The properties of the molecular complexes described above are determined by the nature of the orbitals provided by the components of the complexes for the formation of intermolecular bonds.[75] The nucleophilic centres are the sulfur atoms in the TMTD molecules, the nitrogen atoms in the MBT and DBTD molecules, the nitrogen atoms in the benzothiazolyl and exocyclic HN groups in CBS, and the nitrogen atoms of the secondary amino- and imino-groups in DPG. As regards the excess negative charge, the accelerators containing the benzothiazolyl group hardly differ from one another.[62] On the other hand, the carbon atoms involved in the double bond of the benzothiazolyl fragment of BD and BTD, the carbon atoms of the cyclohexyl group in CBS, and the nitrogen atom in the morpholine fragment of OBS relative to TMTD and DPG, as well as the zinc atoms in ZDMDTC and zinc mercaptide relative to CBS, DBTD, MBT, DPG, and TMTD differ significantly in their electrophilicity.[62,67,71] Therefore the greatest overlap of the molecular orbitals of the donor and the acceptor and hence the formation of the most stable π- and *n*-complexes is to be expected in the ZDMDTC–X and ZnS–X binary systems, where X = TMTD, DPG, CBS, DBTD, or MBT. This is confirmed by the presence of an appreciable convexity in the phase diagrams for these systems between the peritectic and

eutectic points,[28] which indicates the formation of stable complexes[55] and also that some of them exist in an individual state.[76] The absence of a convexity between the peritectic and eutectic melting points on the phase diagrams for the OBS–TMTD, DBTD–TMTD, CBS–TMTD, etc. binary systems[28] is evidence for the low stability of such complexes and for the possibility of their existence only in the presence of the initial components.[55]

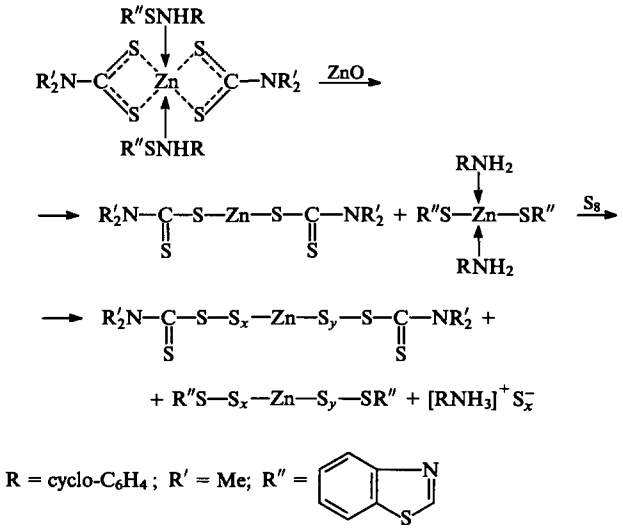
The comparative stability of the molecular complexes formed in the physicochemical modification of binary systems of accelerators promotes synergism in their action in elastomeric compositions because, according to the theory of molecular complexes, the more intense the interaction of the molecules of the complexes the more marked their activation on dissociation.[77]

When complex mixtures of the components of sulfur-based vulcanising systems are used, it is essential to take into account the presence in them of zinc oxide, which adsorbs the molecules of the accelerators, sulfur, and aliphatic acids.[53,78] Zinc oxide is not a molecular crystal and cannot therefore form simple eutectic mixtures or substitutional solid solutions with accelerators and sulfur. On the other hand, the electrophilicity of the zinc atoms ensures the physical and chemical adsorption of the accelerators, stearic acid, and sulfur on zinc oxide as a result of the formation of the corresponding zinc salts of the accelerators and of zinc stearate and through them of dialkyldithiocarbamate, amine, and carboxylate complexes.[78–81]

The adsorption of the accelerators and stearic acid on zinc oxide can be selective and dissociative. In those cases where the components exhibit approximately the same nucleophilic or electrophilic properties, the selective adsorption depends on the configuration of the molecules, which determines the accessibility of the active centres of the interaction with the surface of zinc oxide.

Dissociative adsorption on zinc oxide is characteristic of TMTD, DBTD, and DTDM, which contain disulfide bonds.[53] It is known[75] that aliphatic disulfides react with acceptors (metal oxides) to form 1:1 complexes, which increases the length of the disulfide bond and weakens it. The interaction of aromatic disulfides, having relatively weak S–S bonds, with strong acceptors leads to the homolytic dissociation of these bonds. One can therefore postulate that zinc mercaptide is formed initially in the DBTD–TMTD–ZnO mixture and then the dimethyldithiocarbamate complex is produced. This was subsequently confirmed by other data.[28,79]

The conventional heats of adsorption of chemical additives on zinc oxide, presented in Table 5 and obtained by differential scanning calorimetry,[28] indicate the dependence of the selectivity of the adsorption on the nucleophilicity and configuration of the molecules and also on their ability to be dissociatively adsorbed with formation of the corresponding zinc salts.



The foregoing suggests the following consecutive mechanism of the physicochemical modification of chemical additives in binary and complex eutectic systems.

In the first stage, the crystalline components interact, which is accompanied by an increase in the free energy of the system in the region of contact between the surfaces of unlike crystals. This results in the eutectic fusion of the mixture.

In the second stage, the components pass to the activated state on eutectic fusion, which results in the formation of π- and *n*-complexes between the nucleophilic and electrophilic molecules. This leads to an increase of their reactivity relative to free sulfur.[75]

In the third stage, the molecules to the π- and *n*-complexes interact chemically on raising the temperature with formation of amine, dialkyldithiocarbamate, and carboxylate complexes, whereas in the presence of free sulfur polysulfide compounds with hydroammonium polysulfides are produced.

The interaction of the components of sulfur-based vulcanising systems in complex mixtures can be described schematically in relation to the CBS–ZDMDTC–ZnO–S_x system.

The hydrogen adsorbed in the atomic or ionic form on zinc oxide may participate in the formation of amine ligands and hydroammonium polysulfides.[39]

$$H_2 \longrightarrow 2H \longrightarrow 2H^+ + 2e^-$$

The above mechanism of the physicochemical modification of chemical additives may be applied also to the highly effective synergistic systems of antioxidants obtained in the form of granules from eutectic melts of binary and complex mixtures of components and used in the synthesis of polymers.

Scheme 2

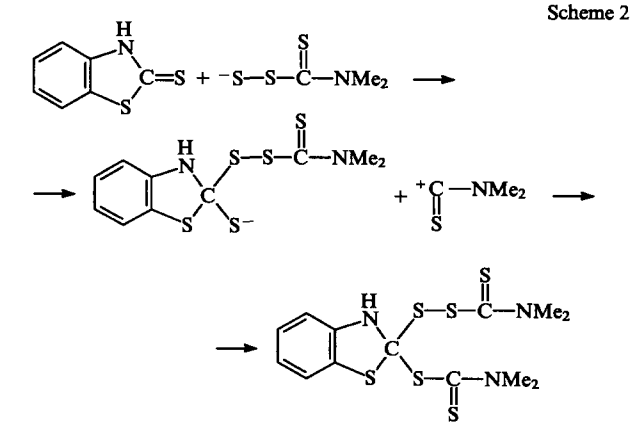


Table 5. Conventional heats of adsorption of the crystalline components of elastomeric compositions on zinc oxide.

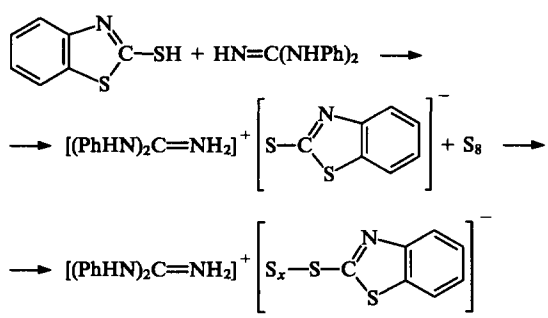
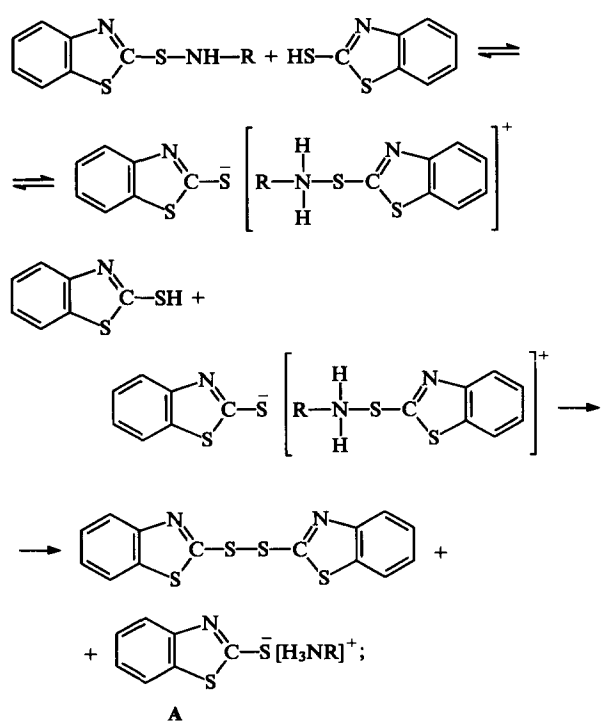
Component	Heat of fusion/kJ mol^{-1}		Conventional heat of adsorption[a]/kJ mol^{-1}
	of individual component	in mixture with zinc oxide	
TMTD	33.2	4.8	28.4
MBT	20.4	4.3	16.1
Stearic acid	43.4	29.9	14.5
Phthalic anhydride	19.7	14.0	5.7
Diafen FP	27.9	23.7	4.8
CBS	27.4	23.8	3.6
DBTD	35.3	32.6	2.7
Sulfur	16.2	15.2	1.0
Santogard PVI	21.4	20.6	0.8
OBS	21.2	21.2	0.0



[a] The measurements were performed at the melting points of the adsorbed components.

3. The formation of new accelerators

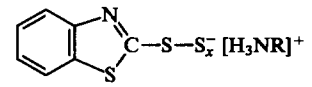
On chemical interaction of the accelerators and binary eutectic systems, two eutectic melting points and a singular point, corresponding to the melting point of the new compound formed, appear on the phase diagram.



In the TMTD–MBT eutectic mixture, the products of the heterolytic decomposition of TMTD which occurs at 100–110 °C interact with the thiono-form of MBT (Scheme 2).[58] This increases the duration of the induction period for the vulcanisation of elastomeric compositions. The higher rate of vulcanisation can be explained by the decomposition of the compound obtained on raising the temperature into the highly reactive benzothiazolyl and dimethyldithiocarbamate fragments. Quantum-chemical cal-culations of the electronic characteristics of the accelerators[62] confirm the possibility of the nucleophilic addition reaction between the products of the heterolytic decomposition of TMTD and MBT.

The reaction between the accelerators in the MBT–DPG binary eutectic mixture leads to the formation of the diphenylguanidinium salt of mercaptobenzothiazole (DSMB), which, as a consequence of the increased nucleophilicity of the benzothiazolyl ion, is more thiophilic relative to free sulfur and is capable of forming an ionic polysulfide compound.[26]

Like hydroammonium polysulfides,[71] this compound exhibits a high vulcanising activity.



According to Ignatov's data,[59] the accelerators CBS and MBT in the CBS–MBT binary eutectic mixture interact in accordance with the following schemes:

A

R = cyclo-C_6H_{11}.

The chemical synergism manifested by this system in elastomeric compositions is due to the formation of more active accelerators than the initial MBT and CBS. Like DSBM, the ionic complex A can interact readily with S_8 to form hydro-ammonium polysulfides

which ensure a high rate of vulcanisation of elastomeric compositions.

The mutual activation of chemical additives, caused by the formation of eutectic mixtures, molecular complexes, and new chemical compounds, also occurs when they are introduced separately into elastomeric compositions. The eutectic mixtures are then obtained only as a result of the collision of the crystalline particles of the components on shear deformations arising during the preparation of the elastomeric compositions, while the main bulk of the components interact with one another in the diffusion regime, i. e. after the dissolution of the accelerators and sulfur and by diffusion of their molecules to the surface of zinc oxide with formation of molecular complexes and polysulfide compounds. Part of the sulfur and of the accelerators fail to interact with one another under these conditions and migrate to the surface on cooling of the elastomeric compositions.

Thus the physical and physicochemical modifications of the crystalline components of sulfur-based vulcanising systems in binary and complex mixtures do not alter the principal characteristics of the sulfur-based vulcanisation of unsaturated elastomers. They merely induce a decrease in the activation energy and a change in the kinetics of the process because its rate-limiting stage—the chemical activation of sulfur by molecular, amine, dialkyldithiocarbamate, and carboxylate complexes—takes place in the kinetic region under favourable conditions and is more effective than in the separate introduction of the chemical additives into the elastomeric compositions.

Furthermore, the modification of chemical additives ensures the most complete fulfillment by the latter of their functions, which makes it possible to diminish the concentrations of the components in the elastomeric compositions (the concentration of zinc oxide in the modified sulfur-based vulcanising systems can be decreased by a factor of 2–2.5 and that of the accelerators by a factor of 1.1–1.3).[28]

4. The influence of the crystal-chemical characteristics of chemical additives on the structure–property relation in the specific formation of their molecules

The attempts to employ quantum-chemical calculations to achieve the deliberate formation of the molecular structure of the chemical additives, starting with the specified properties of polymer compositions, which have been undertaken in recent years,[62,82–85] have not led to the desired results because in these calculations no account was taken of the change in the physical and chemical properties of the components as a result of their interaction with one another in the crystalline state.

Therefore, in the quantum-chemical calculations it is essential to take into account the presence of other crystalline components and the possibility of their interaction with the initial compounds to form eutectic compositions and molecular complexes.

Theoretical studies of the mechanism of the antioxidant activity of sterically hindered phenols in polyalkenes established[83] that their antioxidant activity is determined by the donor–acceptor properties of the *para*- and *ortho*-substituents. It is known[86–87] that the effectivenss of the accelerator increases with increase in its nucleophilicity. On the other hand, studies on the inhibiting effect of aromatic amines for different types of ageing of rubbers have shown[85] that the experimental molecular reactivity indices, characterising the ability of amines to enter into heterolytic and homolytic reactions, differ from the calculated values.

This is due to the physicochemical interaction of aromatic amines in elastomeric compositions with the components of sulfur-based vulcanising systems. Such interaction results in the formation of eutectic mixtures and molecular complexes in which the configuration and orbital state of the molecules[75] and hence the π-electron density and the free valence index have been altered relative to those in the initial components. This hypothesis has been confirmed by the satisfactory correlation between the calculated and experimental data obtained in the study of the influence of sterically hindered phenols in polyalkenes (in the absence of other crystalline components) and in elastomeric compositions—thiophthalimide derivatives—on the vulcanisation processes.[88] They exhibit a low reactivity relative to the nucleophilic and electrophilic components of the vulcanising systems as a consequence of their tendency to enter into homolytic reactions.[89]

The effectiveness of antioxidants and antiozonants in polymer ageing processes is determined by the formation of hydrogen bonds in these systems. It has been established[90] that the presence of hydrogen bonds in crystalline antioxidants and antiozonants is one of the causes of their relatively low solubility in elastomers. An increase in the polarity of the elastomer increases the solubility of the antiageing agent by intensifying the intermolecular interaction up to the formation of hydrogen bonds between the elastomer macromolecules and the molecules of the antioxidants and antiozonants. On the other hand, the formation of hydrogen bonds in the polymer–antioxidant system reduces the effectiveness of the antioxidant.[91]

The functional effectiveness of chemical additives diminishes on formation of hydrogen bonds between the molecules of different components. Thus hydrogen bonds decrease the activity of the amine accelerator in the sulfur-based vulcanisation and the inhibiting activity of resorcinol in the oxidation of rubber.[92]

The molecules of chemical additives incapable of forming hydrogen bonds but exhibiting nucleophilic and electrophilic properties relative to one another can form π- and *n*-complexes, which induces an increase in the effectiveness of the components. The increase in the reactivity of molecules in such complexes compared with their ground state[63] occurs as a result of the interaction of the π^* antibonding orbitals of one component with the nonbonding orbitals of the nitrogen, sulfur, or oxygen atoms of the other component or with the occupied 3*d* orbitals of the zinc atom.[68]

Thus, in order to increase the functional effectiveness of chemical additives to elastomeric compositions, it is useful to achieve a decrease in the probability of the formation of hydrogen bonds between the components and an increase in the probability of the formation of molecular complexes. This can be done by selecting chemical additives on the basis of a comparison of their molecular structures and crystal-chemical characteristics and the phase diagrams for binary systems of the components.[28]

IV. Conclusion

The above analysis shows that comparison of the melting points of the chemical additives, the configurations of their molecules, and the π-electron densities and free valence indices of the atoms in the molecules makes it possible to regulate the formation in the binary and complex mixtures of these components of simple eutectic systems, substitutional solid solutions, molecular complexes, and polysulfide compounds and also to determine the optimum conditions for the formation of systems with prespecified properties. Such systems and compounds are more effective than the initial components, since they ensure a greater defectiveness and dispersity of the crystalline particles and this increases the chemical reactivity of the components. The formation of molecular complexes and new compounds in the eutectic mixtures increases still further the effectivenss of the crystalline accelerators in vulcanisation processes, because this leads to their thiophilicity and facilitates their interaction with sulfur molecules in the formation of polysulfide compounds and hydroammonium polysulfides, which exhibit a high vulcanising activity.

The formation of polysulfide compounds in such mixtures makes it possible to reduce the concentrations of the accelerators and of zinc oxide in sulfur-based vulcanising systems without a decrease or even with an increase in their effectivenss compared with control vulcanising systems.[28] Furthermore, the sharp fall in the melting points of the chemical additives in eutectic mixtures makes it possible to granulate the melts without introducing binders, obtaining thereby strong, friable, and readily fusible granules. The use of such granules eliminates the formation of dust from the powdered components and improves the environmental situation in the processing of elastomeric compositions and polymers.

An important advantage of the physical and physicochemical modification of chemical additives is the possibility of predicting on the basis of the crystal-chemical characteristics and molecular structures of the components the formation in binary and complex systems of simple eutectic mixtures, substitutional solid solutions, and molecular complexes and of estimating their influence on the properties of the elastomeric compositions and rubbers. This advantage may be used for the development of a fundamentally new scientifically based approach to the creation of recipes for elastomeric compositions.

Abstract. The results of studies on the synthesis and transformations of uronic acid nucleosides are surveyed. Various pathways leading to the synthesis of uronic acid nucleosides are examined, including methods involving specific and nonspecific oxidation of nucleosides, and the glycosylation and modification of the sugar residue or the heterocyclic base. The bibliography includes 97 references.

I. Introduction

Uronic acid nucleosides occupy a special place among the numerous modified nucleosides. Replacement of the primary hydroxy-group in nucleosides by a carboxy-group induces appreciable changes in the reactivities of other functional groups due both to the redistribution of electron density in the molecule and to conformational factors. Furthermore, the presence of a carboxy-group extends the possibilities of the syntheses based on nucleosides.

The interest in uronic acid nucleosides is caused primarily by the fact that they are a component of many antibiotics exhibiting a broad spectrum of biological activity.[1] There is much promise for derivatives of adenosine-5′-carboxylic acid, which are agonists of adenosine receptors and in the future may find extensive application in medical practice as hypotensive, cardiotonic, and thrombolytic agents.[2]

Progress in the synthesis of natural antibiotics, in devising new antibiotics, and also in the study of the biological action of uronic acid nucleosides with a wide variety of structures is in many respects determined by current advances in the development of methods for their preparation. The aim of the present review is to examine and treat systematically the existing methods of synthesis of uronic acid nucleosides and their transformations.

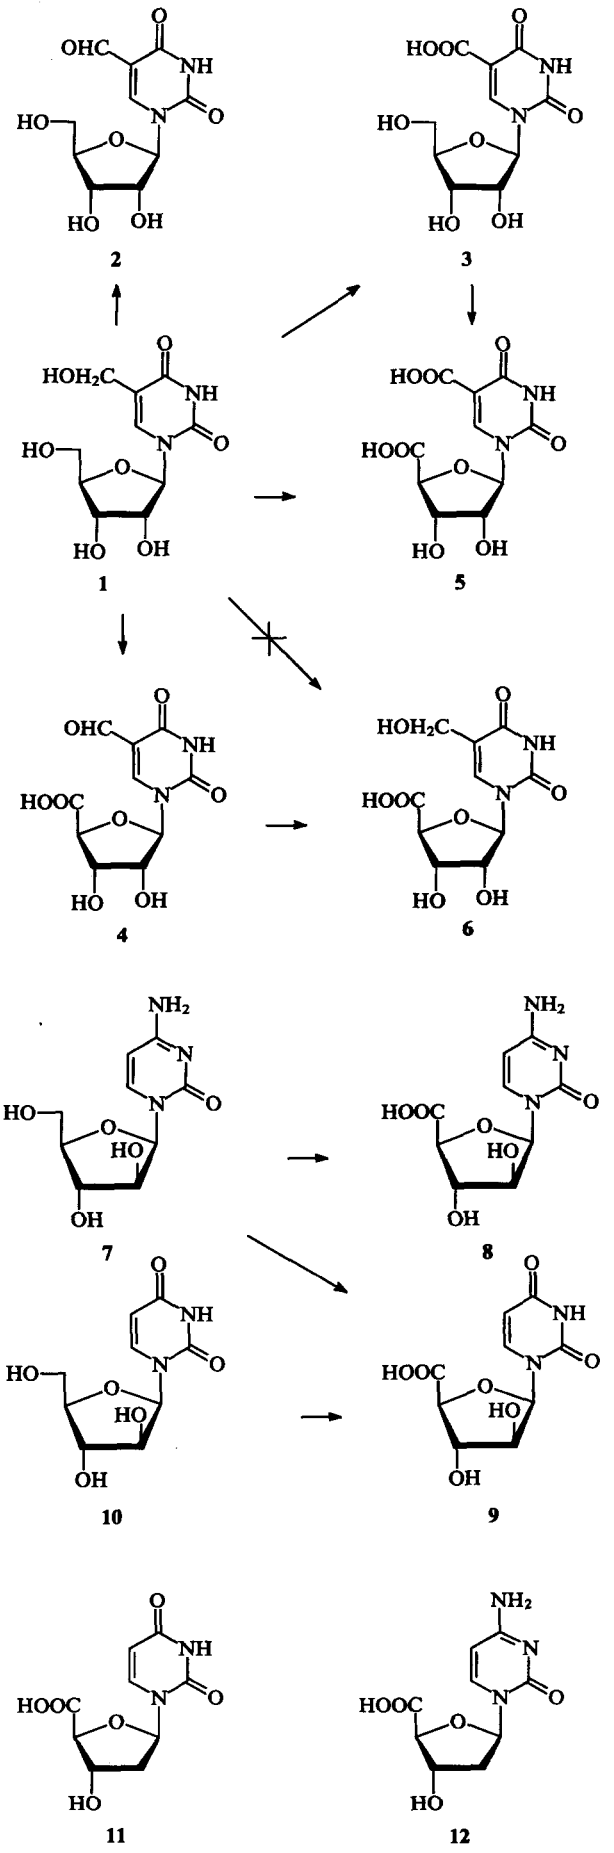
II. Catalytic oxidation of nucleosides to uronic acid nucleosides

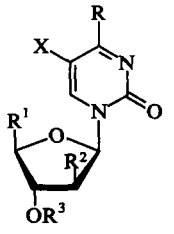


A general method of synthesis of uronic acid nucleosides, involving the selective oxidation of the primary hydroxy-group of the nucleoside to a carboxy-group by oxygen over a platinum catalyst, has been proposed by Todd and coworkers[3] in connection with the solution of the problem of the stepwise degradation of polynucleotides. The catalytic oxidation of uridine, thymidine, adenosine, guanosine, 3′-bromo-3′-deoxy-3-methylthymidine, 3-methylthymidine, thymidine 3′-phosphate and thymidylyl-(3′→5′)-thymidine was investigated. The corresponding nucleoside-5′-carboxylic acids were obtained and characterised. The oxidation of nucleosides to acids is usually carried out in a weakly alkaline medium at 50 – 60 °C by bubbling with finely dispersed oxygen in the presence of platinum on charcoal. The maintenance of a specified solution pH (~7.5) and a high rate of stirring are extremely important factors in the process.

It has been shown[4] that, when the reaction is carried out at room temperature in 50% acetic acid, three oxidation products are formed from 5-hydroxymethyluridine **1**: uridine-5-carboxaldehyde **2**, uridine-5-carboxylic acid **3**, and the aldehydoacid **4**. The oxidation of nucleosides **1** and **3** in the presence of sodium bicarbonate leads to the acid **5**. The reduction of compound **4** with sodium tetrahydroborate affords the nucleoside **6**, which cannot be obtained by direct oxidation of compound **1**.

Together with the acid **8**, its uracil analogue **9** was isolated from the reaction mixture in the oxidation of the arabino-nucleoside **7**. Compound **9** can also be obtained by oxidising the uracil nucleoside **10**.

In the oxidation of 5-halo-derivatives of 2′-deoxyuridine and 2′-deoxycytidine, it was noted that the rate of reaction increases in the sequence H < Br < I.



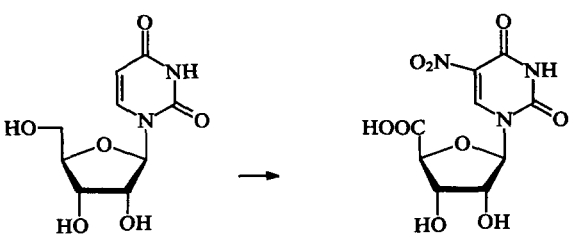
2′-Deoxyuridine-5′-carboxylic acid **11** and 2′-deoxycytidine-5′-carboxylic acid **12** were obtained by catalytic oxidation.

5-Fluoro-2′-deoxyuridine (FUDR) is known to exhibit an antitumour activity. However, the toxic 5-fluorouracil, formed as a result of its hydrolysis by phosphorylase, impairs the therapeutic properties of this preparation. Various attempts have been made to modify FUDR in such a way that it is stable toward phosphorylase and at the same time its ability to penetrate cell membranes is retained. It was found that these requirements are satisfied by 5-fluoro-2′-deoxyuridine-5′-carboxylic acid and its esters. These compounds are more resistant to hydrolysis, their toxicity is relatively low, and they exhibit a higher antitumour activity than FUDR.[5] When FUDR was oxidised in a weakly alkaline medium, the reaction products could not be isolated. Positive results were obtained on oxidation in a weakly acid medium (pH 6.81 ± 0.2).

Thymidine-5′-carboxylic acid has been obtained by the catalytic oxidation of nucleosides. Its nitriles, amides, and esters are inhibitors of thymidylate kinase of Walker 256 carcinoma.[6,7]

Catalytic oxidation of uracil and cytosine nucleosides afforded uronic acids and their derivatives having the general formula **13**.[8]

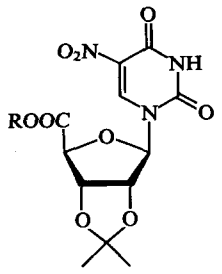
13



R = OH, NH_2;
R^1 = COOH, COOMe, CN;
R^2 = H, OH;
R^3 = H, COMe;
X = H, F, Br, I, Me.

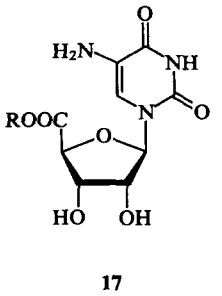
It was observed that uracil nucleosides are oxidised at a higher rate than cytosine nucleosides. The ease of oxidation depends on the nature of the substituent in the 5-position in the pyrimidine ring and decreases in the sequence H > Me > F > Br > I. Thirty five compounds were obtained; the 5-bromo- and 5-iodouracil nucleosides of 2′-deoxyriburonamides possess an antiviral activity.

It is noteworthy that the method involving the catalytic oxidation of nucleosides suffers from disadvantages as well as having evident advantages. Thus the yields of the acids obtained by this method are as a rule fairly moderate (20%–50%), although they sometimes reach 70%–80%. Appreciable deviations from the activities of catalysts obtained by the same procedure, which results in a poor reproducibility of the results, have been noted. Compounds containing sulfur and amino-groups deactivate platinum catalysts. This method is relatively unsuitable for the preparative synthesis of amounts of nucleosides. A significant disadvantage is also the high cost of the catalyst. Methods for the synthesis of uronic acid nucleosides in which oxidants with a nonselective activity are used therefore merit attention.



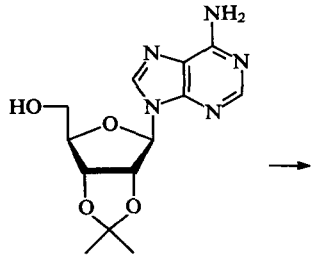
III. Oxidation of nucleosides by nonspecific oxidants

One of the first examples of uronic acid nucleoside synthesis was the oxidation of uridine **14** by nitric acid to 5-nitrouridine-5′-carboxylic acid **15**.[9]

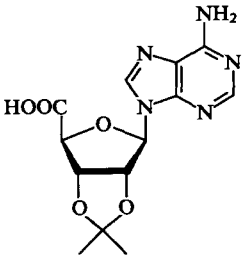


14 15

Later Fox and coworkers, [10] who repeated the synthesis of the acid **15**, confirmed its structure and obtained a series of its derivatives, including the acetonides of the esters **16** and the amine **17**.

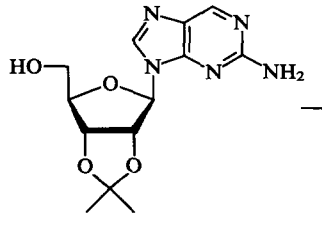


16

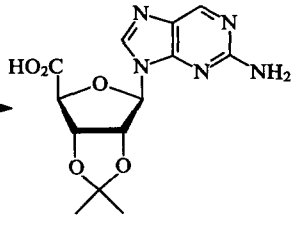


17

Oxidation of thymidine and 2′-deoxyadenosine by chromium trioxide afforded a low yield (~14%) of the corresponding acids. [11] Owing to the low selectivity of the oxidant, the secondary hydroxy-group is oxidised as well as the primary hydroxy-group. The ketoacids synthesised under these conditions are extremely unstable and decompose with formation of thymine and adenine. 2′-Deoxyadenosine-5′-carboxylic acid has been obtained in higher yield (28%) by oxidising 2′-deoxyadenosine with potassium permanganate in an alkaline medium. [12]

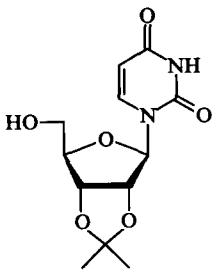


After an unsuccessful attempt at the catalytic oxidation of the adenosine acetonide **18** (the yield of the acids was 2%–5%), Harper and Hampton [13] oxidised it with chromium trioxide in various solvents. In all cases, the reaction mixtures contained several oxidation products. The acids **19** and **21** were obtained in satisfactory yields by oxidising the nucleosides **18** and **20** with potassium permanganate. [14, 15]

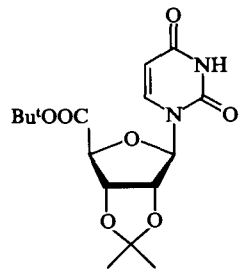


18

19



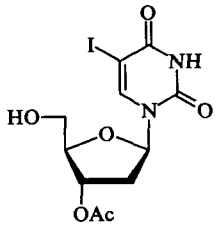
20



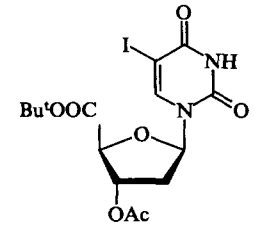
21

In the oxidation of isopropylidene derivatives of guanosine, inosine, and uridine by potassium permanganate, the only reaction product isolated has been oxalic acid. 2′,3′-*O*-Isopropylideneinosine-5′-carboxylic acid has been obtained in high yield using chromium peroxide in glacial acetic acid as the oxidant. [16]

A method of synthesis of guanosine-5′-carboxylic acid has not been described hitherto. In order to obtain derivatives of uridine-5′-carboxylic acid, Corey and Samuelsson [17] developed an unusual variant of the oxidation of 2′,3′-*O*-isopropylidene-uridine **22** coupled with esterification. Treatment of compound **22** with four equivalents of pyridinium dichromate in methylene chloride and dimethylformamide in the presence of acetic anhydride and *tert*-butyl alcohol leads to the formation of the *tert*-butyl ester of the acid **23**.

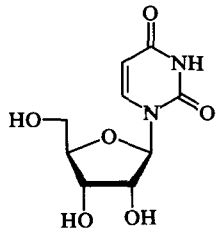


22

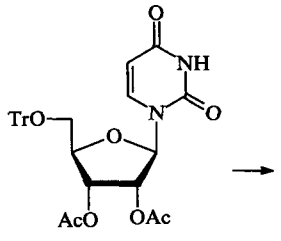


23

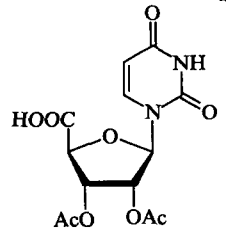
The ester **25** was obtained by this method from the deoxynucleoside **24**. [18]



24

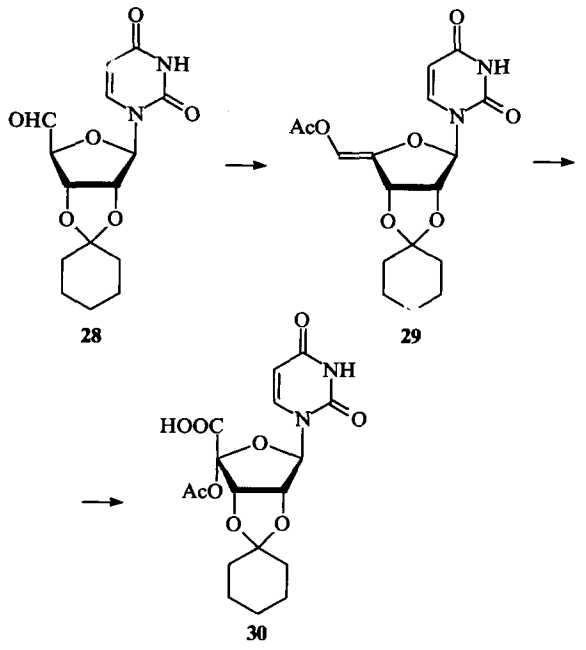


25



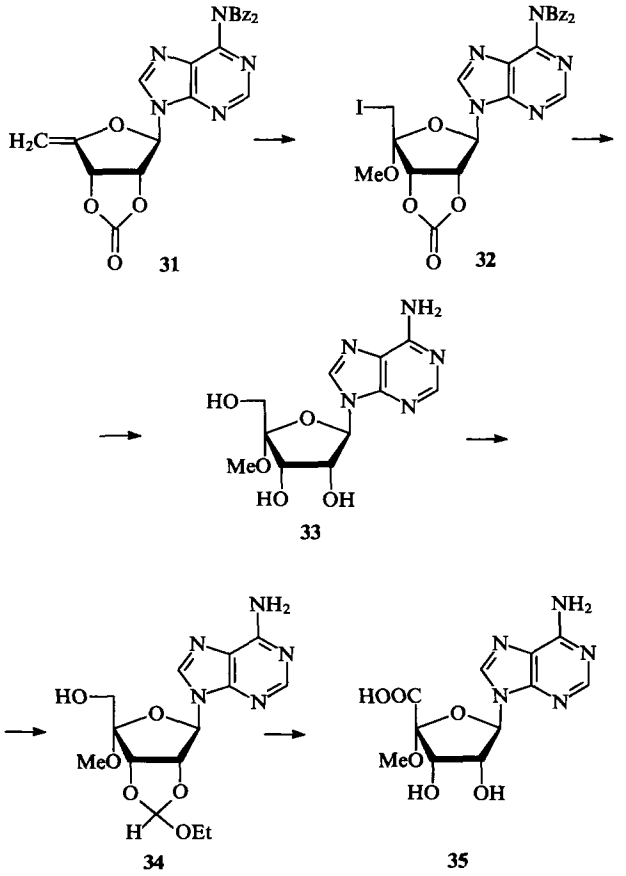
A scheme has been developed for the synthesis of pyrimidine nucleosides of uronic acids involving the treatment of uridine **14** in pyridine initially with chlorotriphenylmethane and then with acetic anhydride, this being followed by the oxidation of the resulting fully substituted nucleoside **26** with chromium peroxide [chromium trioxide? (Ed.)] in acetone in the presence of 50% sulfuric acid (the Jones reagent). The diacetate **27** was obtained by this procedure in 50% yield. [19]

14



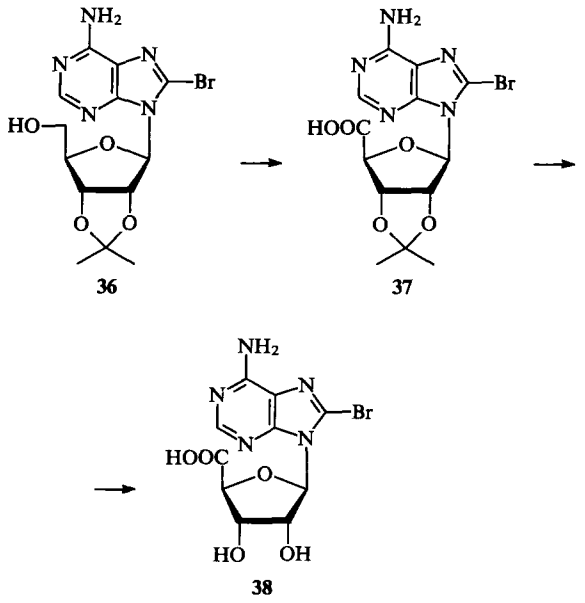
26

27



Tr = $C(Ph)_3$.

Nucleosides with an exocyclic double bond are convenient precursors in the synthesis of 4′-acetoxy- and 4′-methoxy-derivatives of nucleoside-5′-carboxylic acids. When the aldehyde **28** is heated with potassium carbonate in acetic anhydride, the enol acetate **29** is formed readily and its oxidation with *m*-chloroperbenzoic acid in methylene chloride gives the 4′-acetoxy-acid **30**. [20]



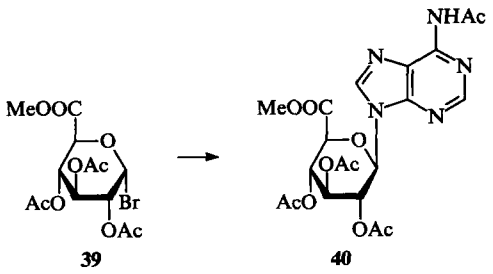
28 29 30

Treatment of the unsaturated nucleoside **31** with iodine leads to the selective formation of the iododeoxynucleoside **32**, which is converted into 4′-methoxyadenosine **33** as a result of hydrolysis, benzoylation, substitution of iodine by the benzyloxy-group, and ammonolysis. The oxidation by potassium permanganate of the ethoxymethylidene derivative **34** obtained from compound **33**, esterification, and the removal of the protecting group lead to the 4′-methoxy-acid **35**.[21]

31 32 33 34 35

Derivatives of adenosine-5′-carboxylic acid with various substituents in the 8-position in the adenine residue are of interest as potential agonists of adenosine receptors.[22] The acid **37** was obtained by oxidising the bromo-derivative **36** with potassium permanganate in an alkaline medium. Its controlled hydrolysis made it possible to remove the isopropylidene protecting group without appreciable cleavage of the *N*-glycosidic linkage, which in the presence of a bulky substituent in the 8-position is very sensitive to the action of acids. The esters obtained from the acids **37** and **38** were found to be able to form only primary amides on treatment with a mixture of primary and secondary amines. The secondary amines substitute the bromine atoms with a high degree of selectivity under these conditions, giving tertiary amines.[23]

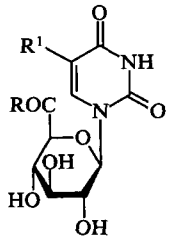
36 37 38



Oxidation of the acetonides of 8-aminoadenosine derivatives with potassium permanganate led to the complete decomposition of the purine residue.[22]

As can be seen from these examples, the oxidation of nucleosides by nonspecific oxidants encounters difficulties due to both the necessity for the preliminary protection of the secondary hydroxy-groups and the sensitivity of the heterocycles to oxidation, which appreciably limits the scope of this method.

