (**Mn**)Li with the chlorides Ph_3ECl led to the formation of the corresponding compounds (**Mn**)EPh_3, where E = Ge, Sn, or Pb.[268] For E = Sn, treatment with HCl results in the simultaneous cleavage of the C − Sn σ-bond (yield of cymantrene approximately 10%) and the substitution of Ph by Cl with formation of (**Mn**)$SnPhCl_2$, which reacts with $NaMn(CO)_5$ to form the trinuclear complex (**Mn**)$SnPh[Mn(CO)_5]_2$.[268] The syntheses of cymantrenylstannanes $(Mn)_2SnR_2$, where R = Cl, Ph, or Fc,[280] and also of $(Mn)_4Sn$ [280] as well as a series of their derivatives[281] have been described. The structures of the chlorostannanes $(Mn)_2SnCl_2$ and $(Mn)_3SnCl$ have been characterised by X-ray diffraction.[282, 283]

The cymantrenylphosphonic acids (Mn)P(O)(OH)H [cymantrenylphosphonous acid? (translator)] and $(Mn)_2P(O)OH$ [cymantrenylphosphinic acid? (translator)] have been obtained by direct phosphorylation under the conditions of the Friedel–Crafts reaction between cymantrene and PCl_3,[100] while the reaction of cymantrene with $Et_2NPCl_2/AlCl_3$ gave rise to the phosphine $(Mn)_3P$.[284] The phosphine $(Mn)PPh_2$ has been synthesised by treating Ph_2PCl with the Grignard reagent (Mn)MgI (obtained from iodocymantrene and magnesium in the presence of 1,2-dibromoethane) and its quaternisation by reaction with $PhCH_2Br$ afforded the quaternary phosphonium salt $(Mn)P^+Ph_2CH_2Ph\ Br^-$. Its decomposition with alkali gives rise to cymantrene (92.3%) and toluene (6.3%), which indicates the high stability of the anion $(Mn)^-$.[285] The phosphines $(Mn)PPh_2$ and $(Mn)CH_2PPh_2$ have also been obtained with the aid of (Mn)Li.[95] The phosphine $(Mn)PPh_2$ is formed in the reaction of the phosphine sulfide $C_5H_5P(S)Ph_2$ with $Mn_2(CO)_{10}$.[286] Dichlorophosphine $(Mn)PCl_2$ and $(Mn)PR_2$, where R = OEt or NEt_2, have been synthesised by the reactions of (Mn)Li with PCl_3 or chlorophosphines.[287] The interaction of $(Mn)P(OEt)_2$ with 1,3-dichloroacetone leads[288] to the cymantrenylphosphonate $(Mn)P(O)(OEt)OC(CH_2Cl)=CH_2$. Treatment of (Mn)Li with $PhPCl_2$ afforded dicymantrenylphenylphosphine $(Mn)_2PPh$.[289] It has been shown that cymantrenylphosphines exhibit all the usual properties of tertiary phosphines, in particular, they are oxidised to phosphine oxides, combine with sulfur, and enter into the Staudinger, Perkow, and other reactions.[284–287] Metallation of $(Mn)PPh_2$ followed by the reaction with Ph_2PCl led to the formation of 1,3-bis(diphenylphosphino)cymantrene — the only compound containing two phosphine substituents in the Cp ligand.[93]

Compounds with (Mn)–As bonds have not been described. The reaction of $BiCl_3$ with (Mn)Ag affords $(Mn)_3Bi$,[256] which has, according to X-ray diffraction data, a trigonal-pyramidal structure.[290] $(Mn)_3Sb$ and $(Mn)_3Bi$ have been obtained by the reaction of (Mn)Li with $SbCl_3$ and $BiCl_3$. Their thermolysis at 330 °C leads to the formation of the following products: cymantrene, CO, a cyclopentadiene polymer, and metallic manganese and antimony for the antimony compound and metallic bismuth and bicymantrenyl for the bismuth compound.[291] The lithio-derivative (Mn)Li reacts with $PhBiCl_2$, whereupon the product is $(Mn)_2BiPh$, which reacts with $CuCl_2$ to form chlorocymantrene, chlorobenzene, bicymantrenyl, and biphenyl.[292]

The sulfonation reaction has been used to obtain compounds with (Mn)–S bonds. Sulfonation of methylcymantrene results in the formation of a mixture of the 1,2- and 1,3-isomers of methylcymantrenesulfonic acid. Sulfonyl chlorides and other derivatives have been synthesised from them by reaction with PCl_5 in accordance with the following scheme:[76,77,99]

$$(Mn)SO_3 \xrightarrow{PCl_5} (Mn)SO_2Cl \xrightarrow{Zn} (Mn)SH \xrightarrow{CH_2N_2} (Mn)SMe.$$



Acylation of the MeS derivatives gives rise to mixtures of ketones.[77,99] The synthesis of cymantrenes with MeS and PhS substituents has been described by Sunkel and coworkers,[39–42] while the preparation of the disulfides has been described in other communications.[43,76,100] Physiologically active derivatives of barbituric acid containing the $(Mn)SO_2CH_2$ fragments have been described.[293] The synthesis of the 1,2-disubstituted derivatives $(CO)_3MnC_5H_3(R)SO_2NMe_2$ was already mentioned above.[94]

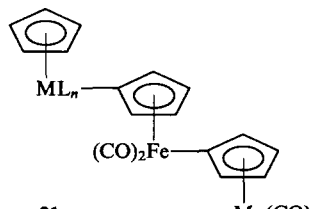
The interaction of $Mn(CO)_3(MeCN)_3^+$ with the ylides $C_5H_5ER_3$ leads to the formation of new cationic complexes $(CO)_3MnC_5H_4-ER_n^+\ X^-$, where ER_n = PPh_3 or SMe_2.[294] The complex with the SMe_2 group was characterised by X-ray diffraction.[295] The interaction of (Mn)Li and also of its Re analogue with free chalcogens affords the relatively unstable intermediates (Mn)ELi as a result of the insertion of the chalcogen in the C–Li bond. On oxidation with atmospheric oxygen, the intermediates are converted into dimetallo-dichalcogenides with the general formula (M)–E–E–(M) [here (M) = $(CO)_3MnC_5H_4$ or $(CO)_3ReC_5H_4$ with E = S, Se, or Te]. The reactions of 2 equiv. of (M)Li with SCl_2, $SeCl_4$, or $TeCl_4$ led to the formation of complexes having the general formula (M)–E–(M).[289]

2. Compounds with transition metals

The reaction of (Mn)Li with Cp_2TiCl_2 affords the complex $Cp_2Ti(Mn)_2$ in which the titanium atom has a tetrahedral environment according to X-ray diffraction data.[296]

A series of studies by Nesmeyanov and coworkers[297–331] on the synthesis and the chemistry of complexes of the type (Mn)–ML_n, where M = Mo, W, Mn, Re, Fe, or Ni, were published in 1974–1984. The properties of the complex (Mn)–$Fe(CO)_2Cp$ **30** were investigated most fully. It is formed either on treatment of $CpFe(CO)_2I$ or $CpFe(CO)_2-CH_2C(O)Fc$ with (Mn)Li [297] or on thermal decarbonylation of $(Mn)C(O)Fe(CO)_2Cp$.[231]

30



The analogous complexes (Mn)–ML_n, where ML_n = $Mo(CO)_3Cp$, $W(CO)_3Cp$,[232–234] $Mn(CO)_5$, or $Re(CO)_5$,[235] are also formed on thermal decarbonylation in accordance with the mechanism

$$(Mn)-C(O)ML_n \longrightarrow (Mn)-ML_n + CO.$$

The complex (Mn)–$Ni(PPh)_3Cp$ with the (Mn)–Ni bond is formed in the reaction of (Mn)Li with $CpNi(PPh_3)Cl$ or with nickelocene.[298] The ready cleavage of the C_5H_4-M bonds by electrophiles [acids, mercury salts, iodine, MeC(O)Cl, etc.] with formation of cymantrene, mercury halides, (Mn)HgX, and iodocymantrene respectively, is characteristic of all compounds of the type (Mn)–ML_n.[235,298] Under the conditions of the thermal or photochemical reaction, there is a possibility of the substitution of CO by PPh_3 at the Fe, Mo, and W atoms[231–234] or of CO at the Mn atom by PPh_3 and tolane in the complex (Mn)–$Ni(PPh_3)Cp$.[299] Thermal decarbonylation has also been used to synthesise the complex $(CO)_2PPh_3MnC_5H_4-Fe(CO)_2Cp$,[300] in which the CO group at the Fe atom is substituted by PPh_3 on UV irradiation.[301] The structure of the complexes (Mn)–Fe(CO)(L)Cp, where L = CO or PPh_3, has been established by X-ray diffraction.[302]

The chemistry of complex **30** and its derivatives has been studied in greater detail. The C–Fe bond is readily cleaved on treatment with I_2 in CH_3Cl or with $MeCO^+BF_4^-$, but it proved resistant to the action of $HgCl_2$ in benzene.[303] Under the conditions of the mercuration of cymantrene, complex **30** reacts with mercury acetate and mercuration takes place in the C_5H_4 ring at the Mn atom. After treatment with $CaCl_2$, the chloromercurio-derivative was obtained, forming readily a symmetrical compound.[304] It was found that the C–H bonds in the Cp ring attached to the Fe atom exhibit a high CH acidity and are capable of participating in the protophilic substitution reaction. Complex **30** enters into hydrogen isotope exchange with EtOD–EtONa (benzene, 100 °C) and is metallated on treatment with BuLi.[305] Carboxylation of the Li derivative of complex **30** affords the acid (Mn)–$Fe(CO)_2C_5H_4COOH$ (pK_a = 5.09 in 50% EtOH), which is three–four times stronger than benzoic acid (pK_a = 5.7 under the same conditions).[305] The capacity of complex **30** to be metallated made it possible to obtain a series of polynuclear complexes based on it. The trinuclear complexes **31**, where ML_n = $Fe(CO)_2$,[306] $Mo(CO)_3$, and $W(CO)_3$,[307] have been synthesised by the reaction of the lithio-derivative with the

organometallic halides $CpFe(CO)_2I$, $CpMo(CO)_3Cl$, or $CpW(CO)_3Cl$.

31

Compounds containing a sequence of metals, Fe–Fe–Mn and Mo–Fe–Mn, have been characterised by X-ray diffraction.[306, 307] Treatment of complex **30** with BuLi and then with C_3F_7I led to the formation of the iodo-derivative **(Mn)**–$Fe(CO)_2C_5H_4I$, which on reaction with the lithio-derivative **(Mn)**–$Fe(CO)_2C_5H_4Li$ affords the analogous tetranuclear complex of the 'ladder' type with the Mn–Fe–Fe–Mn metal sequence.[308] The synthesis of the tetranuclear complex with the sequence Fe–Fe–Fe–Mn, characterised by X-ray diffraction, has been described.[309]

The thermolysis of the complexes **(Mn)**–$M(CO)_3Cp$, where M = Mo [234] or W,[310] results in the formation of complex mixtures of dinuclear and trinuclear complexes containing the products of the migration of the **(Mn)** fragments to the Cp rings attached to Mo and of the $(CO)_3WC_5H_4$ fragment to the Cp ring at Mn. The interaction of **(Mn)**–$Ni(PPh_3)Cp$ with *p*-isocyanotoluene leads to the dissociation of the Ni–C bond.[311]

In the reaction of **(Mn)**Li with *cis*-L_2PtCl_2 at −50 °C, one Cl atom is readily substituted with formation of the complex **(Mn)**–PtL_2Cl (L = PPh_3).[312] The mercury halides **(Mn)**HgX readily react with the zerovalent platinum complex PtL_3 with insertion of the carbenoid fragment PtL_2 in the Hg–Cl or Hg–Br bonds.[313, 314] The structure of the reaction products depends on the conditions: at −20 °C in toluene, compounds with a Pt–Hg bond of the type **(Mn)**–Hg–PtL_2Cl are formed, readily splitting off mercury on heating to 20 °C and forming the complexes **(Mn)**–PtL_2Cl. The two PPh_3 ligands at the mercury atom are readily substituted by the chelating diphosphine $Ph_2PCH_2CH_2PPh_2$. Photolysis of platinum–mercury complexes involves protodemercuration with liberation of mercury and the formation of cymantrene.[314] Dicymantrenylmercury $(Mn)_2Hg$ readily reacts with PtL_3 at −20 °C, forming the compound **(Mn)**–Hg–PtL_2–**(Mn)**, which on heating to 20 °C is converted, as a result of the elimination of mercury, into the complex $(Mn)_2PtL_2$, where the Pt atom is linked simultaneously to two cymantrene residues.[315]

VII. Cymantrene as an organometallic Lewis base

Low-valence transition metal complexes constitute a new class of organometallic Lewis bases. Their basicity is associated with the presence in the metal of fully or partially occupied *d* orbitals,[316–318] which is characteristic mainly of complexes of Group V–VIII metals with the configuration d^6–d^9. Organometallic bases have several potential basicity centres. Depending on the structure of the complex, the ligand environment of the metal, and the nature of the electrophile and the solvent, the attack by the electrophile can be directed to one or several centres. Cymantrene and its phosphine derivatives exhibit all the properties of Lewis bases: they are capable of combining with a proton, aprotic acids, the halogens, etc.

1. Reactions with protic acids

It has been shown by IR and ^1H, ^{13}C, and ^{31}P NMR spectroscopic methods that cymantrene, pentaethylcymantrene, and mono- and di-phosphine derivatives of cymantrene are protonated at the manganese atom on treatment with protic acids.[319–324] Unsubstituted cymantrene is a very weak base: protonation of the metal takes place only in the presence of the strong acid HSO_3F in CH_2Cl_2 at low temperatures. Even at −100 °C, the exchange between the proton in Mn–H and the medium is rapid on the NMR time scale. Pentaethylcymantrene, in which the basicity of the metal is appreciably higher owing to the electron-donating effect of the five ethyl substituents, is wholly protonated under the same conditions with formation of the Mn–H bond. At −105 °C, there is a slow exchange of the proton in Mn–H with the medium.[324] On substitution of one and especially two CO groups by phosphine ligands, the basicity of the metal increases greatly: the mono- and di-phosphine complexes are capable of being protonated at the Mn atom even in the presence of CF_3COOH.[321–325] The proton affinity of $MeC_5H_4Mn(CO)_3$ was determined as 203 kcal mol^{-1} in a study of the gas-phase protonation.[326]

A new type of hydrogen bond in the η-complexes of transition metals has been discovered in cymantrene and benchrotrene derivatives. In a study of the interaction of cymantrene and its phosphine derivatives with weaker proton donors such as $(CF_3)_3COH$ and anhydrous HCl (in solution in liquid xenon at 160–240 K and also in CCl_4 at 293 K), it was possible to detect the formation of hydrogen bonds with the oxygen of the CO ligand. The formation of such bonds is accompanied by a shift of the ν(CO) frequencies and also of the ν(OH) frequency of the proton donor. The frequency shifts $\Delta\nu$(OH) depend greatly on the basicity of the metal and on the number of phosphine ligands, ranging from ~75 cm^{-1} for cymantrene to 240 cm^{-1} and more for the diphosphine complexes. There is a possibility of hydrogen bond formation with both one and two CO groups simultaneously.[327–330]

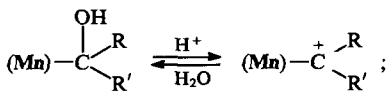
The formation of intramolecular and intermolecular hydrogen bonds as well as the preferred conformations in carbinols containing one **(Mn)** fragment, having the general formula **(Mn)**C(OH)RR', and also in their rhenium analogues have been investigated by IR spectroscopic and molecular mechanics methods.[331]

2. Reactions with aprotic acids

Cymantrene and its phosphine derivatives react as bases not only with a proton but also with aprotic acids — their Hg, Al, Ga, and Sn salts. Unsubstituted cymantrene does not react with $HgCl_2$, while in the case of mercury acetate or trifluoroacetate the final result of the reaction is mercuration with substitution of one or all five hydrogen atoms.[101] It may be that the initial attack by Hg is directed to the metal atom with subsequent migration to the Cp ring. Cymantrene does not react with $SnCl_4$, but pentaethylcymantrene affords an adduct via the Mn atom even on reaction with $SnCl_4$.

Coordination to the oxygen atoms of the CO groups occurs only on interaction of unsubstituted cymantrene with $AlCl_3$ or $AlBr_3$ in benzene.[332, 333] The site of attack by AlX_3 (the centre in the cymantrene molecule with the highest basicity) depends on the nature of the solvent. On passing from the nonpolar C_6H_6 to the polar CH_2Cl_2 or $ClCH_2CH_2Cl$, the site of attack changes: in benzene, AlX_3 affords adducts via the oxygen atoms of the CO groups, while in polar solvents the adducts are formed via the metal atom.[333] The site of attack and of the addition of AlX_3 follows unambiguously from the direction and magnitude of the ν(CO) frequency shifts in the IR spectra. The mono- and di-phosphine complexes react with AlX_3 and $GaCl_3$ only via the Mn atom.

The energetics of the interaction of cymantrene and pentaethylcymantrene with $AlBr_3$ has been studied by calorimetric titration:[334, 335] the enthalpy of formation of the adduct ($-\Delta H$) via oxygen, i.e. $Cp(CO)_2MnCO \cdots AlBr_3$, is 18.9 kcal mol^{-1}, while that of the adduct $(Et_5C_5)(CO)_3Mn \cdots AlBr_3$, formed as a result of coordination to the metal atom, is 22.0 kcal mol^{-1}.



The halogens Cl_2 and Br_2 cleave cymantrene at 20 °C with dissociation of the Mn–ring bond.[1] However, on treatment of cymantrene in solution in CH_2Cl_2 at −50 °C with 1 equiv. of the

halogen in CCl_4, the latter adds to the metal with formation of the ionic complex $[CpMn(CO)_3Cl]^+Cl^-$ or $[CpMn(CO)_3Br]^+Br_3^-$.[336]

Thus the centre with the highest basicity in the cymantrene molecule may be either the Mn atom (H^+, halogens) or the oxygen atom of the CO group (only $AlCl_3$ and $AlBr_3$ in benzene) depending on the type of reagent. On passing to azacymantrene $(\eta^5\text{-}C_4H_4N)Mn(CO)_3$, the situation changes sharply: in this case, the attack by aprotic acids is directed to the nitrogen atom.[337]

VIII. Stabilisation by the cymantrenyl group of the neighbouring cationic and radical centres

Treatment of carbinols of the cymantrene series with acids (for example, with CF_3COOH) leads to the formation, as a result of the elimination of water, of very stable carbonium ions, which are stabilised by 1–3 (**Mn**) residues.[338–343]

R, R′ = H, Me, Et, Ph, Fc.

Treatment of the carbinol $(\mathbf{Mn})_3COH$ with acid afforded the tricymantrenyl carbenium cation $(\mathbf{Mn})_3C^+$, while the corresponding phosphine-containing carbonium ions, the stability of which is appreciably increased by the electron-donating phosphine ligands, were obtained from carbinols containing one or two phosphine ligands.[244] The conversion of the cymantrene carbinols into carbonium ions is accompanied by an increase in the frequency ν(CO) and a displacement of all the signals in the ^1H and ^{13}C NMR spectra, which is associated with the marked delocalisation of the positive charge with participation of the Cp ring and the metal carbonyl fragment. The kinetic stability of the carbonium ions with cymantrene residues has been characterised by measuring the rates of solvolysis of the acetates.[344] Treatment of the carbonium ions with HBF_4 led to the isolation of solid cymantrenylcarbenium tetrafluoroborate salts.[345] The ease of the reactions involving the ionic hydrogenation of cymantrenyl ketones is associated with the high stability of the cymantrenylcarbenium ions and the ability of the cymantrenyl group to stabilise greatly the neighbouring cationic centre.[346] The electrochemical properties of cymantrenylcarbenium salts have been investigated.[347]

In connection with the ability of the cymantrenyl group to stabilise effectively the neigbouring cationic centre mentioned above, it is of interest to estimate the electronic effects of the cymantrenyl group as a substituent. The inductive (σ_I) and resonance (σ_R) components of the overall electronic influence, amounting to 0.172 and −0.02 according to Gubin et al.[348] and 0.141 and −0.024 according to Bitterwolf,[26] have been estimated by the ^{19}F NMR method for the *meta*- and *para*-substituted fluorophenylcymantrenes. The cymantrenyl group is a weak acceptor in terms of its inductive influence and a weak donor in terms of the conjugation mechanism. On substitution of CO by phosphines, its electron-accepting properties are weakened, while its electron-donating properties are enhanced.[26]

The cymantrenyl group can also stabilise the neighbouring radical centre. The reduction with sodium of benzoylcymantrene[349] or dinuclear ketones[66] of the type $(CO)_3MnC_5H_3R-C(O)-C_6H_5RCr(CO)_3$ results in the formation of the corresponding radical-anions (ketyls), in which the radical centre is stabilised by a cymantrenyl, phenyl, or benchrotrenyl substituent. Their structure and th delocalisation of the unpaired electron have been investigated by the EPR method.

In describing the properties of compounds with the (**Mn**)–P bond above (see Section VI), it was noted that the alkaline decomposition of the phosphonium salt $(\mathbf{Mn})P^+Ph_2CH_2PhBr^-$ results in the formation of mainly cymantrene and of an insignificant amount of toluene. This led to the conclusion that the cymantrenyl group is capable of stabilising effectively the neighbouring anionic centre.[285]

* * *

In conclusion, we shall consider several studies which were published during the preparation of the manuscript for printing. The complex $(\eta^5\text{-}PhN{=}NC_5H_4)Mn(CO)_3$ has been obtained in 45% yield from the lithium salt of the phenylazocyclopentadienyl anion by reaction with $Mn(CO)_3(CH_3CN)_2Br$.[350] The preparation of new substituted cyclopentadienylthallium derivatives and the syntheses based on them have been described. The anion of $MeC_5H_4^-Na^+$ reacts with ethyl acetate to form a mixture of 1-acetyl-2-methyl- and 1-acetyl-3-methyl-cyclopentadienyl anions (in proportions of 1 : 1), which on treatment with EtOTl are converted into a mixture of the corresponding thallium derivatives. The latter were separated by recrystallisation from ethanol. The planarly chiral complex 1-acetyl-2-methylcymantrene has been obtained by the reaction of the 1,2-derivative with $Mn(CO)_5Br$.[351] Benzoylcyclopentadienylsodium has been obtained from the anion in Cp^-Na^+ by reaction with ethyl benzoate. On treatment with EtOTl, it gives rise to $TlC_5H_4C(O)Ph$. On reaction with $Mn(CO)_5Br$, the latter affords benzoylcymantrene.[352] Dinuclear complexes having the general formula (**Mn**)–X–(**Mn**), where X = S or $SiPh_2$, have been obtained by the reactions of cymantrenyllithium with SCl_2 and Ph_2SiCl_2. The reduction of 1-acetyl-2-methylcymantrene by $LiAlH_4/TiCl_3$ leads to mixtures of diastereoisomeric complexes of the type $(CO)_3MnC_5H_3Me-C_5H_3MeMn(CO)_3$. Under mild conditions, the products are the pinacols [X = C(OH)Me–C(OH)Me], which are converted into the olefins [X = C(Me)=C(Me)] under more severe conditions as a result of dehydration. The reduction of acetylcymantrene by the $KC_8/TiCl_3$ system results in the formation of a mixture of the analogous dinuclear olefins.[353] Further development of the study by Herberhold and Biersack[289] demonstrated that the lithio-derivatives of cymantrene and $C_5H_5Re(CO)_3$ readily react with the chalcogens, affording (**Mn**)ELi (E = S, Se, Te) and their rhenium analogues. These lithio-derivatives are protonated with formation of the chalcogenols (**Mn**)EH, which are readily oxidised to the disulfides; the reactions of (**Mn**)ELi with CH_2I_2, PhC(O)Cl, and other acid chlorides have been investigated.[354] The interaction of cymantrenyllithium with *C*-carbaboranyl derivatives of mercury or *B*-carbaboranyl derivatives of thallium leads to the synthesis of new dinuclear complexes with (**Mn**)–Hg and (**Mn**)–Tl bonds.[355] The reaction of $(CO)_3MnC_5Cl_4Li$ with the halide $Mn(CO)_5Br$ or $Au(PPh_3)Cl$ affords the complexes $(CO)_3MnC_5Cl_4X$, where X = $Mn(CO)_5$ or $AuPPh_3$.[356]

III. Oligosaccharins as regulators of plant growth and morphogenesis	1061
IV. Interaction of plants with bacterial symbionts	1067
V. Conclusion	1068

Abstract. The review deals with oligosaccharins — biologically active oligosaccharides of the following structural types: the (1 → 6, 1 → 3)-β-D-glucan fragments of the fungal cell wall; the chitin and chitosan fragments; polygalacturonic acid fragments; the xyloglucan fragments of the plant cell wall; lipooligosaccharides synthesised by bacteria — symbionts of leguminous plants. The isolation, determination of the structure, and total syntheses of these complex compounds as well as the results of the study of their biological role as inductors of the immunity of plants to attack by pathogenic fungi and bacteria and as regulators of the morphogenesis in the development processes in plants and of the interaction of the latter with symbiont bacteria are described. The bibliography includes 197 references.

I. Introduction

Biologically active oligosaccharides, fulfilling signalling functions in plants, were discovered about 15 years ago.[1] Several years later, it was suggested that these oligosaccharide bio-regulators be called 'oligosaccharins', the suffix of which was chosen by analogy with the names of the most important phytohormones — auxins, gibberellins, and cytokinins.[2] Oligosaccharins are formed as a result of the partial cleavage of carbohydrate-containing biopolymers of the cell walls of plants or phytopathogenic fungi, act at extremely low concentrations, and participate in biological processes of the greatest importance for plants such as protection against attack by pathogenic fungi or bacteria, regulation of growth and morphogenesis, and interaction with bacterial symbionts.[3] The number of studies devoted to oligosaccharins has been growing at an increasing rate. The interest in these substances is associated not only with the possibility of investigating with the aid of oligosaccharins the detailed mechanisms of intercellular interaction and the regulation of plant metabolism but also with the very attractive prospect of the practical employment of this new class of regulators in the biotechnology of plants in agriculture.[4]

The low availability of oligosaccharins required considerable efforts on the part of carbohydrate chemists to improve the methodological procedures used in the isolation and the determination of the structure of oligosaccharins and the development of new effective approaches to the synthesis of these complex oligosaccharides. Without exaggerating, one may say that the high current level of the analytical and synthetic research in the field of complex oligomeric carbohydrates is in many respects determined by the brilliant studies on the chemistry of oligosaccharins.

There exist in the literature several excellent reviews devoted principally to the biological properties of oligosaccharins,[5–10] but there are no reviews on the chemical synthesis of these substances. There exists only one review in Russian,[11] the authors of which are the founders of this field — Albersheim and Darvill at the Complex Carbohydrate Research Center (Athens, Georgia, USA); it is devoted to the problems and advances in the early stages of the studies on oligosaccharins. The aim of the present review is to give an account of the present state of research into oligosaccharins not so much from the standpoint of the plant physiology as from the standpoint of carbohydrate chemistry in order to draw the attention of Russian investigators to this extremely interesting and practically important problem.

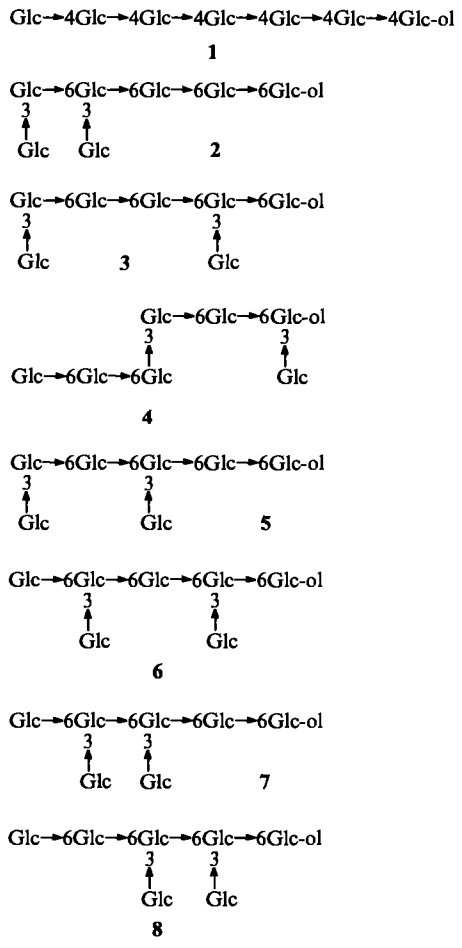
II. Oligosaccharins in the reactions of plants with phytopathogenic fungi and bacteria

1. The oligosaccharide fragment of the fungal cell wall β-glucan

One of the most thoroughly investigated mechanisms of the self-protection of plants against fungal infection is that of the formation of phytoalexins,[12–14] which serve as a kind of plant antibiotic. As a rule, they are hydrophobic, have low molecular masses, and are toxic to a wide range of microorganisms. Several hundreds of phytoalexins have already been isolated from plants. From the chemical standpoint, they belong to different classes of secondary metabolites — flavonoids, terpenoids, polyunsaturated compounds, etc.[15] It is essential to emphasise that there are virtually no phytoalexins in a healthy plant and their appearance in the infected plant is a response to a fully defined signal. Such signals are called elicitors of phytoalexins and they can be of abiotic or biotic origin. Abiotic factors frequently damage the plant cell wall, while biological elicitors are either enzymes which hydrolyse the cell wall biopolymers or fragments of these biopolymers; sometimes the nature of these substances is that of lipids. The accumulation of phytoalexins in plants is a result of the *de novo* formation of enzymes ensuring their synthesis and of RNA coding for these enzymes. Thus the phytoalexin elicitors regulate the metabolism at the level of the

A I Usov Laboratory of Plant Polysaccharides, N D Zelinskii Institute of Organic Chemistry, Russian Academy of Sciences, Leninskii prosp. 47, 117913 Moscow, Fax (7-095)135 53 28; Tel. (7-095) 137 67 91.

Received 7 June 1993
Uspekhi Khimii **62** (11) 1119–1144 (1993); translated by A K Grzybowski

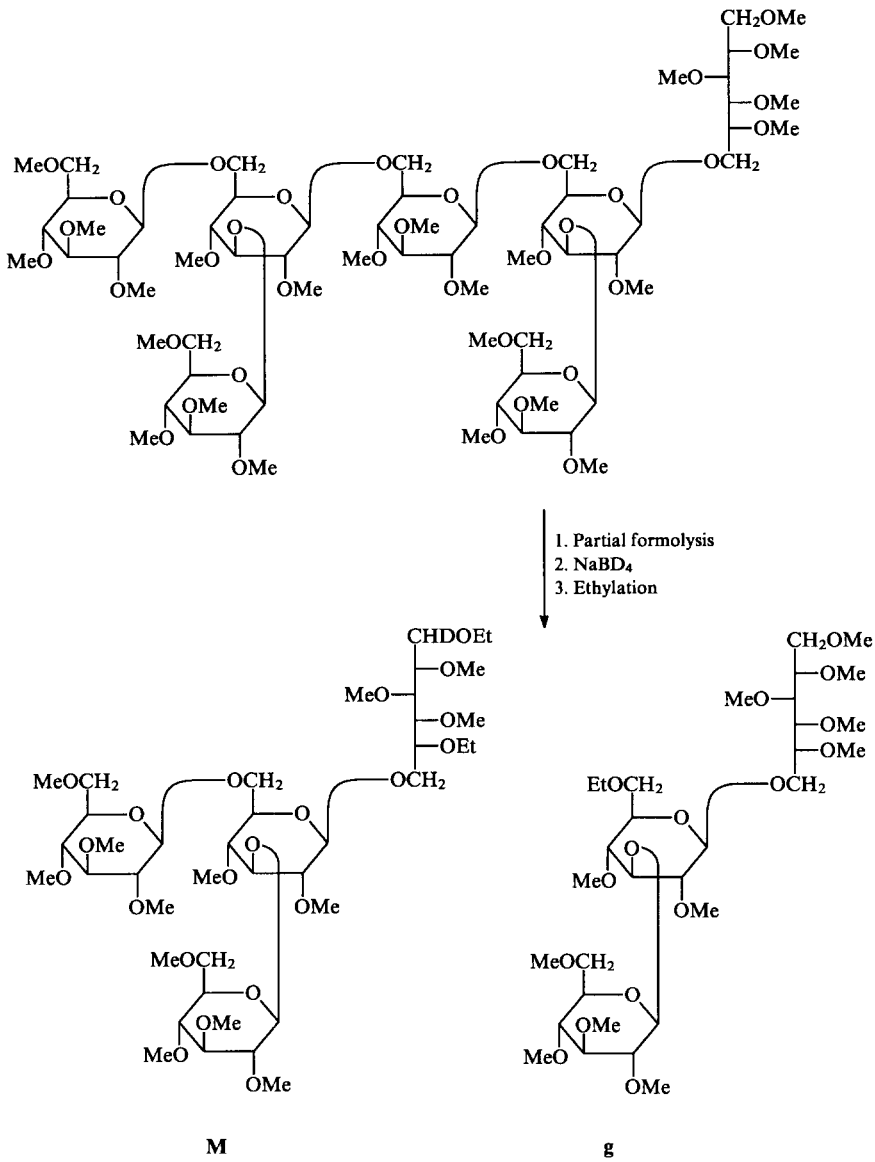


transcription of DNA. For many phytoalexins, there exist sensitive specific detection and quantitative determination methods, so that the elicitor—phytoalexin system can serve as an extremely reliable criterion for the estimation of the elicitor activity of a wide variety of chemical compounds.

The first oligosaccharin was discovered in the study of the responses of plants to attack by phytopathogenic fungi. When soya bean is infected by the pathogenic fungus *Phytophthora megasperma f. sp. glycinea*, the plant begins to produce phytoalexins (glyceollin and glycinol), which are derivatives of pterocarpan, the cell walls of the fungus, consisting mainly of carbohydrates, exhibiting a powerful elicitor activity.[16] The main component of these cell walls is a β-glucan, a sparingly soluble high-molecular-mass polysaccharide, having a branched structure with 1→6 and 1→3 bonds between β-D-glucopyranose residues.[17,18] In order to isolate a specific chemical substance, produced as a result of the elicitor activity, the fungal cell walls were subjected to partial acid hydrolysis, which led to the dissolution of ~50% of the initial material.[19] A mixture of oligosaccharides with degrees of polymerisation of 5–9, in which an appreciable elicitor activity persisted, was obtained with the aid of low-resolution gel chromatography of the hydrolysate in P-2 biogel. The testing technique involved the spectrophotometric determination of carbohydrates by reaction with anthrone, while that of pterocarpan derivatives—based on their intrinsic absorption at 285 nm[20]—enabled the authors to determine the content and activity of the elicitors in all the chromatographic fractions. Next the mixture was separated in terms of degree of polymerisation with the aid of high performance liquid chromatography (HPLC) on P-2 biogel and the heptasaccharide fraction was reduced with sodium tetrahydroborate to polyols (this did not affect the biological activity but facilitated significantly the subsequent separation) and was again separated with the aid of HPLC on a Whatman PAC column. Unfortunately such treatment led to the irreversible loss of about 50% of the oligosaccharides. The active fraction was then separated by reversed-phase chromatography on a Supelco Spherisorb ODS column, eluting with water, which again led to the loss of half the material but made it possible to concentrate the activity in a single peak. The final separation of the components of this peak on an Altex Ultrasphere ODS column (elution with a 2% solution of acetonitrile in water) made it possible to obtain seven components, six of which represented individual reduced heptasaccharides, while the seventh was shown by subsequent studies to be a mixture of such compounds. Only compound **6** (Scheme 1) exhibited elicitor activity.

Thus, in the course of the isolation of the elicitor **6**, the authors[19] were able to solve a problem of truly unique complexity: the only active oligosaccharide was isolated from a mixture of hundreds of closely related compounds. Although the authors of the above investigation had an unlimited supply of the initial cell wall material, the immensely laborious isolation procedure provided the final heptasaccharides in amounts of the order of 50 μg only. In order to establish the structures of these substances, it was necessary to develop a special strategy and methods for structural analysis (see, for example, Darvill and coworkers[21,22]), which made it possible to limit the requirements for the test substances to very small amounts.

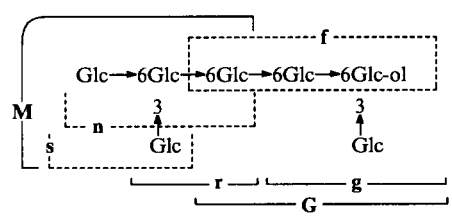
The degree of polymerisation of both unsubstituted and methylated oligosaccharides was determined by mass spectrometry (MS) with bombardment by fast atoms. The monosaccharide composition (and at the same time the absolute configuration) was analysed with the aid of the GLC of the trimethylsilyl derivatives of (+)-2-butylglycosides of the hydrolysate[23] (only D-glucose and sorbitol were found in all cases). The pyranose forms of the monosaccharide residues and the β-configurations of all the glycosidic centres were demonstrated with the aid of ^{1}H NMR spectra of the methylated oligosaccharides. Despite the extremely small amounts of the



Scheme 1

test compounds, it was possible to obtain clear signals due to the anomeric protons and to make sure that the spectral range 5.0–5.5 ppm, in which the signals of the H(1) protons of the α-glucopyranose residues are observed, is unoccupied; furthermore, the H(1) signals observed in the spectrum had spin–spin coupling constants (SSCC) greater than 7.2 Hz, which is characteristic of *trans*-diaxial protons. A four-proton signal at 4.37 ppm, assigned to the anomeric protons of the glucose residues attached to O(6), and a two-proton signal at 4.73 ppm, characteristic of the anomeric protons of the residues bound to O(3) in a neighbouring unit, were observed in the spectra of the methylated compounds **2**–**8**. These signals were assigned by analogy with the methylated gentiobioside and laminaribioside respectively.[24]

The most complex problem, namely the elucidation of the disposition of the intermonomer bonds and the sequence of monosaccharide residues in the oligosaccharides, was solved by means of a mass-spectrometric study of the methylation products. The methylation stage itself was carried out by Hakamori's method modified for microamounts of the test substance,[21,22] while the methylated oligosaccharides were isolated from the reaction mixture with the aid of Sep-Pak C-18 cartridges.[25] The analysis of the derivatives obtained included partial formolysis, the reduction of the formolysis products with $NaBD_4$, ethylation of the reduced fragments at the liberated hydroxy-groups, and the determination of their structure with the aid of GLC-MS. As a result of the application of the method of derivative formation based on the incorporation of a deuterium atom, it was possible to distinguish all the fragments the reducing properties of which are due to elimination from the initial molecule on formolysis; the hydroxyls liberated in this process were marked by ethyl groups (Scheme 2).[26]

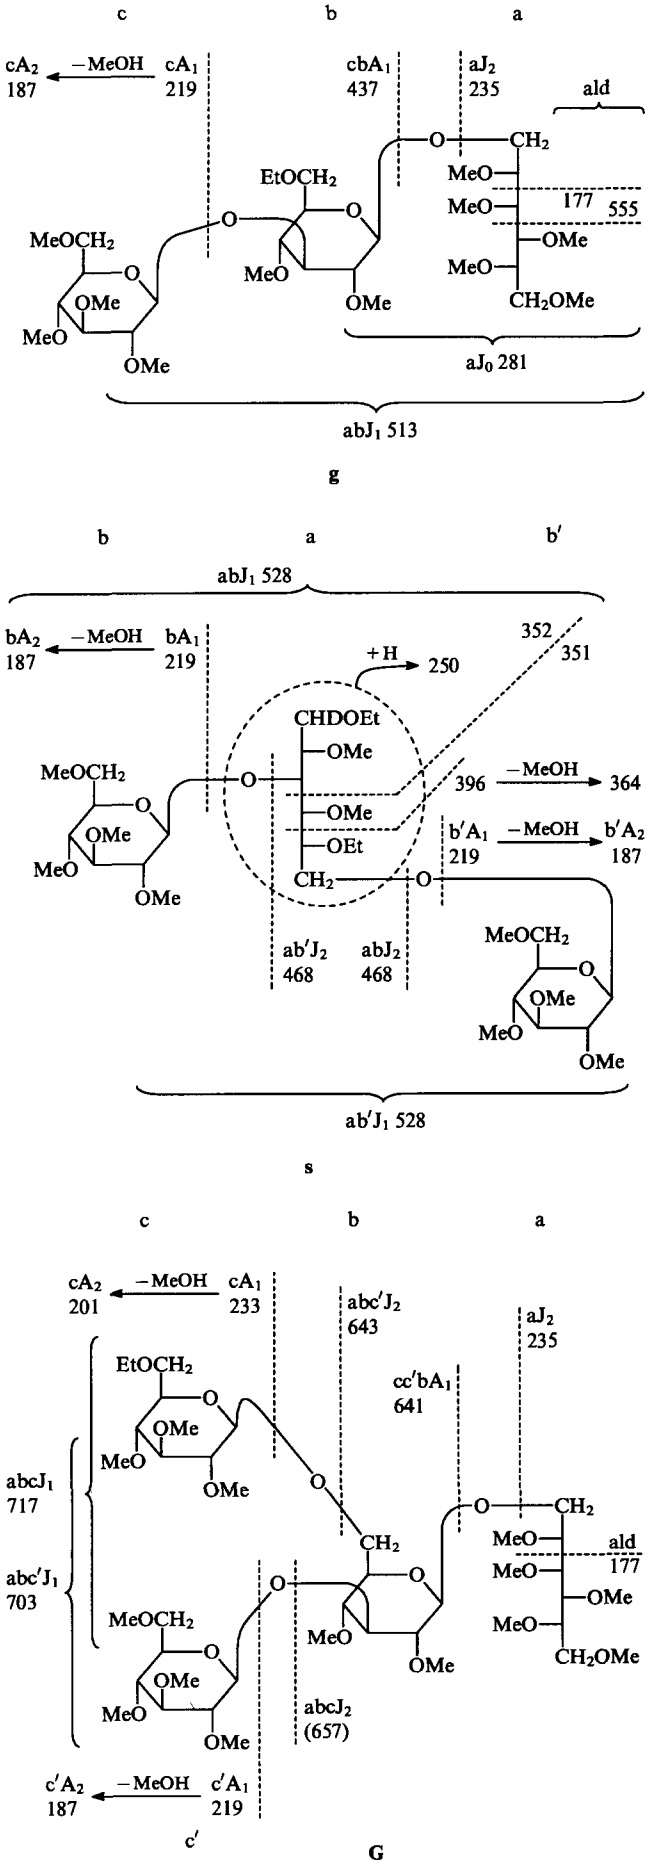


Scheme 2

M g

Naturally partial formolyis results in the formation, apart from the fragments **M** and **g** indicated in Scheme 2, also of many other substances. Overall, in the case of the oligosaccharide **6**, for example, trisaccharide (**f**, **g**, **n**, **r**, and **s**) and tetrasaccharide (**G** and **M**) cleavage products, shown in Scheme 3, were identified.

Scheme 3



Analogous fragments are formed also from other methylated heptasaccharides. They can all be divided into three structural types: linear oligosaccharides, fragments branched at the polyol group, and substances with a branch at an inner glucose residue. The structures of the entire set of fragments, characteristic of each oligosaccharide, can be established with the aid of GLC-MS. Scheme 4 (see over) presents the most probable paths leading to the mass-spectrometric fragmentation and the diagnostic ions for representatives of each of the three structural types mentioned above (**g**, **s**, and **G**). The diagnostic ions in the mass spectrum belong to the A, J, and ald series. The nomenclature used for the fragments is the same as in the communication of Chizhov and Kochetkov[27] and in Aspinall's book.[28]

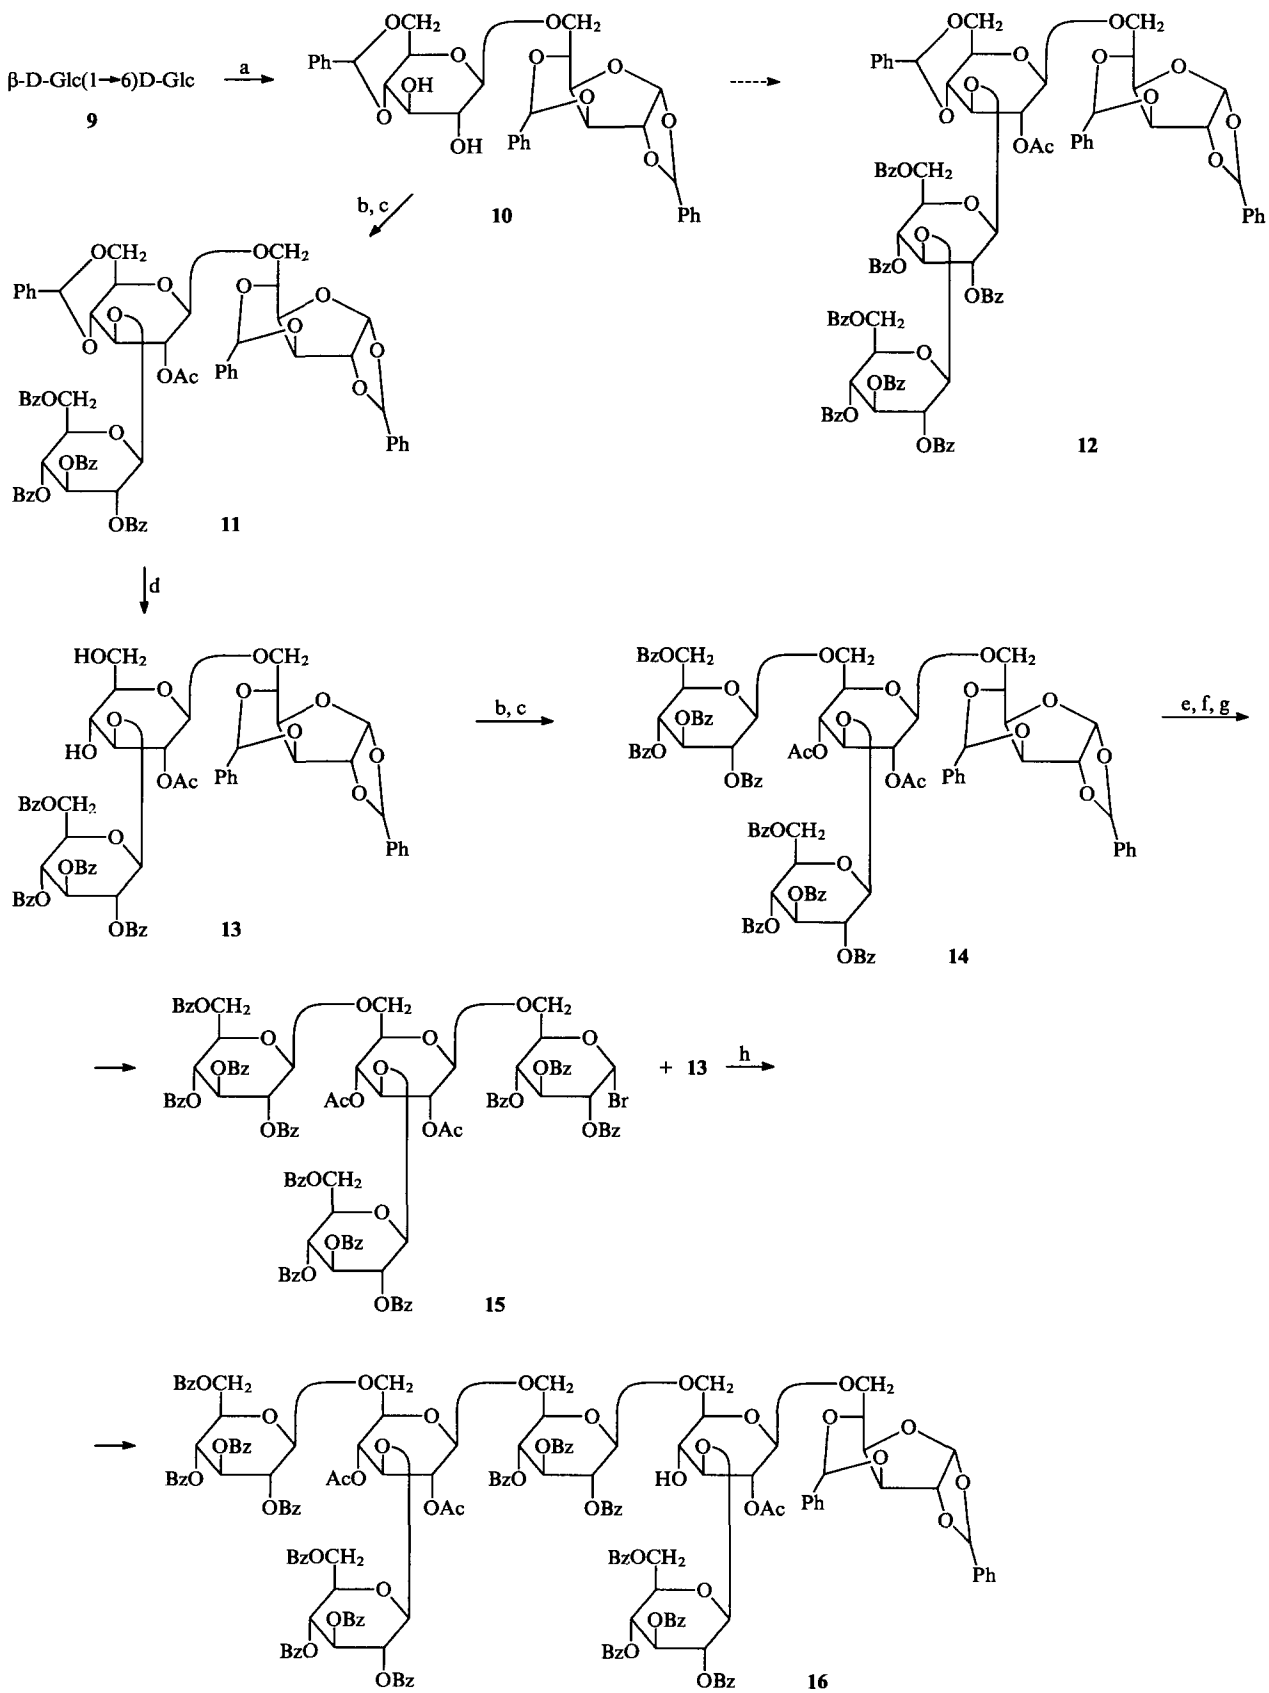
By applying the methods listed above in succession to the compounds isolated, Sharp et al.[26] were able to establish for them the structures shown in Scheme 1 (compounds **3** and **4** were not separated and their structures were determined by analysing the mixture).

The first of the heptasaccharides isolated is a fragment of the cellulose molecule and therefore differs by its origin from all the other heptasaccharides which are fragments of the β-glucan molecules in the fungal cell wall. Despite the evident similarity between the structures of these heptasaccharides, it was found that only one of them exhibits an elicitor activity and that this activity is observed clearly when 1 pmol of compound **6** per millilitre of the plant tissue is used (the highest of the known elicitor activities) and does not change in the presence of a twentyfold excess of the isomeric oligosaccharides. This surprising result demonstrated for the first time that the signalling molecules, in response to the appearance of which the protecting systems of the host plant are mobilised following attack by pathogenic fungi, may consist of purely carbohydrate fragments of the biopolymers in the fungal cell wall, while the

Scheme 4

system receiving the signal is capable of distinguishing clearly even between oligosaccharides which are structurally very similar.

The method of preparation of the heptasaccharide **6** from a natural source entailed, in principle, the possibility that the carrier of biological activity is some other substance, the chromatographic properties of which are only fortuitously identical with those of the heptasaccharide. In order to rule out this hypothesis, an unambiguous synthesis[29] of the heptasaccharide fragment of the fungal β-glucan was undertaken. Its successful completion coincided with the final determination of the structure of the natural product **6**.[26] Communications concerning the isolation,[19] determination of the structure,[26] and the synthesis[29] of this oligosaccharin and the comparative study of the biological activities of the natural and synthetic oligosaccharins[30] were published simultaneously in 1984.



An elegant and extremely rational scheme (Scheme 5) has been developed for the synthesis of compound **6**. Its starting material was gentiobiose **9**. The condensation of this disaccharide with benzaldehyde led to the tri-*O*-benzylidene derivative **10**, containing two free hydroxy-groups. Partial acetylation of this substance afforded a mixture of the 2-*O*- and 3-*O*-acetyl derivatives, but glycosylation by treatment with 2,3,4,6-tetra-*O*-benzoyl-α-D-glucopyranosyl bromide in the presence of silver triflate occurred regiospecifically in the 3-position. Subsequent acetylation afforded the protected trisaccharide **11**. The tetrasaccharide analogue **12** was synthesised similarly, but the glycosylating agent was hepta-*O*-benzoyl-α-laminaribiosyl bromide.

Hydrolysis of compound **11** under fairly unusual conditions—on treatment with a solution of dichloroacetic acid in aqueous acetic acid—led to the selective removal of one of the three benzylidene groups occupying the 4- and 6-positions. This resulted in the formation of a derivative of the trisaccharide **13**—the key compound in the entire synthesis. Indeed, on the one hand, compound **13** served as a precursor of the reducing end of the future heptasaccharide, and, on the other, its glucosylation, occurring selectively at the primary alcoholic group, and subsequent acetylation afford the tetrasaccharide precursor **14** for the nonreducing end of the target heptasaccharide.

The removal of the benzylidene groups from compound **14** was probably accompanied by the partial hydrolytic cleavage of the 1→6 bonds, because the halogenose **15** was obtained in only 24% yield. However, other methods of synthesis of this compound were ineffective. Condensation of the glycosyl halide **15** with the partially protected trisaccharide **13** under glycosylation conditions, which had already been frequently used previously in this synthesis, led to a protected derivative of the required heptasaccharide **16**. The unblocking of the latter afforded the heptasaccharide **17**, which was reduced to a polyol indistinguishable in terms of its chemical properties and biological activity from the substance isolated as a result of the hydrolysis of the cell wall of the fungus *Phytophthora megasperma*.[30] The use of compound **12** instead of compound **11** in the same sequence of synthetic operations led to the octasaccharide **18**; the biological activity of the corresponding polyol was one-third of that of the heptasaccharide elicitor.

The synthesis of the biologically active oligosaccharide removed all doubt concerning the chemical nature of the new class of signalling compounds. Next, it was of great interest to elucidate the mechanism of its signalling activity and the structural elements of the oligosaccharin necessary for the manifestation of biological properties. The first data concerning the variation of their structure and biological activity, obtained on comparing compound **6** with its analogues **2**–**5**, **7**, and **8**, were extremely approximate, since the authors did not have the oligosaccharides in amounts sufficient for a detailed study. After the successful synthesis of compound **6**, it became possible to hope that analogues of this compound could be synthesised.

Scheme 5 continued over.

Scheme 5 (continued)

R = H (**17**), β-D-Glc (**18**).

Admittedly, it was necessary to develop for this purpose new synthetic procedures, because the elegant specific method of synthesis of the oligosaccharin **6** was rather unsuitable for the synthesis of its structural analogues.