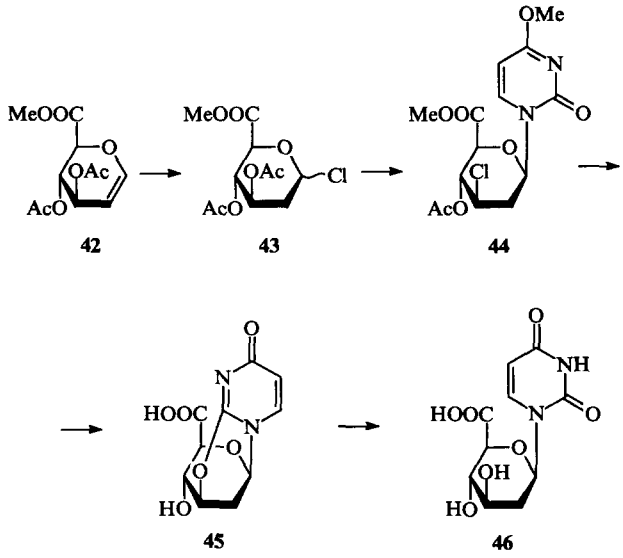
The method involving the glycosylation of a wide variety of purine and pyrimidine heterocycles by uronic acid derivatives, for the preparation of which the range of oxidants employed in organic chemistry is in principle suitable, gives rise to extensive prospects for the synthesis of uronic acid nucleosides. The glycosylation of heterocycles by uronic acid derivatives has its specific features associated with the presence of a carboxy-group, which induces an appreciable redistribution of electron density in the molecule.



IV. Glycosylation of purine and pyrimidine heterocycles by uronic acids

There are numerous examples in the literature of the synthesis of nucleosides via the glycosylation of a wide variety of nitrogen-containing heterocycles by carbohydrate derivatives. At the same time, the use of uronic acid derivatives as glycosylating agents has only recently been systematically studied. Early attempts to synthesise uronic acid nucleosides include the condensation of the bromo-derivative **39** with 6-acetamido-9-chloromercuriopurine in the presence of cadmium carbonate and celite, which gave nucleoside **40** in 57% yield.[24]

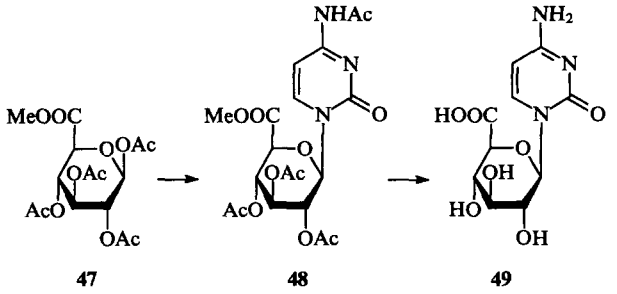
39 40



Hilbert and Johnson's method has been used to synthesise the pyrimidine nucleosides of D-glucopyranouronic acid: the glycosylation of 2,4-dialkoxypyrimidines by the bromo-derivative **39** gave the corresponding *N*-glycosides in 40%–60% yield, their methanolysis, ammonolysis, and alkaline hydrolysis giving rise to the uracil and thymine nucleosides of D-glucuronic acid and its methyl ester and amide having the general formula **41**.[25]

41

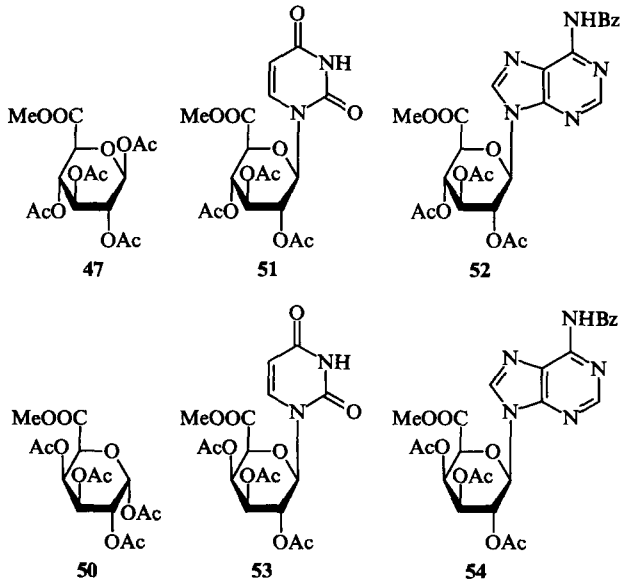
R = OH, OMe, NH_2;
R^1 = H, Me, Br, I.



An interesting scheme for the synthesis of the nucleosides of 2-deoxypyranouronic acid has been described.[26] The chloro-derivative **43**, obtained by adding hydrogen chloride to the glycal **42**, was condensed with 2,4-dimethoxyuracil at 90–95 °C. Subsequent treatment of 3'-chloro-2',3'-dideoxy-β-nucleoside **44** with hydrogen chloride in methanol and with alkali afforded the cyclic nucleoside **45**. The opening of the anhydride ring by treatment with alkali led to the formation of the 2'-deoxynucleoside **46**.

42 43 44

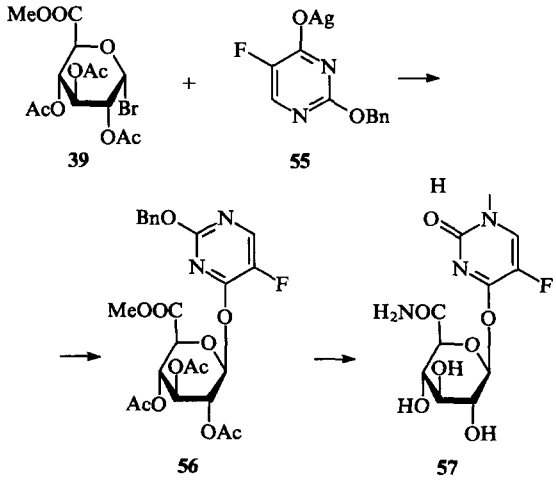
45 46



Fox and coworkers[27] synthesised the acid **49**, which is the cytosine nucleoside of D-glucuronic acid detected among the products of the biosynthesis of the antibiotic blasticidin S. Glycosylation of the silyl derivative of *N*(4)-acetylcytosine by the acetate **47** in the presence of $SnCl_4$ gave the nucleoside **48** in a low yield (20%). The required acid **49** was obtained by the alkaline hydrolysis of the latter.

47 48 49

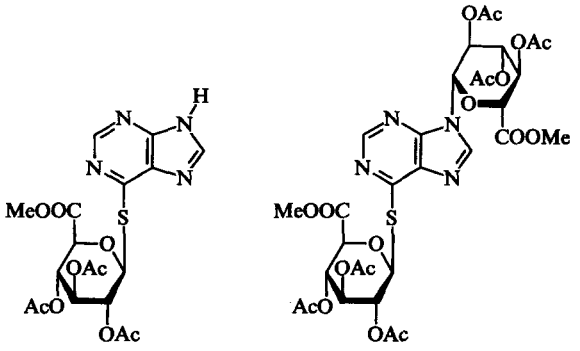
The glycosylation of the silyl derivative of *N*-benzoylcytosine by the acetate **47** in the presence of three equivalents of $SnCl_4$ led to the benzoyl analogue of compound **48** in 70% yield.[28]



Lichtenthaler and coworkers[29,30] investigated the condensation of silyl derivatives of nitrogen-containing heterocycles with peracylated uronic acid esters in the presence of Lewis acids. It was found that, in the glycosylation of uracil and *N*(6)-benzoyladenine by the acetates **47** and **50**, the corresponding nucleosides **51**–**54** are formed in satisfactory yields only in the presence of 2.6 equivalents of $SnCl_4$.

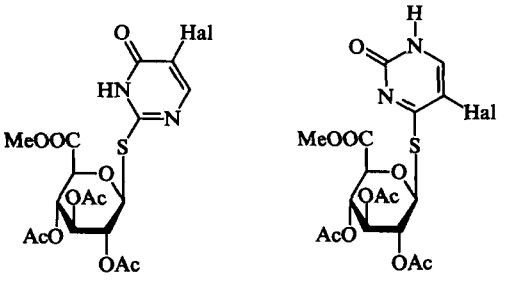
47 51 52

50 53 54



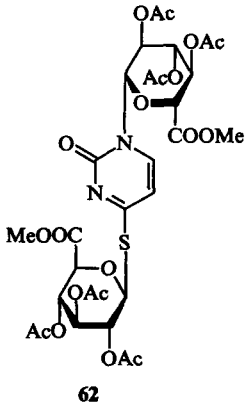
The *O*-glucuronide of 5-fluorouracil **57** has been obtained by condensing the silver salt of 5-fluorouracil **55** with the bromo-derivative **39** and by the subsequent removal of the protecting groups of the nucleoside **56**.[31]

39 55



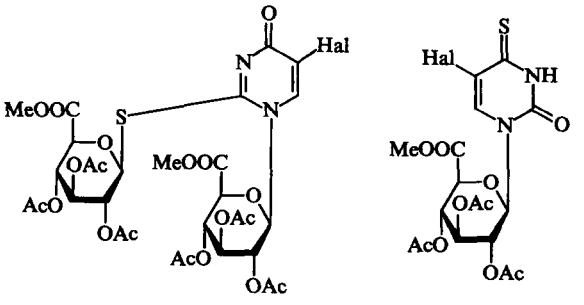
56 57

The reaction of bromo-derivative **39** with 6-mercaptopurine in DMF containing potassium carbonate afforded the *S*-glucuronide **58**. The reaction of **39** with the silver salt of 6-mercaptopurine and also the transglycosylation of the *S*-glucuronide **58** in the presence of $HgBr_2$ led to the formation of *N*(9),*S*-bisglucuronide **59**.[32,33]



58 **59**

Methods for the synthesis of the *S*-glucuronides of 2- and 4-thiouracils, containing halogen atoms in the 5-position of the pyrimidine group, have been developed.[34] The best synthetic procedure was found to be the glycosylation of thiouracils by the acetate **47** in acetonitrile in the presence of 3.3 equivalents of $SnCl_4$. Together with the *S*-monoglucuronides **60** and **61**, a small amount of the *N*(1),*S*-bisglucuronide **62** was found, the latter being formed probably as a result of transglycosylation of the *S*-glucuronides.

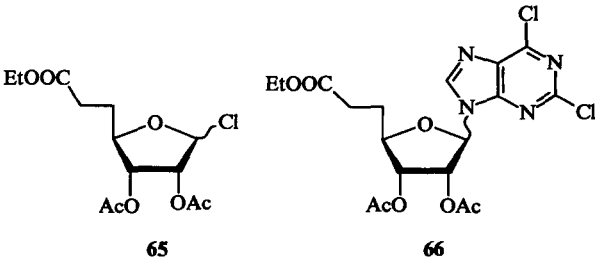


60 **61**

62

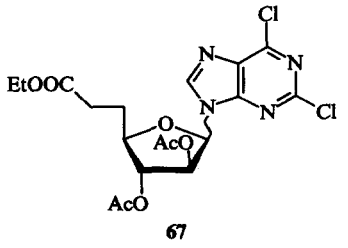
The corresponding 5-halo-derivatives have been obtained by halogenating the *S*-glucuronides and it was shown that 4-thiouracil glucuronides are halogenated less effectively than 2-thiouracil glucuronides. The fluorination of 4-thiouracil glucuronides led to cleavage of the *S*-glycosidic linkage.

The reactions of the *S*-glucuronides of 2, and 4-thiouracils and of their 5-halo-derivatives on treatment with Lewis acids have been investigated.[35] Refluxing of the *S*-glucuronides of 2-thiouracil and of its 5-halo-derivatives **60** in benzene in the presence of $HgBr_2$ led to the *N*(1),*S*-bisglucuronide **63** as a result of the transglycosylation reaction, whereas the *S*-glucuronides of the 5-halo-derivatives of 4-thiouracil gave predominantly the *N*(1),*S*-bisglucuronides **62** and insignificant amounts of the *N*(1)-glucuronides **64** as a result of the S → N transglycosylation of the nucleoside **61**.



63 **64**

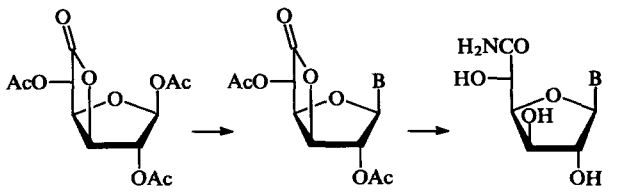
Mahrwald and Wagner[36] examined synthetic approaches to glucuronides of 2-hydroxy and 4-hydroxy- as well as 2-mercapto- and 4-mercaptopyrimidines.



Glycosylation of 5-halouracils (Hal = F, Cl, Br, I) by the bromo-derivative **39** and the acetate **47** has been investigated.[37] The interaction of the bromo-derivative with silyl derivatives of 5-halouracils in benzene in the presence of $HgBr_2$ and $Hg(CN)_2$ led to the corresponding *N*(1)-nucleosides; the formation of small amounts of *N*(1), *N*(3)-bisglucuronides was observed. An increase in the yield of the *N*(1)-nucleosides on passing from uracil to 5-iodouracil was noted. The authors attributed this finding to the decreasing electronegativity of the halogens and the increasing basicity of the *N*(1) atom of the heterocycle.

The condensation of the silyl derivatives of 5-halouracils with the sugars **39** and **47** in acetonitrile and dichlorobutane in the presence of $SnCl_4$ afforded predominantly the *N*(1)-nucleosides, the *N*(3)-nucleosides being found in only two cases.

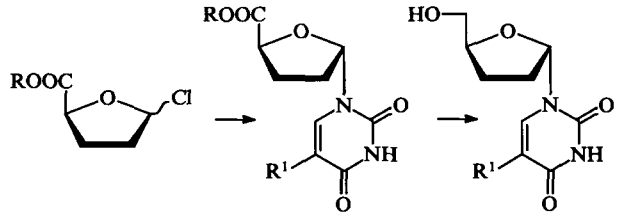
When the chlorosugar **65**, synthesised in six stages from allofuranose, was fused together with 2,6-dichloropurine in the presence of catalytic amounts of toluene-*p*-sulfonic acid with a yield of 47%, the formation of the α- and β-anomeric nucleosides of the D-ribose (compound **66**) and D-arabinose (compound **67**) series was observed.[38]



65 **66**

67

The condensation of silyl derivatives of uracil (U), *N*(4)-benzoylcytosine [*N*(4)-BzC], and also *N*(6)-benzoyladenine [*N*(6)-BzA] with the completely acetatoxylated glucurone **68** in the presence of three equivalents of $SnCl_4$ gave the nucleosides **69**–**71**, the ammonolysis of which led to the amides **72**–**74**.[39–41]

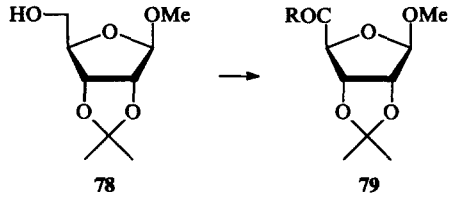


68

69: B = U; **72**: B = U;
70: B = *N*(4)-BzC; **73**: B = *N*(4)-BzC;
71: B = *N*(6)-BzA; **74**: B = *N*(6)-BzA.

The high stereospecificity of the condensation, leading to the formation of nucleosides only in the β-anomeric configuration, was demonstrated.

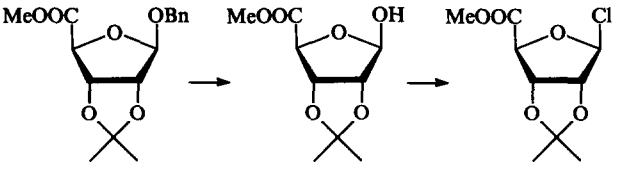
The nucleosides of glucurone and their derivatives have been synthesised by condensing the lactone **68** with the silyl derivatives of 5-fluoro-, 5-bromo-, and 5-iodo-uracil.[42] The condensation of the lactone with silylated uric acid, xanthine, and *N*(2)-acetylguanine has been investigated in dichlorobutane in the presence of trimethylsilyltrifluorosulfonic acid.[43] The formation of a mixture of the *N*(3)-, *N*(7)-, and *N*(9)-nucleosides was observed under these conditions.



The nucleosides **76** have been synthesised by alkylating silylated pyrimidines by the chloro-derivatives of tetrahydrofurancarboxylic acid **75**. The reaction takes place at 20–30 °C with formation of racemic nucleosides having the *trans*-configuration. Reduction of the esters gave the dideoxynucleosides **77**. A small amount of the *cis*-isomer together with the *trans*-isomer was isolated following the alkylation of 5-fluoro-uracil by the chloro-derivative **75** at 100 °C with distillation of the chlorotrimethylsilane formed during the reaction.[44]

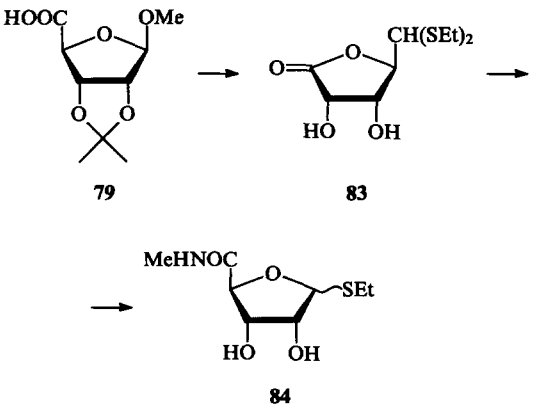
75 76 77

R^1 = Me, H, F.



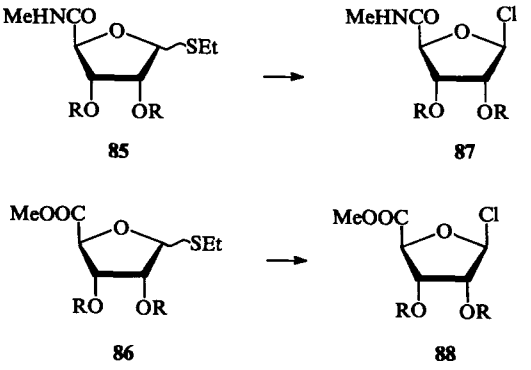
Schmidt and coworkers[45–47] have studied the glycosylation of pyrimidine and purine heterocycles by uronic acid derivatives. They developed methods for the preparation of derivatives of riburonic acid by oxidising the methyl riboside **78** with potassium permanganate. Because of their low reactivity in glycosylation reactions, the esters and amides **79** were found unlikely to be useful in the synthesis of nucleosides.[45]

78 79



R = OH, OR^1, NR_2^2.

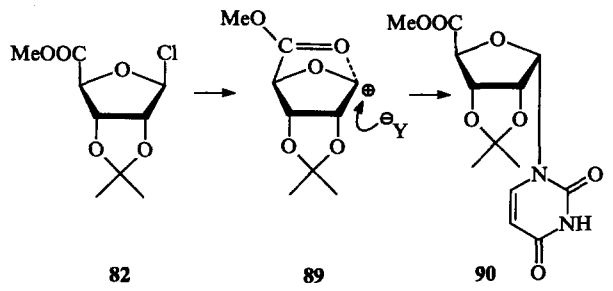
Chlorosugars are more active glycosylating agents. The sugar **81** with a free hemiacetal hydroxy-group was obtained by the hydrogenolysis of the riburonide **80**. Its treatment with thionyl chloride led to the β-anomer of the glycosyl chloride **82**.[46]



80 81 82

The use of the chloro-derivative **82** in order to obtain nucleosides proved to be of limited applicability for the following reason. In contrast to the isopropylidene derivatives of nucleosides, where the protecting group can be removed under the conditions of mild acid hydrolysis, the hydrolytic removal of the isopropylidene protecting group from uronic acid nucleosides requires severe conditions, which leads to appreciable cleavage of the glycosidic linkage. Methods have been described[47] for the synthesis of halo-derivatives of riburonic acid with benzylidene, benzyl, and benzoyl protecting groups. Treatment of the acid **79** with ethanethiol led to the synthesis of the diethylmercaptoacetal of the lactone **83**, which was transformed in two stages into the amide **84**.

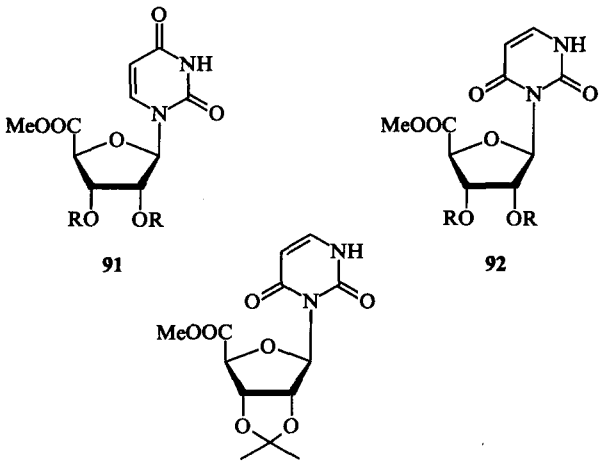
79 83 84



On treatment with chlorine, the benzylidene, benzyl, benzoyl, and acetyl derivatives of the amide **85** and the ester **86** were converted smoothly into the chloro-derivatives **87** and **88**.

85 87

86 88

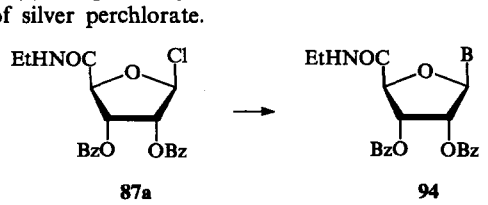


The stereochemical features of the glycosylation of pyrimidine heterocycles by the halo-derivatives of riburonic acid esters and amides with different protecting groups have been investigated. The method involving fusion of the chloro-derivative **82** with silylated uracil in the absence of a catalyst gave only the α-anomeric nucleoside **90**. The stereochemical result of this reaction is probably determined by the steric influence of the methoxycarbonyl group, which prevents the attack on the carbonium ion **89** by the nucleophile from the β-region.[48]

82 89 90

On fusion with uracil, the acetyl and benzoyl derivatives of the chloro-derivative **88** afforded a mixture of anomeric nucleosides, in which the β-anomer predominated. In this case, the stereochemical result was determined by neighbouring group participation, i.e. by the directing effect of the 2-*O*-acyl group.

When the condensation was carried out in benzene in the presence of silver perchlorate, the same behaviour was observed, but an increase in the fraction of the β-anomer was also noted in all cases. When $SnCl_4$ was used as the catalyst, the condensation led only to β-nucleosides, but appreciable amounts of the *N*(3)-nucleosides **92** were found in the reaction mixture under these conditions together with the *N*(1)-nucleosides **91**. Condensation of chloride **82** with uranyl gave only *N*(3) nucleoside **93**. Substitution of chlorine by the acetyl group produced the same result.



91 92

R = Ac, Bz. 93

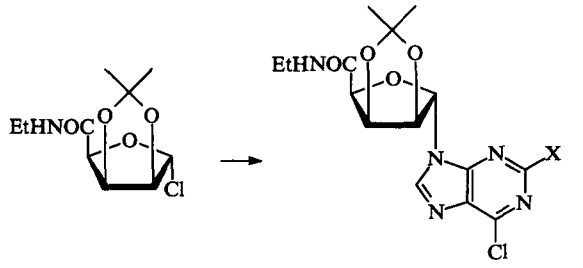
The *N*(1)-α-, *N*(1)-β-, and *N*(3)-β-nucleosides have been obtained in proportions of 2 : 15 : 3 respectively by glycosylation of the silylated *N*(4)-acetylcytosine by the chloro-derivative **82** in the presence of $SnCl_4$. The condensation of the benzoate **88** led to the α- and β-anomers in proportions of 1 : 3 and the *N*(3)-nucleoside was not formed. Fusion with silver perchlorate did not alter significantly the stereochemical result of the reaction.

The ethylamides **94** were obtained in satisfactory yields by glycosylating silylated derivatives of uracil, *N*(4)-acetylcytosine [*N*(4)-AcC], and thymine (T) by the diethylamide **87a** in presence of silver perchlorate.

87a 94

B = U, *N*(4)-AcC, T.

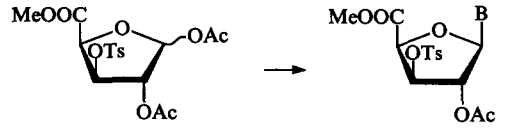
The condensation of activated derivatives of D-riburonic and D-lyxuronic acids with various purines was investigated by Schmidt et al.[49] in order to estimate the effectiveness of the glycosylation of purines as a general method of synthesis of uronic acid nucleosides. The anomeric and regioisomeric [*N*(7),*N*(9)] nucleosides were separated by high performance column chromatography and structural assignments were reliably made on the basis of ^1H and ^{13}C NMR data.



It was established that catalysis by mercury salts and also by $SnCl_4$ and $AgClO_4$ gave nucleosides in acceptable yield only in rare cases. Satisfactory results were obtained by fusing silylated purines with the methyl esters of chloro-derivatives of riburonic and lyxuronic acids with an isopropylidene protecting group. Together with the α- and β-anomers of the *N*(9)-nucleosides, the anomers of *N*(7)-nucleosides were isolated. The ratio of the anomers of the nucleo-sides obtained was shown to be independent of the anomeric configuration of the sugar. Condensation of the riburonic acid derivative with 6-chloropurine led to only one isomer—the α-*N*(7)-nucleoside.

In contrast to the esters, the amides of riburonic acid form exclusively the *N*(9)-nucleosides with approximately equal proportions of the anomers as a result of fusion with purines.

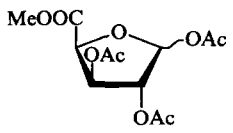
The use of acyl derivatives of riburonamides for condensation with halo-derivatives led to the preferential formation of the β-*N*(9)-nucleosides, as was in fact to be expected in view of the involvement of the 2-*O*-acyl groups.



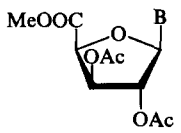
The condensation of purines with the methyl ester of the chloro-derivative of lyxuronic acid carrying an isopropylidene protecting group obeys in the main the same rules, but the formation of a considerable proportion of the β-nucleoside is somewhat unexpected, since all the substituents are then located on one side of the furanose ring.

Purine nucleosides of the ethylamide of lyxuronic acid **96** have also been obtained by fusing the chloro-derivative **95** with 6-chloro- and 2,6-dichloropurines. In contrast to the esters of lyxuronic acid, the condensation of the amide led to the formation of *N*(9)-nucleosides (with a 2 : 1 ratio of the α- and β-anomers) and only trace amounts of the *N*(7)-isomers.[50]

95 96, X = H, Cl.



The reaction of alkoxyuronides with silylated nitrogen-containing heterocycles affords nucleosides in lower yields.[51] The 1-*O*-acetyl derivatives of sugars are less active glycosylating agents than alkyl glycosides and are more stable than halo-derivatives of sugars.[52] The condensation of acetate **97** with silylated uracil in the presence of an equimolar amount of $SnCl_4$ leads to the formation of the nucleoside **98** in 32% yield. When the amount of $SnCl_4$ was increased to three equivalents, the yield rose to 85%. The interaction of the acetate **97** with silylated derivatives of 5-fluorouracil, *N*(4)-benzoylcytosine, and *N*(6)-benzoyladenine afforded the corresponding nucleosides **99**–**101**. The formation of only the β-anomeric nucleosides was observed in all cases.[51,53]



97, Ts = $MeC_6H_4SO_2$.

98: B = U;
99: B = 5-F-U;

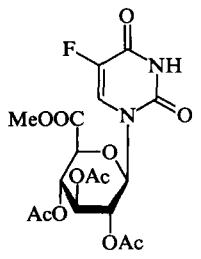
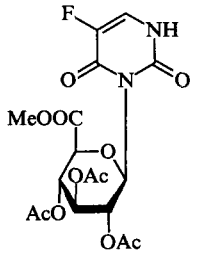
101: B = *N*(6)-BzA.

On glycosylation with the xyluronic acid ester **102** in acetonitrile in the presence of three equivalents of $SnCl_4$, the silyl derivatives of uracil, 5-fluorouracil, and *N*(6)-benzoyladenine give the corresponding nucleosides **103**–**105** in moderate yields.[54]

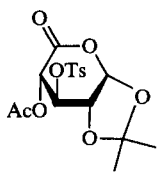


102

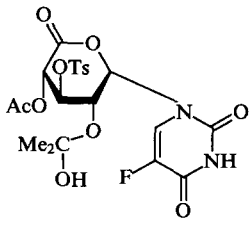


103: B = U;
104: B = 5-F-U;
105: B = *N*(6)-BzA.

The donor–acceptor complexes formed between the silylated pyrimidines and the Lewis acids, the so called *N*(1)-σ-complexes, are capable of reacting slowly with the sugar cation to form *N*(3)-nucleosides.[55]



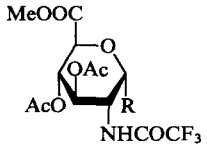
106



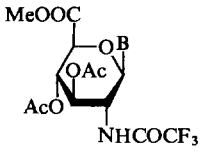
107

The glycosylation of 5-fluorouracil by the acetate **47** using three equivalents of $SnCl_4$ affords the *N*(1)-nucleoside **106** and the *N*(3)-nucleoside **107** in 36% and 6% yields respectively. The replacement of $SnCl_4$ by boron trifluoride etherate gave rise to approximately equal amounts (30.5% and 30%) of the isomeric nucleosides **106** and **107**.[56,57]

The formation of the α-anomeric nucleoside **109** was observed as a result of the glycosylation of 5-fluorouracil by the products of the acetolysis of the lactone **108**.[58,59]



108



109

The first example of the synthesis of the nucleosides of 2-amino-2-deoxyuronic acids has been described by the present author and Kulinkovich.[60] The glycosylation of uracil by the acetate **110** in the presence of $SnCl_4$ proved to be unsuccessful. The condensation of the bromo-derivative **111** was also relatively ineffective. The nucleosides **112**–**114** were obtained in 26%, 36%, and 25% yields respectively by fusing the bromo-derivative **111** with the silylated heterocycles at 130 °C at a reduced pressure (40 Torr).

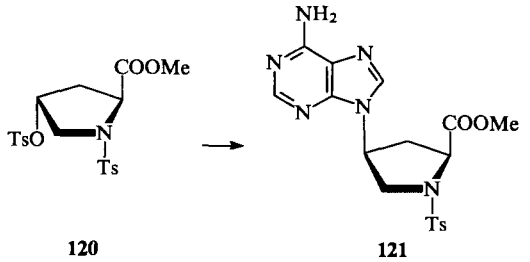
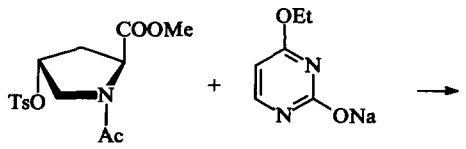
113: B = 5-Br-U;
114: B = *N*(6)-BzA.

The ready availability of esters of the acid **115**, which are obtained in a single stage from diacetoxybuta-1,3-diene and alkyl glyoxylate, makes them convenient precursors in the synthesis of unsaturated uronic acid nucleosides.[61] The antimony pentachloride-catalysed reaction of the acetate **115** with silylated uracil afforded a mixture of the α-nucleoside **116** and the β-nucleoside **117** (overall yield 80%) with a 3:2 anomer ratio. In the case of thymine, the anomer ratio was 2. The α-nucleoside **118** and the β-nucleoside **119** were obtained in an overall yield of 75% and with the anomer ratio α:β = 2:1 by refluxing the acetate **115** in nitromethane with 6-chloropurine in the absence of a catalyst.

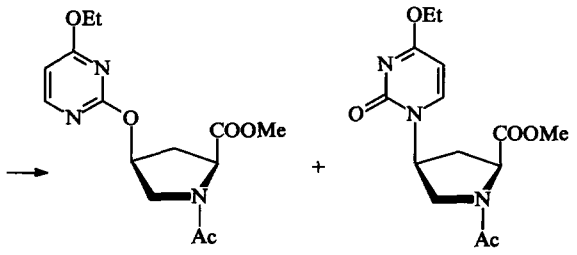


115 **116** **117**



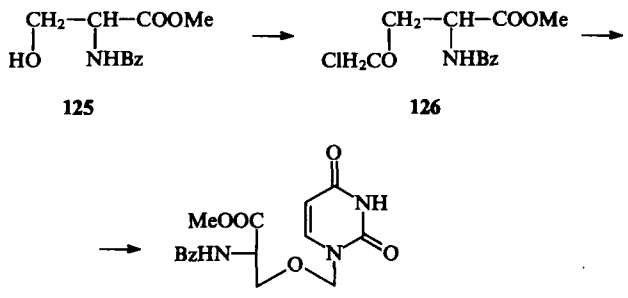
115 **118** **119**

Noncarbohydrate analogues of nucleosides are of undoubted interest as potential biologically active compounds. Certain derivatives of L-hydroxyproline have been used to synthesise them. Thus nucleophilic substitution of the *O*-tosyl group in compound **120** by the sodium salt of adenine led to the nucleoside analogue **121**.[62]

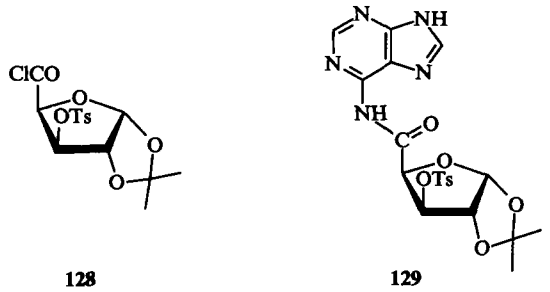


120 **121**

The similar substitution by the sodium salt of 4-*O*-ethyluracil in the pyrrolidine **122** afforded a low yield of the *O*-pseudoglycoside **123** and the *N*-pseudoglycoside **124**.[63]

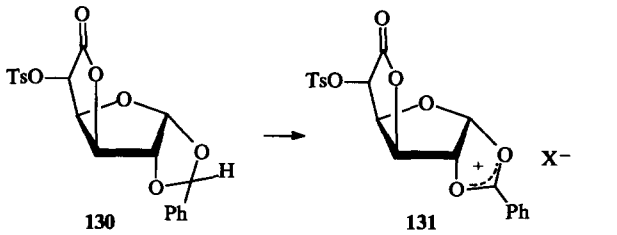


122



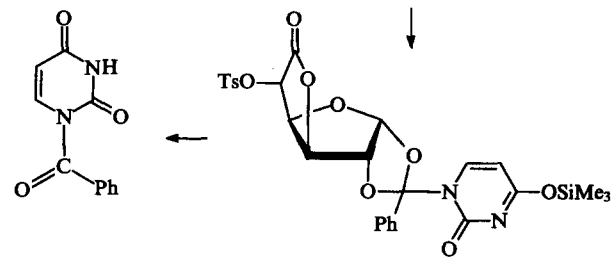
123 124

The possibility of using suitably substituted serine in the synthesis of acyclic analogues of polyoxine antibiotics has been demonstrated.[64] The unstable chloromethyl ether **126** has been obtained by chloromethylating the *N*-benzoyl-DL-serine ester **125**. The condensation of the ether with silylated uracil in acetonitrile led to the acyclic analogue **127** of polyoxine C.



125 126 127

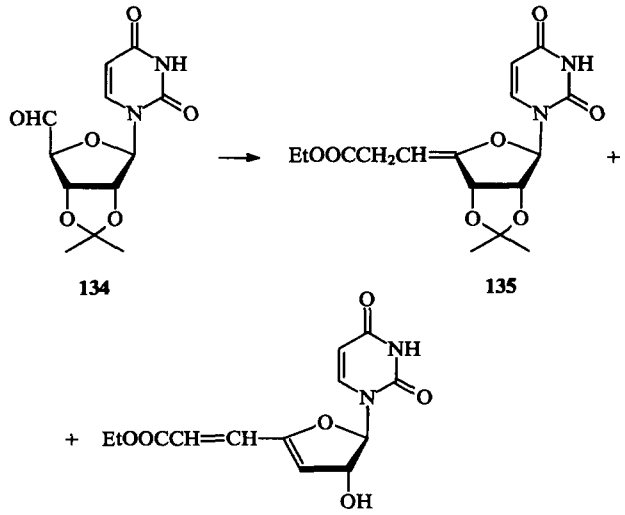
The uronic acid chloride **128** readily reacts with silylated *N*(6)-benzoyladenine to form the xyluronoyl derivative **129**.[65]



128 129

The intermediate formation of an acyloxonium salt has been postulated as the key stage in the mechanism of the synthesis of nucleosides via glycosylation. The generation of such a salt from the benzylidene derivative of the glucuronolactone **130** has been described.[66] The lactone was treated in acetonitrile with an equivalent amount of Ph_3CBF_4 or $Ph_3CCl/SnCl_4$ and the resulting salt **131** was condensed with silylated uracil. This led to the isolation of *N*(1)-benzoyluracil **132**, the yield of which varied from 30% to 50% in different experiments. Contrary to expectation, nucleoside products were not detected in the reaction mixture. The formation of the intermediate **133**, the hydrolysis of which leads to compound **132**, from the benzoxonium salt **131** appears most probable in this reaction.

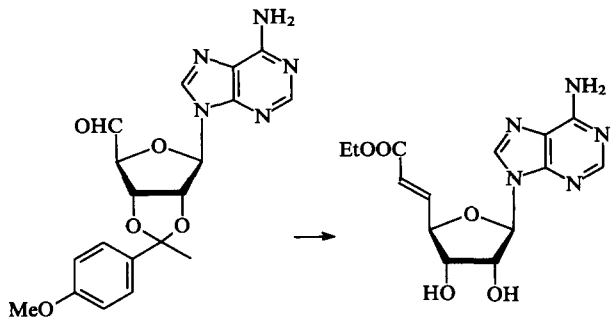
130 131



132 133

The structures of the intermediates in the glycosylation reaction differ from the canonical carbonium ion and the acyloxonium ion, although both structures can be formed sometimes, depending on the reaction conditions, which is indicated by the formation of α-anomeric nucleosides and acylated heterocycles.

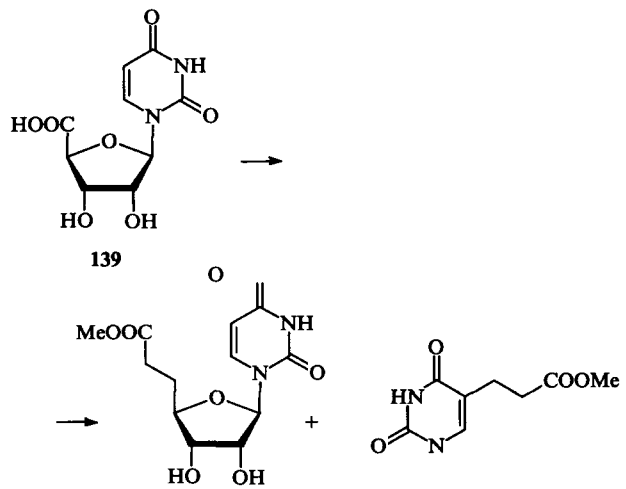
As can be seen from these data, the glycosylation of heterocycles by uronic acids has characteristic features due to the electron-accepting properties of the alkoxycarbonyl group, which is capable of forming stable complexes with Lewis acids. As a result, an excess of the condensing agent is required to obtain acceptable yields of the nucleosides. The presence of the alkoxycarbonyl group in the sugar molecule can appreciably influence the stereochemical result of the glycosylation reaction.



V. Synthesis of uronic acid nucleosides by modifying the sugar and heterocyclic base residues

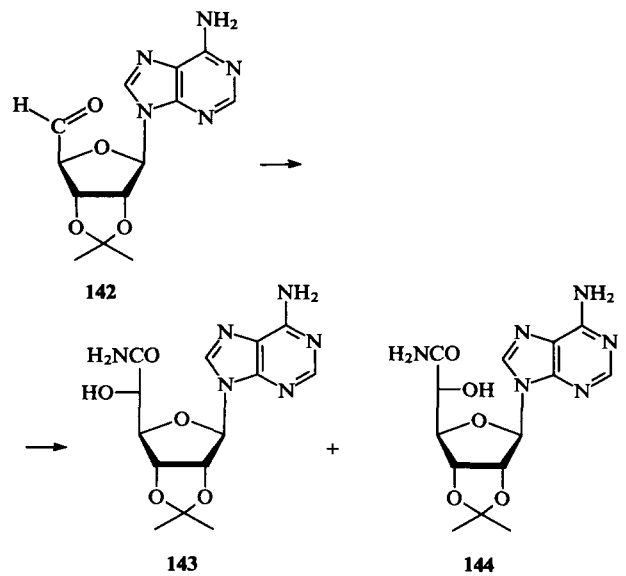
One of the procedures in the synthesis of uronic acid nucleosides is the condensation of phosphoranes with nucleoside-5'-carboxaldehydes. The reaction of the aldehyde **134** with ethoxycarbonylmethylenetriphenylphosphorane afforded the two unsaturated nucleosides **135** and **136**.[67]

134 135 136



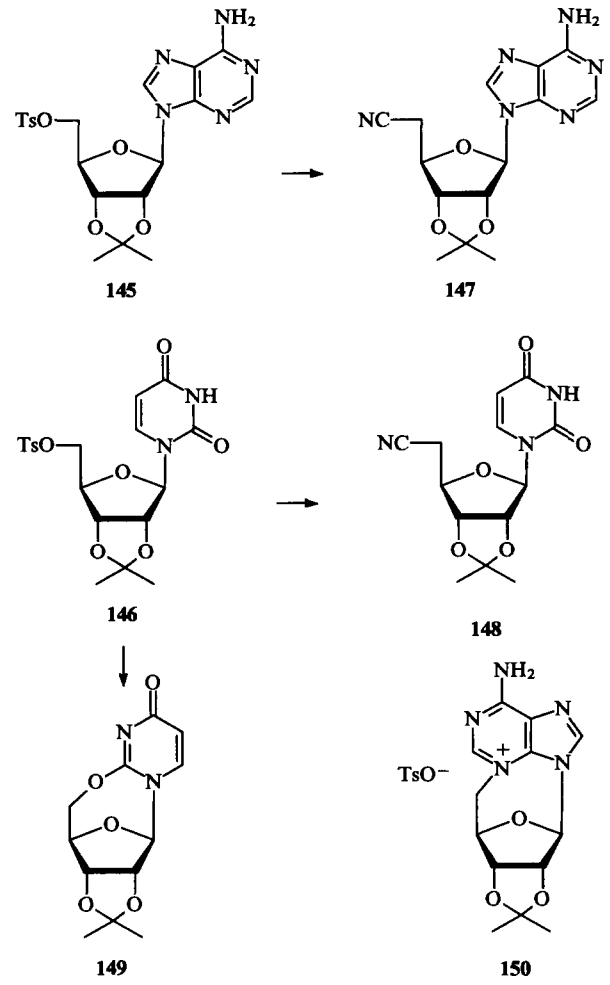
In contrast to the example quoted above, interaction of the aldehyde **137** and the phosphorane under similar conditions gave the nucleoside **138** in a low yield.[68]

137 138



The synthesis of purine and pyrimidine nucleosides having a similar structure has been described.[69-72]

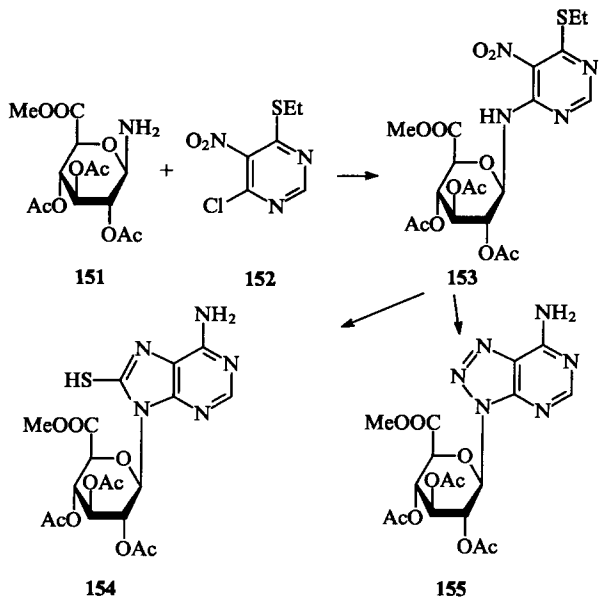
Nucleosides of this type can be obtained by the Kolbe anodic condensation of the acid **139** and the monomethyl ester of succinic acid.[67] The nucleoside **140** and the uracil derivative **141** were obtained by this reaction.



139 140 141

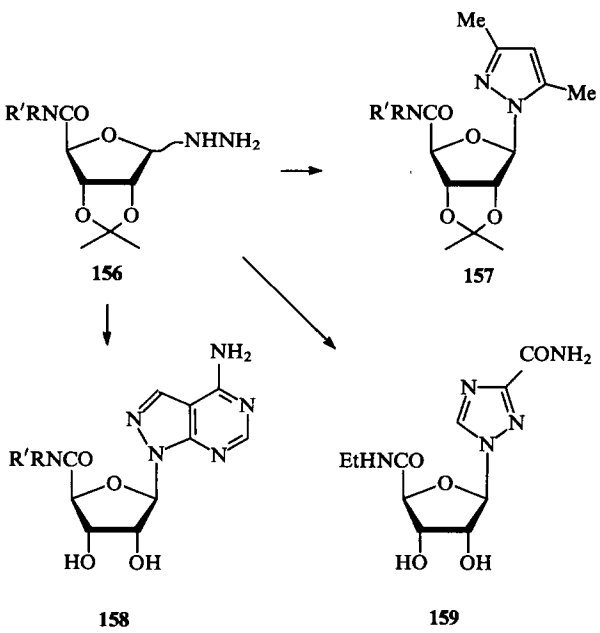
The exocyclic carbon chain of the nucleoside can be developed with simultaneous introduction of a carboxy-group by adding nucleophiles to the carbonyl group of nucleoside-5'-carboxaldehydes. The reaction between the aldehyde **142** and acetone cyanohydrin followed by treatment with hydrogen peroxide at pH 10 of the unstable α-hydroxynitriles formed led irreversibly to the two epimeric amides **143** and **144**.[73]

142 143 144



A method has been developed for the synthesis of nucleosides with a lengthened carbon chain from readily available 5'-*O*-tosyl derivatives of nucleosides.[74] The nitriles **147** and **148**, which were previously difficult to obtain, have been synthesised by treating tosylates of adenosine (compound **145**) and uridine (compound **146**) with potassium cyanide in the presence of a crown-ether. In the case of nucleoside **146**, the crown-ether-activated cyanide acts as a base and deprotonates the *N*(3) atom of the pyrimidine; intramolecular nucleophilic substitution results in the formation of a small amount of the cyclic nucleoside **149**. The purine cyclic nucleoside **150** has also been detected.

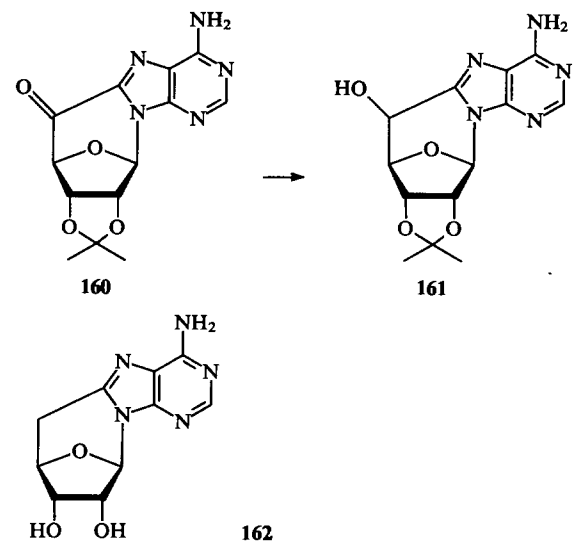
145 147 146 148 149 150



Another route to uronic acid nucleosides, involving modification of the sugar and heterocyclic base residues (the building-on method), is also possible. This variant was applied for the first time in the interaction of the amine **151** with the pyrimidine **152** in the presence of triethylamine.[75] The hydrogenolysis of the *N*-glycoside **153** and refluxing of the resulting amine in a carbon disulfide–pyridine mixture afforded the nucleoside **154**. The reduction of compound **153** with sodium nitrate in aqueous acetic acid led to the 8-azanucleoside **155** (see over).

The building-on method has been used successfully by Schmidt and coworkers[76] to synthesise a wide variety of heterocyclic derivatives of riburonic acid amides. The hydrazinoriburonamides **156** have been used as key compounds for their synthesis. Their condensation with acetylacetone, ethoxymethylenemalononitrile, and oxalic ester thioamide led to the formation of the pyrazole nucleoside **157**, the pyrazolopyrimidine nucleoside **158**, and the virazole analogue **159**.

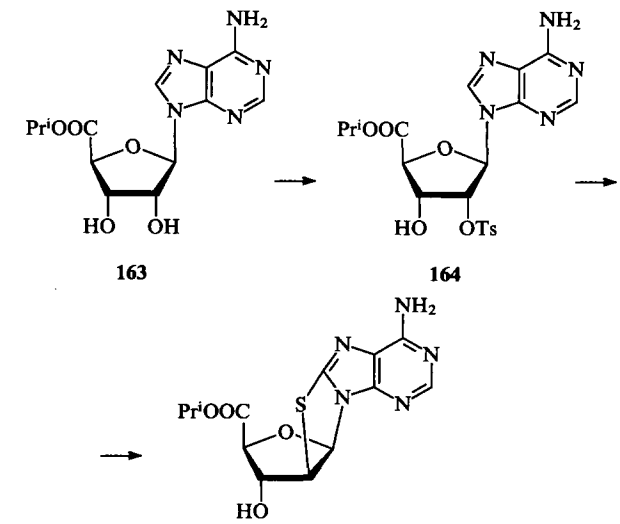
151 152 153



154 155

156 157 158 159

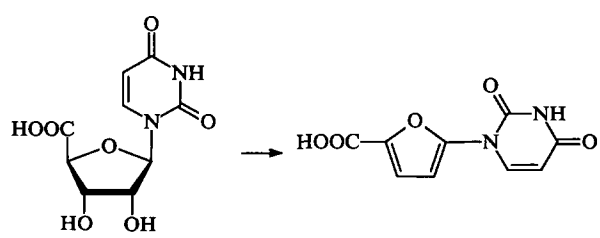
VI. Transformations of uronic acid nucleosides



The presence of the carboxy-group in nucleosides is significantly reflected in their chemical and conformational properties, which has led to new possibilities for the synthesis of diverse nucleosides, the preparation of which by traditional methods involves considerable experimental difficulties. The use of reactions characteristic of the carboxy-group makes it possible to synthesise a whole series of nucleosides with unusual structures. The synthesis of cyclic purine nucleosides may serve as confirmation of the foregoing. Treatment of the acid **19** with methyllithium afforded the ketone **160**, the reduction of which with sodium tetrahydroborate led to the cyclic nucleoside **161**, which is an analogue of deoxycycloadenosine **162**—the product of the photolysis of coenzyme B_{12}.[77] Adenosine-5'-carboxylic acid has been obtained by the photolytic oxidation of the nucleoside **162**.[78]

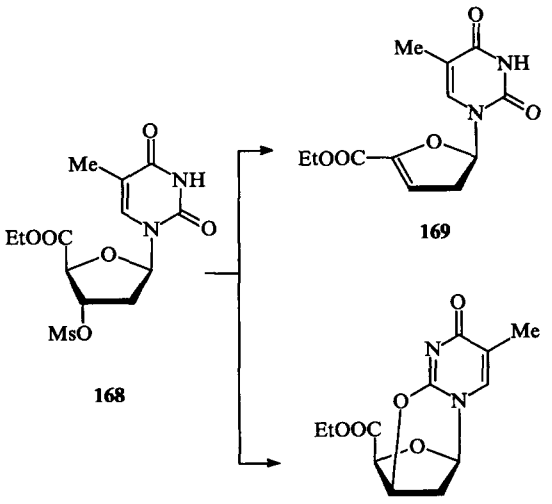
160 161

162



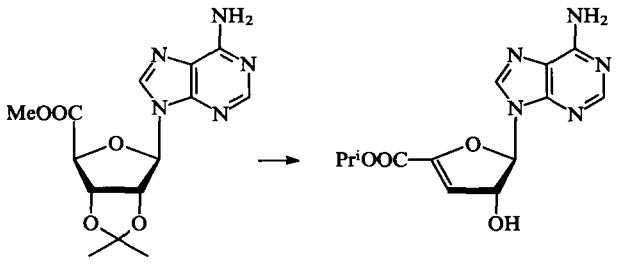
The use of the alkoxycarbonyl group of compound **163** as a kind of protecting group has made it possible to develop an alternative method of synthesis of 2'-deoxyadenosine.[79] Successive bromination and tosylation of the ester **163** afforded the nucleoside **164**, the treatment of which with thiourea gave rise to the *S*-anhydronucleoside **165**. Its reduction over Raney nickel gave 2'-deoxyadenosine in an overall yield of 10%.

163 164 165



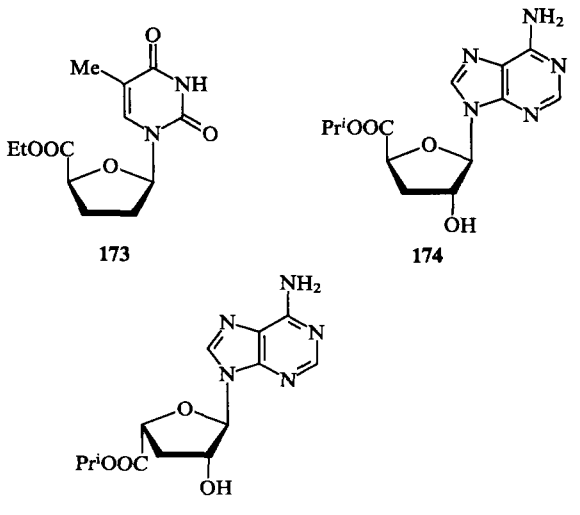
Uronic acids and their nucleosides are known[80] to be capable of giving, by β-elimination, unsaturated compounds, which are of undoubted interest for use in a wide variety of chemical reactions and also for the study of their unusual spectroscopic characteristics.

The β-elimination reaction is observed after brief heating of the acid **166** in acetic anhydride, whereupon the furan derivative **167** is formed.[3]



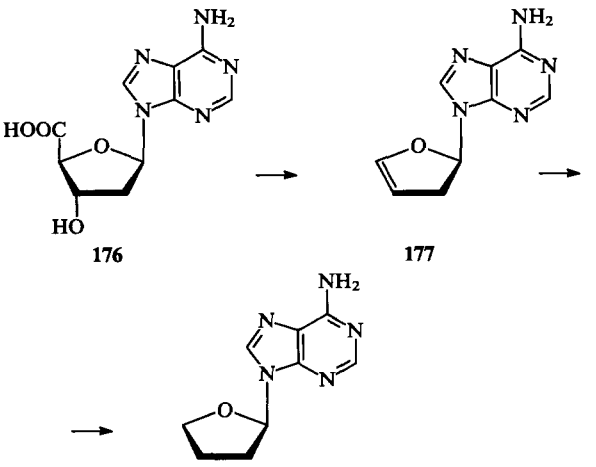
166 167

Uronic acid nucleosides are convenient precursors of 3',4'-unsaturated-nucleosides. Heating of the methanesulfonate **168** with triethylamine or sodium benzoate in DMF leads to the unsaturated nucleoside **169**, while heating with barium carbonate gives the cyclic nucleoside **170**.[81-83]



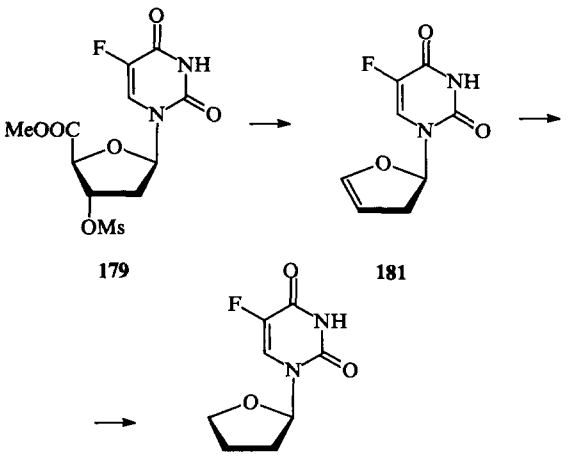
168 **169** **170**

The elimination reaction of acetonide **171** with formation of the unsaturated nucleoside **172** occurred only when sodium isopropoxide was used as the base.[84]



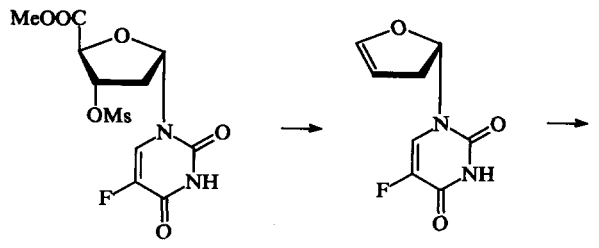
171 **172**

The nucleosides thus obtained were used in the synthesis of the D- and L-series of deoxynucleosides. The catalytic reduction of nucleoside **169** led stereoselectively to the D-isomer **173**, while reduction of nucleoside **172** gave the D- and L-isomers **174** and **175**. Deoxythymidine and deoxyadenosine have been obtained by reducing the esters **174** and **175**.[81,84]



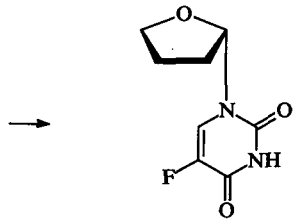
173 **174** **175**

An elimination reaction coupled with decarboxylation has been observed in a series of uronic acid nucleosides.[12] The interaction of nucleoside **176** with the dineopentyl acetal of dimethylformamide in DMF at 80-90 °C leads to a satisfactory yield of the unsaturated nucleoside **177**, the reduction of which makes it possible to obtain the optically active tetrahydrofuran nucleoside **178**.

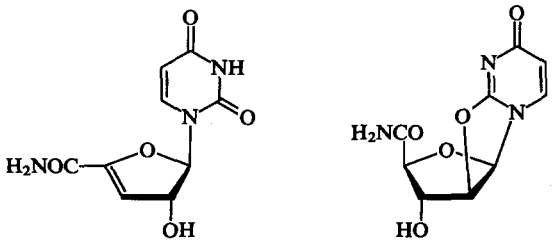


176 **177** **178**

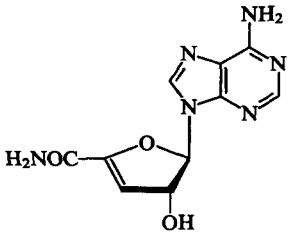
An elimination reaction coupled with dealkoxycarbonylation has been described.[85] Heating of the α- and β-nucleosides **179** and **180** in aqueous pyridine with sodium bicarbonate gave the unsaturated nucleosides **181** and **182**, hydrogenolysis of which led to the optically active nucleosides **183** and **184** (ftorafur).



179 **181** **183**

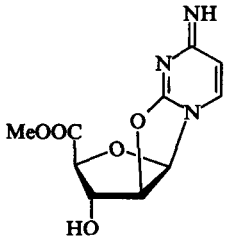


Nucleosides containing derivatives of 3-TsO-D-xyluronic acid as the carbohydrate fragment are readily converted into 3',4'-unsaturated and cyclic nucleosides on treatment with bases.[51,53] The nucleosides **185** and **186** were synthesised by treating the nucleoside **98** with a solution of ammonia in methanol. The nucleoside **185** was also obtained by treating compound **98** with sodium bicarbonate in boiling benzene with subsequent ammonolysis of the unsaturated nucleoside produced. The unsaturated purine nucleoside **187** was synthesised similarly from the tosylate **101**.

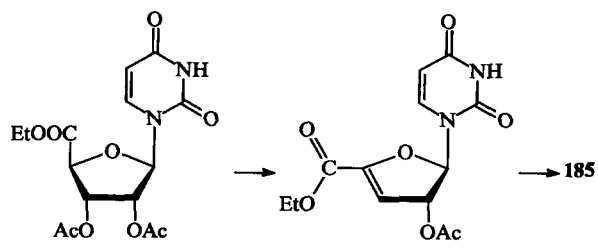


180 182

184

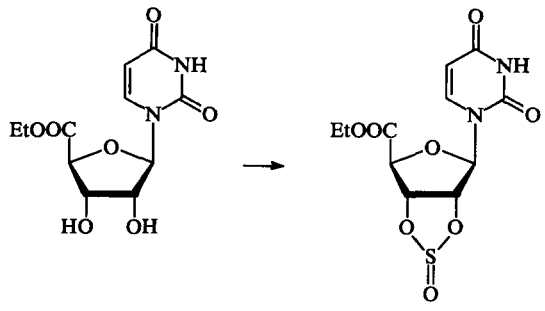


185 186



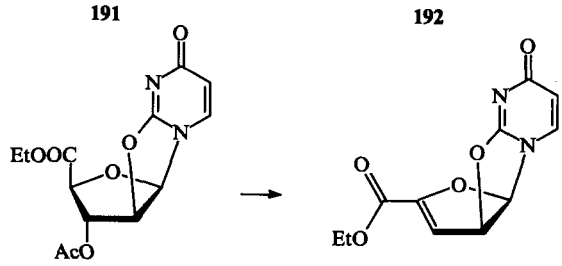
187

For the specific synthesis of the cyclic nucleoside **188**, the nucleoside **100** was initially deacetylated with hydrogen chloride in methanol and then treated with sodium bicarbonate. Under the selected conditions, the dominant process is the intermediate formation of the 2',3'-*O*-anhydronucleoside, which is subsequently converted into the *O*(2),2'-anhydronucleoside **188**.[86]

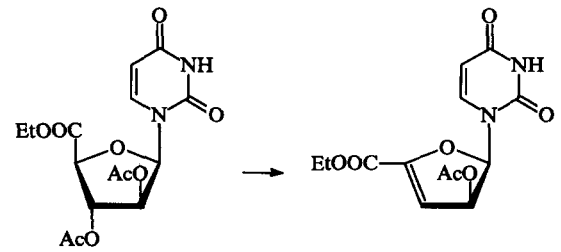


188

The amide **185** has been synthesised by a shorter route from the ester **189**, which was converted into the unsaturated nucleoside **190** on treatment with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU). Ammonolysis gave the amide **185** in a satisfactory yield.[87]

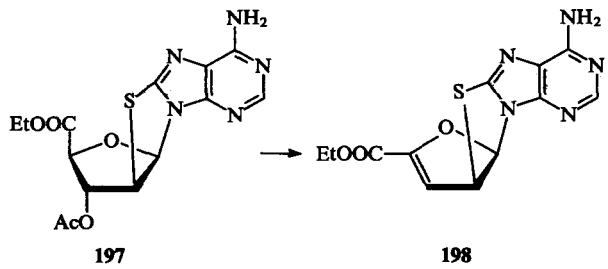


189 190



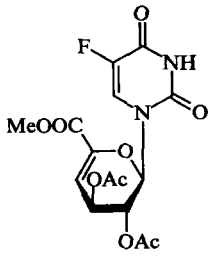
The synthesis of a nucleoside containing an anhydro-ring and a double bond together has been described.[87] Treatment of the ester **191** with thionyl chloride in acetonitrile led to the formation of the sulfite **192**, the heating of which with phthalimide in DMF led to cyclic and arabinosyl nucleosides. The acetates **193** and **194**, obtained from them, gave on treatment with DBU the unsaturated cyclic nucleoside **195** and the nucleoside **196**, which is isomeric in relation to compound **190**.

191 192

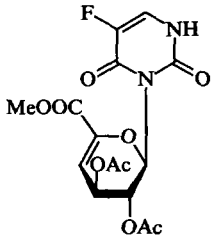


193 195

194 196



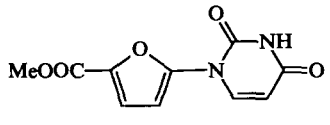
The unsaturated cyclic purine nucleoside **198** was obtained from the *S*-anhydronucleoside **197** on treatment with DBU.[88]



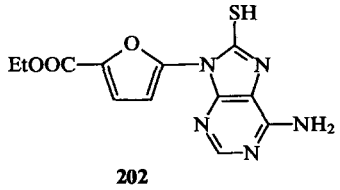
197 198

The Cotton effects observed in the circular dichroism (CD) spectra of the unsaturated nucleosides **195** and **198** are characterised by extremely high molar ellipticities, typical of systems with an internally dissymmetric chromophore.[87,88]

The 4',5'-unsaturated nucleosides **199** and **200** have been obtained by treating the *N*(1)- and *N*(3)-isomeric nucleosides **106** and **107** with DBU.[89,90]

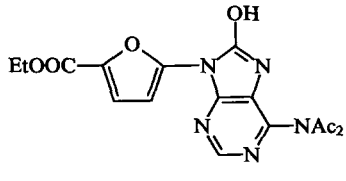


199



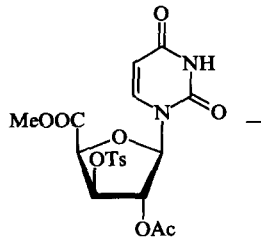
200

There exists in the literature a single point of view on the cause of the anomalies in the CD spectra of unsaturated nucleosides. It has been shown[87] that the sign and amplitude of the Cotton effect in the CD spectra of purine and pyrimidine nucleosides with a double bond in the carbohydrate fragment of the molecule depend on the position of the double bond, the asymmetry of the glycosidic carbon atom, and the sign of the pitch of the weakly or strongly bound internally disymmetric chromophore.

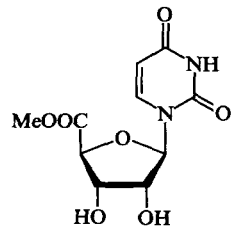


In the presence of an excess of DBU, unsaturated cyclic nucleosides are readily converted into the furancarboxylic acid derivatives **201**–**203**.[87,88,91]

201



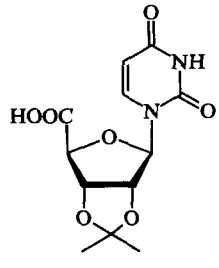
202



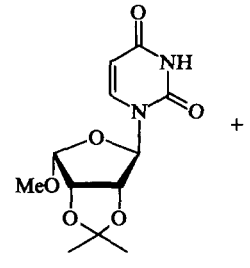
203

Compounds **201**–**203**, which have no asymmetric carbon atom, were found to be optically active.[92] The antiperiplanar conformation of the lone pair of the nitrogen atom (the sp^3-orbital) and of the σ(CO) orbital and their conjugation on passing from anhydronucleosides to furans stabilised the structure with a mutually perpendicular arrangement of the planes of the furan ring and of the nitrogenous base. The stabilisation of such structures as a result of the hindered rotation of the C–N bond leads to the appearance of stereoisomerism, which may be classified as related to the isomerism of allenes and biphenyls but is caused by the stereoelectronic anomeric effect.

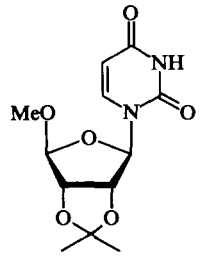
Nucleophilic substitution of the halogens and of the methanesulfonyl and tosyl groups, which proceeds with inversion of the configuration, is one of the most widely used methods for specific transformations in the chemistry of carbohydrates and nucleosides. This method is unsuitable in the series of uronic acids when the group to be substituted is in the β-position relative to the alkoxycarbonyl group. The competing β-elimination reaction then takes place. It has been observed[93] that the nucleosides of 3-TsO-D-xyluronic acid can be converted smoothly into nucleosides with the D-ribo-configuration on treatment with phthalimide. Treatment of the nucleoside **98** with phthalimide in DMF at 130 °C gives rise to a mixture of positional acetate isomers, the deacetylation of which leads to the ribonucleoside **204**.



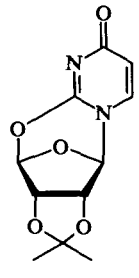
98



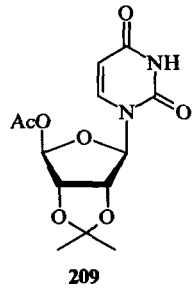
204



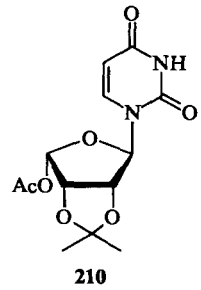
The results of the anodic oxidation of the acid **205** are interesting.[94] A mixture of the methoxynucleosides **206** and **207** has been obtained in a 35% overall yield by the electrolysis of the acid in methanol. The cyclic nucleoside **208** with an unusual structure was isolated from the reaction mixture together with the above compounds. Electrolysis of the nucleoside **205** in acetic acid afforded the acetates **209** and **210**.



205



206



207

208

209

210

It is essential to note one other feature of uronic acid nucleoside. Anisochronicity of the diastereotopic protons in the ^{1}H NMR spectra of the ethyl and isopropyl esters has been observed only in nucleosides with an anhydro-ring or an isopropylidene protecting group. It has been shown that the observed anisochronicity, caused by the presence of anisotropic heterocycles in the chiral molecule, depends on the distance between the alkoxycarbonyl group and the anisotropic group and on their orientation relative to one another in space.[95–97]

Abstract. The results of theoretical and experimental studies on the electronic structure, and nature of interatomic interactions, and the properties of binary metal borides, ternary boron-containing compounds and alloys, and also amorphous binary and multicomponent borides are examined. The prospects for employing the methods of solid-state quantum-chemistry in the description of the fundamental electronic properties of metal borides are discussed. The bibliography includes 255 references.

I. Introduction

Metal borides belong to one of the most interesting classes of solid compounds and possess a set of important physicochemical properties (thermomechanical, magnetic, electrophysical, and others), which permits their wide scale employment as components of refractory alloys, in the development of special purpose ceramics and metalloceramics, as protective coatings for high-temperature alloys, as a base for composite materials, as solid solders, and as corrosion-resistant and abrasive materials.[1–14]

In terms of their thermal properties, strength, plastic properties, and electrical and thermal insulating characteristics, borides compete with other classes of high-temperature compounds—carbides and nitrides.[15,16] The borides possess a series of specific properties determined, in particular, by the nature of the chemical bonding and the electronic structure.

Boron is known to form predominantly covalent compounds with metals, an important role being assumed in this process not only by M–B and M–M bonds (M = metal) but also by direct B–B interactions. The latter are evidently responsible for the great diversity of the structural types of borides,[5,7,9,11,12] in which boron atoms can be both surrounded by metallic centres and can form linear, planar, or three-dimensional structures (Fig. 1).

The ability of many metals to form, in their interaction with boron, a large set of phases with a considerable variation of the M/B ratio—ranging from hemiborides (M_2B) to dodecaborides (MB_{12})—as well as amorphous alloys, is well known.[1–14]

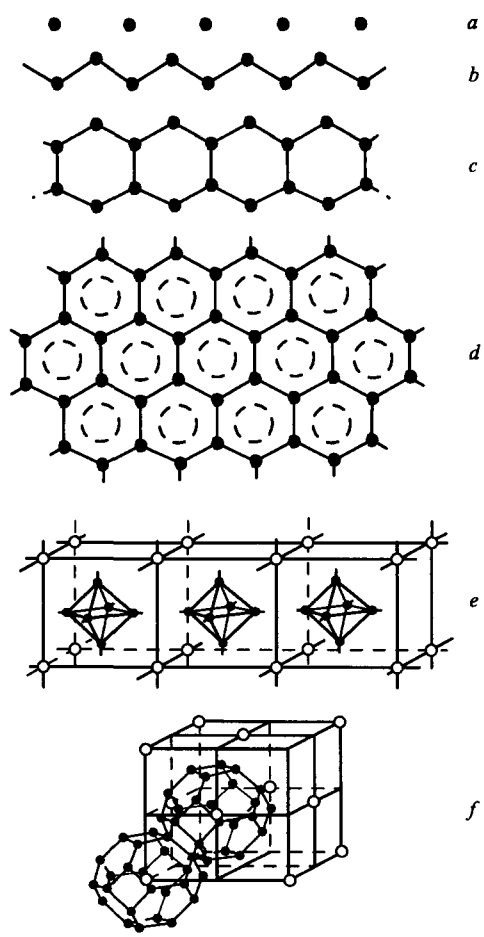

Figure 1. The possible configurations of boron atoms in the structures of the metal borides M_2B (*a*), MB (*b*), M_3B_4 (*c*), MB_2 (*d*), MB_4–MB_6 (*e*), and MB_{12} (*f*).

Relations of the composition–property type are therefore of extreme interest for metal–boron systems.

In the early stages of the relevant investigations, several alternative phenomenological models were proposed for the description of the nature of the interatomic bonds and charge states in borides. Thus the formation of borides containing planar

networks made up of boron atoms has been attributed[17,18] to the formation of sp^2 configurations of the boron atoms, while the appearance in the higher borides of three-dimensional groups of boron atoms (octahedra, cubooctahedra, etc.) has been attributed to the formation of the electronic sp^3 configuration. The existence of graphite-like motifs of boron atoms in a type AlB_2 lattice has been explained[19] by the presence of metal atoms as electron donor and of boron atoms as electron acceptors. Conversely, in the 'interstitial alloy' model,[20] the transfer of additional electron density to metal atoms is postulated.

The correlation of the properties with the specific features of the chemical bonding in borides has been interpreted from the standpoint of the dominant character of the B–B bonds in the overall system of interactions in the crystals,[19,21] whereas in other studies[22,23] preference has been given to covalent metal–boron bonds. Dempsey[20] believed that M–M bonds play a decisive role in bonding (especially for the lower borides). It is noteworthy that, although each of the models examined has had some success in the treatment of the characteristic features of the variation of a specific set of properties of individual groups of borides, they are nevertheless far from being universal.

The aim of the present review is to attempt a consideration of the current state of the theory of the electronic structure, the chemical bonding, and the most important physicochemical properties of the main groups of *s*, *p*, and *d* metal borides on the basis of the study of their fundamental electronic properties within the framework of computational solid state quantum-chemical methods and the most correct experimental methods for the investigation of the electronic structure of crystals—X-ray emission, electronic, and optical spectroscopy and a series of other methods.

The borides have been segregated into individual groups in conformity with the classification adopted and are considered in the following sections:[14,24,25] Group I and II binary metal borides in Section II, *d* metal borides in Section III, ternary metal–nonmetal boron systems in Section IV, metal–metal–boron systems in Section V, and amorphous metal borides (metallic glasses) in Section VI.

II. Group I and II metal and aluminium borides

1. Sodium and potassium borides

The study of the phase diagrams for the alkali metal–boron systems indicates[1–11] the greatest probability of the formation and stability of the borides MB_6. The band structure of the hypothetical sodium hexaboride (CsCl type lattice with interatomic distances corresponding to those found for CaB_6)[7] has been calculated[26] by the tight binding method. The valence band contains 10 partly occupied subbands, the dispersion of which is significantly smaller than in the isostructural calcium hexaboride (see below), the highest occupied states including also the 2*s* states of boron. The 3*s* states of sodium are located predominantly in the conduction band.

There is no forbidden gap in NaB_6. The concentration of valence electrons per unit cell is 19 e, so that some of the highest bonding bands (forming a planar section in the vicinity of the Fermi level) remain unoccupied, which may be the reason for the instability of the phase. The lowest virtual NaB_6 bands are separated from the system of valence states, which makes it likely that the type of conductivity of NaB_6 is intermediate between that of semicon-ductor systems based on Group II metals and that of the quasi-metallic lanthanum hexaborides.

The electronic spectrum of KB_6 has been calculated[26] by the tight binding method. A considerable similarity between the topologies of the NaB_6 and KB_6 bands has been noted. The introduction of the *d* states of potassium into the basis set in the calculation diminishes the width of the forbidden gap at the point *X*. The Fermi level (−8.1 eV) is located near the lower edge of the forbidden gap in the region of a high concentration of electronic states. It is postulated that the stability of the KB_6 lattice is caused primarily by the transfer of some of the 'metallic' electrons (the effective charges on the component atoms are +0.74 e for K and −0.74 e for B) to the bonding states between the boron atoms in the B_6 octahedra and the bonds between the given groups, which are manifested by two intense maxima in the distribution of the density of 2*p* states of boron (Fig. 2). We may note that this treatment conflicts with the Longuet-Higgins and Roberts model,[27] which postulates the existence of the doubly charged anions B^{2-} in the structure of stable hexaborides. The insignificant concentration of holes in the valence band may indicate that the boride is a semiconductor.

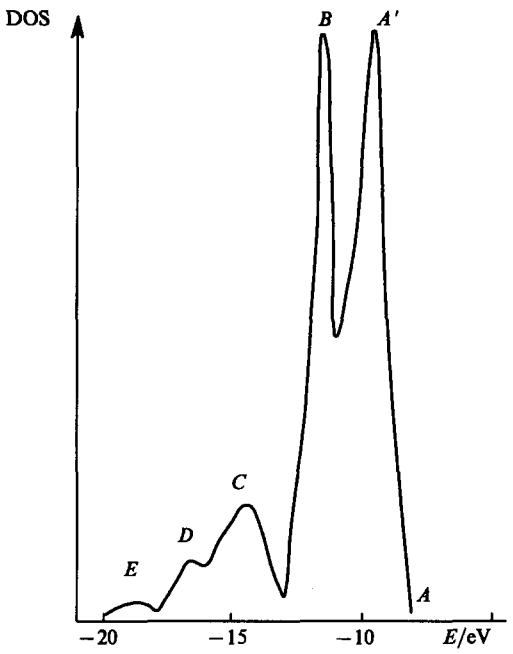

Figure 2. Distribution of the density of B 2*p* states for KB_6.[26]

2. Beryllium borides

According to the literature,[2,7,10] there are at least six individual compounds in the Be–B system (ranging from Be_5B to BeB_9), which differ sharply in their crystal structures and physicochemical properties. However, the increase with increasing boron content of the melting point and of the enthalpy of atomisation of the phase, as well as the change in the type of conductivity (from metallic to semiconducting), etc. still cannot be explained from the standpoint of electronic properties.

The treatment of the electronic processes accompanying the diffusion of boron and beryllium was initially based on the ideas of the configuration theory,[1,17] in which the primary single-electron transition $s \rightarrow p$ with formation of the Be $2s^12p^1$ configuration and subsequent 'trapping' of the boron electrons with the formation of stable sp^2 or sp^3 configurations is postulated.

In the single calculation[28] known to us, the cubic Be_2B phase (structure of the *anti*-CaF_2 type) was considered. Calculations were performed by the self-consistent method of the linearised muffin-tin orbitals (LMTO) and the chemical bonding was analysed within the framework of the self-consistent field X_α-discrete variation (SCF X_α-DV) method.

The calculated data[28] show that the valence band of the boride contains two segregated subbands separated by a minimum in the density of states (DOS) and comprising mainly the *s* and *p* states of the components. The Fermi level is located in the region of the (B, Be) 2*p*-like band. Both the *s* and *p* states of the component atoms overlap significantly, which indicates the formation of covalent bonds of the mixed *s*–*s*, *s*–*p*, and *p*–*p* types.

Comparative analysis of the involvement of individual atomic orbitals in such covalent mixing permits the calculation of the Mulliken bond populations.[28] It follows from these that the greatest contribution to the B–B and Be–Be bonding in Be_2B comes from the overlap of the $2p$ functions; the overlap populations of the s–s orbitals are also of comparable magnitude. The involve-ment of all (s, p) valence states is observed in the Be–B interaction, the outer $2p$ orbitals overlapping to the greatest extent under these conditions.

It is seen from the calculations of the electronic configurations and the effective atomic charges of the [BBe_4B_6] cluster that the unoccupied (in the atomic states) $2p$ orbitals of beryllium are appreciably populated (~1 e) with formation of configurations close to Be $2s^12p^1$. Estimation of the effective atomic charges indicates the partial transfer of charge density to the boron atoms, which indicates the presence of an ionic bond component.

Thus the calculations[28] make it possible to claim that a covalent-ionic type of chemical bonding is characteristic of Be_2B. The covalent component arises due to the overlap of the outer $2s$ and $2p$ functions of the component atoms involved in the Be–Be, Be–B, and B–B interactions. The contribution of the ionic component is due to the polarisation of electron density in the crystals with partial charge transfer in the direction Be → B.

The ideas about the principal effects of orbital hybridisation yield contour maps of the wave functions of the cluster [BBe_4B_6] for which the calculation has been made (Fig. 3). Evidently the lowest valence molecular orbitals $7a_1$ and $3b_2$ are non-bonding and are largely made up of the B $2s$ states with addition of Be $2s$ orbitals. The contours of the molecular orbitals with $9a_1$ symmetry embrace Be–Be pairs of atoms, illustrating the formation of directed covalent σ^{Be-Be}-bonds, in which the $2s$ and $2p$ states of beryllium participate, while the boron states hardly contribute to this molecular orbital. The wave functions of the $2a_1$ molecular orbital (consisting to the extent of 85% of Be s states) have a typical nonbonding character: the contours of the atomic orbitals of the individual centres are separated by lines with a zero value of the wave function. The Be $2s$, Be $2p$, and B $2p$ atomic orbitals contribute to the $11a_1$ molecular orbital, the configuration of the wave function contours indicating the occurrence in the given energy range of combined (Be–B, B–B) interactions. Finally the wave function contours of the highest occupied $12a_1$ molecular orbital (of the B $2p$ type) are distorted in the direction of the 'outer' (in the cluster) boron atoms, which can be treated as indicating the presence of B–B bonds.

Summarising the foregoing, one may claim that 'covalent interactions occur in Be_2B both between the individual components (Be–Be, B–B) and in the Be–B bond.

There is no doubt that further systematic studies are essential in order to gain a complete idea about the electronic properties of beryllium borides.

3. Calcium, strontium, and barium borides

Calcium, strontium, and barium borides have the composition MB_6 (cubic lattice of the NaCl type). It was in fact because of the simplicity of their crystal structure that calcium hexaboride became one of the first boron-containing compounds the energy structure of which was considered within the framework of theoretical approaches.[27,29–31]

The calculation for CaB_6 was performed by the linear combination of atomic orbitals (LCAO) method with a basis set incorporating the $2s$ and $2p$ orbitals of boron without taking into account the Ca–B interactions.[27] Thus in essence only the structure of the bands formed by the states of the boron sublattice was examined,[27] while the presence of the metal was taken into account in the filling of the energy levels in terms of the rigid band approximation.