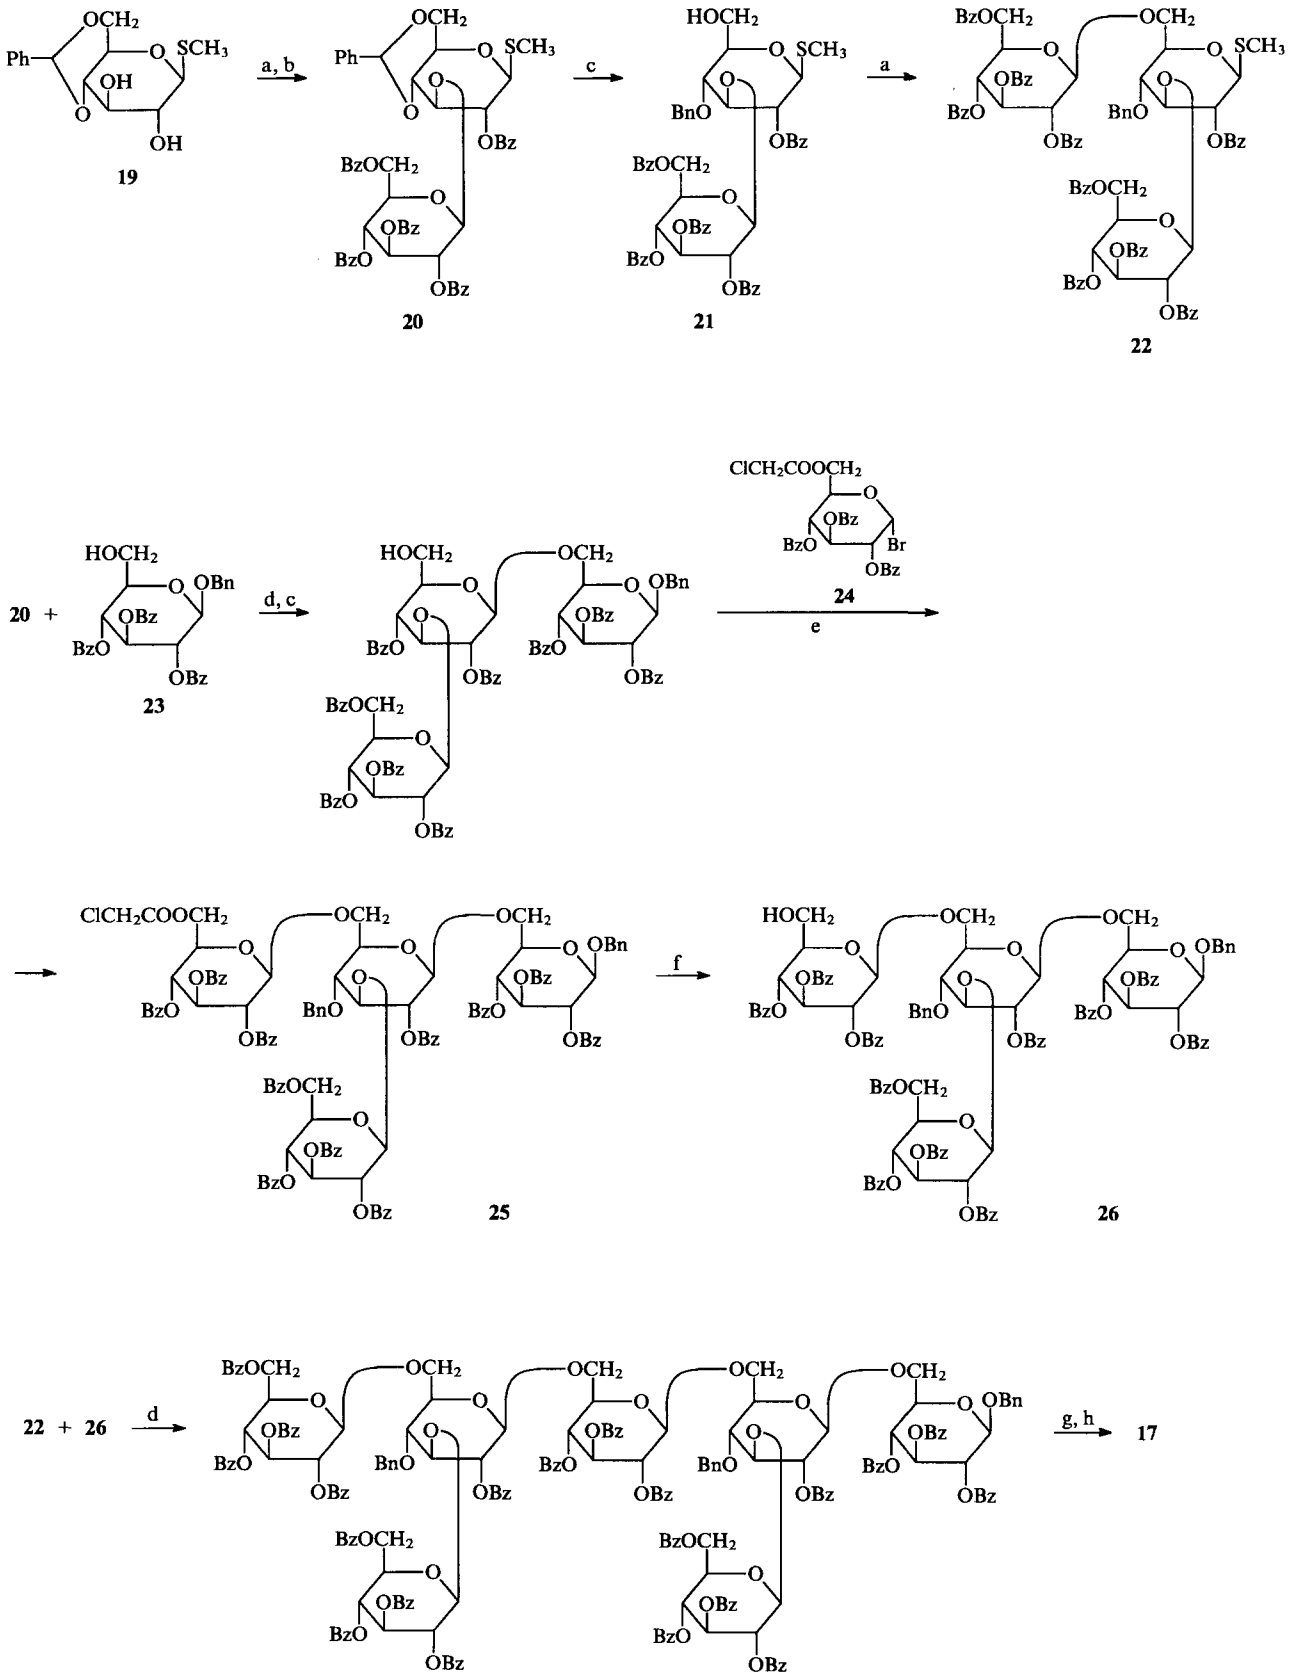
Çhree years later, a communication concerning new methods of synthesis of the oligosaccharide **17** appeared[31] in which the authors used extremely effectively the latest advances in glycoside synthesis.[32] In the first stages of the construction of this complex molecule, as in the first synthesis, use was made of benzoylated glycosyl halides, which ensured the maximum yields and the stereospecificity of the glycosylation as a result of the simultaneous involvement of the benzoyl group at C(2) [33] and of silver triflate as the promoting agent.[34] In the last stages of the block synthesis of the heptasaccharide, the glycosylating agents were thioglycosides in the presence of methyl triflate.[35,36] As regards protecting groups, mention should be made of the extremely successful employment in this synthesis of the regiospecific opening of the 4,6-*O*-benzylidene acetals by reductive cleavage on treatment with the borane—trimethylamine complex and aluminium chloride[37] and also of the chloroacetyl groups attached to the primary hydroxyls, which are selectively removed in the presence of other ester groups on treatment with hydrazine dithiocarbonate[38] or thiourea.[39] The sequence of synthetic operations is clear from Scheme 6.

The starting material for the synthesis of the trisaccharide glycoside donor **22** was the 4,6-*O*-benzylidene derivative of methylthio-β-glycopyranoside **19**. Its glycosylation with 2,3,4,6-tetra-*O*-benzoyl-α-D-glycopyranosyl bromide and subsequent benzoylation led to the protected disaccharide **20**. The subsequent reductive cleavage of the acetal group and the repeated glycosylation by the same reagent afforded the required derivative of the branched trisaccharide **22**. In the synthesis of the tetrasaccharide glycosyl acceptor **26**, compound **20** was used as the glycosylating agent. Its condensation with benzyl-2,3,4-tri-*O*-benzoyl-β-D-glucopyranosyl bromide **23**, the subsequent reductive cleavage of the acetal group, and the glycosylation of the liberated primary hydroxyl with 2,3,4-tri-*O*-benzoyl-6-*O*-chloroacetyl-α-D-glucopyranosyl bromide **24** afforded the tetrasaccharide derivative **25**. The selective removal of the chloroacetyl group led to the acceptor **26**, the glycosylation of which with the thioglycoside donor **22** and subsequent removal of the protecting groups made it possible to obtain the synthetic heptasaccharide **17**, which was identical with the substance synthesised previously in terms of all the parameters.[29]

In order to produce the heptasaccharide in gramme amounts, the method of synthesis was modified (Scheme 7). Compound **21** was glycosylated with the chloroacetylated bromide **24** and the resulting chloroacetylated thioglycoside **27** was used both for the synthesis of the tetrasaccharide glycosyl acceptor **28** and as the glycosyl donor for the glycosylation of compound **28**.

Compared with the first synthesis of the heptasaccharide **17**,[29] the new approach provided incomparably greater possibilities for the preparation of analogues and derivatives of the compound. It is therefore not surprising that the communication of Fugedi et al.[31] was soon followed by new papers in which this approach was developed. The first of these[40] was devoted to the synthesis of the heptasaccharide **30**—an analogue of the oligosaccharin **17** differing from the latter by the position of the branching points. All the intermediates **20** and **22**–**24**, the glycosylation methods, and the combination of protecting groups described above were used in this synthesis (Scheme 8).

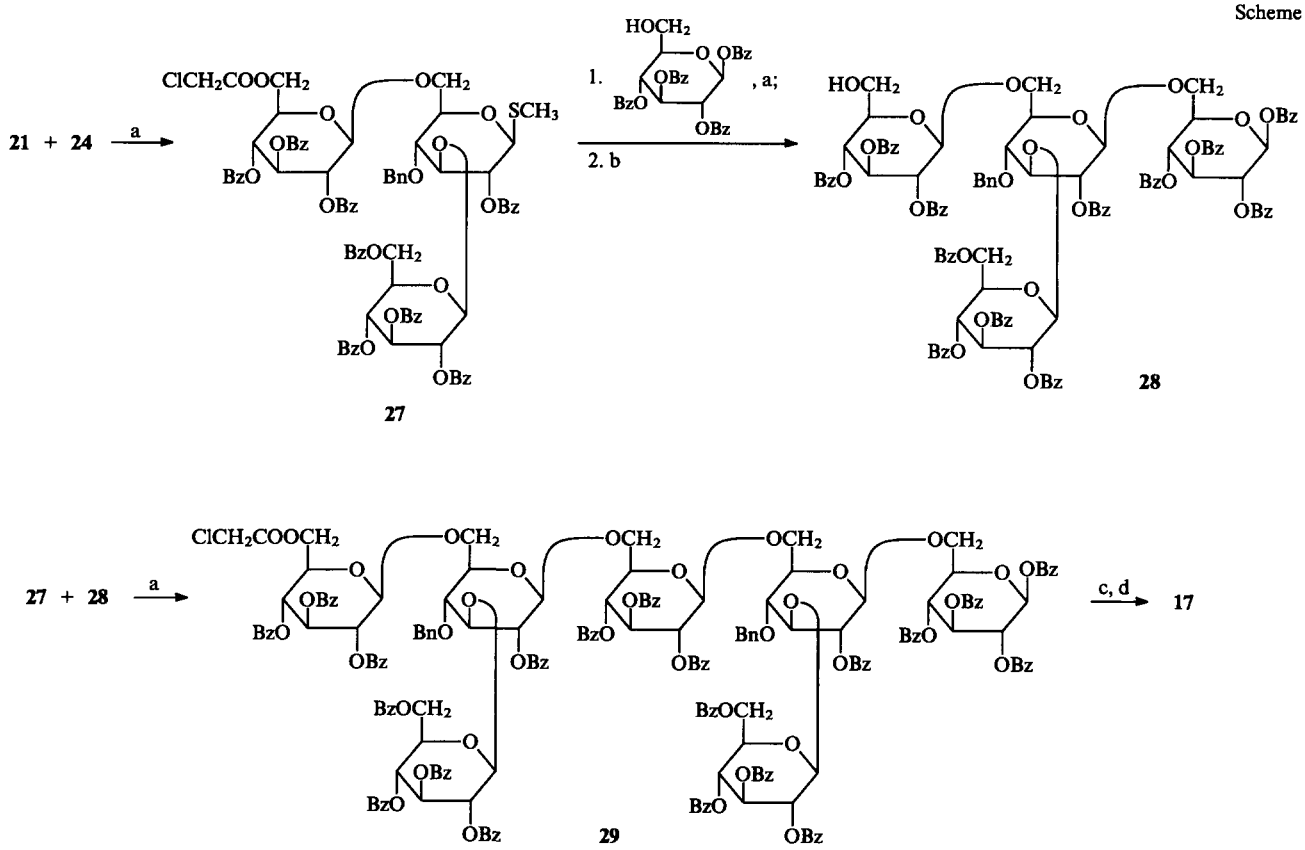
However, the use of the chloroacetylated thioglycosides **27** for the successive introduction of branched trisaccharide units with the required structure into the molecules being synthesised proved to be the most fruitful. In the next study,[41] this approach was employed to obtain two very interesting compounds. One of these is the glycoside of the biologically active heptasaccharide, where the aglycone is the methyl ω-hydroxynonanoate residue (Scheme 9). Evidently, this aglycone can be used as the spacer in the synthesis of affine sorbents designed for the isolation of cell components which exhibit a specific affinity for structure **6** or **17**, i.e. potential receptors which receive the chemical signal.



The second compound synthesised by Birberg et al.[41] is the decasaccharide **31** in which the trisaccharide structural element of compound **17** is repeated yet again. The problem involving the construction of such a complex molecule was solved by the threefold glycosylation of the corresponding precursors of the derivative of the branched trisaccharide **27** (Scheme 10).

A similar approach, in which use was made of the trisaccharide block **32** where the chloroacetyl group is attached to the primary hydroxyl of the glucose residue joined in the 6-position of a neighbouring unit and the other protecting groups are combined with the other hydroxyls, with another method (the trichloroacetimidate method) employed for the construction of the glycosidic linkage,[42] enabled Japanese investigators to obtain allyl α-glycosides of the hexasaccharide **33** and the nonasaccharide **34**, the carbohydrate chains of which are constructed in accordance with the same plan as in compound **6** (Scheme 11).[43] The same workers obtained analogues of the hexasaccharide **33**, containing the residues of β-D-xylose, *N*-acetyl-β-D-glucosamine, or β-D-glucosamine as one of the terminal nonreducing units.[44]

The first observations of the influence of structural modifications on the elicitor activity of the fungal β-glucan fragments date back to the period of the isolation of the heptasaccharide fractions[17] when it was established that the reduction of the heptasaccharides to the corresponding polyols does not affect the activity. This implied that the reducing end of the active heptasaccharide can apparently be subjected to appreciable changes without weakening the elicitor properties. This feature of the heptasaccharide **17** was used by two groups of investigators[44,45] to synthesise its conjugates with tyramine **35** and 2-(4-aminophenyl)ethylamine **37** via the reductive amination reaction. Iodination of these conjugates with radioactive iodine made it possible to obtain the labelled iodo-derivatives **36** and **38**, which are very essential for the investigation of the mechanism of the action of the oligosaccharin in the plant cell and of its fate (Scheme 12).



A comparative study of the elicitor activities of the majority of the synthetic analogues of the natural oligosaccharin mentioned above has been described.[44] As a result of quantitative measurements, it was established that the hexasaccharide allyl glycoside **33** is the smallest active molecule; virtually the same activity is exhibited by the heptasaccharide **17** and the higher oligosaccharides **31** and **34**. The branched trisaccharide fragment of the non-reducing end in these molecules is extremely important for the manifestation of the elicitor activity. Its modification, for example substitution of one of the terminal glucose residues by glucosamine or *N*-acetylglucosamine residues, lowers the activity by a factor of 10–1000. The activity also falls by a factor of 1000 if the glucose side residues are arranged next to one another, as in compound **30**, and are not separated by one unit, as in the natural elicitor. On the other hand, a wide variety of modifications of the reducing end of the heptasaccharide are permissible. Thus the activity is retained in the allyl α-glycosides of the hexasaccharide **33**; the conjugation of the heptasaccharide **17** with tyramine and subsequent iodination also have virtually no effect on the activity.

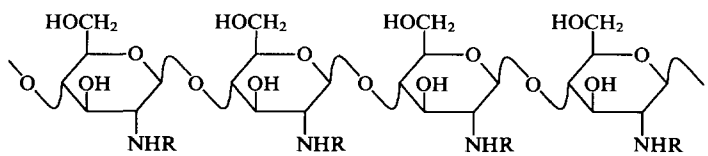
35–38

The first attempts to investigate the mechanism of the action of the oligosaccharide fragments of the fungal β-glucan on plant cells were made using a complex heterogeneous mixture of certain fragments,[46–49] but more reliable data were obtained with the aid of synthetic oligosaccharides.[45,50] In the latter studies, ^{125}I-labelled conjugates of the oligosaccharin with tyramine or 2-(4-aminophenyl)ethylamine were used. It was shown[51] that centres with a specific binding of oligosaccharins exist in the membranes of plant cells and that their binding process is characterised by saturation, reversibility, and an affinity ($K_\alpha = 7.5 \times 10^{-10}$ mol dm^{-3}) comparable to the concentration of compound **6** necessary for the manifestation of elicitor activity. All the binding centres are of the same type and are inactivated on proteolysis or on heat treatment, which is evidence in support of their protein (or glycoprotein) nature. The competitive inhibition of the binding process by numerous analogues demonstrates a direct relation between the affinity for the active centre and the elicitor activity. All these data confirm the hypothesis that the membranes of plant cells contain specific receptors for oligosaccharins. The high level of the specificity and of the discriminating capacity of the recognition system can be explained by the fact that the cells must recognise low concentrations of fragments of the foreign polysaccharide against the background of extremely large amounts of the 1 → 4-, 1 → 3-, and 1 → 3, 1 → 4-β-D-glucans present in the healthy plant under normal conditions.



The initiation of the synthesis of phytoalexins is not the only biological effect of the oligosaccharide **17**. Other plant protecting mechanisms are also mobilised simultaneously (for a more detailed description of a multiplicity of the activities of oligosaccharins, see below in the subsequent sections of the review), in particular the synthesis of β-glucanase — the enzyme present also in healthy plant cells which is capable of cleaving the β-glucan of the fungal cell wall with formation of signalling oligomers — is induced. Whereas the protecting function of enzymes of this type had been treated previously as a direct effect of the phytopathogen on the cell wall, limiting its growth, after the discovery of oligosaccharins the role of β-glucanase appears to be more probably that of generating signalling molecules, which stimulate a multiplicity of mechanisms protecting the host plant.

In conclusion of this section, one may note that, as a result of extremely intensive chemical researches, the heptasaccharide **17** and its analogues have become fairly readily available. An excellent practical manual of the methods of synthesis and of the characteristics of these compounds, including the synthesis of conjugates with tyramine and the introduction of the ^{125}I isotope into the latter, has been published.[52] Therefore, new discoveries in the field of the mechanism of the action of substances of the type considered on plant cells are to be expected in the immediate future.

2. Oligosaccharide fragments of chitin and chitosan

Together with β-glucan, the cell walls of phytopathogenic fungi contain chitin — an insoluble high-molecular-mass homopolymer the linear molecules of which are made up of 1 → 4-linked residues of *N*-acetyl-β-D-glucosamine — and chitosan — the product of the deacetylation of chitin (Scheme 13).[53,54] In higher plants, these polymers are absent but fragments capable of cleaving the carbohydrate chains of chitin and chitosan (chitinases and chitosanases) occur very widely.[55,56] Since it is evident that these enzymes do not participate in the primary metabolism of the plants themselves, it has been suggested that their purpose is to protect the plants against pathogenic fungi. Indeed, by disturbing the finely balanced processes in the biosynthesis and lysis of the components of the growing cell walls of the fungus, the chitino-lytic enzymes of the plants can limit its growth.[57] On the other hand, the oligosaccharide fragments formed in the enzymic hydrolysis of chitin and chitosan serve as signalling molecules, in response to the appearance of which the mechanisms for the synthesis of phytoalexins and other protecting responses of the plant are switched on. This phenomenon should play a no less important role in the interaction of plants with pathogenic fungi.

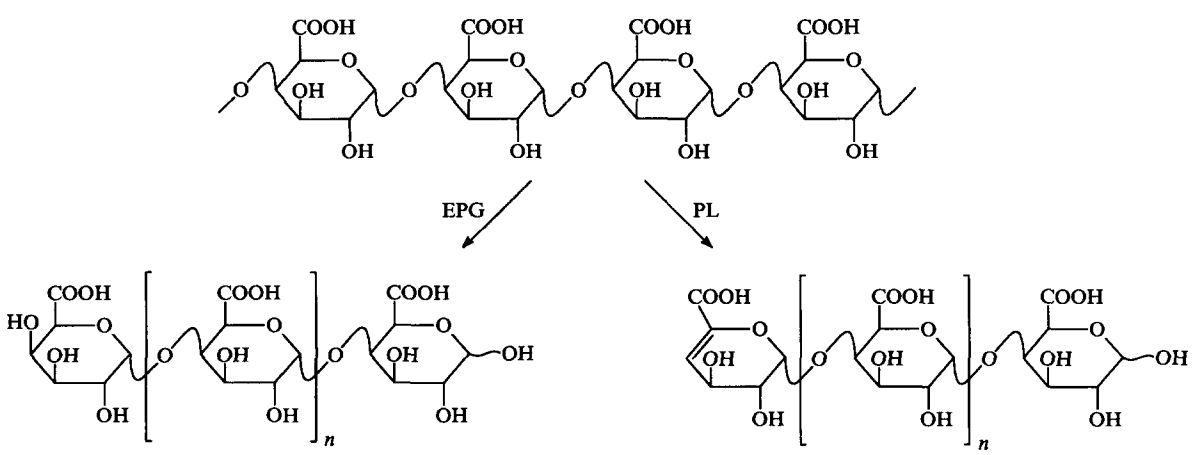
Scheme 13

R = Ac, H.

In contrast to the branched β-glucan, the linear chitin and chitosan, which contain a single type of linkage, afford on fragmentation a comparatively less complex set of oligosaccharides, which can differ from one another only by the degree of polymerisation, the degree of acetylation, and (for incomplete acetylation) by the distribution of the acetyl groups. The oligosaccharide products of the fragmentation of the chitin and chitosan molecules can be obtained from these polysaccharides by chemical methods[58-61] or by enzymic hydrolysis.[62] However, the technical difficulties in the isolation of the individual oligomers are fairly considerable, so that the majority of studies on the biological activities have been carried out using either the whole cell walls of the phytopathogenic fungi or the polymeric chitin and chitosan as elicitors; oligosaccharide fractions containing 2–3 oligomer-homologues are frequently used.

The formation of phytoalexins on treatment with chitosan and its fragments has been observed both in the tissues of the whole plant[63] and in plant cell suspension culture.[64,65] Other protecting systems of the plants are switched on simultaneously—such as the formation of the inhibitors of proteinases[66,67] or the synthesis of the protecting (1 → 3)-β-D-glucan of callose;[65,68] the oligosaccharide fragments of chitin also stimulate the lignification of cell walls.[69-71] The induction of the formation of chitinases[72,73] and chitosanases,[74] which, together with the inhibitors of proteinases and 1,3-β-glucanases, belong to the group of proteins associated with the pathogenesis, is particularly clearly expressed.[75,76] It has been shown that the protecting action of the chitinases does indeed consist both in the direct inhibition of the growth of the fungus[77,78] and in the formation of the elicitors of numerous systems protecting the host plant by cleaving the biopolymers in the cell wall of the phytopathogen.[79] It is of interest to note that the transgenic tobacco plants, carrying the gene of the leguminous plant chitinase, exhibit an increased stability to attack by soil fungi.[80]

As a rule plant chitinases constitute a complex made up of several exo- and endo-enzymes. In the study of the induction of chitinases by individual chitin oligosaccharides, it was established[81] that the hexasaccharide is the best stimulator of the exo-chitinase activity, whereas the endo-chitinase activity is stimulated most effectively by the heptasaccharide; the octa- and nonasaccharides also exhibit an appreciable elicitor activity. The lower oligosaccharides (including the tetramer) and the fraction of higher oligosaccharides with a degree of polymerisation of 13–20 proved to be almost inactive. The response of the plant to the introduction of elicitors was fairly rapid: the maximum activity of the induced chitinases was observed after 12–24 h, the enzymes being detected not only at the site where the oligosaccharides had been introduced (the cotyledons of pumpkin seedlings) but also the remote parts of the plant (leaves). It has been shown that the biosynthesis of chitinases is associated with the activation of the corresponding genes and the formation of mRNA,[82,83] but it has not so far been established whether this phenomenon is due to the permeation of the chitin oligomers into the cell nucleus; the mechanism of the propagation of the signals through the plant tissues is likewise unknown.



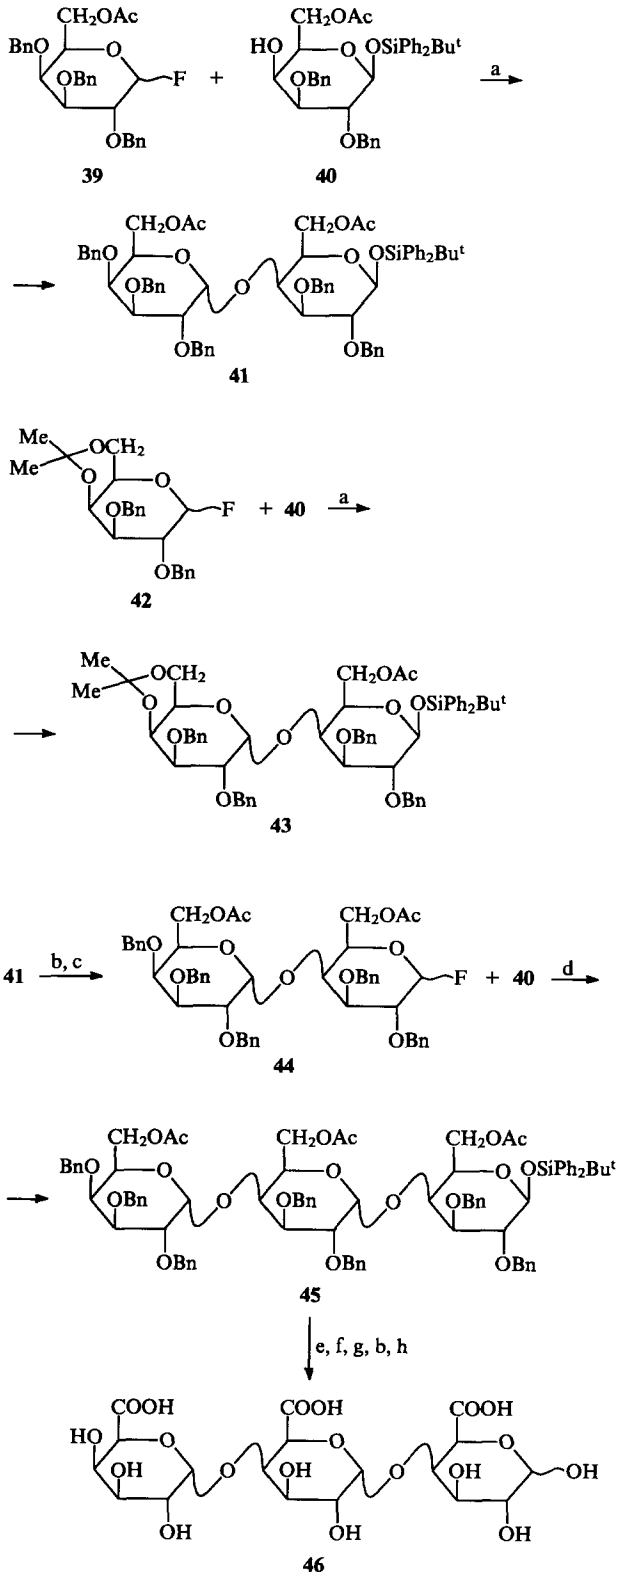
In the manifestation of other types of biological activity, a relation has also been observed beween the effect and the degree of polymerisation or structure of the oligosaccharide, although this problem has not been studied in detail. Thus the lignification of damaged wheat leaves is induced by chitooligosaccharides with a degree of polymerisation in excess of 4 but not by the corresponding fragments of chitosan.[70] However, oligomers of chitosan (degree of polymerisation in excess of 7) and not those of chitin serve as the elicitors of the formation of the phytoalexin pisatin in pea pods.[79,84] However, the deacetylated and partially acetylated oligosaccharides containing more than four monosaccharide residues stimulate equally effectively the formation of the inhibitors of proteinases in tomato and potato leaves.[66,67]

3. Oligogalacturonides

Pectin substances are important structural components of the primary plant cell wall.[5,85] The simplest representative of pectins is homogalacturonan or polygalacturonic acid—a linear polymer consisting of 1 → 4-linked α-D-galacturonic acid residues in the molecules of which some of the carboxy-groups may be present as the methyl ethers. Many microbial phytopathogens (both fungi and bacteria) produce enzymes capable of cleaving homogalacturonan either via a hydrolytic reaction [endopolygalacturonases (EPG)] or via an elimination reaction [pectate lyases (PL)]. The oligosaccharides formed possess the activity of phytoalexin elicitors,[86] the maximum of which corresponds to oligomers with a degree of polymerisation of 12 (Scheme 14).[87-90] Plants contain specific EPG inhibitors,[91] which regulate the activity of the enzymes produced by the phytopathogens, preventing an unduly far reaching cleavage of the polygalacturonic acid and thereby promoting the accumulation of higher oligosaccharides possessing the elicitor activity.[92]

Together with the formation of phytoalexins, other plant protecting mechanisms are switched on under the influence of oligogalacturonides, e.g. endo-(1 → 3)-β-gluconases, chitanases, and lysozyme are induced. They cleave the cell walls of phytopathogenic fungi and bacteria,[93,94] liberating the elicitors of the protecting reactions described in the previous sections. The lignification of protected tissues is also enhanced in the presence of oligogalacturonides.[95,96] It is important to note that the activities of the oligosaccharide elicitors, originating from the fungal or bacterial cell wall, on the one hand, and from the host plant, on the other, exhibit a synergism, i.e. the plant protecting reactions are switched on at lower concentrations of the oligosaccharides of different structure when these act together.[93,97]

Scheme 14

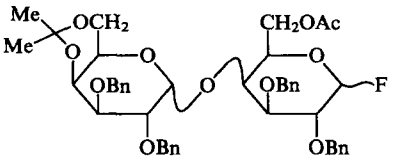


Several other types of biological activity of oligogalacturonides have been described. Compounds with a degree of polymerisation of 2–20 induce the formation of proteins inhibiting insect proteinases; it is believed that the plant is protected in this way against damage inflicted by plant eating insects.[98] In the presence of oligogalacturonides, cell suspension cultures produce endocellular isoperoxidases[96] and hydrogen peroxide.[99] Low concentrations of oligogalacturonides with a degree of polymerisation of 12–15 induce sharp changes in the permeability to K^+ and Ca^{2+} of the cell plasma membrane and its depolarisation.[100] Oligosaccharides with a degree of polymerisation of 14–15 induce the phosphorylation of the 34 kDa protein isolated from the plasma membrane.[101] It still remains to be elucidated to what extent these effects on the cell surface are associated with the elicitor activity of the oligogalacturonides described above.

The structural requirements imposed on the biologically active oligogalacturonides differ significantly from those for the heptasaccharide fragment of the fungal β-glucan described above. Thus the presence of the 'normal' α-D-galacturonic acid residue or even of the Δ^4-unsaturated uronic acid at the nonreducing end of the oligogalacturonide (Scheme 14) hardly affects the activity. On the other hand, reduction with sodium tetrahydroborate to alditol diminishes the activity.[102] The latter may be associated with the general decrease in the charge of the molecule as a result of the lactonisation of the reducing end.[8] The activity also falls on esterification[89] or reduction of the carboxy-groups.[90] A critical degree of polymerisation is apparently necessary for the acquisition by the oligogalacturonide of a stable conformation ensuring a fully defined spatial disposition of the charged groups, because acid oligosaccharides of a different chemical nature (fragments of chondroitin sulphate, hyaluronate) or acid polypeptides (polyglutamate) lack of elicitor properties.[102]

Oligogalacturonides, which are essential for the study of their activity on plant cells, can be obtained in preparative amounts from commercial pectin or polygalacturonic acid preparations in two ways: by partial acid hydrolysis or by enzymic cleavage.[52,103] An advantage of the first method is simplicity and low cost, while that of the second is high yields of the oligosaccharides and the absence of severe influences, which may induce undesirable structural changes in the native molecules. The most difficult task is the separation of the mixture of oligosaccharides with a degree of polymerisation of 10–15 into individual components, which is carried out at the limit of the resolving capacity of the modern chromatographic technique. It has been shown that even in the case of a successful isolation of the homopolymer fractions, the principal target components can contain up to 15% of impurities, which, whilst having the same degree of polymerisation, differ in the structure at the reducing end and also in certain unknown structural elements.[9,10] All this renders the chemical synthesis of oligogalacturonides extremely attractive.

The synthesis of oligomer-homologues of α-D-galacturonic acid appears at first sight to be a completely hopeless task for two reasons: in general, owing to the lack of convenient synthetic methods for the construction of α-glycosidic linkages and, in particular, because the methods for glycosylation by galacturonic acid derivatives have been little investigated. Nevertheless the problem was solved successfully when Nakahara and Ogawa proposed an extremely novel strategy for the synthesis.[104,105] They used data showing that benzylated glycopyranosyl fluorides react with alcohols in the presence of $SnCl_2$ and $AgClO_4$, affording predominantly 1,2-*cis*-glycosides.[106] It was established for galactose derivatives that the protected fluoride **39** interacts under these conditions with the partially protected derivative **40** to form a mixture of α- and β-disaccharides from which the α-isomer **41** was isolated in a satisfactory yield (Scheme 15). The fluoride **42** reacted even more selectively, giving rise almost exclusively to the α-linked



Scheme 15

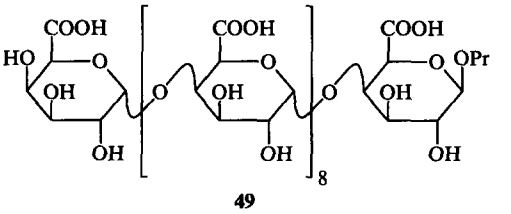
protected disaccharide **43**. It proved easy to convert compound **41** into the disaccharide fluoride **44**, the repeated condensation of which with compound **40** led to the α-linked trisaccharide **45**. On deacetylation of this substance with subsequent two-stage oxidation of the three primary alcohol groups, initially to the



Scheme 16

49

50

aldehyde groups by treatment with dimethyl sulfoxide and oxalyl chloride,[107,108] and then to carboxy-groups by treatment with sodium chlorite in the presence of hydrogen peroxide[109] yielded the trigalacturonide **46**. Using the same procedures, the authors synthesised subsequently a model disaccharide, which, however, was not obtained in a free form but only in the form of the n-propyl glycoside **49** (Scheme 16). The molecule of this compound was constructed using the disaccharide units **44**, **47**, and **48**.[110,111] Compounds **48** and **44** served as the precursors of the reducing and nonreducing ends of the future decasaccharide. The central part of the molecule was constructed by the threefold employment of compound **47** as the glycoside donor: first in the reaction with compound **48** and then, after each glycosylation, the new glycoside acceptor was prepared by removing the isopropylidene group from the terminal non-reducing galactose residue and by partial acetylation at the primary alcohol group. The final stage of the synthesis was the simultaneous oxidation of all ten primary alcohol groups.

The total synthesis of the dodecasaccharide elicitor **50** may be regarded as the completion of this series of studies. In this case, the molecule was assembled from tetrasaccharide units (Scheme 16).[112,113] However, the amount of the oligosaccharin synthesised in this way was small and data concerning the detailed study and the biological activity of the synthetic specimen have still not been published.

Derivatives containing a radioactive label are necessary for the investigation of the mechanism of the activity of oligogalacturonides. The reductive amination method using tyramine and subsequent introduction of radioactive iodine, used for the heptaglucoside **17** (see above), are unsuitable for oligogalacturonides; instead it has been suggested that hydrazones be obtained by reaction with tyrosine hydrazide and then iodinated.[52,114] It was shown in at least one of the biological tests that the conversion of the dodecagalacturonide into the hydrazone does not affect the biological activity.[114]

* * *

Summarising the above section, we may note that, in the interaction of the plant with phytopathogens, there is a possibility of the enzymic cleavage of the biopolymers in the cell walls of both partners. Some of the oligosaccharides thus liberated possess a specific biological activity and act as the elicitors of the protecting reactions of the host plant, oligosaccharides of different origin manifesting a distinct synergism in their activity. Although only one of the types of the plant protecting reactions is analysed in many experimental studies, it appears that in all cases there is a complex response to the appearance of oligosaccharins, whereupon, together with the synthesis of phytoalexins, enzyme systems cleaving the phytopathogen cell wall are activated and the tissue lignification process is intensified, which creates a barrier to further penetration by the phytopathogen, etc. By virtue of their multiple (pleiotropic) action on plants, oligosaccharins thus resemble the 'classical' phytohormones — auxins, gibberellins, cytokinins, abscisic acid, and ethylene. However, it must be emphasised that oligosaccharins are active at significantly lower concentrations. Another analogy with phytohormones involves the lack of species specificity: a similar activity of oligosaccharins has been demonstrated in many representatives of the plant kingdom, the relationship between which is extremely remote. Although the mechanism of the activity of oligosaccharins has still not been established, it is likely that in most cases a highly specific binding of the oligosaccharin to the membrane receptor protein takes place, which in fact constitutes the 'signal of fear' ['give away signal' in Ref. 8 (Ed. of Translation)] for the switching on of the plant protecting mechanisms.[8-10]

III. Oligosaccharins as regulators of plant growth and morphogenesis

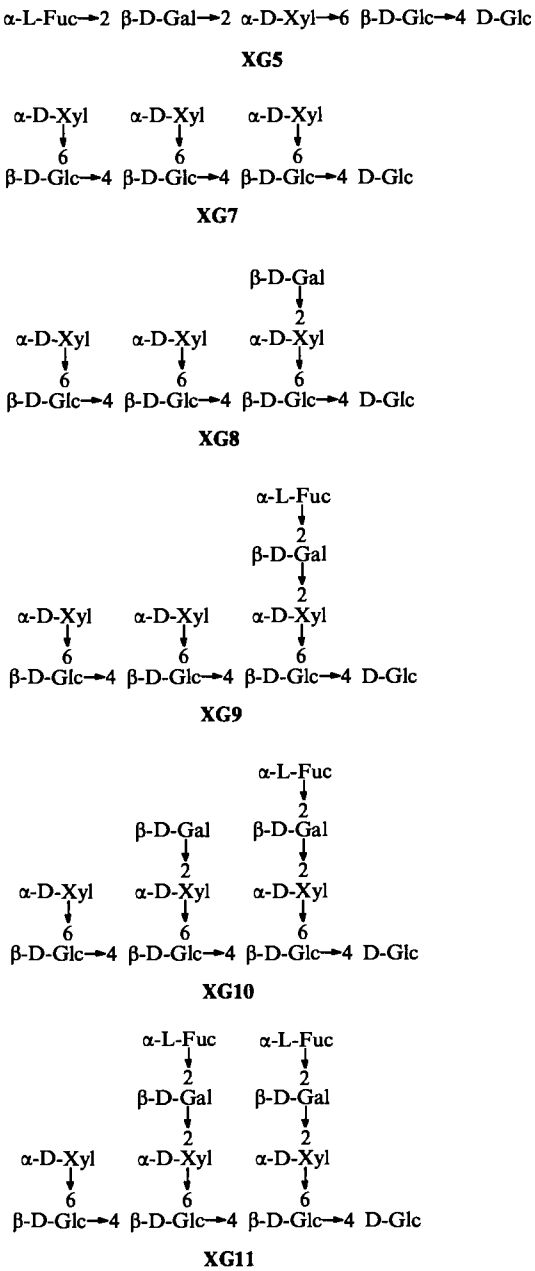
1. Oligogalacturonides

The ability of plant cells to be differentiated and converted into specialised plant organs is controlled by many factors, among which hormones, light, and temperature are of primary importance.[115,116] The influence of various chemical compounds on organogenesis can be followed on explants of tobacco peduncles which, during cultivation on an artificial medium, produce, in the course of 24 days, flowers, vegetative shoots, or roots depending on the auxin and cytokinin concentrations and on the pH.[117] A sensational report stating that the oligosaccharide fragments of plant cell walls (tentatively the fragments of the pectin polysaccharides) alter the specificity of the action of phytohormones in relation to organogenesis appeared in 1985.[118] However, several years elapsed before it was possible to characterise more thoroughly the chemical structure of the active oligosaccharides and to achieve reproducible results in this fairly capricious biological test.[119,120]

It was believed for some time that fairly complex fragments of pectin substances containing, apart from D-galacturonic acid, the residues of neutral monosaccharides serve as regulators of organogenesis. However, it was shown subsequently that the active principle nevertheless comprises the simple linear oligogalacturonides, which have already been considered as elicitors of phytoalexins. It is now known [119-121] that oligogalacturonides with a degree of polymerisation of 10–14 induce the formation of flowers and inhibit the formation of roots under conditions where without the addition of oligosaccharins tobacco explants form only roots or altogether fail to produce new organs. Oligogalacturonides act at concentrations of the order of 10^{-7} M, the highest activity being shown by compounds with a degree of polymerisation of 12–14. The existence of two types of activity in these oligosaccharins is probably associated with the fact that the same groups of genes are activated both in organogenesis in a healthy plant and in the biosynthesis of proteins associated with pathogenesis.[122]

Several other examples of the influence of oligogalacturonides on plant development processes are known. Thus a mixture of these oligosaccharides retards the auxin-induced growth of segments of pea plant stems, acting at a fairly high concentration (10^{-4} M).[123] This type of activity has been investigated in greater detail for xyloglucan fragments (see below). Oligogalacturonides induce the formation of ethylene in tomatoes (tomato fruits)[124,125] and in a pear cell culture suspension.[126] Hence they can participate in the complex process involving the hormonal regulation of the ripening of fruits.[127]

2. Oligosaccharide fragments of xyloglucan



Xyloglucan is a universal component of the hemicelluloses in higher plants.[5,128-130] Its content in the primary cell walls of dicotyledonous plants is usually 20%–25%, while in the *Gramineae* its content may be significantly lower (2%–5%). Xyloglucan is deposited in large amounts in the seeds of certain plants, where it serves as a reserve of nutrient material used during growth. Apart from glucose and xylose, xyloglucans have been found to contain galactose, fucose, and arabinose. Whilst having a common regular design, xyloglucans of different origin can differ in the proportions of monosaccharides. In particular, storage xyloglucans usually virtually lack fucose residues. We shall consider below the structures of typical xyloglucans in dicotyledonous plants, which have been isolated from the cell walls or from the medium cell in suspension cultures.[131]

The basis of the xyloglucan molecule is a linear chain made up of 1 → 4-linked β-D-glucopyranose residues, which have the same structure as cellulose. About 75% of the glucose residues in this chain have been substituted in the 6-position by α-D-xylopyranose residues (a small proportion of these substituted glucose residues carry in addition α-L-arabinofuranose, β-D-xylopyranose, or 3-*O*-α-L-arabinofuranosyl-β-D-xylopyranose residues in the 2-position). From one-third to half of the xylose residues are substituted in their turn in the 2-position by β-D-galactopyranose residues. Finally, many lactose residues have in the 2-position a substituent in the form of a α-L-fucopyranose residue. In those cases where it was possible to isolate the polysaccharide without using alkaline extraction, it was demonstrated that certain galactose residues may carry one or two acetyl groups in the 6-, 3-, or 4-positions.[132,133]

In the structural analysis of xyloglucan, enzymic cleavage has played a most important role. The effect of a mixture of fungal enzymes, known under the commercial name 'Driselase' (Sigma), which results in the formation of 6-*O*-α-D-xylopyranosyl-D-glucose (isoprimeverose), is a diagnostic feature for the polysaccharide.[134] Other carbohydrate components of the plant cell wall do not contain such a structural fragment. Since the above disaccharide can be readily distinguished in terms of its chromatographic behaviour from other disaccharide products of enzyme treatment, the detection of isoprimeverose in the hydrolysate can serve as convenient and reliable evidence for the presence of xyloglucan in the raw material or in the mixture of polysaccharides analysed.

Fungal cellulases cleave xyloglucan at the glycosidic linkages connecting the unsubstituted β-D-glucopyranose in the main chain. The main products of such cleavage are a heptasaccharide and a nonasaccharide [designated in the literature by XG7 and XG9 (Scheme 17)], which demonstrates the considerable regularity of the distribution of substituents in the main chain, where each fourth glucose residue is free. Together with the XG7 and XG9 oligosaccharides, it is possible to detect in the hydrolysate the XG5, XG8, XG10, XG11, and higher oligosaccharides containing the L-arabinose residues, although their amounts are smaller.[21,131,134-138]

Scheme 17

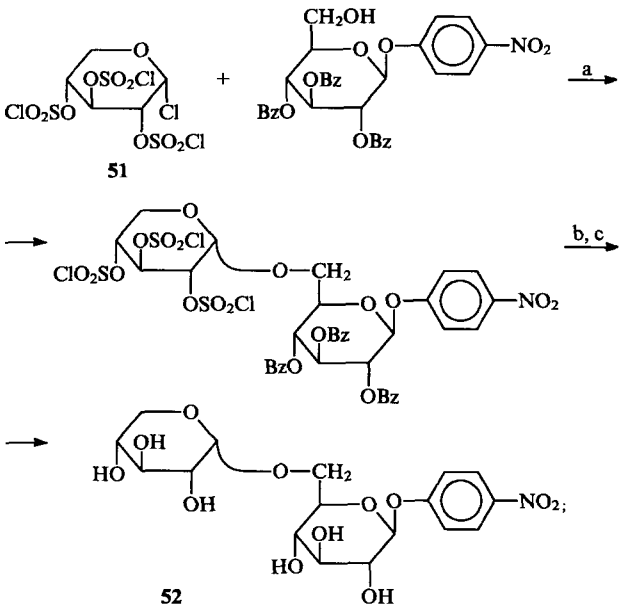
Paper chromatography,[139,140] chromatography in a thin silica gel layer,[141] gel chromatography on P-2 biogel,[131,142] and high performance liquid chromatography (HPLC)[143] have been proposed for the separation of the products of the enzymic hydrolysis of xyloglucan. This includes the separation of the products in the form of pyridylamino-derivatives obtained by reductive ammination using 2-aminopyridine.[144] The determination of the structures of these complex oligosaccharides is due to several groups of investigators. We may note that in this field too the leading place is occupied by the team headed by Prof. Albersheim, who developed the most effective physicochemical methods for the characterisation of the structures of xyloglucan fragments—^{1}H NMR spectroscopy and mass spectrometry with bombardment by fast atoms.[137,138] In order to obtain well resolved NMR spectra, it has been suggested that the oligosaccharides be reduced with sodium tetrahydroborate to the corresponding alditols (this procedure also helps to improve the separation and purification of oligosaccharides with the aid of HPLC). The observed rules governing the positions and forms of the signals due to the anomeric protons[137,145] make it possible to establish the structures of the majority of oligosaccharides from one-dimensional ^{1}H NMR spectra.

Reduced oligosaccharides are also used for mass spectrometry with bombardment by fast atoms. The spectra of the negative ions of compounds which have not been converted into their derivatives then indicate the presence of intense pseudomolecular ions $[M - H]^-$, while the fragment ions formed as a result of the dissociation of the intermonomer bonds originate from the reduced end of the molecule. On the other hand, for acetylated oligosaccharide alditols most information is yielded by the spectrum of the positive ions, which contains the intense pseudomolecular ion $[M + NH_4]^+$, while the fragment ions originate from the nonreducing end of the molecule. The combination of two such mass spectra makes it possible to determine the sequence of the monosaccharide residues in the test compounds.[136,145,146] The effectiveness of these methods has been demonstrated particularly strikingly in the latest studies by the group of investigators mentioned above, which were devoted to the establishment of the structures of the higher oligosaccharide fragments of xyloglucan containing between 17 and 20 monosaccharide residues.[145,146]

The primary wall of a plant cell constitutes an extremely involved complex of biopolymers of several types: celluloses, xyloglucan, polysaccharides of the pectin group, and structural protein.[147,148] In all probability the xyloglucan molecules in the cell wall are bound covalently to the pectins and the latter are bound to the structural protein, whereas the cellulose microfibrils form stable noncovalent complexes with xyloglucan molecules via hydrogen bonds. It has been suggested that cell growth is ensured by the partial cleavage of the xyloglucan molecules, which enables the cellulose microfibrils to be displaced relative to one another. Indeed, it is well known that auxins stimulating cell growth activate cell cellulases and, as stated above, these enzymes are capable of cleaving xyloglucan.[149-151]

In this connection, the discovery of a specific biological activity of the XG9 nonasaccharide proved to be extremely interesting: at a very low concentration of the order of 10^{-8} M, this compound inhibited the auxin-induced growth of segments of pea plant stems.[152] Surprisingly, this effect diminished not only at low but also at high XG9 concentrations; the latter observation implied, incidentally, that the inhibition of growth is not a consequence of the cytotoxic activity of the preparation. The closely related XG7 oligosaccharide completely lacked the antiauxin activity. The hypothesis arose that the biologically active XG9 fragment of the xyloglucan participates in the regulation of cell growth, acting in accordance with the negative feedback principle: an increase in the amount of auxin should induce the appearance of the inhibitor which prevents unrestricted growth.[152]

The test for the antiauxin activity is not unduly reliable and is not very convenient in practice, but the existence of the antiauxin activity of XG9 described above has been confirmed in two other laboratories—both in similar experiments on the inhibition of the lengthening of stem segments[153,154] and in experiments on the regeneration of the cell walls of protoplasts.[155] It has also been possible to observe the formation of the nonasaccharide fragment of xyloglucan *in vivo*.[134] The set of oligosaccharides obtained by the enzymic hydrolysis of xyloglucan made it possible to carry out interesting observations on the relation between structure and biological activity.[142,156]



It was shown that the presence of the α-L-fucose residue is a necessary condition for the manifestation of the antiauxin activity, because all oligosaccharides lacking fucose proved to be inactive. However, the XG10 oligosaccharide, containing the fucose residue but having also an additional galactose residue in the neighbouring chain likewise failed to exhibit an antiauxin activity; on the other hand, XG11 with two fucose residues in the molecule had an activity higher than that of XG9.[157]

Other structural elements were less important: the activity of the reduced XG9 did not differ from that of the initial oligosaccharide; the activity did not fall even after the enzymic elimination of the α-D-xylo-pyranose residue most remote from the reducing end of XG9.[157] A biological activity was also shown by the fucose-containing XG5 and 2-*O*-α-L-fucopyranosyl-lactose—a trisaccharide which is not a xyloglucan fragment but has been isolated from human milk; admittedly, these oligosaccharides were active at higher concentrations. In the case of XG5, an optimum in the concentration dependence of the antiauxin activity, so characteristic of XG9, was also not observed.[142,146]

At significantly higher concentrations (1—200 μM), the XG9 oligosaccharide activates cellulase;[158] a similar effect is shown to a smaller extent by XG5 and XG7. This second activity of XG9 helps one to understand why the oligosaccharide loses its antiauxin activity at relatively high concentrations.[159] At extremely low concentrations (of the order of 1 nM), XG9 and XG10 inhibit the lengthening of segments of the pea plant stems induced by acidification,[160] from which it follows that the antiauxin activity of XG9 is not associated with the suppression of the entry of hydrogen ions into the cell wall under the influence of auxin[161] but involves some hitherto unknown common stages in the influence of auxin and the pH on cell growth.

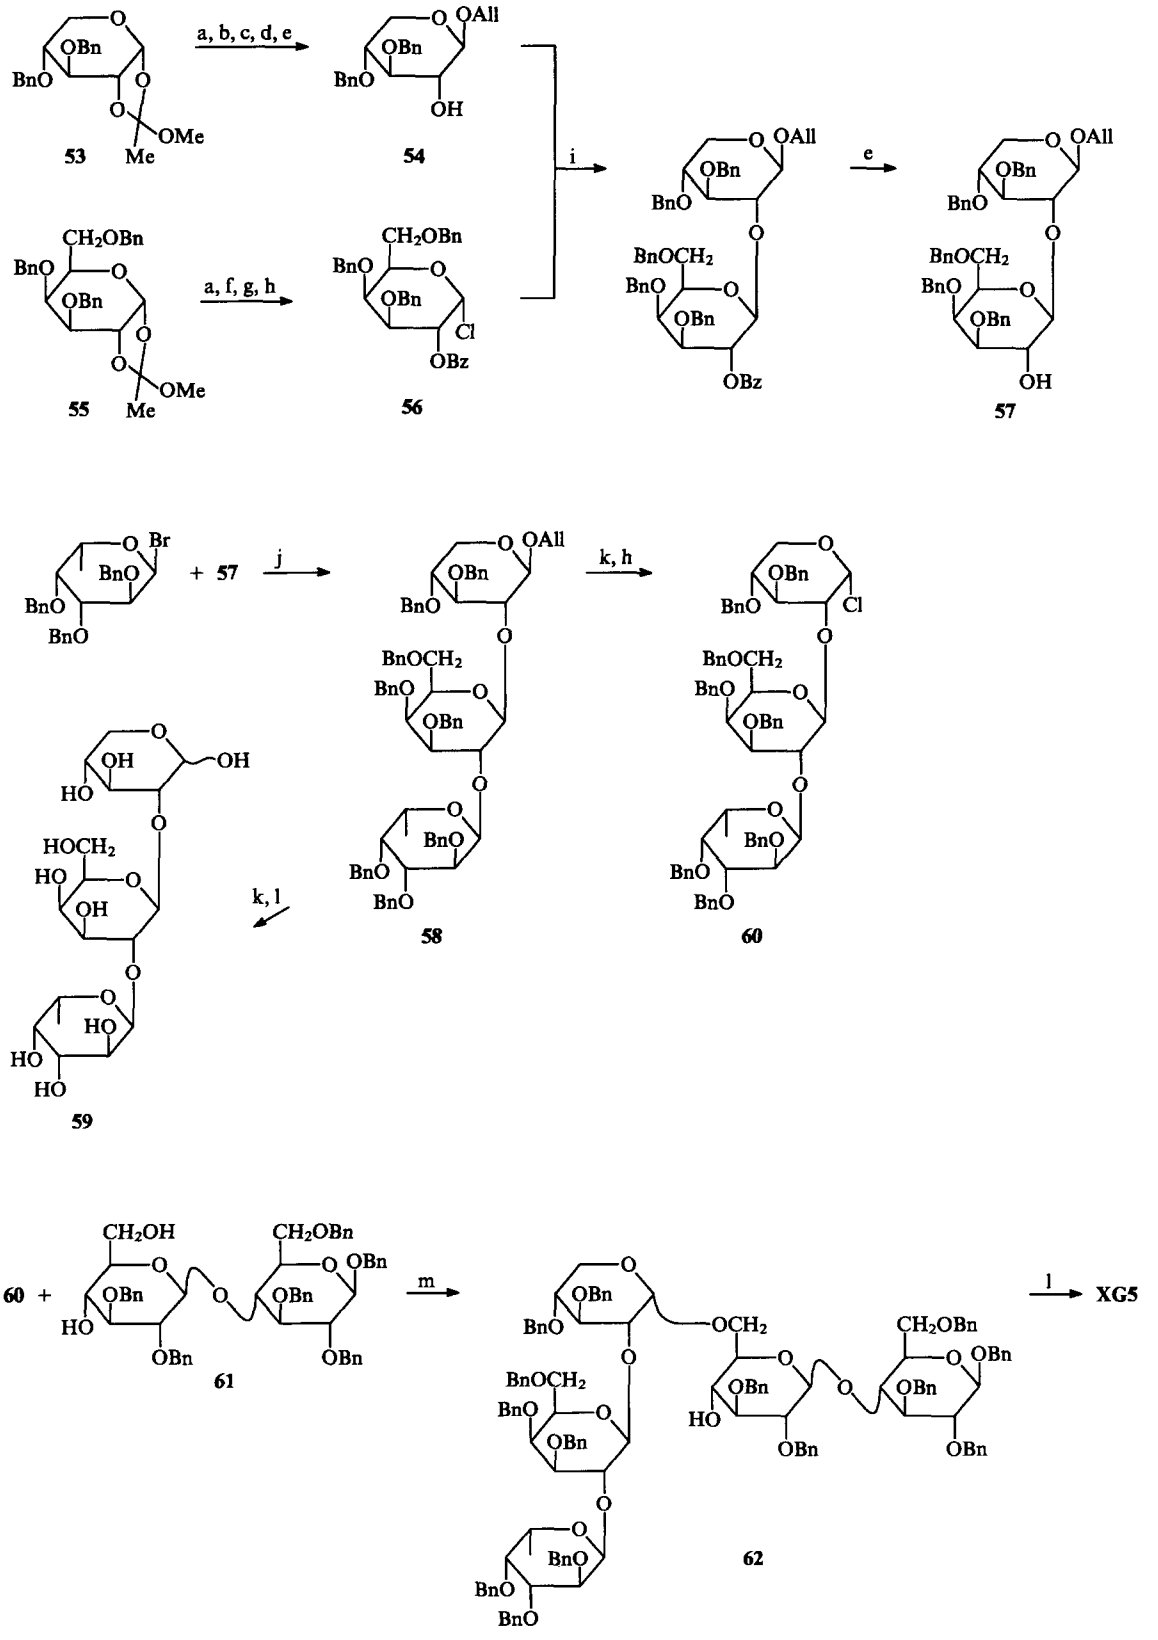
The biological activity of the xyloglucan fragments aroused an increased interest by chemists engaged in synthetic chemistry in the problem of the synthesis of these oligosaccharides. As early as 1986, a communication was published concerning the synthesis of *p*-nitrophenyl β-isoprimaveroside **52** (Scheme 18).[162]

Scheme 18

(a) Ag_2CO_3, $AgClO_4$, $CHCl_3$; (b) NaI, MeOH—H_2O; (c) MeONa, MeOH.

The method used by the authors to form the α-xyloside bond is noteworthy: the glycoside donor employed is a tris(chlorosulfate) of α-xylopyranosyl chloride—a compound containing at the C(2) atom a group incapable of participating in the glycosylation process. It is obtained in one stage from xylose on treatment with sulfuryl chloride. Compound **52** was subsequently used to synthesise an artificial antigen (by reduction to *p*-aminophenyl glycoside, diazotisation, and azo-coupling to bovine serum albumin), with the aid of which antibodies specific to the β-isoprimeverose residue were obtained.[163] Analogous artificial antigens were also prepared using the XG7, XG8, and XG9 oligosaccharides isolated from the enzymic hydrolysates of the natural xyloglucan.[164] The corresponding antibodies can find applications in the study of the location of xyloglucan in plant cell walls, as had been done earlier with the antibiodies to native xyloglucan,[165] and for the quantitative determination of the polysaccharide by the immunosorbent method (ELISA).[166] It is of interest to note that the antibodies specific to XG7 and XG8 (as well as lectins, which bind fucose residues)[167] inhibit the auxin-induced lengthening of segments of the epicotyls of the beans of *Vigna angularis* but do not affect the growth of the segments of the oat coleoptiles[168] despite the fact that in both plants the antibodies prevent the decrease in the molecular mass of xyloglucan under the influence of auxin. These data confirm that the cleavage of xyloglucan in dicotyledonous plants is an important stage in cell growth, but in monocotyledonous plants the cleavage of hemicelluloses of another type can play a more significant role.