Solutions of the secular equation for the crystal made it possible to devise a qualitative scheme for the structure of the energy bands of CaB_6,[27] which showed that a forbidden gap (~4.4 eV) appears between the bonding and antibonding orbitals. Since CaB_6 is a conducting substance,[1–4] the authors[27] explained these contradictions both by the possibility of the population of the lowest unoccupied states by the metal electrons and by the probable transfer of valence electrons to the conduction band on irradiation of the crystal.

In describing the energy bands of CaB_6, Yamazaki[29] took into account the Ca $4s$ states in addition to the B s and B p states. It was shown that the bonding bands of the hexaboride are fully occupied while the antibonding ones are unoccupied. This explains the stability of this structural type of borides (in conformity with phenomenological ideas,[32] the hexaborides can be regarded as the complexes $M^{2+}B_6^{2-}$ containing doubly charged metal cations). According to Yamazaki,[29] the width of the forbidden gap is ~1.5 eV.

In Flodmark's calculations,[30,31] the CaB_6 band structure was considered as a function of the choice of the exponent $z/3$ for the d orbitals (z = 1–5). It was noted that the inclusion of the M shells in the basis set has a very appreciable effect on the energies of the valence bands, leading, in particular, to a further decrease in the width of the forbidden gap.

The conclusions reached[27,29] about the structure of the CaB_6 valence band are consistent with the results of the calculation performed by the LCAO method taking into account only the boron functions[33] and also by the semiempirical

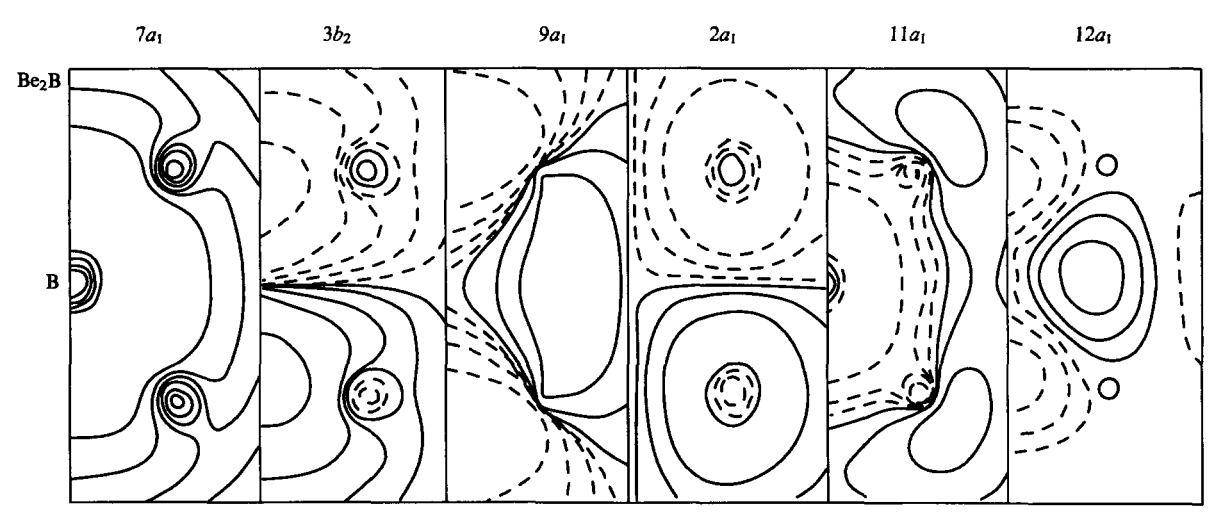

Figure 3. Contour maps for the wave functions of the valence orbitals of the BBe_4B_6 cluster according to the X_α-DV calculation.[28]

LCAO method in terms of the Gaussian orbitals basis set (GO-LCAO),[34] using a basis set comprising the *sp* functions of boron and calcium.

The LCAO method in terms of the tight binding approximation has been used[35] in calculations for CaB_6, where account was taken of the B 2*s*, B 2*p*, and Ca 3*s* states. At the same time, in order to discover the role of calcium in the organisation of the electronic centre of the hexaboride, a band calculation was performed[35] for a hypothetical 'boride' with the parameters of the CaB_6 lattice in which the metal sublattice sites remained unoccupied.

As the energy bands of this 'boride' are filled on the hypothesis that the number of valence electrons of the system (per formula unit) corresponds to that for MB_6 (20 e), it is found that the lowest ten bands are fully occupied. In this case, the minimum 'straight' forbidden gap corresponds to the splitting of the states at the point *X* and its width is 2.11 eV, which exceeds somewhat the values obtained by Johnson and Daane.[36] This discrepancy may be eliminated by including the highest states of the metal (*p* and *d*) in the basis set.[35]

Comparison of the 'B_6' and CaB_6 bands indicates an appreciable role of the metallic states in bonding, which is manifested by an increase in dispersion for a series of bands (along the Λ, Σ, and Δ directions) and also by the initiation of the appearance of new levels in the conduction band.

Calculations have shown[35] that the Ca → B_6 charge transfer does not exceed 0.9–1.0 e, although according to Longuet-Higgins and Roberts[27] the transfer of two electrons is required to stabilise the CaB_6 structure—for the complete filling of the bonding states band. This electron deficiency leads mainly to a weakening of the $p_\sigma p_\sigma$ and $p_\pi p_\pi$ bonds between the B_6 groups without having a significant influence on the 'intracluster' interaction, i.e. without leading to a critical destabilisation of the structure as a whole. This situation is analogous to that for alkali metal hexaborides, where the M → B_6 charge transfer does not exceed 1 e.[35]

The CaB_6 band structure, calculated by the augmented plane wave (APW) method with a Slater exchange-correlation contribution (α = 2/3),[37] differs significantly from that presented in other communications.[27,29–31,35] The absence of a forbidden gap between the valence and conduction bands and also the appreciable concentration of pre-Fermi states (at the point Γ), which conflicts with X-ray electron spectroscopic data, are noteworthy. These discrepancies have been explained[37] by the absence of self-consistency in the calculation for the boride.

A self-consistent study of the influence of metallic *d* states on the electron spectrum of CaB_6 has been carried out by Hasegawa and Yanase,[38] who carried out the calculation by the self-consistent symmetrised APW method. The relativistic effects were described in terms of the scheme presented by Koelling and Harman.[39] The calculations were performed in terms of both the standard muffin tin (MT) approximation and with a correction for the nonsphericity of the potential.

Both calculations yield fairly similar structures of the CaB_6 valence band (Fig. 4), containing a low-energy (lower by ~1.05 Ryd than E_F; Ryd = Rydberg number) B 2*s* band and a system of occupied bands (which are filled by 18 electrons per unit cell) in the range E_F–0.70 Ryd. The lowest virtual band is characterised by an appreciable dispersion due to the effect of the *p*–*d* hybridisation typical for the hexaborides with a very significant contribution by the Ca 3*d* function at the point *X*. The resolution of the states in the MT spheres into individual components also indicates the involvement of the Ca 3*d* orbitals in the pre-Fermi level X_3.

The most remarkable difference in the results of the calculation taking into account the nonsphericity of the potential is the increase in the energy of the X_3 state with appearance of a forbidden gap [$\Delta E(X_3 - X_{3'}) \approx 0.02$ Ryd (Fig. 4)]. The observed changes in the fine structure of the density of states are caused, in particular, by the increase in the amplitude of the Ca *d* states with decrease in the potential, whereupon the given functions assume the form of plane waves.

According to the MT calculation,[38] the surface of the CaB_6 Fermi level consists of electron and hole layers (Fig. 5). The number of carriers is ~2×10^3 electrons and the same number of holes are present in the unit cell. The role of the spin–orbital interactions in the establishment of the pre-Fermi bands has been analysed.[38] It was noted that, when the spin–orbital interactions are taken into account for a slight (~0.01 Ryd) overlap of the valence and conduction bands (according to

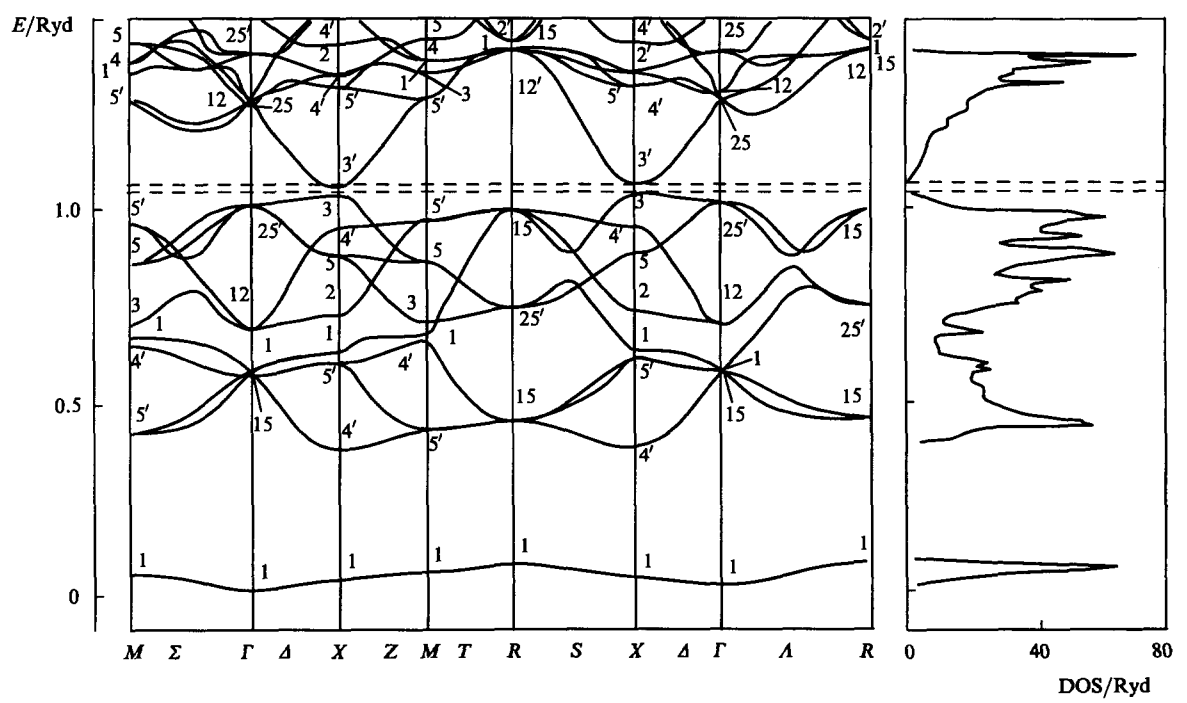

Figure 4. The band structure and the total density of states in CaB_6. SCF-APW calculation with a correction for the nonsphericity of the potential.

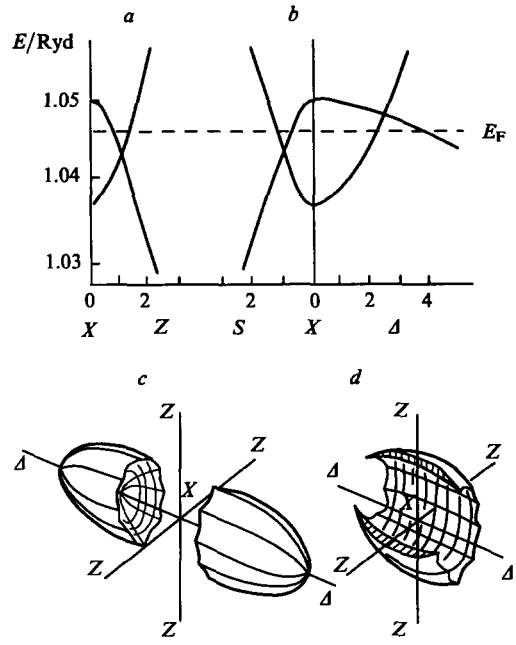

Figure 5. Energy bands near the bottom of the conduction band (*a*) and the upper edge of the valence band (*b*) and schematic representation of the hole (*c*) and electrons (*d*) layers on the Fermi surface in the vicinity of the symmetry point *X* for CaB_2.[38]

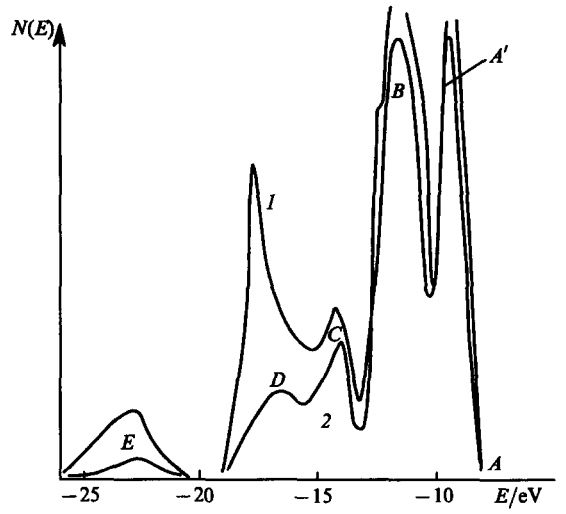

Figure 6. The total (curve *1*) and local (curve *2*) densities of B 2*p* states in BaB_6.[35]

calculations with the MT approximation), a forbidden gap should appear with an indirect transition energy of $\sim 0.001\ R_\infty$, which makes it possible to assign CaB_6 to the class of semiconductors.

The following borides have been investigated by X-ray emission, absorption, and electron spectroscopy: CaB_6,[37,40] BaB_6,[41] ScB_2,[44,46,78] TiB_2,[42–46] VB_2,[46–53] Cr_2B, CrB, CrB_2,[44–46,49,51,54,56,79] Mn_4B, Mn_2B, MnB, Mn_3B_4, MnB_2, MnB_4,[46,54,57,58] Fe_2B, FeB,[43–45,55,58–68] Co_3B, Co_2B, CoB,[44,54,60,65,67,69,70] Ni_3B, Ni_2B, Ni_4B_3, NiB,[44,45,54,58,59,67,71,78,80–82] YB_6,[40] ZrB_2,[37,51,74–76] Nb_2B, Nb_3B_2, Nb_3B_4, NbB, NbB_2,[51,72,73] MoB,[77] HfB_2,[51] and TaB_2.[51,74]

The conducting properties of calcium hexaboride have been treated[1–14] as being either of the semimetallic or semiconducting type. The dependence of the forbidden gap on the method of synthesis of the specimens[83] and on the presence of a wide variety of impurity centres or crystal defects,[83] in particular vacancies in the metal sublattice, is evident. The possibility of the formation of the latter for CaB_6 has been noted, for example, in the study of the fusion of CaB_6, whereupon dissociation takes place with the preferential evaporation of calcium.[84,85] This finding can be readily accounted for by the specific features of the energy structure of CaB_6, because the bonds between the atoms of the nonmetal sublattice of the boride play a dominant role in the organisation of the inter-species interaction.

Calculations for strontium and barium hexaborides within the framework of the LCAO formal treatment[35] indicate that the structures of their electronic spectra are similar to that for CaB_6 (Fig. 4). Therefore, without going into their details, we shall only note that the form of the valence DOS is determined primarily by the type of the distribution of states in the B_6 groups (Fig. 6) and is characterised by five principal maxima *A*–*E*. Comparison with the data obtained by X-ray emission BK_α spectra of BaB_6 shows (when account is taken of the simplifications used in the calculation)[41] a fairly reasonable agreement between the energies of the principal B 2*p* maxima with the exception of the intense peak *A* manifested on the spectral line in the form of a weak high-energy bulge.

4. Aluminium borides

The phase diagrams for the Al–B system indicate[86–95] the existence of at least two stable binary phases—aluminium diboride AlB_2 and aluminium dodecaboride AlB_{12}. Two possible modifications have been identified for the latter compound—monoclinic and tetragonal.[10] The existence of the AlB_{10} phase,[90–92,95] found by Kuz'ma,[11] was not unambiguously confirmed.

In terms of the aspect under discussion, the most interesting compound is the diboride AlB_2—a phase the structural type of which (or one related to it) is characteristic of a large number of binary and more complex *d* metal borides (see below). Aluminium diboride has one of the simplest structures and contains two alternating networks of atoms—the metal and boron (Fig. 1).

General ideas about the nature of the metal–metal bond in the diborides AlB_2 have been discussed within the framework of the Hückel model.[96,121] It is claimed that the system of chemical bonds in such crystals is based on the M–B and B–B interactions, whereas the M–M interactions (in the direction perpendicular to the network of B atoms) are antibonding.

The band structure of AlB_2 (calculation by the LCAO method)[97] is determined by the presence of filled boron bands (the structure of which is found to be similar to that for graphite) split into states with σ are π symmetries. Part of the charge density is transferred to the latter from the metal atom, whereupon the metal atoms acquire the effective charges +1.884 e (Al) and −0.942 e (B). The B–B bonds have a stabilised π component; the $Alp_{x,y}$ functions are mixed with the band comprising these states, giving rise to the B–Al bond. We may note, however, that in the calculations[97] the basis set did not include the Al 3*d* states, allowance for which (see above) may significantly amend the fine structure of the band in the energy spectrum of the crystals.

Overall, the calculations[97] are in satisfactory agreement with X-ray emission spectroscopic data[98] and have been used to interpret the anisotropy of the electrical properties of AlB_2 (on the basis of the analysis of the topology of the Fermi surface and estimates of the differences between the effective masses of the carriers for different directions in *k* space).

The molecular orbital scheme for the fragment modelling AlB_{12}, for which semiconducting properties have been predicted, has been calculated[99] by the LCAO method in terms of the Gaussian orbital basis set (GO LCAO).

III. Transition *d* metal borides

Transition *d* metal borides constitute one of the most numerous and thoroughly investigated groups of binary boride phases, and numerous monographs and reviews have been devoted to their crystal chemistry and physicochemical properties.[1-14]

The analysis of the possible approaches to the description of the electronic structure and properties of compounds of this type will be begun with the Ti–B system.

1. Titanium borides

Numerous studies have been devoted to phase formation in the Ti–B system.[1-3,5,7,9,11-14] It is suggested that not less than five individual phases exist in the Ti–B system.

Most of the investigations of the electronic properties of the boride phases of titanium refer to titanium mono- and di-borides. However, before turning to the consideration of the results, we shall mention the calculations of the perturbations in the electronic states of titanium when boron atoms are introduced into its interstices (the corresponding region in the binary system with a low content of the nonmetal is designated as the α-phase on the phase diagrams).[100]

The LMTO Green function method (LMTO-GF) has been used[100] in the calculation for the Ti–B system, in which the nonmetal atom was placed at the centre of an octahedral interstice of the face-centred cubic structure of titanium. It follows from the analysis of the distribution of the local density of states (LDOS) of boron that the quasi-core B 2*s* functions form a discrete impurity peak near the lower edge of the valence band of the matrix, while the B 2*p* function overlaps the lower part of the valence band of titanium, promoting the formation of Ti–B bonds.

The perturbing effect of the impurity on the electronic states of the matrix (ΔN) has also been considered. It was established that in the region of energies corresponding to the localisation of the impurity states, two positive $\Delta N(E)$ peaks are observed. The first and second peaks correspond respectively to the states of titanium mixing with the 2*s* and 2*p* orbitals of the interstitial atom respectively.[100] In the pre-Fermi region, a characteristic oscillating $\Delta N(E)$ structure is observed, reflecting the redistribution of the high-energy states of the metal atoms in the vicinity of the interstitial element. Negative values of $\Delta N(E)$ correspond to spectral ranges with a lower electron density $N(E)$ than for pure titanium and conversely. We then have $\Delta N(E_F) > 0$, i.e. the doping of titanium with small amounts of added boron leads to some increase in $N(E_F)$ for the alloy primarily owing to the disturbance of the bond system in the ideal crystal. Nonequivalent Ti–B and Ti–Ti bonds are formed in this case in the vicinity of the impurity *p* centre. Concentration of electron density in the region of energies of the B 2*s* and B 2*p* functions corresponds to bonds of the first type, whilst positive pre-Fermi $\Delta N(E)$ maxima correspond to bonds of the second type.

The next step was to investigate the effect of the interstitial elements on the electronic states of titanium atoms in the face-centred cubic structure constituting the first and second coordination spheres of the impurity atoms.[100] The γ-Fe_4N structure was used as a model.

The total and local DOS of the hypothetical Ti_4B are presented in Fig. 7. In contrast to the isolated impurity, the B 2*s* and B 2*p* states now form bands of finite width. It is especially interesting to emphasise that the LDOS for titanium atoms at nonequivalent (relative to the centre of insertion) sites are markedly different. Thus, whereas the titanium atoms in the closest sphere make appreciable contributions to the subbands of the nonmetallic 2*p* states, the extent of such mixing is smaller for the Ti atoms in the next sphere, which indicates the local character of the Ti–B bond. This is also reflected in the charge and energy states of the crystallographically nonequivalent metal atoms.

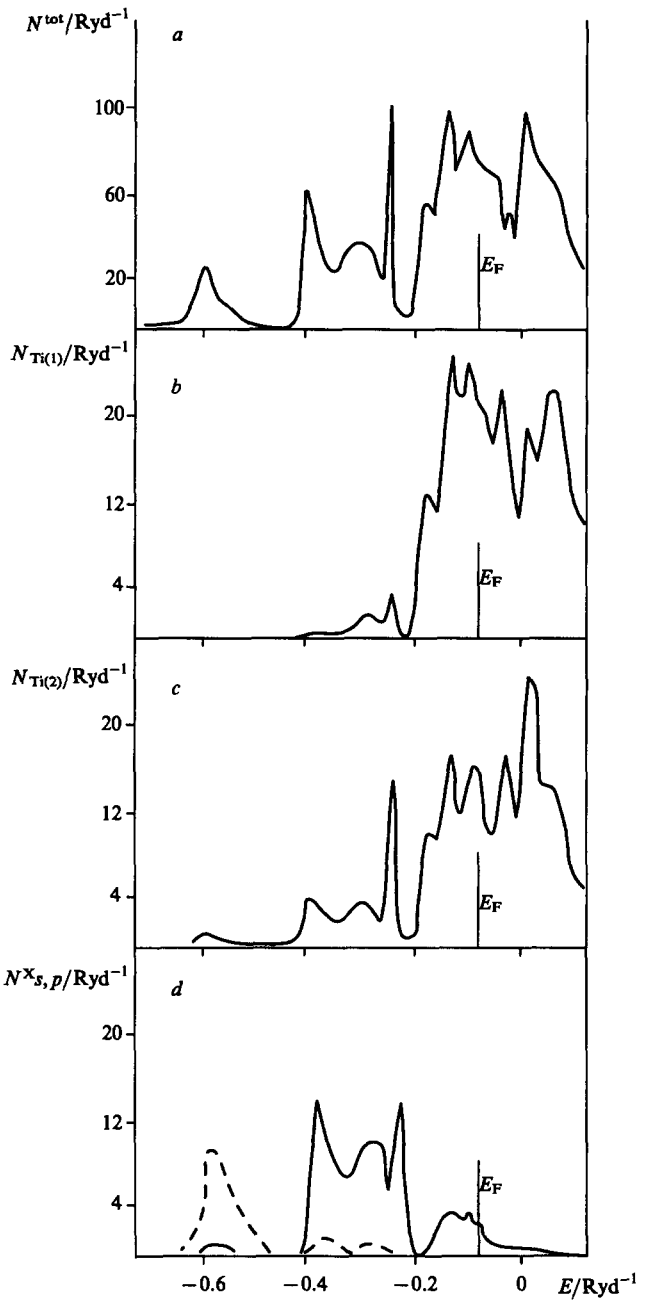

Figure 7. The band structure of Ti_4B (γ-Fe_4N structural type) according to LMTO calculations:[100] (*a*) total density of states; (*b*) and (*c*) LDOS for titanium atoms in the second and first (relative to the nonmetal) spheres; (*d*) densities of B 2*s* (dashed curve) and B 2*p* (continuous curve) states.

Analysis of the valence subbands showed that the maximum contribution to the hybrid Ti_4B band comes from the *d* states of the nearest atoms, i.e. the Ti–B bonds are organised in conformity with the *p*–*d* hybridisation mechanism typical for refractory phases.[101-104] One cannot also neglect the involvement of the *s* and *p* functions of titanium in these interactions. Thus it is mainly the Ti 4*s* functions of the titanium atoms constituting the second metal sphere which enter into the interaction with the nonmetals. In other words, both the energies and the nature of the bonds between the interstitial elements and the titanium atoms in the first and second spheres are different.

These differences in the nature of the Ti–B bonds are reflected in the distribution of the states of the metal band, i.e. lead to the anisotropy of the Ti–Ti bonds.

We may note that the calculated data[100] have been used for a qualitative treatment (in relation to the Ti–B and Ni–B systems) of the phase relations observed on the phase diagrams for metal–boron systems. For this purpose, use was made of the changes in the total energy (ΔE) of the face-centred cubic titanium matrix when a nonmetal atom is introduced into an interstice. These changes were obtained by solving the single-impurity problem by the method proposed by Anisimov et al.[105] It was found that $\Delta E < 0$ for the systems considered, i.e. the introduction of nickel and boron atoms, involved in covalent interactions with the matrix, into the interstices of the face-centred cubic titanium and nickel structures is energetically favourable. However,

$$|\Delta E^{Ti-B}(-0.767\ \text{Ryd})| > |\Delta E^{Ni-B}(-0.673\ \text{Ryd})|\ .$$

In other words, the boron in the octahedral positions in titanium is more strongly bound than in the nickel matrix. This agrees with the known fact that compounds up to the diborides are formed in the Ti–B system, whereas the maximum content of boron in the nickel compound does not exceed Ni/B $\approx$ 1. Naturally, in analysing the results[100] one cannot fail to take into account the direct B–B interactions arising in the boride phases, which should introduce significant corrections to the overall energy relations of the systems under discussion. However, the above data[100] make it possible to gain a general idea about the role of the metal–nonmetal interactions in the boride phases considered.

With increase in boron content, the compound Ti_2B (orthorhombic structure of the Al_2Cu type) was detected on the Ti–B phase diagram. In its structure, all the boron atoms are surrounded by metal atoms.[5,11] The increase in the B/M ratio is accompanied by a further transformation of the electron energy spectra (EES) of the matrix [calculation by the method of augmented spherical waves (ASW)].[106] The B 2*p* states are then mixed in throughout the width of the occupied part of the valence band, which is predominantly of the Ti 3*d*, *s* type. In addition, the valence band contains near its lower edge two subbands of the B 2*s* type separated by a narrow energy gap. The bonds are formed as a result of two types of interactions: Ti–Ti and Ti–B; direct B–B bonds were not detected. The Fermi level is located on the high-energy slope of the intense Ti *d* type DOS peak.

The further genesis of the band structure of titanium boride as the boron content increases will be considered by comparing the EES of the higher borides—TiB and TiB_2.

Titanium monoboride crystallises with a structure of the FeB type.[11] There are also data concerning monoborides crystallising with structures of the NaCl and ZnS types.[7–10] It has likewise been suggested[11] that the cubic monoboride (NaCl structural type) can be obtained either in the form of a high-temperature phase or in the form of a phase stabilised by added carbon.

Calculations for the orthorhombic TiB have been carried out.[107–109] The dispersion of the bands and the total density of states (TDOS) in TiB have been investigated[107] by the nonself-consistent LCAO method in the tight binding approximation.[35,110] A broadening of the dispersion in the k_z direction ($\Gamma-Z$, $T-Y$, $R-S$, $U-X$) compared with k_x and k_y was noted. This should indicate the predominance of the bonding effects along the *c* axis of the crystal, along which the chains of boron atoms are oriented, i.e. a pronounced cohesion anisotropy. The TDOS in TiB comprises (in order of decreasing binding energy) the B 2*s*, B 2*p*, and Ti *d*, *s* states (Fig. 8). The Fermi level is located at the DOS minimum in the vicinity of the intense virtual *d* type resonance. Calculations of the populations of the atomic orbitals made it possible to estimate the charge states of titanium (−1.31 e) and boron (+1.31 e).

The bond indices of various atoms, forming layers in the TiB crystals, have been calculated[107] in the cluster approximation by the method proposed by Bell and Perkins.[111] The calculation was carried out taking into account all the interacting neighbours in accordance with the Born–Carman principle.

The results show that the B–B covalent bonds are most highly populated.[107] In the calculations of the bond indices in other similar

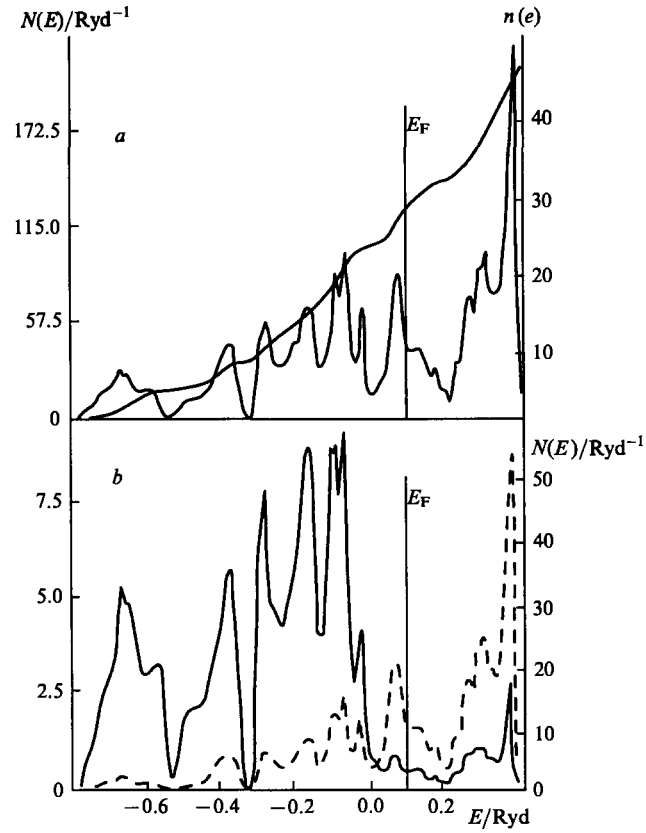

Figure 8. The total (*a*) and local (*b*) densities of states in TiB (FeB structural type). Calculation by the LMTO method.[109]

TiB clusters, where the lowest unoccupied levels lying 0.01 and 0.1 eV above E_F (this simulated the thermal excitation of the boride) were filled, the bond indices of the B–B and Ti–B types remained virtually unchanged, but the index of the Ti–Ti type diminished significantly. Consequently, heating of the specimens affects primarily the bond system in the metal sublattice of the boride.

Calculations for TiB using the more accurate self-consistent augmented spherical waves method[112,113] have been performed.[108] Here a study was made of the structural stability of 3*d* metal monoborides for five possible crystallographic modifications (structures of the FeB, CrB, NaCl, CsCl, and CuAu types). For this purpose, the total crystal lattice energies were calculated for the six cell volumes differing by ±15% from the equilibrium value in the case of all the structures listed above (Fig. 9). Evidently, in conformity with experiment, the orthorhombic modification is energetically most favourable for the boride under discussion, while the CsCl and CuAu structural types are least likely; an intermediate value was obtained for the NaCl type. The equilibrium volume of the TiB unit cell was reasonably well produced and the volume modulus of elasticity was calculated (Table 1).

Table 1. Theoretical (I)[108] and experimental (II)[114–116] unit cell volumes *v*, atomic magnetic moments μ, and volume moduli *b* of titanium monoboride.

Compound	v/Å^3		μ/μ_B		*b*/kbar
	I	II	I	II	
ScB	25.6	—	0	—	3100
TiB	22.6	21.3	0	0	2400
VB	19.5	18.8	0	0	2800
CrB	18.0	17.1	0	0	3400
MnB	17.3	17.2	2.00	1.83	2600
FeB	16.8	16.4	1.25	1.12	2500

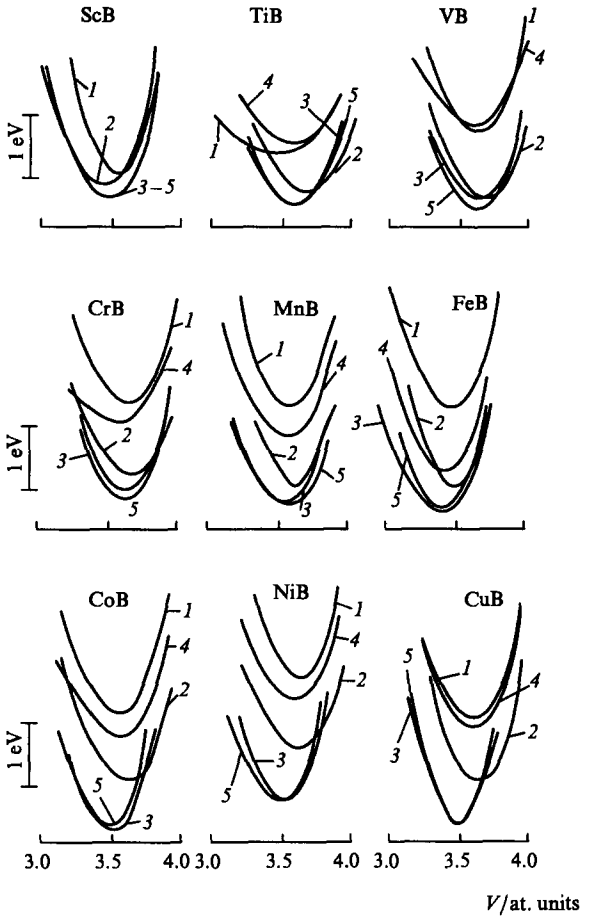

Figure 9. Variation of the total one-electron energy of 3*d* metal borides as a function of the crystal structure of the phase and the volume of the unit cell (calculation by the ASW method).[108] Type of structure: (*1*) CuAu; (*2*) NaCl; (*3*) FeB; (*4*) CsCl; (*5*) CrB.

A somewhat different approach to the discussion of the relative stabilities of the structural modifications of TiB, based on the calculations of the band spectrum of the crystals, has been used in a study[109] where the calculation for TiB with structures of the NaCl and FeB types was carried out by the LMTO method in the atomic spheres approximation in terms of the formal treatment of Sabiryanov et al.[117]

A multipeak TDOS structure was obtained for the orthorhombic monoboride TiB (FeB structural type) (Fig. 8). Taking into account the decomposition of the TDOS into atomic components, one can segregate arbitrarily two low-energy bands, predominantly of the B *s* and B *p* types, separated by a narrow forbidden gap from the band with an energy lower by approximately −3.14 to −0.1 Ryd than E_F and having a mixed $p-d$ character. The intense resonance of the Ti *d* and Ti *s* states in the vicinity of the Fermi level is also noteworthy. A significant difference between the results of the calculation by the self-consistent LMTO method[109] and the data of Armstrong and Perkins[107] concerns the position of the lowest unoccupied *d* band, which is separated from E_F by a deep DOS minimum according to Sabiryanov and Ivanovskii[109] (Fig. 8).

The DOS of the cubic monoboride (NaCl structural type)[117-119] differs significantly from that examined above for the orthorhombic TiB (FeB type). It has a two-band form[101-104] characteristic of NaCl-like phases (carbides, nitrides, etc.) with a distinct separation of the bands of the B 2*s* and B 2*p* states. Adjustment for self-consistency[119] then leads to the appearance of a forbidden gap between the bands, whereas in the absence of such adjustment their overlap is observed.[118]

We shall now analyse the energy relations of the paired bonds (E_b) in TiB (with structures of the FeB and NaCl type) using the method described by Sabiryanov et al.[117] The energies E_b for the orthorhombic borides are listed in Table 2. Evidently the interactions between boron atoms located in the closest layers of the crystal make the greatest contribution to the energy of the covalent bonds. This result differs fundamentally from the conclusions reached by Armstrong and Perkins,[107] who postulate that the interaction between boron atoms located in one layer predominates. Evidently, the analysis of the cohesive properties of crystals, based solely on the calculations of the parameters of the overlap of wave functions,[107] may not be always correct.

Table 2. Pair energies of the covalent bond in titanium borides.[102]

Pair	Energy of covalent bond/mRyd	Pair	Energy of covalent bond/mRyd
TiB (NaCl)		**TiB (FeB)**	
Ti(1)–Ti(1)[a]	−56.16	Ti(3)–Ti(2)	−33.18
Ti(1)–B(2)	−674.04	Ti(3)–Ti(3)[a]	−15.06
B(2)–B(2)[a]	8.12	Ti(3)–Ti(3)[b]	−98.92
		Ti(3)–Ti(1)	−210.14
TiB_2		B(7)–Ti(1)	−341.74
Ti(1)–B(2)	−350.40	B(7)–Ti(2)	−246.22
Ti(1)–Ti(1)[a]	−21.14	B(7)–Ti(4)[a]	−48.70
Ti(1)–Ti(1)[b]	−95.02	B(7)–Ti(3)	−212.00
B(2)–B(3)	−975.42	B(7)–B(8)	−705.40

[a] Atom from the cell displaced by unit translation vector along the *a* axis.
[b] Atom from the cell displaced by unit translation vector along the *c* axis.

In conclusion, we may note that the total covalent interaction energy is 1887.9 mRyd for the cubic boride and 1907.1 mRyd for the orthorhombic boride,[109] which indicates unambiguously the greater stability of the orthorhombic phase and is fully consistent with the conclusions reached by Mohn and Pettifor.[108]

Proceeding now to the consideration of the energy spectra of the higher titanium boride TiB_2 (AlB_2 structural type), we may note the calculation for the diboride[120] carried out by the LCAO cluster method in the tight binding approximation[18] as one of the first approximate calculations. The calculations were performed for a lattice fragment (with D_{3h} symmetry) taking into account the fourth- and fifth-order neighbours in terms of a basis set comprising the B *s*, *p* and Ti *s*, *p*, *d* orbitals. The resolution of the resulting molecular orbitals into atomic contributions makes it possible to estimate the width of the TiB_2 valence band (~13.56 eV), the lower edge of which is made up mainly of the *s* and *p* states of boron with progressively increasing contributions by the Ti *s* orbital as the energy of the molecular level decreases. Analysis of the parameters of the electronic structure of TiB_2, calculated by Samsonov et al.,[120] indicates the Ti → B charge transfer as additional p_x states of boron are filled. The latter form B–B bonds both within planes (π-bonds) and between layers (σ-bonds), the maximum filling of the p_x states (in the TiB_2–VB_2–CrB_2 series) being responsible, according to Samsonov et al.,[120] for the extrema in the melting point, the coefficient of thermal expansion, the microhardness, and the phonon component of the thermal conductivity.

Band calculations for TiB_2 have been carried out by the LCAO method[26] in terms of Hückel's formal scheme,[121] the augmented spherical wave method,[37] and the LMTO method.[109,122] The electron energy spectrum of the diborides has been investigated by spectroscopic methods.[42-46] The $E(\vec{k})$ dispersion relations for TiB_2 have a number of characteristic features compared with the monoborides (Fig. 10). There is no forbidden gap between B 2*s* and the hybrid B 2*s*, B 2*p*, and Ti *d*, *s* bands and there are random degeneracy points in the vicinity of E_F in the $\Gamma-K$, $K-M$, and

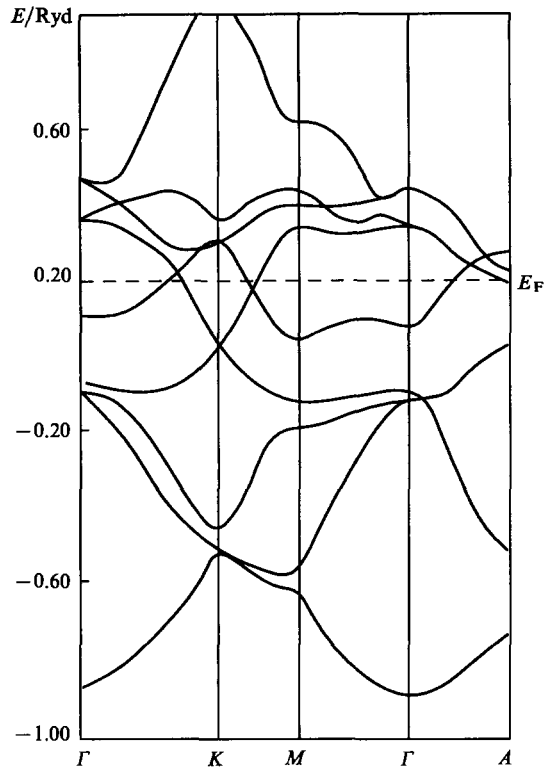

Figure 10. The band structure of TiB_2.[109]

$\Gamma-A$ directions. Three principal subbands, made up of the B 2*s* state, the B 2*s*, 2*p* and Ti *d*, *s* states, and the Ti *d*, *s* states respectively, can be differentiated in the TiB_2 valence band. The Fermi level is located in a deep DOS minimum separating the valence and conduction bands, which agrees well with the results of X-ray emission analysis.[41]

Analysis of the energy relations of the paired bonds (Table 2) shows that the interaction between the boron atoms located in one plane (network) is most significant whereas bonds between networks were not detected. The next in magnitude is a type Ti–B interaction, the Ti–Ti bond energy being an order of magnitude smaller. The results of calculations of the partial energies of the pair interactions proved somewhat unexpected.[109] According to these calculations, the Ti 4*p*–B 2*p* (72 mRyd) and Ti 4*p*–B 3*s* (66 mRyd) bond energies are comparable to the Ti 3*d*–B 2*p* (92 mRyd) bond energy.