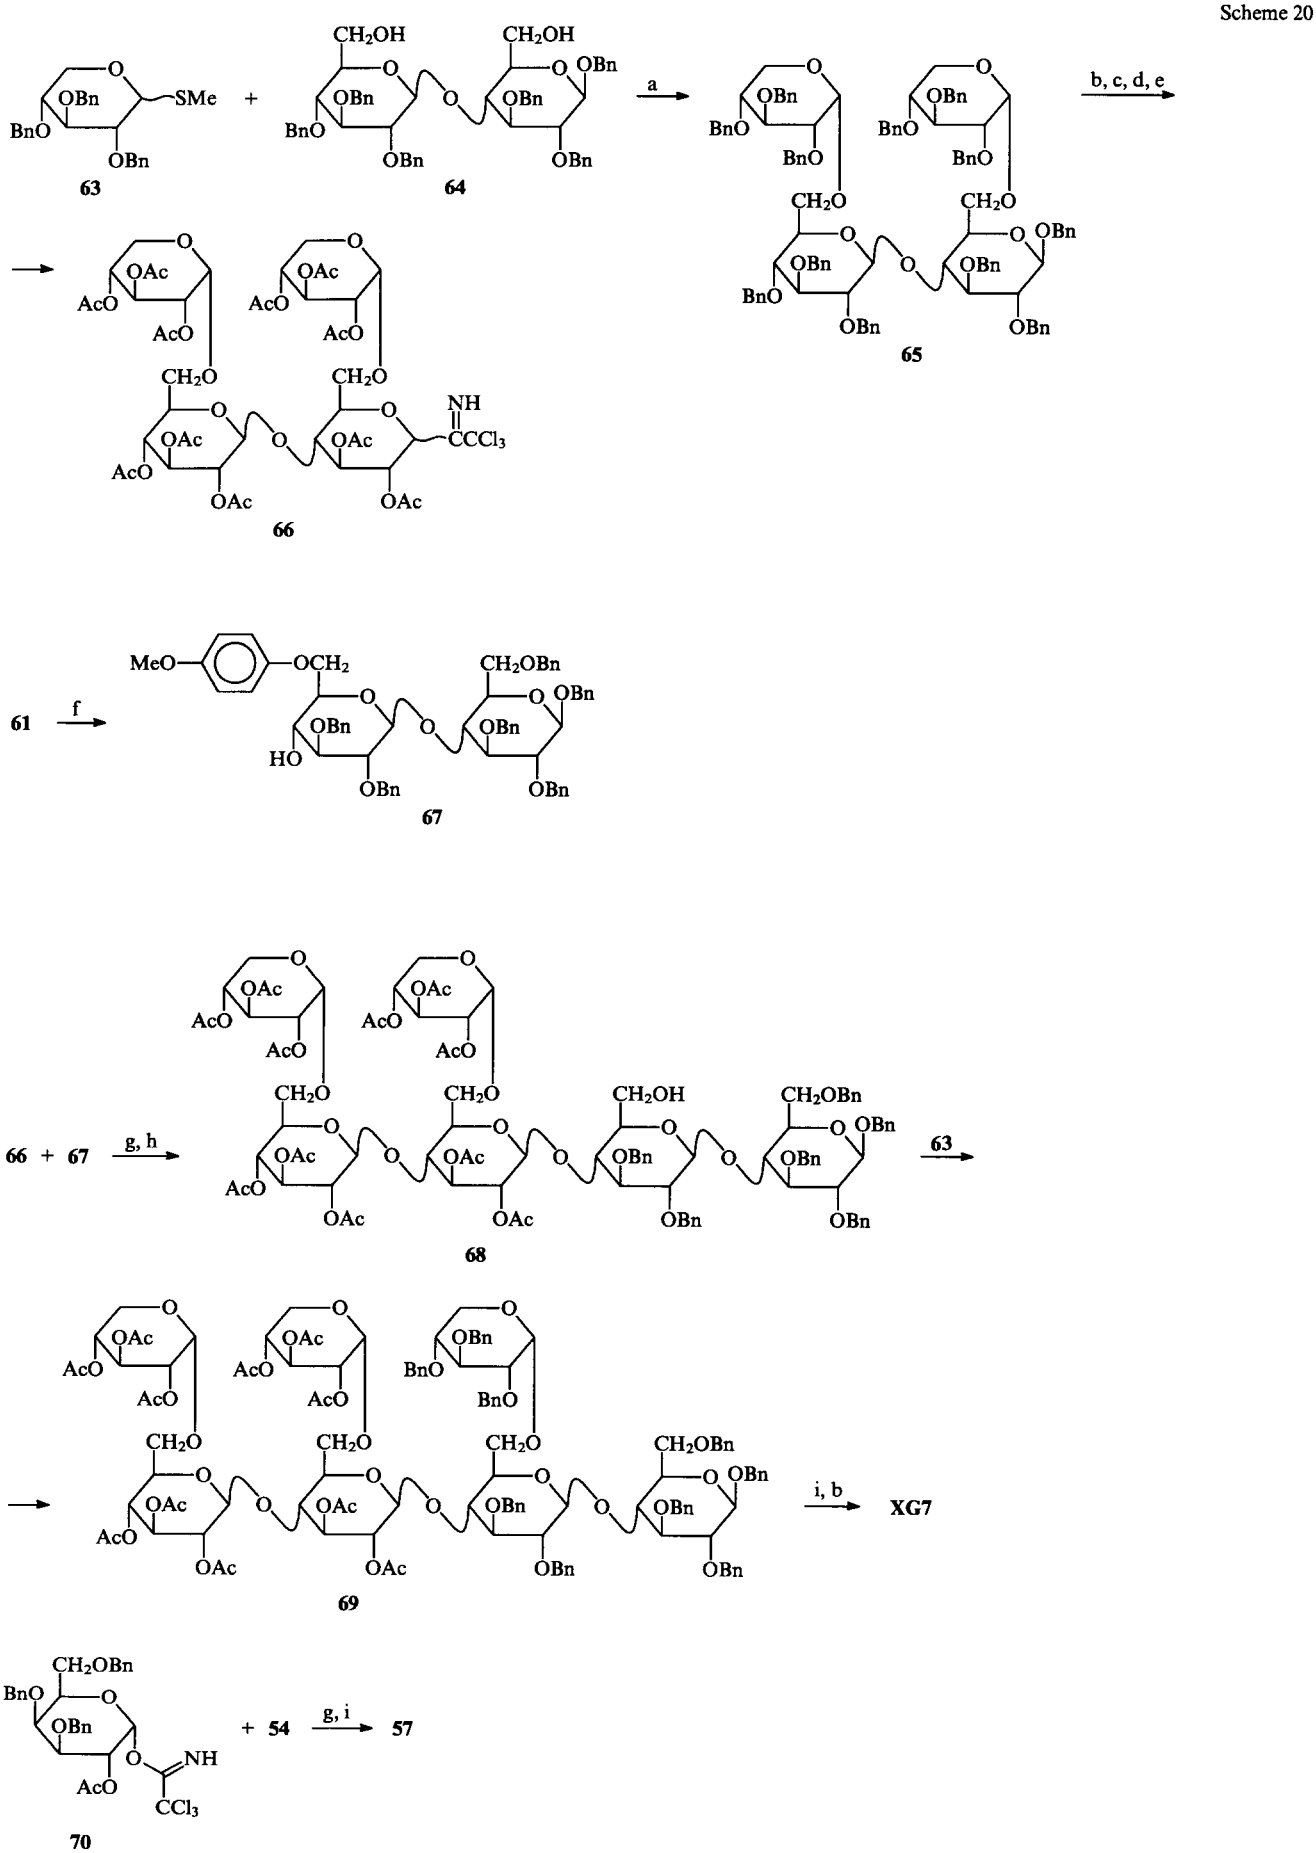
A communication concerning the synthesis of the tri- and penta-saccharide fragments of xyloglucan, containing L-fucose residues, appeared in 1990.[169] The benzylated 1,2-orthoacetates **53** and **55** were used to liberate the hydroxy-groups at C(2) in D-xylose and D-galactose derivatives. The trisaccharide **59** was synthesised by the stepwise addition of monosaccharide residues, starting with the reducing end of the molecule (Scheme 19).



The interaction of the protected allyl xyloside **54** with the galactose derivative **56** and subsequent removal of the benzoyl group afforded the partly protected disaccharide **57**, the fucosylation of which under the conditions of the preferential formation of the α-glycosidic linkage led to the protected disaccharide **58**.[170] As a result of the removal of the protecting groups, this compound gave rise to the free trisaccharide **59** and in addition it was converted into the protected glycosyl chloride **60**, the reaction of which with the partly benzylated benzyl β-cellobioside **61** led to the protected pentasaccharide **62**. The deblocking of the compound afforded XG5.

Biological studies on the synthetic pentasaccharide led to the discovery of new types of activity of this compound.[171] It was found that the oligosaccharin at a concentration of the order of 10^{-8} M inhibits the growth of the fusicoccin (a hormone, the activity of which is close to that of auxins)-stimulated growth of pumpkin cotyledons but does not affect their growth if 6-benzylaminopurine (a hormone belonging to the group of cytokinins) is used as the stimulator. When a tissue culture of wheat germ was acted upon simultaneously by the auxin and the pentasaccharide, the formation of callus tissue was accelerated together with its faster growth, whereas in the absence of the auxin the pentasaccharide induced the vigorous formation of roots instead of the callus. The biological activity of the oligosaccharide fragments of xyloglucan was thereby confirmed on the synthetic specimen and the involvement of these compounds not only in growth processes but also in the processes associated with the morphogenesis of plants was observed.

Whilst developing approaches to the synthesis of XG9, the group of investigators[172] who described this synthesis also reported the synthesis of the second part of the XG9 molecule—6,6′-bis(*O*-α-D-xylopyranosyl)cellobiose. However, at the same time the total syntheses of XG7 and XG9 were achieved by another team of investigators (Scheme 20).[173]



The key compound for the synthesis of both XG7 and XG9 was the hexasaccharide precursor **68**. In order to synthesise it, the derivative **64** of benzyl β-cellobioside with two free primary alcohol groups was glycosylated with the protected methyl thioxyloside **63** under the conditions of the preferential formation of α-glycosidic bonds,[174] which led to the tetrasaccharide derivative **65**. This compound was converted in several stages into the acetylated trichloroacetimidate **66**, which was used for the specific glycosylation of the protected benzyl β-cellobioside **67** obtained from compound **61** (Scheme 19) and *p*-methoxyphenol by Mitsunobu's reaction.[175] The removal of the *p*-methoxyphenyl group from this glycosylation product by

treatment with cerium ammonium nitrate[176] led to the derivative **68**. Unfortunately, its xylosylation with methyl thioxyloside **63** under the conditions described above afforded a mixture of the α- and β-anomers in proportions of 4 : 3. Nevertheless, the mixture was separated, after which the deblocking of the derivative **69** led to the target heptasaccharide XG7.

The trisaccharide glycosyl donor, necessary for the conversion of compound **68** into the XG9 derivative, was synthesised in the following way. Allyl xyloside **54** and the galactose derivative **70** with the selectively protected O(2) atom were obtained, using the 1,2-orthoesters of the corresponding sugars, by procedures similar to that used by Torgov et al.[169] The disaccharide derivative **57** was glycosylated with the benzylated methyl thio-β-L-fucopyranoside **71**. The α-glycosidic bonds were formed preferentially in this stage (the ratio of the α- and β-anomers was 81 : 7). The trisaccharide derivative **58**, obtained by a fairly long although sufficiently effective method, was converted into the protected methyl thioglycoside **72**. Glycosylation of the hexasaccharide derivate **68** by this thioglycoside again led to a mixture of the α- and β-anomers in proportions of 3 : 1, but the required α-anomer **73** was isolated in a pure state and was converted into XG9 after the removal of the protecting groups.

The biological properties of the synthetic XG7 and XG9 were investigated with the aid of the classical test—inhibition of the auxin-induced growth of segments of the pea plant stems. The results agreed fully with data obtained in the study of fragments of the natural xyloglucan: XG7 was inactive, while the activity of XG9 did not differ from that of the natural specimen.[157]

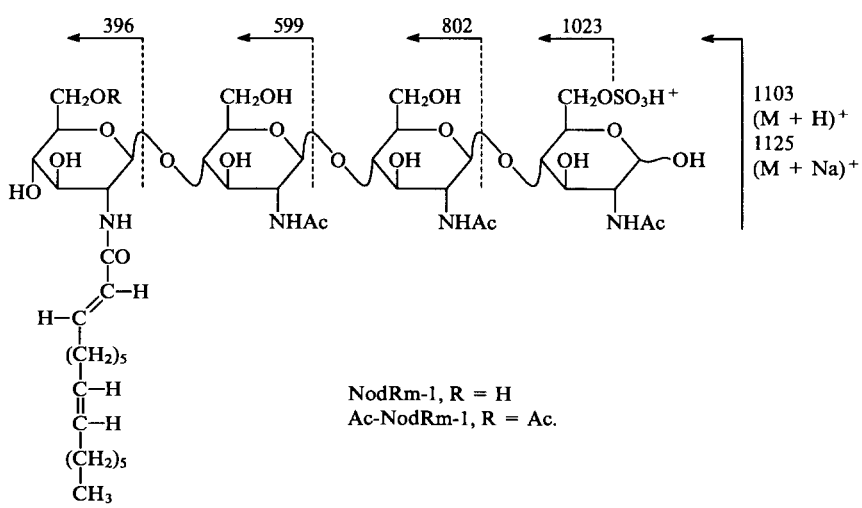
* * *

In conclusion of this section, one should note that cell growth and the differentiation of plant tissues are accompanied by the partial cleavage of the carbohydrate polymers in the cell walls. Some of the oligosaccharide fragments thus formed play the role of signalling molecules: they control the hormonal influence on growth or include different groups of genes in morphogenesis. The antiauxin activity of the XG9 nonasaccharide fragment of the xyloglucan is the most thoroughly investigated example of such biological activity. The mechanism of this phenomenon is so far unknown, but fairly rigid structural requirements, the fulfillment of which is necessary for the manifestation of biological activity by the substances, have been established. The oligosaccharin XG9 acts at extremely low concentrations. As in the case of auxin,[177] in all probability the specific binding of the oligosaccharide to the membrane cell proteins serves as the signal. Presumably the influence of the xyloglucan fragments on cell growth is fairly universal and depends little on the plant species; only the cells of plants deficient in xyloglucan, the growth of which is evidently ensured by the partial cleavage of hemicelluloses of another type, constitute an exception. The discovery of morphogenetic activity in xyloglucan fragments is of great interest,[171] but these studies are still in the very initial stage.

IV. Interaction of plants with bacterial symbionts

A classical example of symbiosis is the interaction of leguminous plants with bacteria of the *Rhizobium* genus, which leads to the formation of new plant organs ('nodules') and the transformation of bacteria into bacteroids, which affords overall a biological system capable of fixing atmospheric nitrogen.[178,179] This interaction is specific: individual bacterial biovars can settle only on quite definite species of the leguminosae. The formation of nodules (nodulation) requires an extensive and concerted rearrangement of the activity of the gene apparatus of both partners, which is achieved as a result of the exchange of chemical signals. The cells of the root cortex are known to synthesise flavones or isoflavones, in response to the presence of which the bacteria begin to produce the 'nodulation factor'.[179,180] The host plant possesses a full genetic programme for the organogenesis of nodules, which is switched on in response to the appearance of this factor. The chemical structure of the first representative of the nodulation factors was established in 1990. The substance proved to be an extremely unusual lipooligosaccharide.[181,182]

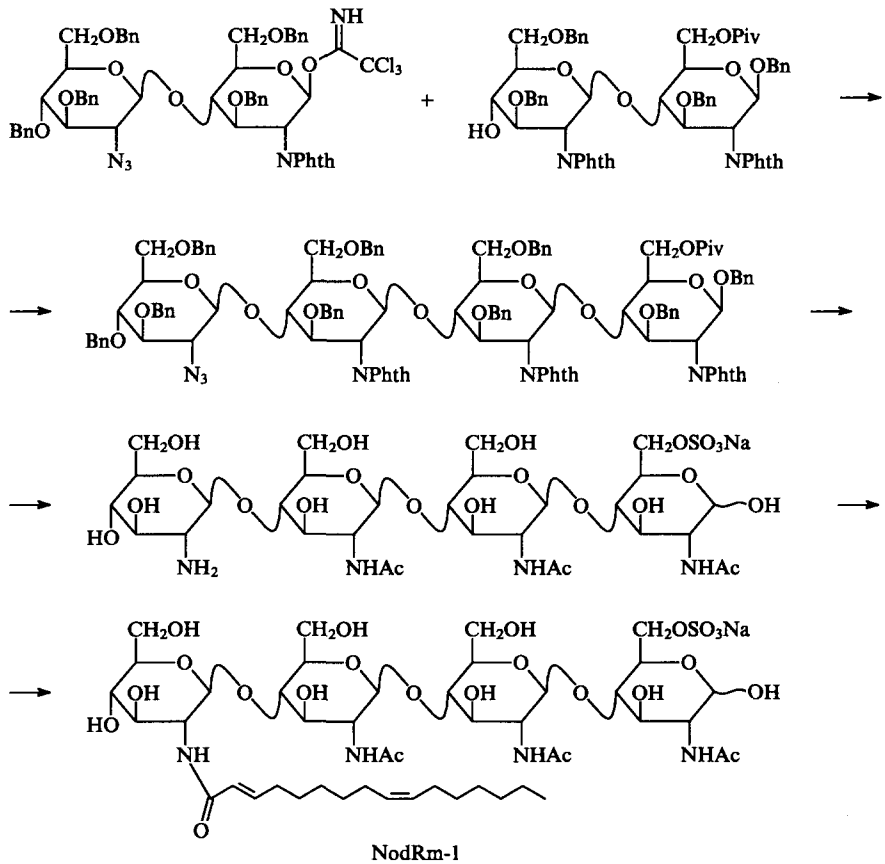
The preparative isolation of this compound required much preliminary work. A reliable test was found, which made it possible to determine the activity of the nodulation factor from the deformation of the root hairs of the host plant.[183] In order to facilitate the processing of the culture liquid, a mutant strain *Rhizobium meliloti*, incapable of producing exocellular polysaccharides, was chosen for cultivation. The production of the nodulation factor by the cells of this strain was increased approximately by a factor of 100 by genetic engineering methods. The extraction of the culture liquid with butanol and subsequent purification of the extract by preparative chromatography on the C(18) reversed phase, on Sephadex LH-20, on DEAE-trisacryl and again with the aid of reversed phase HPLC led to the formation of a substance (about 4 mg from 10 litres of the culture) exerting a specific activity on the alfalfa root hairs. The preparation isolated was designated as NodRm-1.[181,182]



The structure of this substance is illustrated in Scheme 21. It was established using several chemical cleavages as well as mass-spectrometric and NMR spectroscopic data. The presence of the sulfate group was confirmed by the incorporation of the ^{35}S-labelled sulfate in the biosynthesis of the oligosaccharide. Glucosamine, the D-configuration of which was demonstrated with the aid of gas–liquid chromatography (GLC) of (−)-2-butyl glycosides, was identified in the products of the total acid hydrolysis. The nature of the intermonomer bonds was established by the methylation method and the configurations of the glycosidic centres and of the double bonds in the aliphatic acid residue were determined with the aid of the NMR spectra. Mass spectrometry with bombardment by fast atoms made it possible to determine the positions of the double bonds in the aliphatic acid and to find the locations of the substituents in the native oligosaccharides (the mass numbers of the most informative ions for NodRm-1 are indicated in Scheme 21). An admixture of a minor component, the tetrasaccharide Ac-NodRm-1 containing in addition the *O*-acetyl group in the 6-position in the terminal nonreducing glucosamine residue, was detected in the preparation by the same method.

Thus it was found that the signalling function was assumed by a compound having an extremely unusual structure for bacterial metabolites. Its carbohydrate chain is a tetrasaccharide whose structure is identical with that of the corresponding fragment of the molecule of chitin (which is absent from bacteria) and carries the lipophilic substituent in the form of a doubly unsaturated higher aliphatic acid residue at the non-reducing end and a highly polar substituent consisting of the sulfate group at the reducing end. The substance induces the deformation of the root hairs in alfalfa (the host plant for the chosen strain) but not in the closely related vetch, acts at very low concentrations (10^{-8}–10^{-11} Ũ), and is capable of inducing the organogenesis of nodules in the absence of bacteria.[184] The reduction of the double bonds in the aliphatic acid residue or the elimination of the sulfate group fully deprive NodRm-1 of its specific activity.[185] Admittedly, the tetrasaccharide from which the sulfate group has been removed is capable of inducing the deformation of the root hairs and nodulation at relatively high concentrations but only in leguminous plants other than the normal host plant (alfalfa).[184,185]

A more thorough analysis of the signalling oligosaccharide produced by *Rhizobium meliloti* demonstrated the presence of a further three minor components. One of them differed from the compounds described above solely by the structure of the higher aliphatic acid ($C_{16:3}\Delta^{2,4,9}$), containing an additional double bond in the 4-position. Two others differed from one another by the higher aliphatic acids ($C_{16:2}\Delta^{2,9}$ or $C_{16:3}\Delta^{2,4,9}$) and from the three preceding compounds by the fact that the carbohydrate basis of their molecules comprised a pentasaccharide and not a tetrasaccharide fragment of the chitin molecule.[186]



Lipooligosaccharides with a similar molecular structure have been found also in other bacterial species. Thus *R. leguminosarum var. viciae*, a symbiont of the pea plant, produces derivatives of chitotetraose and chitopentaose, lacking sulfate groups, in which the amino-group of the terminal nonreducing glucosamine residue has been acetylated by the $C_{18:4}\Delta^{2,4,6,11}$ or $C_{18:1}\Delta^{11}$ aliphatic acid, while the 6-position in this residue and all other amino-groups are acetylated.[187] The oligosaccharins of *Bradyrhizobium japonicum*, a symbiont of the soya bean plant and certain other leguminous plants, are derivatives of chitopentaose in which there are 2-*O*-methylfucose

Scheme 21

NodRm-1, R = H
Ac-NodRm-1, R = Ac.

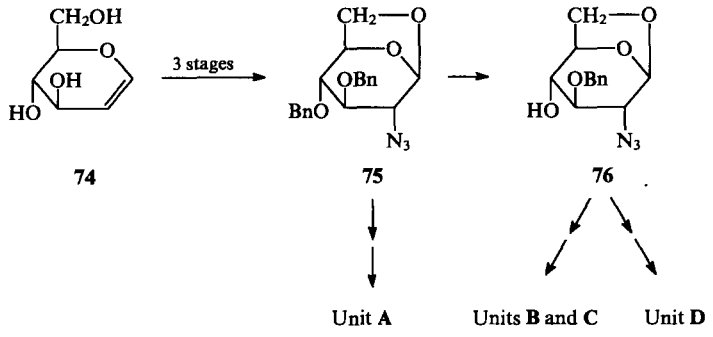
Scheme 22

NodRm-1

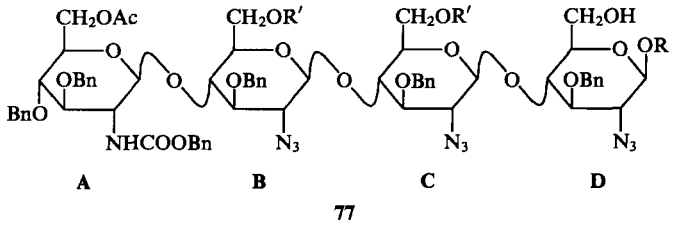
derivatives in the 6-position at the reducing end instead of sulfate groups; the substances differ in the nature of the higher aliphatic acid residues ($C_{18:1}\Delta^9$, $C_{16:1}$ or $^{*}_{16:0}$) and by the presence or absence of the acetyl group in the 6-position at the nonreducing end.[188-190]

Despite the limited amount of the available information, an impression has thus been created that the symbiotic bacteria are capable of synthesising a chitotetraose or a chitopentaose as a common basis of the future signalling molecules, while the necessary specificity of the structure of oligosaccharin is achieved by the addition of definite substituents to the nonreducing and reducing terminal residues of these oligosaccharides.[191] Since the isolation of the individual signalling compounds produced by bacteria remains a complex task, there is so far no information about the mechanism of the reaction of these substances. The synthesis of these oligosaccharides is also fairly complex. Despite the relative availability of chitotetraose or chitopentaose, which can be obtained by the fragmentation of chitin or chitosan (see above), it has not so far been possible to put forward a satisfactory synthetic scheme which would permit the introduction of specific substituents into the complete chitooligosaccharide molecule. Two total syntheses of the nodulation factors have been published[192,193] (in the form of reports delivered at the XVI International Symposium on Carbohydrates without experimental details). In one of them (Scheme 22) the NodRm-1 molecule is assembled from two disaccharide derivatives substituted in different ways. The successive removal of the protecting groups and reduction of the azide group of the terminal nonreducing residue of the tetrasaccharide molecule permit the introduction of the sulfate group and the higher aliphatic acid residue in the required positions.[192]

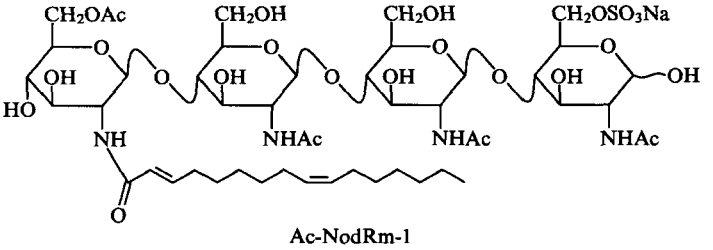
In another synthesis (Scheme 23),[193] the molecule is assembled from derivatives of monosaccharides, the necessary **A**–**D** units being obtained from 2-azido-2-deoxy-3,4-di-*O*-benzyllaevoglucosan **75**. This substance was synthesised in only three stages from the D-glucal **74** using oxidative 1,6-iodocyclisation[194] and was converted into the monobenzyl ether **76** by a standard method.[195] Subsequent synthesis of the tetrasaccharide derivative **77** made it possible to place in the required positions not only the sulfate group and the higher aliphatic acid residue but also the acetyl group, so that the final result of the synthesis was the compound Ac-NodRm-1.



* * *



The oligosaccharins described in this section differ significantly from the substances examined in the previous sections of the review. They are not fragments of carbohydrate-containing biopolymers in the cell walls but represent the product of specific biosynthesis: the set of genes controlling this process in the bacterial cell is well known.[181,185,196] The nodulation factors are also characterised by a higher specificity, since their biological activity is manifested only in relation to a very limited number of plant species. It is extremely probable that the part of the plant receptor complex receiving the nodulation signals comprises lectins located on the surface of the cytoplasmic membrane of the cells in the root hairs and capable of the specific binding of oligosaccharins. The transfer of the pea lectin gene to the seedlings of white clover led to the transfer of susceptibility to the infection and nodulation by the *Rhizobium* strain specific to the pea plant.[197]



V. Conclusion

In the present review, we have examined five types of oligosaccharins which are used by plants to regulate most important physiological processes, such as growth and morphogenesis, and the relation with phytopathogens and symbiotic bacteria. Impressive results have already been

Scheme 23

achieved in this field of study, although many processes associated with the role of oligosaccharins *in vivo* and with the mechanism of their action still remain to be elucidated. The interest in oligosaccharins can be explained not only by the new possibilities of investigating with their aid the physiology of the plant cell but also with the extremely promising prospects for the creation on their basis of ecologically harmless growth regulators and plant protecting agents. However, oligosaccharins continue to remain difficult to obtain. Further progress in this field will depend in many respects on the development of new economical procedures for the preparation of oligosaccharins from natural sources and methods for the synthesis of both the oligosaccharins themselves and their analogues necessary for the elucidation of the dependence of the biological activity on the chemical structure of these compounds.

VIII.	Conclusion	1082

Abstract. Spin selective chemical reactions must also be magnetically sensitive. The susceptibility of chemical reactions to magnetic interactions produces two generations of magnetic effects: the first includes the magnetic field effect, the magnetic isotope effect, and the chemical polarisation of nuclei, all induced by external or internal magnetic fields. The second generation effects are stimulated by external electromagnetic fields interacting with the chemically active spin systems. The bibliography includes 31 references.

I. Two scenarios of chemical reaction

Any chemical event, including its feasibility and its result, is traditionally rationalised according to its energy scenario: how much energy is required, how to pump this energy into the reacting species, and how efficiently is this energy exploited in the chemical system.

However, another physical property besides energy is of paramount importance in chemistry: the angular momentum (spin) of the electrons and nuclei of the reagents. The fundamental ruling principle of chemical reactions is that both the spins and their projections remains unchanged in elementary chemical events. The conservation of the total spin has important consequences: the chemical reactions are spin selective, they are allowed only for spin states of the products whose total spin is identical to that of reagents, and they are strictly forbidden if they require spin change. For example, the transformation of the radical pair into the molecule (through recombination or disproportionation) is allowed only from the singlet spin state of the pair, and forbidden from the triplet one. The reaction $H + O_2 \rightarrow HO_2$ takes place in the doublet spin state of the reagent ($H\cdots O_2$) since the total spin of the pair in this state is identical to that of the reaction product, but it is forbidden in the quartet spin state of the pair. Of the nine possible spin states of the pair of triplet carbenes Ph_2C:, each having spin $S = 1$, only one can undergo a spin allowed reaction and produce the recombination product tetraphenylethylene. The spin of the other eight states ($S = 1$ and 2) is not equal to that of the reaction product ($S = 0$), and therefore these states are chemically nonreactive.

In general the spin selectivity of chemical events implies that chemically identical but spin different intermediates (the reaction product precursors) have different, spin dependent chemical reactivities. The only interactions which can alter the spin of reaction precursors and transform nonreactive, spin forbidden into the reactive, spin allowed states are magnetic interactions. Their contribution to the total energy is insignificant, but they control the spin behaviour of the chemical species, they modify their chemical reactivity, and they establish a new, magnetic scenario of chemical reactions.[1–4]

Spin selectivity (and therefore also the magnetic sensitivity of chemical reactions) gives rise to two generations of magnetic effects, illustrated in Fig. 1 for the particular but widely met case of a radical pair (RP). The nonreactive, triplet spin state RP can be transformed into the reactive, singlet spin state pair either by magnetic interactions, characteristic of the reaction itself, or by external radiofrequency or microwave (mw) magnetic fields. The triplet-singlet spin conversion induced by 'native' magnetic interactions is responsible for the magnetic effects of the first generation, or native magnetic effects, while the triplet–singlet conversion stimulated by rf or mw magnetic fields induces the magnetic effects of the second generation. The former includes Magnetic Field Effect (MFE), Magnetic Isotope Effect (MIE) and Chemically Induced Dynamic Nuclear Polarisation (CIDNP) — three effects originating from the dependence of the reaction probability P in RP on the magnetic field H, hyperfine (Fermi) electron-nuclear interaction, and nuclear spin orientation I_z. The latter are the basis of Reaction Yield Detected Magnetic Resonance (RYDMR), Radio Induced Magnetic Isotope Effect (RIMIE) and Stimulated Nuclear Polarisation (SNP). The relation between these two generations of magnetic effects is schematically shown in Fig. 1*b*.

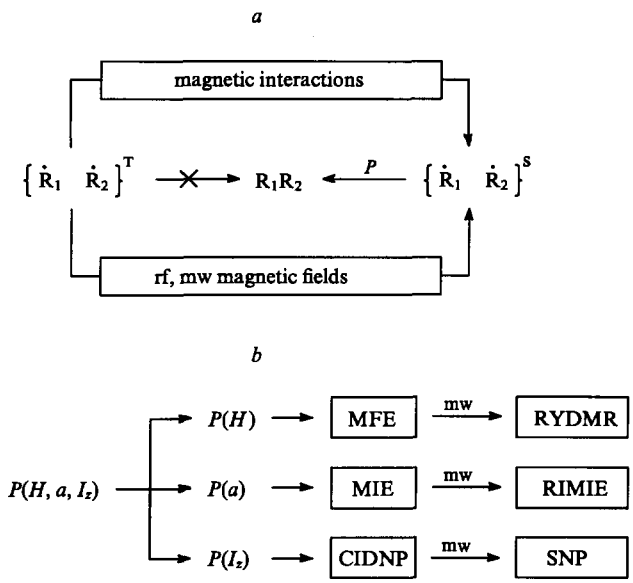

Figure 1. (*a*) Transformation of an unreactive triplet radical pair into a chemically active singlet pair under the influence of magnetic interactions and electromagnetic fields (radio-frequency or microwave); (*b*) relationship between first and second generation magnetic effects.

II. Spin dynamics of the radical pair

A radical pair is a dynamic intermediate or chemical microreactor from which the partners can diffuse without reacting, travel randomly in space and time, and then return and reencounter. The time between partner contacts, or repeated encounters, is used by the pair for its own spin conversion which is driven by magnetic interactions in the radicals resulting either in triplet–singlet transformation of the pair (if its starting spin state is triplet) or in singlet-triplet conversion (for pairs with singlet starting state).

To transform the triplet RP into a molecule at least four simultaneous events are required.

Firstly, the radicals leaving the RP at time $t = 0$ should return and reencounter at some time t. This process of regeneration of the contacts between RP partners is described by molecular dynamics. Secondly, at the same instance t the pair must have completed its triplet–singlet conversion and be ready to form a molecule. This process is controlled by spin dynamics. Thirdly, during their diffusional travels the radicals must not undergo chemical transformations: for the primary molecule to be reformed the initial pair must survive to time t. The probability of this event is determined by the chemical dynamics. Fourthly, the RP now ready to react (i.e. having survived to time t and being in a singlet state with the partners in contact) will recombine into a molecule only if a favourable orientation of the partners is achieved by rotational dynamics. Thus, the birth of a molecule from the RP is a result of the collective and coordinated efforts of three dynamics: spin, molecular and chemical.

The key act of the chemical interaction is spin conversion, controlled by the magnetic interactions, among which Zeeman and electron–nuclear (Fermi) hyperfine interaction (HFI) are the most important. Spin dynamics are modulated by molecular dynamics, which produce random variations of the distance between radicals and therefore of the exchange interaction potential. This, in its turn, influences the rate of spin conversion and ultimately the spin dynamics of the RP. The chemical reactions of RP partners destroy the pair, so that the spin dynamics are controlled by chemical dynamics.

The extended spin dynamics of the RP are the combination of all three dynamics considered cooperatively. The rate of triplet–singlet conversion is directly related to the matrix element Q of the RP spin Hamiltonian evaluated with the spin wave functions of triplet (T) and singlet (S) states.

For the multinuclear RP these Q_{ab} values are

$$Q_{ab}(T_0 - S) = \tfrac{1}{2}\left[\Delta g\mu_B H + \sum_i i m_i^a - \sum_j j m_j^b\right], \quad (1)$$

$$Q_{ab}(T_+ - S) = -\left(\tfrac{1}{8}\right)^{1/2} a_i\left[I_i(I_i+1) - m_i(m_i-1)\right], \quad (2)$$

$$Q_{ab}(T_- - S) = \left(\tfrac{1}{8}\right)^{1/2} a_i\left[I_i(I_i+1) - m_i(m_i+1)\right], \quad (3)$$

where the first describes the contribution of the T_0-S transition to the total rate of T–S conversion, the other two give the contributions of T_+-S and T_--S transitions; T_0, $T_\pm$ are the substates of the triplet spin state, with different electron spin projections: 0 for T_0 and ±1 for $T_\pm$ respectively. The term $\Delta g\mu_B H$ is the difference of Zeeman energies of the radical partners; Δg is the difference of their g-factors, $\Delta g = g_1 - g_2$; μ_B is the Bohr magneton; H is the strength of magnetic field; a_i and a_j are the HFI constants for the i-th and j-th kind of nuclei, with spins I_i and I_j: m_i^a are the quantum numbers of the projections of the nuclear spins I_i in the first radical of the pair and m_j^b are those for its partner.

It follows from Eqns (1)–(3) that the rate of triplet–singlet conversion (and consequently the probability of chemical reaction in the RP) depends firstly on the magnetic field strength H through the difference in electron Zeeman energies $\Delta g\mu_B H$; secondly on the nuclear magnetic moments through the HFI constant a, since $a = (8\pi/3)\mu_e\mu_n|\psi(0)|^2$, where μ_e and μ_n are the magnetic moments of the electron and nucleus, $|\psi(0)|^2$ is the electron spin density at the nucleus; thirdly on the nuclear spin orientation I_z through the quantum numbers m_i^a and m_j^b.

The reaction probability of the RP may be represented in the closed form as $P = F(H, a, I_z)$. This compact formula embodies the three main magnetic effects of the first generation (see Fig. 1*b*).

III. First generation of magnetic effects

1. Magnetic field effect

The modern theory of the MFE, based on the extended spin dynamics, identifies two main MFE sources.

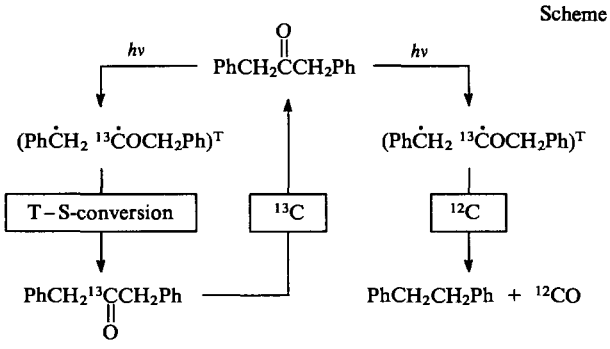
1. In zero and in very low magnetic fields the S and T spin states are almost degenerate and the spin conversion involves all four states (S, T_0, $T_\pm$). In high fields the degeneracy of triplet substates is lifted and the $T_\pm$ levels are separated from the S state by Zeeman interaction and excluded from the spin conversion, so that the rate of the triplet–singlet RP transformation is reduced to approximately one third of the rate in zero field.

If the starting spin state of the pair is singlet the magnetic field closes the $S-T_\pm$ channels and partly locks the pair, increasing its chance to react. Conversely, if the starting state is triplet the magnetic field switches off the T–S conversion and partially suppresses (by about 60%) intra-pair chemical reactions.

The $T_\pm-S$ spin conversion is induced by HFI (usually in the 1–150 G range),† and therefore even these low magnetic fields ($H \approx a$) are sufficient to decouple electron–nuclear spin subsystems and produce marked and even multiple changes in reaction rates.

† 1 G = 10^{-4} T.

2. The rate of spin conversion by the T_0-S channel is magnetic field dependent according to Eqn (1). As in the previous case, the sign of the MFE is a function of the starting spin state: the magnetic field enhances the leakage of the reactive singlet pairs into nonreactive triplet pairs, and has the opposite effect on triplet pairs. As a result the magnetic field accelerates the reactions starting from triplet pairs (and triplet RP precursors) and hinders the reactions in singlets and in their precursors.



These two sources of MFE are easily distinguished because of the difference in their response to changes in the magnetic field: the field dependence for the MFEs originating from $T_{\pm}-S$ spin conversion channels reaches saturation at $H \gtrsim a$, while the magnitude of MFEs induced by T_0-S conversion varies monotonically with the magnetic field. For the RP with short-lived radicals (life-time $\tau \ll |Q_{ab}|^{-1}$) the effect is proportional to $(\Delta g \mu_B H)^2$, whereas for long-lived RPs ($\tau \gg |Q_{ab}|^{-1}$) the effect is proportional to $(\Delta g \mu_B H)^{1/2}$.[5] Furthermore it is evident that the signs of MFEs arising from these two sources are opposite; this provides an important criterion for identifying the spin states of the RPs and their precursors through the sign of the MFE.

2. Magnetic isotope effect

The coupling between chemical species or spin carriers (between radicals, in particular), being electron spin selective, must also be nuclear spin selective, since the two spin subsystems (electronic and nuclear) are coupled by Fermi HFI interaction. The nuclear spin system affects the magnetic behaviour of the electron spin system, thus influencing the chemical reactivity. The nuclear spin selectivity of chemical reactions produces a difference between the reaction rates of radicals (or, in general, of any other spin bearing chemical species) having magnetic or nonmagnetic nuclei. The name magnetic isotope effect (MIE) has been suggested by the present writer for this phenomenon, in contrast to the well known classical isotope effect (CIE) which follows from the nuclear mass selectivity of chemical reactions.[4,7]

A striking result of the MIE is the chemically induced separation of magnetic from nonmagnetic isotopes. MIE-induced isotope selectivity may be clearly exemplified by the photolysis of dibenzylketone (DBK), which is known to occur via the fragmentation of the excited triplet molecule and generation of a triplet RP (Scheme 1). The triplet RP can either undergo triplet–single spin conversion (driven by HFI) and recombine, recreating the starting ketone, or it can dissociate into the separate radicals $Ph\dot{C}H_2$ and $PhCH_2\dot{C}O$; the latter decomposes into $Ph\dot{C}H_2$ and CO. The main reaction products are dibenzyl $(PhCH_2)_2$ and carbon monoxide (Scheme 1).

Scheme 1

The rate of triplet–singlet conversion for magnetic RPs (i.e. the pairs with magnetic ^{13}C nuclei in benzoyl or benzyl radicals) is higher than that for nonmagnetic pairs (with nonmagnetic ^{12}C nuclei). Therefore the magnetic RPs will preferentially recombine and regenerate the starting ketone molecules, while the time lag of the triplet–singlet conversion in nonmagnetic RPs makes dissociation more likely for these pairs. As a result ^{13}C magnetic nuclei are accumulated in the ketone molecules, while carbon monoxide and dibenzyl are enriched in the ^{12}C nonmagnetic isotope. Thus, because of the difference in the rates of triplet–singlet spin conversion, the RPs can separate the nuclei according to their magnetic moments: they dispatch the magnetic and the nonmagnetic nuclei into the different chemical products.

MIE is a phenomenon of fundamental importance. It establishes a new chemical principle of isotope separation, it provides a new method of detection and identification of paramagnetic intermediates in chemical and biochemical processes, and it offers new ideas and approaches to problems in geochemistry, space chemistry, and molecular biology.[4,6,7]

3. Chemical polarisation of nuclei

Chemically induced dynamic nuclear polarisation (CIDNP) is the result of the nuclear spin selectivity of chemical reaction. The rate of T–S spin conversion according to Eqn (1) is a function of nuclear spin orientation, and therefore RPs which differ in nuclear spin orientation have different chemical reactivities. Hence the RP as a chemical reactor can not only separate magnetic from nonmagnetic nuclei (as it does in the MIE), but it can also assign differently oriented magnetic nuclei to different reaction products.

This is the first mechanism of CIDNP, which operates in high magnetic fields where the T_0-S channel of spin conversion is predominant. It selects the magnetic nuclei with respect to their orientations according to Eqn (1), and therefore the CIDNP is directly related to Δg and to a_i and to a_j.

The second CIDNP mechanism operates in low fields ($H < a$), where the $T_{\pm}-S$ channels also contribute to the RP spin evolution. The $T_{\pm}-S$ spin transitions are accompanied by reorientation of the nuclear spins, unlike the T_0-S transition which selects only the oriented nuclei without changing their alignment.

An excess of nuclear spins oriented with or against the field in the product molecules corresponds to overpopulation of the lower or the upper Zeeman nuclear levels respectively (for ^1H, ^{13}C, and ^{31}P nuclei with a positive magnetic moment). This non-equilibrium population manifests itself in the NMR spectra of the molecules as an anomalously strong absorption or emission, the latter corresponding to population inversion of Zeeman levels.

CIDNP is a well-known phenomenon, widely used as an efficient method of identifying reaction mechanisms and of detecting radicals and radical intermediates. CIDNP is a powerful means of defining the spin multiplicity of the radical pairs and of their molecular precursors, it can be used to separate radical from nonradical reaction pathways and to identify unstable intermediate products and reversible radical stages which cannot be detected by other methods. From the CIDNP kinetics we can determine the reaction rate constants, including those of fast reactions (10^8-10^9 s^{-1}). CIDNP can determine the signals of HFI constants in radicals in radicals and the spin-spin coupling constants in molecules, and it can also detect the hot, energy-rich radicals. The mechanisms of many types of chemical reaction have been studied by CIDNP and much valuable information has been collected.[8,9]

IV. Principles of chemical reception of microwaves

We should stress that the magnetic interactions do not influence the chemical reaction itself, i.e. that they do not affect the motion of chemically reacting atomic systems along the potential energy surface. Their effect is to switch the reaction from the spin-forbidden channels into spin-allowed ones, controlling the spin behaviour of the reactants (or vice versa, depending on whether the starting spin state of the reactants is spin-forbidden or spin-allowed). This statement applies to both the magnetic interactions (Zeeman, Fermi, dipolar, spin-orbital), specific to the reaction itself, and to the external electromagnetic fields and their influence on the spin-carrying reaction precursors (radical pairs in particular).

The principles of chemical reception of microwaves will be demonstrated by considering the RP example. The scheme of Zeeman energy levels of the RP is shown in Fig. 2. Let the pair be produced in a singlet spin state strongly coupled (for example, by HFI) with the triplet T_0 substate, so that the population of the mixed, ready-to-react ST_0 state is much higher than that of the T_+ or T_- substates. Resonant transitions between the T_0 and $T_\pm$ levels stimulated by an electromagnetic field (EMF) depopulate the reactive ST_0 mixed state and suppress the intrapair reactions, lowering the yield of reaction product from the singlet reaction channel. Conversely, if the starting spin state of the pair is triplet the reaction along the singlet channel depletes the population of the mixed ST_0 state: however, the $T_\pm - T_0$ pumping induced by the EMF additionally populates the reactive ST_0 state and increases the yield of reaction products. In general the EMF rearranges the spin system, switching the reaction between channels of different spin multiplicity and modifying the chemical reactivity of the RP as is found with other magnetic interactions.

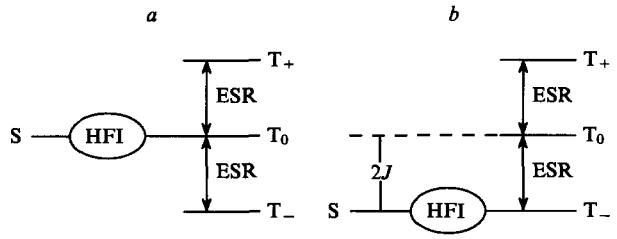


Figure 2. Microwave pumping of the Zeeman levels of a radical pair: (*a*) without exchange interaction ($J = 0$) the $T_\pm - T_0$ transitions stimulated by the EMF populate or depopulate (by hyperfine interaction) the ST_0 state; (*b*) in the presence of exchange interaction ($2J \approx g\mu_B H$) microwave pumping populates or depopulates the reactive mixed ST_- state. Possible ESR transitions are shown by arrows.

The exchange interaction J which appears at small inter-radical distances splits the S and T_0 levels, so that the T–S mixing now occurs only in the level crossing region (Fig. 2*b*), where $g\mu_B H \approx 2J$. However, in the spin evolution of the RP with distant partners the exchange interaction can be ignored. This situation is often met because the RP spends most of its lifetime in the state with remote partners.

Microwave pumping of the spin transitions modifies the rate of spin evolution of the RPs and therefore also their chemistry, providing a new principle of resonant, frequency-tuned chemical reception of microwaves. The change of the yield of products is the true chemical response to the perturbation of the reacting spin system by the EMF. (The frequency spectrum of the response is equivalent to the microwave absorption spectrum of the RP, and is therefore identical to its ESR spectrum.) Varying the external magnetic field H_0 allows us to detect the ESR spectrum of the RP by monitoring the yield of any product related to the reaction in the RP. Frankevich, who discovered the phenomenon, suggested the name Reaction Yield Detected Magnetic Resonance (RYDMR) for it.[10]

In order to visualise the spin transition induced by the EMF we shall consider the vector representation of spin dynamics in the radical pair.[2] To extract magnetic energy from the electromagnetic wave a particular polarisation is required: the magnetic vector $\vec{H}_1$ of the wave should lie in a plane normal to the permanent external magnetic field $\vec{H}_0$ (Fig. 3). The magnetic moment $\vec{M}_1$ of the spin carrier [assumed to have a spin $S = (1/2)\hbar$, so that $M_1 = (1/2)g_1\mu_B$] precesses with a Larmor frequency $\omega = \gamma H_0$ round the $\vec{H}_0$ magnetic field directed along the Z axis; $\gamma = g_1\mu_B/\hbar$ is the gyromagnetic ratio. The $\vec{H}_1$ vector of the EMF is directed along the Y axis: its value is $2\vec{H}_1 = 2H_1 \cos \omega t$. The total motion of the vector $2\vec{H}_1$ can be

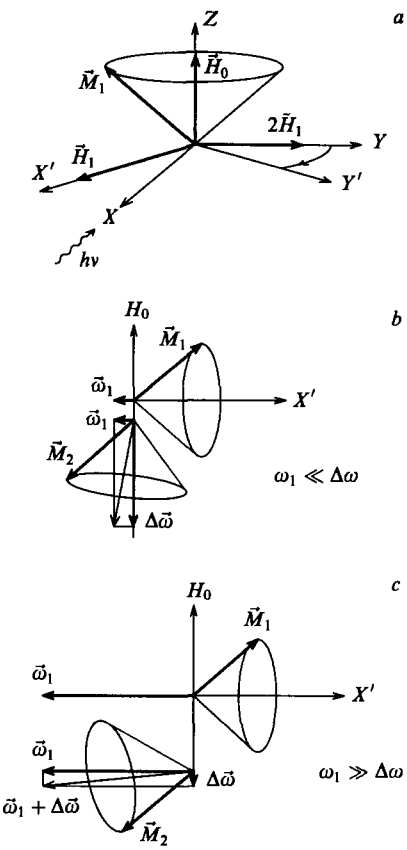

Figure 3. Vector diagram of the spin dynamics of a radical pair developed under the influence of the microwave field $\vec{H}_1$ (symbols defined in the text).

resolved into two circularly polarised vectors $\vec{H}_1$ rotating with a frequency ω in the XY plane in mutually opposite directions (Fig. 3*a*). One of these vectors, $\vec{H}_1$, rotating in phase with the Larmor precession appears to be motionless in a new frame of coordinates X', Y', Z chosen to rotate with the magnetic moment $\vec{M}_1$.

In this new, rotating frame the vector $\vec{M}_1$ experiences only the magnetic field $\vec{H}_1$ which is now permanent, and rotates round its direction with a frequency $\omega_1 = \gamma H_1$. This motion is equivalent to a periodic reorientation of the $\vec{M}_1$ vector with respect to the Z axis and therefore to $\vec{H}_0$. The magnetic moment $\vec{M}_2$ of the partner behaves similarly if the Larmor frequency of its precession is also equal to ω. These orientations are easily seen to correspond to $T_\pm - T_0$ spin transition.

We shall now assume that the magnetic moments $\vec{M}_1$ and $\vec{M}_2$ are not equivalent, owing to the difference Δg between their g-factors or to the hyperfine coupling a_2. Then the difference in the precession frequencies of the $\vec{M}_1$ and $\vec{M}_2$ vectors, $\Delta\omega$, is equal to $\Delta g\mu_B H_0/\hbar$ or $g_2\mu_B a_2/\hbar$ respectively. In the X', Y', Z frame rotating with the Larmor frequency of M_1 this vector is again motionless. However, the vector $\vec{M}_2$ now precesses with respect to $\vec{M}_1$ with a frequency $\Delta\omega$. This motion is equivalent to a $T_0 \rightleftarrows S$ spin evolution (Fig. 3*c*).

Switching on an EMF small enough (H_1) to satisfy the condition $\omega_1 \ll \Delta\omega$ stimulates the $T_0 \rightleftarrows T_\pm$ transitions responsible for the RYDMR phenomenon. At higher values of H_1, when $\omega_1 \geqslant \Delta\omega$, the vector $\vec{M}_1$ precesses round the vector $\vec{H}_1$ (or $\vec{\omega}_1$) as before, but the magnetic moment $\vec{M}_2$ now precesses round a total vector $(\vec{\omega}_1 + \Delta\vec{\omega})$ with a frequency $(\omega_1^2 + \Delta\omega^2)^{1/2}$ (see Fig. 3*c*). This means that the singlet–triplet spin mixing now takes place with new difference frequency

$$\Omega = (\omega_1^2 + \Delta\omega^2)^{1/2} - \omega_1 \approx \frac{\Delta\omega^2}{2\omega_1},$$

which is less than $\Delta\omega$ itself. This implies that at high enough EMF amplitudes the mw irradiation alters the spin behaviour of the radical pair: instead of stimulating triplet–singlet transitions it begins to suppress them. The spin state of the pair at high EMF amplitudes when $\omega_1 \gg \Delta\omega$ (see Fig. 3*c*) appears to be locked, so that the phenomenon is called spin locking. It manifests itself in distortion and ultimately in phase inversion of the RYDMR spectra.[11]

The jump of the $S-T_0$ mixing frequency from $\Delta\omega$ to $\Delta\omega^2/\omega_1$ can influence the properties of the mixed ST_0 state only under conditions such that the lifetime of the pair τ satisfies the relation $\tau < \omega_1/\Delta\omega^2$. Conversely, for $\tau \gg \omega_1/\Delta\omega^2$ the ST_0 mixing as well as the chemical properties of the pair will not depend on ω_1 and, therefore, on H_1 (spin scrambling). By varying ω_1 over wide limits and studying the dependence of the RYDMR spectra on ω_1 (or H_1) we may determine both $\Delta\omega$ and the lifetime τ of the radical pairs.[2]

V. Reaction yield detected magnetic resonance

The frequency spectrum of the chemical response to mw pumping is essentially the RYDMR spectrum, which may be recorded by monitoring any parameter of the chemical system under investigation providing that it is kinetically related to the RP reaction (and therefore to the population of spin substates of the pair). Among the most easily and precisely measurable parameters used to detect RYDMR spectra are the luminescence intensity, optical absorption, electric conductivity and radical concentration.

Electronically excited molecules able to emit from their singlet or triplet states (fluorescence or phosphorescence respectively) are usually produced by the recombination of ion-radical pairs (or, more precisely, by electron transfer reactions between partners). For example, the reaction between the ion radicals $D^{\cdot+}$ and $A^{\cdot-}$ may occur along singlet or triplet channels:

$$D^{\cdot+} + A^{\cdot-} \longrightarrow {}^1(D^{\cdot+}\,A^{\cdot-}) \longrightarrow {}^1D + A_0 \longrightarrow$$
$$\longrightarrow D_0 + A_0 + h\nu \qquad \text{(fluorescence)}$$

$$D^{\cdot+} + A^{\cdot-} \longrightarrow {}^3(D^{\cdot+}\,A^{\cdot-}) \longrightarrow {}^3D + A_0 \longrightarrow$$
$$\longrightarrow D_0 + A_0 + h\nu \qquad \text{(phosphorescence)}$$

The mw pumping of the singlet pairs stimulates their singlet–triplet conversion, thus suppressing the fluorescence in favour of the phosphorescence. Conversely, the mw pumping of triplet pairs induces the opposite effect. However, the intensity of fluorescence is usually small, and therefore fluorescence is seldom used to detect RYDMR spectra. Most of the RYDMR experiments are based on fluorescence intensity measurements.

Fig. 4 shows the RYDMR spectrum for the ion-radical pair $(M^{\cdot+}\ M^{\cdot-})$ generated by positron irradiation of a solution of naphthalene in squalane.[12] The reactions resulting in the formation and recombination of aromatic ion-radical pairs are:

$$S \longrightarrow S^{\cdot+} + e,$$
$$M + e \longrightarrow M^{\cdot-},$$
$$M + S^{\cdot+} \longrightarrow M^{\cdot+} + S,$$
$$M^{\cdot+} + M^{\cdot-} \longrightarrow M^* + M,$$

where S and M are solvent and aromatic molecules, respectively, $M^{\cdot+}$, $M^{\cdot-}$, $S^{\cdot+}$ are their cation and anion radicals, and M^* is the excited aromatic molecule (the fluorescence emitter). The pairs $(M^{\cdot+}\ M^{\cdot-})$ are mostly formed in the Onsager sphere and in the singlet spin state, so that their reaction product along the spin-allowed channel is an excited M^* molecule in the singlet spin state.

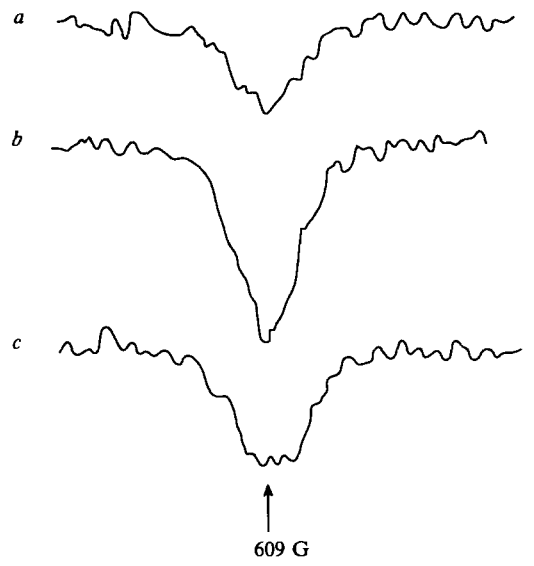

Figure 4. RYDMR spectra of an ion-radical pair [(naphthalene)$^+$/(naphthalene)$^-$] for a microwave pumping power of 1.3 (*a*), 3.8 (*b*), and 7.6 W (*c*).[12]

In order that the mw pumping may influence the spin evolution of the pair, two dynamic requirements must be satisfied:

$$\tau_{S-T_0} \lesssim (\gamma H_1)^{-1} \quad \text{and} \quad \tau_{RP} \approx (\gamma H_1)^{-1},$$

where H_1 is the amplitude of the mw field, $(\gamma H_1)^{-1}$ is the characteristic time of the mw-stimulated $T_0-T_\pm$ transitions, τ_{S-T_0} and τ_{RP} are the characteristic time of the $S-T_0$ spin evolution and of the lifetime of the ion-radical pair respectively.

The first relation ensures the fast $S-T_0$ transition and efficient chemical leakage of ion-radical pairs along the singlet channel, the second ensures that the pair undergoes mw-stimulated $T_0-T_\pm$ transitions before its disappearance.

The RYDMR signals (Fig. 4) are a single line with a halfwidth of 14 G, evidently due to the unresolved hyperfine structure of positive and negative naphthalene ion radicals, since the total HFI splitting is comparable to the width of the line. The centre of the RYDMR spectrum lies at 609 G, which corresponds to the *g*-factor of aromatic ion radicals at an operating frequency of 1704.6 MHz.

The optically detected RYDMR spectrum with resolved HFI splitting shown in Fig. 5 belongs to the ion-radical pair $(M^{\cdot+}\ M^{\cdot-})$, where M is biphenyl, generated under conditions similar to those used to generate the naphthalene ion-radical pair.[13]

As well as the radical–radical interactions, the chemical and physical processes in triplet–triplet and triplet–doublet pairs can be studied by the RYDMR technique in liquids and in molecular solids. The dynamics and mechanism of the triplet exciton annihilation and the quenching of triplet molecules by radicals and other spin carriers can also be elucidated by this technique. The mw pumping changes the population of the Zeeman spin levels in T–T or T–D pairs (as it does in D–D pairs) and thus controls the intensity of the prompt or the delayed fluorescence.[14]

The scheme of spin levels and mw-stimulated interlevel transitions in a pair of triplet excitons is shown in Fig. 6 as an example. In a strong magnetic field H two of the nine spin states of the pair (SQ_1 and SQ_2) include singlet components with amplitudes equal to $\frac{1}{2}$ and $\frac{2}{3}$ respectively. The singlet components of these states are mixed with the components of the quintet state, but the other states of the two-triplet pair ($Q_{\pm1}$ and $Q_{\pm2}$) are pure triplets and quintets.

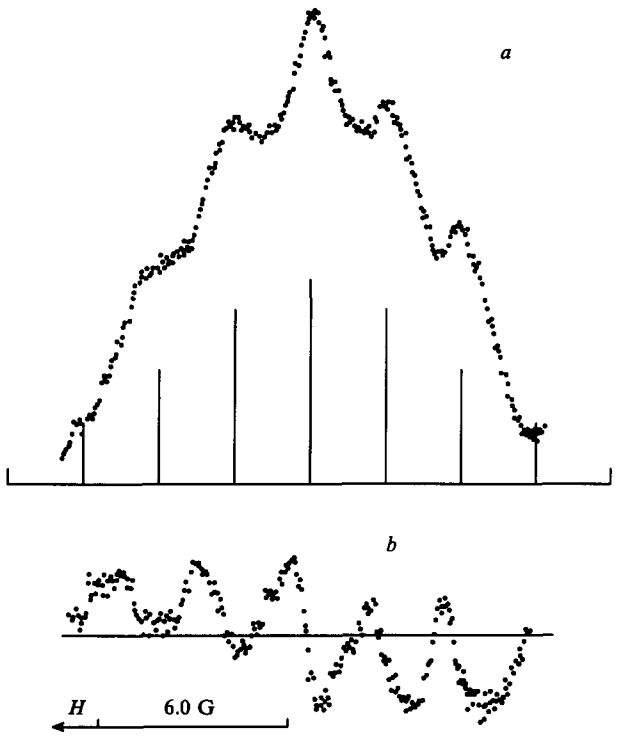

Figure 5. RYDMR spectrum of the (biphenyl)$^+$ – (biphenyl)$^-$ radical pair (*a*) and its first derivative (*b*).[13]

Upon exposure to a resonant mw field, transitions involving a change in the projection of the magnetic quantum number m by $\Delta m = \pm 1$, with the total spin S preserved ($\Delta S = 0$) are allowed. These transitions, shown by arrows in Fig. 6, increase the population—the SQ_1 and SQ_2 states which generate the annihilation product: the excited molecule which emits the fluorescence.

The mw-stimulated spectrum of the triplet exciton pair detected by the prompt fluorescence of the tetracene molecule in a tetracene single crystal is shown in Fig. 7 for

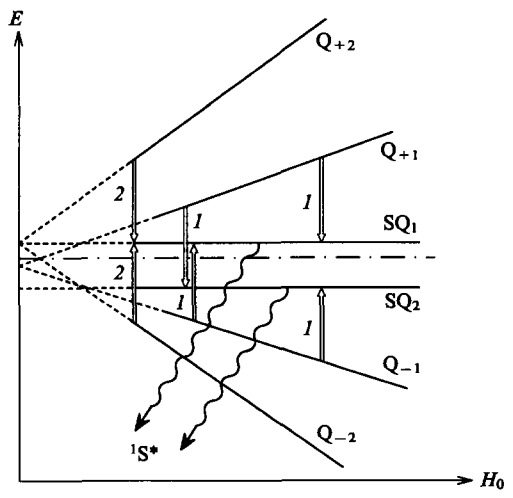

Figure 6. Energy level diagram of a triplet molecule pair: the Q levels are pure quintet states, SQ_1 and SQ_2 are levels of mixed quintet – singlet states. Triplet-levels do not contribute to the spin transitions and are not shown in the diagram. The arrows indicate transitions which populate the mixed SQ states and the formation of a source of fluorescence (the $^1S^*$ molecules).

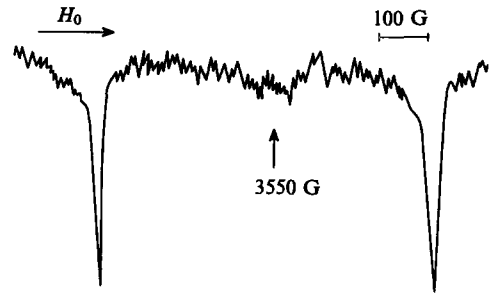

Figure 7. RYDMR spectrum of a pair of triplet excitons in a tetracene single crystal, detected by the prompt fluorescence.[15]

one particular orientation of the crystal with respect to the magnetic field.[15]

RYDMR spectra have been observed in studies of excitons and of charge-transfer complexes in liquids and in solids, F-centres in alkali halide crystals, electron-hole pairs in amorphous semiconductors, the reaction centres in photosynthetic systems, etc.[2,5]

The sensitivity of the RYDMR technique can be estimated. The relative variation $\Delta\gamma$ in the yield of the reaction in pairs produced by resonant mw-induced transitions is determined by the product of the probability P of the transition under the action of mw magnetic field H and of the lifetime τ of the pair:

$$\frac{\Delta\gamma}{\gamma} = \varkappa P\tau \,. \tag{4}$$

For a radical as a particle with a spin of $\frac{1}{2}$

$$P = \frac{1}{2}\left(\frac{g\mu_B}{\hbar}\right)^2 \frac{H_1^2\tau}{1 + (g\mu_B/\hbar)(H_0 - H_{res})} \,. \tag{5}$$

The coefficient $\alpha \leqslant 1$ determines the relative variation in the yield γ if the multiplicity of the pair is completely changed. At resonance ($H_0 = H_{res}$)

$$\frac{\Delta\gamma}{\gamma} = \alpha\omega_1^2\tau^2 \,, \tag{6}$$

where $\omega_1 = (g\mu_B H_1/\hbar)$. It is easily seen that for pairs with a lifetime $\tau = 5 \times 10^{-9}$ s a value of $\Delta\gamma/\gamma$ of about 1% is achieved for $H_1 = 1$ G at $\alpha = 1$. The very high sensitivity of the RYDMR technique is strikingly illustrated for the aromatic ion-radical pairs in liquids. They are generated at the rate of 2×10^8 s^{-1}, and have a lifetime of 10^{-7} s,[12] and hence the average concentration of the radical pairs available for detection by fluorescence intensity measurements is about 20 per sample, i.e. well below the sensitivity limit of modern ESR spectroscopy ($\sim 10^{11}$ spins per sample).[12]

The RYDMR spectra can be detected also by the optical absorption of triplet molecules produced by the pair-wise coupling of ion-radicals along the triplet channel. These molecules are usually sufficiently long-lived to be accumulated in measurable amounts and monitored by the triplet–triplet absorption of the probing light (in pulse excitation experiments, in particular).

The dissociation of ion-radical or electron-hole pairs produces free charge carriers in concentrations which are susceptible to the mw pumping of the pairs. Therefore RYDMR spectra can be also recorded by monitoring the electric conductivity both in crystals and in liquids.[2] Similarly, the dissociation of pairs of neutral radicals in solutions generates free radicals. This process is spin-independent, but it competes with the spin-selective intrapair coupling, and therefore the yield of free radicals which have escaped recombination should be as

sensitive to the mw pumping as the recombination itself (but, of course, in anti-phase).

RYDMR spectra detected by counting free radicals were first reported by Okazaki et al.,[16] who studied the photoreduction of menadione (MD, 2-methylnaphthoquinone) in sodium dodecyl sulfate (SDS) micelles. The reaction includes the removal of a hydrogen atom from the SDS molecule by the excited MD in triplet state:

$$^3MD + SDSC \longrightarrow (\dot{M}DH\ \dot{S}DS) \begin{cases} \longrightarrow \text{coupling products} \\ \longrightarrow M\dot{D}H + \dot{S}DS \end{cases}$$

Only $\dot{S}DS$ radicals are trapped by the added water-soluble nitroso spin trap TNO (perdeuterodimethylnitrosobenzene sulfonate) because the chemical reactivity of the spin trap towards the semiquinone radical $M\dot{D}H$ is negligibly low. The yield of the stable spin adduct [the nitroxyl radical T(SDS)NO] measured by ESR was shown to decrease under mw-pumping (in keeping with the reaction scheme). Indeed, stimulating the triplet-singlet conversion of the RP by resonant mw irradiation induces chemical annihilation of the pair. As a result, the leakage of free radical out of the pair (and consequently the yield of spin adduct) decreases quite noticeably, as shown by Fig. 8. The largest reduction in the yield reaches 8% for the photolysis of protonated SDS micelles and about 14% if the photolysis is carried out in deuterated micelles. The magnetic field dependences of the mw-stimulated chemical response are in fact RYDMR spectra detected by radical escape measurements. The difference in their hyperfine structure confirms the difference in isotopic composition of one of the RP partners: the SDS radical, in which hydrogen nuclei are replaced by deuterons.

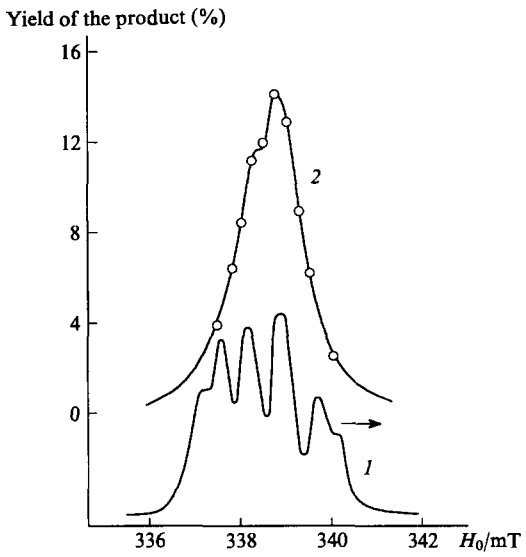

Figure 8. Dependence of the yield of the spin adduct under microwave pumping on the strength of the magnetic field H (or RYDMR spectra) for the photolysis of menadione in SDS (*1*) and deutero-SDS micelles (*2*).[16]

VI. Radio induced magnetic isotope effect

As a means of resonant chemical reception of microwaves RYDMR is nonselective because all the RPs are subjected to the mw perturbation. If the mw pumping is selective with respect to magnetic nuclei it induces a new, Radio Induced Magnetic Isotope Effect (RIMIE). The microwave irradiation of magnetic RPs should accelerate their spin conversion and stimulate their pair-wise reactions (usually recombination), enhancing the nuclear isotope selectivity induced by MIE of the first generation.

The concept of the RIMIE was clearly formulated[17] in 1981 and experimentally embodied[18] in 1991 in the photolysis of dibenzyl ketone (DBK) in SDS micelles. The photolysing laser pulses were synchronised with the mw pulses, and their lengths were chosen so that the RP generated by short laser pulses were exposed to the mw pulse throughout their life time. The frequency of the mw irradiation was chosen to pump selectively only the magnetic RPs [$Ph\dot{C}H_2$ $^{13}\dot{C}(O)CH_2Ph$], while the non-magnetic RPs [$Ph\dot{C}H_2$ $^{12}\dot{C}(O)CH_2Ph$] remained unperturbed by the microwaves (see Scheme 1).

The isotope enrichment S of dibenzyl ketone as a function of chemical conversion is described by the expression

$$\ln S = (1-\alpha)\ln(1-f^*), \qquad (7)$$

where $S = \delta/\delta_0$, δ_0 and δ are respectively the ^{13}C content in the starting ketone and in its residue after the chemical conversion of the 'magnetic' ketone $PhCH_2{}^{13}C(O)CH_2Ph$ has reached the value f^*.[4] The coefficient α is the efficiency of the isotope separation (a one-step enrichment coefficient similar to that introduced by Bernstein[19] for the classical, mass-dependent isotope effect).

The experimentally measured isotope enrichment S of DBK as a function of $1-f^*$ in the parameters of Eqn (7) is shown in Fig. 9. As can be seen the one-step enrichment coefficients are different: for the photolysis in the presence of mw $\alpha_{mw} = 1.25 \pm 0.01$, while without mw pumping we have $\alpha_0 = 1.21 \pm 0.01$. Thus the mw irradiation is found to increase the isotope selectivity in the RP and the isotope enrichment of the recovered ketone.

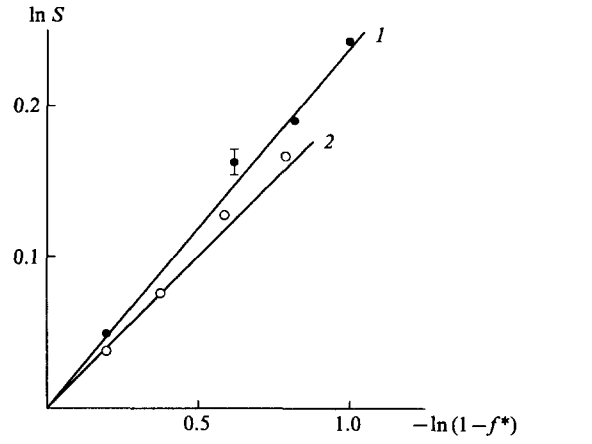

Figure 9. Isotope enrichment S as a function of the chemical conversion f^* of ^{13}C dibenzyl ketone in the coordinates of Eqn. (7):[18] (*1*) with microwave pumping (H_1 = 4.5 G); (*2*) without pumping.

The net contribution of the mw pumping to the recombination probability of the magnetic radical pair is about 6%. This value seems too small at first sight, but allowance should be made for the unfavourable experimental conditions. Firstly, the pumping of only one RP was carried out, which reduces the efficiency of mw irradiation at least two-fold. Secondly, the low amplitude of the mw pumping (H_1 = 0.3 mT) corresponds to the characteristic time of the mw-induced electron spin flip (the time of equilibrating the populations of $T_\pm - T_0$ spin levels) $\tau_{mw} = (\gamma H_1)^{-1} = 120$ ns. It is much larger than the time interval between radical reencounters in the radical pair (τ_{enc} = 136 ns), so that the pair has not enough time between reencounters to complete the mw-induced spin reorientation, and therefore the $T_\pm - T_0$ transition. This unfavourable relation ($\tau_{mw} > \tau_{enc}$) is probably the main reason for the relatively low efficiency of the mw pumping in the isotope selection. High amplitude microwave pumping would be desirable to bring τ_{mw} closer to τ_{enc} in order to equilibrate the

populations of the $T_{\pm}$ and T_0 states of the radical pair before the moment when the probing contact of the partners takes place.

From this viewpoint the spin locking regime for the nonmagnetic pairs ($PhCH_2$ $^{13}C(O)CH_2Ph$) is thought to be favourable to the separation of isotopes, since it prevents their recombination and thus increases the efficiency of isotope selection. A combination of the two regimes (spin locking for the nonmagnetic pairs and stimulating microwave pumping for the magnetic pairs) would be most efficient.

In these experiments the ideal selectivity of mw pumping is achieved, because the ESR transitions of 'magnetic' and 'nonmagnetic' RP do not overlap and are separately accessible to the pumping action. The radio induced magnetic isotope effect with partially selective pumping was observed by Okazaki et al.[20] even earlier (in 1988) in the photolysis of menadione in SDS micelles consisting of a mixture of protonated and of deuterated sulfonate molecules in a 1 : 1 ratio. The RYDMR spectra of this system were detected from the yield of SDS radicals (see Section V), taken up by the spin trap and measured as nitroxyl radicals. The spectra are shown in Fig. 8: their overlap prevents the separate pumping of the isotopic forms of the radical pairs, but even with joint, nonselective pumping the yields of protonated and of deuterated SDS are markedly different.[20]

VII. Microwave stimulated nuclear polarisation

Stimulated Nuclear Polarisation (SNP) is the result of mw pumping of ensembles of RPs with selected orientations of the nuclear spins. It is similar to CIDNP, the only difference being that in CIDNP the nuclear spin selection in the RPs via triplet-singlet conversion is accomplished by existing magnetic interactions characteristic of the radicals, whereas in SNP the selection is produced by the resonant microwave field. Again, the radical pair acts as a selective chemical microwave receiver, but now the indicator of the reception is the nuclear polarisation in reaction products.[21]

In chemical reaction subjected to resonant (and therefore nuclear spin selective) mw pumping these two phenomena, CIDNP and SNP, can coexist, so that the experimentally measured NMR spectrum of the product molecules displays both contributions. The experimental technique which can distinguish between them by performing the pumping and the detection separately in time and space was developed by Sagdeev and his coworkers,[26] the pioneers and leaders of SNP studies.[22–25] This technique eliminates the CIDNP contribution and measures the net nuclear polarisation, induced by mw pumping.

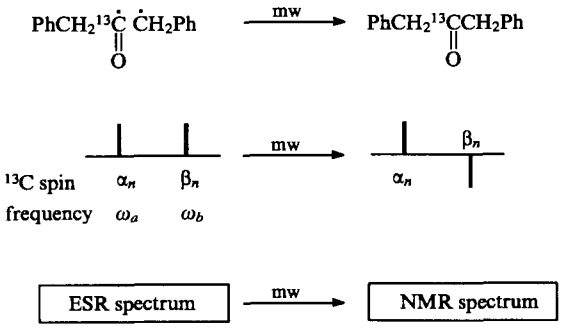

Figure 10. Development of SNP. The selective pumping of the ensemble of radical pairs with α_n and β_n orientations of the spins of ^{13}C nuclei at frequencies ω_a and ω_b accelerates their triplet-singlet conversion and transforms the ESR spectrum of the pair into the NMR spectrum of the molecule produced by its recombination (the molecule inherits the nuclear orientations of its precursor: the radical pair).[2]

The fundamental physics of the SNP phenomenon can again be clearly exemplified by the spin processes in the triplet radical pair [$PhCH_2{}^{13}C(O)CH_2Ph$], generated by the photolysis of DBK (Fig. 10). The ESR spectrum of the pair consists of a central group of lines (not shown in Fig. 10) which belong to the $PhCH_2$ radical, and of a doublet from the $PhCH_2{}^{13}CO$ radical with hyperfine splitting $a(^{13}C)$. Since $a(^{13}C)$ is known to be positive, the low-field line of the doublet is attributed to the ensemble of RPs with ^{13}C nuclei oriented with the field (α_n, spins on the lower Zeeman level), whereas the high-field line belongs to the ensemble with ^{13}C nuclei oriented against the field (β_n, spins on the upper Zeeman level). The fast intersystem T_0-S conversion induced by the HFI equalises the populations of these two spin levels. The mw pumping of the ESR transitions in the first ensemble of pairs at a frequency ω_a stimulates the $T_{\pm}-T_0$ spin conversion and additionally populates the T_0 states of the pairs with nuclear spins α_n causing acceleration of their recombination and the dominant formation of the DBK molecules with α_n spins (the positive SNP). The mw pumping of the second RP ensemble with β_n nuclear spins at frequency ω_b selectively produces DBK molecules with ^{13}C nuclei having β_n spins (the negative SNP). As a result the mw pumping transforms the ESR spectrum of the radical pair into NMR spectrum of a molecule with polarised nuclei, or an SNP spectrum of the absorption-emission, A/E type (Fig. 10, absorption in the high-field component and emission in the low-field component).

As a physical phenomenon SNP offers a powerful method of investigating the chemical reaction mechanisms and of detecting their radical intermediates. This is clearly illustrated by the SNP in the photolysis of deoxybenzoin $PhCOCH_2Ph$ in SDS micelles.[22] The quantum yield of its photolysis is very low: the products are formed in undetectable amounts. In the ^{13}C CIDNP spectra no lines are produced by photolysis with the exception of a single line belonging to the carbonyl ^{13}C nuclei of the starting ketone. It shows strong emission and indicates reversible photochemical processes accompanied by the almost complete regeneration of the starting ketone, so that the reaction scheme is:

$$PhCOCH_2Ph \rightleftharpoons X,$$

where X is the unknown intermediate responsible for the CIDNP of this ketone.

Tarasov and Bagryanskaya[25] have studied the ^{13}C SNP in this system and interpreted the strong SNP spectra (Fig. 11) as a superposition of two doublets. The first (A/E, with a splitting of 120 G) has been attributed to the acyl radical $Ph^{13}CO$, whereas the second, a poorly resolved A/E doublet with a smaller splitting (30 G), was attributed to the radical

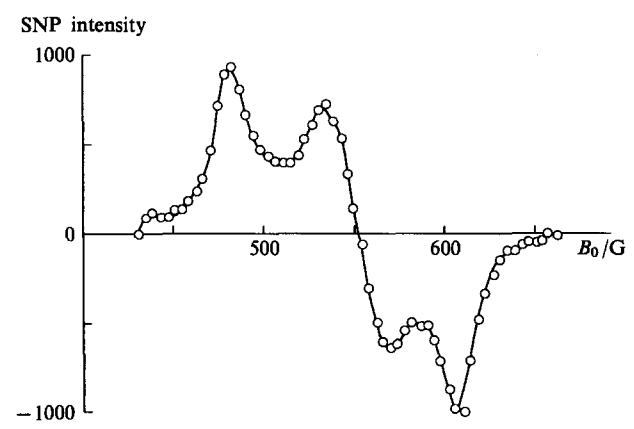

Figure 11. SNP spectrum detected during the photolysis of deoxybenzoin in SDS micelles.[25]

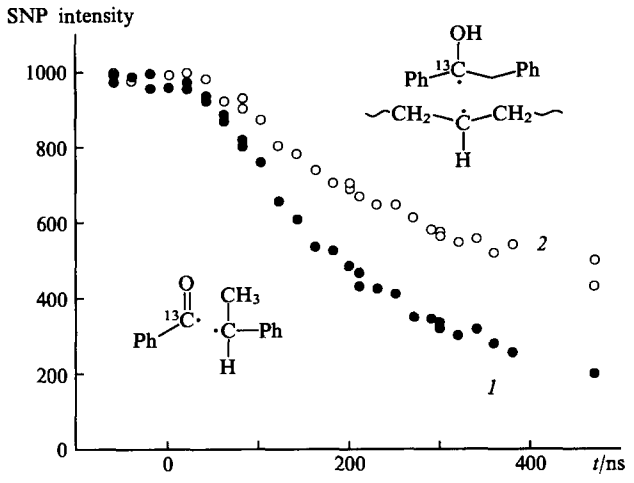

Figure 12. Kinetic behaviour of radical pairs generated by the photodissociation (*1*) and photoreduction (*2*) of deoxybenzoin in SDS micelles.[25]

$Ph^{13}C(OH)CH_2Ph$, the primary product of the photoreduction of the excited triplet ketone by the SDS molecule (RH). These SNP spectra suggest two competing paths for the photochemical transformation of deoxybenzoin: photodissociation and photoreduction via two different intermediates X {the radical pairs $(PhCOCH_2Ph)^T$ and $[PhC(OH)CH_2Ph\ R]^T$ respectively}. Both are highly reactive with respect to the ketone regeneration reaction, though their kinetic behaviour (Fig. 12) is different: the recombination is faster in the former than the disproportionation is in the latter.[25]

In stationary SNP detection the radical pairs are exposed to mw pumping throughout their lifetime. In time-resolved (TR) SNP experiments the laser and mw pulses are separated by the time delay τ_d, and therefore TR SNP offers a new possibility of influencing the ensembles of RPs with lifetimes in selected time domains but not shorter than the time resolution (about 30 ns in the best experiments by Sagdeev and coworkers[26–28]).

The study of the photolysis of benzoyl peroxide in CD_3OD [26] is a good illustration of the application of TR SNP. The reaction is known to involve a sequence of singlet RPs, including the pair $(PhCO_2Ph)$ which contains a phenyl radical not accessible by conventional ESR technique under standard conditions. The SNP spectra recorded at $\tau_d = 0$ (Fig. 13) show SNP of opposite signs for the cage (phenyl benzoate) and the escape (benzene) products, in excellent agreement with the reaction scheme and the SNP mechanism. However the TR SNP spectra taken with $\tau_d > 50$ ns are found to be completely inverted for both products. This is because, in the time domain of 50–200 ns, in which the inverted TR SNP spectra have been observed, the SNP is generated in the diffusional RPs such as $(PhPh)$ or $(PhCD_2OD)$. The sign of the SNP in these pairs is the same as in triplet RP. At times $\tau_d < 50$ ns the SNP is completely attributed to the geminal RP $(PhCO_2Ph)$ in the singlet state. The phase inversion as a function of τ_d is shown in Fig. 13*b*: two time domains corresponding to SNP in geminal and in diffusional radical pair ensembles are clearly shown.

A micelle (a microreactor with a boundary surface) confines the RP in a restricted volume. Hence the interradical exchange energy J in micellised RP should be a function of the micelle size, so that the SNP spectra, being sensitive to J, are in fact probes which monitor the exchange energy in RP.

A convincing confirmation of this statement was given by Tarasov et al.,[29] who studied the photolysis of methyldeoxybenzoin (99% ^{13}C abundance in the carbonyl group) in micelles of varying size controlled by the number n of carbon atoms in the detergent molecule $CH_3(CH_2)_{n-1}SO_4Na$. As expected the SNP spectra were strongly dependent on n and therefore on the micelle size (Fig. 14). Both the line broadening and the decrease in doublet splitting are evidence of an increase in J in the

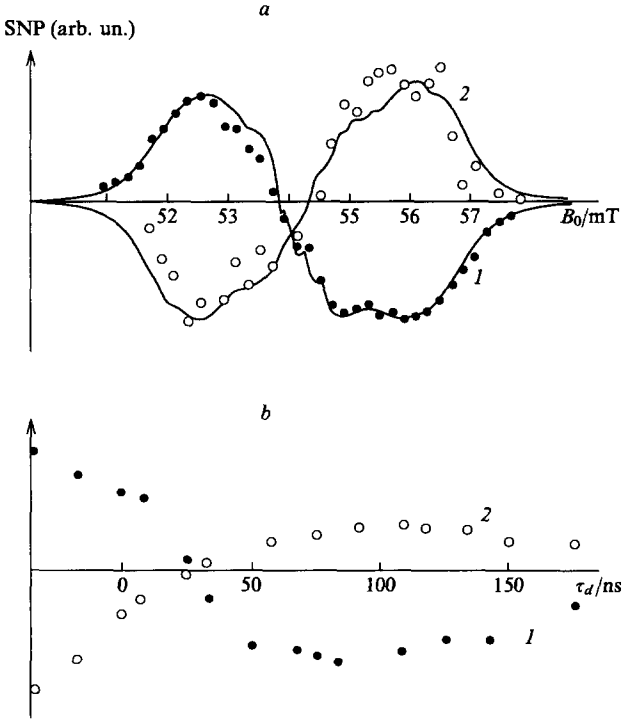

Figure 13. TR SNP spectra of phenyl benzoate (*1*) and benzene (*2*), detected by ^{13}C NMR during the photolysis of benzoyl peroxide (*a*), and their phase inversion as a function of τ_d (*b*).[26]

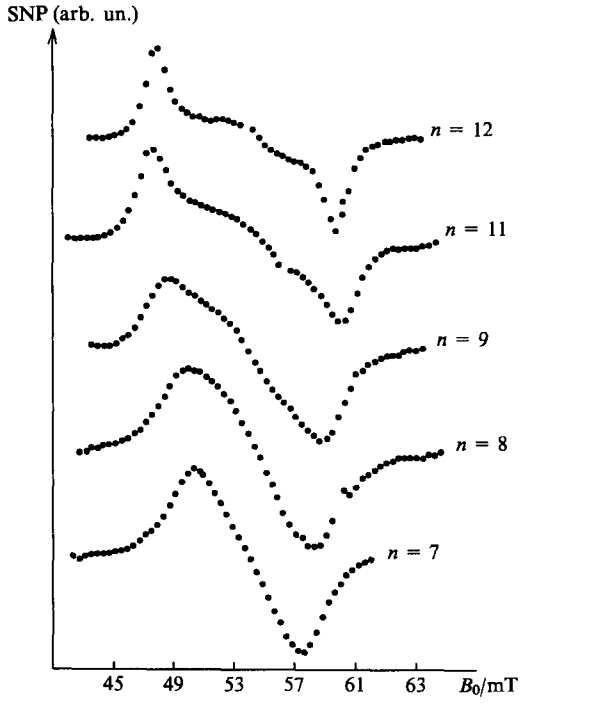

Figure 14. ^{13}C SNP spectra of the radical pair generated by photodissociation of deoxybenzoin in micelles of different size (n is the number of carbon atoms in the detergent molecule).[25]

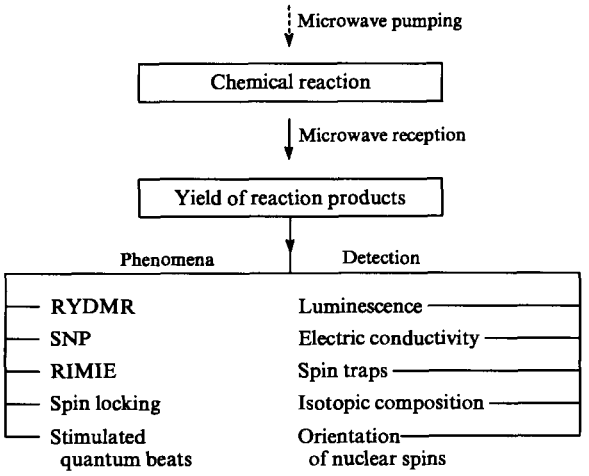
[Ph^{13}ĊO ĊHMePh] RP as the micelles become smaller. Only in SDS micelles (n = 12) J is negligibly small and the doublet splitting corresponds to the hyperfine coupling constant $a(^{13}C)$ in the PhĊO radical (124 G). The doublet splitting and the J values are given below:[29]

n	$a(^{13}C)$/mT	J/mT
12	12.4	<0.1
11	12.0	0.5
9	10.0	3.4
8	8.4	8.0
7	7.6	14.0



This information is of value for constructing the potential energy surfaces of the interradical reactions and for calculating the spin dynamics and the magnetic effects more exactly.

The strategy of magnetically probing the exchange potential (by SNP spectroscopy, in particular) along the reaction coordinate of chemical bond formation or dissociation is an important supplement to the transition state spectroscopy based on the femtosecond time-resolved optical spectroscopy developed by Zewail.[30] The difference is that femtosecond spectroscopy probes the transition state at short interatomic distances, where $J \gg kT$, whereas magnetic probing deals with the long-distance exchange potential ($J \ll kT$). From this point of view microwave magnetic probing can be treated as the radio spectroscopy of the transition state (the analogue of Zewail's transition state optical spectroscopy).[31]

VIII. Conclusion

Magnetic interactions (as a principal factor in the magnetic scenario of chemical reactions) regulate the spin dynamics and control the spin multiplicity of the radical pairs (as well as the pairs of other spin bearers), and therefore they also control their chemical reactivity. Electromagnetic fields influence the spin dynamics as a new factor which plays new scenes and initiates new phenomena: RYDMR, SNP, RIMIE, spin locking, quantum beats (the latter is beyond the scope of this paper). These remarkable magnetic effects of the second generation are schematically summarised in Scheme 2 as indicators of the chemical reception of radiowaves and microwaves.

Scheme 2

Abstract. The results of experimental studies of the dynamic surface tension and of the nonequilibrium surface electric potential of aqueous solutions of surfactants at various concentrations and temperatures are reviewed. Special aspects of the changes in these quantities as a function of the surface area are analysed. An equation of the thermodynamics of irreversible processes which relates the nonequilibrium properties of the surface to the adsorption and a correlation expression which relates the changes in surface tension to those in the surface potential are discussed. Methods of determining the adsorption mechanism are described. The bibliography includes 65 references.

I. Introduction

Many processes associated with the adsorption of surface-active substances (SAS), including separation, foaming, dispersion, wetting, etc., take place under conditions in which the surface layer and the bulk of the solution are not mutually in equilibrium. Therefore information on the nonequilibrium properties of the surface and on the kinetics of adsorption is needed in order to understand the mechanism of action of the SAS in natural and in technological processes.

Many studies of the kinetics of formation of adsorption layers have been published: this work is aimed mainly at the diffusion of the SAS from the bulk solution in the presence of complicating surface processes such as the electric interaction of the ions, the reorientation of the SAS molecules or ions, adsorption processes in the surface layer, etc. These results have already been extensively reviewed,[1-5] but more recent work aimed specifically at the measurement of the surface tension and the surface electric potential is not included. It should be stressed that the complexity of the nonequilibrium processes taking place on the surface make it impossible to allow for all the factors which affect the measurements. The lack of precision of the hydrodynamic models used to describe the kinetics of the adsorption adds to the unreliability of the results. Lastly, the difficulty met in the purification of the materials and the great sensitivity of the kinetics to a number of trace impurities should not be forgotten.

All these factors point to an urgent need for improving the existing methods of studying the surface properties of solutions and for discovering entirely new methods. The aim of the present review was to examine the results of the experimental and the theoretical studies of the relaxation of the two most important surface properties of solutions of SAS: their surface tension and their surface potential, and to analyse the methods of determining the adsorption mechanism of the SAS.

II. Experimental study of dynamic surface tension

The first experimental study of the dynamic surface tension of soap solutions was reported by Dupré.[6] In a study of the stability of soap films Rayleigh[7] measured the dynamic surface tension in a jet of soap solution, and showed that in a surface 'aged' for less than 0.01 s the surface tension has a value equal to that of pure water. Different methods of measuring the dynamic surface tension were developed in later work. The oscillating jet, the funnel, the falling meniscus, and other methods were used[4,8-12] to study the fast relaxation of the surface ($10^{-1}-10^{-2}$ s). Slower relaxations (seconds, minutes, hours) were studied successfully by using the maximum bubble pressure, the capillary wave, and some other methods.[4,11-13] The oscillating jet and the maximum bubble pressure method were used most widely.

The relaxation of the surface tension can usually be studied over a reasonably wide range of time by monitoring the maximum pressure in a gas bubble. However, it has been reported[2,12] that in the range of $10^{-3}-10^{-2}$ s the results become less reliable and need additional corrections. The oscillating jet method also requires corrections, both traditional (though often ignored) and recently identified. Let us examine this problem in greater detail.

1. Corrections in the oscillating jet method

The oscillating jet method[14] is one of the most fully developed and accurate dynamic methods. It was proposed by Rayleigh in 1879 as a method of measuring the surface tension of an 'almost ideally pure and continuously regenerated surface'.[7] The changes in shape of a jet emerging under pressure from a noncircular orifice had previously been studied by Bidon and by Magnus and Buff. When the jet emerges from a circular orifice its cross-section remains circular but decreases in area. The cross-section of a jet emerging from an elliptical orifice oscillates about the equilibrium circle because the capillary forces are tending to produce a cylindrical jet. Rayleigh showed how the surface tension is related to the wavelength λ of the oscillations and to other parameters of the jet.

Substantial developments in the theory of the oscillating jet method were introduced by Niels Bohr,[14,15] who allowed for the effects of the viscosity, of the finite amplitude of the jet oscillations, of the density of the surrounding medium, and of the hydrodynamic profile of the velocity within the jet. Eqn (1) shows the modern form of the Bohr formula for the surface tension γ:

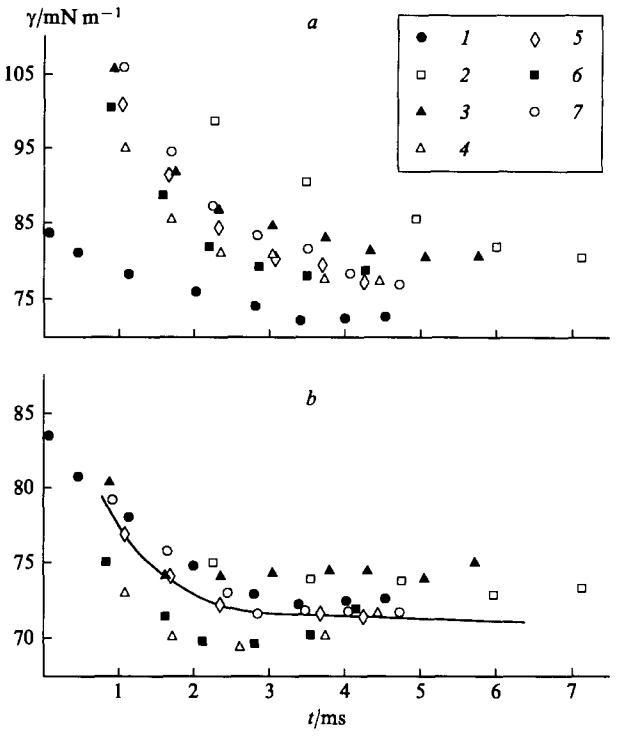
$$\gamma = \frac{4G^2(\rho+\rho_1)[1+(37/24)b^2/a^2]}{6a\lambda^2+10\pi^2a^3}K, \qquad (1)$$

where G is the volume flow of liquid, ρ is the density of the liquid, ρ_1 is the density of air, a is the mean radius of the jet, b is the amplitude of the jet oscillations, λ is the wavelength of the oscillations, and K is a coefficient which allows for the effect of the velocity profile in the jet.

The theory of the oscillating jet method requires as precise a description as possible of the form of the flow in the jet issuing from an elliptical orifice, i.e. we must define the velocity profile in the cross-section in order to calculate the correction K. The velocity is substantially greater at the axis of the jet than at its surface, especially near the origin of the jet. Rideal and Sutherland[16,17] pointed out that near the orifice the velocity of an element of the jet is 10% lower than the average velocity calculated from the flow of liquid. As a result of the viscosity of the liquid the scatter of the velocities gradually decreases along the jet.

While attempting to explain the effect of the flow hydrodynamics of the jet on the measured parameters, various workers[8-20] studied the dependence of the wavelength of the oscillations on the wave number, on the average velocity of the jet, and on the dimensions of the elliptical orifice. Semiempirical corrections have been introduced[21-25] to allow for the effect of the velocity profile on the dynamic surface tension. Thus, Hansen et al.[24] used the factor $V_s^{0.64}$ to correct for the wavelength of the fourth and subsequent waves, where $V_s = v_s/v_0$ is the ratio of the velocities of an element of the jet near the surface to the average velocity of the jet. A corresponding general expression for the first three wavelengths could not be obtained. However, Bohr[15] formulated the problem of the oscillations of a jet with a nonuniform velocity profile and proposed the following expression for the correction coefficient:

$$K \equiv \left[4\int_0^1 V(y,Z)y^3\,dy\right]^2, \qquad (2)$$



where

$$V(y,Z) = \frac{v_s}{v_0}, \quad y = \frac{r}{a}, \quad Z = \frac{\mu z}{\rho v_0 a^2}.$$

Here v_s is the axial velocity of the element of jet; $v_0 = G/\pi a^2$ is the average velocity of the jet; r is the radial coordinate; z is the axial coordinate (measured from the orifice where the jet is generated).

The present writers have calculated[26] the coefficient K. The theoretical velocity profile $V(y, Z)$ can be described by a Bessel function.[14] In calculations by formula (1) we used the initial velocity profile $V(y, 0)$ obtained experimentally[24] for a tube with a circular cross-section. Data on the velocity profile in a jet of liquid issuing from a capillary orifice have recently been published. A comparison of calculations of the K coefficient from the Bohr velocity profile[14] and from an experimental profile obtained by laser anemometry[27] gave adequately consistent results, tabulated in Ref. 26. The greater the distance z from the orifice, the closer to unity are the K values.

Special experiments[28] in which the dynamic surface tension was measured by using elliptical capillaries having different lengths and radii and different jet velocities showed that introducing the correction coefficient greatly lowers the scatter of the experimental data obtained in experiments carried out under different hydrodynamic conditions. Good agreement with the dynamic surface tension values determined by another method

Point	Length of capillary/cm	Radius of capillary/cm		v_0/cm s^{-1}
		r_{min}	r_{max}	
2	0.702	0.0211	0.0342	242.05
3	0.489	0.0297	0.0322	462.69
4	0.415	0.0160	0.0280	441.36
5	0.415	0.0160	0.0280	400.14
6	0.415	0.0160	0.0280	412
7	0.415	0.0160	0.0280	371

Figure 1. Dependence of the surface tension of water on time at 25 °C (*a*) without and (*b*) with allowance for the velocity profile in the jet. (*1*) from Ref. 29; (*2–7*) from Ref. 28.

(the falling meniscus method) is obtained (Fig. 1).[29] Applying the K coefficient to measurements[30] of the dynamic surface tension of carbon tetrachloride showed that in a simple liquid the dynamic and the static surface tension are identical, whereas in water and in aqueous solutions the two surface tensions are markedly different.

An additional correction is needed if the dynamic surface tension is determined by the oscillating jet method with an SAS solution rather than with a pure liquid.

The adsorption of the SAS at the liquid–gas interface can induce a marked elasticity of the surface, which influences the nature of the flow and of the oscillations of the jet of liquid in a way for which no allowance is made in the Bohr formula (1). In this case the difference between the true surface tension γ' and the value calculated by Eqn (1) is given by the formula[31]

$$\frac{\gamma'-\gamma}{\gamma'} = -\frac{2E(\pi g a v_0\mu/\lambda - E)}{g[E^2+(\pi g a v_0\mu/\lambda - E)^2]}, \qquad (3)$$

where $E = -(\Gamma\,d\gamma/d\Gamma)$ is the surface elastic modulus, Γ is the adsorption, $g \equiv (\pi a^2\mu_0\rho/\lambda\mu)^{1/2}$, and μ is the viscosity.

As E is increased (and therefore as Γ is increased and γ is decreased) the correction changes from zero to $-1/g$, after which it again approaches zero and changes sign at $E = gka\,v_0\mu/2$, then continues to increase, reaching $1/g$ as $E\to\infty$. According to our calculations[31] adding a correction to the experimental data for an aqueous solution of heptanol gives a satisfactory agreement between measurements of the surface tension by the oscillating

jet method and the adsorption potential jump method (in which the hydrodynamics of the liquid jet can be legitimately ignored).

Each measured value of the dynamic surface tension should be related to the age of the surface to which the measurement applies, whose accurate determination presents a separate problem.

The age of an element of fresh surface formed when the jet emerges from its orifice is defined by the expression

$$t = \frac{z}{v_s(z)}, \tag{4}$$

where z is the distance to the orifice and $v_s(z)$ is the velocity of the element of surface of the jet.

The quantity $v_s(z)$ can be determined, allowing for the velocity profile in the jet, by using Hansen's tabulations.[24,32] The error in the determination of the surface tension by formula (1) and of the age of the surface by formula (4) varies with the distance from the orifice. Near the orifice we usually find $\gamma \simeq \pm 2.5\%$, $t \simeq \pm 1\%$, and far from the orifice $\gamma \simeq \pm 1.5\%$ and $t \simeq \pm 0.1\%$.[26]

Let us examine some special features of the relaxation of the surface tension. The magnitude and the form of the change in the dynamic surface tension depend on the age of the surface, the composition of the solution, and the temperature. In different time intervals their rates of change can increase or decrease. The latter behaviour indicates the presence of an adsorption barrier.

On a young surface we also observe phenomena such as temperature and concentration inversion. The relaxation of the surface properties is also strongly influenced by the presence of inorganic salts in the SAS solutions.

2. Temperature inversion of the dynamic surface tension

For short growth times (1–3 ms) of water[29,33] and of binary solution surfaces[34,35] the surface tension increases with temperature (Figs 2–4), whereas on older surfaces it decreases with temperature, i.e. we see an inversion of the temperature dependence of the surface tension. However, in ternary water–SAS–salt systems the inversion is not always observed (see Figs 5 and 6). By comparing this behaviour with equilibrium data we conclude that an inversion of the temperature dependence of the surface tension is seen only rarely and only in solutions, where it can be attributed to differences in the temperature dependence of the adsorption (which affects the surface tension) and of the surface tension. On the other hand in pure liquids thermodynamic considerations allow only one type of dependence: a decrease in surface tension with increase of temperature. This is evident from the expression

$$\frac{d\gamma}{dT} = \tau\rho_s(s_\alpha - s_s), \tag{5}$$

where γ is the thickness, ρ_s is the molar density, s_α is the molar entropy of the bulk phase, and s_s is the molar entropy of the surface layer.[37] Under equilibrium conditions the entropy in the surface is higher than in the bulk, and therefore $d\gamma/dT < 0$.

It can be assumed that in surfaces departing only slightly from equilibrium, as in our measurements, the thermodynamic relationship (5) is valid (even if only qualitatively). In this case a positive value of $d\gamma/dT$ shows that the molar entropy of the layer is lower than the corresponding value for the bulk phase. However, we know[38] that under nonequilibrium conditions the dependence of γ on T is not the only reason for the difference between s_s and s_α.

A temperature inversion is observed in young surfaces, on which the adsorption is still far from equilibrium, and the dynamic surface tension of the solution of SAS is close to the dynamic surface tension of water and largely determined by the character of the relaxation of the surface structure of the water.

Special experiments with a jet of water showed[39] that heating the jet to 40–50 °C restores the equilibrium value in 3 ms. In water a temperature of 40 °C is known as the Mendeleev temperature, at which the network structure of the water is loosened, the activation energy of the electrical conductivity decreases, and the extent of dissociation increases. These processes also strongly increase the rate at which the equilibrium structure of the water surface is established upon increasing the temperature. For $T_1 > T_2$ we have

$$\left|\frac{d\gamma}{dt}\right|_{T_1} > \left|\frac{d\gamma}{dt}\right|_{T_2}.$$

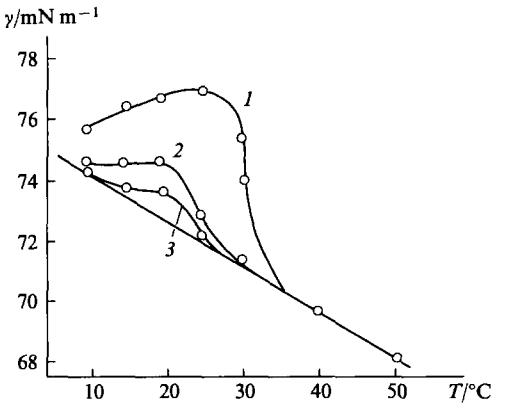


Figure 2. Temperature dependence of the dynamic surface tension of water. t/ms: (*1*) 1.4; (*2*) 2.2; (*3*) 3.0; the straight line corresponds to the equilibrium tension.

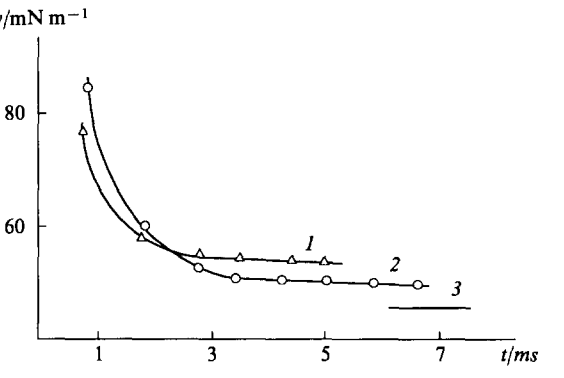

Figure 3. Dynamic surface tension in the water–sodium monobutylnaphthalenesulfonate system. c/mol dm^{-3} = 2.8 × 10^{-4}; T/°C: (*1*) 15; (*2*) 25; (*3*) $\gamma = \gamma_\infty$.

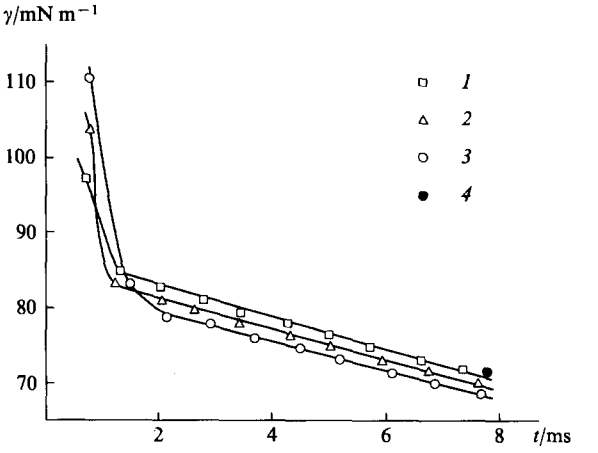

Figure 4. Dynamic surface tension in the water–cetyltrimethylammonium bromide (CTAB) system.[35] $c/10^{-4}$ mol dm^{-3} = 5.6; T/°C: (*1*) 15, (*2*) 20, (*3*) 25, (*4*) from Ref. 36.

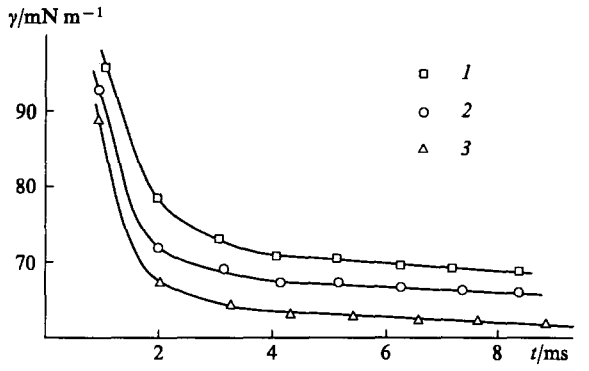

Figure 5. Dynamic surface tension in the water–potassium chloride–CTAB system.[35] $c_{KCl}/10^{-4}$ mol dm^{-3} = 5.6, c_{CTAB}/mol dm^{-3} = 0.56; T/ C°: (*1*) 15, (*2*) 20, (*3*) 25.

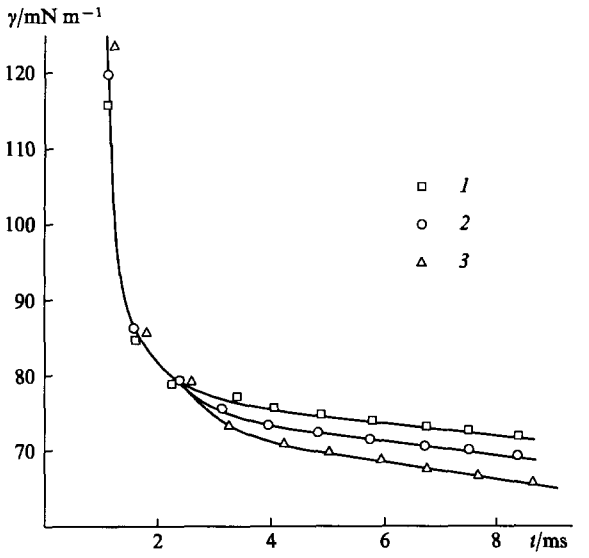

Figure 6. Dynamic surface tension in the water–potassium iodide–CTAB system.[35] c_{KI}/mol dm^{-3} = 0.56, $c_{CTAB}/10^{-4}$ mol dm^{-3} = 1.4. T/°C: (*1*) 15, (*2*) 20, (*3*) 25.

3. Conversion inversion of the dynamic surface tension

Fig. 7 shows the time dependence of the dynamic surface tension for water and aqueous solutions of cetyltrimethylammonium bromide (CTAB) at 25 °C. For t < 1.5 ms the rate of decrease of the surface tension is high and almost independent of the concentration of SAS. For $t \simeq 2$ ms the process becomes slower and the curves for different concentrations diverge (but intersect again at longer times). As a result the dynamic surface tension of SAS solutions at times between 1.5 and 6 ms is higher than that of water, and the effect is magnified as the concentration is increased. Under equilibrium conditions the surface tension of the solution of SAS decreases as the concentration is increased.

Thus under dynamic conditions we observe an inversion of the concentration dependence of the surface tension. A similar anomalous effect, in which the surface tension of the SAS exceeded that of the pure solvent during the initial period of adsorption, was observed by Thomas and Hall,[36] who attributed it to orientation effects involving the SAS molecules. As suggested, at high surface concentrations the SAS molecules 'inhibit' the orientation of their neighbours, and the higher the concentration, the slower is the molecular reorientation on the surface, with a corresponding decrease in the surface

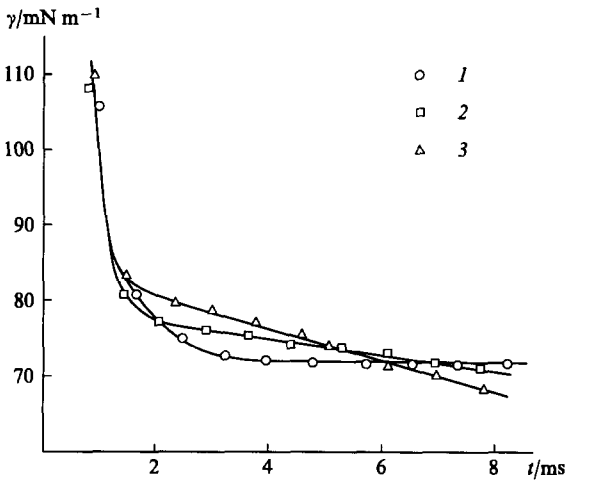

Figure 7. Dynamic surface tension in the water–CTBA system at 25 °C.[35] $c/10^{-4}$ mol dm^{-3}: (1) 0, (*2*) 2.8, (*3*) 5.6.

tension. Therefore as long as the structure of the surface layer differs substantially from the equilibrium structure the surface tension for high concentrations in solution remains higher than at low concentrations.

4. Effect of salts on the change in the surface tension of SAS solutions

In water–SAS–salt systems the ageing of a freshly created surface is accompanied by adsorption of the SAS, desorption of the salt, and relaxation of the properties of the solvent (water). The combined effects of these changes complicate the relaxation of the surface properties of the solutions.

Experiments[22,35] with water–salt solutions of SAS have shown that the addition of a salt accelerates the decrease in surface tension (Fig. 8).

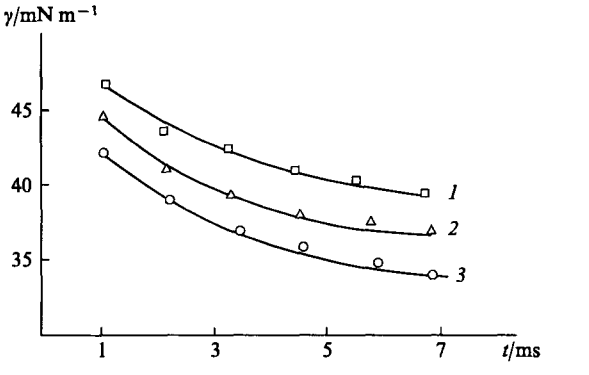

Figure 8. Effect of a salt on the dynamic surface tension of an aqueous solution of sodium dodecyl sulfate (c/mol dm^{-3} = 0.03) at 52 °C.[22] (*1*) no electrolyte; (*2*) c_{NaCl}/mol dm^{-3} = 0.03; (*3*) c_{MgCl_2}/mol dm^{-3} = 0.03.

The faster adsorption of the SAS produced by the desorption of the salt is explained by the salting-out effect of the salt itself, which increases with its concentration. This phenomenon is most clearly seen when the composition of the salt includes a structure-forming ion. It is evident from the results[35] reproduced in Fig. 9 that the addition of KI (a salt containing the strongly structure-forming iodide ion) accelerates the decrease in surface tension of a CTAB solution more markedly than the addition of KCl.

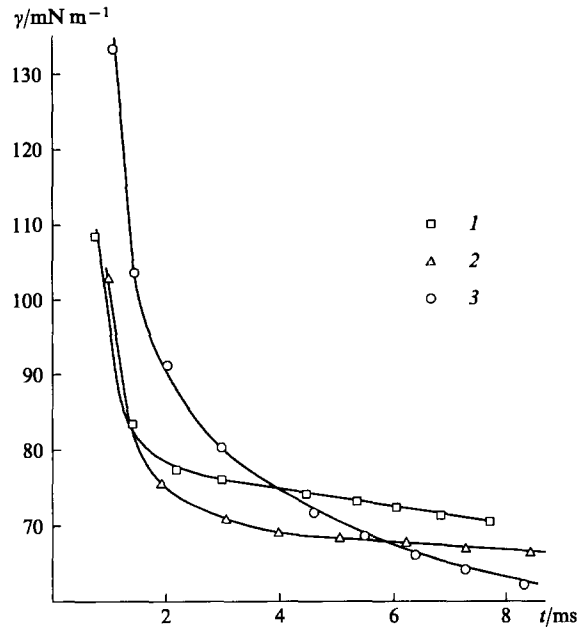

Figure 9. Effect of KCl and KI on the dynamic surface tension of an aqueous solution of CTAB at 25 °C.[35] (*1*) H_2O–CTAB; (*2*) H_2O–KCl–CTAB; (*3*) H_2O–KI–CTAB; $c_{CTAB}/10^{-4}$ mol dm^{-3} = 2.8, c_{KCl}/mol dm^{-3} = 0.56, c_{KI}/mol dm^{-3} = 0.56.

III. Experimental study of the nonequilibrium surface electric potential

The measurement of the electric potential of the surface is an independent method of studying the nonequilibrium properties of solution surfaces. The theory of the oscillating jet method is based on observing the flow and the vibrations of the jet emerging from an elliptical orifice, and relies on a number of assumptions. Unlike the surface tension, the surface potential is determined directly during the experiment (as opposed to being calculated from hydrodynamic equations). This offers some definite advantages in studies of the adsorption kinetics of SAS. The surface potential χ is the difference between the electric potentials at the boundary of two phases. In particular, at the solution–air interface χ is equal to the change in the electric potential between the air and the solution (treated as positive if the potential is increased, and negative if it is decreased on passing from the air to the solution). Being a Galvani potential the surface potential is not directly measurable. We can only determine changes in surface potential $\Delta\chi$ (for example, the time-changes caused by the ageing of a fresh surface or by changing the concentration of the solution). The change in surface potential seen on going from a standard to an experimental solution (containing additions of an adsorbable substance) is called the adsorption electric potential φ.

The methods most commonly used to measure $\Delta\chi$ or φ include the vertical jet method (Thomson–Kenrick), the radioactive probe method (Frumkin–Guyot), and the vibrating condenser method (Thomson–Zisman). The relaxation of a fresh surface is most conveniently studied by using a jet of liquid. In this case the age of the surface is easily calculable (as in the oscillating jet method), and the time-changes of the surface potential or of the adsorption potential can be determined without difficulty.