Estimates of the charge polarisation,[120,122] indicating a displacement of the electron density to the nonmetal atoms, are consistent with experimental X-ray diffraction data.[123]

The possibility of the appearance of high-temperature superconductivity in layered titanium borides has been examined[124] on the basis of the generalised Hubbard–Emery model[125,126] (taking into account the integrals of the jumps between nearest neighbours). The presence in such borides of separated $d_{xz,yz}$ states, tunnelling through boron ions in the degenerate $p_{x,y}$ states, has been postulated. Calculations of the amplitude of the kinematic interaction (by Dyson's method) taking into account the possible filling of the bands for the hexagonal TiB_x phases showed that superconductivity can occur in the composition range $TiB_{26/17}$–TiB_2 (Fig. 11). The conclusions reached by Zaitsev[124] agree qualitatively with the results of other studies,[127,128] in which the possibility of superconductivity in the $TiB_{1.5-1.6}$ phases and its absence in the TiB_2 and Ti_3B_4 phases was indicated.

The quantitative microscopic description of the parameters of the superconducting state of the borides undoubtedly requires special consideration.

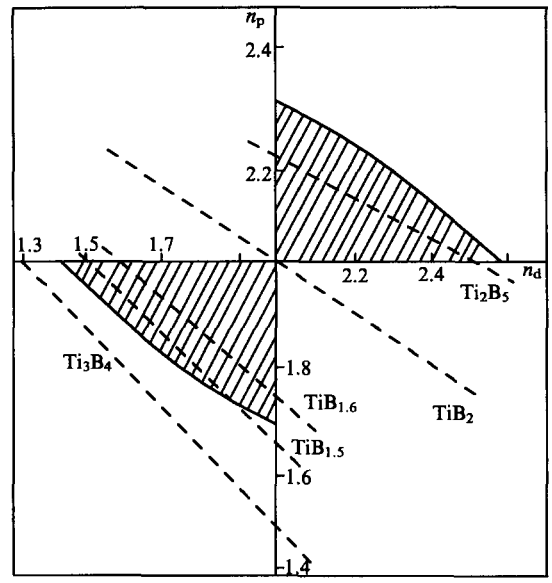

Figure 11. Phase diagram for the compound TiB_x. The regions of possible superconductivity are shown cross-hatched.

2. 3*d* Metal borides

Proceeding now to the discussion of the electronic properties of the borides of other 3*d* metals, we may note that the boride phases formed by specific 3*d* metals have been investigated to significantly different extents. Systematic calculations have been performed only for the hemiborides[106] and monoborides.[108] It follows from them that the dispersion relations and the energy distributions for these phases are similar to those for Ti_2B and TiB (see above), provided that account has been taken of the increase in the filling of the *d* bands as a function of the concentration of the valence electrons (CVE) and of the consistent low-energy shift of the metallic subbands with increase in the atomic number of the transition metal along the Period.

Most studies carried out hitherto have been devoted to the description of the characteristic features of the electronic structures of iron and nickel borides. We shall consider in greater detail their principal results.

The hemiboride Fe_2B and the monoboride FeB have been differentiated in the Fe–B system as equilibrium phases.[1,2,9,11]

The hemiboride has a body-centred tetragonal structure of the Al_2Cu type ($a = b = 4.249$ Å, $c = 5.110$ Å, space group *I4/mcm*), where the boron atoms are located between layers of iron atoms.[11] Iron monoboride crystallises with formation of an orthorhombic structure in which there are four molecules in the unit cell.[1]

The spectroscopic properties of iron borides have been investigated.[43–45,54] The results of numerical quantum-chemical calculations for Fe_2B and FeB have been published.[106,108,129–131]

One of the most complete calculations of the electron energy spectra of Fe_2B has been carried out[131] by the linearised APW-(LAPW) method, in which the energies of the core electrons were calculated in accordance with the full relativistic Dirac–Slater scheme. A semirelativistic approach, taking into account the contributions to the Dirac equation of the Darvin and mass–velocity terms, was used to calculate the energy of the valence electrons. In the solution, account was taken of plane waves (~270) with energies of up to 6.15 Ryd and angular momenta $l \leqslant 8$. Adjustment for self-consistency (with respect to energies) was carried out until the attainment of the condition $\Delta E \leqslant 4$ mRyd.

Analysis of the dispersion curves and of the total and partial densities of states in Fe_2B shows that the bands due to the B 2*s* and B 2*p* states lie below the partially filled Fe 2*s* states. Two lowest bands are made up of 2*s* states of two boron atoms in a unit cell.

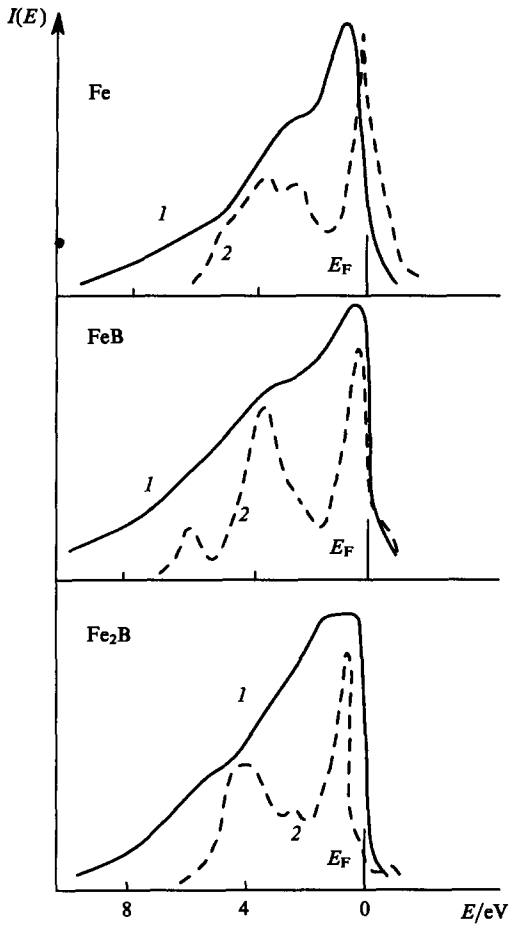

Figure 12. Fe 3*d* electron spectra (curves *1*) and densities of Fe 3*d* states (curves *2*) in Fe, Fe_2B, and FeB.

The degenerate B *p* states are located in the range −0.6 to 0.2 Ryd. An appreciable superposition of the iron and boron states occurs higher along the energy scale. Finally, the highest energy peak reflects the concentration of the bonding Fe 3*d* orbitals, while a further two resonances, corresponding to the nonbonding Fe 3*d* states, are observed in the immediate vicinity of E_F.

Comparison of the DOS and the photoelectron spectra of Fe_2B (Fig. 12) shows that they are acceptably consistent with one another.[131] Evidently the Fermi level coincides with the local Fe 3*d* resonance band, where the DOS (calculated per iron atom) reaches ~1 Ryd^{-1}. If account is taken of the fact that the Stoner parameter *I* (for pure iron) is ~0.92, it becomes evident[131] that, since $IN(E_F) \gg 1$, the manifestation of ferromagnetic properties is to be expected for Fe_2B. Unfortunately the calculations[131] were performed solely in the spin-limited variant, which made it impossible for the authors to estimate the atomic magnetic moments.

Table 3. Distribution of valence electrons among the MT spheres of Fe_2B and FeB (calculated by the LAPW method).[131]

Compound	Type of sphere	Number of electrons		
		s	*p*	*d*
Fe_2B	Fe	0.3205	0.3907	6.0726
	B	0.3654	0.6329	0.0161
FeB	Fe	0.2973	0.4027	6.1631
	B	0.3667	0.6785	0.0171

Analysis of the interatomic bonds in Fe_2B, based on the calculation of the distribution of states in the MT spheres (Table 3) and charge density maps [in the (120) plane] for the boride leads to the conclusion that there is significant B 2*p*–Fe 3*d* hybridisation between the boron atoms and the eight nearest iron atoms. Thus the charge density contours indicate the concentration of charge density along the B–Fe line and also between the nonmetallic centres, which is evidence for the existence of direct B–B bonds.

We may also note that charge transfer between the iron atoms in the hemiboride was not observed.[131] The formation of direct covalent Fe–B and B–B bonds enhances the cohesive properties of Fe_2B compared with Fe.[131]

Direct calculations of the Fe_2B core orbital energies (Table 4) and of electron densities on the iron nuclei, which have been used to calculate the isomeric shifts (measured by Mössbauer spectroscopy), are of interest.

The spin-labelled LAPW calculation for FeB has been performed by the method described above. The boron 2*s* states are concentrated in the vicinity of the bottom of the valence band. The higher-energy *A* and *B* maxima correspond to the hybridised Fe 3*d*–B 2*s* states, whereas in the vicinity of the Fermi level predominantly the Fe 3*d* functions make the main contribution to the DOS (Fig. 13). Comparison of the results of the calculation with emission spectroscopic data[61–63] shows that they are in agreement.

The formation of covalent bonds (as a result of *sp*–*sp* hybridisation) between boron atoms constituting the linear chains is characteristic of iron monoboride as well as Fe_2B. Charge transfer between the iron and boron atoms in FeB has not been observed (Table 3). It is seen from the data presented in Table 4 that the calculation in the study of Joyner et al.[131] correctly reproduced the sequence of the energies of the core levels of FeB, which are somewhat displaced in the direction towards E_F relative to the experimental results.[62,63] We may note that, following the transition $Fe_2B \rightarrow FeB$, the energy relations for these levels remains virtually unchanged (within the limits of ±0.1 eV), which is also consistent with experiment. The Fe_2B and FeB valence band schemes are presented in Fig. 14.

Table 4. The energies (Ryd) of the core levels of Fe_2B and FeB.

Compound	Fe 2*s*[a]	Fe $2p_{1/2}$	Fe $2p_{3/2}$	Fe 3*s*	Fe $3p_{1/2}$	Fe $3p_{1/2}$	B 1*s*
Calculated data[131]

[a] The energies are quoted relative to the Fermi level.

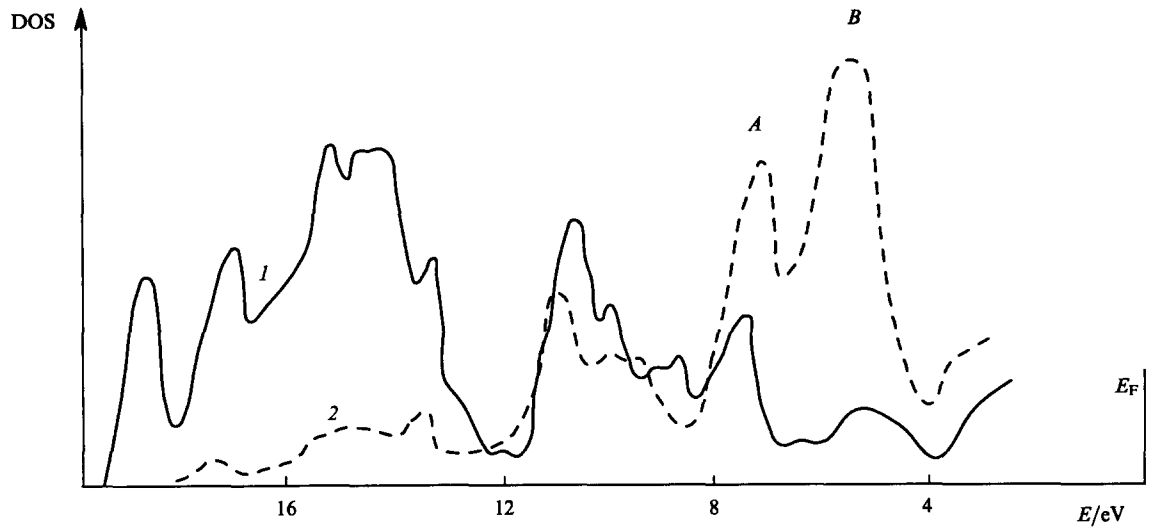

Figure 13. The local densities of B 2*s* (curve *1*) and B 2*p* (curve *2*) states in FeB.[131]

The energy structure of nickel monoboride (type CrB structure)[11] has been calculated[106] by the ASW method (Fig. 15). The relative positions of the total and local DOS make it possible to differentiate the sections of the electronic state spectrum corresponding to the *p*–*p* bonds in the chains of metalloid atoms (peak *A*), to the Ni–B interactions (peaks *B* and *B'*), and to nonbonding *d*–*d* states (peak *C*). The calculated value of the volume modulus [of elasticity] and of the unit cell volume are presented in Table 2.

The value of $N(E_F)$ for crystalline NiB is not quoted in Mohn's study,[106] although it is seen from Fig. 15 that it is insignificant and is much smaller than for manganese and iron monoborides. Measurements of magnetic susceptibility made it possible to assign NiB to the class of weak paramagnetic materials and to estimate $N(E_F) \approx 0.18$ state eV^{-1} $atom^{-1}$,[132,133] in which the contributions of the *s* and *p* states predominate.

The parametrised LCAO method with the Slater–Coster (SC) tight binding approximation has been used[134] in calculations for the lowest nickel boride Ni_3B (Fe_3C structural type).

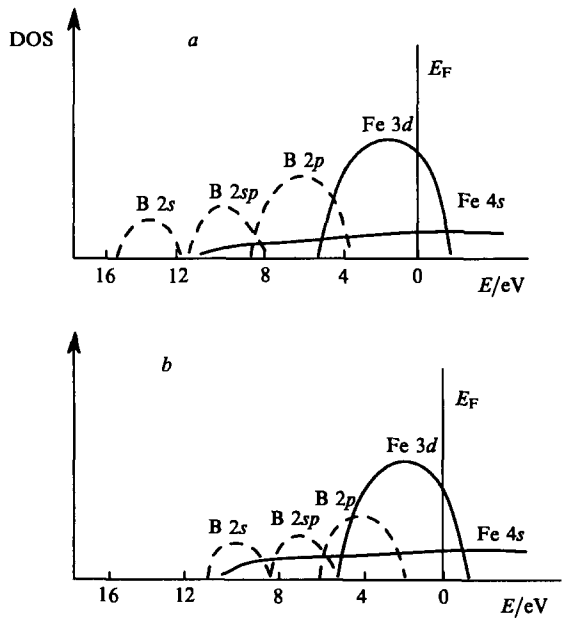

Figure 14. Schematic illustrations of the structures of the valence bands of FeB (*a*) and Fe_2B (*b*).

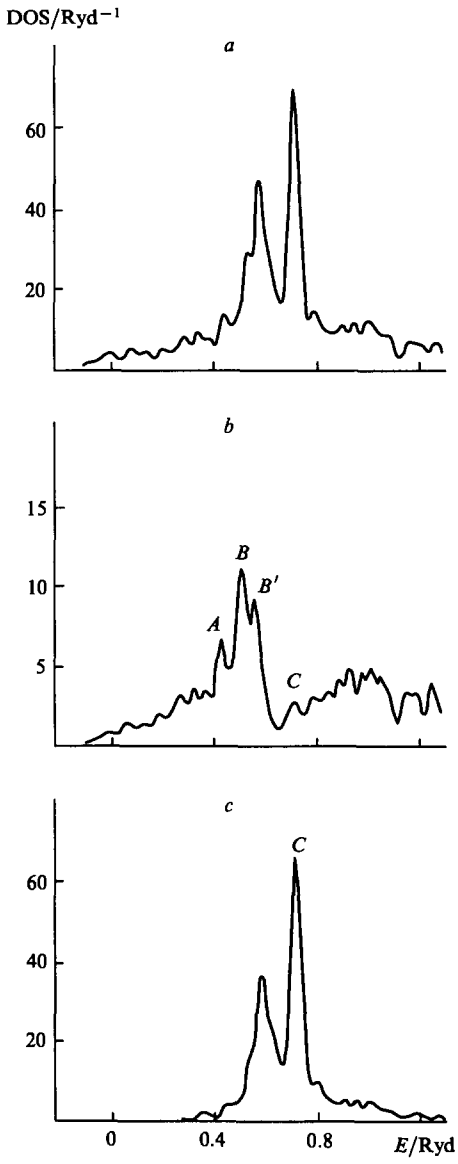

Figure 15. The total (*a*) and partial densities of B 2*p* (*b*) and Ni 3*d* (*c*) states in NiB.

The *B* 2*s*, B 2*p*, and Ni 3*d* functions were included in the basis set and account was taken of the interaction of only the nearest neighbours. The SC parameters for the Ni–Ni bond were taken from calculations performed for metallic nickel,[135,136] while the parameters of the B–B bond were obtained by extrapolating the SC parameters for carbon.[134]

The energy spectrum of the valence electrons of Ni_3B is typical of binary borides and contains two lowest bands (E = 0.0315 and 0.0607 Ryd) made up of B 2*s* states. The following twelve bands (0.433–0.569 Ryd) reflect the hybrid Ni 3*d*–B 2*p* states, the upper band having predominantly the *d* character. The higher energy free bands ($E \geqslant 1.135$ Ryd) also have a mixed B 2*p*–Ni *d*, *s* character.

The band structure in the vicinity of E_F makes it possible to assign Ni_3B to the class of paramagnetic materials, which is consistent with the available experimental data.[138,139]

3. 4*d* Metal borides

Proceeding now to the discussion of 4*d* metal borides, we may note that the energy structure of these compounds has been investigated in much less detail than that of the 3*d* analogues. Zirconium diboride, which has a series of valuable physicochemical properties, namely a high melting point, high electrical and thermal conductivities, and a high hardness, has attracted most attention hitherto.[1–4,8–11] This makes it possible to employ it as a cathodic material, as an abrasive, and as a component of heat-resistant alloys, composite materials, etc.

Nonself-consistent calculation for ZrB_2 by the APW method using the exchange potentials specified by Slater and Kohn-Shem[140] showed that the density of states in ZrB_2 is defined by three characteristic maxima. The first is linked genetically to the bands of the B 2*s* states, while the next two correspond to the 2*p* states of the nonmetal.

The ZrB_2 band structure has been investigated[141] by the self-consistent Korringa–Kohn–Rostoker (KKR) method in terms of the MT spheres approximation. The initial potential was determined by the Mattheiss method[142] with the initial atomic configurations Zr $4d^{2.5}5s^{1.5}$ and B $2s^22p^1$. The exchange-correlation parameters α were taken from Schwarz,[143] whilst the remaining parameters were taken from Ham and Segal[144] and Segal.[145] Adjustment for self-consistency proved most critical in relation to the energies of a series of virtual DOS peaks and the distribution of the Zr *d* electrons. Their number in the MT sphere of the metal (compared with the nonself-consistent calculation) increased by ~0.667 e.

The dispersion $E(k)$ proved extremely complex, which hindered a clear interpretation of the nature of the interatomic bonding. In describing the structure of the energy bands, Johnson et al.[141] confine themselves to only several preliminary remarks. In particular, it is noted that the lowest bands (T_1, T_4, Z_1, Z_4) resemble the sp^2 σ-bonding states in graphite[146] and can be made up of the bonding states of boron (s, p_x, p_y). Nevertheless, one cannot fail to take into account the admixture of metal functions in this region.

By analogy with 'two-dimensional' graphite, it is suggested that the band intersecting the Fermi level (T_1) is associated with the π band of boron, while the lowest unoccupied Σ_3 and all the s_4 bands are made up of the antibonding B π states significantly hybridised with the Zr *d* orbitals. A detailed analysis of the remaining states has been carried out by Johnson et al.,[141] who examined also the principal differences between the energy structure of ZrB_2 and the intercalated layered phases of the KC_8 and LiC_8 types.[147,148] They also analysed the composition of the orbitals forming the pre-Fermi region — the predominance of the Zr *d* states was noted.

The results of the calculation[141] were also used for the theoretical interpretation of the optical properties of zirconium diboride. Fig. 16 presents the imaginary part of the relative permittivity of the ZrB_2 film[149] and the calculated curve (calculated on the hypothesis of constant matrix elements).

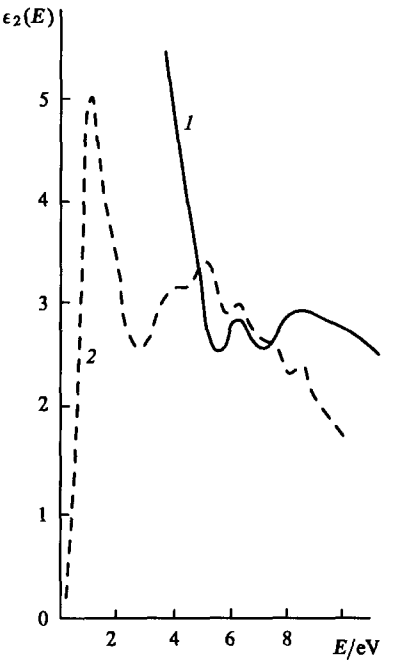

Figure 16. The energy dependence of the dielectric function for ZrB_2:[141] (*1*) experiment; (*2*) calculation.

Evidently, within the framework of the approximations adopted, the most reasonable description of the relative permittivity is attained in the range 6–7 eV. Its variation in the given energy range may be correlated with the transitions between sets of one-electron band states located directly above and below the Fermi level.

The melting point of ZrB_2 has been estimated[141] (from the Lindemann equation).[150] It was noted that the high melting point $T_m \approx 3000$ °C is due primarily to the significant covalent Zr–B interactions.

A fairly good agreement has also been observed between the quantity $N(E_F) = 0.20$, calculated using the low-temperature heat capacity γ data, and the values obtained in calculations:[141] 0.31 eV (nonself-consistent calculation) and 0.26 eV (self-consistent calculation) per unit cell. In conclusion, we may note that the results of the above study[141] have also been used for the qualitative interpretation of the X-ray electron spectra, the Hall effect, the conductivity, and the ^{11}B NMR spectra of the diboride. As regards the problem of charge transfer in ZrB_2, the data obtained permit the claim that there is partial charge polarisation in the crystal in the B → Zr direction.

The remaining 4*d* metal borides have been investigated to a much lesser extent or not at all. Among the available results, we may note the LMTO calculations for the hypo-thetical cubic ZrB,[118,119] in relation to which the problem of the effect of point defects — zirconium and boron vacan-cies — on the spectrum of the monoboride (calculations by the LMTO-GF method) was considered. The marked *s*-type resonance in the region of the minimum in the DOS for the matrix between the *p*, *d* and *d*-like bands of two additional low-energy peaks (in the region of the *s* and *p*–*d* bands of the boride) was established on the LDOS distribution curve of the B defect.[151] Their appearance may be accounted for (by analogy with the similar effects in non-stoichiometric carbides and nitrides)[103] by the increase in the energy of a series of Zr 4*d* states (on dissociation of some of the Zr–B bonds) with appearance of 'lateral' Zr–Zr interactions, which is manifested in the ZrB_x spectrum by the 'vacancy' resonances already mentioned.

The behaviour of $\Delta N(E)$ (the change in the electronic states of the matrix under the influence of vacancies) (Fig. 17) reflects the electronic processes accompanying the removal of a boron atom:

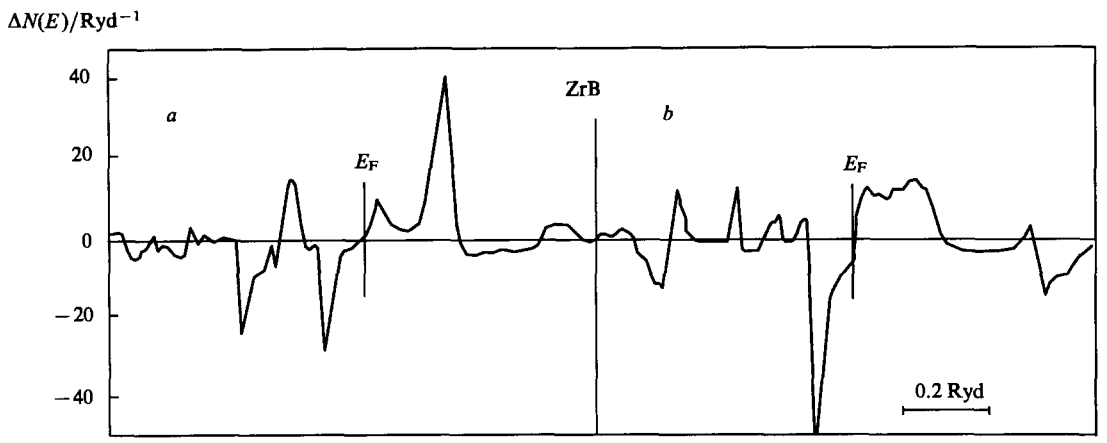

Figure 17. Variation of the density of states in ZrB following the introduction of B (*a*) and Zr (*b*) vacancies.[151]

negative values of $\Delta N(E)$ predominate in the region of the $p-d$ band of the valence band. In other words, the overall DOS of the nonmetallic band of the nonmetal-deficient phase decreases both as a result of the subtraction of the p states of the boron atoms removed and as a result of the transition of some of the d states of the metal to a higher-energy state. This is indicated by the positive $\Delta N(E)$ resonances in the pre-Fermi region (the region of the Zr–Zr bonds).

The nature of the states of the vacancies in the metal sublattice proved to be generally similar.[151] The 'vacancy peaks' are in this case caused by the subtraction of some of the B s,p states ('ruptured B–Zr bonds'), by the increase in their energy, and by a transition to a nonbonding state. The concentration of additional electron density is observed in this range (near E_F).

Estimates of the change in the one-electron energy of the system ΔE in the presence of boron of zirconium vacancies (by the method developed in the study of Ivanovskii et al.[103]) showed that $\Delta E(\text{Zr}) = 0.459$ Ryd and $\Delta E(\text{B}) = 0.508$ Ryd,[131] i.e. $\Delta E(\text{Zr}) < \Delta E(\text{B})$, which reflects the specific features of the bonding in borides. Indeed, the formation of Zr vacancies requires the rupture of only six nearest Zr–B bonds, whereas the formation of boron vacancies presupposes the dissociation of a further twelve B–B bonds. This is the reason why the formation of metallic defects is relatively favoured on energy grounds and in the general case ensures the possibility of the existence in the system of boron-rich phases (up to dodecaborides).[11]

With increase in the atomic number of the 4*d* metal, the ratio $x = \text{B/M}$ diminishes sharply and does not exceed $x = 1/3$ in the case of palladium for example. This fact can be qualitatively attributed to the destabilisation of the structures of the higher borides of the metals at the end of the 4*d* series, while the increase in the CVE leads to a progressive filling of the band of the antibonding s and d functions of the metal. This can be clearly traced by comparing the ZrB_2 (see above) and TcB_2 band structures.[152]

The energy structure of the hexagonal TcB_2 (space group $P4/mnc$, $a = 2.892$ Å and $c = 7.453$ Å)[153,154] has been calculated[152] in terms of the approximate Hoffmann scheme[155] and a basis set comprising Bloch functions including the B 2*s*, 2*p* and Tc 4*d*, 5*s*, 5*p* orbitals. The number of unit cells for which account was taken of the interaction with the 'central' cell was 2024.

In the analysis of this dispersion of the TcB_2 bands along certain symmetrical directions of the Brillouin band, the compact group of bands, made up of Tc 4*d* states, in the range −5 to 10 eV is striking. According to Armstrong,[152] this determines the conducting properties of the phase. At the same time the $k_{x,y}$ components of the wave vectors form fairly broad (in terms of energy) $\Gamma-M$, $\Gamma-K$, $A-H$, and $A-L$ bands.

The Fermi level has an energy of about −7.5 eV and is located in the region of *d* resonance. The most distinct pre-Fermi valence band maxima with energies of −8.0, −8.6, and −10.3 eV are also generated by the *d* functions of the metal. Charge transfer takes place in the Tc → B direction and reaches 0.87 e per boron atom, the electronic configuration of boron assuming the form $s^{1.30}p_\sigma^{1.61}p_\pi^{0.96}$.

The nature of the Tc–B bonds may be inferred from the composition of the occupied levels, the decomposition of which into orbital contributions has been examined for the point k with the coordinates 1/3, 3/9, and 1/4 (Table 5). Thus, whereas the four lowest levels mainly include the boron functions and

Table 5. The Mulliken populations (in %) of the occupied TcB levels.[152]

Level	E/eV	B s	B p_σ	B p_π	Tc s	Tc p	Tc d_σ	Tc d_π
1	−18.68	54	39	3	1	0	1	2
2	−18.58	57	34	0	4	0	2	2
3	−14.20	26	62	0	2	0	8	2
4	−13.84	21	62	2	1	0	2	12
5	−12.16	18	7	40	8	0	23	4
6	−11.70	5	60	3	0	0	14	19
7	−11.50	2	65	10	3	0	17	14
8	−10.65	0	15	40	1	0	43	2
9	−10.32	1	10	35	2	0	8	44
10	−9.85	0	8	26	0	0	10	56
11	−8.63	0	5	4	0	1	38	51
12	−8.30	1	3	6	2	5	80	2
13	−7.61	0	14	2	2	1	49	32

the three highest the technetium functions, the middle (5–10) are of a mixed type and indicate the hybridisation of the corresponding states.

Finally a qualitative conclusion about the energy of the Tc–B bonds can be reached by comparing the total energies of the boride and of the initial components.[152] Judging from the data presented, the stabilising role in the formation of technetium diborides can be attributed precisely to the bonds noted above.

4. 5*d* Metal borides

The available information about the electronic structure of binary 5*d* metal borides is extremely limited. A LMTO calculation for the hypothetical cubic HfB (NaCl structural type) has been carried out;[119] the charges on the MT spheres were analysed for a qualitative description of the nature of the interatomic bonds.

The bands of the hexagonal ReB_2 (a = 2.900 Å, c = 7.478 Å) have been calculated[152] by Hoffman's method.[155] The $E(k)$ relation is on the whole a repetition of that for the isostructural and isoelectronic TcB_2. Fundamental differences are not observed also for the TDOS. One may note only a closer disposition in terms of energy of the principal Re 5*d*-like maxima (−9.0, −9.8, and −10.3 eV), a smaller charge transfer from Re to B (0.44 e), and some differences between the atomic configurations of boron (B $s^{1.26}p_\sigma^{1.38}p_\pi^{0.79}$).

For the analysis of the role of individual components (B and Re) in the formation of the overall band structure, calculations were performed for the hypothetical 'Re' and 'B_2' crystals with the ReB_2 structure.[152] A system of bands, concentrated in a narrow energy range, was obtained for 'Re'. On the other hand, the dispersion of the bands of 'Re' and 'B_2' with the energy structure of the real boride indicates a greater dispersion of the states of the latter, which is associated with the 'inclusion' of the direct Re–B interaction.

The analysis of the composition of the occupied Re_2B levels, carried out[152] by analogy with that described previously, and calculation of the total energy of the boride make it possible to postulate that the Re–B interactions are important in the stabilisation of the ReB_2 lattice.

The data on the electronic structure of osmium and iridium borides are limited at the present time to those of the study of Novikov et al.,[156] in which the Os_3B_{14} fragment was used within the framework of the nonself-consistent X_α-DV method in the calculation for the $OsB_{1.2}$ phase (hexagonal system, WC structural type). A calculation was performed for a cluster of a similar composition in the case of the hypothetical hexagonal iridium boride. It was established that, in contrast to the isostructural molybdenum and tungsten borides in which the M–C bond predominates, the (Os, Ir)–B interaction is antibonding and the interatomic interactions are based on the B–B bonds, the populations of which are smaller for 'IrB' (~9.04) than for 'OsB' (~11.63). The stability of the structures of the borides has been attributed[156] to this fact: in contrast to osmium boride, iridium boride with the WC structure has been obtained only in the form of the high-temperature modification.[9]

IV. Metal–nonmetal–boron ternary systems

Together with binary systems, ternary and more complex compounds and solid solutions constitute an extensive group of boron-containing phases. The crystallographic and certain physicochemical properties of these systems have been investigated in fair detail.[1,2,5–11] However, the general microscopic models of the conditions governing their formation, stability, the nature of chemical bonding, and properties, based on the results of quantum-chemical calculations, are lacking at the present time. The principal results of the studies of the electronic properties of ternary borides will be examined below within the framework of theoretical and experimental approaches.

1. The M–B–C systems

Studies on the interactions of metal borides with carbon demonstrated that continuous solid solutions (SS) are as a rule not formed in the M–B–C systems (where M is a metal).[157–166] The reasons for this are the significant differences between the atomic radii of boron and carbon and also between their energy characteristics.[157,158] Thus the products of the reactions of Group IV and V metals with boron and carbon are as a rule mixtures of boride, carbide, and borocarbide phases. Their structures, compositions, and proportions are determined by many factors (the annealing temperature, the duration of annealing, the pressing conditions, etc.).[162–166]

In the search for materials to be used in the manufacture of instruments and in construction, a study has been made of the Ti–C–B system.[157–166] An appreciable solubility of the diboride in TiC, an increased microhardness of the TiC_x-based phase, and some increase in the lattice parameter of the carbide have been noted for the TiB_2–TiC_x section.[157,158]

The conclusion reached initially[158] that the TiB and TiC_x components are infinitely miscible was not confirmed subsequently in the study of the section of the Ti–C–B phase diagram bounded by the TiB and TiC_x straight lines (x = 0.48–1.00). Three phases were identified in the specimens obtained: TiB_2, TiC_xB_4, and TiB (FeB structural type).

The phase formation process in the TiB–$TiC_{0.93}$ pseudobinary systems in the temperature range 1670–2070 K can be divided into two components according to X-ray diffractometric and scanning electron microscope data. Such subdivision is due to the different nature of the TiC_x interactions with the cubic and orthorhombic modifications of the monoboride.[165,166] The dominant involvement of the orthorhombic TiB in reactions leading to the formation of the higher borides Ti_3B_4 and TiB_2 has been postulated.

The quantum-chemical description of the heterophase systems is an extremely complex problem, which has not so far been solved. Only a few attempts[167–169] at calculations of the energy states of one of the components of the given polycrystalline materials—a borocarbide phase (a solid solution of the MC_xB_{1-x} type)—are known to have been made.

The local perturbation of the electron density of the hypothetical TiB following the introduction of a single carbon atom into the boron sublattice has been examined.[167] This simulated the initial stage in the formation of the $TiB_{1-x}C_x$ solid solution. The calculations were performed by the LMTO–GF method. The results indicate that the valence *s* and *p* functions of the carbon admixture are located in the region of the B 2*s* and Ti *d*,*s*–B 2*p* bands of the boride and the occurrence of the hybrid C–Ti–B interaction in the alloy cannot therefore be ruled out. Estimation of the perturbation of the LDOS of the titanium atoms (by the method described by Anisimov et al.[105]) shows, however, that the most marked effect, occurring when a boron atom is replaced by carbon, is the appearance of localised σ(Ti–C) bonds in the CTi_6 octahedron, as happens in refractory monocarbides.[103]

The converse problem, involving a single boron impurity atom at a C site of $TiC_{1.0}$, has been solved.[168] It is noted that the impurity states form two subbands. The lower subband has a markedly pseudoatomic form and corresponds to the localisation of the B 2*s* functions in the energy range between the C 2*s* and C 2*p*–Ti 3*d* bands. On the other hand, the B 2*p* states form a broad subband which overlaps almost fully the *p*–*d* hybrid band to TiC, indicating the formation of bonds of the Ti–B type in the TiC–B system.

A similar problem for the VC–B system has been solved by the LMTO-GF method.[169] Taking into account the uncertainty in the data concerning the processes involving the formation of the intergrain boundaries in the V–C–B system, the calculation was made for the case where boron substitutes both carbon and metal centres in $VC_{1.0}$. Whereas for the first type of substitution the LDOS of the impurity is similar to that for TiC–B, in the replacement of V by B (the formation of type

BC_6 'microclusters') the valence states of boron shift significantly into the region of lower bond energies, being partly superimposed on the C 2*s* states. Estimates of the change in the overall single-electron energy of the system show that ΔE in the latter is positive (~0.09 Ryd). This can be evidently attributed to the incomplete energy compensation for the 'rupture' of the strong V–C bonds due to the formation of new, weaker B–C bonds. Consequently, according to Sabiryanov,[169] in the solid-phase interaction of VC_x and boron (borides) the formation of borocarbides is less likely than that of vanadium borides.

A cluster analysis of the nature of the bonding in the Ti–C–B system has been carried out,[168] adopting titanium monocarbide as a basis. Its carbon sublattice was doped with boron atoms (the TiC_6Ti_{12}, TiC_5BTi_{12}, $TiC_4B_2Ti_{12}$, and $TiC_3B_3Ti_{12}$ fragments). The calculations were peformed in terms of the extended Hückel method (EHM). It was established that, when a carbon atom is replaced by a boron atom, the system of Ti–X (X = C, B) paired bonds is significantly transformed. Thus, if it is assumed that σ_{2p}(Ti–C) and π_{2p}(Ti–C) participate in the Ti–C interaction, then the Ti–B interaction includes the σ_{2s}(Ti–B), σ_{2p}(Ti–B), and π_{2p}(Ti–B) bonds, the populations of which (estimated in accordance with Mulliken's scheme) are comparable. In addition, the occurrence of a significant B–B interaction was established.

Hence, when account is taken of the known criteria of the formation of homogeneous solid solutions,[169–179] one may conclude that the absence of a continuous series of borocarbide solid solutions is associated with the specific features of the chemical bonds formed in the M–B–C systems apart from the dimensional factors.

Together with the variable-composition M–C–B solid solutions, fairly numerous crystalline *p* and *d* metal borocarbides have now been synthesised and their structures and some of their properties have been determined.[9,11] However, there have been no systematic studies of their microscopic properties and the available literature data refer solely to individual representatives of these compounds.

Table 6. The electron populations of bonds (e) in yttrium borocarbides.

Bond	YC_2	YBC	YB_2C_2	YB_2C	YB_4
Y–Y	0.351	0.165	0.235	0.302	0.121
Y–C	0.254	0.582	0.011	0.053	—
Y–B	—	0.196	0.372	0.400	0.827
C–C	1.785	0.012	1.236	0.012	—
C–B	—	1.339	0.976	1.321	—
B–B	—	1.457	1.245	2.132	2.736

A series of yttrium borocarbide phases, formed in the Y–B–C system and including the compounds YBC, YB_2C_2, and YB_2C, have been investigated[169] within the framework of the extended Hückel method. It was noted that there is a significant superposition of the (B, C) *s,p* and Y *s,p,d* states, the form of the LDOS of the individual centres depending critically on the type of their coordination in the crystal. This situation leads to the appearance of a complex system of interatomic bonds differing greatly in their nature and populations. The results presented in Table 6 show that, whereas the C–C interactions between pairs of nearest carbon atoms predominate in YC_2, in YBC there is competition between the B–B and C–B bonds, the role of the B–B bonds increasing with increase in the B/C ratio, which results in the formation of ordered structural motifs made up of the given atoms. It has been noted[169] that the B–B and B–C bonds arise as a consequence of the hybridisation of the B 2*s*,2*p*–C 2*p* orbitals, while the involvement of the metal atoms is secondary.