The adsorption potential of SAS is usually measured in solutions containing electrolytes as additives. Our measurements[40] on a liquid jet were aimed at monitoring the changes of the surface potential in aqueous solutions without added electrolytes. Furthermore the measurement method automatically excluded changes in the potentials of the measuring electrodes in air and in the solution during the experiment.[40] This was achieved by making measurements for a reference point at a fixed distance (in our experiments,[40] ~0.6 cm) from the orifice of the capillary which produced the jet. At this distance the surface potential has reached its equilibrium value and does not show any further changes along the jet. Thus we obtain from the experiment

$$\Delta\chi_t = \chi_t - \chi_0 , \qquad (6)$$

where χ_t is the surface potential for an element of surface of age t, [see formula (4)], and χ_0 is the surface potential at the reference point.

The adsorption potential φ_t for a surface of age t is determined from the difference $\Delta\chi_t$ between the experimental and the standard solution. Let us examine the results obtained in studies of the adsorption potential of various substances.

1. Alcohols

Several studies of aqueous solutions of normal primary alcohols (from propanol to decanol) have been reported.[41–46] The time interval needed to establish the equilibrium value of the potential is determined by the concentration of the solution and by the length of the hydrocarbon chain of the alcohol. As the molecular mass of the alcohol is increased, the concentration range in which a change in potential takes place at times between 2 and 20 ms is shifted towards lower values. An increase in the age of the surface makes the potential more positive (Fig. 10). The potential is relatively insensitive to changes in temperature: $d\varphi/dT \approx -0.0002$ V K^{-1}. A similar dependence was obtained[46] for the equilibrium potential.

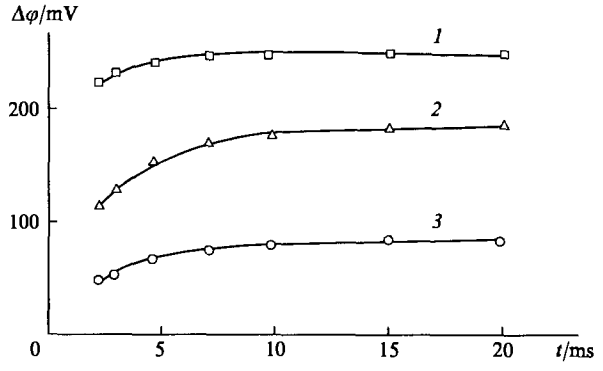

Figure 10. Adsorption potential step of solutions of hexanol in HCl (0.01 mol dm^{-3}) at 20 °C.[45] c/mmol dm^{-3}: (*1*) 10, (*2*) 4, (*3*) 2.

2. Aliphatic acids

Normal aliphatic acids are anion-active SAS. These electrolytes are weaker than the corresponding saturated alcohols: their surface activity is suppressed by the presence of the more polar carboxyl group.

Aqueous solutions of pentanoic, heptanoic, and octanoic acids have been studied in our laboratory.[47] In the lower homologues adsorption equilibrium is reached in less than 10^{-3} s, and the time dependence of the adsorption has not yet been established for these materials. On the other hand acids with a longer hydrocarbon chain (beginning with nonanoic acid) are very sparingly soluble in water, and meaningful measurements are not possible at the very low concentrations which are experimentally accessible. It is found that the adsorption of pentanoic acid is completed in 2×10^{-3} s, and that the equilibrium adsorption potential is ~100 mV at a concentration of 7.5×10^{-3} mol dm^{-3} and ~140 mV at 1.25×10^{-2} mol dm^{-3}. Within the error limits of ±5 mV the φ values are consistent with the equilibrium values given by Frumkin.[48]

Results for hexanoic, heptanoic, and octanoic acid are shown in Figs 11–13. The potential changes towards more positive values during the measurements. The largest change in the potential is observed for octanoic acid: in the other two acids the initial region (up to 7 ms) shows an initially fast change in potential followed by a slower change.

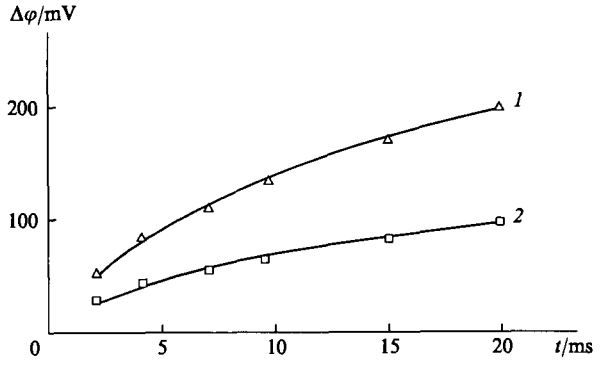

Figure 13. Electric adsorption potential of solutions of octanoic acid.[47] $c/10^{-3}$ mol dm^{-3}: (*1*) 0.75, (*2*) 1.5.

3. Cation-active SAS

Published measurements[41,49] show that in the case of cation-active SAS the potential usually changes (over times between 1 and 2 ms) towards more negative values, corresponding to the location of the cations closer to the air interface than the anions (Figs 14–17). For a given concentration the rate of the process decreases as the lifetime of the surface increases, and for a given lifetime it increases with the concentration. The absolute value of $\Delta\chi$ increases with the age of the surface, and with increasing concentration, indicating an increase in the adsorption of the SAS. At very low concentrations of the SAS, corresponding to low adsorptions, we observe a time dependence of the surface potential similar to that seen in water: $\Delta\chi$ moves towards more positive values (Fig. 17).

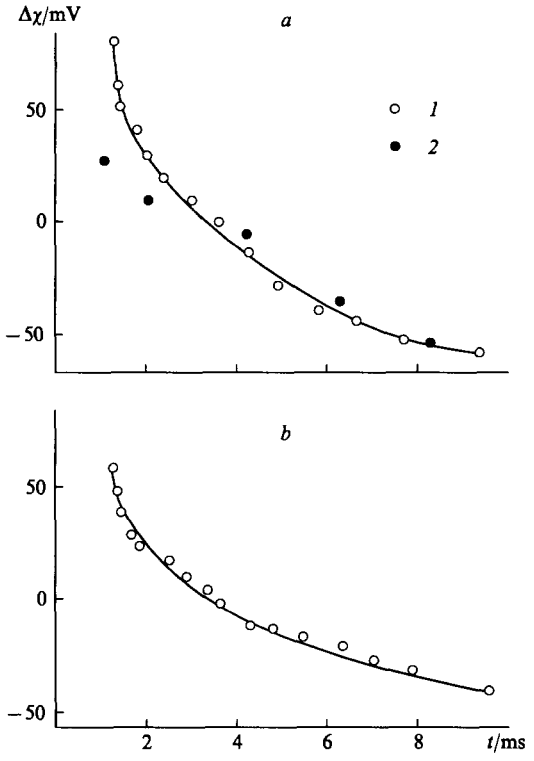

Figure 14. Time changes of the surface electric potential in the water–CTAB system. (*a*) c/mol^{-4} mol dm^{-3} = 5.6; (*1*) from Ref. 49, (*2*) from Ref. 41; (*b*) $c/10^{-4}$ mol dm^{-3} = 2.8.

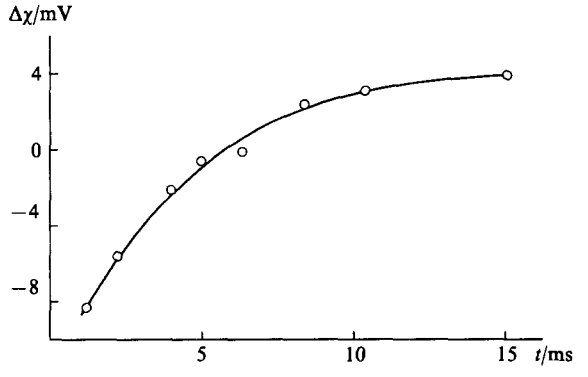

Figure 17. Changes in the surface electric potential of a solution of dodecylammonium chloride. $c/10^{-3}$ mol dm^{-3} ≈ 2.6.

4. Cation-active SAS with added inorganic salts

The time-dependences of the surface potentials for aqueous solutions of cetyltrimethylammonium bromide and chloride with additions of KCl and KI are shown in Figs 18–21. By comparing the $\Delta\chi$ values in solutions of the SAS with and without salt additions we conclude that in young surfaces (up to 6–8 ms) the change in potential is almost independent of the salt concentration. On the other hand, data on the dynamic surface tension indicate a salting-out effect associated with the additions of salt. Evidently, this behaviour is due to the differences in the polarity and in the relative electric potentials of the SAS and inorganic salt double layers, which make the relationship between the adsorption of the SAS and the surface potential less unambiguous than in the binary SAS–water system.

As the age of the surface is increased we observe a shift in the potential towards more positive values (most clearly seen in the solution with KCl additions, but relatively weak in the solution with KI). The effect becomes more marked as the salt concentration is increased, though it is relatively insensitive to the concentration of the SAS. These effects were explained by assuming micelle formation under dynamic conditions:[49] as the flow of adsorbed SAS ions meets the flow of desorbed salt in the near-surface layer the critical concentration may be exceeded, inducing micelle formation. Being surface-inactive the micelles should migrate towards the bulk of the solution, removing some of the SAS from the surface layer and as a result lowering the charge on the surface double layer and producing a positive shift of the potential.

Unfortunately there are no published data on the non-equilibrium surface potential for other SAS.

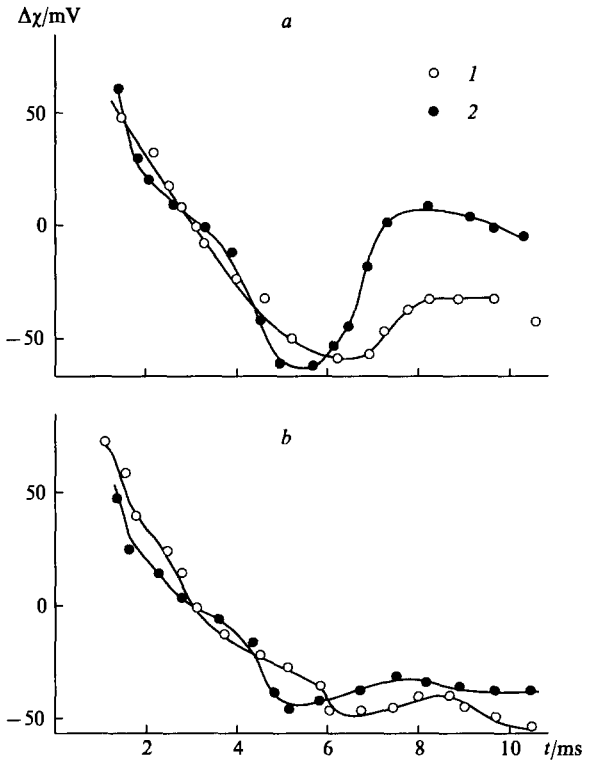

Figure 18. Time changes in the surface electric potential in the water–potassium chloride–CTAB system.[49] $c_{CTAB}/10^{-4}$ mol dm^{-3}: 5.6 (*a*), 2.8 (*b*); c_{KCl}/mol dm^{-3}: 0.12 (*1*), 0.56 (*2*).

IV. Thermodynamic relation between surface tension and the surface electric potential under nonequilibrium conditions

1. Adsorption equation for a nonequilibrium surface

The most general and commonly met case of adsorption with polarisation of a fresh solution surface as a result of the orientation of polar molecules and of the formation of a double layer has been studied during the development of the thermodynamics of irreversible processes.[38, 50, 51] Whereas the double layer is formed naturally during the adsorption of the ions, and can be described without introducing additional variables, the orientation of the polar molecules creates a new specific problem which complicates the thermodynamics of the surface phenomena.

As was shown by Sanfeld,[50] six variables are sufficient to describe the orientation of dipoles: for example, the average components of the dipole moment $\langle m_x \rangle$ and of its square $\langle m_x^2 \rangle$, or of the modulus $\langle |m_x| \rangle$ ($x = x, y, z$). In Defay's multilayer model the multicomponent two-phase liquid–gas system with a flat surface layer is divided into elementary layers (within which the electrochemical or chemical potentials are assumed to be constant), and the generalised adsorption equation for the nonequilibrium surface becomes

$$d\gamma = -\bar{s}\,dT - \sum_i \Gamma_i\, d\tilde{\mu}_i^{\alpha} - \sum_{i,k} \frac{N_i^k}{A} d(\tilde{\mu}_i^k - \tilde{\mu}_i^{\alpha}) - \frac{1}{A}\sum_{i,k,x}\left(A_{ix}^k\, d\langle m_{ix}^k \rangle + B_{ix}^k\, d\langle m_{ix}^{k\,2} \rangle\right), \quad (7)$$

where $\bar{s}$ is the entropy excess per unit surface area, T is the temperature, A is the area of the surface, Γ_i and $\tilde{\mu}_i$ are the adsorption and the electrochemical potential of the particles of species i, N_i^k is the number of particles of species i in the sublayer k of the surface layer, $\langle m_{ix} \rangle$ and A_{ix}^k are the average component of the dipole moment of the molecules of species i in the direction ($x = x, y, z$) and the corresponding affinity; $\langle m_{ix}^2 \rangle$ and B_{ix} are the mean-square component of the dipole moment of the molecules of species i and the corresponding affinity. The difference $\tilde{\mu}_i^k - \tilde{\mu}_i^{\alpha}$ plays the role of the adsorption affinity for the k-th elementary layer in the region between the phases. The superscript α refers to the bulk phase α (the liquid solution). In the right-hand side of Eqn (7) the last two sums allow for the presence of nonequilibrium processes. At equilibrium these processes disappear, and Eqn (7) reduces to the Gibbs adsorption equation. This equation can be used as the relaxation equation for the fresh surface, and also as an equation describing the dependence of the surface tension on the parameters of state (and in particular on the concentration of the SAS).

2. Relaxation equation for the fresh surface

Eqn (7) can be simplified when applied to the relaxation of a surface for a given composition and state of the bulk phase α. The first two terms in the right-hand side vanish because the temperature and the chemical potentials of the phase α are fixed. In a single relaxation process $\langle m_{ix}^k \rangle^2$ values can be assumed to be proportional to m_{ix}^k (in practice we have only one component of $\langle m_{ix}^k \rangle$ in the direction of the normal z to the surface, since both $\langle m_{ix}^k \rangle$ and $\langle m_{iy}^k \rangle$ are equal to zero according to the symmetry conditions).[50] Noting also that each orientational affinity is proportional to the rate of change of the corresponding variable the relaxation equation which follows from (7) can be written in the form[52]

$$\frac{d\gamma}{dt} = -\sum_{i,k} N_i^k \frac{d(\tilde{\mu}_i^k - \tilde{\mu}_i^{\alpha})}{dt} - \sum_{i,k} C_i^k \left(\frac{d\langle m_{iz}^k \rangle}{dt}\right)^2, \quad (8)$$

where t is the time and C_i^k are constants.

The right-hand side of the relaxation equation (8) consists of two terms: a diffusion term and an orientation term. The quantity $\langle m_{iz}^k \rangle$ is related to the dipole component χ_d of the surface potential χ by the electrostatic equation

$$\chi_d = 4\pi \sum_{i,k} \langle m_{i,z}^k \rangle \frac{N_i^k}{A}. \quad (9)$$

Since the orientation is established mainly in the surface monolayer we can put $k = 1$. To simplify the problem we shall assume that only one component undergoes orientation, i.e. that $i = 1$. In this way we obtain from Eqn (9)

$$\langle m_z \rangle = \frac{\chi_d A}{4\pi N^{\sigma}}, \quad (10)$$

where N^{σ} is the number of molecules in the monolayer. In this model we obtain the following expression from Eqn (8):

$$A\frac{d\gamma}{dt} = -\sum_{i,k} N_i^k \frac{d(\tilde{\mu}_i^k - \tilde{\mu}_i^{\alpha})}{dt} - C\frac{d\langle m_z \rangle}{dt}. \quad (11)$$

Here C is equal to the C_i^k value for the monolayer model with one component. Obviously, $C > 0$, since the surface tension decreases as more molecules become oriented. It is clear from Eqn (11) that the decrease in surface tension is independent of the signs of $\langle m_z \rangle$ and χ_d.

Eqn (11) can be used to establish the relation between the dynamic surface tension and the nonequilibrium surface potential. We shall examine the two extreme cases in which only the orientation or only the diffusion relaxation mechanism (respectively) is operating.

a. Orientational relaxation mechanism

We shall assume initially that the orientation process is much slower than the diffusion of ions or molecules, so that in practice the process takes place under the condition of diffusion equilibrium ($\mu_i^k = \mu_i^\alpha$). Obviously, the electrochemical potentials in the surface layer is held constant by a change in the number of adsorbed ions and molecules during the orientation process. However, if we are considering a relaxation state close to equilibrium (as is found experimentally) in which the adsorption layer remains relatively dense we can assume that $N^\sigma = \text{const}$, and $d\chi = d\chi_d \approx d(m_z)$. Allowing for (10), Eqn (11) can then be rewritten

$$\frac{d\gamma}{dt} = -\frac{CA}{(4\pi N^\sigma)^2}\left(\frac{d\chi}{dt}\right)^2. \tag{12}$$

Hence we arrive at the expression

$$\frac{d\gamma}{d\chi} = -\frac{CA}{(4\pi N^\sigma)^2}\frac{d\chi}{dt}, \tag{13}$$

which shows that $d\gamma/d\chi \to 0$ for $t \to \infty$, since $d\chi/dt \to 0$.

b. Ion-diffusion relaxation mechanism

We shall now assume that the diffusion and the orientation of polar molecules are very fast processes and that the rate-limiting step of the relaxation is the formation of an ionic double layer.

In this case Eqn (11) gives

$$d\gamma = -\sum_{i,k}\left(\frac{N_i^k}{A}\right)d(\tilde{\mu}_i^k - \tilde{\mu}_i^\alpha), \tag{14}$$

where the summation with respect to i refers to the ions. Using the standard expressions for the electrochemical potentials,

$$\tilde{\mu}_i = \mu_i + q_i\varphi, \tag{15}$$

where μ_i is the chemical potential, q_i is the charge on the ion, and φ is the electric potential at the place where the ion is sited. Inserting (15) into (14) and dividing by $d\chi$ gives

$$\frac{d\gamma}{d\chi} = -\sum_{i,k}\frac{N_i^k}{A}\frac{d(\tilde{\mu}_i^k - \tilde{\mu}_i^\alpha)}{d\chi} - \sum_k q^k\frac{d(\varphi^k - \varphi^2)}{d\chi}, \tag{16}$$

where q^k is the charge on the elementary layer k per unit area,

$$q^k \equiv \sum_i \frac{q_i N_i^k}{A}.$$

The right-hand side of Eqn (16) contains two terms. The first describes the effect of the adsorption of ions (accompanied by the formation of the surface potential χ) on the distribution of chemical potentials in the double layer. The derivative $d\mu_i^k/d\chi$ should be large in the case of massive surface-active ions at the formation stage of the adsorption monolayer. If this stage dominates the formation of the equilibrium diffusion layer of counterions the derivative is small during the final stage of the relaxation. Obviously, the same derivative is small for the counter-ions, which usually have a small mass, if their concentration is small.

The second term of Eqn (16) is purely electrostatic. We note that it differs from zero even in an electrically neutral surface layer, and it lowers the surface tension irrespectively of the sign of the surface potential. For the last elementary layer we can write $d(\varphi^k - \varphi^\alpha)/d\chi = -1$ (By definition of χ); it follows immediately that the right-hand side of Eqn (16) remains finite at $t \to \infty$. This means that, in contrast to the orientational relaxation, a linear term appears in the dependence of $(\gamma - \gamma_\infty)$ upon $(\chi - \chi_\infty)$.

Thus the presence or absence of a linear term in the asymptotic dependence of $(\gamma - \gamma_\infty)$ upon $(\chi - \chi_\infty)$ allows us to identify the relaxation mechanism. If it is found experimentally that the dependence does not contain a term in which $(\chi - \chi_\infty)$ appears in the first power we may conclude that the surface potential is formed by the reorientation of the polar molecules. If a first-power term is detected the surface potential is the result of the formation of an ionic double layer.

3. Concentration dependence of the surface tension

When considering the concentration dependence of the surface tension (at constant temperature) we must allow for the second term in the right-hand side of the adsorption equation (7) as well as for the effects discussed above. Using once again the expression (15) we can write

$$\sum_i \Gamma_i\, d\tilde{\mu}_i^\alpha = \sum_i \Gamma_i\, d\mu_i^\alpha + \sum_i \Gamma_i q_i\, d\varphi^\alpha$$
$$= \sum_i \Gamma_i\, d\mu_i^\alpha + q\, d\chi,$$
$$q \equiv \sum_i \Gamma_i q_i, \tag{17}$$

where q is the overall charge on the surface. The electroneutrality condition ($q = 0$) is usually assumed for systems in equilibrium (which may, however, be charged), but in dynamic processes electroneutrality is not, of course, a necessary condition.

It has been reported [52-55] that the formation of a fresh surface may involve local breakdown of the electroneutrality of the electric double layer. According to Lopatenko and Kontush [54] the charging of a liquid surface takes place in a particular time interval during the formation of the surface because of the presence of a nonequilibrium electric potential which varies along the surface. The formation conditions of the fresh surface have a strong influence on the resulting surface charge. Thus, in the formation of an air bubble in an aqueous solution of NaCl the surface charge [52] is 4×10^{-5} to 4×10^{-7} C cm^{-2}, whereas in the formation of a drop of the same solution in air the charge [54] is $\sim 1.5 \times 10^{-12}$ C cm^{-2}. The formation of surface charge is most likely at low concentrations of electrolyte, when the electric double layer is relatively stretched and easily deformed. The Jones–Ray effect (the appearance of a minimum on the surface tension isotherm at low concentrations of electrolyte, of the order of 10^{-3} mol dm^{-3}) has been attributed [56] to the formation of surface charge.

The charging of droplets of electrolyte solutions has been observed not only with inorganic electrolytes but also with solutions of SAS. As an example we show in Fig. 22 the dependence of the charge on drops of an aqueous solution of cetylpyridinium chloride on the concentration of the solution.[57]

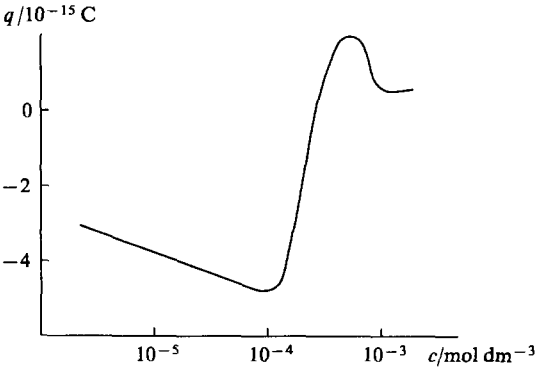

Figure 22. Dependence of the charge of drops on the concentration of a solution of cetylpyridinium chloride.[57]

We shall now rewrite Eqn (7) for the case of constant temperature in the system and on the assumption that the orientation and diffusion processes are significantly faster than the re-establishment of the electroneutrality of the surface:

$$d\gamma = -\sum_i \Gamma_i \, d\mu_i^{\alpha} - q \, d\chi . \tag{18}$$

In particular, for a dilute solution of a 1-1 electrolyte Eqn (8) simplifies to

$$d\gamma = \frac{-2RT\Gamma}{c} dc - q \, d\chi , \tag{19}$$

where c is the conconcentration of electrolyte in the bulk phase. This equation can be used, for example, to determine the dependence of the surface tension on the concentration.[56] In the case of an SAS on a fairly well aged surface, when the adsorption is substantial, the first term in the right-hand side of Eqn (19) can play the dominant role. The second term can make a significant contribution when the surface is still relatively fresh.

V. Methods of studying the adsorption mechanism

We know that the kinetics of the adsorption of SAS can be diffusion-controlled (in which case the relaxation time is determined by the diffusion of the SAS to the surface), adsorption-controlled (with an energy barrier on the surface), or under mixed control (when both the diffusion and the rate of establishing equilibrium in the surface and the subsurface layers must be allowed for). Even for one given substance different types of kinetics may be observed, depending on the concentration and temperature of the solution and on the duration of the process:[4, 58, 59] this must be allowed for when experimental data are analysed. Let us now examine the methods of studying the mechanism of adsorption of the SAS.

1. Calculations from experimental data by the diffusion theory

The relaxation of the surface properties of aqueous solutions of SAS characterises their adsorption kinetics. The time dependence of the adsorption can be obtained from experimental values of the surface tension $\gamma(t)$, of the surface electric potential $\Delta\chi(t)$, or of the adsorption potential $\varphi(t)$ by using the equilibrium isotherms of the surface tension $\gamma(c)$, of the adsorption potential $\varphi(c)$, and of the adsorption $\Gamma(c)$. Identical dependences of the dynamic surface tension or of the adsorption potential on the adsorption for equilibrium and for nonequilibrium conditions are assumed. In other words it is assumed that the molecules become oriented relatively rapidly and that the process is controlled exclusively by the rate of arrival of the adsorbate at the surface.

In the case of purely diffusion-controlled kinetics the dependence of the adsorption Γ on the time t can be calculated using the Ward–Tordai equation[60]

$$\Gamma(t) = 2c_0\left(\frac{Dt}{\pi}\right)^{1/2} - \left(\frac{D}{\pi}\right)^{1/2} \int_0^t \frac{\bar{c}(t')}{(t-t')^{1/2}} dt' , \tag{20}$$

where c_0 is the bulk concentration of the SAS, D is the diffusion coefficient, and $\bar{c}(t)$ is the concentration of SAS in the part of the bulk solution directly adjacent to the surface layer (known as the subsurface concentration). Because of the difficulty of determining this quantity experimentally the parameter c is often obtained by using one of the conventional adsorption isotherms. Thus, by adopting the linear adsorption isotherm

$$\Gamma = \varepsilon c , \tag{21}$$

Sutherland[61] converted Eqn (21) into:

$$\Gamma(t) = \varepsilon c_0\left[1 - \exp\left(\frac{Dt}{\varepsilon^2}\right) \operatorname{erfc}\left(\frac{\sqrt{Dt}}{\varepsilon}\right)\right]. \tag{22}$$

The adsorption kinetics are often studied in a jet of liquid. A study[61] of the effect of the velocity profile in the jet on the adsorption gave the following expression for $\Gamma(t)$:

$$\Gamma(t) = 2c_0\left(\frac{Dt}{\pi}\right)^{1/2} - \left(\frac{D}{\pi}\right)^{1/2} \int_0^t \frac{c(t')}{(t-t')^{1/2}} dt'$$

$$+ \frac{1}{(2\pi D)^{1/2}} \int_0^t \int_0^{t'} \int_0^{\infty} \frac{y'}{(t'-t'')^{3/2}} \exp\left[-\frac{(y')^2}{4D(t'-t'')}\right]$$

$$\times v_r(y', t') \, F(y', t'') \, dy' dt' dt'' \tag{23}$$

Here $v(r)$ is the radial component of the velocity, and $y' = a - r$ (where a is the radius of the jet and r is the radial coordinate); also,

$$F(y', t'') = \left(\frac{\partial c}{\partial y'}\right)_{t''} .$$

The first two terms of Eqn (23) are identical to the right-hand side of the Ward–Tordai equation, and therefore they allow for the transport of matter by molecular diffusion. The third term is a small correction for the effect of a nonuniform velocity profile.

Experimental dependences of the adsorption on time can be compared with dependences calculated by the diffusion theory [Eqns. (20)–(22)]. Good agreement between experimental and calculated values of $\Gamma(t)$ denotes diffusion-controlled adsorption kinetics. This is found, for example, for aqueous solutions of alcohols with moderately long hydrocarbon chains.[44] Data for an aqueous solution of heptanol are shown in Fig. 23 as an example. The curve was calculated by the Ward–Tordai equation. The points give the $\Gamma(t)$ values obtained from measurements of the adsorption potential.[45] The agreement between the experimental results and those calculated by the theory of diffusion is satisfactory.

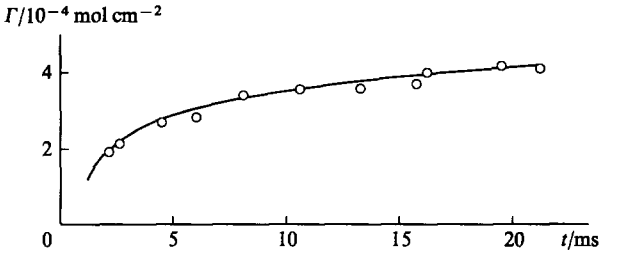

Figure 23. Time dependence of the adsorption of heptanol.[45] $c/10^{-3}$ mol dm^{-3} = 2.5.

In some cases the association of the dissolved substance is one of the main factors responsible for slow adsorption, as was shown by measurements of the adsorption potential of solutions of aliphatic acids.[47] The most significant difference between acids and alcohols is the presence of the polar carboxylic acid group –C(O)OH, which balances the hydroxyl and the hydrophobic parts of the acid molecule. For this reason the normal aliphatic acids can form associations, unlike the corresponding alcohols. The carboxylic acid group also enables the aliphatic acids to form relatively strong hydrogen bonds (as compared with the alcohols). Experimental results (Figs 24 and 25) show that the rate of adsorption is suppressed (as compared with the diffusion-controlled kinetics by increasing the concentration of the solution and by shortening the hydrocarbon chain. The adsorption barrier is lowered by the transition from C_6 to C_7, but it is raised by an increase in concentration. These results justify the conclusion that the adsorption is hindered by the formation of associations of the aliphatic acids.

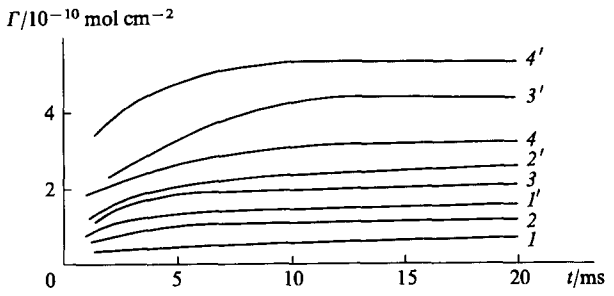

Figure 24. Time dependence of the adsorption of hexanoic acid.[47] $c/10^{-3}$ mol dm^{-3}: (*1*,*1'*) 1, (*2*,*2'*) 2, (*3*,*3'*) 4, (*4*,*4'*) 6; (*1*–*4*) calculated from experimental adsorption potential data, (*1'*–*4'*) calculated by the Ward–Tordai equation.

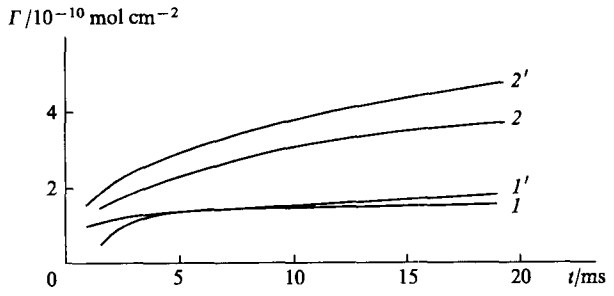

Figure 25. Temperature dependence of the adsorption of heptanoic acid.[47] $c/10^{-3}$ mol dm^{-3}: (*1*,*1'*) 1; (*2*,*2'*) 2; (*1*) and (*2*) calculated from experimental adsorption potential data, (*1'*) and (*2'*) calculated by the Ward–Tordai equation.

In the case of a purely diffusional adsorption mechanism we can replace the calculation of $\Gamma(t)$ by a calculation of the surface tension followed by a comparison with the experimental value. The surface tension is determined from the surface pressure $\pi(t)$:

$$\gamma(t) = \gamma_{H_2O}(t) - \pi(t) = \gamma_{H_2O}(t) - RT\Gamma(t), \qquad (24)$$

where $\gamma_{H_2O}(t)$ is the experimental value of the dynamic surface tension of water, and $\Gamma(t)$ is defined for a purely diffusional mechanism [for example, by formula (22)]. This approach does not require the traditional stipulation of local equilibrium between the surface and the subsurface layers, which is legitimate only for a purely diffusional adsorption mechanism.

Fig. 26 shows the experimental time dependence of the surface tension of a solution of CTAB and the same dependence calculated by formula (24). For surfaces aged up to 1.5 ms the two dependences are indistinguishable, but the curves show a significant deviation for $t > 1.5$ ms, probably associated with the appearance of an adsorption barrier. In this case the barrier is probably of the electrostatic type, since it has been shown [35] that in the adsorption of CTAB the absolute value of the surface electric potential increases, with a corresponding increase in the mutual repulsion of the adsorbed active cations and of those approaching the surface. The concept of an activation barrier was first proposed by Doss.[62]

An alternative method of revealing the presence of an adsorption barrier was discussed by Owens.[22] The rate of diffusion is markedly temperature-dependent. It follows that a lack of a temperature dependence of the rate of decrease of the surface tension (i.e. the rate of increase of adsorption) indicates the appearance of an adsorption barrier. Let us consider the above example of a solution of CTAB (see Fig. 26), in which an adsorption barrier appears to be formed for $t > 1.5$ ms (see also Fig. 4).

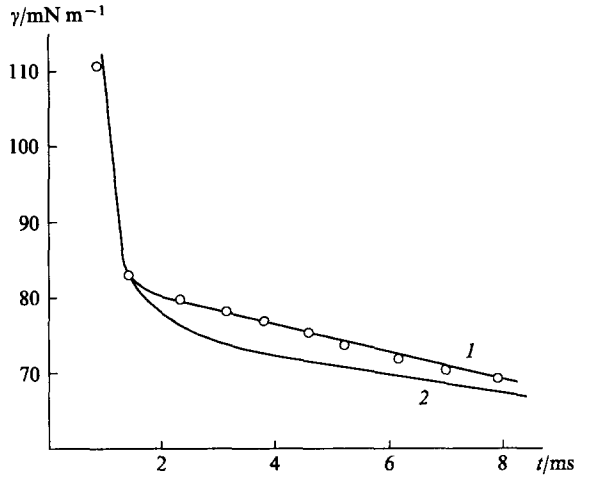

Figure 26. Experimental (*1*) and calculated time dependences (*2*) of the surface tension in the water–CTAB system at 25 °C with $c/10^{-4}$ mol dm^{-3} = 5.6 (see Rakhimov et al.[35]).

At $t > 1.5$ ms the rate of decrease of the dynamic surface tension becomes independent of temperature: this is interpreted by Owens as evidence for the formation of an adsorption barrier.

Thus we conclude from the behaviour of the CTAB solution that the different methods of identifying the mechanism of adsorption by studying the relaxation of the surface properties of the solution give adequately consistent results.

2. Analysis of the experimental dependence of the surface tension on the surface potential

Under equilibrium conditions the contribution to the surface tension from the orientation of the dipoles is proportional to the square of the discontinuity in the electric potential created at the surface.[63,64] As was said above, when the ionic double layer is formed under nonequilibrium conditions we find a term proportional to the first power of $\Delta\chi$.

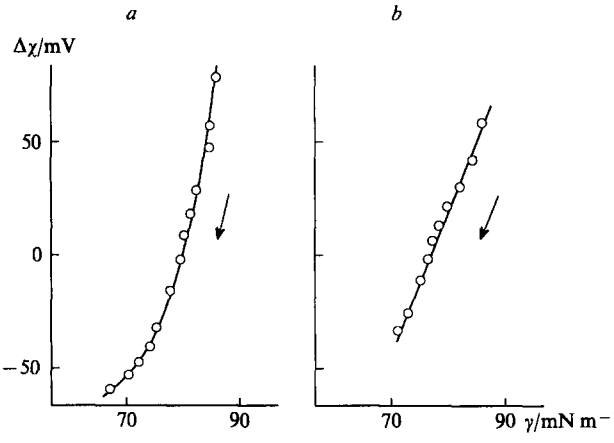

Figure 27. Dependence of $\Delta\chi$ on γ in the water–CTAB system with $c/10^{-4}$ mol dm^{-3} = 5.6 (*a*) and 2.8 (*b*).

Fig. 27 shows the $\gamma(t)-\Delta\chi(t)$ dependence for solutions of CTAB of two concentrations. At the lower concentration the $\gamma-\Delta\chi$ correlation is linear, but at the higher concentration we find a deviation from linearity. This means that in the former case the adsorption mechanism is diffusion-controlled, whereas in the latter case an adsorption barrier may be present.

3. Analysis of the experimental dependence of the adsorption on the surface potential

It has been shown[65] that under equilibrium conditions the adsorption potential increases linearly with the adsorption. This is explained by assuming that the molecular orientation is retained when the adsorption is increased. For a purely diffusional mechanism the calculation of adsorption by the Ward–Tordai equation assumes the presence of local equilibrium between the surface and the subsurface. It may be thought that for a diffusion-limited adsorption mechanism the parameter $\Delta\chi$ should be linearly dependent on Γ ($\Delta\chi$ and Γ are compared at the same instant). Therefore if Γ is calculated by the Ward–Tordai equation and φ(or $\Delta\chi$) is taken from experimental results a linear dependence of $\Delta\chi$ on Γ suggests a diffusion-controlled mechanism whereas deviations from linearity suggest the presence of a barrier.

The correctness of these views is confirmed by experiments with aqueous solutions of CTAB.[35] In the time region for which other methods had detected an adsorption barrier the dependence of $\Delta\chi$ on Γ was nonlinear. A similar analysis for aqueous solutions of hexadecylpyridinium bromide and dodecylammonium and cetyltrimethylammonium chlorides showed that in every case (except the cetyltrimethylammonium chloride of concentration 5.6×10^{-4} mol dm^{-3}) a linear relation between $\Delta\chi$ and Γ was obtained, indicating diffusion-controlled adsorption. In the exceptional case an adsorption barrier appears to be rate-limiting at short times (Fig. 28).

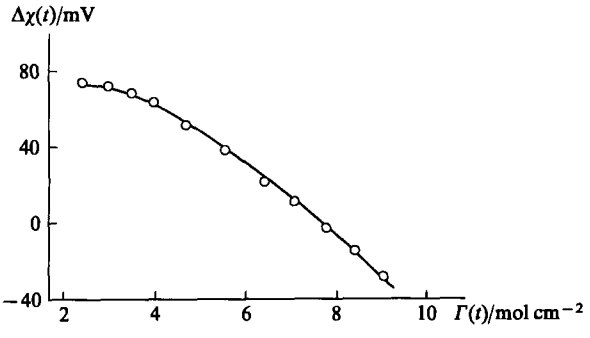

Figure 28. Dependence of $\Delta\chi$ on Γ calculated from experimental data for a solution of CTAC with $c/10^{-4}$ mol dm^{-3} = 5.8.

* * *

Thus the study of the properties of freshly created surfaces such as dynamic surface tension and surface electric potential allows us to compare different views on the structure of SAS solution surfaces.

The thermodynamic description of the relaxation of the surface layer offers practiclally useful conclusions on the mechanism of adsorption.

Cycloaddition of nitrile oxides to multiple bonds containing a heteroatom

A A Esipenko, L I Samarai

Contents

I. Introduction	1097
II. General characteristics of the cycloaddition reactions of nitrile oxides	1097
III. Reactions involving the addition of nitrile oxides to multiple bonds	1098

Abstract. The review presents a compilation and a systematic account of the reactions involving the cycloaddition of nitrile oxides to multiple bonds containing noncarbon atoms. An attempt is made to trace the rules governing these processes on the basis of the available experimental data. The bibliography includes 219 references.

I. Introduction

The oxides of carboxylic acid nitriles occupy and important place among the 1,3-dipoles used widely in organic synthesis. These readily available compounds interact fairly easily with various dipolarophiles. They are therefore frequently used to obtain heterocyclic products and also in the synthesis of biologically active compounds with definite stereochemical parameters and of analogues of natural products. Nitrile oxides have recently found applications as modifying additives to polymeric materials. Their use as model compounds in theoretical studies on 1,3-cycloaddition reactions is no less important.

A monograph[1] and a series of reviews[2–5] on the chemistry of nitrile oxides are available at the present time. They cover the literature up to 1989. Attention is concentrated in these publications on the most thoroughly investigated reactions involving the cycloaddition of the dipoles to C=C and C≡C bonds. On the other hand, studies on the reactions of nitrile oxides with multiple bonds containing noncarbon atoms are adequately dealt with in the above monograph[1] but only up to 1970. In the subsequent reviews, only slight attention was devoted to such interactions. Furthermore, the reactions of nitrile oxides with certain multiple bonds (for example, C=As, C=P^{V}, C≡P, and Ge=S) began to be investigated comparatively recently and these are not mentioned in the above reviews.

The present review presents a systematic account of the literature (up to 1992 inclusive) on the reactions involving the addition of nitrile oxides to multiple bonds and an attempt is also made to trace certain rules governing these processes on the basis of the above experimental data.

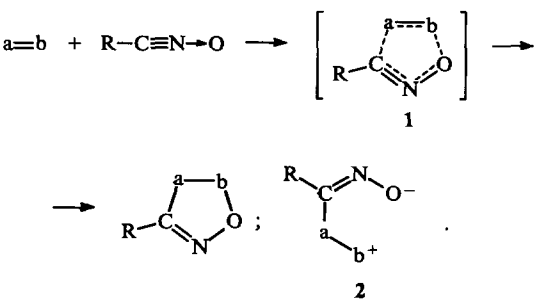
II. General characteristics of the cycloaddition reactions of nitrile oxides

Before proceeding to the consideration of the reactions of nitrile oxides with particular multiple bonds, one should note certain features characteristic of all the cycloaddition reactions of nitrile oxides associated with their general mechanism.[2,6–9]

1. The high stereospecificity of the cycloaddition. The dipole adds in the *cis*-position relative to the multiple bond. The configuration, for example that of *cis*- and *trans*-olefins, is not then affected.



This property has found extensive application in the synthesis of analogues of natural products and biologically active compounds with specific stereochemical parameters.

2. Moderate enthalpies of activation (E_a = 9 – 16 kcal mol^{-1}) and high negative entropies of activation ($\Delta S_a^{\neq}$ = from −18 to −30 cal mol^{-1} K^{-1}), which are characteristic of a highly ordered transition state (TS).

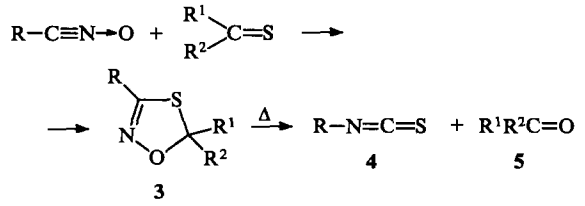
3. A weak dependence of the rate of reaction on solvent polarity, indicating an insignificant charge separation in the transition state. This finding is also confirmed by the weak dependence of the rate of reaction on the nature of the substituents in the dipole and the dipolarophile. The values of the parameter ρ in the Hammett equation are in the range from 0.3 to 1.3.

Such experimental data indicate a concerted asynchronous mechanism of the cycloaddition reactions of nitrile oxides via the four-centre cyclic transition state **1** and rule out a stepwise mechanism via the formation of the highly charged zwitter-ions **2**.

The concerted mechanism of the cycloaddition presupposes the simultaneous dissociation of two π-bonds in the initial compounds and the formation of two new C–a and O–b σ-bonds. However, the new σ-bonds are formed at different rates and this is the reason why the cycloaddition reactions of nitrile oxides are somewhat asynchronous, which leads to a slight separation of the charges on the atoms of the transition state.

The structure of this transition state and the magnitude and signs of the charges depend both on the nature of the atoms a and b and on the nature of the substituents R in the dipole and the dipolarophile. The rate of reaction and the selectivity of the addition depend in their turn on the extent to which the formation of the transition state is favoured by energy factors.

In the description of the reactions under consideration, quantum-mechanical methods have been used recently to estimate the direction and relative rate of the addition. It is also possible to explain the influence of the nature of the substituents in the initial reactants on the course of the process.[2,9-13]

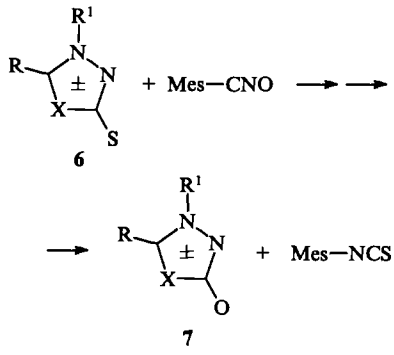


The lack of sufficient experimental data precludes at the present time a quantitative estimation of the reactivities of multiple bonds with different heteroatoms in the reactions with nitrile oxides. In purely qualitative terms, these bonds can be arranged in the following sequence based on decreasing reactivities: C=S, N=N, P^{V}=C > C=P^{III}, C=As (As=C), C=C, C=N, C=Se, B=N > C≡P, C≡C, Ge=S > P^{V}=N, C≡N > C=O. The atoms in each bond are arranged in an order such that the first adds to the oxygen atom at the end of the nitrile oxide group C≡N → O and the second adds to carbon atoms.

Next we shall consider the reactions of nitrile oxides with compounds containing all the bonds listed above (with the exception of C=C and C≡C which have been described in detail in other reviews[2-5]) in order of their decreasing reactivities.

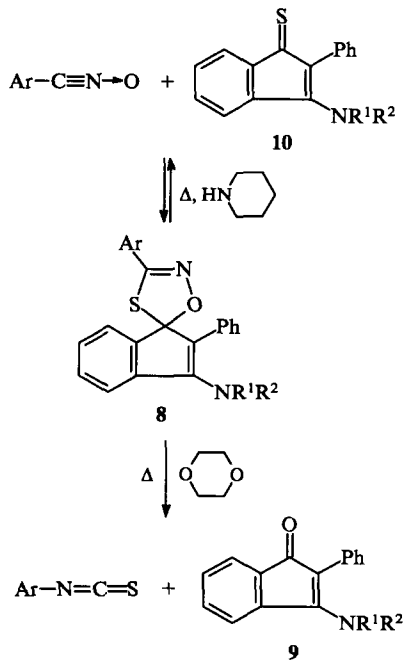
III. Reactions involving the addition of nitrile oxides to multiple bonds

1. Addition to the C=S bond



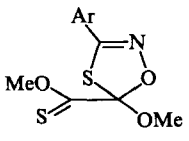
The C=S bond is the most reactive multiple bond in the series considered. At room temperature, the reactions involving the addition of nitrile oxides to C=S bonds take place over a period lasting from several minutes to several hours and lead to the formation of 3,5-disubstituted 1,4,2-oxathiazolines **3** in a satisfactory yield.[1,14-17]

Even in the case of sterically hindered aromatic nitrile oxides, the reaction with diphenyl thioketone at room temperature terminates after 30 min and leads to the cyclic product **3** in 80% yield.[18] In those cases where the dipolarophile molecule contains, apart from the C=S bond, also other reactive bonds, for example C=C [19,20] or C=N,[21,22] the nitrile oxides undergo cycloaddition primarily to the C=S bond.

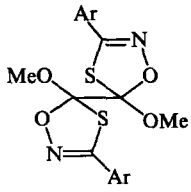


In most cases, compounds **3** are stable crystalline substances. On heating to 100-180 °C, they are cleaved to form the isothiocyanates **4** and the corresponding carbonyl compounds **5**.[14,23,2] Oxathiazoles containing an amino-group (NMe_2, NHR^3)[16,23,25,26] or the *p*-$Me_2NC_6H_4$ group[7] as the substituent R^1 (or R^2) are cleaved already at the instant of the reaction in the absence of heating. The influence of such substituents on the stability of the heterocycle is transmitted even through the C=C bond.[19,22]

In certain cases, the reactions of nitrile oxides with thiocarbonyl compounds are used to replace the sulfur atom by oxygen.[22,27,28] This method is particularly convenient for the synthesis of cyclic ketones from the more readily available thioketones.[21,28-32] A method for the conversion of the *meso*-ion of azolium thiolate **6** into the *meso*-ion of azolium olate **7** with the aid of the cycloaddition of mesityl cyanide has also been described.[33]



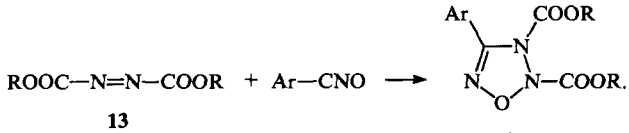
The fact that the cycloaddition reactions may be reversible under certain conditions is of interest. It has been shown[20] that, when the oxathiazole **8** is heated in dioxane, benzene, and dimethylformamide (DMF), its decomposition takes place with formation of the carbonyl compound **9**. The thermolysis of this compound in piperidine leads to the initial thioketone **10** (Scheme 1).



Scheme 1

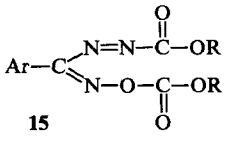
O,O-Dimethyl dithiooxalate forms stable products of the cycloaddition of one (compound **11**) or two (compound **12**) molecules of a nitrile oxide.[34] Compound **12** exists in two diastereoisomeric forms, which have been separated. Dimethyl tetrathiooxalate reacts similarly with nitrile oxides, but the adducts proved to be unstable in this case.[34]

11



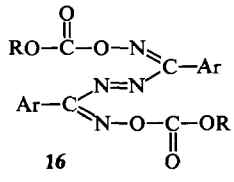
12

Kinetic studies on the reactions of nitrile oxides with 4,4'-disubstituted diphenyl thioketones have been carried out.[7] The regioselectivity of the addition of benzonitrile oxide to 2- thionoadamantane has been discussed[11] from the standpoint of the molecular orbital theory.



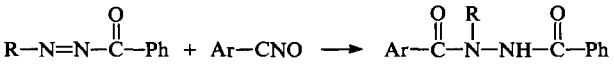
2. Addition to the N=N bond

Nitrile oxides readily react with the azodicarboxylates **13**.[35]



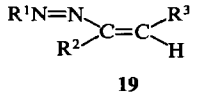
13 14

The process proceeds so vigorously that it is carried out at temperatures from −20 °C to −15 °C in order to prevent the formation of side products.[36, 37] The cycloaddition products—1,2,3,5-oxatriazolines **14**—were isolated only for the methyl esters of azodicarboxylic acid **13** (R=Me). At room temperature, they isomerise in solution to the linear products **15**. The latter can combine with yet another molecule of the nitrile oxide at the N=N bond, affording compound **16**.



15

16



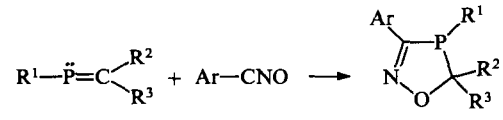
Only the isomerisation products **15** and **16**, the ratio of which depends on the nature of the group Ar, were isolated in the case of the ethyl esters **13** (R=Et). It has been suggested that the azo-compounds **15** and **16** obtained as a result of this reaction be used in the manufacture of dyes.[38]

Only the linear product **18** was isolated in the reactions of nitrile oxides with *N*-substituted *N*-benzoyl compounds **17**. The mechanism of its formation has not been established.[37]

17 18

Despite the high reactivity of the N=N bond, the cycloaddition of nitrile oxides to the conjugated azoolefins **19** and azonitriles **20** takes place regioselectively at the C=C [39] or C≡N [40] bond.

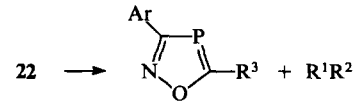
19



20

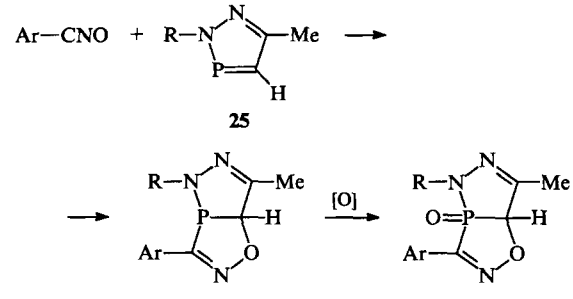
3. Addition to the C=P bond

In this group of dipolarophiles, it is necessary to distinguish compounds with trivalent and pentavalent phosphorus atoms. Their behaviour in reactions with nitrile oxides differs appreciably.



a. Addition to the C=P^{III} bond

Compounds of trivalent phosphorus are known to reduce nitrile oxides to nitriles.[1] However, in those cases where the reactivity of the phosphorus in the phosphaalkenes **21** is lowered due to steric factors, nitrile oxides undergo cycloaddition to the multiple bond with formation of 1,2,4-oxazaphospholines **22**.[41–45]

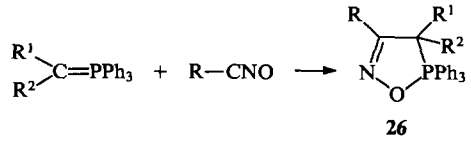


21 22

Compounds **22** are unstable in most cases. They either split off the R^1R^2 molecule and are converted into 1,2,4-oxazaphospholes **23** or are oxidised to compounds **24** with pentavalent phosphorus.[13]

23

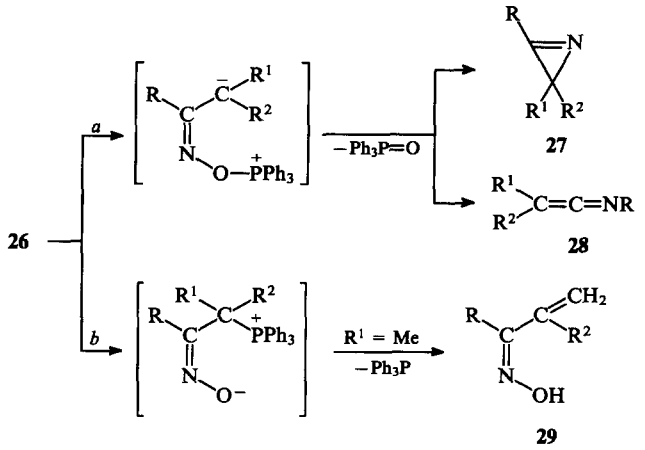
$R^1 = Me_3Si$; $R^2 = Me_3SiO$ [39,40];
$R^1 = Cl$; $R^2 = Me_3Si$ [40,44,45].



25 24

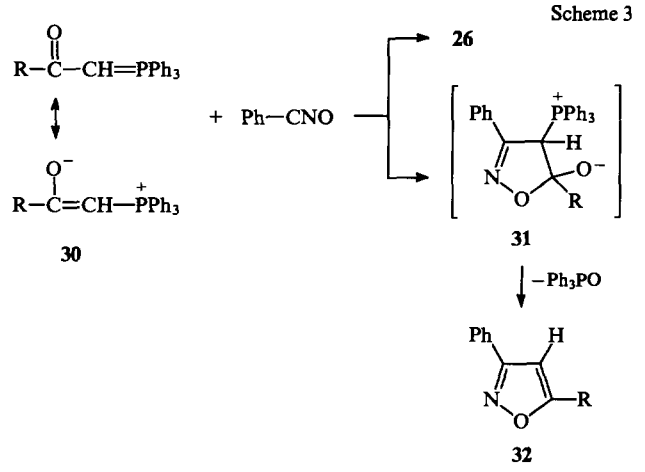
It has been shown[13] that the selectivity of the cycloaddition of nitrile oxides to compound **25** agrees well with quantum-mechanical calculations.

b. Addition to the C=P^{V} bond



In the case of phosphinomethylenes, the cycloaddition of nitrile oxides proceeds with the opposite orientation of the atoms and leads to the formation of the P–O bond.[48–52]

26

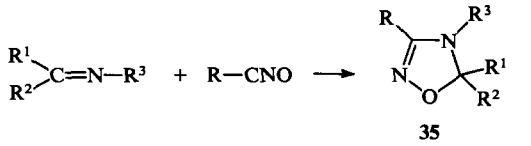


The resulting 1,2,5-oxazaphospholines **26** are unstable and in most cases are cleaved spontaneously. It has been noted in the literature that the cleavage usually begins with the dissociation of the C–P bond in the heterocycle (pathway *a*) and leads to the substituted azirines **27** or ketene imines **28**.[48, 50, 53–55] However, there are instances of the cleavage of the P–O bond (pathway *b*) with formation of the corresponding ketoximes **29**.[49] The mode of decomposition and the ratio of the final products depend on the nature of the substituents R, R^1, and R^2 (Scheme 2).

Scheme 2

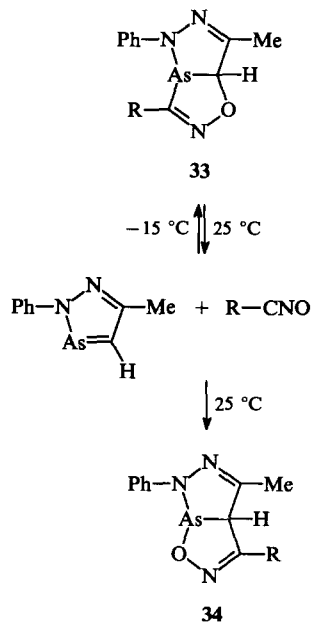
The cycloaddition of nitrile oxides to phosphorus ketoylides **30** takes place at both C=P and C=C bonds. In the second case, the unstable cyclic adducts **31** are formed. They split off triphenylphosphine oxide and are converted into the oxazoles **32** (Scheme 3).[51,53]

Scheme 3



4. Addition to the C=As bond

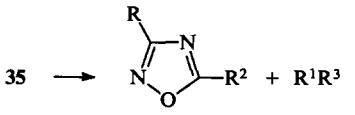
The cycloaddition of nitrile oxides to the C=As bond began to be investigated comparatively recently, the first communication having appeared in 1981.[44] So far, this reaction is the only example where, depending on the conditions, one obtains either the product of the 'direct' (compound **33**—an As–C bond is formed) or 'reverse' (compound **34**—an As–O bond is formed) mode of addition (Scheme 4).[13,44,56]



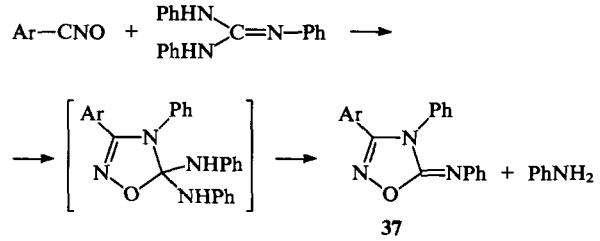
Compound **33** is obtained at a reduced temperature (−15 °C). At room temperature, it is spontaneously converted after 2 h into the isomer **34**. It has been shown that the change in the mode of addition takes place with cleavage of the oxazarsenoline ring of compound **33** to give the initial compounds. It is believed[44] that compounds **33** and **34** are formed via kinetic and thermodynamic mechanisms respectively.

5. Addition to the C=N bond

Among the reactions involving cycloaddition to multiple carbon–heteroatom bonds, those involving compounds containing the C=N bond have been studied most widely.



Scheme 4

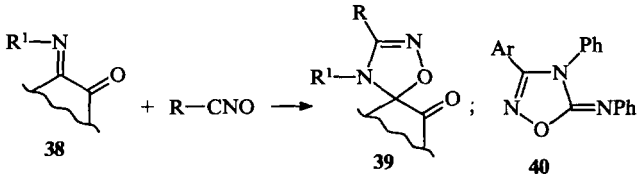


Nitrile oxides add fairly readily to this bond, forming substituted 1,2,4-oxadiazolines **35**.[1,57]

Compounds **35** are in most cases stable and can be readily isolated. At the same time, for a certain combination of the substituents R^1 and R^3, the R^1R^3 molecule is split off spontaneously and 1,2,4-oxadiazoles **36** are formed.

$R^1 = NH_2$; $R^3 = H$;[58,61]
$R^1 = OAlk$; $R^3 = H$;[58,59,62–64]
$R^1 = H$; $R^3 = OH$;[65–71]
$R^1 = CH_2C{\equiv}N$; $R^3 = H$;[72,73]
$R^1 = SMe$; $R^3 = H$.[58]

The product of the reaction of a nitrile oxide with *N,N',N''*-triphenylguanidine is stabilised somewhat differently. In this case, the aniline molecule is split off and 1,2,4-oxadiazoline **37** with an exocyclic C=N bond is formed.[74]



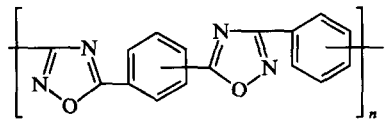
Studies have now been carried out on the interaction of nitrile oxides with virtually all classes of compounds containing the C=N bond: imines,[8,26,66,72,73,75–91] oximes,[56,65–71,92–94] derivatives of hydroxamic acid,[95] iminoesters,[58,59,62,64,96] iminothioesters,[58] amidines,[58,59,61] guanidine derivatives,[60,74,97] hydrazones,[98–101] azines,[99] and *O*(*S*)-alkyl-substituted ureas (thioureas).[58] However, despite extensive experimental data and the constantly growing interest in reactions involving the cycloaddition of nitrile oxides to the C=N bond, any kind of quantitative studies on this interaction are so far lacking. It is therefore at present impossible to determine unambiguously the dependence of the reactivity on the nature of the reactants and also to compare

the reactivity of the C=N bond with the reactivities of other multiple bonds in this reaction.

Analysis of the experimental data permits the hypothesis that electronic factors exert an insignificant influence on the reactivity of the C=N bond. As regards nitrile oxides, electron-accepting substituents in the *para*-position of the aromatic ring facilitate the reaction, shortening the time and increasing the yield of the cyclic product.[58,76]

The steric characteristics of the reactants have a much greater influence on the rate of cycloaddition. Benzonitrile oxide and its derivatives with substituents in the *meta*- or *para*-position react readily (frequently over a period of several minutes or hours at room temperature) with the C=N bond of the dipolarophile. On the other hand, in the case of sterically hindered nitrile oxides containing substituents in the *ortho*-position, the reaction does not take place at all[81] or leads to the formation of cyclic products in a low yield. In order to increase the yield, it is necessary to increase the reaction time,[102] to use more severe conditions, or to employ a catalyst.[71,94] With increase in the number and bulk of the substituents, the reactivity of the imino-group also diminishes somewhat. However, even in the case of trisubstituted imines the yield of the target product remains comparatively high: from 30% [77] to 60%–70% (provided that at least two substituents are methyl groups)[66] and up to 90% in the reaction with the reactive *p*-nitrobenzonitrile oxide.[76]

The above rules are obeyed also by the reactions involving the cycloaddition of nitrile oxides to exocyclic C=N bonds. Interaction with compounds of type **38** takes place at room temperature over a period of several hours and does not require the use of catalysts. The corresponding spirans **39** are then formed.[92,103,104]

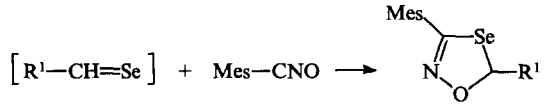


38 **39** **40**

On the other hand, more severe conditions are essential for the reactions of nitrile oxides involving the C=N bond of compound **40**; the reaction mixture is heated for several days in DMF at 75 °C with $BF_3 \cdot Et_2O$ as the catalyst.[74] The yield of the spiro-products is between 50% and 90% in all cases.

As in the case of linear azomethines, endocyclic C=N bonds in the ring readily combine with nitrile oxides, forming the corresponding bicyclic products. However, these reactions have certain unusual features. Together with the influence of steric characteristics of the substituents on the reactivity of the endocyclic C=N bond, in cyclic dipolarophiles there is an increased importance of electronic factors and a new important factor appears—that of ring strain. With increase in ring strain, there is an increase in reactivity of the imino-group, but the stability of the bicyclic compounds formed diminishes. It is noteworthy that it is stabilised in all cases with retention of the oxadiazoline ring formed.[96,105,106]

Reactions involving the cycloaddition of nitrile oxides to the C=N bonds in three-membered,[107] four-membered,[108,109] five-membered,[13,44,96,105,106,110–121] six-membered,[37,59,66,110,119,121–129] and seven-membered[102,123,130,131] rings have been investigated.

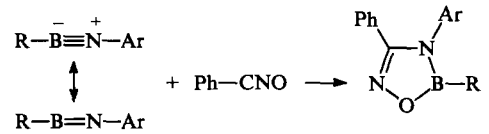


In conclusion of this Section, one should note that the reactions of nitrile oxides with imines can be used to obtain polymers or to modify them. Unfortunately, hitherto there has been only one study on this subject.[70] It was reported that the polycondensation of the bisoxides of the nitriles of terephthalic and isophthalic acids with the bisoximes of *para*- and *meta*-substituted benzaldehydes leads to polymers having the general structure **41**.

41

6. Addition to the C=Se bond

It has been reported recently that the oxide of mesityl cyanide adds even at 25 °C to the C=Se bond of selenoaldehydes, generated *in situ*, with formation of 1,4,2-oxaselenazolines **42**.[132]

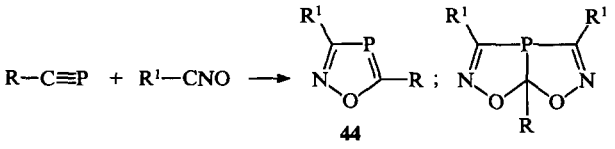


42

R^1 = H, Ph.

7. Addition to the N=B bond

There have been only two studies in which the reactions of nitrile oxides with borimides were described.[133,134] Cycloaddition products were obtained in both cases—2-bora-1,3,5-oxadiazolines **43**. It was noted that the reaction does not occur for R = C_6F_5 and Ar = mesityl.[134]

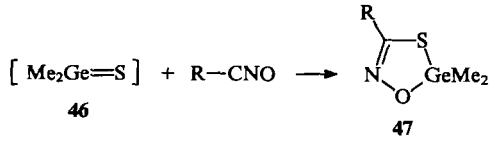


43

Ar = Ph; R = Ph;
Ar = Ph; R = 4-$MeOC_6H_4$.

8. Addition to the C≡P bond

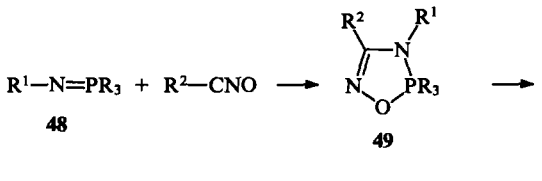
As in the case of phosphaalkenes, the cycloaddition of nitrile oxides to phosphaalkynes is preferred to the oxidation-reduction process. The interaction even with a sterically hindered nitrile oxide terminates at room temperature in the course of 24 h and leads to the formation of stable 1,2,4-oxazaphospholes **44**. Compounds **44** combine fairly readily with a second nitrile oxide molecule via the endocyclic C=P bond, forming the bicyclic product **45** (R^1 = Ph, 4-ClC_6H_4).[45,136,137]



44 **45**

R = 1-Ad,[41] Bu^t.[135,136]

9. Addition to the Ge=S bond

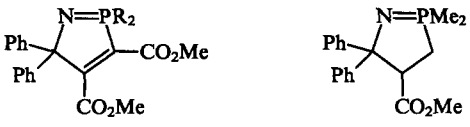


It has been reported[138] that the reaction of dimethyl germathione **46**, generated *in situ*, and nitrile oxides leads to the cyclic products **47**—2-germa-1,3,5-oxathiazolines—in 70% – 80%99 yield. Triethylamine is used as the catalyst.

46 **47**

10. Addition to the N=P^V bond

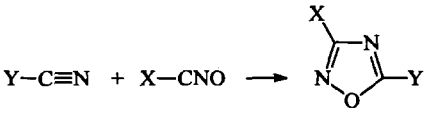
Nitrile oxides react readily with iminophosphoranes **48**. As in the case of phosphinomethylenes, cycloaddition leads to the formation of products with the 'reverse' orientation—1,2,4,5-oxadiazophospholines **49**.[139-141] The rings formed are as a rule unstable and are cleaved during the reaction to the carbodiimides **50**.[140]



48 **49**

$\longrightarrow$ $R^2-N=C=N-R^1 + R_3P=O$

50



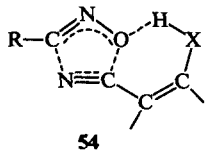
A product of type **49** can be isolated only in those cases where the N=P^{V}group is part of the composition of the ring (for example, in the azaphosphole **51** and the azaphospholine **52**) [141] or contains sufficiently powerful electron-accepting substituents ($R^1 = ArSO_2$, R = Cl).[142]

51 **52**

11. Addition to the C≡N bond

The interaction of nitrile oxides with nitriles has been investigated fairly widely. In all cases, the products are stable 3,5-disubstituted 1,2,4-oxadiazoles **53**.[1]

53

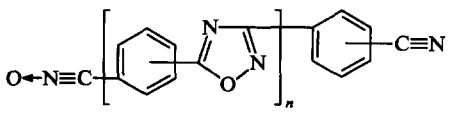


In the study of this reaction, use was made of nitriles containing a wide variety of substituents Y: Ar,[6,64,65,69,89,143-151] RC(O),[66,145,151] C_nH_m,[68,145,147,152-156] $C_nH_mHal_k$,[66,144,147,151,157-159] $R_2C(C\equiv N)$,[66,151,161-163] $R_2C=CH$,[164-173] $R_2C=C(C\equiv N)$,[162,172,174,175] $RN=N$,[40,66] $R(NR^1_2)C=CH$,[9,72,73,176] $RN=CR^1$,[177]), $R_nE^+-N^-$ (where E = S, P, N),[179] $R_2N-C(NH)-NH$,[97,139,180-182] ArO,[183,184] ArS,[185] $ArSO_2$,[186] $(AlkO)_2P(O)$ and $(AlkO)_2P(S)$,[187] $(NO_2)_3C$,[188] R_2N,[178] and Het.[66,134,136,139-141,151,189-192]

Kinetic studies have been carried out on the reaction under consideration.[6,138,154] The influence of the substituents in the reactants on the rate of cycloaddition can be determined unambiguously from the results of these studies and also from other experimental data. It was found that the reactivity of nitriles increases on passing from aliphatic to aromatic substituents and also following the introduction of electron-accepting groups and diminishes after the introduction of electron-donating groups.[66,72,150,160,190] As regards nitrile oxides, electron acceptors and donors increase somewhat the reactivity of benzonitrile oxides[72,154,187] but do not affect the reactivity of the oxides of benzoyl cyanides [$X-C_6H_4-C(O)-CNO$].[161]

Steric factors exert a much greater influence on the reactivity of the reactants. In the case of aromatic nitriles[148,150] and nitrile oxides,[187,189] it falls sharply after the introduction of substituents in the *ortho*-position. In many instances, such nitrile oxides fail altogether to enter into the reaction considered.[189]

The reactivity of unreactive nitriles and also the yield of cycloaddition products can be increased appreciably by employing catalysts (for example, $BF_3 \cdot Et_2O$).[137,152,163]

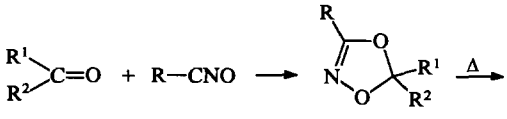


Despite the low reactivity of the C≡N bond in reactions with nitrile oxides, the cycloaddition of the dipole to unsaturated nitriles can be achieved in many instances exclusively or predominantly at the nitrile group.[9,40,66,72,97,162,164,171,174-176,182,189,191] Such increase in the reactivity of the C≡N bond has been explained[72,150,177,191] by the stabilisation of the transition state **54** and of the final product as a result of the formation of the O···H hydrogen bond.

54

X = NR^1, O.

On the other hand, in other cases the lower reactivity of the C=C bond has been explained by the influence of electronic or steric factors.[9,162]



55

The possibility of using the above reaction for the synthesis of polymers has been investigated. The copolymers of the bisoxides of the nitriles of terephthalic and isophthalic acids with the bisnitriles of these acids. **41**,[70,193,194] as well as the polymer **55**, formed from *p*-cyanobenzonitrile oxide,[194,195] have been obtained. It was noted that these substances exhibit an increased stability. Their decomposition begins only at 400 °C.

12. Addition to the C=O bond

The cycloaddition of nitrile oxides to the C=O bond has been little investigated despite the fact that the first publication on this topic appeared as early as 1961.[196] In all cases, the occurrence of this interaction leads to the formation of stable 1,4,2-dioxazolines **56**.[1]

56

$\longrightarrow$ $R^1R^2C=O + R-N=C=O$

57

On heating above 150 °C, the dioxazoline ring **56** is cleaved with formation of the initial carbonyl compound and the corresponding isocyanate **57**.[57,197,198]

The interaction of compounds containing the C=O group, such as aliphatic[152,199] and aromatic[26,133,143,196,197,200] aldehydes, ketones,[75,87,196,201] vinyl ketones,[202,203] amides,[204] acid chlorides,[92,169,205] and trichlorocarbonyl isocyanate,[206] with nitrile oxides has been investigated. A series of studies have been devoted to the cycloaddition to exocyclic C=O bonds, which leads to the formation of the corresponding spiro-compounds.[91,103,129,152,199,207-210]

Merely the fact that the reactivity of the C=O bond decreases appreciably after the introduction of electron-accepting groups in the α-position relative to C=O has been firmly established for the reactions of nitrile oxides with carbonyl compounds. Thus carbonyl compounds which do not contain such substituents can interact with nitrile oxides only in the presence of catalysts

($BF_3 \cdot Et_2O$,[57,145,152,204,211] NEt_3 [203]). On the other hand, the reactions with aldehyde and ketones in which there are electron-accepting groups [CCl_3,[196,197,206] CF_3,[87,200,201] C(O)R, C(O)OR [196,197]] proceed without catalysts over a period of several hours and the yield of the cyclic adduct is 50%–90%. Aromatic aldehydes also exhibit an increased reactivity.[89,145,197,200] The behaviour of aromatic ketones in reactions with nitrile oxides has not been investigated.

The reactions of nitrile oxides with quinones have been investigated in fair detail. It was shown that *ortho*-quinones (*o*-benzoquinone, *o*-naphthoquinone, phenanthrenenequinone, and chrysenequinone) are active dipolarophiles and readily combine with2.9 nitrile oxides via the C=O (one or two) or C=C bonds depending on the nature of the substituents and the solvent.[92,103,210]

In contrast to *ortho*-quinones, the reactivity of *para*-quinones is very low. For example, the yield of the products of the cycloaddition of nitrile oxides to *p*-benzoquinone does not exceed 15%,[70,212–214] but increases appreciably when the $BF_3 \cdot Et_2O$ catalyst is used.[145,211]The reactions of nitrile oxides with substituted *p*-benzoquinones have been studied systematically since 1977.[12,198,215–218]

The dependence of the rate and mode (via the C=C or C=O bonds) of the addition on the number and nature of the substituents in the quinone has been demonstrated. The experimental data have been explained by the influence of steric and electronic factors[215,218] and have been compared with quantum-mechanical calculations.[12,217]

* * *

It is seen from the data described above that the cycloaddition reactions of nitrile oxides can be used successfully for the construction of five-membered heterocyclic structures. The latter can be both the final and intermediate products in the synthesis of various cyclic or acyclic compounds.

We hope that this review and also the recently published review of the reactions of nitrile oxides with heterocumulenes[219] will expand the range of applications of these readily available and fairly stable 1,3-dipoles.

Selenium- and tellurium-centred radicals

E N Deryagina, M G Voronkov, N A Korchevin

Contents

I. Introduction	1107
II. Selenyl and telluryl radicals	1107
III. Perselenyl and selenuranyl radicals	1114
IV. Seleninyl and selenonyl radicals	1116

Abstract. The principal types of radicals formed in various types of initiation of the reactions of organic compounds of selenium and tellurium, the methods for their detection, and their properties and reactivities are examined. The bibliography includes 98 references.

I. Introduction

During recent years the chemistry of selenium and tellurium has begun to develop vigorously, promoted to a considerable extent by their extensive application in medicine, the electronics industry, etc. Selenium plays an important role as a trace element in living organisms.

Selenium- and tellurium-centred radicals are short lived intermediates in many photolytic thermal reactions of organoselenium and organotellurium compounds. The first information about them appeared in the literature little more than twenty years ago and their study began to develop vigorously only in recent years. This was promoted primarily by the discovery of the important role of selenium as a trace element in living organisms, in food products for animals and man, and in biochemical processes,[1] as well as its employment in microelectronics.[2,3] In the second half of the present century, eight natural selenoproteins were discovered. It was observed that the deficiency of selenium in food and in soil can induce certain diseases in animals and anomalies in the growth and development of a number of plant species.[1]

Organoselenium and organotellurium compounds are used in the electronics industry, in xerography, in photoelectronics and in the glass, ceramics, and pigments industries. Selenium-containing polymers with semiconducting properties and photosensitivity have been obtained.[2,3] Neurotropic and psychotropic medicinal preparations, with much lower toxicity than their sulfur analogues, have been developed based on selenophene.[4,5]

Homolytic processes, which include the formation of free selenium- and tellurium-centred radicals, play an important role in the reactions of organoselenium compounds and to a lesser extent of their tellurium analogues. This is due to the low energies of the C–Se, Se–Se, and Se–E (E = heteroatom) as well as C–Te and Te–Te bonds, which are responsible for their ready homolytic dissociation.[4,7]

This review deals with the main types of radical formed in various types of initiation of reactions of organic compounds of selenium and tellurium, the methods for their detection, and their properties and reactivities. A comparison is made with the analogous data for sulfur-centred radicals.

Whereas radical reactions of the organic compounds of sulfur have been investigated quite fully,[7–10] information about the fairly similar free-radical reactions of organoselenium compounds, mainly photochemical reactions, has been surveyed only in brief reviews.[11,12] Data on the radical reactions of organotellurium compounds are scattered among various communications and the aim of the present review is to survey the existing literature on this question.

The following types of selenium- and tellurium-centred radicals are known: for selenium, these are the selenyl (RSė), perselenyl (RSeSė), selenuranyl [$R_2S\dot{e}-SeR$ and $R_2S\dot{e}-X$; X = Cl, Br, $OSiMe_3$, C(Me)OMe, SC(O)R′], seleninyl (RSėO), and selenonyl ($RS\dot{e}O_2$) radicals and for tellurium only the telluryl radicals (RTė).

II. Selenyl and telluryl radicals

1. Detection and physical properties

The simplest selenium-centred radicals—the selenyl radicals RSė—were first detected in the photolysis of diorganyl diselenides.[13]

Selenyl (HSė) and telluryl (HTė) radicals are generated by passing hydrogen through a microwave absorption cell, the walls of which are coated with selenium or tellurium respectively, in a silent electric discharge (the HṠ radicals are generated similarly). Certain physicochemical characteristics of the radicals HĖ (E = Se, Te, S) are presented in Table 1.

Table 1. Physicochemical characteristics of the radicals.[14]

Parameter	HSė	HTė	HṠ
I	60	3	240
P/Torr	5	1	10
$10^{-8}D$/electrostatic units	0.2	0.1	0.3
A_0/cm^{-1}	1600 ± 50	2250 ± 200	–

Note. I is the intensity of the microwave radiation, P the partial pressure, D the dipole moment, and A_0 the spin–orbit coupling constant of the ground state of the radical measured by the EPR method.

E N Deryagina, M G Voronkov, N A Korchevin Agricultural Chemicals Laboratory, Irkutsk Institute of Organic Chemistry, Siberian Division of the Russian Academy of Sciences, ul. Favorskogo 1, 664033 Irkutsk, Russian Federation. Tel. (7-395-2) 46 02 45.

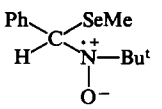
Received 7 September 1993
Uspekhi Khimii **62** (12) 1173–1183 (1993); translated by A K Grzybowski

The adiabatic ionisation potential of the radical HSe (9.845 ± 0.003 eV) and the bond dissociation energies D_0(HSe–H) = 78.99 and D_0(H–Se) = 74.27 kcal mol^{-1} were determined on photoionisation of the radical HSe generated in the spectrometer cell during the interaction of atomic hydrogen with hydrogen selenide.

$$\dot{H} + H_2Se \longrightarrow H\dot{S}e + H_2$$

Organoselenyl radicals RSe are formed on photolysis of diorganyl diselenides.[13] Their direct detection by the EPR method is difficult (particularly in the liquid phase) owing to the high degree of spin–orbit coupling and in certain cases the occurrence of specific interactions,[16] which lead to orbitally degenerate (or almost degenerate) ground states and to a greater anisotropy of the *g*-factor.[17] As a result of this, the radicals RSe have short relaxation times and give rise to extremely broad lines in the EPR spectra.[9,16,17] Nevertheless, the selenyl radicals formed on photolysis of toluene-ω-selenol, and didodecyl, dioctadecyl, and diphenyl selenides have been detected by the EPR method. Because of anisotropy of the *g*-factor, selenyl radicals have (like thiyl radicals[11]) asymmetric spectra, the *g*-factor differing significantly from the values characteristic of the free electron and carbon-centred radicals.[18,19]

Radical	$g_\perp$	$g_\parallel$
PhSe	2.003	2.016
$PhCH_2Se$	2.091	2.124
$Me(CH_2)_{11}Se$	2.088	2.122
$Me(CH_2)_{17}Se$	2.083	2.115



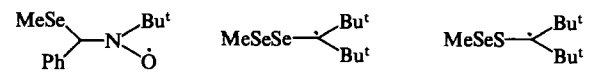
The methylselenyl radical MeSe could not be detected directly by the EPR method[18] and the available information concerning the measurement of the EPR spectrum of the PhSe radical is fairly contradictory.[18,20] The detection of the RTe radicals by the EPR method has not been reported at all.

Arylselenyl radicals can be detected by UV spectroscopy.[21,22] The absorption band of the radical PhSe is in the region of 490 nm (like that of PhS), while that of the radical 4-$MeOC_6H_4Se$ is in the region of 535 nm (in methanol). The corresponding absorption bands of the radicals 4-$MeOC_6H_4S$ and 4-$MeOC_6H_4Te$ are in the region of 525 and 508 nm.[22,23]

Like thiyl radicals,[9] selenyl radicals RSe can be readily identified by the EPR method as adducts with nitroso-compound spin-trapping agents.[24]

Methylselenyl radicals, formed on photolysis of dimethyl diselenide, do not interact with 2-methyl-2-nitrosopropane but are effectively bound by *tert*-butyl phenyl nitrone.[17] The adduct **1** is characterised by a high value of the *g*-factor (2.0097), the hyperfine structure (hfs) constants confirming its structure: a_N = 13.5 G, a_H(1H) = 2.06 G, and a_H(3H) = 0.85 G.[17]

$$Me_2Se_2 \xrightarrow{h\nu} 2MeSe \xrightarrow{PhCH=N(O)Bu^t}$$



1

The arylselenyl radicals PhSe and 4-$O_2NC_6H_4Se$ have been detected as adducts with nitrosodurene.[17,25]

The radical complexes RSe·MX_3 (X = Cl, Br), formed from selenides and diselenides on their interaction with aluminium and gallium halides, can also be detected by EPR spectroscopy. The EPR spectra of the Ar_2Se_2–$AlBr_3$–C_6H_6 system consists of three singlet signals ($g \sim 2.07$, $g \sim 2.03$, and $g \sim 2.0025$). They have been assigned to the radicals Ar, ArSe, and ArSeSe bound in the complex.[26]

2. The formation reactions of organic compounds of selenium and tellurium on photolysis and radiolysis

The selenyl radicals generated by the photolysis of diorganyl selenides readily add to the C=C, C=S, C=Se, etc. multiple bonds. The methylselenyl radicals formed on photolysis of dimethyl diselenide add to the multiple bonds of the corresponding spin-trapping agents, affording adducts of the following type:[17]

The photolysis of dibenzyl diselenide takes place differently, beginning with the dissociation of the Se–C bond and the formation of dibenzyl selenide and selenium. The benzylselenyl radical is then generated in the stage involving the decomposition of the benzylperselenyl radical formed initially and then interacts rapidly with the benzyl radical.[27]

$$PhCH_2SeSeCH_2Ph \xrightarrow{h\nu} \begin{cases} 2\,PhCH_2Se \\ PhCH_2SeSe + \dot{C}H_2Ph \end{cases}$$

$$PhCH_2SeSe \longrightarrow PhCH_2Se + Se$$

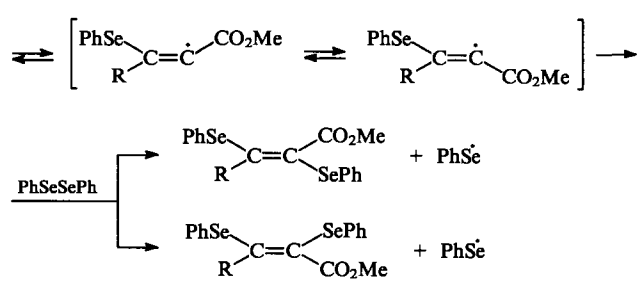
$$Ph\dot{C}H_2 + PhCH_2SeSeCH_2Ph \longrightarrow PhCH_2Se + PhCH_2SeCH_2Ph$$

$$PhCH_2Se + \dot{C}H_2Ph \longrightarrow PhCH_2SeCH_2Ph$$

$$2\,PhCH_2Se \longrightarrow PhCH_2SeSeCH_2Ph$$

When dibenzyl diselenide in solution in benzene is irradiated in air or in acetonitrile, benzaldehyde, benzyl alcohol, and elemental selenium are formed,[28] whereas in carbon tetrachloride the product is benzyl chloride.[29] This confirms the preferential dissociation of the C–Se bond on photolysis of dibenzyl diselenide. Photolysis of diphenyl diselenide leads to the formation of phenylselenyl radicals PhSe, which are distinguished by a low reactivity in their reactions with hydrogen, oxygen, or halogen donors but add readily to activated olefins.[23,30,31]

$$PhSeSePh \overset{h\nu}{\rightleftharpoons} 2\,PhSe$$



$$PhSe + CH_2{=}CHR \rightleftharpoons PhSeCH_2{-}\dot{C}HR$$

The rate constant for the addition reaction ranges from 2.0×10^6 mol^{-1} s^{-1} for α-methylstyrene to $\sim 10^3$ mol^{-1} s^{-1} for vinyl acetate. These values are lower by a factor of 10–50 than in the case of the radical PhS, which indicates a greater stability of the phenylselenyl radical.

The phenylselenyl radicals generated on UV irradiation add effectively to activated acetylenes, but their addition to non-activated acetylenes, for example to dec-1-yne, is very slow.[32]

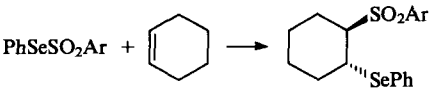
$$PhSeSePh \overset{h\nu}{\rightleftharpoons} 2\,PhSe$$

$$PhSe + RC{\equiv}CCOOMe \rightleftharpoons$$

The (*E*)-isomers predominate in the mixture of the di(phenylseleno)ethylenes formed. Owing to steric hindrance, dimesityl diselenide reacts with activated acetylenes only slowly.

Phenylselenyl radicals are also generated on photolysis of phenylareneselenosulfonates, inducing the chain decomposition of the latter with formation of diphenyl diselenide and arenesulfonic anhydride.[33]

$$PhSeSO_2Ar \xrightarrow{h\nu} PhSe^{\cdot} + {}^{\cdot}SO_2Ar$$



$$PhSe^{\cdot} + PhSeSO_2Ar \longrightarrow PhSeSePh + {}^{\cdot}SO_2Ar$$

$$2\,ArSO_2^{\cdot} \longrightarrow \left[ArS(=O)(=O)-O-S(=O)(=O)Ar \right] \longrightarrow \longrightarrow$$

$$\longrightarrow ArS(=O)(=O)-O-S(=O)(=O)Ar + \text{other products}$$

$$2\,PhSe^{\cdot} \longrightarrow PhSeSePh$$

The photolysis of phenylareneselenosulfonates in the presence of alkenes leads to aryl β-phenylselenoalkyl sulfones. The reaction is strictly stereoselective and involves the formation of *trans*-adducts.[34]

The photolytic addition of selenosulfonates to alkenes is faster than the thermal addition (in boiling chloroform or benzene). In both cases, the reaction proceeds via a free-radical chain mechanism. It is accelerated on initiation with azobisisobutyronitrile (AIBN) and is inhibited by 2,6-di-*tert*-butyl-*p*-cresol.[35]

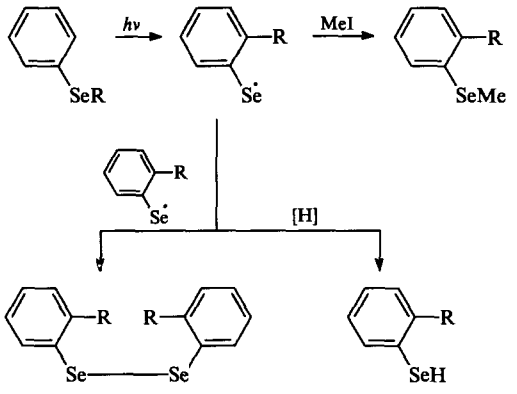
$$ArSO_2SePh \xrightarrow{h\nu \text{ or } \Delta} ArSO_2^{\cdot} + Se^{\cdot}Ph$$

$$ArSO_2^{\cdot} + \underset{R^2}{\overset{R^1}{}}\!\!=\!\!\underset{R^4}{\overset{R^3}{}} \longrightarrow \underset{ArSO_2}{\overset{R^1}{}}\!\!-\!\!\underset{R^4}{\overset{R^2}{}}\!\!-\!\!\overset{R^3}{\cdot} \xrightarrow{ArSO_2SePh}$$

$$\longrightarrow \underset{ArSO_2}{\overset{R^1}{}}\!\!-\!\!\underset{R^4}{\overset{R^2}{}}\!\!-\!\!\underset{R^3}{\overset{SePh}{}} + ArSO_2^{\cdot}$$

The aryl β-phenylselenoalkyl sulfones formed eliminate spontaneously benzeneselenol in the presence of *m*-chloroperbenzoic acid or hydrogen peroxide and are converted into the corresponding vinyl sulfones.

The photolysis of diorganyl diselenides is accelerated by tertiary phosphines, whereupon the Se–Se bond dissociates preferentially both in diphenyl diselenide and in dibenzyl diselenide.[36–38]



$$RSeSeR \overset{h\nu}{\rightleftharpoons} 2\,RSe^{\cdot}$$

$$RSe^{\cdot} + R'_3P \longrightarrow RSe{-}\dot{P}R'_3$$

$$RSe{-}\dot{P}R'_3 \longrightarrow \dot{R} + Se{=}PR'_3$$

$$\dot{R} + RSeSeR \longrightarrow RSeR + Se^{\cdot}R$$

Arylselenyl radicals are generated[39] also in the photorearrangements of aryl benzyl selenides containing a weakened Se–C bond.

R = CH_2Ph.

The photoinduced reaction of organocobaloximes with diphenyl diselenides involves the intermediate formation of phenylselenyl radicals.[40]

$$RCo(dmgH)_2Py \longrightarrow \dot{R} + Co(dmgH)_2Py$$

$$\dot{R} + PhSeSePh \longrightarrow RSePh + Se^{\cdot}Ph$$

$$Co(dmgH)_2Py + PhSeSePh \longrightarrow PhSeCo(dmgH)_2Py + Se^{\cdot}Ph$$

$$\dot{R} + Se^{\cdot}Ph \longrightarrow RSePh$$

$$Co(dmgH)_2Py + Se^{\cdot}Ph \longrightarrow PhSeCo(dmgH)_2Py$$

$dmgH_2$ = dimethylglyoxime

Diphenyl diselenide reacts via a similar mechanism with organic complexes of zirconium,[11] metal carbonyls,[42,43] and the adamantyl radical.[44,45]

The photolytic reaction of diphenyl diselenide with diazomethane proceeds via a free-radical chain mechanism.[45]

$$PhSeSePh \xrightarrow{h\nu} 2\,PhSe^{\cdot}$$

$$PhSe^{\cdot} + CH_2N_2 \longrightarrow PhSeCH_2N{=}\dot{N}$$

$$PhSeCH_2N{=}\dot{N} \longrightarrow PhSe\dot{C}H_2 + N_2$$

$$PhSe\dot{C}H_2 + PhSeSePh \longrightarrow PhSeCH_2SePh + Se^{\cdot}Ph$$

The photochemical reaction of diphenyl diselenide or benzeneselenosulfonate with alkylmercury halides is also initiated by the generation of selenyl radicals.[46]

$$PhSeY \xrightarrow{h\nu} PhSe^{\cdot} + \dot{Y}$$

$$\dot{Y} + RHgCl \longrightarrow \dot{R} + YHgCl$$

$$\dot{R} + PhSeY \longrightarrow RSePh + \dot{Y}$$

$$PhSe^{\cdot} + \dot{R} \longrightarrow PhSeR$$

Y = SePh or SO_2Ar.

Vinyl selenides are formed similarly from vinylmercury halides.[47] The reaction mechanism includes a stage where the phenylselenyl radical adds to the double bond.

$$PhSe^{\cdot} + \underset{HgCl}{\overset{R}{}}\!\!=\!\!\!\!\diagup \xrightarrow{h\nu}$$

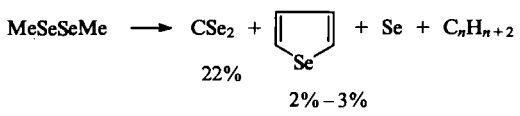
$$\longrightarrow \underset{H}{\overset{R}{}}\!\!-\!\!\underset{HgCl}{\overset{SePh}{}} \longrightarrow \underset{SePh}{\overset{R}{}}\!\!=\!\!\!\!\diagup + Hg^{\cdot}Cl$$

$$Hg^{\cdot}Cl + PhSeSePh \longrightarrow PhSeHgCl + Se^{\cdot}Ph$$

Pulse radiolysis of bis(4-methoxyphenyl) diselenide in methanol generates[48] two types of radicals, $ArS\dot{e}$ and $ArSeS\dot{e}$, whereas only the radicals $ArT\dot{e}$ are formed from the ditellurides under similar conditions.

On irradiation, benzeneselenol reduces via a radical mechanism α,β-unsaturated carbonyl compounds, activated olefins, and β-phenylseleno-substituted ketones to the corresponding saturated ketones and alkanes, while hydrazones, oximes, and anilides are reduced to hydrazines, hydroxylamines, and anilines.[49]

Benzyl phenyl selenide generates a benzyl radical under analogous conditions, the radical reacting with benzeneselenol to form toluene.[50]



$$PhCH_2SePh + PhSeH \xrightarrow{h\nu} PhMe + PhSeSePh$$

3. The generation in thermal reactions of organic compounds of selenium and tellurium and their reactions

Diorganyl selenides and diorganyl diselenides decompose at 450–600 °C with formation of elemental selenium, hydrogen selenide, and a mixture of hydrocarbons. Pulse thermolysis of dimethyl diselenide *in vacuo* (0.1 Torr) at 550 °C leads to dimethyl selenide, methaneselenol, methane, and selenium as well as selenoformaldehyde.[51]

$$MeSeSeMe \longrightarrow MeSeMe + MeSeH + CH_4 + Se$$

On the other hand, the main product of the thermolysis of Me_2Se_2 at 430–500 °C under atmospheric pressure is carbon diselenide.[52] Selenophene and a mixture of gaseous hydrocarbons and selenium are formed together with carbon diselenide.

The corresponding alkaneselenol and dialkyl selenide predominate among the liquid products of the thermolysis of dialkyl diselenides $(C_nH_{2n+1})_2Se_2$ ($n = 2-4$) at 300–500 °C. Their formation is accompanied by the liberation of solid selenium and gaseous hydrogen selenide and alkenes as well as traces of selenophene.[51]

$$Pr^iSeSePr^i \longrightarrow CH_2{=}CHMe + Pr^iSeH + H_2Se + Se$$

Pulse thermolysis *in vacuo* (20 Torr) at 600 °C of dihexyl, didodecyl, and bis(2-phenylethyl) diselenides leads merely to the corresponding alkenes and selenium.[53]

$$RCH_2CH_2SeSeCH_2CH_2R \longrightarrow RCH{=}CH_2 + Se$$

90%–95%

R = Ph, Bu, C_6H_{13}.

Dibenzyl selenide and dibenzyl diselenide are converted on pulse pyrolysis *in vacuo* primarily into bibenzyl and selenium.[54,55] Their substituted derivatives react similarly.

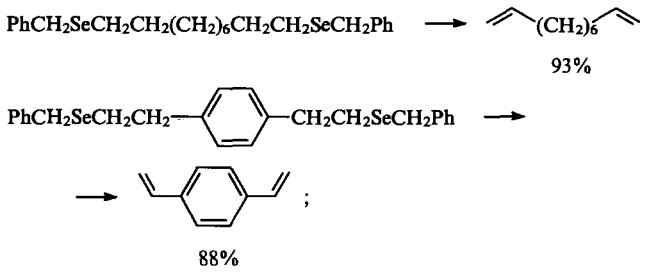
$$ArCH_2SeCH_2Ar \xrightarrow{600\,^\circ C} ArCH_2CH_2Ar + Se$$

63%–89%

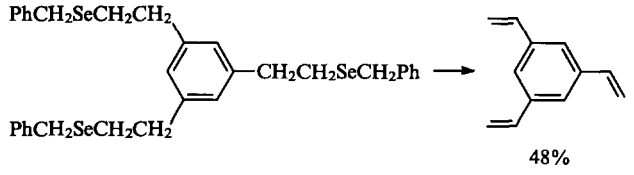
$$PhCH_2SeCH_2Ar \xrightarrow{600\,^\circ C} PhCH_2CH_2Ph + PhCH_2CH_2Ar + ArCH_2CH_2Ar + Se$$

13% 24% 8%

$$PhCH_2SeSeCH_2Ph \xrightarrow{210\,^\circ C} PhCH_2CH_2Ph + Se$$



99.4%



Pulse pyrolysis *in vacuo* of alkyl benzyl selenides is accompanied by the formation of the corresponding alkenes and methane together with bibenzyl and selenium.[53]

$$PhCH_2SeCH_2CH_2Ph \xrightarrow{600\,^\circ C} (Ph\dot{C}H_2 + S\dot{e}CH_2CH_2Ph) \longrightarrow PhMe + PhCH_2CH_2Ph + PhCH{=}CH_2 + Se$$

49% 37% 96%

The following alkenes have been similarly obtained from bis- and tris-(benzyl selenides) respectively:[53]

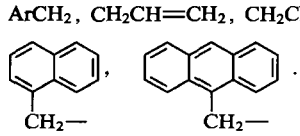
At comparatively low temperatures (150–170 °C), the thermolysis of dibenzyl diselenide leads to a mixture of dibenzyl polyselenides and the liberation of selenium.[56]

$$PhCH_2SeSeCH_2Ph \longrightarrow PhCH_2Se_nCH_2Ph + Se$$

$$PhCH_2Se_nCH_2Ph + m\,Se \longrightarrow PhCH_2Se_{n+m}CH_2Ph$$

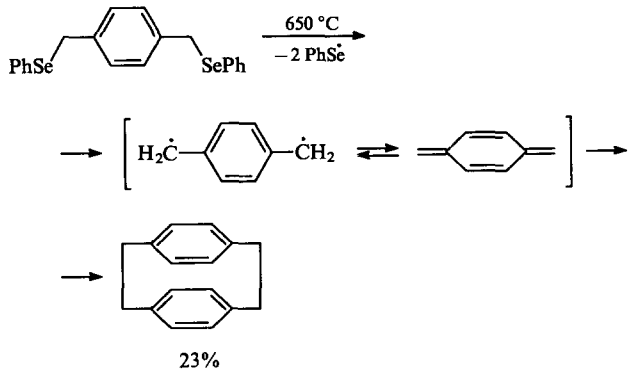
$n = 1-3$.

Bis(diphenylmethyl) selenide reacts similarly.[55]



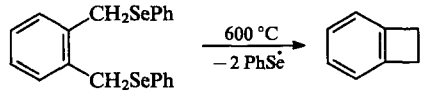
$$Ph_2CHSeCHPh_2 \xrightarrow{140\,^\circ C} Ph_2CHSe_nCHPh_2 + Se$$

Organyl phenyl selenides RSePh, where R represents a relatively stable radical, dissociate on thermolysis with rupture of the R–Se bond. The phenylselenyl radical is then generated.[53,57] Both radicals then dimerise.

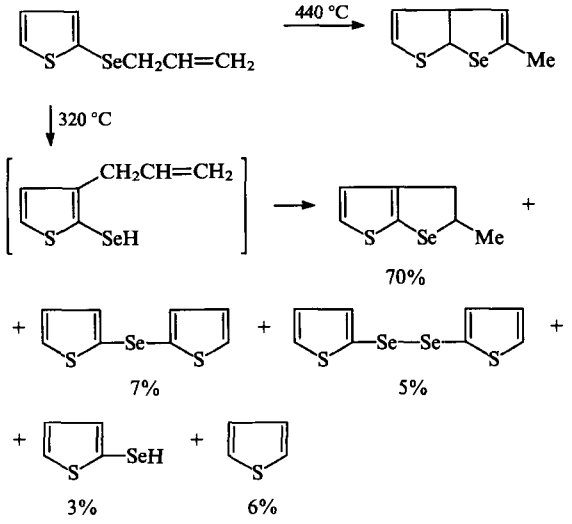


$$RSePh \xrightarrow{600\,^\circ C} \dot{R} + S\dot{e}Ph \longrightarrow R{-}R + PhSeSePh$$

50%–90% 80%–90%

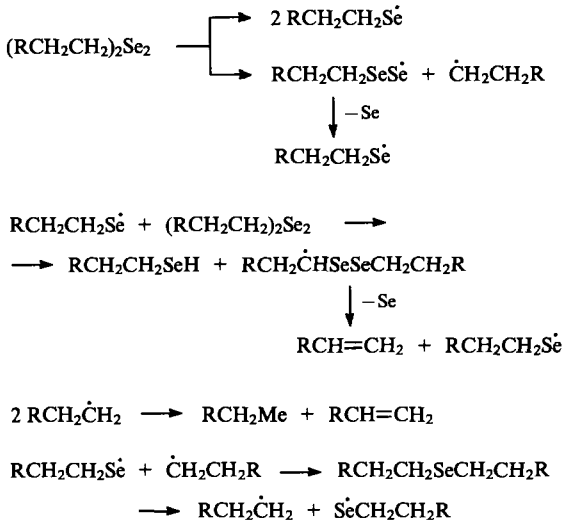


R = $ArCH_2$, $CH_2CH{=}CH_2$, CH_2CN, CH_2COMe,



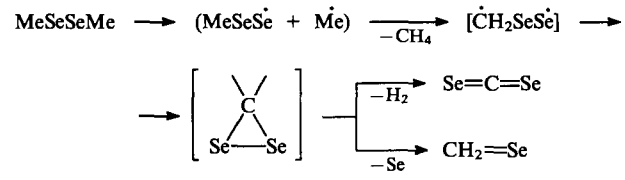
This mode of thermal decomposition of phenyl selenides makes it possible to employ the thermolysis of 1,4-bis(phenylselenomethyl)benzene in order to obtain [2,2]paracyclophane.[53,57]

The strained benzocyclobutene is formed similarly from 1,2-bis(phenylselenomethyl)benzene.[53,57]



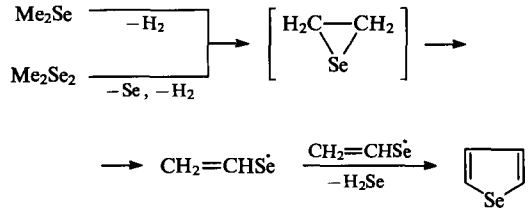
Allyl 2-thienyl selenide readily cyclises at 320 °C, this being preceded by the seleno-Claisen rearrangement.[58]

The reaction side products indicate the generation of thienylselenyl radicals. On vacuum distillation, allyl thienyl selenide cyclises quantitatively and at 440 °C is converted into 2-methylselenopheno[2,3-*b*]thiophene.



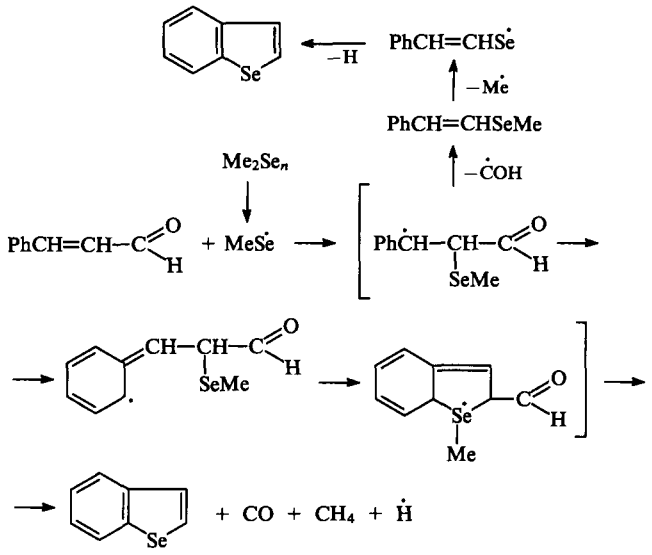
The mode of the thermal decomposition of diorganyl selenides and diorganyl diselenides is determined by the generation of selenyl, perselenyl, and carbon-centred radicals, the reactions of which are determined by their relative stabilities.

Free-radical chain mechanisms have been proposed for the thermal decomposition of diorganyl selenides and diorganyl diselenides.[52]



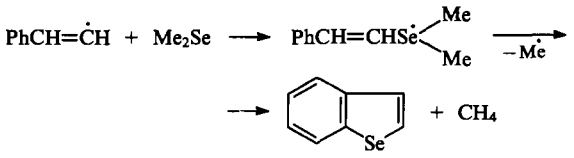
R = H, Me, Et, Ph.

The thermolysis of dimethyl diselenide proceeds via a different mechanism.[52]



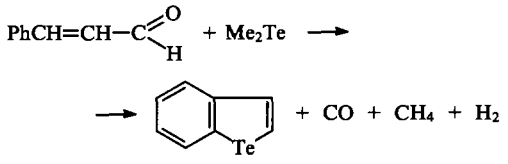
The formation of selenophene as a side product in the thermolysis of dimethyl selenide and dimethyl diselenide is due to the generation of vinylselenyl radicals.

The thermolysis of benzyl organyl selenides always involves the generation of stable benzyl radicals, which recombine to form bibenzyl. Organyl phenyl selenides eliminate phenylselenyl radicals, which also tend to recombine.

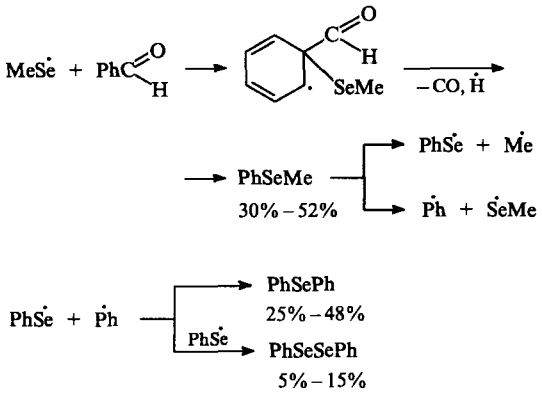


The selenyl and telluryl radicals generated on thermolysis of organic compounds of selenium and tellurium react in the gas and liquid phases with various unsaturated compounds.

A number of chemical trapping agents have been proposed for the alkylselenyl radicals formed as a result of the thermolysis. Thus the reaction of cinnamaldehyde with dimethyl selenide or dimethyl diselenide at 600–650 °C leads to benzoselenophene, the yield of which reaches 53%.[59] The reaction mechanism involves a stage where the methylselenyl radical adds to the double bond of cinnamaldehyde.

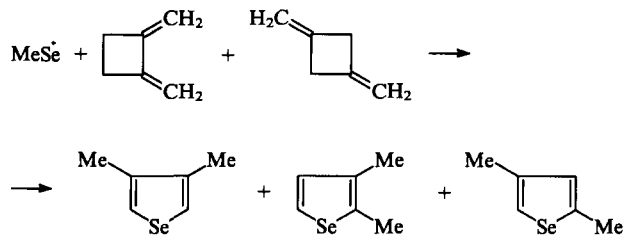


$n = 1, 2.$



The possibility of the occurrence of the following reaction cannot be ruled out either:

Dimethyl telluride reacts with cinnamaldehyde at a lower temperature (500–550 °C) with formation of benzotellurophene, but its yield does not exceed 12%–17%.

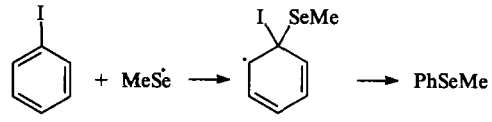


The reaction of Me_2Se or Me_2Se_2 with benzaldehyde takes place already at 400–500 °C with formation of mainly methyl phenyl selenide and diphenyl selenide.[60] Here too methylselenyl radicals attack the carbon atom of the benzene ring bound to the aldehyde group, which is followed by its substitution.

The reaction of ethylselenyl radicals with benzaldehyde is much more difficult (the yield of PhSeEt is 6%–9%).

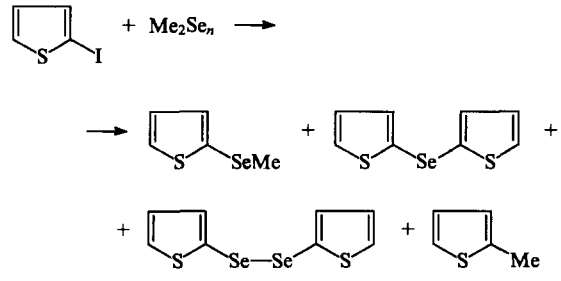
Dimethyl telluride reacts with benzaldehyde similarly to dimethyl selenide, affording PhTeMe (40%) and PhTePh (3%–6%) at 350–400 °C.

The thermal reaction of dimethyl selenide with 1,2- and 1,3-dimethylenecyclobutanes (a mixture of isomers in proportions of 3:1)[61] leads to a mixture of 3,4-, 2,3-, and 2,4-dimethylselenophenes in proportions of 3:1:1.5. Their overall yield is 58%.



The predominance of the 1,2-isomer in the mixture of the isomeric dimethylenecyclobutanes and the easier, from the electronic and steric standpoints, attack by the radical $MeSe^{\cdot}$ on the ring bond remote from the methylene groups are responsible for the preferential formation of 3,4-dimethylseleneophene.

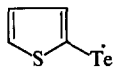
Alkylthiyl radicals react similarly with dimethylenecyclobutanes, but the yields of dimethylthiophenes do not then exceed 42%.



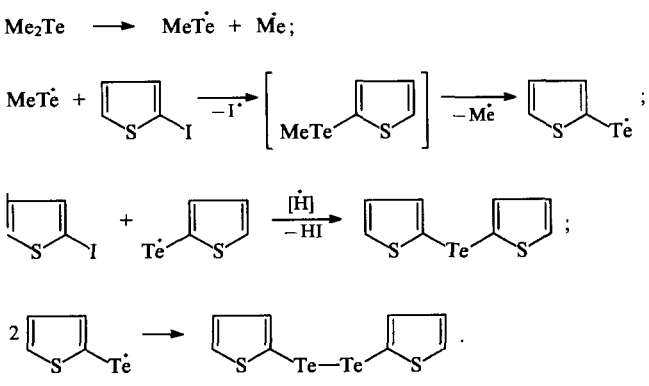
Alkylselenyl radicals react effectively with iodobenzene and iodothiophene in the gas phase.

The cothermolysis of Me_2Se or Me_2Se_2 with iodobenzene at 430 °C leads to selenoanisole (in 33% yield).[62]

The simultaneous formation of selenophenol, diphenyl selenide, and diphenyl diselenide indicates the successive thermal decompositon of selenoanisole accompanied by the formation of the $PhSe^{\cdot}$ radicals.



The main product of the reaction of 2-iodothiophene with Me_2Se_2 at 400 °C is methyl 2-thienyl selenide, the yield of which reaches 64%. The latter decomposes to di(2-thienyl) selenide (16%–28%), di(2-thienyl) diselenide (7%–8%), and 2-methylthiophene (2%–4%).[63]

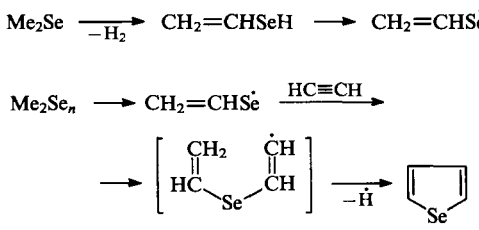


$n = 1, 2.$

Chloro- and bromo-derivatives of benzene and thiophene do not react with selenyl radicals (in contrast to thiyl radicals[7]).

The reaction of 2-iodothiophene with Me_2Te is accompanied by appreciable decomposition of the latter to metallic tellurium and hydrocarbons. Nevertheless the formation under these conditions of thiophene (30%), di(2-thienyl) telluride (8%), and di(2-thienyl) ditelluride (15%) indicates the initial trapping of methyltelluryl radicals by iodothiophene. The unstable methyl thienyl telluride subsequently generates the radical:

in accordance with the following scheme:

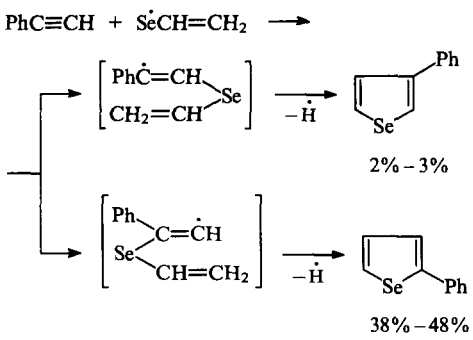


The mobile halogen atom in allyl bromide and benzyl chloride is substituted by radicals under fairly mild conditions already at 90–180 °C in the liquid phase.[64] Alkylselenyl radicals are then generated from dialkyl diselenides.

$$2\,PhCH_2Cl + R_2Se_2 \longrightarrow 2\,PhCH_2SeR + Cl_2$$

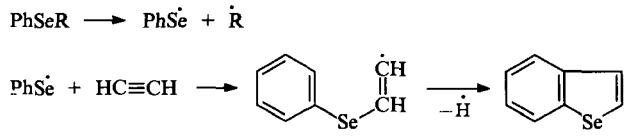
$$2\,CH_2{=}CHCH_2Br + R_2Se_2 \longrightarrow 2\,CH_2{=}CHCH_2SeR + Br_2$$

R = Me, Et.



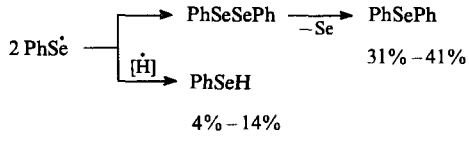
The gas-phase reactions of alkylselenyl radicals with acetylene do not lead to adducts—alkyl vinyl selenides. This may be due to either the low stability of the radical-adduct of acetylene and akylselenyl radicals or the low reactivity of the latter in the given reaction. However, the cothermolysis of dimethyl selenide and dimethyl diselenide with acetylene at 420–470 °C results in the formation of selenophene,[65] the yield of which reaches 80%–94%. The reaction mechanism involves the generation of vinylselenyl radicals from Me_2Se and Me_2Se_2. The vinylselenyl radicals subsequently add to acetylene and the resulting radical-adduct cyclises.

n = 1, 2.



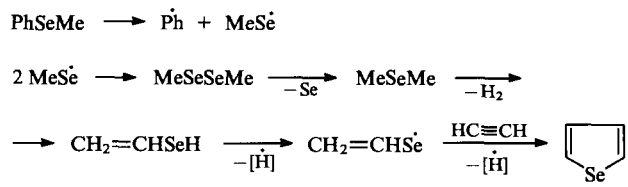
The use of other dialkyl selenides R_2Se (R = Et, Pr, Bu) in the reaction also leads to selenophene, the yield of which depends on R in the following way: Me > Et ≫ Pr > Bu.

The mechanism of the thermal decomposition of dialkyl selenide, including the stage involving the generation of vinylselenyl radicals, has been confirmed by the reaction of dimethyl selenide or dimethyl diselenide with phenylacetylene. The main product of this reaction at 490–500 °C is 2-phenylselenophene, the yield of which reaches 38% in its formation from Me_2Se and 48% in its formation from Me_2Se_2. The formation of phenylselenophene has been represented by a mechanism which involves the addition of vinylselenyl radicals to the triple bond of phenylacetylene predominantly in the α-position.

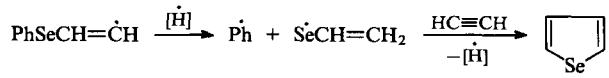


Selenophene, 3-phenylselenophene, and aromatic hydrocarbons are formed as side products.

The cothermolysis of methyl phenyl or allyl phenyl selenide with acetylene at 480–500 °C leads to benzoselenophene—the product of the addition of the phenylselenyl radical to the triple bond.[66]



The radical PhSe rccombines simultaneously to diphenyl diselenide. The latter readily eliminates a selenium atom and is converted into diphenyl selenide.