The Sc_2BC_2 alloy is yet another representative of borocarbides the electronic structure of which has been calculated within the framework of the extended Hückel and tight binding methods.[170] This phase (space group *I4/mmm*, lattice parameters $a = 3.300$ Å and $c = 10.691$ Å)[171] differs from most of the known lanthanide borocarbides, which have a layered structure,[172] by the fact that it contains in the bulk phase BC_2 groups similar to those present in the boron carbide $B_{13}C_2$.[173]

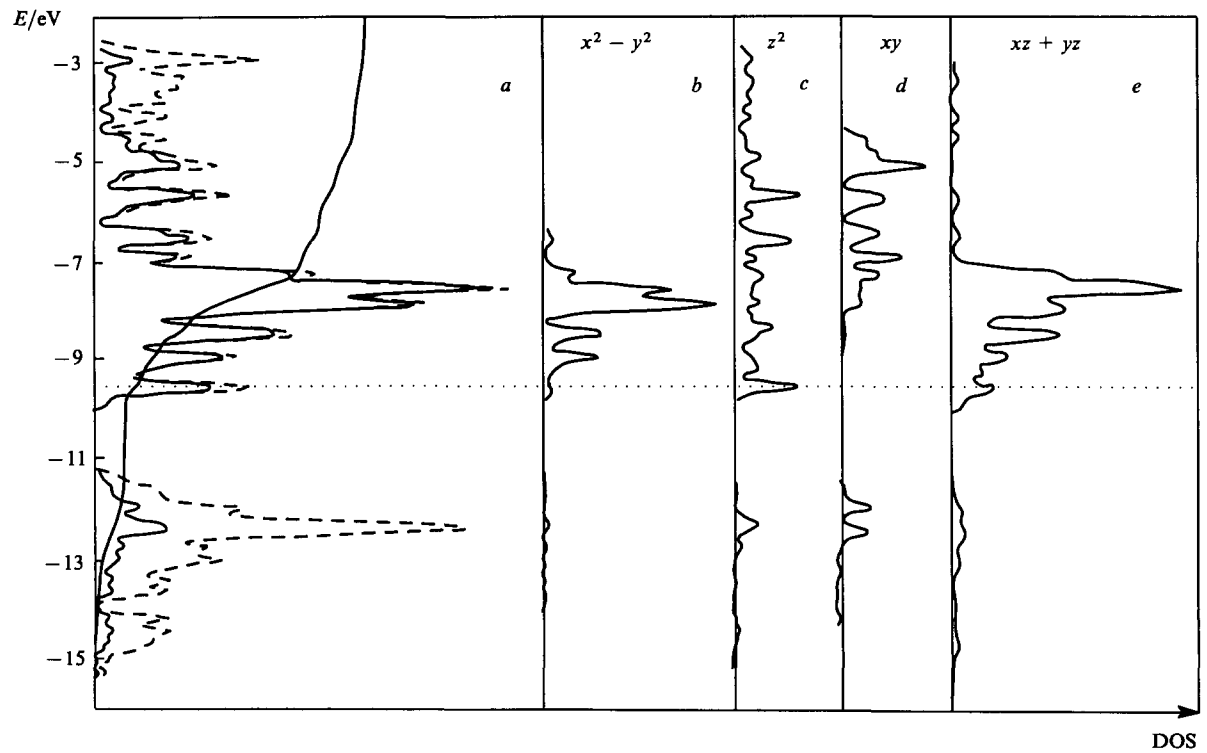

Figure 18. Densities of states in Sc_2BC_2:[170] (*a*) the total density of states of scandium (dashed curve) and the density of Sc 3*d* states (continuous curve); (*b*)–(*e*) partial contributions of the scandium *d* states.

EHM calculations for the BC_2 'molecule' indicate an appreciable separation of the nonbonding π_u- and antibonding π_u^* levels. The molecular charge has been estimated as approximately -5 e, i.e. this borocarbide can be regarded as a crystal containing the BC_2^{5-} anions. Allowance for the contribution by the atomic orbitals of the metal leads to a somewhat smaller overall charge (-2.48 e). The splitting of the electronic levels of the metal atom in the ligand field has been considered in relation to calculations for the $[ScB_5C_{10}]^{22-}$, $[Sc_2B_6C_{12}]^{25-}$, and $[Sc_2B_8C_{16}]^{35-}$ fragments with different configurations of the BC_2 groups.

The energy spectrum of Sc_2BC_2, obtained with the aid of the tight binding method, is presented in Fig. 18 (see previous page). Evidently, the low-energy bands are made up largely of the (B, C) 2*p* functions with an admixture of the Sc 3*d* orbitals and are separated from the nonbonding partly occupied bands by an energy gap. The Fermi level ($E_F \approx -9.5$ eV) is located in the region of the peak corresponding to the Sc 3*d* states, which is the reason for the metallic type of conductivity of the borocarbide.[171]

The energy dispersion of the bands in the pre-Fermi region suggests the anisotropy of the conductivity of Sc_2BC_2 when the Fermi level is intersected by the bands along the $\Sigma(M \rightarrow \Gamma)$ and $\Delta(\Gamma \rightarrow X)$ lines, which corresponds to the [010], [100], and [110] directions in the crystal. These bands are made up to the extent of 80%–100% of the Sc $d_{xz,yz,zz}$ states. Thus conduction is predominantly effected by Sc atoms separated by 3.144 Å distances in the (110) plane.

2. The M–B–N systems

As for the borocarbides, the available information about the phase relations in the M–B–N systems has remained extremely scattered and refers mainly to systems with participation of Group IVA and VA 3*d* and 4*d* metals. The efforts of investigators have been concentrated mainly on two aspects: on the creation of boronitride compositions of the TiB_2–TiN, ZrB_2–ZrN, and similar types[180–182] in order to improve the parameters of the initial phases and on the study of the formation of the boundary of the region of homogeneity in variable-composition boronitride phases.[183–187]

From the standpoint of the electronic theory, the description of the boronitride systems repeats that of borocarbide phases examined above and the difficulties arising are caused by the lack of correct methods permitting theoretical calculations for heterophase systems. The calculations of the energy states in the M–N–B systems carried out hitherto either involve the consideration of the problem of the single boron impurity in the nitride[167,168] or they resort to fragmentary approaches for the description of the transformation of the electronic states at the grain boundaries in composite boronitrides.[187,188]

In the first group of calculations, performed by LMTO-GF method for the TiN : B, ZrN : B, VN : B, and NbN : B impurity (as regards boron) systems, the form of the LDOS in boron was considered as a function of the EES of the matrix.[167,168] As in the case of the boron impurity in the carbides, the LDOS in the boron impurity in the nitrides has a two-peak structure comprising the B 2*s* and B 2*p* states, the degree of localisation of which (taking into account their position relative to the TiC and TiN valence bands) is found to be significantly more marked.

The rearrangement of the charge states and the system of orbital functions arising when a boron atom is incorporated in the cubic titanium nitride have been considered within the framework of the Mulliken–Wolfsberg–Helmholtz (MWH)[186,187] and X_α-DV[168] methods.

We may note that, according to the data of Zainulin et al.[185] the region of the existence of the homogeneous boronitride TiN_zB_y is extremely narrow: $z+y = 0.62-0.94$, $y \leqslant 0.03$. It follows from other data[186,187] that the electron energy spectrum of TiN_zB_y is markedly different from that of TiN. The lower group of orbitals, corresponding to the band of the quasi-core N 2*s* states, becomes narrower. The form of the rearrangement of the principal valence-bonding band is especially interesting. Whereas in TiN this band is made up predominantly of the N 2*p* states, which are significantly hybridised with metallic e_g-like orbitals, in TiN_zB_y an appreciable admixture of the B 2*s* states and a small admixture of B 2*p* states appears in TiN_zB_y in the region of the same energies. In the region of energies close to the edge of the filled part of the spectrum, there is an appreciable admixture of the 2*p* states of boron together with the Ti 3*d* type-t_{2g} atomic orbital.

Consequently, together with the Ti *d*–N 2*p* interaction, the Ti *d*–B 2*s* and Ti *d*–B 2*p* interactions play a significant role in TiN_zB_y. This becomes evident from an analysis of the bond populations and electronic configurations of the fragments for which calculations have been made.[186,187] The charge on the metal atom diminishes when boron atoms are introduced into its closest sphere. This finding is correlated with the results of a study[188] where the chemical shifts of the internal levels of the component atoms of a series of homogeneous TiN_xB_{1-x} solid solutions were investigated by electron microscopy.

Calculations have been made for simple octahedral clusters[186] in the Ti–N–B system for an increasing B/N ratio (the TiN_4B_2–TiN_2B_4 fragments). These groups can arise at the intergrain boundaries in polycrystalline boronitrides. It has been noted[186] that a steady increase in the number of states of the B *s,p* type entails a sharp alteration in the mechanism of interatomic bonding where Ti–B bonds of π_{2p} and σ_{2s} types predominate. Conversely, the Ti–N paired bonds are negligibly weak, which may affect the mutual diffusional mobility of the nitrogen and boron atoms and thus determine the processes involving the mutual dissolution of the boride and nitride phases.

3. The M–B–O system

A series of studies[167–169,187] have been devoted to the possibility of the partial substitution of oxygen atoms by boron atoms (in the TiO, VO, and ZrO structures) and to the formation of ternary solid solutions of the type MB_xO_{1-x}. Calculations for the VO : B system by the LCAO method have indicated, in particular, the appearance of a sharp anisotropy of the V–O and V–B bonds and also of significant B–B interactions, which may lead to the 'clustering' of the boron impurities in the bulk of the oxide.

Calculations by the LMTO method have been used[189] to predict the compositions of the possible stable cubic phases in the Ti–O–B system. The estimated energy of the substitution of B atoms by O atoms as well as the dependence of the total pressure and of the bonding and antibonding pressures on the number of valence electrons (in the range 6.5–9 e) indicate the probable existence of the stable phase $TiB_{0.75}O_{0.25}$.

A series of phases of the M–B–O systems with individual structural types have been examined.[190,191] The electronic spectrum of $Li_2B_4O_7$—a promising material for acousto-electronics—has been calculated.[190] Taking into account the characteristic features of the crystal structure of $Li_2B_4O_7$[192] and on the basis of phonon spectra,[193] a series of structural fragments (BO_3, BO_4, LiO_4, LiO_6) were identified in the crystal and for each of them a secular equation was set up. The effect of environment was taken into account within the framework of the perturbation theory. The interband intervals were corrected on the basis of the maxima in the imaginary component of the relative permittivity.

The band structure of $Li_2B_4O_7$ thus obtained represents in essence a superposition of the electronic states of the structure-forming elements of the phase, included in the consideration and arranged in an energy sequence.[190] It was noted that the covalent bonds in the boron–oxygen groups are the most significant (degree of covalence ~ 0.94, Harrison's data[194]), but the maximum mount of ionic character (~ 0.17) was found in the LiO_{4-6} fragment.

Problems concerning the chemical bonding in $LiBO_2$, which is formed in the Li–B–O system, have been examined[191] with the aid of the X-ray diffraction method and dynamic deformation electron density (DED) maps.[195–197] The crystal structure of

$LiBO_2$ can be represented as an assembly of BO_3 'triangles' making up the chain and oriented in the $(\bar{1}05)$ plane, the lithium atoms being located in their vicinity.[198] There are different B–O distances in the BO_3 groups, varying in the range from 1.324 to 1.409 Å. The differences in the distance from the lithium atom to the oxygen atoms constituting its closest sphere (1.955–2.473 Å) are extremely significant.

The published[191] DED maps indicate the formation of B–O covalent bonds in the BO_3 groups. The estimated amount of ionic character of the bonding indicates the B → O charge transfer. The charges are (assuming +1 for Li) 2.6+ for B, 1.8– for O^1, and 1.9– for O^2. The DED maps for planes incorporating lithium demonstrate only a slight overlap of the cationic and oxygen states. The interaction of lithium with its environment in the metaboride is therefore largely electrostatic.

4. The M–B–P systems

The preparation of the crystalline borophosphide $Fe_3(P_xB_{1-x})$ has been reported.[199] The initial interpretation of its properties was based on a simplified model postulating charge transfer from nonmetal atoms to the iron atom.[200,201]

The ternary $Fe_3B_{0.9}P_{0.1}$ alloy (Fe_3B structural type) has been investigated[202] by photoelectron X-ray spectroscopy (AlK_α radiation, ~0.2 eV resolution) with the aid of the method described by Wertheim and coworkers.[203,204] The binding energies for the Fe 3*s*,3*p*, P 2*p*, and B 1*s* core levels were determined and were found to be similar to those for the pure elements (within the limits of experimental error), which precludes the hypothesis of an ionic model for the given alloy. The X-ray photoelectron spectra of Fe, Fe_3P, and $Fe_3B_{0.9}P_{0.1}$ demonstrate a fairly complex profile of the spectral lines.[202] Taking into account the degrees of photoionisation of states of different symmetry, one may claim that the most intense pre-Fermi maxima correspond to emission from the band of *d* states. The lower energy maxima correspond to states similar to B *s*,*p*. The widths of the valence bands, which are ~17 eV for Fe_3P and ~14 eV for $Fe_3B_{0.9}P_{0.1}$, differ appreciably.

On the basis of calculations,[201] the high-energy maxima were assigned to the *s* states of iron and nonmetals, while the lower-energy peaks reflect the splitting of the *d* functions of the iron atoms in structurally nonequivalent positions and their mixing with the *p*-type subbands of phosphorus and boron. Finally, the greater width of the spectrum at the half maximum level in the case of $Fe_3B_{0.9}P_{0.1}$ (5.1 eV) compared with Fe_3P (4.5 eV) is treated as a consequence of the shorter Fe–B distances and greater hybridisation of their valence orbitals. Hence it follows that the observed change in the magnetic moments and parameters of the hyperfine fields on formation of the ternary iron alloys is associated with the reordering of the orbitals of the iron atoms as a result of interactions with the atoms in the immediate environment and not with electron transfer effects.[198]

V. Metal–metal–boron ternary systems

All the ternary compounds formed in metal–metal–boron systems can be arbitrarily divided into two groups.[11] The first comprises ternary boride phases having individual crystal structures, while the second consists of solid solutions with limited or infinite miscibility on formation of which the substitution of part of the metal atoms of the binary phase by metal atoms of a different kind takes place statistically.

Most of the studies on the electron energy spectra of ternary ordered phases by quantum-chemical methods have been devoted to compounds containing *f* elements. Their consideration is outside the scope of the present review. We shall only mention studies[205–207] in which band calculations were performed for the borides $Y_2Fe_{14}B$ and $Y_2Co_{14}B$. By virtue of their magnetic characteristics, the latter have attracted attention as promising materials for the construction of permanent magnets.[208,209]

Calculations by the LCAO method[205] and in terms of the tight binding model,[206,207] carried out for the above borides, lead to similar electron energy spectra of these compounds: the valence band is made up predominantly of a complex superposition of Fe(Co) states which are significantly different for structurally

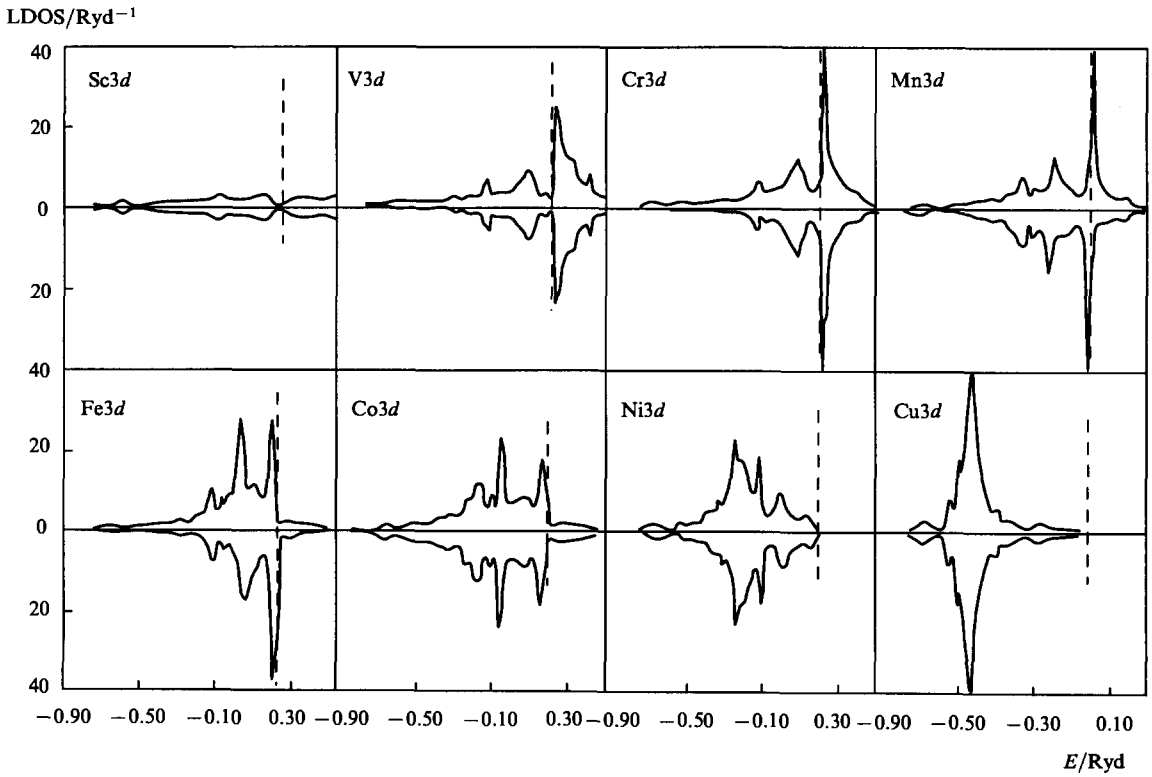

Figure 19. The local densities of states of 3*d* impurities in TiB_2. Spin-polarised calculation by the LMTO-GF method.

nonequivalent centres (six positions) with an admixture of yttrium and boron states. Most attention has been devoted in the above investigations[205-207] to calculations of the magnetic parameters of the phases. It was established that, depending on the type of the immediate environment, the local magnetic moments (LMM) on the iron atoms in $Y_2Fe_{14}B$ can vary appreciably (from 2.11 to 2.74 μ_B); the local magnetism for $Y_2Co_{14}B$ is appreciably weaker — the LMM on the cobalt atoms vary in the range 1.28 to 1.48 μ_B.

The energy states of the 3*d* metal impurities in TiB_2 (these systems can be treated as the starting materials in the formation of $M_xTi_yB_2$ solid solutions) have been investigated[210] by the LMTO-GF method. The local densities of states of the impurity elements make it possible to trace the rules governing their formation throughout the series of 3*d* metals (Fig. 19).

Evidently, the similarity of the orbital energies of the dopand metal atoms at the beginning of the *d* series (Sc, V) to the energies of the states of the titanium atom promotes the establishment of a LDOS similar to that for titanium. The LDOS for the *d* metals at the end of the series assume a significantly different form. With increase in the valence of the impurity (on passing from Cr to Cu), there is a progressive low-energy shift of the occupied states of the dopand atoms with generation of additional (nonbonding) DOS lines in the region of a local minimum in the spectrum of the matrix (between the *s*- and *p*-like bands) and also in the vicinity of the lower edge of the valence band of the diboride. This effect can be traced most distinctly for the LDOS in copper.

The increase in the concentration of the impurity states in the region of the principal bonding bands of TiB_2 indicates an increase in the covalent component of the bonding in the ternary systems. The estimated changes in the total one-electron energy of the matrix following the introduction of the dopands (ΔE) are presented in Fig. 20. Although in terms of the single-site approximation these quantities can reflect only the qualitative behaviour in the series of such systems, we may note that the substitution of Ti atoms by Sc and V atoms leads (as for the *d* metals at the end of the series) to the destabilisation of the system of interatomic bonds in the crystal. Conversely, it follows from the data obtained that doping of the diborides with admixtures of Cr, Mn, Fe, and Co tends to decrease the one-electron energy. This can indicate stronger binding of the additives in the bulk of TiB_2 compared with the centre being substituted.

The transformation of the high-energy *d* band of the impurity (which is unoccupied for Sc and V) is of interest. With increase in the atomic number of the impurity element, the energy of the *d* band falls sharply and, for example, in the case of chromium, is located in the immediate vicinity of E_F, being subsequently partly (Mn, Fe) or completely (Co, Cu) filled. Such behaviour of the LDOS leads to the appearance of spin polarisation with splitting of the bands corresponding to the opposite spin orientation and hence the formation of appreciable LMM on centres comprising *d* metals in the middle of the series (Fig. 20). This finding can be accounted for on the basis of Stoner's criteria, according to which one of the conditions for the formation of the LMM in the crystal is a high DOS in the vicinity of E_F, which is in fact observed for chromium, manganese, and iron. For cobalt, nickel, and copper, these states are fully occupied and there are therefore no magnetic moments on the given atoms.

In conclusion, we may note that the results agree with those obtained for the series of 3*d* and 4*d* metal carbides and nitrides. This suggests that the characteristics of the band structure of the matrix, in the first place the presence of a deep DOS minimum in the vicinity of the Fermi level, are decisive in the generation of local magnetic moments on *d* impurities in binary phases. One may expect that a similar situation occurs also in the ZrB_2: M and HfB_2: M systems (M = 3*d* metal), while the 4*d* impurities in diborides are nonmagnetic in the vast majority of cases.

VI. Amorphous metal borides

We shall consider yet another class of boron-containing systems — amorphous metal borides [metallic glasses (MG)], which exhibit interesting mechanical properties, a high corrosion resistance, and a series of unusual magnetic characteristics.[210,211]

There are several phenomenological theories which explain the stability of the amorphous state of the glasses near the composition $M_{80}X_{20}$. In the model proposed by Nagel and Tauc,[212] the metallic glasses are described as systems with almost free electrons. Their stability is explained by the position of the Fermi level in a deep DOS minimum, which is attained by introducing nonmetal atoms into the alloy. The role of such atoms reduces to the regulation of the electron concentration in the system. In the statistical theory taking into account the degree of packing of 'hard spheres' (metal atoms), the involvement of *p* elements is accounted for by the need to fill the cavities in the polyhedra of the 'matrix'. This is manifested most effectively for the ratio $M/X \approx 4$.[213] The possible role of chemical metal–nonmetal bonding in the transition of the system to the amorphous state has been pointed out by Shen and Park.[214]

The role of chemical bonding has been analysed within the framework of fragment models.[215,216] A calculation has been carried out[215] for the $[Ni_2Fe_2B]$ group in the $Ni_{40}Fe_{40}B_{20}$ structure by the spin-polarised multiple scattering method (Fig. 21). The structure is represented with the aid of Bernal polyhedra, the

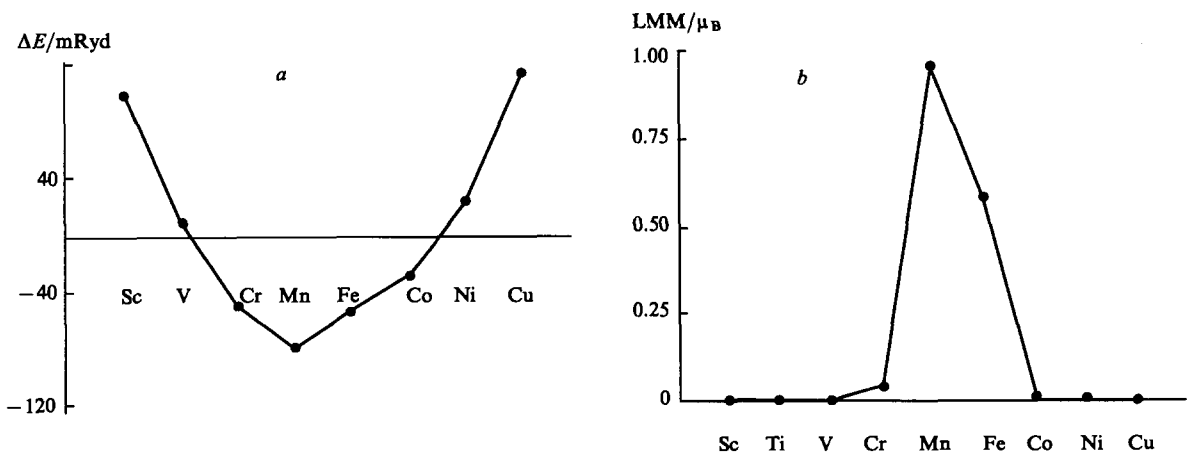

Figure 20. The changes in the total one-electron energy of TiB_2 on introduction of *d* metal impurities (*a*) and in the local magnetic moment on the 3*d* centres in TiB_2 (*b*).

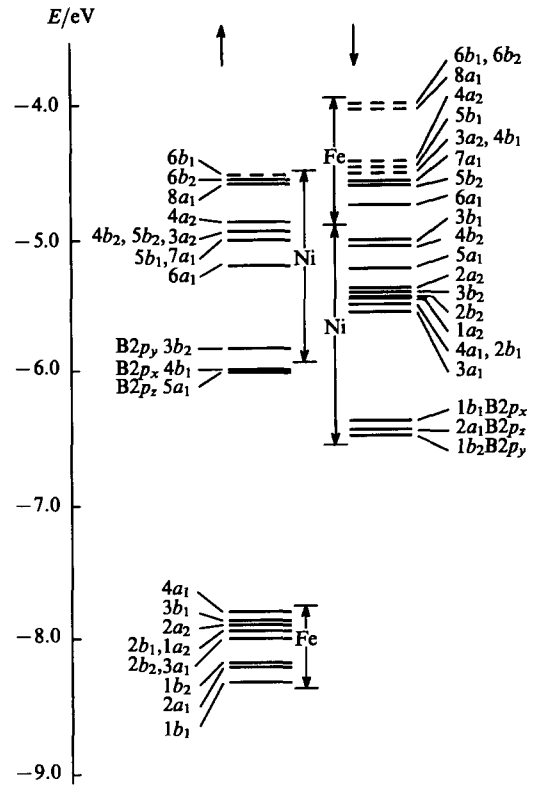

Figure 21. Molecular orbital diagram for the Ni_2Fe_2B cluster. Spin-polarised calculation by the scattered wave method.

smallest cluster (a tetrahedron) simulating the alloy being employed. A significant hybridisation of the boron *p* states with a series of low-energy molecular orbitals containing an appreciable contribution due to Ni *d* orbitals has been established. The boron–iron states exhibit a much smaller overlap. The local nature of these bonds and their anisotropy have been emphasised.[215] In this case, the charge density is concentrated mainly in the BNi_2 plane, which indicates the preferential bonding of boron to one of the metals, namely nickel. This results in the formation of microclusters of the type BNi_x in the metallic glass region.[217]

A similar approach has been used in calculations for the $[Co_8B_2]$, $[Co_4Fe_4B_4]$, $[Co_8B_4]$, and $[Fe_8B_4]$ clusters taking into account the possible formation of direct B–B bonds.[216] The greater stability of the $[Co_8B_2]$ system, compared with $[Co_8]$, has been interpreted[217] as a consequence of the decrease in the energy of a series of molecular orbitals (by ~1 eV) genetically related to the Co 3*d* states. This is due to their mixing with the B 2*p* functions accompanied by a weakening of the Co–Co bonds. The introduction of the iron impurity into the alloy hardly affects the energy states of cobalt, i.e. the decisive role of the Co–B bonds is retained, which leads to the appearance of local Co_nB ordering in the bulk of the metallic glass. It has been concluded[217] that cluster type boride metallic glasses (Co_3B, Fe_3B) are more stable than the corresponding crystal structures.

An attempt has been made to apply to the description of the amorphous $Fe_{80}B_{20}$ alloy the spin polarised LMTO method developed for calculations relating to invariant crystals.[218] A structure of the Fe_4N type, in which the coordination numbers of the Fe and N atoms are closest to those in the amorphous alloy, was selected as a model.[219–221] It was established that the conductivity band of the 'Fe_4B' metallic glass is determined by the states of the iron atom while the Fe 3*d*–B 2*p* hybridised states are concentrated near the bottom of the conductivity band (Fig. 22).

A fairly extensive series of studies have been carried out in recent years on the modification of the band approaches to calculations on amorphous systems.[222–231] Thus the problem of the relation between atomic structure and electron distributions in the $Fe_{100-x}B_x$ amorphous alloys has been considered.[222] The structure of the metallic glass was described in terms of an assembly of particles (several hundreds) interacting in accordance with the Morse function. The densities of states were calculated by the recursion method for a tight binding Hamiltonian with Harrison's parametrisation. A satisfactory agreement was obtained between the calculated data and experimental atomic radial distribution functions. The agreement between theoretical electronic and photoemission data is satisfactory.

The magnetic properties of $Fe_{100-x}B_x$ valence bonds amorphous alloys have been calculated.[230] Using the spin-polarised LMTO tight binding method and the recursion technique, the hyperfine fields on the iron nuclei as well as the isomeric shifts were calculated. The results agree quite well with Mössbauer spectroscopic data. A correlation was established between the directions of the shifts and the local environment of the ^{57}Fe nuclei (the number of boron atoms in the first coordination sphere of iron).

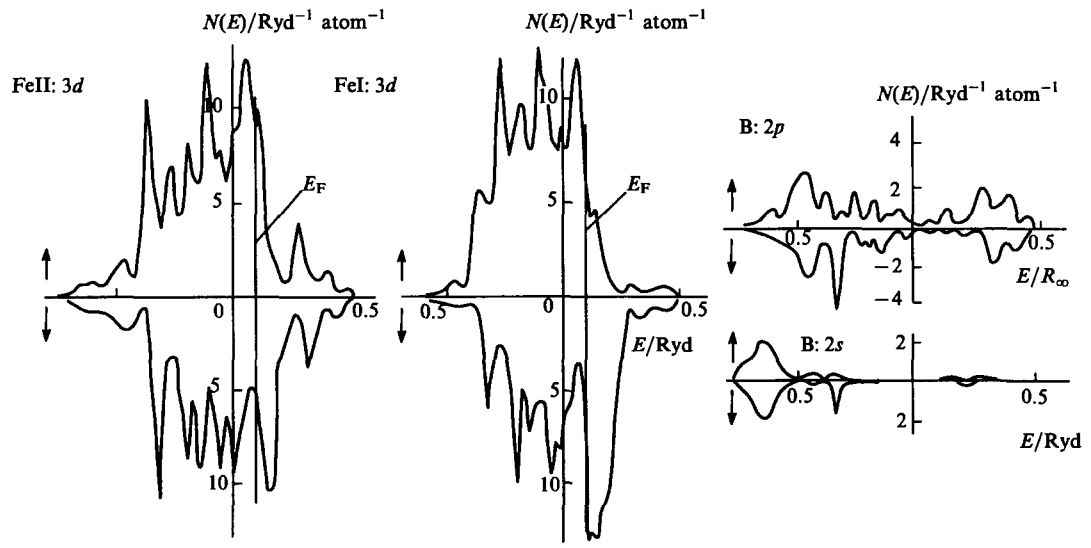

Figure 22. Partial densities of states in Fe_4B. The designations FeII and FeI correspond to iron atoms in the first and second coordination spheres of boron.

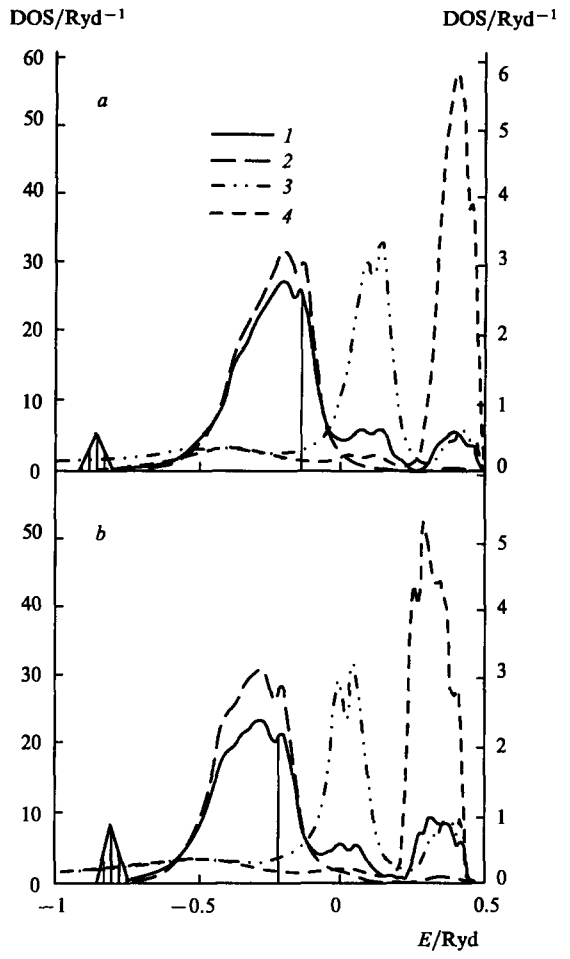

Figure 23. The total density of states (curve *1*) and the partial densities of Fe 3*d* (curve *2*), Fe 4s (curve *3*), and B 2*p* (curve *4*) states in the $Fe_{85}B_{15}$ (*a*) and $Fe_{75}B_{25}$ (*b*) amorphous alloys. The cross-hatched triangles indicate the position and 'centre of gravity' of the B 2*s* bands.

The structures of the $Fe_{85}B_{15}$ and $Fe_{75}B_{25}$ valence bands (Fig. 23) have been calculated by the LMTO method in terms of the atomic spheres approximation (LMTO ASA) and the recur-sion method.[228] The valence band of the alloy is made up of hybridised Fe 3*d*–B 2*p* states, the contributions of which to the occupied part of the spectrum vary in accordance with the composition of the boride. With increase in the boron content, the local magnetic moment diminishes from 1.795 μ_B for $Fe_{85}B_{15}$ to 1.705 μ_B for $Fe_{75}B_{25}$. The relation between the electronic parameters and the atomic configurations of the metallic glass has also been discussed in other investigations.[224–226]

The LMTO ASA method combined with the recursion technique has been used in calculations for a metallic glass of the $Co_{100-x}B_x$ (x = 17, 23, and 32) type.[231] As in the case of $Fe_{100-x}B_x$, the valence band of cobalt boride is of the Co 3*d*–B 2*p* hybrid type and the bonds between unlike atoms are determined by the Co–B covalent interactions. The charge transfer from Co to B is insignificant (~0.68 e) and is stable for the concentrations considered. The local magnetic moment diminishes sharply as the alloy becomes enriched in boron (for example, from 1.32 μ_B for $Co_{83}B_{17}$ to 0.94 μ_B for $Co_{68}B_{32}$).

Whereas the range of metallic glasses for which theoretical calculations have been made is fairly limited, the class of such glasses whose electronic structure has been investigated experimentally is much more extensive:

Alloy	Ref.
$Fe_{80}B_{20}$	234, 243, 247
Fe_xB_{100-x} (x = 88, 87, 86, 80, 75)	239, 255
$Fe_{1-x}B_x$ ($x \leqslant 0.2$)	246
Fe_xB_{100-x} (x = 86, 82, 28, 24, 20)	248
$Co_{80}B_{20}$	232
$Fe_{82}B_{18}$; $Ni_{81.5}B_{18.5}$	253
$Co_{81.5}B_{18.5}$	248
$Co_{76}Fe_4B_{20}$; $Co_{70}Fe_{10}B_{20}$	233
$Co_{80-x}Fe_xB_{20}$ (x = 6, 10, 20)	232
$Co_{85-x}Fe_xB_{15}$ (x = 65, 73)	235
$Fe_{80}M_3B_{17}$ (M = Fe, Co, W, Pt)	235
$Fe_{40}Ni_{40}B_{20}$	234, 243
$Fe_{75}Si_{10}B_{15}$; $Ni_{75}Si_{10}B_{15}$	253
$Fe_{76}Si_{12}B_{12}$; $Fe_{76}Si_{18}B_{12}$	248
$FeSi_{10}B_{12}$; $Fe_{45}Ni_{45}P_{8.5}B_{1.5}$	244
$Fe_{40}Ni_{40}P_{14}B_6$; $Fe_{32}Ni_{36}Cr_{14}P_{12}B_6$	252
$Fe_{82}B_{18-x}Be_x$	254
$Ni_{40}Fe_{40}P_{14}B_6$	251
$Fe_{70}Ni_8Si_{10}B_{12}$	250
$Co_{78}P_{14}B_8$	249
$Fe_{40}Ni_{40}P_{16}B_6$	234, 242, 245
$Fe_{67}Co_{18}B_{14}Si_{12}$	236
$Fe_{40}Ni_{38}Mo_4B_{18}$; $Ni_{76}Si_{12}B_{12}$	237
$Fe_{32}Ni_{32}Cr_{14}P_{12}B_6$	238
$Ni_{36}Fe_{32}Cr_{14}P_{12}B_6$	240, 241

The main problem discussed in the above investigations involves the consideration of the energy structure of the amorphous alloys, the establishment of the differences between the electron energy spectra of the amorphous and crystalline states, and also the determination of relations of the composition–property type for a fairly representative set of systems.

The BK_α-XES presented as an example in Fig. 24 for a series of metallic classes and crystalline phases based on iron and nickel and their joint representation in terms of a single energy scale with K_β and L_α lines[253] illustrate the main results obtained within the framework of the approaches mentioned above. Thus the following points have been noted:[253] (1) the valence band of the metallic

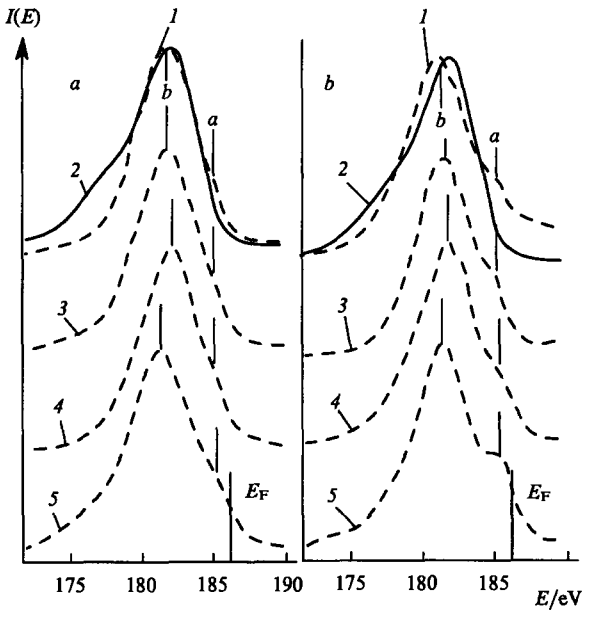

Figure 24. The BK_α X-ray emission spectra of amorphous iron and nickel borides and the spectrum of crystalline boron. (*a*): (*1*) α-$Fe_{82}B_{18}$; (*2*) B (crystalline); (*3*) α-$Fe_{75}Si_{10}B_{15}$; (*4*) Fe_2B; (*5*)FeB; (*b*): (*1*) α-$Ni_{81.5}B_{18.5}$; (*2*) B (crystalline); (*3*) α-$Ni_{75}Si_{10}B_{15}$; (*4*) Ni_2B; (*5*) NiB.

glass is made up of overlapping subbands of the B $2p$–(Fe, Ni) $3d$ states; (2) the maximum in the BK_α spectrum (peak *b*) is located near the bottom of the valence band and the substructure *a* [the intensity of which diminishes with increase in the (Fe, Ni)/B ratio], can be clearly traced on the short-wavelength slope of the line; (3) apart from the main maximum (located in the pre-Fermi region, which indicates the predominance of states with $3d$ symmetry near E_F), bulges, which have the same energies as the *a* and *b* maxima of the BK_α line, can be clearly seen in the L_α spectra, indicating an appreciable hybridisation of the B $2p$–(Fe, Ni) $3d$ states; (4) the peaks in the BK_α spectra of nickel-based metallic glasses, corresponding to the bonding states of NiB, are the most intense and are displaced into the long-wavelength part of the spectrum relative to the Fe-containing metallic glasses (this is probably the reason why Ni–B interactions are preferred in more complex systems containing simultaneously the Fe and Ni components); (5) comparison of the characteristics of the XES of the metallic glasses [similar to those noted in (4)] with those of binary crystals may indicate the probable cause of the transition to the amorphous state and its stability.

The XES, ES, and ESCA methods have also been used to investigate the chemical shifts of the inner levels (charge states) in metallic glasses,[233,235,238,239,252] for the description of the effects of the doping of the metallic and nonmetallic 'sublattices' of the glasses,[232,235,238,240–242,244,245,250,255] and for the oxidation of surfaces of amorphous materials.[238,250] The optical properties of boride metallic glasses have been considered, for example, by Lustig et al.[246]

In conclusion, we may note a series of studies[234,236,241] in which transitions from the crystalline to the amorphous state in a series of binary iron, cobalt, and nickel alloys and the compositions of the surfaces of the latter were investigated by Auger electron spectroscopy. In particular, the concentration profiles constructed for the distribution of the elements in the 'bulk' of $Fe_{80}B_{20}$ and $Fe_{40}Ni_{40}P_{16}B_4$ specimens[234] indicate the enrichment of their surface layers in the nonmetals during crystallisation.

This review has been written with the financial support of the Russian Fundamental Research Fund (Project No. 94-03-09524).

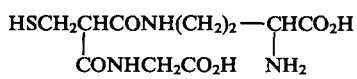
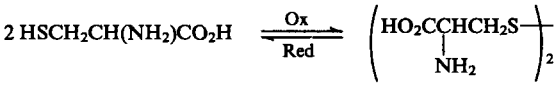
The chemistry of disulfides

I V Koval'



Contents

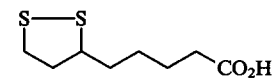
I. Introduction	735
II. The structure and physicochemical properties of disulfides	736
III. Methods of synthesis of disulfides	736
IV. Reactions with participation of disulfides	739



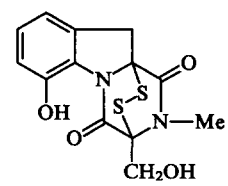
Abstract. The results of studies in the chemistry of disulfides during recent years are surveyed and treated systematically. The structures, methods of synthesis, and the physicochemical and chemical properties of disulfides are examined. The bibliography includes 151 references.