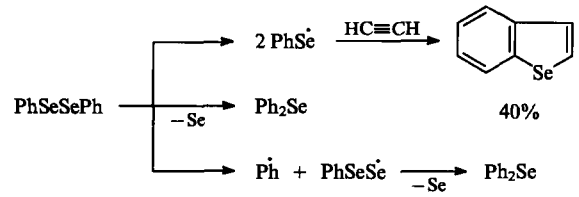


The PhSe radical is partly stabilised as a result of the abstraction of a hydrogen atom from the substrate, affording selenophenol.

The cothermolysis of PhSeR (R = Me, $CH_2{=}CHCH_2$) with acetylene also results in the formation of selenophene, the yield of which reaches 32% in the case of selenoanisole (R = Me).

It has been suggested that the thermolysis of selenoanisole is accompanied by the generation of methylselenyl radicals, the subsequent reactions of which lead to the vinylselenyl radical.

For allyl phenyl selenide, this pathway to selenophene is impossible and therefore the possibility cannot be ruled out that the vinylselenyl radicals, from which the selenophene molecule is formed, are generated on degradation of the radical-adduct.

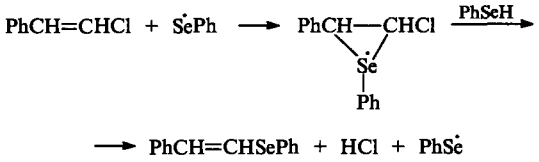


The cothermolysis of alkyl phenyl selenides with acetylene demonstrates the difference between the reactivities of radicals such as PhSe and $CH_2{=}CHSe$. The latter reacts more readily with acetylene. On the other hand, in the case of the isostructural radicals PhS and $CH_2{=}CHS$ the opposite relation is observed.

Allyl phenyl telluride does not react with acetylene at 440 °C but decomposes fully to diphenyl telluride and diphenyl ditelluride. However, at 500 °C the reaction takes place with formation of benzotellurophene and tellurophene in an overall yield not exceeding 3%–4%. This indicates the low reactivity of the PhTe· radicals in the interaction with acetylene. The radicals CH_2=CHTe·, generated in the thermolysis of divinyl telluride, add even at 420–450 °C to the acetylene triple bond with formation of tellurophene (yield 40%).[67]

$$CH_2{=}CHTeCH{=}CH_2 \xrightarrow[-(CH_2{=}\dot{C}H)]{} \rightarrow CH_2{=}CH\dot{T}e \xrightarrow[-\dot{H}]{HC{\equiv}CH}$$

The reaction of diphenyl diselenide with acetylene at 500–580 °C leads to benzoselenophene, selenophene, and diphenyl selenide as a result of the generation of the radical PhSe· and the elimination of a selenium atom.



Only traces of benzotellurophene were detected in the reaction of diphenyl ditelluride with acetylene.

Benzeneselenol adds to styrene at 80–140 °C with formation of 1-phenyl-2-phenylselenoethane (i.e. the anti-Markovnikov adduct), which indicates a radical reaction mechanism.

$$PhCH{=}CH_2 + \dot{S}ePh \rightarrow Ph\dot{C}HCH_2SePh \xrightarrow{PhSeH} \rightarrow PhCH_2CH_2SePh + Ph\dot{S}e.$$

In the interaction of β-chlorostyrene with benzeneselenol in the liquid phase (80–140 °C), the chlorine atom is substituted by the PhSe· radical; the reaction takes place strictly stereospecifically.

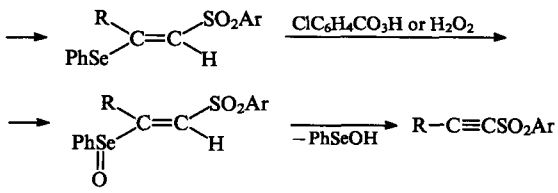
At the same time, β-chlorostyrene is partly reduced to styrene, which subsequently reacts with PhSe· in accordance with the mechanism presented above; the phenylselenyl radicals recombine at the same time.

4. Generation of radicals and the reactions involved in chemical initiation

A series of reactions involving reduction by selenols proceed via a radical mechanism which includes a chemical initiation stage. Thus arenediazonium fluoroborates are converted into a mixture of aryl phenyl selenides and arenes in their reaction with PhSeH.[68]

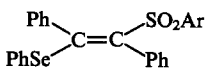
$$ArN_2^+BF_4^- + HSePh \rightarrow ArSePh + N_2 + HBF_4$$

$$ArN_2^+ + PhSeH \rightarrow Ar\cdot + Ph\dot{S}e + N_2 + H^+$$



$$Ar\cdot + PhSeH \rightarrow ArH + Ph\dot{S}e$$

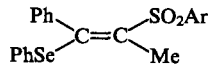
$$2\,Ph\dot{S}e \rightarrow PhSeSePh$$



$$Ar\cdot + PhSeSePh\ (or\ PhSe)\cdot \rightarrow ArSePh$$

Selenosulfonates react with activated acetylene even on slight heating and chemical initiation with formation of anti-Markovnikov adducts. The latter are readily oxidised by H_2O_2 to selenoxides, which spontaneously eliminate selenophenol and are converted into acetylenic sulfones.[69–71]

$$R{-}CH{\equiv}CH + ArSO_2SePh \xrightarrow{\Delta\ (AIBN)}$$



$$PhC{\equiv}CPh + ArSO_2SePh \xrightarrow[C_6H_6,\,\Delta]{AIBN}$$

52%

$$PhC{\equiv}CMe + ArSO_2SePh \xrightarrow[C_6H_6,\,\Delta]{AIBN}$$

97%

The mechanism of the reaction of selenosulfonates with monosubstituted acetylenes is the standard mechanism adopted for free-radical chain reactions (see above).

III. Perselenyl and selenuranyl radicals

The perselenyl radicals RSeSe· are formed together with selenyl radicals RSe· in the photolysis and thermolysis of diorganyl diselenides. They are less stable than the perthiyl radicals RSS·, but are more stable than the pertelluryl radicals RTeTe·.

$$RSeSeR \rightarrow RSeSe\cdot \rightarrow RSe\cdot + Se$$

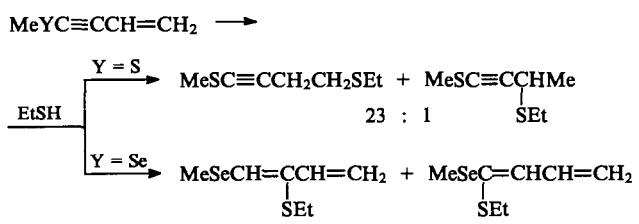
The radicals RSeSe· are more readily detected by the EPR method[30] than the radicals RSe· owing to the delocalisation of the unpaired electron over the neighbouring selenium atom, which leads to the removal of the degeneracy of the levels.[16,72]

The anisotropies of the *g*-factor for the selenyl and perselenyl radicals are significantly different,[30] for example:

Radical	$g_\perp$	$g_\parallel$
PhSe·	2.003	2.016
PhSeSe·	2.026	2.043

λ_{max} = 600 nm corresponds to the radical 4-$MeOC_6H_4SeSe$· in the UV spectra.[21]

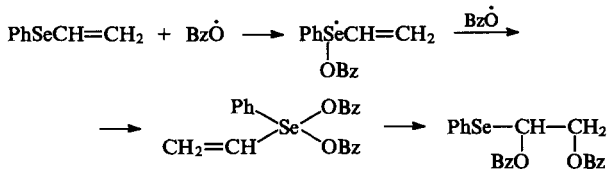
Like their sulfur and tellurium analogues, the selenuranyl radicals $R_2Se{-}X$ are intermediates in the S_N2 homolytic substitution reactions at the selenium atom occurring on treatment of organoselenium compounds with free radicals.[73,74]



$$\dot{X} + R_2Se \rightarrow [R_2Se{-}X] \rightarrow RSeX + \dot{R}$$

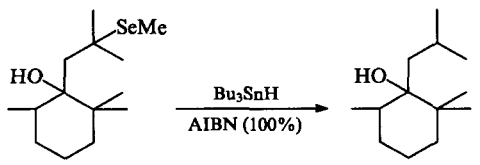
X = $OSiMe_3$, SCF_3, SCOEt, $SCOBu^t$.

The radicals $Ph_2Se{-}X$ are formed on X-irradiation of triphenylselenium halides Ph_3SeX and can be detected by the EPR method. Their unpaired electron is localised predominantly on the orbital connecting the selenium and halogen atoms and oriented at right angles to the CSeC plane (the σ* orbital). The spin density is ~80% localised on the selenium atom and ~20% on the halogen atom.[75]

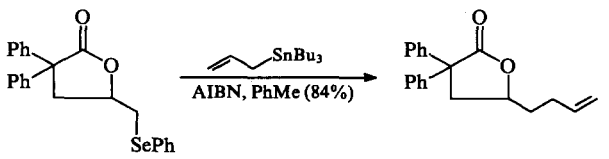


The structure of the σ*-type radical has also been confirmed by the EPR method for other selenuranyl radicals $R_2\dot{S}e-X$ [R = Me, Et, Ph, Ad (1-adamantyl)] and for their asymmetric derivatives with X = EtC(O)S, *tert*-BuC(O)S, CF_3, *tert*-BuO, and Me_3SiO.[76] For example, $a(^{77}Se)$ = 162.6 G for 1-$(Ad)_2\dot{S}e-SC(O)Bu^t$ which corresponds to 3% spin population of the 4*s* orbital of the selenium atom. The spin population of the 4*p* orbital of selenium (38%–71%), which determines the shift of the spin density in $Me_2\dot{S}e-X$, is consistent with the nature of the σ* orbital of the Se–X bond, which depends in its turn on the electronegativity of the atom X.[76]

The geometrical structure of the selenuranyl radical is identical with that of the radical-cations $(Me_2Se-SeMe_2)^{\cdot+}$, formed on γ-irradiation of dimethyl diselenide.[77] The different regiospecificities of certain reactions have been explained by the generation of selenuranyl radicals.[78]



Evidently, when Y = Se, the thiyl radicals $\dot{S}Et$ attack the Se atom with formation of the selenuranyl radical, which subsequently rearranges with migration of the EtSe group to the neighbouring triple bond. Under these conditions, thiuranyl radicals are apparently not formed.



The interaction of phenyl vinyl selenide with benzoyl peroxide, which leads to the product resulting from the dibenzoyloxylation of the double bond, evidently proceeds via selenuranyl radicals.[79,80]

On initiation with AIBN, tributylstannane causes the reductive cleavage of the C–Se bond in hydroxyalkyl selenides.[81]

On chemical (AIBN) and radiation-induced initiation, allyltributylstannane reacts with phenyl selenides to form a new carbon–carbon bond (reductive allylation).[81]

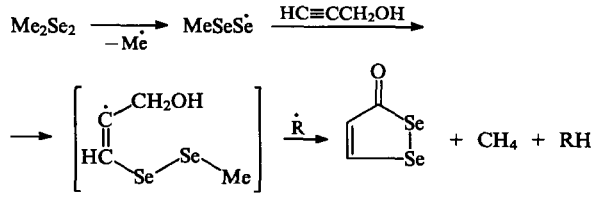
The trialkylstannyl radicals, generated on photolysis of hexaalkylstannanes, cleave the alkyl–selenium bond in dialkyl selenides as well as the analogous bonds in dialkyl sulfides and dialkyl tellurides. The rate of reaction decreases in the sequence $R_2Te > R_2Se > R_2S$.[82]

$$RYR + \dot{S}nBu_3 \longrightarrow RYSnBu_3$$

Y = S, Se, Te.

Triphenylstannane reacts in accordance with a similar scheme with alkyl phenyl selenides in boiling toluene. It has been suggested that these reactions proceed by a free-radical mechanism via the intermediate formation of selenuranyl radicals.[83–88]

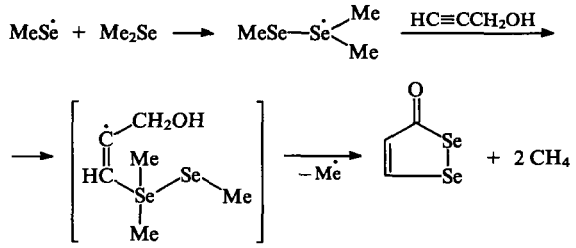
$$Ph_3SnH \longrightarrow Ph_3\dot{S}n + \dot{H}$$



$$Ph_3\dot{S}n + RSePh \longrightarrow PhSe(SnPh_3)R \longrightarrow \dot{R} + Ph_3SnSePh$$

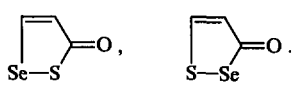
$$\dot{R} + Ph_3SnH \longrightarrow RH + Ph_3\dot{S}n$$

The reduction of organyl phenyl tellurides by tributylstannane apparently proceeds via similar radical states.



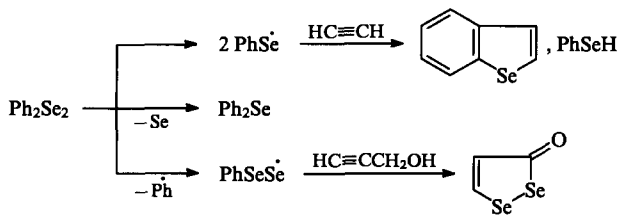
$$PhTeR + HSnBu_3 \longrightarrow PhTeSnBu_3 + RH$$

The cothermolysis of propargyl alcohol with Me_2Se at 460 °C or with Me_2Se_2 at 400–430 °C leads to 1,2-diselenol-3-one in 16%–25% and 73% yields respectively.[89] The reaction mechanism includes a stage in which propargyl alcohol binds perselenyl or selenuranyl radicals generated on thermolysis of dimethyl selenide and dimethyl diselenide.



$$Me_2Se \longrightarrow MeSe\cdot + Me\cdot$$

$$2\,MeSe\cdot \longrightarrow Me_2Se_2 \xrightarrow[-Me\cdot]{} MeSeSe\cdot$$



Other dialkyl diselenides, i.e. Et_2Se_2 and $Pr^i_2Se_2$, react similarly with propargyl alcohol. Propargyl alcohol traps perthiyl (sulfuranyl) radicals much less effectively and their tellurium analogues are not trapped at all

The thermolysis of a mixture of Me_2S_2 and Me_2Se_2 also results in the generation of mixed perchalcogenyl radicals, which form two mixed thiaselenolones on interaction with propargyl alcohol:

The gas-phase reaction of diphenyl diselenide with propargyl alcohol and the product of its thermolysis (acetylene) at 500–550 °C also leads to 1,2-diselenol-3-one (in 14%–16% yield). Diphenyl selenide (26%–31%), benzoselenophene (8%–12%), selenophene (2%–14%), and selenophenol (3%) are formed together with 1,2-diselenol-3-one.

Ph_2Te_2 hardly reacts with propargyl alcohol even at high temperatures.

IV. Seleninyl and selenonyl radicals

Seleninyl radicals PhSeȮ and selenonyl radicals $PhSe\dot{O}_2$ are generated on X-radiolysis of diphenyl selenoxide[25] and on ^{60}Co γ-radiolysis of diphenyl selenone[90] respectively. They have been detected by the EPR method in the solid phase and the distribution of the spin density on the selenium, sulfur, and oxygen atoms has been determined (Table 2). In chalcogeninyl radicals, the spin density is concentrated to a greater extent on the chalcogen atoms than in chalcogenonyl radicals. In the sulfur analogues of these radicals, the spin density is localised on the sulfur atom to a greater extent than on the selenium atom in the selenium analogues.

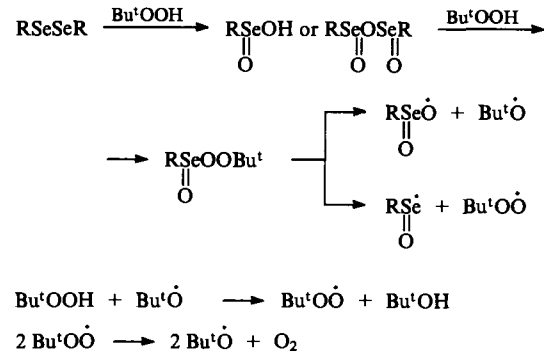


Table 2. Distribution of the spin density.

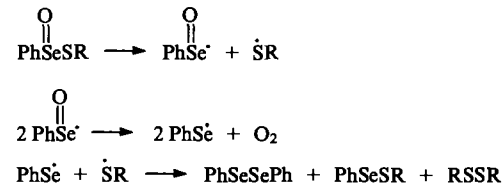
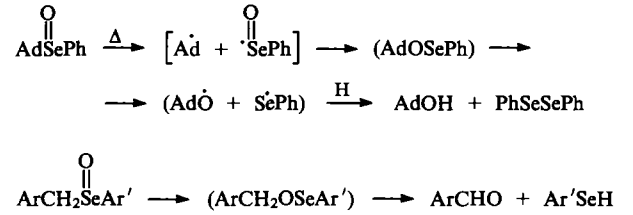
Radical	Spin density (%)		Ref.
	S, Se	O	
MeSO	87	13	92
$PhSO_2$	42 (38)	29 (31)	90 (91)
$PhSO_2$	46	27	90
PhSeO	78	22	25
$PhSeO_2$	40	30	90



The seleninyl radicals PhSeȮ, in which the selenium atom is in a positive oxidation state, are generated as a result of the radical attack on the anhydride of the corresponding seleninic acid or on *S-tert*-butyl benzenethioseleninate [PhSe(O)SBu^t].[93]

The catalytic decomposition of *tert*-butyl hydroperoxide by diselenides, seleninic acids, or their anhydrides apparently involves the formation of peroxyseleninates as intermediates. Their subsequent homolysis with dissociation of the O–O or Se–O bond leads to the radicals $RSe\dot{O}_2$, RSeȮ, Bu^{t}Ȯ, and Bu^{t}OȮ.



Selenium-containing radicals are subsequently converted into selenium acids or their anhydrides via a hitherto unknown mechanism.[94,95]

It has been suggested that thioselenates are formed as intermediates on oxidation of thiols by benzeneseleninic acid. They are subsequently destroyed via a radical mechanism.[96]

The thermolysis of aryl selenoxides includes stages involving the generation of the radicals ArSeȮ.[97,98]

Contents

I. Introduction	1119
II. Synthesis of organic and organoelement polycarbodiimides	1119
III. The structure and certain physical properties of polycarbodiimides	1123
IV. Chemical properties of polycarbodiimides	1124
V. Practical use of polycarbodiimides	1134

Abstract. The literature data on the synthesis, structure, and properties of a promising class of polyfunctional polymers — polycarbodiimides — are surveyed. The polymerisation reactions of the carbodiimide groups of the polymers and the reactions involving polyaddition to various functional groups with formation of linear and network polymers are described. Certain aspects of the practical use of polycarbodiimides are considered. The bibliography includes 320 references.

I. Introduction

The most promising aspect of the synthesis of heat resistant and thermostable composite polymeric materials is believed at the present time to be their formation from thermoreactive polymers and oligomers capable of being converted into network structures without evolving volatile products.[1–17] Polycarbodiimides, polymers containing the N=C=N groups in the macrochain, are of undoubted interest in this connection.

Carbodiimides can be regarded as alkyl(aryl) derivatives of their simplest representative HN=C=NH, which exists mainly in the tautomeric form $NH_2-C\equiv N$. These compounds belong to the group of heterocumulenes, which comprise a large class of unsaturated compounds based on the allene structure.

Whereas 20 years ago carbodiimides were used solely for preparative purposes, nowadays they are widely employed in various branches of industry, particularly in polymer chemistry. This has been promoted by the discovery of selective catalysts for the decarboxylation of isocyanates, which make it possible to synthesise under mild conditions carbodiimides in virtually quantitative yields.

The preparation of low-molecular-mass carbodiimides and their physical and chemical properties have been described in a series of review articles.[1,18–25] However, to date there have been no surveys of polycarbodiimides and their properties. This review deals with the methods of synthesis of both low-molecular-mass and high-molecular-mass carbodiimides, attention being concentrated on the most promising and technological methods of synthesis, referring precisely to polycarbodiimides, which have been developed in recent years. The structures and properties of polycarbodiimides and of the products of their structure formation reactions are also dealt with in the review as regards the understanding of the principal aspects of their practical applications.

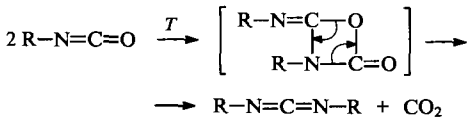
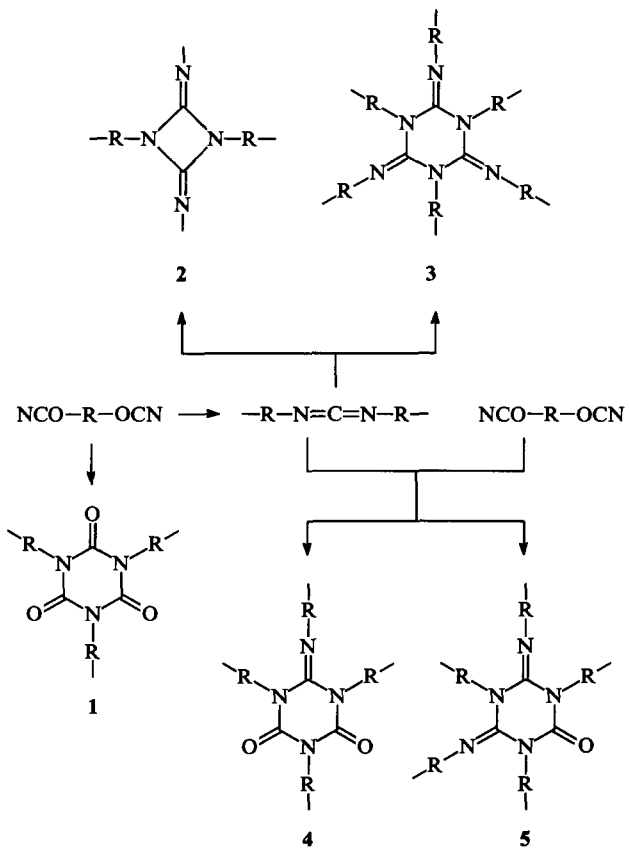
II. Synthesis of organic and organoelement polycarbodiimides



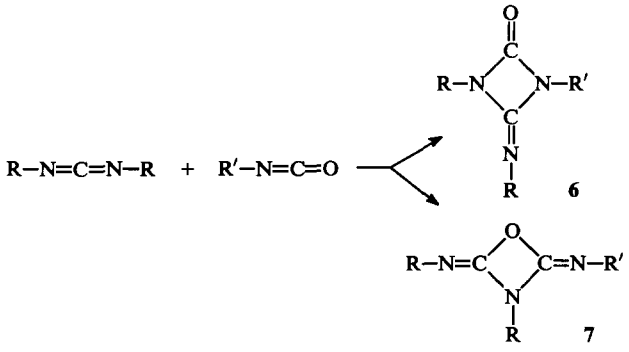
A large number of different methods of synthesis of carbodiimides have now been described in the literature. The principal of these are the desulfurisation of thioureas, the dehydration of urea, and the decarboxylation of isocyanates.[1,18–25]

The commonest method involves the decarboxylation of isocyanates.

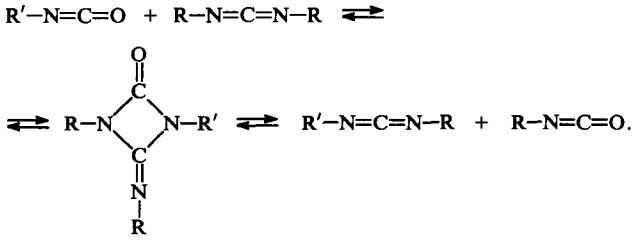


$$2\,R-N=C=O \longrightarrow R-N=C=N-R + CO_2 .$$

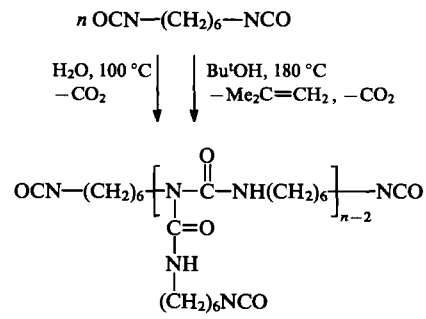
At elevated temperatures, this reaction can proceed vigorously even in the absence of catalysts.[26] Certain aromatic carbodiimides, for example, diphenylcarbodiimide (heating of phenyl isocyanate for 24 h at 180 °C), were in fact obtained for the first time in this way.[26] After prolonged heating, diisocyanates afford polycarbodiimides.



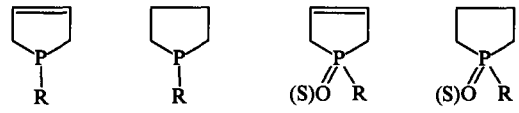
Neuman and Fischer[27] established that the thermal conversion of isocyanates into carbodiimides is autocatalytic and suggested that it proceeds via the formation of intermediate unsymmetric cyclic dimers.



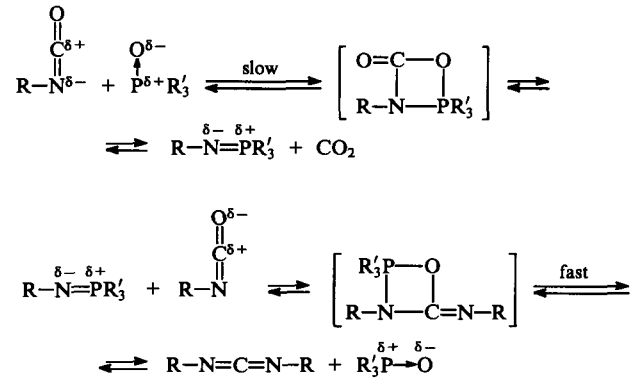
Unfortunately, the purely thermal decarboxylation of isocyanates is accompanied by numerous side reactions, for example the cyclotrimerisation of isocyanates (adduct **1**), the cyclodimerisation and cyclotrimerisation of carbodiimides (adducts **2** and **3**), and the interaction of isocyanates with carbodiimides (adducts **4** and **5**).



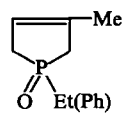
In the study of the reaction of carbodiimides with isocyanates in the absence of oxygen and moisture at 100–160 °C, Neuman and Fischer[27] isolated the unstable cyclic adducts **6** and **7**.



It was shown in the same study that adducts of type **6** (uretone imines) decompose on heating to an isocyanate and a carbodiimide with exchange of substituents in accordance with the following scheme:

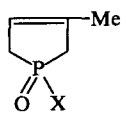


Acceleration of the decarboxylation reaction can be achieved by adding small amounts of water, *tert*-butyl alcohol, and mono- and di-amines to the reaction mixture. Polyisocyanates **8**, with a biuret main chain, have been obtained.[28] They function as catalysts of the carbodiimide formation reaction.



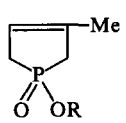
Numerous compounds have been proposed as catalysts, but the highest catalytic activity was found for P-substituted phosphacyclopentenes (phospholenes) **9** and phosphacyclopentanes (phospholans) **10**[29] as well as the *P*-oxides or sulfides **11** and **12**.[30–32]

The mechanism of the catalytic conversion into a carbodiimide has been investigated[33–36] and a two-stage mechanism has been proposed for the process.



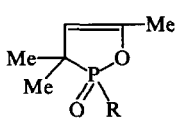
By comparing the catalytic activities of various phosphorus compounds in the carbodiimide formation reactions, Monagle et al.[36] established the following activity series: phosphine oxides > phosphinates > phosphonates > phosphates. Tertiary phosphine oxides, containing the phospholene ring, proved to be the most active.[29,34–38] The use of these catalysts ensured the formation of pure carbodiimides under mild conditions (60–100 °C) in high yields. 1-Ethyl-1-oxo- and 1-oxo-1-phenyl-3-methylphospholenes have been used most frequently as catalysts.

The ethyl derivative proved to be the most active but the phenyl derivative is most readily available.



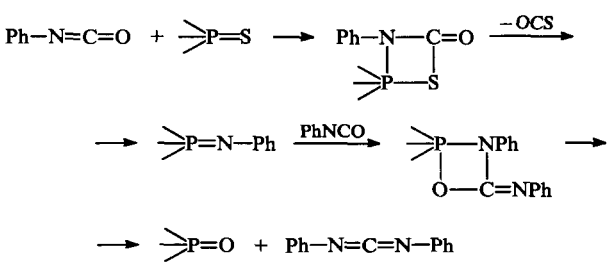
Much work has been done by Arbuzov and co-workers in the study of the influence of the structures of various phospholene derivatives on the catalytic activity in the carbodiimide formation reaction.[39] The catalytic activity in the series of phospholene-phosphinic acids was estimated from the rate constants for the conversion of phenyl isocyanate into diphenylcarbodiimide in solution in toluene at 20 °C.

It was shown that the conversion of the esters **14** (X = OR) into the amides (X = NR_2), the replacement of the alkyl group R in the esters by an aryl or alkylaryl group, the migration of the double bond in the ring, as well as the presence or absence of substituents at the carbon atoms of the phospholene ring induce only slight changes in the reaction rate constant [$k = (0.8-3.0) \times 10^4\ s^{-1}$]. On the other hand, all the compounds investigated are significantly inferior as regards catalytic activity to phospholene oxide (X = Ph) ($k = 68.6 \times 10^4\ s^{-1}$). On the basis of the results obtained, the authors[39] propose the following catalytic activity series: phospholene oxides > phospholenephosphinates > acyclic phosphine oxides > phosphinates.

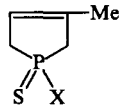


14

Subsequently Arbuzov and coworkers[40] investigated the influence of the environment of the phosphorus atom in organophosphorus compounds on their catalytic activity in carbodiimide formation reactions. The conversion of phenyl isocyanate into diphenylcarbodiimide at 242 °C in the presence of derivatives of phospholene **15** and oxaphospholene **16**, containing the same numbers of P–C and P–O bonds, was chosen as the model reaction.

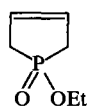


15

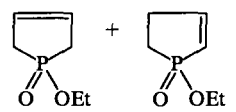


16

The replacement of the phospholene isomer by the oxaphospholene isomer led to a significant decrease in the catalytic reaction rate constant (from 17×10^4 to $3.8 \times 10^4\ s^{-1}$ for R = Et and from 14×10^4 to $0.8 \times 10^4\ s^{-1}$ for R = Ph). The conversion of exocyclic esters into amides (–NR_2 instead of –OR) caused by a further decrease in the carbodiimide formation reaction rate constant—approximately by a factor of two. The specific properties of phospholene derivatives, ensuring the maximum catalytic activity, were thereby confirmed.



The replacement of the oxygen atom by a sulfur atom in phospholene oxides also diminished greatly the catalytic activity of these compounds. Kinetic experiments carried out on phosphoryl and thiophosphoryl compounds revealed a significant difference in the mechanisms of the reactions involving these compounds.[40] In the case of thiophosphoryl compounds, the plot of the relation $\ln(1-P)^{-1} = f(\tau)$ (P is the degree of conversion and τ the time) showed an inflection, which indicated an increase in the activity of the catalyst during the process. The following reaction mechanism was proposed:

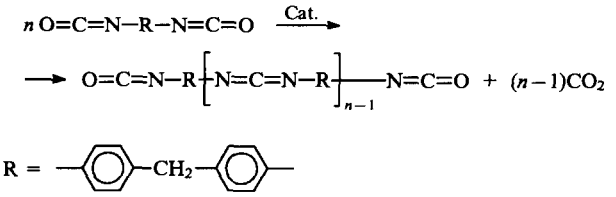


The phosphoryl catalyst accumulated during the reaction, increasing the overall reaction rate constant. The authors therefore determined two reaction rate constants: k_1 at the beginning (when the content of the phosphoryl compound was low) and k_2 at the end of the reaction (when virtually the entire thiophosphoryl catalyst was converted into the phosphoryl catalyst). For initial catalysts of the type

the ratio of the rate constants for the condensation of phenyl isocyanate at 442 K changed from ~1.5 (X = OEt) to ~6.5 (X = SEt). Guberman et al.[41] investigated the influence of the structure of the phosphospholene catalysts **13**, **17**, and **18** and of substituted initial phenyl isocyanates $X-C_6H_4-N=C=O$ on the kinetics of the conversion of the latter into carbodiimides.

17

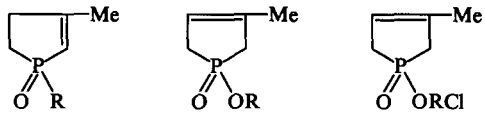
18



The reactions were carried out in benzene or toluene at concentrations of the isocyanates and the catalysts of 1 kmol m^{-3} and 0.04 kmol m^{-3} respectively. The catalyst **13** proved to be significantly more active than the catalysts **14** and **15**, which agrees well with the results of previous studies. The influence of the substituents (X) on the reactivities of substituted phenyl isocyanates was determined from the results.

$$o\text{-Cl} < H < p\text{-Cl} < m\text{-Cl} < m\text{-}CF_3 < m\text{-}NO_2 .$$

The relation obtained agrees well with the reaction mechanism proposed previously[33–36] (electron-accepting substituents, with the exception of those giving rise to steric hindrance, facilitate the nucleophilic attack of the phosphoryl group on the carbonyl carbon atom of the isocyanate).

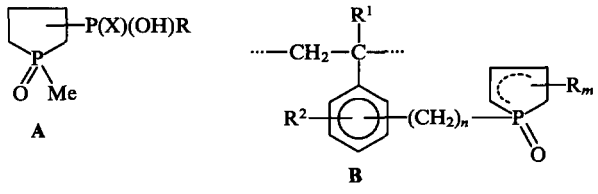


Aliphatic carbodiimides have also been obtained[33] in reactions catalysed by oxaphospholenes but at higher temperatures and in lower yields. Thus n-butyl isocyanate was converted into di-n-butylcarbodiimide to the extent of only 17% on refluxing for 20 h with 1.4 mol.% of 1-ethyl-3-methyl-1-oxo-3-phospholene. The yield was increased to 60% by carrying out the reaction in high-boiling solvents. The reaction was faster for high-boiling aliphatic isocyanates. For example, 2-octyl isocyanate was converted after 2 h at 413–433 K into the corresponding carbodiimides to the extent of 89%.

The influence of the chemical structures of a series of phospholene oxides on the rate of formation of polycarbodiimide

from bis(4-isocyanatophenyl)methane has been estimated.[42]

Derivatives of 3-methyl-1-oxophospholene of three types were used as catalysts: tertiary phosphine oxides **19**, phosphinates with unsubstituted ester groups **20**, and phosphinates with haloester groups **21**.



19 20 21

In all cases, the reaction was carried out in benzene at 353 K and diisocyanate and catalyst concentrations of 1 and 0.02 kmol m^{-3} respectively.

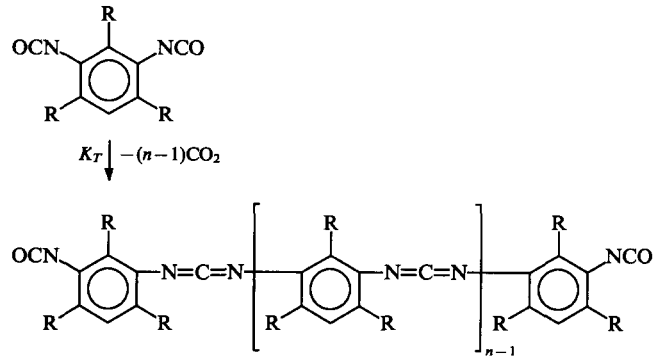
It was found that the catalytic activities of the phospholene derivatives investigated depend significantly on the catalyst structure, primarily on the nature of the exocyclic substituent at the phosphorus atom. Compounds **19** exhibited the highest catalytic activity. When the phosphinates **20** were used, the reaction rate constant fell by a factor of approximately 50. The haloesters **21** were found to be even less active. Thus the dependence of the rate constants for the carbodiimide formation reaction on the electronegativity of the substituents at the phosphorus atoms was also observed for the series of compounds investigated, as had been found for monoisocyanates.[39-41]

Insoluble polymeric catalysts for the condensation of isocyanates have found extensive application. They were synthesised in two ways. The first is based on the addition of soluble derivatives of phospholene oxides **A** (R = OH, Me; X = O, S) to an ion-exchange matrix with formation of insoluble high-molecular-mass carbodiimide formation catalysts.[43-46] The second procedure is based on the chloromethylation of the styrene–divinylbenzene copolymer (molar ratio 98:2).[47] The product thus obtained was treated, for example, with 1-chloro-3-methyl-3-phospholene, catalysts containing the repeating unit **B** (where R = Hal, Alk, AlkO, PhO, HalAlk; R^1 = H, Me; R^2 = radical not containing substituents interacting with isocyanate groups; m = 1–3; n = 0, 1) being obtained after oxidation with hydrogen peroxide.

A B

Since the polymeric catalysts are less active than the soluble phospholene derivatives, the condensation of isocyanates in their presence was carried out at higher temperatures (413–423 K). The advantages of the polymeric catalysts include the possibility of repeated use and the possibility of obtaining stable polycarbodiimides not containing an admixture of the catalyst.[43-50]

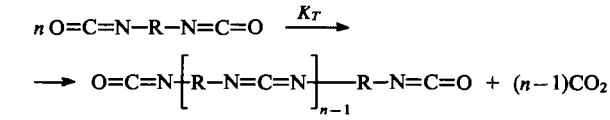
Apart from the phospholene derivatives, it has been suggested that acyclic trialkyl phosphine oxides,[51-53] phosphates,[51-54] alkoxyphosphines,[55] and triphenyl-n-butylphosphonitrobromide [bromo(n-butyl)triphenylphosphorane (Translator)],[56] as well as the product of the interaction of a bicyclic terpene (camphene) with dichlorophenylphosphine[57] be used as carbodiimide formation catalysts.



Certain organic compounds of arsenic, containing the highly polarised As–O bond, for example triphenylarsine oxides, also exhibit a fairly high catalytic activity.[51]

In order to obtain insoluble arsenic-containing catalysts, brominated or chlorinated polystyrene was treated with diphenylarsonium chloride and then oxidised with hydrogen peroxide. The polymers obtained contained the $AsO(C_6H_5)_2$ and $CH_2AsO(C_6H_5)_2$ groups. These catalysts were used to obtain low-molecular-mass carbodiimides from bis(4-isocyanatophenyl)-methane.[58-60]

It has been suggested that derivatives of *s*-triazine[61-65] or their mixtures with derivatives of hexahydro-*s*-triazine[66] as well as dialkyl sulfates, sulfites, or sulfoxides[67] be used as catalysts for the condensation of diisocyanates in industry, especially in the manufacture of polyurethane foams containing a controllable amount of carbodiimide groups.



Despite the fact that the chemistry of carbodiimides has developed over a period of over 100 years, these compounds have found practical applications only recently. There is no doubt that this is to a large extent associated with the discovery of the possibility of obtaining polymeric carbodiimides from the corresponding industrial diisocyanates. The interest shown in polycarbodiimides is due to their high thermal stability and heat resistance and satisfactory physicomechanical parameters.

Neuman and Fischer[27] obtained by the catalytic condensation of isocyanates in the presence of phospholene oxides oligomeric ($M \leqslant 2000$) α,ω-diisocyanatopolycarbodiimides with aliphatic substituents in aromatic nuclei, which prevented the formation of cross-linked structures.

R = Me, Et, Pr^i.

Campbell and Smeltz[68] synthesised polycarbodiimides by the polycondensation of aromatic diisocyanates in hydrocarbon solvents in the presence of 1-ethyl-3-methyl-1-oxo-3-phospholene.[68]

R = Ar.

Polycarbodiimides have been synthesised by the polycondensation of a series of aromatic and aliphatic diisocyanates in hydrocarbon solvents or in mixtures with dimethyl sulfoxide (metastable solutions were formed in the latter case) in the presence of 3-methyl-1-oxo-1-phenyl-3-phospholene.[69] The polymers had high softening temperatures (200–350 °C) and were converted into pale-yellow films by pressing under pressure. Aliphatic polycarbodiimides formed weak and brittle films, whereas films based on aromatic polycarbodiimides were strong and rigid.

In order to reduce the softening temperatures of the polycarbodiimides and to obtain soluble polymers, it has been suggested that the polycondensation of diisocyanates be terminated at the stage involving the formation of low-molecular-mass oligomers. The reaction was carried out after a definite degree of conversion (3%–60%) of isocyanate groups into carbodiimide groups with subsequent cooling of the reaction mixture.[46,53,59,60,70-74] Liquid diisocyanatooligocarbodiimides based on bis(4-isocyanatophenyl)methane were synthesised in this way. They are stable during storage for 3–6 months.[60,70,75-78]

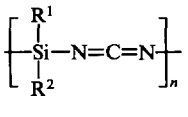
Studies on the synthesis of carbodiimide-containing polymers with a specified molecular mass by the introduction of monofunctional isocyanates into the reaction system are of considerable interest.[1,78-82] It was shown that the thermal characteristics of the polymers, synthesised from a mixture of di- and

mono-functional isocyanates, are close to the characteristics of high-molecular-mass carbodiimides based on diisocyanates alone. The polymers obtained for the molar ratios of the di- and mono-functional isocyanates ranging from 6:1 to 20:1 have a mechanical strength close to that of the high-molecular-mass polymer. The softening temperatures of such polymers were in the range 230–260 °C and the decrease in mass on heating in air at 300 °C was ~2% (at a heating rate of 15 K min $^{-1}$).[79]

Polycarbodiimides with an exceptionally high thermal stability have been obtained by the joint condensation of various aromatic diisocyanates.[24] For example, the copolymers of *p*-phenylene diisocyanate and 1,5-naphthylene diisocyanate had a softening temperature of about 300 °C. The average molecular masses of these α,ω-diisocyanatopolycarbodiimides were low, since limiting solubilities in inert solvents are reached with increase in the molecular mass of the polymers and the latter precipitate from the solution. After this, the increase in molecular mass ceases. Ternary mixed polycarbodiimides, consisting of 2,4-tolylene diisocyanate and the aromatic diisocyanates indicated above in proportions of 1:1:1, had average molecular masses of about 3500.

It has been established[24] that oligomeric α,ω-diisocyanatocarbodiimides are formed from 2,4-tolylene diisocyanate at room temperature in the presence of phospholene oxides as catalysts. Wagner et al.[24] synthesised a homologous series of carbodiimide oligomers based on 2,4-tolylene diisocyanate by fractionation in cyclohexanone or in a petroleum ether–hexane mixture. The oligocarbodiimides obtained in this way are of interest for use in polymer-analogue reactions.

The synthesis of organoelement polycarbodiimides $[-E-N=C=N-]_n$, the N=C=N groups of which are linked directly to the atom of the [inorganic] element, differs fundamentally from the synthesis of organic polycarbodiimides.



Thus polymeric silicon-containing carbodiimides are formed from silver cyanamide and dialkyl- or diaryl-dichlorosilanes.[83] The tetramer of dibutylbis(carbodiimido)stannane has been obtained similarly from $Bu^n_2SnCl_2$.[84]

$$n\,Ag_2NC{\equiv}N + n\,RR'MCl_2 \longrightarrow \longrightarrow \left[MRR'-N=C=N\right]_n + 2n\,AgCl$$

M = Si; R = Me, Ph, EtO; R′ = Me, Ph, Vinyl, EtO;
M = Sn; R = R′ = Bu; n = 4.

The corresponding polysilylcarbodiimides have been synthesised from dicyanodiamide and polysilazanes.[85]

Oligomeric silicon carbodiimides have been obtained by heating $Me_3SiN=C=NSiMe_3$ with dihalosilanes, trihalosilanes, or haloorganosiloxanes with simultaneous distillation of the Me_3SiCl evolved.[86,87]

R^1 = Me, Ph; R^2 = Ph.

A distinctive feature of polysilylcarbodiimides is the direct linkage between the carbodiimide group and the silicon atom, which alters significantly the reactivity of the former. In contrast to organic analogues, such compounds can react not only via the carbodiimide group but also via the silicon–nitrogen bond.

The oligomers obtained are highly viscous liquids or solids at room temperature. Their molecular mass, determined by the ebullioscopic method, is in the range 3000–5000, which corresponds to a polarisation coefficient in the range 15–25. Polysilylcarbodiimides exhibit a high thermal stability and do not undergo structure formation on heat treatment in contrast to their aromatic analogues. They do not lose mass on heating to 400 °C and retain their solubility in organic solvents under these conditions. The IR spectra of the initial polydiphenylsilylcarbodiimides and those heated at 350 °C for 2 h hardly differ. The temperature of the onset of the decrease in mass is 450 °C for these polymers. Oligomeric polysilylcarbodiimides contain a fairly high percentage of coke (up to 30% at 900 °C).[86,87]

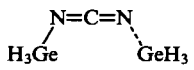
In order to investigate the influence of the relative content of rigid aromatic and flexible siloxane units on the properties of oligocarbodiimides, the copolymers of aromatic diisocyanates—4,4′-bis(isocyanatophenyl)methane and 2,4-tolylene diisocyanate—with organosilicon macrodiisocyanates were obtained.[88] The molar ratio of the aromatic and organosilicon macrodiisocyanates varied from 0–1 to 50–1 (moles). Thermal and physicomechanical studies on these polymers showed that their properties depend significantly on the ratio of the starting materials taken for the reaction (Table 1).

Table 1. The properties of the linear copolymers obtained by the polycondensation of di(4-isocyanatophenyl)methane (**A**) and an organosilicon macrodiisocyanate (n = 14) (**B**) for different proportions of the starting materials.[88]

Molar ratio **A**:**B**	η_{int}/dl g^{-1}	Yield (%)	T_{soft}/°C	σ_t/kgf cm^{-2}	ε (%)
0:1	0.63	92	−84	72	118
10:1	–	93	140	190	95
20:1	0.84	89	160	240	70
30:1	–	95	170	300	45
40:1	0.89	96	180	350	20
50:1	–	94	190	420	10
C[a]	0.9	–	280	500	5

[a] The thermal and physico-mechanical parameters of the linear aromatic polycarbodiimide based on di(4-isocyanatophenyl)methane (**C**) are included for comparison.

The data presented show that the carbodiimides can be obtained by easy and varied procedures, in many instances in high yields. The practical value of polycarbodiimides consists in their high reactivity in relation to many organic compounds, which makes it possible to obtain from them a wide variety of polymeric materials, including those with high thermal stabilities and heat resistances. Therefore we shall consider below their structural features and also their physical and chemical properties.



III. The structure and certain physical properties of polycarbodiimides

According to X-ray diffraction data, the carbodiimide group is not linear, the N=C=N angle varying in the range from 166° to 170° for both aliphatic and aromatic carbodiimides.[89–93] The dihedral angle between the substituents at the nitrogen atom is approximately 90°, but the C=N–Ar angle exceeds the expected value of 120° and varies in the range 123°–180°.

The anomalous value of the N=C=N angle has been explained[89] by the influence of the packing factors in the crystals. However, the fact that all the carbodiimides investigated[89–93] exhibit such anomaly casts doubt on the validity of this explanation. It has been shown that in other heterocumulenes the X=Y=Z triatomic group has a not entirely linear structure. Thus a microwave spectroscopic study of chlorine azide (ClN_3) yielded a N=N=N angle of ~172°.[94] According to microwave spectroscopic data and quantum-chemical calculations, the isocyanate group is also non-linear, the O=C=N angle amounting to 171°–175° depending on the nature of the group at the nitrogen atom.[95–97]

These data indicate that the bent structure of the carbodiimide group can arise also as a result of electronic effects and not only due to crystal packing effects.[22]

The results of both electron diffraction[98] and X-ray diffraction[99] studies on organoelement carbodiimides indicate the existence of nonlinear and linear structures of digermylcarbodiimide **22** and bis(triphenylsilyl)carbodiimide **23** respectively.

22

23

An electron diffraction study has also indicated a linear configuration of the NCNSi group in disilylcarbodiimide.[100]

The electronic structures and stereochemistry of aliphatic and organoelement low-molecular mass carbodiimides as well as nuclear magnetic resonance, IR, photoelectron, and UV spectroscopic, and mass-spectrometric data for these compounds have been examined in detail in a series of reviews,[18-25] so we need not dwell on their discussions in the present review. However, the physicochemical characteristics of high-molecular-mass carbodiimides merit a more detailed description.

Linear high-molecular-mass carbodiimides, obtained under mild conditions, exhibit film- and fibre-forming capacities, possess high thermal characteristics and effective strength parameters, and are resistant to the action of corrosive liquids.[68,69]

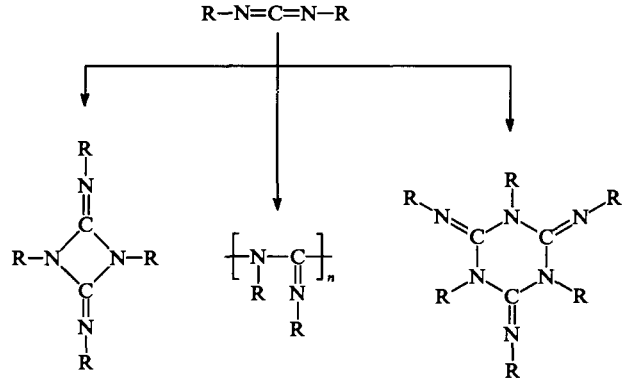
The effective physico-mechanical and dielectric properties of polycarbodiimides may be illustrated in relation to the film of poly(3,3'-dimethoxy-4,4'-diphenyl)carbodiimide obtained by pressing at 300 °C and oriented at 115 °C.

Initial modulus of elasticity/kgf cm^{-2} †	86200
Tensile strength/kgf cm^{-2}	2900
Elongation (%)	6.2
ε ($10^2 - 10^5$ Hz)	3.8 (170 °C)
tan δ ($10^2 - 10^5$ Hz)	0.006–0.02 (170 °C)

The study of the thermal properties of polycarbodiimides with blocked terminal groups established that oligocarbodiimides are characterised by a satisfactory fluidity in the temperature range 240 –270 °C, their fusion being accompanied by an increase in the viscosity of the melt and the transition of the specimen to the highly elastic state.[80] An increase in the viscosity of the melt with increase in the molecular mass of the initial oligocarbodiimide has been noted. Polycarbodiimides based on di(4-isocyanatophenyl)-methane have a glass point of 220 °C and pass to the highly elastic state at 250 °C, a further increase in temperature leading to an increase in the modulus of elasticity.

The preparation of polycarbodiimides and layered plastics based on them, containing reinforcing fibrous fillers, has been discussed.[101] The polycarbodiimides were obtained by heating di(4-isocyanatophenyl)methane at 20–150 °C in solution, for example in benzene, in the presence of 3-methyl-1-phenyl-2-phospholene 1-oxide with subsequent addition of monoisocyanates. The decrease in the mass of the resulting polymers in air (thermogravimetric analysis, heating rate 10 K min^{-1}) at 250 °C and 300 °C was 0.7% and 1.7% respectively. The polymer specimens, obtained by pressing in preheated moulds at 180–200 °C, had a tensile strength of 680 kgf cm^{-2}, a modulus of elasticity on extension of 10 100 kgf cm^{-2}, an elongation of 7%, and a glass point of 208 °C.

Polymeric organosilicon carbodiimides of the type $[-SiRR'N=C=N-]_n$, where R,R' = Me, Ph, or vinyl, obtained by the reaction of polychlorosilanes, or chlorosilanes with $Me_3SiN=C=NSiMe_3$, are colourless or pale-brown products, which on heating above 100 °C are gradually converted into viscous oils. Their thermal stability is apparently determined by the presence of a certain number of siloxane units in the macromolecular chain,[83] because the onset of the loss of mass by these products is observed already at 200 °C. The IR spectra of the specimens hardly change even on heating up to 350 °C for 2 h *in vacuo*, which indicates a higher thermal stability of the silylcarbodiimide groups.

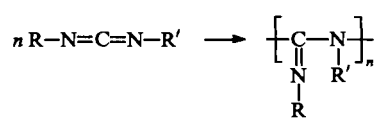


Organoelement carbodiimides possess N=C=N groups which are much more stable as regards polymerisation than in their organic analogues; silicon-, germanium-, tin-, and lead-containing monocarbodiimides can be stored virtually without change for many months.[102] Under these conditions, an increase in viscosity as a consequence of polymerisation, which is so characteristic of organic carbodiimides, is not observed. Organosilicon monocarbodiimides can be as a rule vacuum-distilled without decomposition at 250–260 °C.[102] This can be explained by the increased strength of their Si–N bond as a result of the $d_\pi - p_\pi$ interaction of the silicon and nitrogen atoms.[103]

Organosilicon polycarbodiimides are stable when irradiated, which makes it possible to use them under the conditions of intense irradiation. For example, mass loss is not observed for the polysilylcarbodiimide $[-Ph_2SiN=C=N-]_n$ with a molecular weight of 4285 on heating to 400 °C under a nitrogen atmosphere and it retains its elasticity on irradiation with a dose of 2000 Mrad.[86]

IV. Chemical properties of polycarbodiimides

The chemical properties of carbodiimides are determined primarily by the highly unsaturated nature of these compounds and hence by their tendency to undergo polymerisation and addition reactions.



Like isocyanates, carbodiimides are capable of polymerising via the nitrogen–carbon bond with formation of linear polymers, and also of cyclodimerisation and cyclotrimerisation.[1,18-25]

Unfortunately, these interesting reactions have been inadequately investigated and there exist only a limited number of communications on this topic in the literature.[79-82,104-110]

1. Linear polymerisation of carbodiimides

The anionic polymerisation of carbodiimides, analogous to the polymerisation of isocyanates,[111] was first reported by Robinson.[112]

R, R' = Et, Bu, Hex, All, Ph.

† 1 kgf cm^{-2} = 0.9807 × 10^5 Pa.

The reaction was carried out in hydrocarbon solvents in the presence of n-butyllithium at 0–25 °C. Table 2 presents certain data on the polymerisation of carbodiimides and on the properties of the resulting polymers.

Table 2. The properties of the polymers obtained by the anionic polymerisation of carbodiimides.[112]

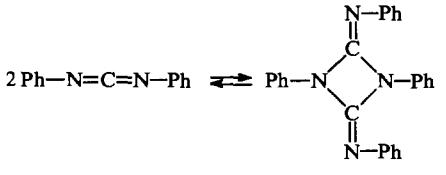
$CH_2-CH=CH_2$	"	37	0.13	92
Bu^n	n-heptane	15	0.15	96
n-C_6H_{13}	"	15	0.12	90
Me	"	38	0.14	95

[a] Intrinsic viscosity in formic acid at 30 °C.
[b] Onset of polymerisation at 25 °C and then at 0 °C.
[c] Thermal polymerisation in the absence of a solvent.

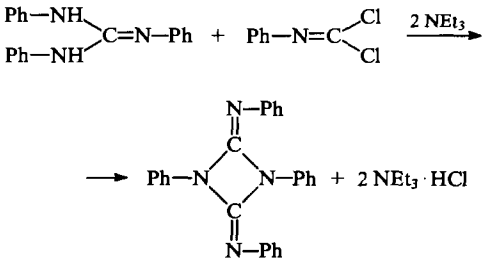
The polymers are white powders insoluble in organic solvents. On heating, they partly decomposed to the initial monomers, the greatest thermal stability being shown by the polymers based on diphenylcarbodiimide. It has also been observed[112] that cationic catalysts do not polymerise carbodiimides but form ionic compounds with the latter.

$$p\text{-BrC}_6\text{H}_4\text{SO}_2\text{Cl} + \text{R–N=C=N–R}' \longrightarrow \longrightarrow \left[p\text{-BrC}_6\text{H}_4\text{SO}_2\text{–}\overset{\text{R}}{\underset{|}{\text{N}}}\text{–}\overset{+}{\text{C}}\text{=N–R}'\right]\text{Cl}^-$$



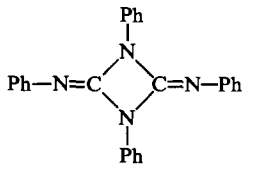
The characteristic features of the linear polymerisation of monocarbodiimides suggest that polycarbodiimides can react similarly, but such data are not available in the literature.

2. Polymerisation of mono- and poly-carbodiimides with formation of cyclic structures

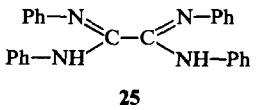


Since the study of the structures of network polymers, formed on polymerisation of polycarbodiimides, presents considerable difficulties, at the beginning of this section we shall consider studies devoted to the cyclodimerisation and cyclotrimerisation reactions of monocarbodiimides as well as studies on the low-molecular-mass structures of the resulting individual products. Investigation of such systems, modelling the corresponding processes in polymers, helps to interpret the more complex structures of the network polymers obtained from polycarbodiimides.

a. Cyclodimerisation and cyclotrimerisation of monocarbodiimides



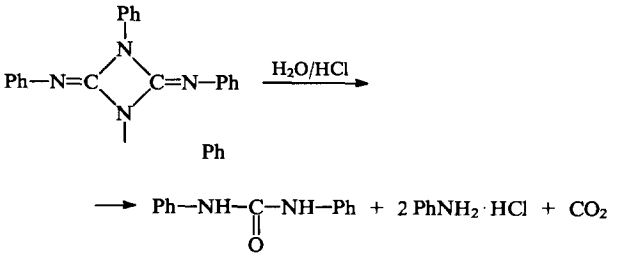
The cyclodimerisation of carbodiimides based on diphenylcarbodiimide has been investigated by Richter.[113] It was found that it occurred on heating even in the absence of a catalyst.



With increase in the reaction temperature, the yield of the dimer also rose, reaching a maximum at 165–175 °C (43% after 16 h). A further increase in temperature reduced the yield to 30% at 200 °C and 13.5% at 230–235 °C. On the basis of these results, Richter suggested that the thermal dimerisation of diphenylcarbodiimide is reversible. Tertiary phosphines proved to be its active catalysts. By adding, for example, tri-n-butylphosphine, it proved possible to attain a yield of the dimer of 75% at a reaction temperature of only 90 °C. In order to demonstrate the cyclic structure of the diphenylcarbodiimide dimer, Richter carried out its unambiguous synthesis[113] by the reaction of triphenylguanidine with phenyl isocyanide dichloride [*N*-phenylcarbonimidic dichloride (Translator)].