I. Introduction

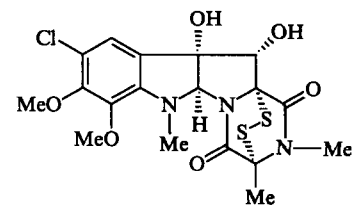
Disulfides play an important role in living organisms. In the formation of the tertiary structure of proteins, covalent disulfide bonds are known [1] to ensure the formation of cross-links, which are much stronger than hydrophobic interactions and hydrogen bonds. The disulfide cross-link renders relatively permanent the disposition of the peptide chains established initially as a result of weaker bonding forces. The biochemical importance of the disulfide bond is also determined by the uniqueness of the nature of the thiol–disulfide system, in which the S–S bond can be formed under conditions appropriate for biological processes — via disulfide exchange with participation of glutathione. [2]



Cystine, which contains a disulfide bond, is a component of aerobic systems. [1] It is formed as a result of the ready oxidation of cysteine.



In the hormone insulin, the disulfide bonds of cystine join two different peptide chains, one of which contains 21 and the other 30 aminoacid residues. [1] The composition and form of the protein of hair are to a large extent determined by the cystine S–S bonds and the chemical permanent wave in hair is based on this fact. [1] Hair is initially treated with a reductant in order to cleave the S–S bonds and convert them into sulfhydryl groups. Hair, the proteins of which no longer have cross-links, readily assumes the required form by virtue of the regeneration of the protein S–S cross-links as a result of oxidation by air or a chemical oxidant, and retains it for a long time.



Lipoic acid

participates in the oxidative decarboxylation of α-oxoacids and is a common unit in two fundamental biochemical processes in which the thiol–disulfide system participates: electron transfer and generation of thioester linkages. [2,3]

Disulfides such as glyotoxin and sporidesmin

are the main representatives of the group of metabolites of fungi. [1] Many disulfides enter into the composition of various natural products. For example, (−)-bis(3-acetoxyundec-5-enyl) disulfide has been isolated from Hawaiian seaweed of the genus *Dictyopteris*. [4] Di-n-propyl disulfide is a component of the mixture of substances responsible for the specific smell of the onion. [2]

Certain disulfides can be used as accelerators of the vulcanisation of rubber, [5] as chain transfer agents in radical polymerisation processes, [6] as biologically active substances, [7] and as complex-forming agents. [8] A very important application of disulfides is in fine organic synthesis. The lability of the S–S bond in disulfides and its ability to be cleaved by both nucleophiles and electrophiles as well as the active reaction centre with a variable valence (sulfur) impart to disulfides the properties of extremely valuable synthons, which are widely used in multistage organic syntheses and in particular for the introduction of the sulfide functional group.

The interest shown by many investigators gave rise at one point to the appearance of a series of reviews [2,3,9–15] reflecting to some extent the state of the chemistry of disulfides during that period. Unfortunately, the reactions occurring with an increase in the valence of sulfur and in particular the oxidative imination reactions and the formation of sulfonium complexes were hardly considered in these communications. On the other hand, since the publication of these reviews many new experimental data on

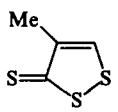
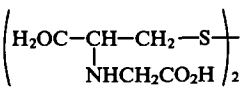
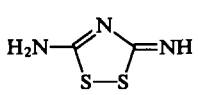
the chemistry of disulfides have accumulated and these are surveyed in the present review. The literature is covered up to 1992 inclusive.

II. The structure and physicochemical properties of disulfides

Virtually all the possible physicochemical research methods have been used in the study of the structure of disulfides and also of the main characteristics of the S–S bond in disulfides.[2,3,15–17] In particular, it has been established[2,15,16] that the molecules of disulfides have a zig-zag shape with a X–S–S–X dihedral angle of ~90°.

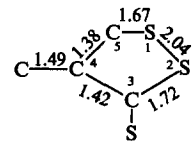






The strongest bonds between two identical atoms are formed by Group V–VII elements of the Third Period, which has been explained[17] by the contribution of the $p-\pi$ and $d-\pi$ interactions. By virtue of these interactions, the S–S bond in disulfides is much stronger than the O–O, Se–Se, and Te–Te bonds in the isostructural peroxides, diselenides, and ditellurides. The S–S bond dissociation energies for certain disulfides are listed in Table 1.

Table 1. The S–S bond dissociation energies.[3,17]



Disulfide	E_{dis}/kcal mol^{-1}
PhS–SPh	55.0 ± 1.5
FS–SF	60.0 ± 4.0
PhS–SMe	65.0 ± 1.5
HS–SH	66.0 ± 2.0
EtS–SEt	70.0 ± 2.0
EtS–SMe	72.0 ± 2.0
MeS–SMe	74.0 ± 2.0

As can be seen from the data in Table 1, the structures of the alkyl groups linked directly to sulfur in disulfides have little influence on the strength of the S–S bond. Aryl groups exert a greater influence on the strength of the bond, which has been explained by the involvement of the sulfur p electrons in conjugation with the π electrons of the benzene ring (p,π conjugation). The enthalpy of the S–S bond is 63 kcal mol^{-1}. The S–S bond lengths in certain disulfides are listed in Table 2.

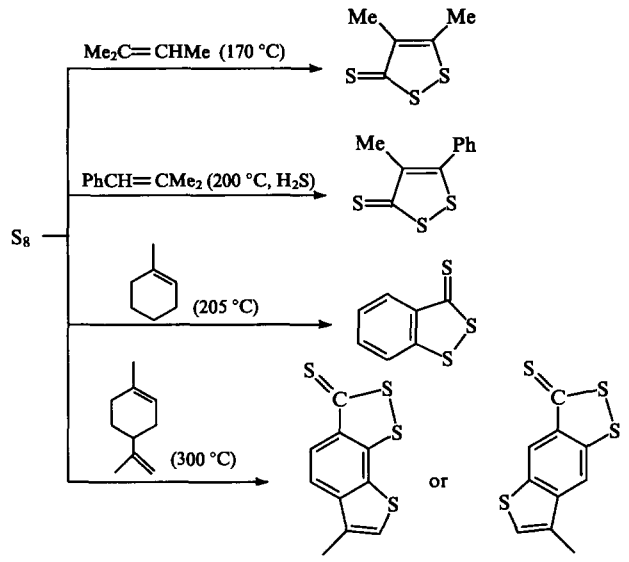
Table 2. The S–S bond lengths.[3]

Compound	S–S bond length/Å
	2.03
MeS–SMe	2.04
	2.04
HS–SH	2.04
ClS–SCl	2.05
CF_3S-SCF_3	2.05
	2.09

By comparing the S–S bond lengths in Table 2 with the values calculated by Pauling's equation,[3] it is possible to estimate the amount of double-bond character in the S–S bond. In 4-methyl-1,2-dithiacyclopent-4-ene-3-thione, it amounts to 20%, which indicates the aromatic nature of such trithione compounds and hence their high stability, which is also indicated by the results of the structural analysis of 1,2-dithiolane-3-thione.

The C(5)–S(1) bond (1.67 Å) in 4-methyl-1,2-dithiacyclopent-4-ene-3-thione is much shorter than the usual C–S bond (1.83 Å), while the C(4)–C(5) bond (1.38 Å) has virtually the same length as the C–C bond in aromatic hydrocarbons.

The structure of the terminal alkyl groups in disulfides hardly affects their dipole moments, which is apparently associated with the retention of the configuration of the C–S–S–C group.[3] The experimental molecular refractions of certain disulfides are numerically greater than the values calculated from atomic refractions.[3]



The absorption maximum in the UV spectra of dialkyl disulfides is in the range 240–280 nm. It undergoes a hypsochromic shift on passing from Me to Et, to Pr^i, and then to Bu^t, which is believed[3] to be associated with hyperconjugation. The absorption maximum in the UV spectra of *para*-substituted diphenyl disulfides *p*-$XC_6H_4SSC_6H_4Y$-*p* (X = H, Cl, NO_2, MeO; Y = NO_2, MeO) is in the range 240–324 nm (ε = 4.07–4.34). As the electron-accepting properties of the substituents in the benzene ring become more pronounced, a bathochromic shift of the absorption maximum is observed. The S–S bond stretching vibrations in disulfides are manifested in the range 470–503 cm^{-1}.[3] The chemical shift δ of the protons in the H_3C-S group is in the region of 2 ppm and that of the protons in the >CH–S group is in the region of 3.2 ppm.[18] UV irradiation of diphenyl disulfide at −200 °C leads to the formation of a radical product, the EPR spectrum of which is characterised by an axially anisotropic g-factor. This is apparently due to the localisation of the unpaired electron on the sulfur atom in the PhS$^\cdot$ radical. The absorption spectrum of this radical contains bands at 355 and 380 nm and its luminescence spectrum has bands at 374 and 240 nm.[17]

When diaryl disulfides react with strong electron acceptors (aluminium and gallium halides), the S–S bonds undergo homolytic cleavage with formation of the stable radical-complexes $ArS^\cdot \cdot MCl_3$ (Ar = Ph, *p*-MeC_6H_4, *o*-$NO_2C_6H_4$, α-$C_{10}H_7$; M = Al, Ga), which are solid deeply coloured substances capable of being stored under a nitrogen atmosphere for a long time.[19] It has been suggested that the donor–acceptor bond in the radical-complex is formed with participation of the lone pair of the sulfur atoms. In contrast to diaryl disulfides, dialkyl disulfides form under similar conditions 1:1 complexes with the above electron acceptors without the homolytic cleavage of the S–S bond. When the radical-complexes react with stronger electron donors, for example with pyridine, the thiyl radical is displaced and forms a disulfide as a result of recombination.

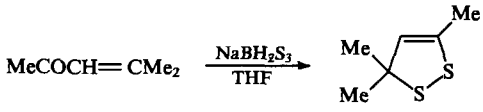
III. Methods of synthesis of disulfides

1. Syntheses based on sulfur and its inorganic derivatives

The use of sulfur in the synthesis of disulfides has been known for a relatively long time.[3] For example, a preparative method of synthesis of bis(*p*-aminophenyl) disulfide involves the heating of sulfur with aniline. A series of cyclic disulfides have been obtained by heating sulfur with unsaturated hydrocarbons.[3]

One of the preparative methods of synthesis of dialkyl disulfides involves the interaction of sulfur with alkyl iodides and sodium in liquid ammonia.[2]

$$RI + S_8 + 2\,Na \xrightarrow[NaI]{NH_3} RSSR$$



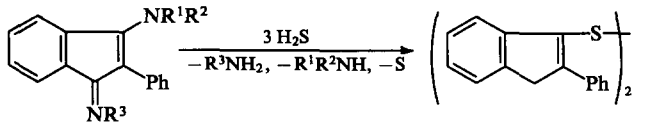
The interaction of elemental sulfur with trialkylboranes and subsequent alkaline hydrolysis of the products also lead to the formation of dialkyl disulfides.[2]

$$R_3B \xrightarrow{S_8\,(\Delta)} RSBR_2 \xrightarrow{OH^-} RSSR$$

On treatment with sulfur-containing sodium tetrahydroborate, aldehydes and ketones are converted into disulfides, while 1,2-epoxides and α,β-unsaturated ketones are converted into bis(1,2-hydroxyethyl) disulfides and cyclic disulfides respectively.[2,20]

$$PhCHO \xrightarrow{NaBH_2S_3} PhCH_2S-SCH_2Ph$$

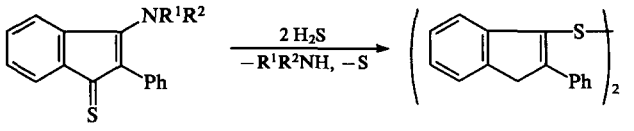
The interaction of alkyl halides with sulfur in the presence of alkoxides leads to the formation of the corresponding dialkyl disulfides and dialkyl trisulfides.[21]



$$RCH_2Hal + S_8 + RO^- \longrightarrow (RCH_2)_2S_n$$

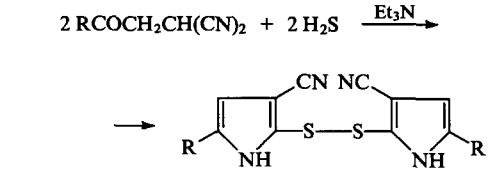
$n = 2, 3.$

The synthesis of alkynyl disulfides based on the reaction of elemental sulfur with lithium acetylides and subsequent sulfenylation of lithium thiolates by sulfenyl chlorides has been described.[22]

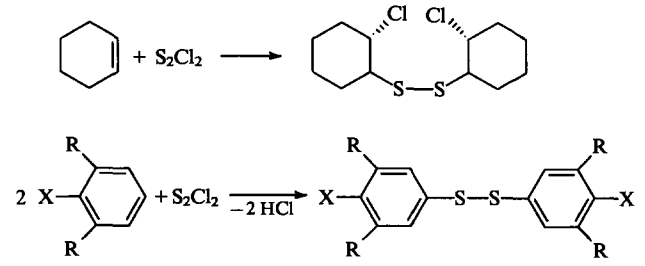


$$RC{\equiv}CLi + S_8 \longrightarrow RC{\equiv}CSLi \xrightarrow[-LiCl]{R^1SCl} RC{\equiv}CSSR^1$$

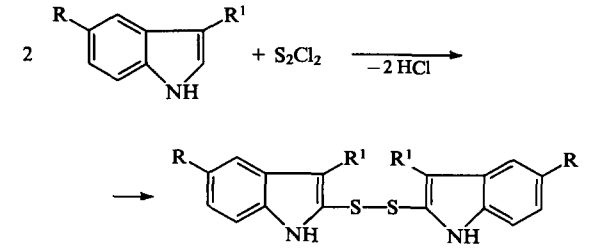
Among the inorganic derivatives of sulfur, sodium disulfide has found the most extensive application in the synthesis of disulfides. A whole series of preparatively very easy methods of synthesis of dialkyl and diallyl disulfides, described in handbooks and in the scientific literature, have been developed on the basis of the reactions involving the alkylation and arylation of sodium disulfide by alkyl halides and activated aryl halides as well as arenediazonium salts. Dialkenyl disulfides are obtained similarly from sodium disulfide.[23] Among other inorganic derivatives of sulfur, hydrogen sulfide and sulfur monochloride are also used in the synthesis of disulfides. For example, it has been noted[24,25] that bis(indenyl) disulfide is formed in the reaction of hydrogen sulfide with 3-amino-1-imino-2-phenylindenes in an alcoholic medium in the presence of piperidine.



$R^1 = R^2 = H$; R^3 = Alk.



The same disulfide is obtained in the reaction of hydrogen sulfide with 3-amino-2-phenylindene-1-thiones.[25]



The reaction of hydrogen sulfide with alkyl(aryl) β,β-dicyanoethyl ketones in an organic solvent in the presence of triethylamine affords bis(5-R-3-cyanopyrrol-2-yl) disulfides.[26]

The use of sulfur monochloride in the synthesis of disulfides is based on the reactions involving its addition to unsaturated bonds[27] and also on substitution reactions involving aromatic and heterocyclic compounds.[2,3]

R = H, Bu^t; X = OH, NMe_2.

R, R^1 = Alk.

It has been noted[28] that the interaction of malonic ester with the $SF_4-HF-S_2Cl_2$ system leads to the formation of bis-[di(ethoxycarbonyl)fluoromethyl] disulfide.

2. Synthesis of disulfides from thiols

a. Oxidation of thiols

Thiols are relatively readily oxidised by various oxidants to disulfides. A whole series of preparatively extremely convenient methods of synthesis of disulfides have been developed on the basis of this reaction. The oxidation of thiols by oxygen catalysed by metal ions (Fe^{3+}, Cu^{2+}), UV irradiation, and other initiators of radical processes, is used very often in the synthesis of disulfides. Despite the great importance of this reaction in biological processes and its importance for the removal of sulfur from petroleum products, its mechanism has not been ultimately elucidated.[2] The stoichiometric equation of this reaction in a basic medium is as follows:

$$4RSH + O_2 = 2RSSR + 2H_2O.$$

Flavins oxidise anaerobically the excess thiol to the disulfide in a high yield and are simultaneously reduced to dihydroflavins.[2]

Hydrogen peroxide,[3] iron trichloride,[3] potassium hexacyanoferrate(III),[29] hypohalites,[29] cobalt-disulfophthalocyanine,[29] manganese tris(acetylacetonate),[29] iodine,[30] carbon tetrachloride,[31] *N*-chloro-compounds,[32–34] yeast,[35] and other compounds are also used as oxidants.

b. Photolysis of thiols

In the synthesis of asymmetric disulfides, both individual thiols and their mixtures with disulfides are photolysed. For example, the photolysis of a mixture of ethanethiol and dimethyl disulfide leads to the formation of ethyl methyl disulfide.[36]

$$EtSH \xrightarrow{h\nu} EtS^{\cdot} + H^{\cdot},$$

$$EtS^{\cdot} + Me_2S_2 \xrightarrow{h\nu} EtSSMe + MeS^{\cdot},$$

$$EtS^{\cdot} + MeS^{\cdot} \longrightarrow EtSSMe.$$

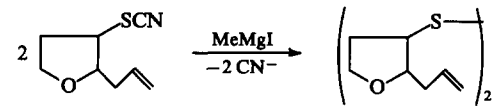
c. Sulfenylation of thiols

The sulfenylation of thiols by sulfenyl halides is a preparative method of synthesis of asymmetric disulfides.[29,37–39]

Alkali metal[29] and silver[40] thiolates as well as alkyl(aryl)-thiotrimethylsilanes[41] are sometimes used instead of thiols.

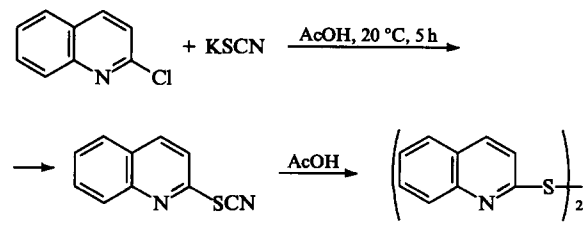
$$RSSiMe_3 + R^1SCl \xrightarrow[-Me_3SiCl]{} RSSR^1$$

R = Ph, $PhCH_2$; R^1 = Et, Ph, 4-MeC_6H_4.



Thiols may be sulfenylated also by sulfenamides,[42–44] carboxylic acid thioloesters,[2] phosphonyl dithioformates,[45] phosphine sulfides,[46] alkyl(aryl)dithiopyridine *N*-oxides,[47] and other divalent sulfur compounds.[48,49] However, these methods have not found extensive application owing to the formation of side products which hinder the isolation of the disulfides.

3. Synthesis of disulfides from thiocyanates



Symmetrical disulfides can be obtained relatively easily by cleaving thiocyanates with alkali.[3]

$$RSCN \xrightarrow{OH^-} RSSR + NH_3 + CO$$

The similar cleavage of 2-allyl-3-tetrahydrofuryl thiocyanate in the presence of methylmagnesium iodide affords bis(2-allyl-3-tetrahydrofuryl) disulfide.[50]

The synthesis of bis(quinolin-2-yl) disulfide by the reaction of 2-chloroquinoline with potassium thiocyanate in acetic acid has been described.[51]

The reaction of thiols with dithiocyanogen affords sulfenyl thiocyanates, the interaction of which with thiols leads to disulfides. This sequence of reactions has been used in the synthesis of cystine derivatives.[29]

$$RSH \xrightarrow[-HSCN]{(SCN)_2} RSSCN \xrightarrow[-HSCN]{R^1SH} RSSR^1$$

$R = HO_2CCHCH_2$ (NH_2); $R^1 = HO_2CCHCH_2$ ($NH_2 \cdot HCl$).

4. Syntheses of disulfides based on tetravalent and hexavalent sulfur compounds

The reduction of sulfinic acids by hydrogen bromide or of their chlorides by a mixture of trichlorosilane and tripropylamine is sometimes used to obtain symmetrical disulfides.[2] The chlorides of aromatic sulfonic acids are reduced comparatively readily to disulfides by hydrogen iodide in acetic acid. The preparation of asymmetric disulfides by the reaction of thioloesters of sulfinic acids with alkylthiotrimethylsilanes has been described.[52]

$$RS(O)SR + R^1SSiMe_3 \xrightarrow[-RSOSiMe_3]{} RSSR^1$$

5. Other methods of synthesis of disulfides

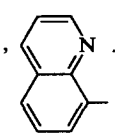
Asymmetric disulfides are frequently obtained by the thiol–disulfide exchange reaction.[2] For example, treatment of thiols with an excess of dimethyl disulfide in the presence of triethylamine leads to the formation of the corresponding alkyl methyl disulfides.

$$RSH + MeSSMe \xrightarrow{Et_3N} MeSSR + MeSH$$

The reaction of silyl sulfides with disulfides involves the exchange of the RS groups and the formation of asymmetric disulfides.[52]

$$RSSiMe_3 + R^1SSR^1 \rightleftharpoons R^1SSiMe_3 + R^1SSR$$

Asymmetric disulfides have also been obtained by treating alkyl disulfide anions, generated electrochemically from thiolate ions, with haloalkanes.[54]



$$ArSS^- + RX \longrightarrow ArSSR$$

Ar = Ph, 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$; R = Alk.

It has been noted[54] that alkoxy- and acetoxy-disulfides are formed as a result of the ring opening and dimerisation of thiiranes in alcohols and acetic acid in the presence of germanium salts.

The monodesulfurisation of trisulfides by treatment with phosphines is sometimes used in the synthesis of symmetrical disulfides.[2] Depending on the nature of the phosphine, this entails either the removal of the terminal or the central sulfur atom. Thus, when tris(dimethylamino)phosphine is used, the terminal sulfur atom is mainly removed, whereas triphenylphosphine displaces the central sulfur atom. In order to retain the configuration in the conversion of sporidesmin trisulfide into the corresponding disulfide, triphenylphosphine is therefore employed. Disulfides are also formed in the interaction of sodium thiolates with chlorodiphenylmethane in an alcoholic medium.[55]

$$RSNa + Ph_2CHCl \xrightarrow[-NaCl]{O_2} RSSR + Ph_2C{=}O$$

R = 2,4-$(NO_2)_2C_6H_3$,  .

IV. Reactions with participation of disulfides

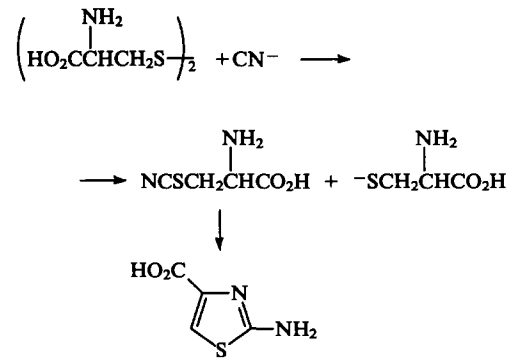
All the reactions with participation of disulfides can be divided into three large groups: (1) reactions occurring with cleavage of the S–S bond; (2) reactions occurring with cleavage of a C–S bond; (3) reactions leading to an increase in the valence of sulfur.

1. Reactions occurring with cleavage of the S–S bond

a. Cleavage by nucleophiles

The cleavage of the S–S bond in disulfides by nucleophiles proceeds via a S_N2 mechanism.[2]

$$RSSR + Nu^- \longrightarrow \left[RS{-}\underset{\displaystyle Nu}{\overset{\displaystyle -}{S}}R\right] \longrightarrow NuSR + RS^-$$



In the absence of steric influences, the sequence based on the relative S-nucleophilicities (thiophilicities) for reactions with aryl disulfides is as follows: $P(EtO)_3 > R^-$, HS^-, $EtS^- > PhS^- > PPh_3$, $CN^- > SO_3^{2-} > OH^- > 2,4\text{-}(NO_2)_2C_6H_3S^- > N_3^- > SCN^-$, I^-, $PhNH_2$. This sequence is not identical with that based on the relative C-nucleophilicities and depends to a much greater extent on the polarisability of the nucleophile.[2]

Cleavage by C-nucleophiles. The cleavage of disulfides by C-nucleophiles has been thoroughly investigated for reactions with the cyanide anion and carbanions generated by various methods.

The rate of cleavage of disulfides by the cyanide anion as well as the composition and structure of the reaction products are determined primarily by the nature of the initial disulfide. For example, simple dialkyl disulfides do not react with the cyanide anion, while diphenyl disulfide does react with it and forms an equilibrium mixture of products.

$$PhSSPh + CN^- \rightleftharpoons PhSCN + PhS^-$$

The interaction of the cyanide anion with cystine results in the formation of 2-aminothiazoline-4-carboxylic acid.[2]

On treatment with the cyanide anion, tetramethylthiuram disulfide undergoes monodesulfurisation,[3] which proceeds via a S–S bond cleavage stage.

$$Me_2NC(=S)SC(=S)NMe_2 + CN^- \longrightarrow Me_2NCS^- + Me_2NC(=S)SCN \longrightarrow$$

$$\longrightarrow Me_2NC(=S)SC(=S)NMe_2 + SCN^-$$

The cleavage of asymmetric disulfides by the cyanide anion proceeds relatively smoothly.[3]

$$ArSSR + CN^- \longrightarrow RSCN + ArS^-$$

Ar = 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$; R = Alk.

The rate of cleavage then depends directly on ΔpK_a—the difference between the pK_a for the thiols the residues of which form part of the disulfide molecule. The cleavage of disulfides with ΔpK_a = 1.8 proceeds in one direction. Disulfides with ΔpK_a = 1.65 to 1.05 can be attacked by the cyanide ion at both sulfur atoms. Disulfides with ΔpK_a = 0, i.e. symmetrical disulfides, do not react with the cyanide anion.[56]

The composition and nature of the products of the cleavage of asymmetric disulfides by the cyanide ion are also determined by thermodynamic factors, i.e. the cleavage takes place with formation of the thermodynamically more stable thiolate anion. The electronic factor (the cyanide anion attacks the sulfur atom with a lower electron density) and steric factors can also play a significant role.

In the presence of strong bases (KOH, Bu^tOK), dialkyl disulfides react with acetylene and its homologues to form mono- and di-(alkylthio)ethenes.[57,58]

$$RSSR + R^1C{\equiv}CH \xrightarrow[H_2O\ (or\ DMSO)]{ROH\ (or\ Bu^tOK)}$$

$$\longrightarrow RSC(R^1){=}CHSR + RSCH{=}CHR^1$$

R = Et, Pr^n, Bu^n; R^1 = H, Pr^n, Bu^n, Bu^t, Ph.

The mechanism of this reaction includes a stage in which the S–S bond is cleaved by the acetylide anion.

$$R^1C{\equiv}CH + OH^- \longrightarrow R^1C{\equiv}C^- + H_2O,$$

$$R^1C{\equiv}C^- + RSSR \longrightarrow [R^1C{\equiv}CSR] + RS^-,$$

$$RS^- + R^1C{\equiv}CH \longrightarrow R^1\bar{C}{=}CHSR \xrightarrow{R^1C{\equiv}CH} \longrightarrow R^1CH{=}CHSR,$$

$$[R^1C{\equiv}CSR] + RS^- \longrightarrow \underset{\displaystyle SR}{R^1C{=}\bar{C}SR} \xrightarrow{R^1C{\equiv}CH} \longrightarrow \underset{RS}{\overset{R^1}{}}\!\!>C{=}C<\!\!\overset{H}{}_{SR}.$$

The cleavage of the S–S bond in disulfides by organolithium compounds[27] leads to thiolates and sulfides as in the case of organomagnesium compounds.[29]

$$PhLi + PhSSPh \longrightarrow PhSLi + PhSPh$$

The carbanions generated by treatment with Pr^i_2NLi also cleave the S–S bond in disulfides. This is one of the procedures most widely used in fine organic synthesis for the introduction of the sulfide functional group. It is used, for example, in the syntheses of α,β-unsaturated carbonyl compounds and α-oxoesters.[59,60]

$$R_2CHCHCO_2R \xrightarrow[2.\ PhSSPh]{1.\ LiN(Pr^i_2)} R_2CHCCO_2R \xrightarrow[MeOH]{NaIO_4} \longrightarrow R_2CHCCO_2R \xrightarrow{\Delta} R_2C{=}CCO_2R$$

$$RCH_2CO_2R \xrightarrow[2.\ PhSSPh]{1.\ LiN(Pr^i_2),\ THF\ (-78\ ^\circ C)} R{-}C(SPh)_2{-}CO_2R \xrightarrow[2.\ CF_3CO_2H]{1.\ I_2,\ MeOH} \longrightarrow RC(=O){-}C(=O)R$$

The nucleophilic substitution of the tributylstannate group by the thiolate anion obtained from disulfides by treatment with butyllithium has been described.[61]

$$Bu_3SnCH{=}CHSnBu_3 \xrightarrow[-Bu_3SnLi]{RSSR\ (BuLi,\ -78\ ^\circ C)} Bu_3SnCH{=}CHSR$$

The addition of disulfides to the double bonds of cyclopentadiene in the presence of sodium hydride[62] also evidently proceeds via a stage involving the cleavage of the S–S bond by the carbanion.

Cleavage by O-nucleophiles. The reaction of disulfides with OH^- ions can proceed via one of three mechanisms depending on the structure of the initial disulfide.[2] In the absence of active α- or β-hydrogen atoms in the disulfide molecule, nucleophilic substitution takes place at a sulfur atom with formation of a thiolate anion and a sulfenic acid,[63] which disproportionates to the sulfinic acid.

$$2ArSSAr + 4OH^- = 3ArS^- + ArSO_2^- + 2H_2O$$

In the case of asymmetric disulfides, the hydroxide ion attacks the sulfur atom furthest from the electron-accepting group and the cleavage proceeds more readily the more stable the anion split off.

In the presence of an acid α-hydrogen atom, there is a possibility of a 1,2-elimination reaction with the initial formation of a thione, which hydrolyses to a ketone or isomerises to an enethiol.[2]

$$RS{-}S{-}\underset{Me}{\overset{H{\leftarrow}OH^-}{C}}CO_2^- \longrightarrow RS^- + S{=}\underset{Me}{C}{-}CO_2^- \xrightarrow{H_2O} \longrightarrow \underset{Me}{O{=}C}{-}CO_2^-$$

R = $CHMeCO_2^-$.

The cleavage of aryl diphenylmethyl disulfides on treatment with an alkoxide anion proceeds similarly.[2]

$$RO^- + Ph_2CHSSAr \longrightarrow \left[RO^{\delta-}\cdots H^{\delta+}\cdots \underset{Ph}{\overset{Ph}{C}}\cdots S^{\delta+}\cdots SAr^{\delta-}\right] \longrightarrow Ph_2C{=}S + ROH + ArS^-$$

In the presence of an acid β-hydrogen atom, 1,2-elimination results in the formation of an alkene and a hydrodisulfide anion, which is converted into a thiolate anion and further into a sulfide.[2]

$$^-OOC{-}\underset{H_2N}{\overset{H{\leftarrow}OH^-}{C}}{-}CH_2{-}SSR \longrightarrow {}^-OOC{-}\underset{H_2N}{C}{=}CH_2 + RSS^-$$

$$RSS^- \longrightarrow RS^- + S$$

$$^-OOC{-}\underset{H_2N}{C}{=}CH_2 + RS^- + H_2O \longrightarrow {}^-OOC{-}\underset{H_2N}{CH}{-}CH_2SR$$

R = $CH_2CH(NH_2)COO^-$.

Cleavage by P-nucleophiles. The composition and structure of the products of the cleavage of disulfides by phosphorus compounds are determined by the nature of the organophosphorus compounds. Thus the cleavage of disulfides in the presence of dialkylaminophosphines proceeds with formation of sulfides and *N,N*-dialkylphosphoramidothioates.[27] The reaction takes place stereospecifically with inversion at one of the α-carbon atoms.

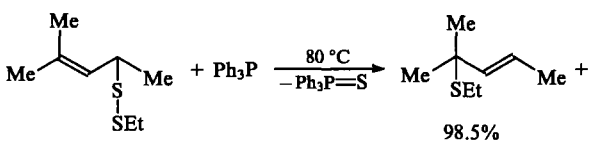
$$(R_2N)_3P + \cdots\!\!>\!\!C{-}S{-}SR^1 \longrightarrow \cdots\!\!>\!\!C{-}S{-}\overset{+}{P}(NR_2)_3 + R^1S^-$$

$$R^1S^- + \cdots\!\!>\!\!C{-}\overset{+}{S}{-}P(NR_2)_3 \longrightarrow R^1S{-}C\!<\!\cdots + (R_2N)_3P{=}S$$

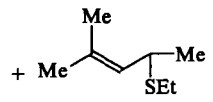
Symmetrical diallyl disulfides are more reactive than dialkyl disulfides, while asymmetric disulfides react even at room temperature.

Primary and secondary phosphines convert disulfides into thiols.[3]

$$RPH_2 + 2\,R^1SSR^1 \longrightarrow RP(SR^1)_2 + 2\,R^1SH$$



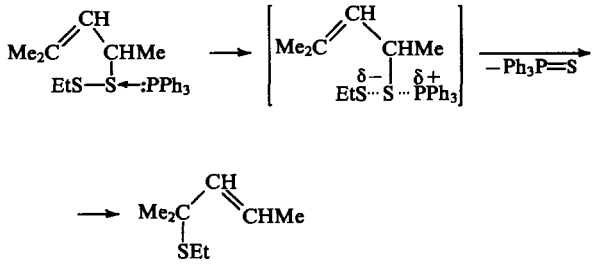
$$R_2PH + R^1SSR^1 \longrightarrow R_2PSR^1 + R^1SH$$



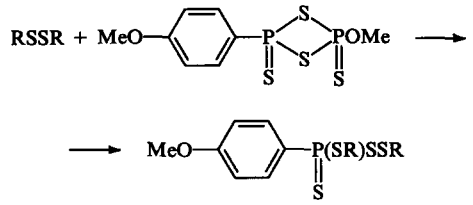
Triphenylphosphine in aqueous dioxane reduces disulfides to thiols;[64] triphenylphosphine oxide is formed simultaneously owing to the hydrolysis of the cation formed in the first stage of the reaction. In the absence of a solvent, a monosulfide and triphenylphosphine sulfide are formed.[3]

$$RSSR + Ph_3P \longrightarrow RSR + Ph_3P{=}S$$

R = $CH_2{=}CHCH_2$, $MeCH{=}CHCH_2$, $Me_2C{=}CHCH_2$ etc.



When dialkenyl and alkenyl alkyl sulfides are heated with triphenylphosphine, a mixture of two sulfides and triphenylphosphine sulfide is formed.[65]



1.5%

The authors[65] believe that the reaction proceeds via an intermediate polarised complex formed as a result of the nucleophilic attack by triphenylphosphine at one of the sulfur atoms, further cleavage occurring via a S_Ni mechanism with migration of the double bond.

It has been noted[66] that the interaction of disulfides with dithiadiphosphetanes in anhydrous toluene at 120–130 °C proceeds with formation of phosphonotrithioates.

Cleavage by S-nucleophiles. The cleavage of disulfides by the thiolate anion — the thiol–disulfide exchange reaction — plays a very important role in biological processes. For example, it has been suggested[3] that the permeation of a bacteriophage through the wall of the rectum in animal organisms occurs as a result of the cleavage of the S–S bond by the thiolate anion. Asymmetric disulfides are cleaved more readily by the thiolate anion than symmetrical ones. In this case, the thermodynamic factor, i.e. the thermodynamic stability of the newly formed thiolate anion, plays an important role. The steric factor is likewise important. For example, the cleavage of di(*tert*-butyl) disulfide is approximately 10^6 times slower than that of di(n-butyl) disulfide, which is evidence in support of a S_N2 mechanism of this reaction. 1,2-Dithiolanes exhibit an anomalously high reactivity in their reaction with the thiolate anion, which has been explained[3] by the removal of the torsional strain as a result of ring opening.

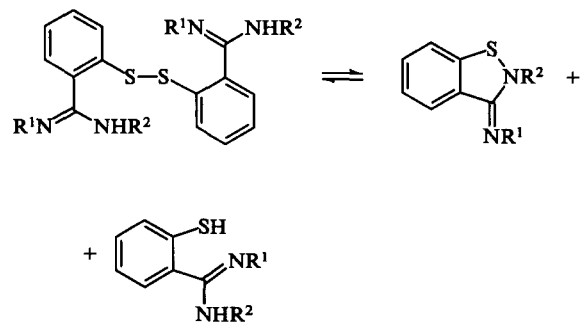
The behaviour of lipoic acid in biological systems has also been explained by a similar anomalous reactivity.

Cleavage by N-nucleophiles. The cleavage of the S–S bond in bis(dialkoxyphosphonyl) and bis(dialkoxythiophosphonyl) disulfides in the presence of amines leads to sulfenamides.[67]

$$RSSR + 2\,R^1R^2NH \longrightarrow RSNR^1R^2 + RS^- + R^1R^2\overset{+}{N}H_2$$

R = CN, $(AlkO)_2P(S)$, $(AlkO)_2P(O)$.

$R^1 = R^2 = Me, H$.

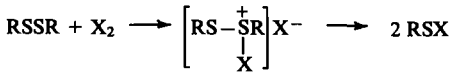


The reactivity of amines in this reaction diminishes in accordance with their basicity in the following sequence: $Me_2NH > MeNH_2 > NMe_3 > NH_3$.

The cleavage of diaryl disulfides by *N*-arenesulfonylsulfilimines in chlorobenzene leads to the formation of *N,N*-bis(arylthio)arenesulfonamides.[68]

$$ArSSAr + Ph_2S{=}NR \xrightarrow[PhCl]{\Delta} (ArS)_2NR + Ph_2S$$

Ar = 4-MeC_6H_4, Ph; R = Ts, $PhSO_2$.

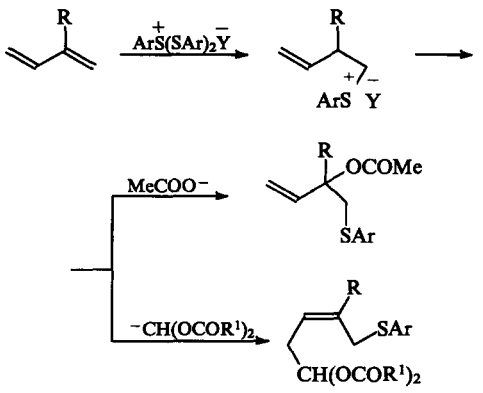


Diaryl disulfides containing amidine groups in the *ortho*-position are cleaved at the S–S bond on heating, with participation of the more nucleophilic nitrogen atom of the amidine group.[69]

$R^1 = R^2 = H$, Alk, Ar.

b. Cleavage of the S–S bond by electrophiles

The cleavage of the S–S bond in disulfides by the halogens and halogenating agents has long been known and has been thoroughly investigated. A series of preparative methods of synthesis of sulfenyl halides have been developed on the basis of this reaction.[70–72] The reaction proceeds with formation of chlorosulfonium intermediates, the cleavage of which leads to two



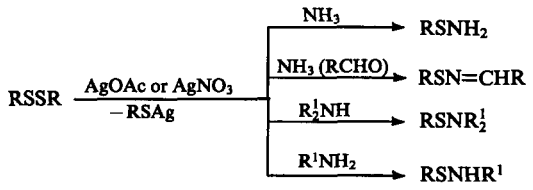
molecules of a sulfenyl halide.[70]

The interaction of disulfides with sulfenyl halides can proceed in different ways depending on the conditions. In the absence of catalysts, the reaction between diaryl disulfides and arenesulfenyl chlorides takes place with cleavage of the S–S bond and the exchange of arenesulfenyl groups.[2]

$$ArSSAr^1 + ArSX \longrightarrow \left[ArS-\overset{+}{\underset{Ar}{S}}-SAr^1\right]X^- \longrightarrow$$

$$\longrightarrow ArSSAr + Ar^1SX$$

In the presence of Lewis acids, diaryl disulfides and arenesulfenyl halides form the complexes $ArS^+(SAr)_2Y^-$ ($Y = SbCl_6$, $SbCl_4$, SbF_6, BF_4), which are effective agents for the transfer of the arylthio-cation in reactions with alkenes.[73-75]



R = H, Me; R^1 = Me, Et;

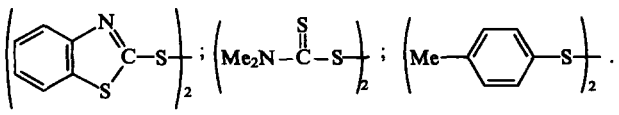
Ar = Ph, 4-ClC_6H_4, 4-MeC_6H_4, C_6F_5;

Y = BF_4, SbF_6, $SbCl_6$.

In the syntheses of various sulfenamides from disulfides, the joint action of electrophiles and nucleophiles (for example Ag^+ ions and amines) is used to cleave the S–S bond.[2,76,77]

R = 4-MeC_6H_4, 3-$NO_2C_6H_4$, 4-$NO_2C_6H_4$ etc.;

R^1 = Me, Et, Pr^i, Bu, etc.