Tsuzuki and Iwakura[114] investigated the reactions of diphenylcarbodiimide in the presence of sodium naphthenate in an aprotic solvent, leading to the formation of both cyclic and linear structures. The cyclic dimer **24**, with a characteristic band due to the stretching vibrations of the ring C=N bond at 1690 cm^{-1}, as well as the linear dimer **25**, the structure of which was characterised on the basis of the IR absorption band near 1637 cm^{-1}, were obtained, isolated, and identified.

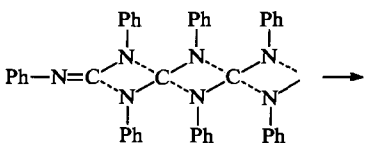
24



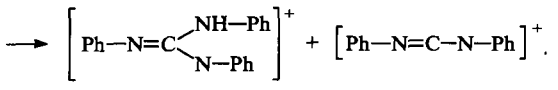
25

The authors[114] showed that the structure of compound **25** is formed in the presence of considerable amounts of sodium naphthenate and of protons in the reaction mixture. The formation of the diphenylcarbodiimide trimer was not observed under the conditions investigated.

There are also other examples of the study of the dimerisation of carbodiimides.[115–117]

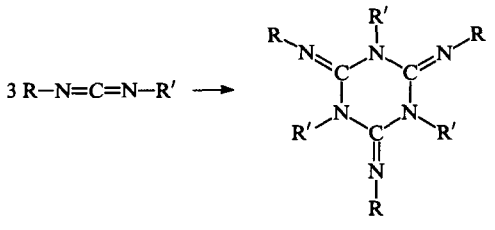


Pankratov et al.[118] synthesised the diphenylcarbodiimide dimer by prolonged heating of diphenylcarbodiimide at 160–170 °C in the absence of a catalyst. The product recrystallised from a 1 : 1 (by volume) benzene–ethanol mixture consisted of a white powder with a melting point of 162.5–163 °C. It was readily soluble in benzene, chloroform, and acetone. The diphenylcarbodiimide dimer was identified[118] by mass spectrometry and IR spectroscopy (the C=N bond absorption band at 1690 ± 10 cm^{-1}) and also on the basis of the composition of the hydrolysis products.



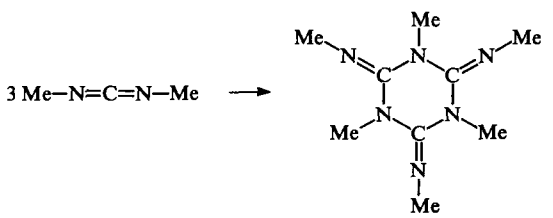
As early as the last century, it was known[119] that diphenylcarbodiimide polymerises slowly at room temperature with formation of the so called 'β-diphenylcarbodiimide', to which a trimeric structure was attributed.[120] The structure of this compound has not been established up to the present time apparently owing to its sparing solubility in organic solvents and instability on heating. Richter[113] obtained 'β-diphenylcarbodiimide' in a high yield by heating diphenylcarbodiimide in the presence of catalytic amounts of tris(diethylaminomethyl)-phosphine.

An attempt has been made[118] to identify 'β-diphenylcarbodiimide'. According to the authors,[118] their structure of 'β-diphenylcarbodiimide' agrees with IR spectroscopic data and the results of hydrolysis in the presence of hydrochloric acid and explains the sparing solubility of this compound in organic solvents in the cold as well as its low stability on heating.

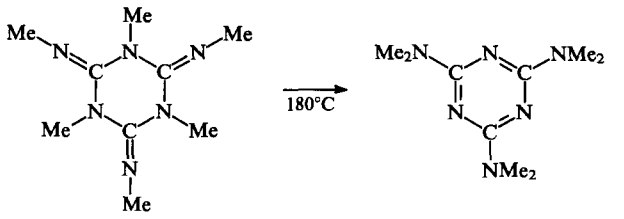


The peaks due to ions with m/e = 286 (intensity ~1%) and with m/e = 194 (intensity ~100%) were observed in the mass spectrum of 'β-diphenylcarbodiimide'. Taking into account the structure of this compound proposed in the above study, the mechanism of its decomposition by electron impact has been represented as follows:[118]

However, the above structure of 'β-diphenylcarbodiimide' still remains only tentative.



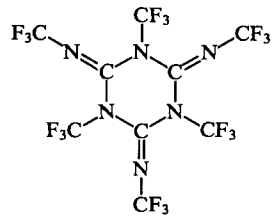
The cyclotrimerisation of carbodiimides with formation of derivatives of 1,3,5-hexahydro-2,4,6-triazine **26** is one of some comparatively little investigated reactions.[104,105,110,117,118,121–124]



26

According to Busch and coworkers,[121,122] the cyclotrimerisation of diphenylcarbodiimide with formation of a cyclic trimer (hexaphenylisomelamine) takes place when dry hydrogen chloride is passed into a benzene solution of diphenylcarbodiimide containing a small amount of phenol.

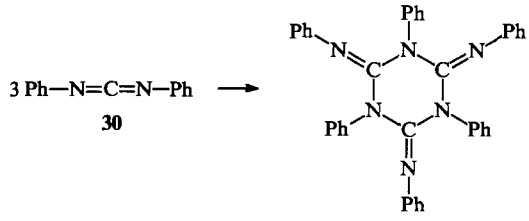
The cyclotrimerisation of dimethylcarbodiimide has been reported.[106]



On heating to 180 °C, the isomelamine form **27** of the trimer is converted into the more stable melamine form **28**.

27 **28**

In the course of their synthesis of fluorinated carbodiimides by the reaction of $F_3C-N=CF_2$ with equimolecular amounts of amines RNH_2, Flowers et al.[117] isolated compound **29** as a side product.



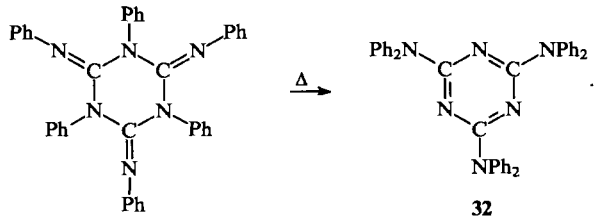
29

Hexaphenylisomelamine has also been isolated after heating phenyl isocyanate with *N*-methylhexamethyldisilazane.[125]

The literature contains a series of communications describing the cyclotrimerisation of carbodiimides with azomethines,[126,127] isocyanates,[128,132] acyl isocyanates,[133] chlorosulfonyl isocyanates,[134] and isothiocyanates,[135] which leads to the formation of *s*-triazine derivatives.

Pankratov et al.[118] obtained hexaphenylisomelamine **31** with a melting point of 196–196.5 °C by the cyclotrimerisation of diphenylcarbodiimide **30**.

30 **31**



Comparison of the thermal stabilities of derivatives of diphenylcarbodiimide enabled Pankratov et al.[118] to arrange them in a series in terms of increasing thermal stability: 'β-diphenylcarbodiimide' < dimer < hexaphenylisomelamine.

'β-Diphenylcarbodiimide' decomposed on heating above 100 °C in the presence of high-boiling organic solvents, for example 1,1,2,2-tetrachloroethane. Its only decomposition product was diphenylcarbodiimide.[118]

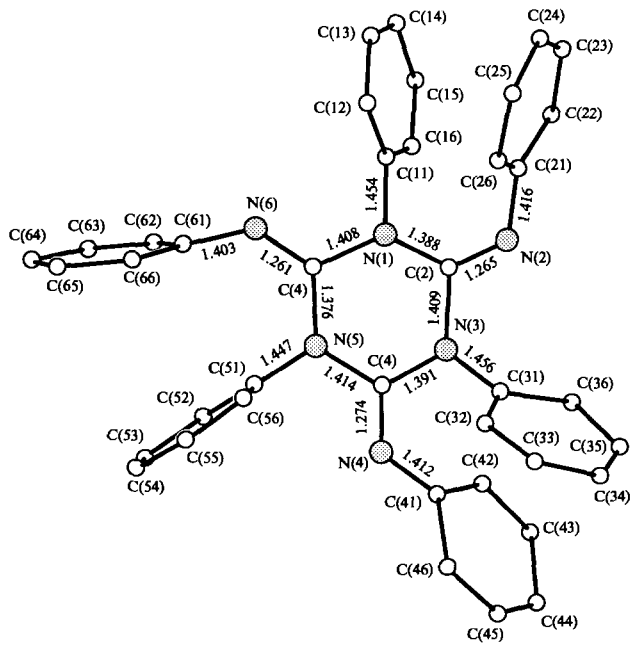
The dimer melted without decomposition at 162.5–163 °C and decomposed vigorously only on heating above 200 °C. Diphenylcarbodiimide was obtained in 80% yield on thermal decomposition of the dimer at 250 °C.

Hexaphenylisomelamine underwent no changes whatever even on prolonged (40 h) boiling in high-boiling liquids, for example in *N*-methyl-2-pyrrolidinone, decalin, and benzyl alcohol. In contrast to triphenylisomelamine,[136] it does not

isomerise to the melamine derivative on heating in benzyl alcohol in the presence of alkali metal alkoxides. On heating in the absence of solvents, hexaphenylisomelamine is stable up to 300–320 °C. However, on heating at a higher temperature for 12 h under an inert atmosphere, hexaphenylmelamine was nevertheless obtained in 80% yield.[118]

32

In order to elucidate the causes responsible for the thermal isomerisation of the iso-form of hexaphenylmelamine to the normal form and to explain the greater thermal stability of the latter, the structures of the isomeric hexaphenylmelamines were investigated by X-ray diffraction.[104] It was established that the central heterocycle of the iso-form (Fig. 1) is nonplanar and has the configuration of a skewed flattened boat. In contrast to the planar configuration of the heterocycles in analogous compounds (cyanuric acid[139,140] and triphenyl isocyanurate[141]), such nonplanar configuration is probably a consequence of intramolecular steric strain. Distortions of the plane of the exocyclic bond angles and also distortions of the plane of the exocyclic C=N double bonds, the torsional angles of which reach 20°, indicate the phenyl–phenyl steric interactions. Such twisting is usual in the presence of bulky substituents at a double bond.[142] The steric repulsion in pairs of phenyl substituents proved to be so great that the C(21), C(41), and C(61) atoms were displaced from the average plane of the neighbouring atoms to the extent of approximately 0.06 Å, but the configuration of the C(11), C(31), and C(51) atoms remained virtually planar.[104]



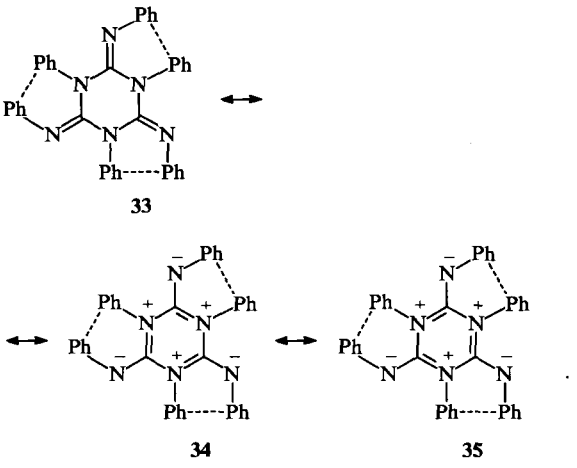


Figure 1. Projection of the hexaphenylisomelamine molecule onto the average plane of the heterocycle.

The lengths of the endocyclic C–N bonds in the hexaphenylisomelamine molecule (d_{av} = 1.398 Å) are intermediate between the lengths of single (1.47 Å) and double (1.23 Å) carbon–nitrogen bonds. This fact is partly due to the contribution to the molecular structure of hexaphenylisomelamine, apart from that of the main form **33**, also by the resonance forms **34** and **35** with alternation of double and single bonds in the heterocycle (the intramolecular contacts between the phenyl substituents are indicated by dashed lines in the formulae below).

33 34 35

The lengthening of the C–N exocyclic bonds on average to 1.267 Å is also associated with the contribution of the resonance forms **34** and **35**.[104]

In hexaphenylmelamine **31**, the atoms of the heterocycle as well as the exocyclic nitrogen atoms are located in a single plane (Fig. 2). The structure of this compound is of the usual type for n-melamine derivatives. The greater rotation of the benzene rings relative to one another than relative to the triazine ring leads to a weaker intramolecular interaction of the 'phenyl–phenyl' type compared with the 'phenyl–triazine ring' interaction. On this basis, the greater stability of the normal form of hexaphenylmelamine has been explained[104] by the significantly smallest steric strain in its molecule.

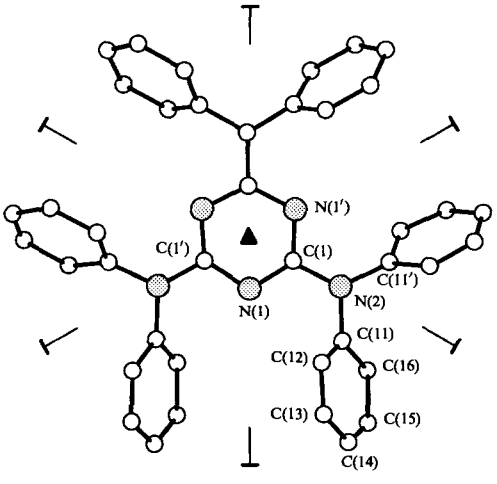

Figure 2. Projection of the hexaphenylmelamine molecule onto the plane perpendicular to the vertical symmetry axis.

Lebedev et al.[110] investigated the thermodynamic characteristics of a series of reactions modelling the processes occurring in the synthesis of oligocarbodiimides and structure formation in the latter.

The temperature dependence of the heat capacities of crystalline hexaphenylmelamine, hexaphenylisomelamine, as well as phenyl isocyanate and diphenylcarbodiimide in the crystalline, vitreous, supercooled liquid, and ordinary liquid states has been investigated in an adiabatic vacuum calorimeter in the temperature range 13.8–330 K with an accuracy to within ~0.3%; the enthalpies of combustion of the test substances at 298.15 K and a pressure of 101.325 kPa were investigated in an isothermal bomb calorimeter.

The functions $H^0(T)-H^0(0)$, $S^0(T)-S^0(0)$, and $G^0(T)-G^0(0)$ were calculated from the results in the temperature range 0–330 K; the zero point entropy and the difference between the zero point enthalpies of the vitreous and crystalline diphenylcarbodiimides and the thermochemical parameters of formation (ΔH_f^0, ΔS_f^0, ΔG_f^0) of the test substances were calculated at the standard temperature and pressure.

It was found that the enthalpy of the decarboxylation of phenyl isocyanate is comparatively small: $\Delta H_r = -(40.6 \pm 2.9)$ kJ mol^{-1}.

The enthalpies, entropies, and Gibbs free energies of the direct conversion of diphenylcarbodiimides into hexaphenylisomelamine and hexaphenylmelamine and of the isomerisation of hexaphenylisomelamine to the normal form are presented in Table 3.

Table 3. Thermodynamic parameters of the cyclotrimerisation of diphenylcarbodiimide to hexaphenylisomelamine and hexaphenylmelamine.[110]

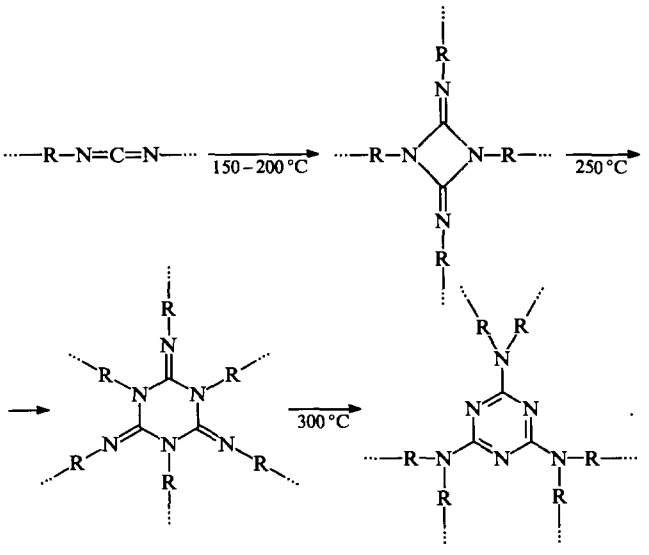
T/K	Physical state of reactants	$-\Delta H^0$/ kJ mol^{-1}	$-\Delta S^0$/ J mol^{-1} K^{-1}	$-\Delta G^0$/ kJ mol^{-1}
	Cyclotrimerisation of compound **27** to **28**			
0	c, c	168.4	0	168.4
100	c, c	170.5	38.85	166.6
200	c, c	174.2	64.80	161.3
298.15	l, c	236.4	283.6	151.8
	Cyclotrimerisation of compound **27** to **29**			
0	c, c	326.6	0	326.6
100	c, c	329.7	61.76	323.5
200	c, c	334.5	94.42	315.6
298.15	l, c	397.4	316.3	303.1
	Isomerisation of compound **28** to **29**			
0	c, c	158.3	0	158.3
100	c, c	159.4	22.91	157.1
200	c, c	160.3	29.63	154.4
298.15	c, c	161.1	32.73	151.3

Note. The following designation of the states of the reactants has been adopted: l = liquid state, c = crystalline state.

In the temperature range 0–298 K, the cyclotrimerisation of the imide **30** and the isomerisation of compound **31** to **32** are thermodynamically allowed ($\Delta G < 0$). The upper limiting temperatures of these processes, found by extrapolation, exceed appreciably the temperatures of the onset of the thermal degradation of the reactants. The free energies of formation of compounds **31** and **32**, 1232.9 ± 7.4 and 1081.1 ± 13.1 kJ mol^{-1} respectively, indicate a greater thermodynamic stability of the latter compound, which confirms the conclusion that compound **31** may isomerise to compound **32** under kinetic conditions.[110]

Pankratov et al.[105] investigated in the temperature range 250–550 °C the thermal, thermooxidative, and thermohydrolytic stabilities of diphenylcarbodiimide **30**, the cyclic diphenylcarbodiimide dimer **24**, hexaphenylisomelamine **31**, and hexaphenylmelamine **32** — compounds which model the principal fragments of the network polymers based on oligo- and polycarbodiimides.

It was shown that, on thermolysis *in vacuo*, the stabilities of these compounds are approximately the same (the formation of the solid and liquid degradation products is observed at temperatures above 400 °C), but the thermooxidative stability of the products of the cyclotrimerisation of diphenylcarbodiimide, namely hexaphenylisomelamine and hexaphenylmelamine, is appreciably higher than that of the initial monomer. On the other hand, under the conditions of thermohydrolysis, the trimer **32** begins to decompose at 400 °C, which is 150 °C higher than the temperature of the decomposition of the N=C=N group in carbodiimide and the isomelamine ring.[105]



Taking into account the entire set of data concerning the chemical reactions of diphenylcarbodiimide under the influence of temperature, one may postulate that the reaction involving the formation of network polymers from oligocarbodiimides may involve, depending on the hardening conditions, the formation of three types of nodal fragments: uretediimine, isomelamine, and melamine fragments. Under these conditions, an increased number of melamine fragments in the structure of the cross-linked polymer should increase its thermal stability.

b. Polycyclisation of oligo- and poly-carbodiimides

There are literature data on the polycyclisation of polycarbodiimides. It has been stated in a number of studies[79,80,143,144] that the N=C=N groups of linear oligo- and poly-carbodiimides may polycyclise at elevated temperatures, but the structures formed have not been analysed.

In a number of studies[12,15,81,87,104,105,107–110,118,136,145–156] it was shown that, when aromatic oligocarbodiimides were heated, polymerisation took place with participation of the reactive N=C=N group and was accompanied by the loss of solubility and an increase in hardness and mechanical strength. At the same time, a weakening of the absorption band due to the carbodiimide groups in the range 2115–2145 cm^{-1} and the appearance of absorption bands in the range 1500–1700 cm^{-1}, corresponding to the vibrations of cyclic and dimeric (1690 cm^{-1}), isomelamine (1640 cm^{-1}), and n-melamine fragments (1530 cm^{-1}), were observed.

The influence of temperature and of process time on the degree and mode of isomerisation of oligocarbodiimides has been investigated by IR spectroscopy. A study was made of the dependence of the degree of conversion of the carbodiimide groups of the oligomers based on di(4-isocyanatophenyl)-methane and phenyl isocyanate (n = 25) on the duration of isothermal polymerisation at 150, 200, 250, and 300 °C. An increase in temperature from 150 to 300 °C induced an increase in the degree of conversion from 25%–30% to 70%–80%. The polymerisation temperature influenced significantly also the structure of the network polymers formed. Thus at 150–200 °C the principal reaction was cyclodimerisation, whilst on raising the temperature to 250 °C cyclotrimerisation of the carbodiimide groups predominated. At 300 °C and above, the appearance of an absorption band in the region of 1530 cm^{-1}, assigned to the vibrations of *sym*-triazine rings, was noted. Thus it is believed[81,105,107–109,118] that the following processes take place in the polymerisation of aromatic polycarbodiimides at different temperatures:

With increase in the temperature of the polymerisation of oligocarbodiimides, the degree of structure formation in the latter also increases. As a consequence of the preferential formation of the thermally more stable cyclotrimeric network nodes, the temperatures of the onset of mass loss and of the onset of deformation of the polymerisation products increase and there is also an increase in their hardness and mechanical strength (Table 4).

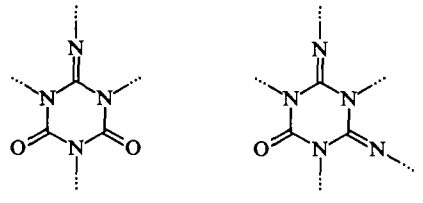
Table 4. Physicomechanical properties of the cross-linked polymers obtained by pressing the oligocarbodiimide (n = 25) based on di(4-isocyanatophenyl)methane and phenyl isocyanate (specific pressure 600 kgf cm^{-2}, material maintained for 1–3 min mm^{-1} at 25 °C).

Temperature/°C	Degree of structure formation (%)	Bending strength/ kgf mm^{-2}	Specific impact strength/ kJ m^{-2}	Brinell hardness/ kgf mm^{-2}
120	22–25	4.0–5.0	4–5	12.0–12.5
150	60–65	8.5–9.0	9–12	16.0–17.0
180	71–74	10.0–10.5	22–25	18.0–19.0
200	76–78	12.0–12.5	13–16	22.0–23.0
250	80–85	8.0–9.0	8–10	25.5–26.0
300	85–88	7.0–8.0	3–5	27.0–27.5

Analysis of the variation of the bending strength, specific impact strength, and Brinell hardness of the polymer specimens obtained by the compression pressing of the given oligomer under different conditions showed that an increase in the pressing temperature from 150 to 300 °C induces an increase in the Brinell hardness from 12–12.5 to 27–27.5 kgf mm^{-2}, while its specific impact strength and bending strength rise to a maximum for specimens structured at 180–200 °C and then fall again.

It has been shown [118] that the addition of 0.5 mass per cent of a cyclotrimerisation catalyst to oligocarbodiimides induced not only a 5%–10% increase in the degree of conversion of the carbodiimide group but also promoted the formation of isomelamine rings already at 150 °C. In the presence of catalysts, cyclotrimerisation becomes the dominant process at 220–250 °C. A further increase in the polymerisation temperature to 300 °C led to the formation of *sym*-triazine rings. Comparison of the IR spectra of the products of the purely thermal (at 300 °C) and catalytic polymerisation (at 250 °C) demonstrated a great similarity of their structures. In both cases, the polymer networks were constructed mainly from six-membered nitrogen-containing heterocycles.

A systematic survey has been made [107] of the thermal, thermooxidative, and thermohydrolytic stability of the structures of polycarbodiimides containing isomelamine and melamine fragments. A comparative study has also been made of linear polycarbodiimides based on 1,3-phenylene diisocyanate, 2,4-tolylene diisocyanate, and di(4-isocyanatophenyl)methane.



The kinetics of the degradation of these polymers have been investigated. [105, 107, 109] It was shown that the decomposition takes place as a first order reaction and obeys the Arrhenius equation. The rate constants and effective activation energies for the formation of gaseous degradation products as well as the effective activation energies for the decomposition reaction of the polymers were calculated.

Comparative study of the degradation reactions of polycarbodiimides *in vacuo* and in saturated water vapour demonstrated [107, 109] that the rate of decomposition of polycarbodiimides increases appreciably in a moist atmosphere. It was shown that the preliminary structure formation in the carbodiimide polymers *in vacuo* increases their resistance to thermal hydrolysis.

The principal types of oxidation reactions of polycarbodiimides have been established. They consist of the oxidation of the aliphatic and aromatic fragments of the macrochain and thermal structure formation involving the N=C=N groups.

Compounds containing melamine structures exhibit the highest thermo-oxidative stability. [105, 107, 109] The structure formation temperatures and times, ensuring an appreciable increase in the thermo-oxidative stability of network polymers relative to linear polycarbodiimides, have been determined. [107, 109]

There are literature data [144, 156] on the copolymerisation of diisocyanates with carbodiimides, which may result in the cocyclotrimerisation of the isocyanate and carbodiimide groups with formation of mixed cyclic trimers of the type

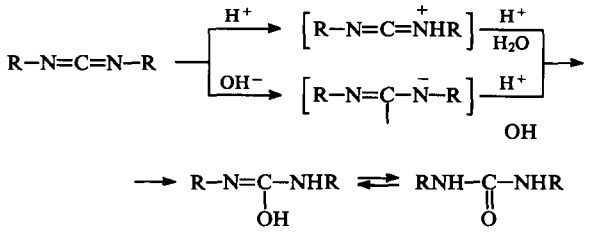
apart from the isocyanate and melamine rings.

3. Interaction of polycarbodiimides with various compounds

The existing numerous literature data concerning the interaction of polycarbodiimides with various compounds can be divided arbitrarily into two types.

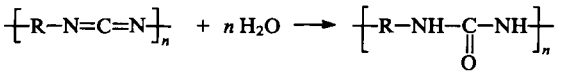
1. Polymer-analogue reactions of polycarbodiimides based on the polymer chain of the polycarbodiimide, the reactive carbodiimide groups of which usually interact with monofunctional compounds of different nature.

2. Modification of various polymers by polycarbodiimides and monocarbodiimides. These reactions are no longer based on polycarbodiimides but on other polymers with other functional groups. In many cases, small amounts of added carbodiimides play the role of cross-linking agents, stabilisers, strengthening components, and agents imparting hydrophobic properties, i.e. substances which impart particularly valuable properties to the polymers.



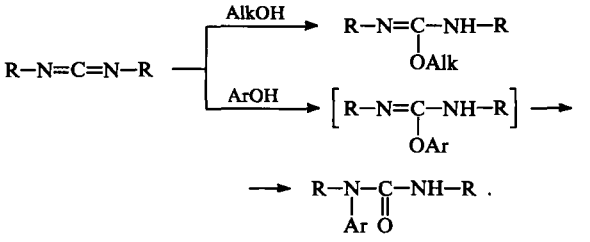
The chemical reactions of polycarbodiimides will be examined in this order in the present part of the review, resorting to examples of reactions of low-molecular-mass carbodiimides for a better understanding of the course of the reactions and of the structures of the products. There exist also other types of reactions of the carbodiimides. They have all been examined in detail in a series of thorough reviews on the chemistry of low-molecular-mass

carbodiimides.[18–25] However, they have not yet found applications in the chemistry of polycarbodiimides and we shall therefore not consider them.



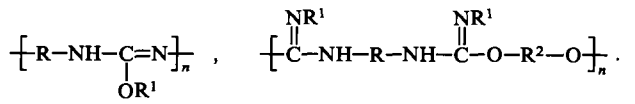
a. Polymer-analogue reactions of polycarbodiimides

The central carbon atom in the carbodiimide molecule exhibits striking electrophilic properties, so that nucleophilic addition reactions are the main type of reactions characteristic of carbodiimides.[18–25]

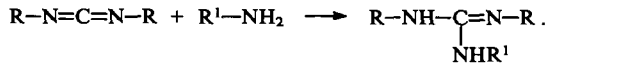


Hydrolysis of carbodiimides is a comparatively slow reaction catalysed by H^+ and OH^- ions.[157,158]

This reaction has been used to obtain polyureas.[69]

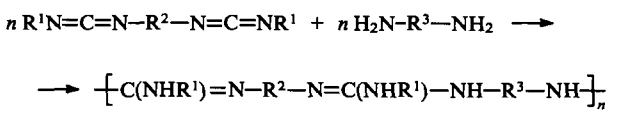


The interaction of carbodiimides with alcohols[159–162] results in the formation of *O*-alkylisoureas, whilst their interaction with phenols[163–165] affords *N*-phenylureas, which are formed via a stage involving the formation of *O*-arylisoureas.

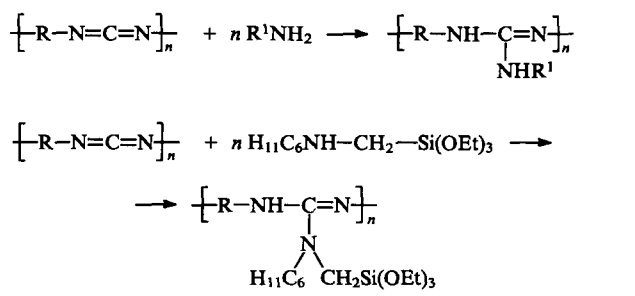


Reactions with certain acid phenols lead to the formation of *O*-phenylisourea derivatives.[166–171] They were obtained from pentachlorophenol[168,169] and 2,6-dichloronitrophenol.[172] It was postulated that the bulky *o*-chloro-substituents block the usual O→N shift in these compounds.[172]

However, picric acid reacts with carbodiimide to form *N*-arylurea, although the mechanism of this reaction apparently involves the formation of *O*-arylisourea as an intermediate.[173]

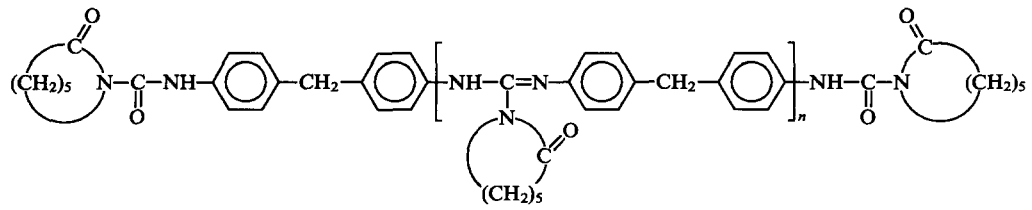


The application of this reaction to polymers[69,174] led to the formation of polyisoureas having the following structure:

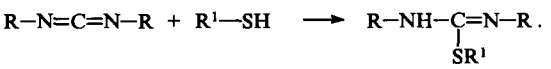


The study of the interaction of carbodiimides with amines showed that the products of this reaction are various guanidines.[175–177]

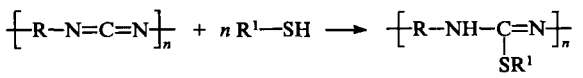
Polyguanidines were obtained as a result of the addition of biscarbodiimides to diamines.[178,179]



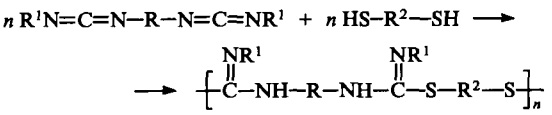
The synthesis of polyguanidines via the addition of primary and secondary amines to polycarbodiimides has also been described.[69,179]



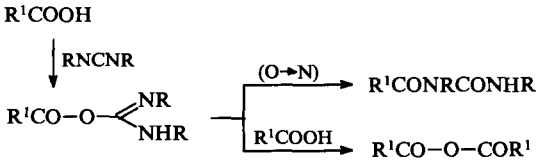
Interesting data have been obtained in a study of the interaction of ε-caprolactam with polycarbodiimides.[24] ε-Caprolactam is not only an excellent solvent for the sparingly soluble high-molecular-mass carbodiimides but it also adds quantitatively to polycarbodiimides on heating to 120 °C without the opening of the lactam ring (see the structure at the bottom of the page).



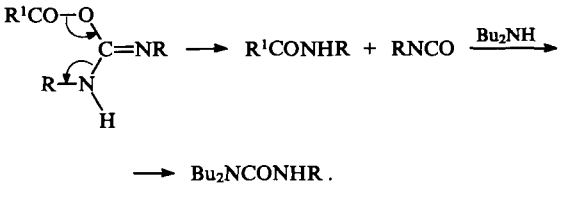
The adduct (n = 30) melted at 210–214 °C, i.e. at a temperature 70 °C lower than the melting point of the initial polycarbodiimide, and dissolved in dimethylformamide and *N*-methylpyrrolidinone. The polymers treated with ε-caprolactam had a wide molecular mass distribution with an average molecular mass of 11 000.



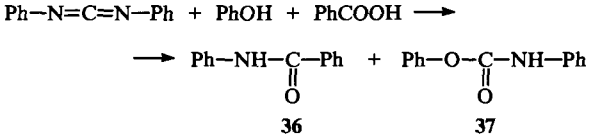
Mercaptans and thiophenols[180] interact with carbodiimide to form symmetrical alkyl(aryl)isothioureas.



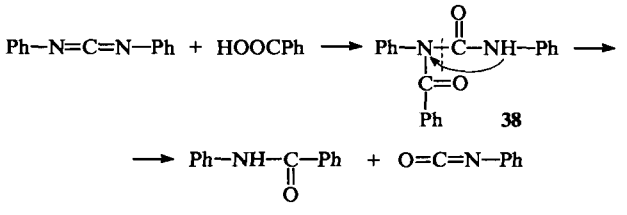
A similar reaction with polycarbodiimides[174,179] leads to the formation of polyisothioureas.



The interaction of carboxylic acids with carbodiimides has been investigated (together with the kinetics of such interaction) in fair detail.[181-190] The reactivity of the acids increases with their strength.[187] The reaction mechanism includes a stage involving the formation of anhydride via *O*-acylisourea and is complicated by the O→N shift.

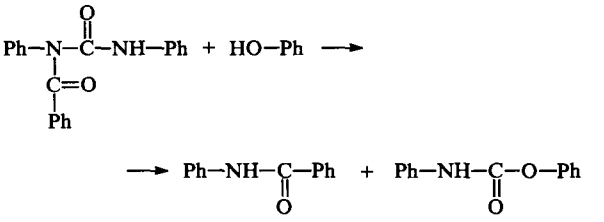


Another complication is the formation of the isocyanate (R—NCO) on decomposition of *O*-arylurea.[191]



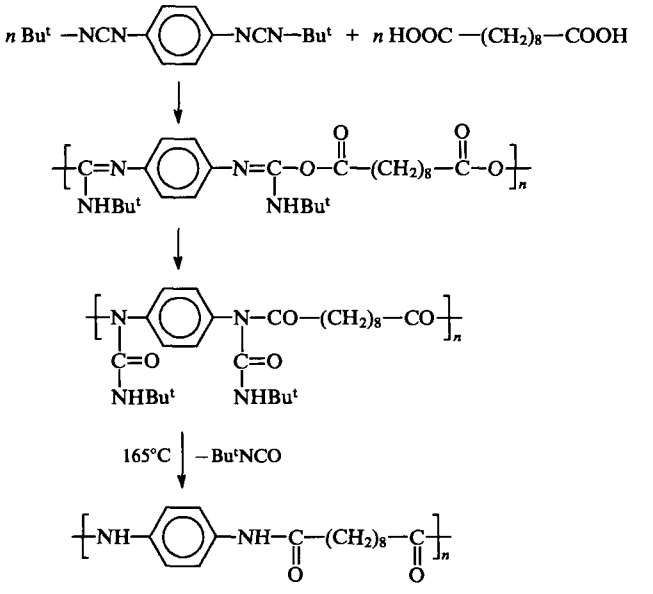
Di-n-butylamine was used as a 'trapping agent' for this isocyanate.[192]

The formation of isocyanates in the reactions of carbodiimides with carboxylic acids has been observed also in a study of the reaction of diphenylcarbodiimide with a mixture of benzoic acid and phenol.[193] Benzanilide **36** and phenylcarbamylate **37** were obtained as the products of this reaction.

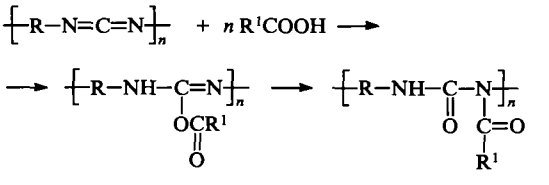


36 **37**

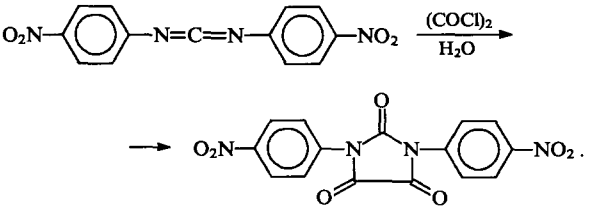
It was suggested that the anilide **36** is a product of the decomposition of *N*-benzoyl-*N,N'*-diphenylurea **38** formed in the first stage of the interaction of diphenylcarbodiimide with benzoic acid.



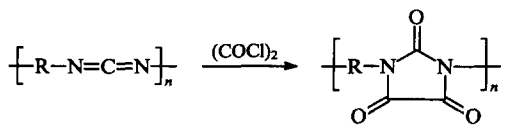
In order to test this hypothesis, compound **38** was allowed to react with phenol under the same conditions. This afforded benzanilide **36** in a satisfactory yield (80%).



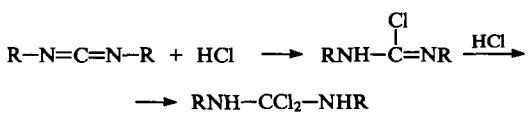
In addition, benzanilide **36** was isolated in 72% yield together with phenyl isocyanate from compound **38** itself on heating under the reaction conditions.



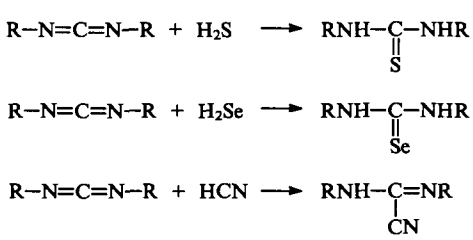
An interesting synthesis of the polymer has been achieved by the reaction of biscarbodiimide with dicarboxylic acids.[194] This synthesis was based on the use of the O→N shift of the acyl group.



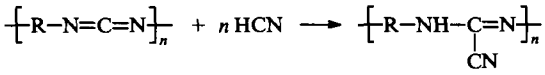
The interaction of monocarboxylic acids with polycarbodiimides leads to the formation of poly-*N*-acylurea, possibly via a stage involving the formation of poly-*O*-acylisourea.[195]



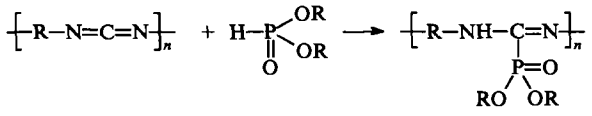
When arylcarbodiimides react with oxalyl chloride in the presence of water, the derivatives of parabanic acid are formed.[196]



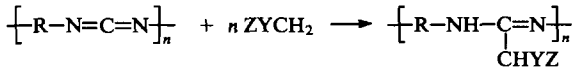
This reaction has been used [197] to obtain the highly thermally stable polyparabanic film by treating the polycarbodiimide film with oxalyl chloride.



Dry hydrogen chloride reacts vigorously with carbodiimides with evolution of heat. Depending on the reactant ratio, one or two HCl molecules are added. [18]

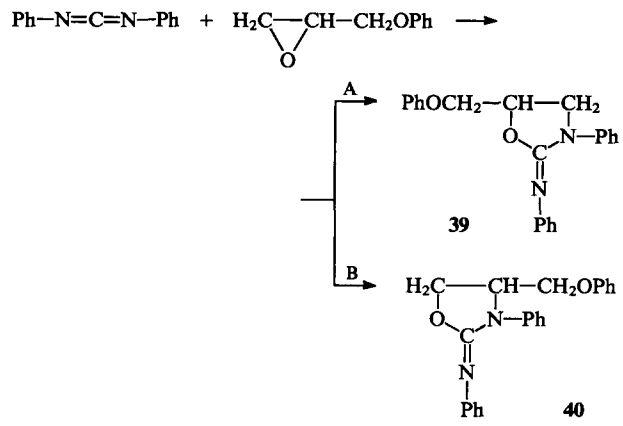


Carbodiimides react with weak acids, such as hydrogen sulfide [198] and hydrogen selenide, [199] to form the corresponding thio- and seleno-ureas, while the addition of hydrocyanic acid [200] leads to the formation of *N,N'*-dialkyl(aryl)-α-cyano-formamidines.

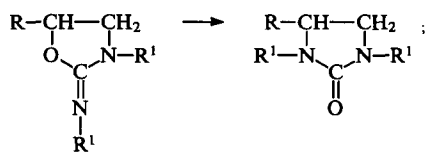


Among the reactions described above, that with hydrocyanic acid has been applied to polycarbodiimides, which resulted in the formation of polycyanoformamidines. [24]

Polymer-analogue reactions of polycarbodiimides involving the addition to the latter of dialkyl phosphites have also been carried out. [24]



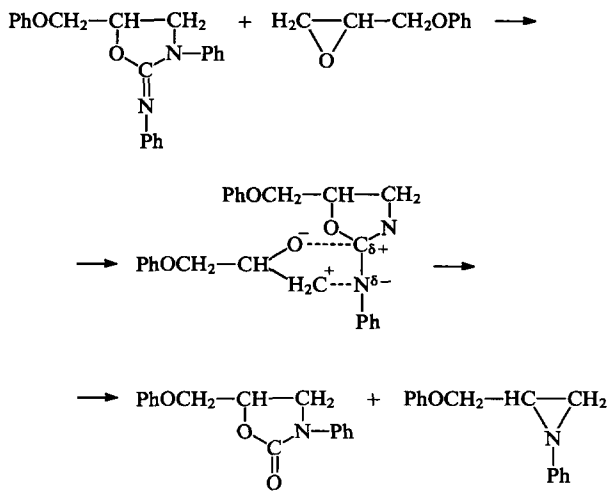
Polymers with formamidine fragments in the chain have been obtained by the addition of CH acids, for example malonic ester, to polycarbodiimides. [24]



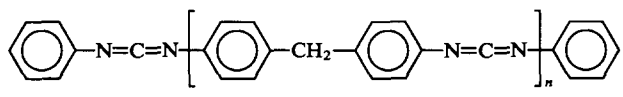
Z = COOEt, COMe;
Y = COOEt.

The interaction of the epoxide ring with the N=C=N groups of carbodiimides has been studied in detail on model and polymeric systems. [145–152] The model compounds employed were glycidyl phenyl ether and diphenylcarbodiimide. [145–147, 150–152]

Depending on the mode of opening of the epoxide ring, [12] there is a possibility of the formation of two isomeric structures: 5-phenoxymethyl-3-phenyl-2-*N*-phenyliminooxazolidine **39** and 4-phenoxymethyl-3-phenyl-2-*N*-phenylimidooxazolidine **40**.



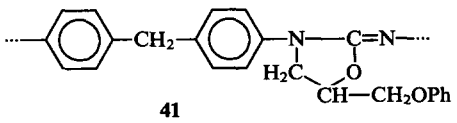
Analysis of the hydrolysis products as well as X-ray diffraction demonstrated [145, 147] that this reaction results in the formation of structure **39**. The X-ray diffraction data [147] made it possible to account for the absence of the isomerisation of compound **39** to the corresponding imidazolidinone, which is characteristic of iminooxazolidines with other substituents. [201, 202]



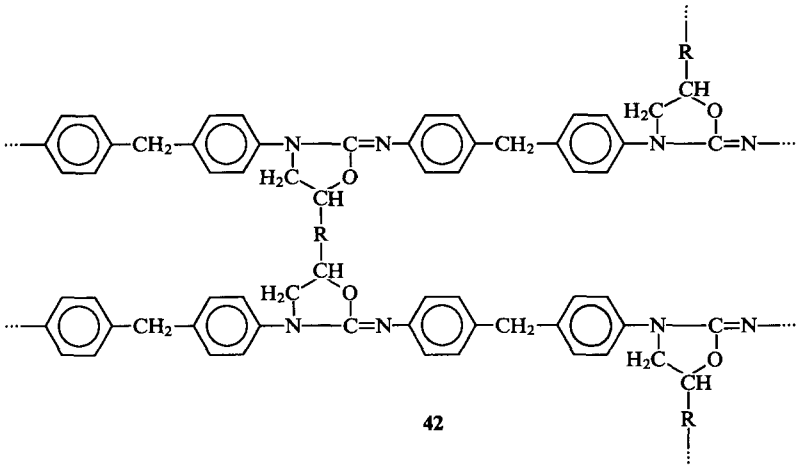
R = H, Ph; R^1 = Alk, Ph.

This is apparently associated with the fact that the phenoxymethyl substituent in structure **39** shields the ring oxygen atom, creating steric hindrance to the isomerisation process. [147]

It has been shown [150] that compound **39** interacts with an excess of glycidyl phenyl ether to form oxazolidinone.

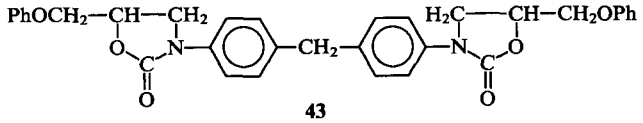


The interaction of oligocarbodiimides, synthesised from di(4-isocyanatophenyl)methane and phenyl isocyanate, i.e.

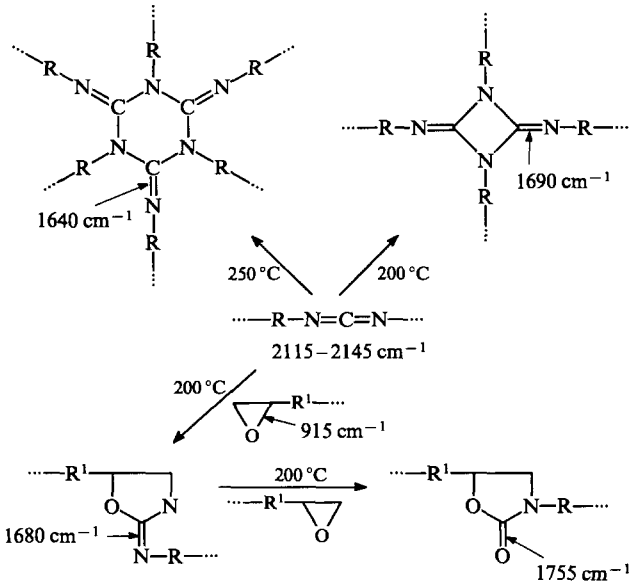


n = 30.

with glycidyl phenyl ether and the diglycidyl ether of di(hydroxyphenyl)propane has been investigated. The resulting polymeric structures are based on the fragments **41** and **42**. [146, 149]



41

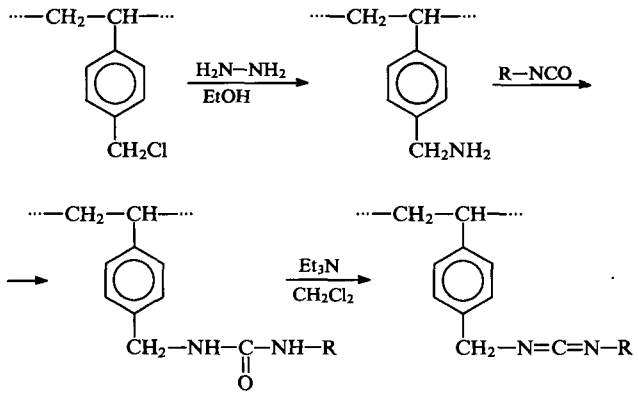


42

When an excess of glycidyl phenyl ether was used in the reaction with oligocarbodiimide,[146,149] bisoxazolidinone **43** was isolated, since iminooxazolidines decompose in an excess of the epoxide, which has been demonstrated in model reactions.[150]

43

The study[12,146,149] of the structures of network polymers obtained from oligocarbodiimides and oligoepoxides of different structure demonstrated the presence, together with imino-oxazolidine and other heterocyclic fragments, also of fragments obtained as a result of side reactions.

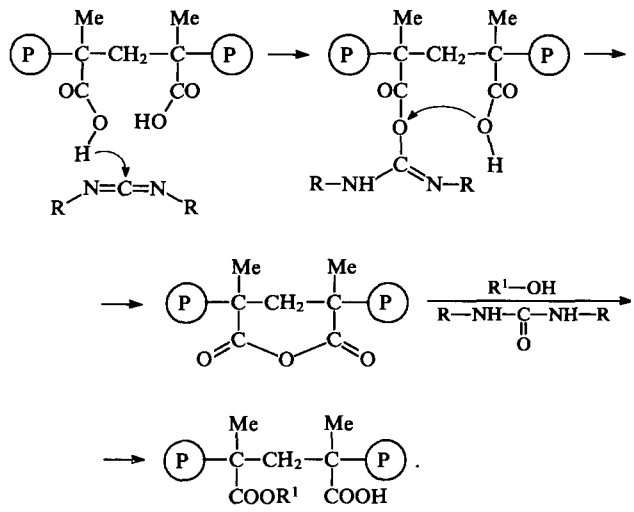


By altering the ratio of the carbodiimide and epoxide groups in the initial mixture of oligomers, the authors[12,146,149] regulated the content of heterocyclic fragments in the final product. In the presence of an excess of the oligocarbodiimide, urete diimine rings predominate in the structure, while at higher hardening temperatures (250 °C) the isomelamine groups predominate; in the presence of an excess of the epoxide component, the reaction involving the formation of iminooxazolidine and oxazolidine rings takes place preferentially.[12,146,149]

b. Modification of various polymers by mono- and polycarbodiimides

The development of new catalytic methods of synthesis of carbodiimides from available industrial isocyanates promoted the wide scale employment of mono- and poly-carbodiimides for the modification of various polymers.

Polystyrenes with carbodiimide side groups were obtained in this way. They were used subsequently as dehydrating agents.[203,204]



The cross-linking of butadiene–acrylonitrile copolymers, containing 0.09% of carboxy-groups, has been achieved.[205] The cross-linking agents were the bifunctional carbodiimides Ph–N=C=N–$(CH_2)_6$–N=C=N–Ph.

It has been shown in a patent[206] that hydroxyethylcellulose can be modified by means of dicyclohexylcarbodiimide in the presence of tetrafluoroboric acid with formation of a hydrophobic polymer containing *O*-alkylisourea units. Guanidine groups can also be introduced into the polymer under the conditions of such modification.[207]

When polyacrylic acids and polystyrenes with side carboxy-groups are treated with carbodiimides, polymers containing anhydride groups are formed.[208,209]

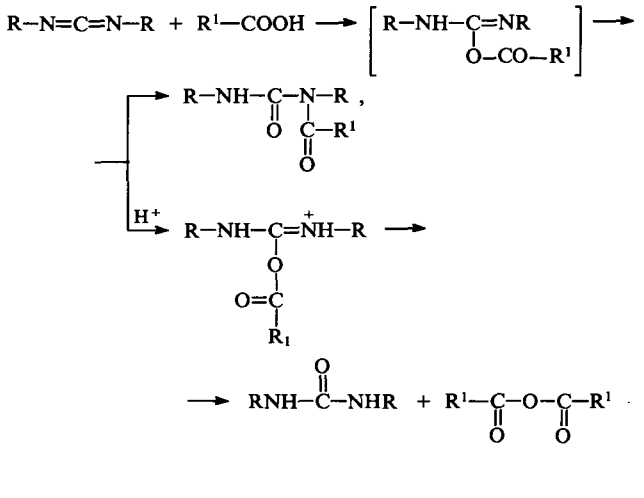
Syndiotactic polymeric methacrylic acid has been esterified by alcohols in the presence of carbodiimides and compounds with ester linkages have been obtained.[210–212] It has been suggested[210] that the formation of anhydride groups in accordance with the following scheme is an intermediate stage of the reaction:

Water-soluble carbodiimides have been used to bind ethyl glycinate to polyacrylic acid. It is suggested the reaction proceeds via the intermediate formation of a carboxylic acid anhydride.[208]

Scott et al.[209] investigated by IR spectroscopy the interaction between the carboxy-groups in cross-linked polystyrene in the presence of dicyclohexylcarbodiimide. It was postulated that *N*-acylurea groups are formed initially (absorption bands in the region of 1660 cm^{-1}) after which anhydride fragments appear, indicated by the presence of absorption bands at 1785 cm^{-1}.

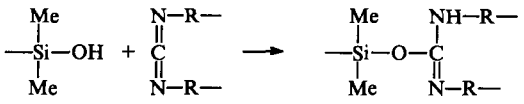
Polymers containing amino- and carboxy-groups have been hardened with the aid of ditolylcarbodiimide.[213] The polymer films thus obtained are distinguished by improved physico-mechanical parameters.

Dicyclohexylcarbodiimide induces the formation of a sticky fire-resistant polyphosphoramide from diamines and inorganic phosphate.[214]



Carbodiimides have found extensive applications as hardening agents for gelatine.[215–227] The effect of carbodiimide consists in the binding of carboxy- and amino-groups in the gelatine chains, which leads to the cross-linking of the polymer.[227]

Polycarbodiimides have been used as dehydrating agents in the binding of peptides. Both linear polycarbodiimides and polymers containing carbodiimide groups in the side chain have been used for this purpose.[228–231]



The storage time of liquid polyisocyanates can be increased by adding carbodiimides, which apparently remove water.[232–237]

Mono- and poly-carbodiimides are widely employed to prevent the hydrolysis of the ester bonds in polyesters[81,190,193,238–254] and as stabilising additives to polysiloxanes.[255,256]

It is believed[238] that the stabilising effect of carbodiimides is due to their interaction with the carboxy-groups of polymers.

It has been shown[255] that the siloxane linkages in polydimethylsiloxane are cleaved with formation of silanols at a temperature above 200–220 °C in the presence of water as well as alcohols and phenols. Such degradation leads to a decrease in the molecular mass of polydimethylsiloxane and hence to the loss of the initial physicomechanical parameters of the articles based on it. Piotrovskii and Metkin[255] state that the presence of polycarbodiimides during the hydrolysis of polydimethylsiloxanes may retard the decrease in the molecular mass of the latter as a consequence of the reaction of the silanol end groups with the polycarbodiimide.

V. Practical use of polycarbodiimides

The data presented above permit the conclusion that polycarbodiimides are promising polyfunctional thermoreactive compounds, which have found practical applications in various branches of technology, including the formation of highly heat-resistant and thermostable materials.

Polycarbodiimides are synthesised from available raw material in accordance with a technologically simple scheme. The high reactivity of carbodiimide groups permits both the thermal hardening of the polymers and different types of chemical modification of the latter. These positive qualities of polycarbodiimides promote their varied practical employment.

An important aspect of the practical use of polycarbodiimides is the formation on their basis of thermostable foams, the industrial manufacture of which has been initiated in recent years. They do not require the introduction of foam-forming agents (the role of which is assumed by the carbon dioxide evolved in the conversion of di- and poly-isocyanates into carbodiimides), their thermal stability is high, and they have effective physico-mechanical properties.[257–278]

It has been shown[259] that the modification of a polycarbodiimide composition by polyfunctional hydroxylated compounds makes it possible to economise on the carbodiimide formation catalyst, eliminates the differences between the technologies used for the preparation of foam polycarbodiimide and foam polyurethane, and increases the apparent density of the material. Under these conditions, 50% of the initial isocyanate groups of the polyisocyanate can be consumed on the formation of urethane fragments. The strength parameters of the resulting foam plastic are retained over a wide temperature range. For example, on raising the temperature to 127 °C, the relative elongation on rupture changes by only 50%.

It has been established[259] that foam polycarbodiimides, modified by urethane, exhibit a high fire resistance, have effective thermophysical parameters, and their water absorption capacity is low. This set of properties makes it possible to recommend them as insulating and constructional materials to be used at temperatures up to 200–250 °C.

Another possibility of modifying the polycarbodiimide structure arises from the simultaneous occurrence of the cyclotrimerisation of isocyanate groups with formation of isocyanurate fragments together with the polycarbodiimide.[259,269] They are highly fire-resistant: the mass loss does not exceed 15%–20% and the oxygen index is 29–32 in tests by the 'fire tube' method.[259]

A review has been devoted to fire-resistant carbodiimide foam plastics based on polyols derived from trichlorobutene oxides or epichlorohydrin.[279]

Organic[238,239,245–253,255,280–299] and organo-element[240,300–302] low-molecular-mass polycarbodiimides are used widely

as hydro- and thermo-stabilisers of polyesters,[238-254,280-284,290,291,295-298,300,301] polyurethanes,[299,300,301] polyamides,[280,292,298] polysiloxanes,[255,293] poly(vinyl chloride),[298,302] and other polymers.[46,53,59,70,72,215-237,285-288,294]

Aliphatic fluorocarbodiimides have been used to impart oil- and water-repelling properties to articles made from nylon and polyester [77] and also to impart these properties to leather. [77,303]

The addition of carbodiimides has made it possible to improve the adhesion of photographic emulsion to poly(ethylene terephthalate) carriers. The mechanism of the effect of carbodiimides apparently involves the formation of ester bonds. [304]

Mono- and poly-carbodiimides are used widely in the microencapsulation involved in the manufacture of pressure-sensitive copying paper. [305-307]

Organosilicon polycarbodiimides are stable in relation to irradiation, which makes it possible to employ them in various kinds of seals to be used under the conditions of intense irradiation. [25,86] Organotin carbodiimides are effective catalysts of the urethane formation reaction. [308,309] Thus $Bu_3N=C=NBu_3$ has been used as the catalyst for the preparation of film-forming polyurethane coatings based on organosilicon polyols and aliphatic isocyanates with the biurethane structure. [308]

Polycarbodiimides have been employed as nylon and polyester fibre and film strengthening agents. [310,311]

Polycarbodiimides have been used as composite binding materials: adhesives,[312-314] reinforced plastics,[15,82,197,315-317] compound materials,[12,79,146,149,156,232-237] electrically insulating materials,[153,155,318,319] and others. [77,320] This made it possible to obtain polymers with improved thermal and physicomechanical characteristics.

There is no doubt that further study of this promising class of polymers — organic and organoelement polycarbodiimides — will expand the scale of their practical applications‡.