It has been noted[78] that, on heating in acetic anhydride, diphenyl disulfide is cleaved, affording the following products: PhSH, PhSAc, and $(PhS)_3CMe$.

c. Homolytic cleavage of the S–S bond

Many disulfides exhibit thermochromism (they are reversibly coloured on heating). In order to account for this phenomenon, the erroneous hypothesis has been put forward that the thermochromism is due to the reversible dissociation of disulfides into thiyl radicals, which are present at an appreciable concentration.

$$RSSR \rightleftarrows 2RS^{\bullet}$$

When disulfides are heated, the homolysis of the S–S bond does indeed take place but with very low rate constants (k), which have the following values at 100 °C:[2]

$k = 8.3 \times 10^{-5}\ s^{-1}$ $k = 5.5 \times 10^{-6}\ s^{-1}$ $k \leqslant 2 \times 10^{-8}\ s^{-1}$

The pyrolysis of dialkyl disulfides in the gas phase begins at 200 °C. The thermal decomposition temperature is then reduced with increase in the length of the alkyl groups and the degree of their branching.[79] The pyrolysis of dimethyl disulfide in the gas phase at 316–317 °C under reduced pressure (3.2 to 3.0 kPa) takes place with formation of hydrogen sulfide, ethylene, sulfur, and other products. It has been suggested[27] that the pyrolysis begins with the homolytic cleavage of the S–S and C–S bonds; the radicals MeS$^{\bullet}$ and atomic sulfur, formed under these conditions, react subsequently with the initial disulfide. (In a high vacuum, dimethyl disulfide dissociates into thioformaldehyde and methanethiol.)

$$MeSSMe \longrightarrow CH_2{=}S + MeSH$$

Judging from the nature of the final products, the pulsed vacuum pyrolysis of diisopropyl disulfide at 500 °C begins with the homolytic rupture of a C–S bond accompanied by the formation of isopropyldisulfane as an intermediate, which subsequently decomposes into propene, hydrogen sulfide, and sulfur.[80]

$$Me_2CHSSCHMe_2 \longrightarrow [Me_2CHSSH] \longrightarrow$$

$$\longrightarrow MeCH{=}CH_2 + HSSH$$

$$HSSH \longrightarrow H_2S + S$$

The pyrolysis of di(*tert*-butyl) disulfide also begins with the homolysis of a C–S bond and is completed by the formation of H_2S, CS_2, CH_4, and $CH{\equiv}CH$.[27,79] Hence, on passing from dimethyl disulfide to diisopropyl and di(*tert*-butyl) disulfides, the probability of the cleavage of a C–S bond increases owing to the decrease in the dissociation energy of this bond in the above series.

The vacuum pyrolysis of diphenyl and di(naphth-2-yl) disulfides at 400–700 °C takes place with formation of thiyl radicals owing to the homolytic cleavage of the S–S bond.[27]

The thiyl radicals obtained by the pyrolysis of disulfides are used in organic synthesis as highly reactive intermediates. For example, the thiyl radicals generated from the diphenyl disulfide in the liquid phase at 125–230 °C react with bromoarenes in hydrogen sulfide to form the corresponding asymmetric sulfides.[81]

$$2\,ArBr + Ph_2S_2 \xrightarrow{H_2S} 2\,ArSPh + 2\,HBr$$

$$PhSSPh \xrightarrow{\Delta} 2\,PhS^{\bullet}$$

$$ArBr \longrightarrow Ar^{\bullet} + Br^{\bullet}$$

$$PhS^{\bullet} + H_2S \longrightarrow PhSH + HS^{\bullet}$$

$$Br^{\bullet} + H_2S \longrightarrow HBr + HS^{\bullet}$$

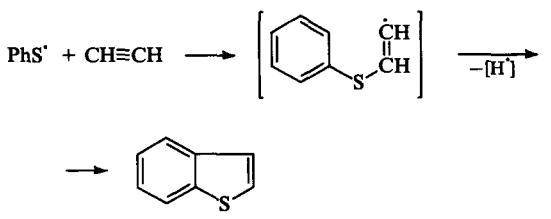
$$Ar^{\bullet} + H_2S \longrightarrow ArH + HS^{\bullet}$$

$$PhSH + Br^{\bullet} \longrightarrow PhS^{\bullet} + HBr$$

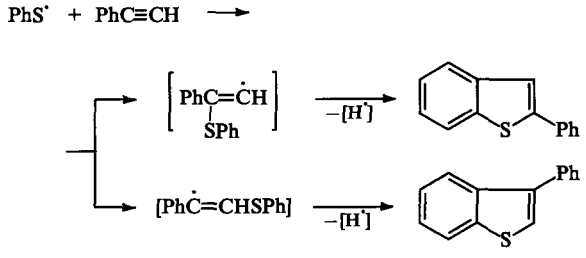
$$PhSH + Ar^{\bullet} \longrightarrow PhS^{\bullet} + ArH$$

$$ArBr + PhS^{\bullet} \longrightarrow \left[R\text{–}\langle\rangle\text{(SPh, Br)}\right] \xrightarrow[-HBr]{PhSH}$$

$$\longrightarrow ArSPh + PhS^{\bullet}$$



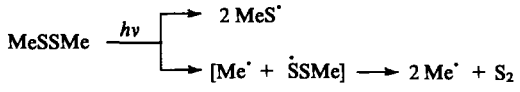
The radicals PhS$^{\bullet}$ play also the role of agents transferring hydrogen atoms from H_2S to the Br$^{\bullet}$ and Ar$^{\bullet}$ radicals in this reaction. The temperature of the thiylation of bromoarenes in



accordance with this scheme decreases after the introduction of a π-dative substituent into the benzene ring. Chloro-derivatives of benzene, thiophene, and naphthalene react with disulfides at higher temperatures than the bromo-derivatives owing to the greater resistance of the C–Cl bond to thermal homolysis.[82–84]

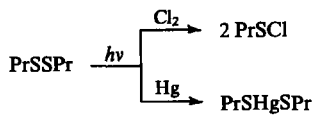
$$RSSR + R^1Cl \xrightarrow{600-630\ ^\circ C} RSR^1 + RSCl$$

R = Alk; R^1 = Ph, 4-MeC_6H_4, $C_{10}H_7$, C_4H_3S, 2-ClC_6H_4, 4-$CF_3C_6H_4$, 3,4-$Cl_2C_6H_3$.



The thiyl radicals generated by the thermolysis of diphenyl disulfide at 550 °C react with acetylene and phenylethyne to form benzo[*b*]thiophene and 2- and 3-phenylbenzo[*b*]thiophenes respectively.[85]

At higher temperatures, the addition of the phenylthiyl radical to phenylethyne and other acetylene homologues leads to phenyl vinyl sulfides.[86,87]



Depending on the wavelength of the radiation, the gas-phase photolysis of disulfides can proceed with homolytic cleavage of both the S–S and C–S bonds.[27] Thus, on irradiation of dimethyl disulfide with UV light at a wavelength < 195 nm, the ratio of the products formed as a result of the homolysis of the C–S and S–S bonds is 1.35 : 1.

When sources of radiation with a wavelength of 254 nm are used, the photolysis of the C–S bond becomes insignificant provided that the alkyl radical is not stabilised by the corresponding functional groups. The main process in this case becomes the homolysis of the S–S bond with formation of thiyl radicals. In the case of primary and secondary dialkyl disulfides, these radicals readily recombine in solution; this is used in the synthesis of asymmetric dialkyl disulfides.

$$RSSR + R^1SSR^1 \overset{h\nu}{\rightleftharpoons} 2\,RSSR^1$$

The equilibrium position is determined by the nature of the alkyl group. In the case of alkyl groups having the normal structure, the ratios RSSR : $RSSR^1$: R^1SSR^1 are 1 : 2 : 1.[27] The photochemical homolysis of the S–S bond in disulfides in the presence of chlorine or elemental mercury leads respectively to sulfenyl chlorides and mercury thiolates.[27]

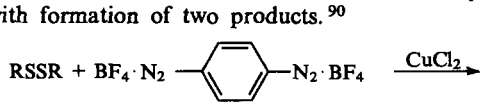
The thiyl radicals generated in the photolysis of diaryl disulfides enter into the homolytic chlorine substitution reaction in trichloro- and tetrachloroethenes, affording $ArSCH=CCl_2$, $ArSCCl=CHCl$, and $ArSCCl=CCl_2$.[88] In liquid ammonia, on UV irradiation in a quartz bulb for 12 h diaryl disulfides react with trifluoromethyl iodide, forming the corresponding aryl trifluoromethyl sulfides.[89]

$$XC_6H_4S-SC_6H_4X \xrightarrow{2\,CF_3I\ (h\nu)} 2\,XC_6H_4SCF_3$$

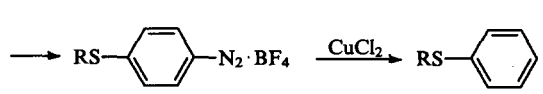
X = H, 4-Cl, 2-NO_2, 4-NO_2.

After prolonged irradiation of diphenyl disulfide and its *para*-chloro-derivative, a series of side products are formed, so that the yields of the corresponding sulfides are 12% and 36% respectively. The presence of the nitro-group hinders the radical side processes and the yields of *p*- and *o*-nitrophenyl trifluoromethyl sulfides reach 58% and 72%.

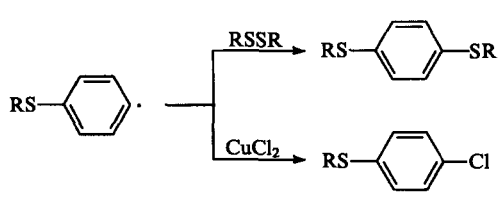
The homolytic cleavage of the S–S bond in disulfides also takes place in the presence of free radicals and compounds which are sources of free radicals (peroxides, diazo-compounds, azo-compounds, etc.). The homolytic cleavage of the S–S bond in disulfides by free radicals constitutes the basis of the polymer chain transfer process in radical polymerisation.[6]



The aryl radicals formed as a result of the cleavage of diazonium salts afford sulfides on reaction with symmetrical disulfides.[90]



$$4\text{-}ClC_6H_4N_2X \xrightarrow[-N_2,\ -X^-]{CuCl_2} 4\text{-}ClC_6H_4^{\bullet}$$



$$4\text{-}ClC_6H_4^{\bullet} + RSSR \longrightarrow 4\text{-}ClC_6H_4SR + RS^{\bullet}$$

R = Bu, $PhCH_2$, Ph; X = Cl, BF_4.

Benzenebisdiazonium tetrafluoroborates arylate disulfides with formation of two products.[90]

R = Bu, Ph, $PhCH_2$.

d. Reduction of disulfides

The reduction of disulfides takes place with cleavage of the S–S bond and the formation of thiols.

$$RSSR \xrightarrow{Red} 2\,RSH$$

A series of preparative methods of synthesis of thiols, described in the scientific literature and in handbooks, have been developed on the basis of this reaction. Zinc in acetic, hydrochloric, and sulfuric acids,[70] metallic sodium in xylene,[70] sodium hydrogen sulfide in alcohol,[29] lithium tetrahydroaluminate in ether or tetrahydrofuran,[91] and the $BF_3 \cdot H_2O - Et_3SiH$ system[92] are used as the reductants. Bis(trifluoromethyl) disulfide is relatively easily reduced in the presence of powdered activated copper in dimethylformamide[89] or acetonitrile.[93]

$$CF_3SSCF_3 \xrightarrow{2\,Cu\ (DMF\ or\ MeCN)} 2\,CF_3SCu \cdot DMF(MeCN)$$

In dimethylformamide, the reaction is exothermic and is completed after 1 h, whereas in acetonitrile the reduction takes place over a period of 14–16 h. The ease of the cleavage of the S–S bond in bis(trifluoromethyl) disulfide in the presence of copper has been explained[93] by the high oxidising capacity of this compound.

The traditional method for the reduction of disulfide bonds in proteins involves the treatment of the protein with a large excess of a thiol. The thiol–disulfide exchange reaction then takes place.[2]

$$RSSR + 2\,R^1SH \rightleftharpoons 2\,RSH + R^1SSR^1$$

Dithiothreitol $HSCH_2CH(OH)CH(OH)CH_2SH$ is used nowadays for such purposes. The reduction of cystine to cysteine in living organisms takes place mainly as a result of the action of the enzyme glutathionecystine-oxidoreductase.[2]

e. Insertion of sulfur and other reagents in the S–S bond

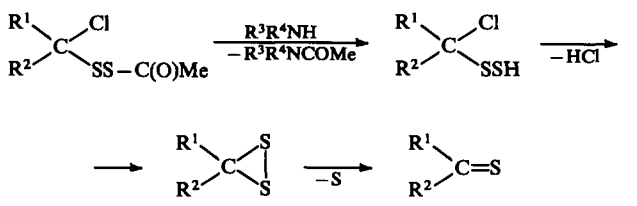
Certain cyclic sulfides and disulfides are converted into trisulfides on interaction with a dihydrodisulfide. It has been suggested[2] that the reaction proceeds via the insertion of sulfur in the S–S bond and not via nucleophilic substitution at a carbon atom.

$$RSSR \xrightarrow{HSSH} \left[RS-\overset{S}{\overset{\|}{S}}R\right] \longrightarrow RSSSR$$

This hypothesis has been confirmed to some extent by the fact that the conversion of sporidesmin (S_2 bridge) into sporidesmin E (S_3 bridge) in the presence of dihydrodisulfide takes place with retention of configuration.

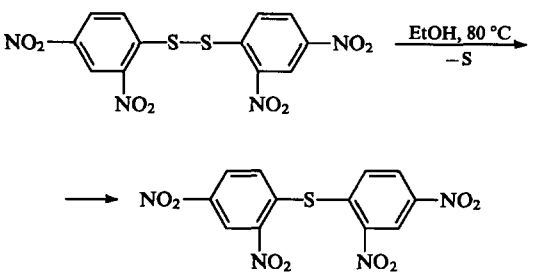
The insertion of carbenes in the S–S bond of disulfides leads to the formation of thioacetals.[94]

$$RSSR + :CH_2 \longrightarrow RSCH_2SR$$



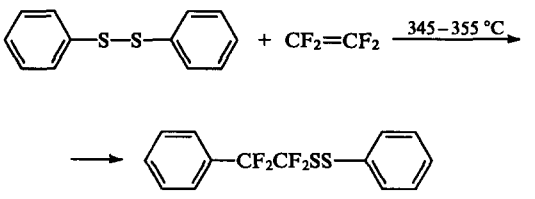
2. Reactions involving the cleavage of a C–S bond

The cleavage of a C–S bond is less characteristic of disulfides than the cleavage of the S–S bond. The cleavage of the S–S bond is sometimes accompanied by the cleavage of a C–S bond, which has already been noted in the case of the photolysis or the thermolysis of disulfides.



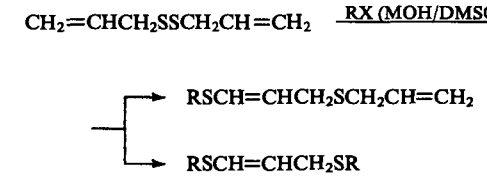
Disulfides containing readily removable groups at the sulfur atom, such as RCO, $PhCH_2$, $HOOCCH_2$, $2,4\text{-}(NO_2)_2C_6H_3$, etc. show the greatest tendency towards the cleavage of a C–S bond. For example, when a diacyl disulfide is acted upon by chlorine, the S–S bond and not a C–S bond is cleaved with formation of acyldisulfenyl chlorides.[72]

$$RC(O)SSC(O)R \xrightarrow{Cl_2} RC(O)SSCl + RC(O)Cl$$



A C–S bond in acetyl α-chloroalkyl disulfides is cleaved by secondary amines with formation of α-chloroalkyl disulfones, which are converted into unstable cyclic disulfides as a result of the elimination of hydrogen chloride.[95]

On heating in alcohol, bis(2,4-dinitrophenyl) disulfide is readily converted into the corresponding sulfide, as a result of the cleavage of the C–S and S–S bonds.[96]



The thermal insertion of tetrafluoroethene in a C–S bond of diphenyl disulfide with formation of phenyl β-phenyltetrafluoroethyl disulfide has been described.[97]

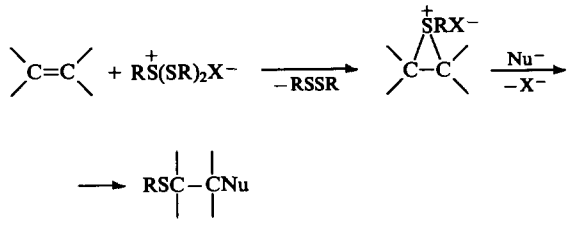
40%

The cleavage of a C–S bond also occurs in various rearrangements of disulfides. Thus diallyl disulfide and its substituted derivatives rearrange to the thioanion $CH_2{=}CHCH_2.SCH_2CH{=}CHS^-$ on treatment with the dimethyl sulfoxide (DMSO)–MOH (M = K, Na) superbasic system.[98] Under the same conditions, the disulfides $RSSCHCH{=}CH_2$ (R = Et, Pr) rearrange to the corresponding thioanions, the subsequent alkylation of which by alkyl iodides leads to the bissulfides $RSCH_2CH{=}CHSR^1$ (R^1 = Pr, Pr^i). The alkylation of diallyl disulfides by alkyl halides in the DMSO–NaOH(KOH) superbasic system leads to 1-alkylthio-3-allylthio-1-propenes and 1,3-di(alkylthio)-1-propenes.[99]

Under similar conditions, 1-alkylthiobuta-2,3-dienes rearrange to 2-alkylthio- and 1-alkylthio-buta-1,3-dienes.[99]

3. Reactions involving an increase in the valence of sulfur

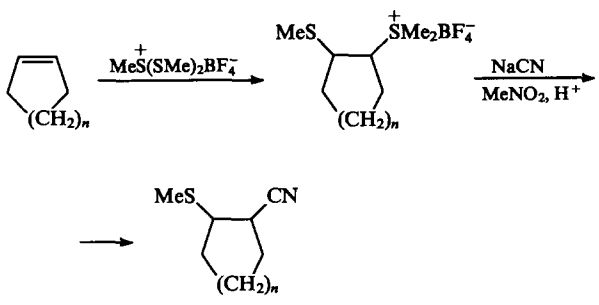
a. The formation of sulfonium complexes



As already mentioned, the interaction of disulfides with sulfenyl halides in the presence of Lewis acids leads to the formation of sulfonium complexes in which the sulfonium cation is stabilised by the anionoid fragment of the Lewis acid.[27,73–75]

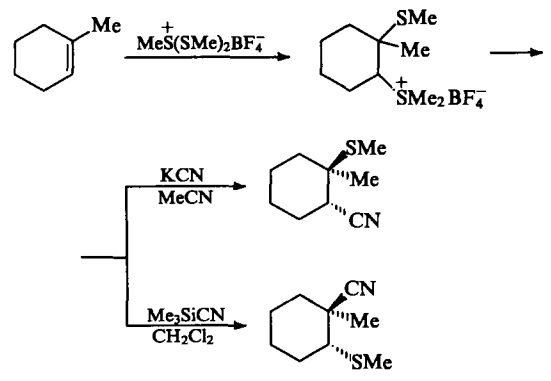
$$RSSR + RSCl + SbCl_5 \longrightarrow R\overset{+}{S}(SR)_2SbCl_6^-$$

Complexes of a similar structure are also formed in the interaction of disulfides with the alkyl esters of trifluoromethanesulfonic acid.[100]



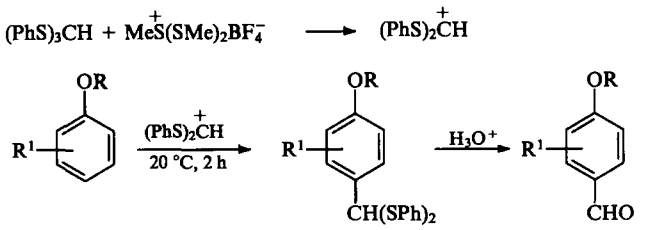
$$(MeS)_2 + CF_3SO_3Me \xrightarrow{CH_2Cl_2,\ 0\,^\circ C,\ N_2} Me\overset{+}{S}(SMe)_2CF_3SO_3^- \quad 84\%$$

Such complexes have found applications in organic synthesis as RS^+ group transfer agents. The interaction of sulfonium complexes with alkenes can proceed differently. In some cases, the reaction involves the formation of episulfonium ions, which undergo ring opening on treatment with nucleophiles, giving rise to sulfides.[100-102]



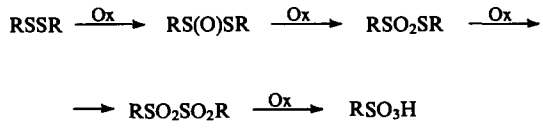
R = Alk, Ar; X = CF_3SO_2, $SbCl_6$, BF_4, etc.

In other cases, for example in the addition of sulfonium complexes to cycloalkenes, adducts are formed, their behaviour in reactions with nucleophiles being similar to that of episulfonium salts. A general mild cyanosulfenylation method has been developed on the basis of this reaction.[27]

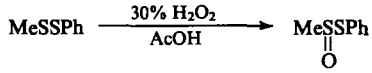


n = 1, 2.

Depending on the conditions in the reaction with nucleophiles, both regioisomers may be obtained.[27]



A method for the regioselective formylation of phenols and naphthols has been developed using sulfonium complexes and thioacetals.[103]



35%-87%

b. Oxidation of disulfides

Depending on the nature of the oxidant and the reaction conditions, the oxidation of disulfides can lead to the formation of thiolosulfinates, thiolosulfonates, disulfones, and sulfonic acids.

Symmetrical thiolosulfinates are formed as a result of the oxidation of symmetrical disulfides by peroxyacids, sodium metaperiodate, and ammonium persulfate or by photosensitised oxidation in the presence of Methylene Blue.[70] Asymmetric thiolosulfinates are formed in the oxidation of asymmetric disulfides by 30% hydrogen peroxide in acetic acid.[104] The oxidation then proceeds regioselectively at the more nucleophilic sulfur atom.

The use of an excess of hydrogen peroxide leads to thiolosulfonates, which are also formed in the oxidation of disulfides by cold nitric acid and vanadium pentoxide[70] or by chlorine in acetic acid with subsequent hydrolysis.[105] The oxidation of asymmetric disulfides by *m*-chloroperbenzoic acid also takes place regioselectively at the more nucleophilic sulfur atom.[106]

The oxidation of disulfides RSSR (R = Me, Bu, Ph, $PhCH_2$) by the $H_2O_2-Na_2WO_4$ system in the presence of acetyltrimethylammonium chloride leads to the formation of the disulfones RSO_2SO_2R in 46%-81% yield.[107]

Disulfides are oxidised by hot nitric, chromic, and performic acids or potassium permanganate to sulfonic acids.[2] The reaction of disulfides with the radical-anion $^-O-O^-$, generated from KO_2 and anhydrous 18-crown 6-ether in dry pyridine at 25 °C, leads to the formation of a mixture of RSO_2^- and RSO_3^-.[108]

The standard method for the cleavage of disulfide bonds in proteins involves treatment of the latter with performic acid. The cysteine and cystine residues are then converted after hydrolysis[2] into cysteic acid $HO_2CCH(NH_2)CH_2SO_3H$. Chlorination of disulfides by chlorine in acetic acid leads to the formation of the chlorides of sulfinic[109] or sulfonic[2] acids.

c. Oxidative imination of disulfides

The reactions accompanied by the oxidation of an element and the formation of the imino-group have come to be called oxidative imination.[110] The oxidative imination of disulfides by *N*-chloro- and *N,N*-dichloro-compounds can lead to the formation of the chlorides, amides, and esters of iminosulfinic acids.

The formation of the chlorides of iminosulfinic acids. The interaction of disulfides with *N,N*-dichloroamides or

N,N-dichloroamines in anhydrous aprotic organic solvents for a 1 : 1 reactant ratio leads to the formation of the chlorides of *N*-substituted iminosulfinic acids and sulfenyl chlorides.[112–115]

$$RSSR + R^1NCl_2 \longrightarrow RS(=NR^1)Cl + RSCl$$

R = Ph, $PhCH_2$, 4-ClC_6H_4, 4-$NO_2C_6H_4$, 2-$NO_2C_6H_4$;
R^1 = $ArSO_2$, ArCO, Bu^t, $Me_2C(CN)$, CF_3SO_2.

In the case of asymmetric disulfides, the sulfenyl chlorides formed contain more highly electron-accepting groups, since the sulfur atom with a high electron density undergoes oxidative imination. The sulfenyl chlorides formed can react further under more severe conditions with *N,N*-dichloro-compounds to form *N*-substituted chlorides of iminosulfinic acids, so that for preparative purposes the reaction is carried out in a single stage without isolating the sulfenyl chlorides. The chlorides of *N*-(benzenesulfonyl)areneiminosulfonic acids are formed in the reaction of diaryl disulfides with chlorine in acetic acid and subsequent treatment of the reaction mixture with the *N,N*-dichloroamide of benzenesulfonic acid.[116]

$$ArSSAr \xrightarrow[AcOH]{Cl_2} 2\,ArS(O)Cl \xrightarrow[-Cl_2]{2\,PhSO_2NCl_2} 2\,ArS(Cl)(O)=NSO_2Ph$$

In the reaction of disulfides with the *N*-chloroamides of carboxylic acids, the chlorides of *N*-acyliminosulfinic acids are obtained.[117]

$$ArSSAr + 3\,RCONHCl \longrightarrow 2\,ArS(=NCOR)Cl + RCONH_2 + HCl$$

The reaction takes place in stages. For a 1 : 1 reactant ratio, *N*-acylsulfenamides and sulfenyl chlorides are formed initially and then react further with the *N*-monochloroamide.

$$ArSSAr + RCONHCl \longrightarrow ArSNHCOR + ArSCl$$

$$ArSNHCOR + RCONHCl \longrightarrow ArS(=NCOR)Cl + RCONH_2$$

$$ArSCl + RCONHCl \longrightarrow ArS(=NCOR)Cl + HCl$$

The interaction of diaryl disulfides with the alkyl esters of *N*-chlorobenzenecarboxyimidic acid for a 1 : 1 reactant ratio leads similarly to the formation of the corresponding alkyl esters of *N*-(arylthio)benzenecarboxyimidic acid and arenesulfenyl chlorides. The latter react further with the *N*-chloroimino-ester, affording the chlorides of *N*-benzoylareneiminosulfinic acids.[118]

$$ArSSAr + ClN{=}C(OAlk)Ph \longrightarrow ArSN{=}C(OAlk)Ph + ArSCl$$

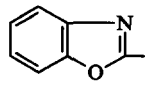
$$ArSCl + ClN{=}C(OAlk)Ph \longrightarrow ArS(=NCOPh)Cl + AlkCl$$

The oxidative imination of disulfides by sodiochloroamides of sulfonic acids in aqueous media leads to the amides of aminosulfinic acids.[119–121] As in the oxidation of thiols to disulfides,[122] the reactivity of the disulfides with respect to the sodiochloroamides of sulfonic acids is then directly related to the pK_a of the corresponding thiols the residues of which form the disulfides. Consequently the acid properties of thiols can be used as a quantitative criterion for the estimation of the reactivities of disulfides with respect to the sodiochloroamides of sulfonic acids. Indeed, it has been shown[121] that the disulfides for which the pK_a for the corresponding thiols are in the range 7–11 are relatively easily iminated by the sodiochloroamides of sulfonic acids. A decrease in the pK_a for the thiols to 5–6 leads to a decrease in the rate of the imination reaction and in the yield of the amides of iminosulfinic acids. The disulfides where the pK_a for the corresponding thiols are less than 5 are not iminated by the sodiochloroamides of sulfonic acids. Such disulfides contain as a rule highly electron-accepting groups at the sulfur atoms which reduce the nucleophilicity of the latter. The imination of asymmetric disulfides by the sodiochloroamides of sulfonic acids takes place regioselectively at the more nucleophilic sulfur atom.[123] From the standpoint of the acid properties of the corresponding thiols, this means that the pK_a for the thiol the residue of which is iminated is higher than that for the thiol the residue of which is eliminated. This residue gives rise to symmetrical disulfides.

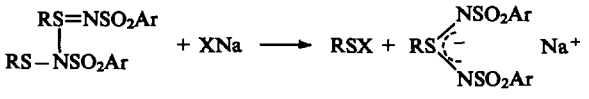
$$RSSR^1 + 2\,PhSO_2NNaCl\cdot xH_2O \xrightarrow[-0.5\,R^1SSR^1,\ -2\,NaCl]{} RS(=NSO_2Ph)NHSO_2Ph$$

R = Bu; R^1 = 4-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$;
R = Ph; R^1 = 4-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$;
R = 4-MeC_6H_4; R^1 = 2,4-$(NO_2)_2C_6H_3$;
R = $PhCH_2$; R^1 = 2,4-$(NO_2)_2C_6H_3$.

The interaction of *N,N*-dichloro-compounds with sodium thiolates, which results in the formation of the sodium salts of the amides of iminosulfinic acids,[125–133] proceeds via a disulfide formation stage.

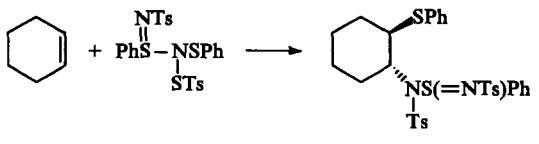


$$5\,RSNa + 2\,R^1NCl_2 \xrightarrow[-2\,RSSR,\ -2\,NaCl]{} RS(=NR^1)N(Na)R^1$$



R = Alk, Ar, Het, $AlkOCOCH_2$, $ArNHCOCH_2$;
R^1 = $ArSO_2$, ArCO, $(PhO)_2P(O)$, $(NCCH_2CH_2)_2NC(O)$.

In inert solvents and in the absence of moisture, diaryl disulfides react with the sodiochloroamides of sulfonic acids, forming *N*-arylthio-*N,N'*-bis(arenesulfonyl)arenesulfinamidines,[134–136] which are also obtained on interaction of sodium thiolates with the dichloroamides of sulfonic acids for a 2 : 1 reactant ratio.[137–140] These compounds have found applications in organic synthesis as ArS^+ transfer agents in reactions with nucleophiles[138] and unsaturated compounds.[135]



$$RSSR + 2\,ArSO_2NNaCl \xrightarrow[-NaCl]{} RS(=NSO_2Ar)N(SR)SO_2Ar$$

$$4\,RSNa + 2\,ArSO_2NCl_2 \xrightarrow[-RSSR,\ -4\,NaCl]{} RS(=NSO_2Ar)N(SR)SO_2Ar$$

R = Ph, 4-MeC_6H_4, 

X = OH, RS, RO, $ArSO_2NH$.

It is believed[124,133,138] that *N*-arylthio-*N,N'*-bis(arenesulfonyl)arenesulfinamidines are intermediates in the reactions of disulfides with the sodiochloroamides of sulfonic acids in aqueous media and also of sodium thiolates with the dichloroamides of sulfonic acids for a 5 : 2 reactant ratio. The sequence of the reactions in the imination of thiols by the sodiochloroamides of sulfonic acids is therefore as follows:

$$2\,RSH + ArSO_2NNaCl\cdot xH_2O \longrightarrow RSSR + ArSO_2NH_2 + NaCl$$

$$RSSR + 2\,ArSO_2NNaCl \longrightarrow$$

$$\longrightarrow RS(=NSO_2Ar)N(SR)SO_2Ar + 2\,NaCl$$

$$RS(=NSO_2Ar)N(SR)SO_2Ar + H_2O \longrightarrow$$

$$\longrightarrow RS(=NSO_2Ar)NHSO_2Ar + RSOH$$

$$RSOH \longrightarrow 0.2\,RSO_3H + 0.4\,RSSR + 0.4\,H_2O.$$

The introduction into the reaction of yet another mole of the sodiochloroamide of the sulfonic acid can lead to the formation of an additional amount of the iminosulfinamide, but the disulfide does not fully disappear from the reaction mixture, since it is reformed as a result of the disproportionation of the sulfenic acid. The formation of an appreciable amount of side products naturally reduces the yield of the amides of iminosulfinic acids, which does not as a rule exceed 60% in this case.

The interaction of disulfides with the *N*-chloroamides of carboxylic[117,141,142] and phosphonic acids[143] in anhydrous organic solvents (CH_2Cl_2, CCl_4) in the presence of pyridine leads to the formation of *N,N'*-disubstituted amides of iminosulfinic acids.

$$RSSR + 4\,AcNHCl + 3\,C_5H_5N \xrightarrow[-2\,C_5H_5N\cdot HCl \\ -\,C_5H_5N\cdot Cl_2]{} 2\,RS(NAc)-NHAc$$

R = Me, Bu, C_5H_{11}, C_7H_{15}, Ph, 4-MeC_6H_4, 4-$NO_2C_6H_4$;

Ac = PhCO, $(PhO)_2PO$.

In the absence of bases and for a 1 : 2 reactant ratio, diazasulfonium salts are formed. They decompose on heating with formation of *N,N'*-diacylsulfinamidines.[117]

$$ArSSAr + 2\,RCONHCl \longrightarrow Ar\overset{+}{S}(NHCOR)_2Cl^- \xrightarrow[-\,HCl]{\Delta}$$

$$\longrightarrow ArS(=NCOR)NHCOR$$

The formation of iminosulfinic acid esters. The interaction of disulfides with the sodiochloroamides of sulfonic acid in alcoholic media leads to the formation of a mixture of amides and alkyl esters of iminosulfinic acids.[144] The formation of iminosulfinic acid esters is due to the interaction, according to the authors,[144] of the intermediate chlorides of the iminosulfinic acids with alcohols.

$$RSSR + TsNNaCl \longrightarrow \left[RS(Cl)=NTs\right] \longrightarrow$$

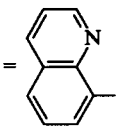
$$\xrightarrow[-Cl^-]{TsNH^-} RS(=NTs)NHTs$$

$$\xrightarrow[-HCl]{R^1OH} RS(=NTs)OR^1$$

On the other hand, according to Levchenko,[124] the formation of iminosulfinic acid esters is caused in this case by the imination of the sulfenic acid esters formed as a result of the cleavage of *N,N'*-bis(arenesulfonyl)-*N*-(R-sulfenyl)sulfinamidines in the presence of alcohols.

$$RSSR + 2\,TsNNaCl \xrightarrow[-2NaCl]{} RS(=NTs)N(SR)Ts$$

$$RS(=NTs)N(SR)Ts + R^1OH \longrightarrow$$



$$\longrightarrow RS(=NTs)NHTs + RSOR^1$$

$$RSOR^1 + TsNNaCl \xrightarrow[-NaCl]{} RS(=NTs)OR^1$$

The formation of the alkyl esters of iminosulfinic acids has been noted[145,146] in the reaction of disulfides with the *N,N'*-dichloroamides of sulfonic acids in the presence of alkalis in alcoholic media.

$$RSSR + 2\,PhSO_2NCl_2 + 2\,R^1OH + Na_2CO_3 \xrightarrow[-2NaCl,\,-2CO_2,\\ -Cl_2,\,-H_2O]{}$$

$$\longrightarrow 2\,RS(=NSO_2Ph)OR^1$$

R =  ; R^1 = Me, Et.

4. The applications of disulfides

a. Biological activity

Disulfides occur to a much lesser extent in many biologically active preparations than other compounds of divalent sulfur. They are used much more often as initial compounds or intermediates in the manufacture of biologically active substances.[7] However, individual representatives of disulfides exhibiting a relatively high biological activity are also encountered. For example, it has been noted[2,3] that 1-methylthiopropyl propenyl and *sec*-butyl 3-methylthioallyl disulfides, isolated from the resin of *Asa foetida*, exhibit a relatively high insecticidal activity. Glyotoxin and sporidesmin possess antifungal, antibacterial, and antiviral activities.[147]

b. The use of disulfides in polymer chemistry

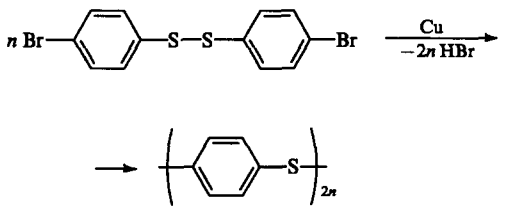
Certain disulfides, in particular bis(2-benzothiazolyl) disulfides have found extensive applications as accelerators of the vulcanisation of rubbers.[5] Bis(*o*-benzamidophenyl) disulfide is used as the accelerator of the plasticisation of cured rubbers and bis(2,4-dimethylphenyl) disulfide is employed as an accelerator of the regeneration of cured rubbers.[148]

Disulfides are effective polymer chain transfer agents in radical polymerisation reactions,[6] since the thiyl radical formed as a result of chain transfer is relatively reactive and participates in the initiation of a new chain.

$$\sim CH_2\dot{C}H(R) + RSSR \longrightarrow \sim CH_2CH(R)SR + RS^{\cdot}$$

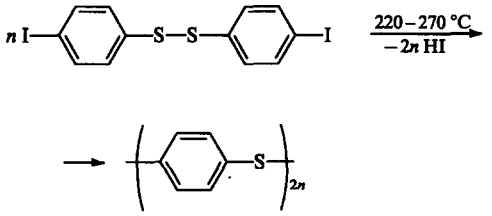
$$RS^{\cdot} + CH_2{=}CHR \longrightarrow RSCH_2\dot{C}H(R)$$

The ability of disulfides to transfer a polymer chain is characterised by the transfer constant *C*, which is equal to the ratio of the transfer rate constant K_f to the chain propagation constant K_p:



$$C = K_f / K_p$$

The higher the transfer constant, the more readily are disulfides subjected to attack by a free radical.



The chain transfer constants for disulfides are lower than for the corresponding peroxide compounds. For example, the chain transfer constant for dibenzoyl disulfide is five times lower than for benzoyl peroxide, which can be explained, on the one hand, by the smaller strength of the O–O bond in peroxides compared with that of the S–S bond in disulfides and, on the other, by a different chain transfer mechanism in the case of peroxide compounds. The main reaction for disulfides is the cleavage of the S–S bond by the macroradical, while for peroxide compounds it is the abstraction of a hydrogen atom.

It has been noted [149] that bis(glycylaminophenyl) disulfides are iniferters, which make it possible to obtain hydrophobic [poly(methylmethacrylate), polystyrene] and hydrophilic (poly-*N*-methylmethacrylamide) macroinitiators with a wide set of molecular masses, which can be used for the synthesis of block-copolymers of the A–B–A type.

The synthesis of poly(1,4-phenylene sulfide) in which bis-(4-bromophenyl) disulfide is used as a monomer has been described. [150]

The synthesis is carried out in a boiling mixture of quinoline and pyridine in the presence of equimolecular amounts of copper powder. The reaction takes place over a period of 8 h with formation of poly(phenylene sulfide) with a molecular mass $\leqslant 4000$ and in 76% yield. The synthesis of poly(1,4-phenylene sulfide) by the thermolysis of bis(4-iodophenylene) disulfide has been described. [151]

The thermolysis is carried out at 220–270 °C in diphenyl ether. The polymer formed has a molecular mass of 20 000 and a high mechanical strength and thermal stability.

* * *

Thus the studies in the chemistry of disulfides during the last 10–15 years have been largely directed to further development of the methods of synthesis of disulfides already known and to the search for new ones (syntheses based on alkylthiotrimethylsilanes, thiocyanates, sulfenyl thiocyanates, etc.). Much attention has been devoted to the study of the reactivity of disulfides and in particular of reactions occurring with formation of sulfonium complexes and imino-compounds of tetravalent sulfur. The previous studies on the use of disulfides in polymer chemistry underwent further development in recent years.

Abstract. The reaction pathways leading to the degradation of the carbon chain in the liquid-phase oxidation reactions of saturated hydrocarbons and their oxygen-containing derivatives are examined. The relative importance of the pathways and their dependence on the structure of the substrate and of the oxidation conditions are discussed. The bibliography includes 151 references.

I. Introduction

Reactions involving the extensive oxidation of saturated hydrocarbons by molecular oxygen in the liquid phase lead to a wide variety of oxygen-containing compounds. The formation under these conditions of compounds with a lower molecular mass than that of the initial hydrocarbon is associated with the degradation of the carbon chain, which occurs to some extent in virtually all the stages of these complex radical-chain processes.

In conformity with the ideas which arose in the 1950s – 1960s and which have been quite fully surveyed in monographs [1,2] and reviews, [3,4] it was assumed that the carbon chain is ruptured mainly in the stages following the formation of ketones, for example in the stage involving the decomposition of α-ketohydroperoxides. However, later experimental data were obtained indicating that, in the oxidation of alicyclic, [5] aliphatic, [6] and to a lesser extent aromatic [7–9] ketones, the decomposition of α-hydroperoxyketones leads preferentially to α-ketoalcohols and α-diketones and that the reactions of these substances actually provide the main routes to the degradation of the carbon chain, including those associated with the formation of carboxylic acid anhydrides. [10–20]

The possibilities for the occurrence of reactions leading to the dissociation of the C – C bond in liquid-phase oxidation processes are discussed in the present review. An attempt is made to trace the influence of the structure of the substrate, temperature, and the medium on the probability of the occurrence of such reactions. The principal pathways leading to the formation of esters in autoxidation reactions are examined.

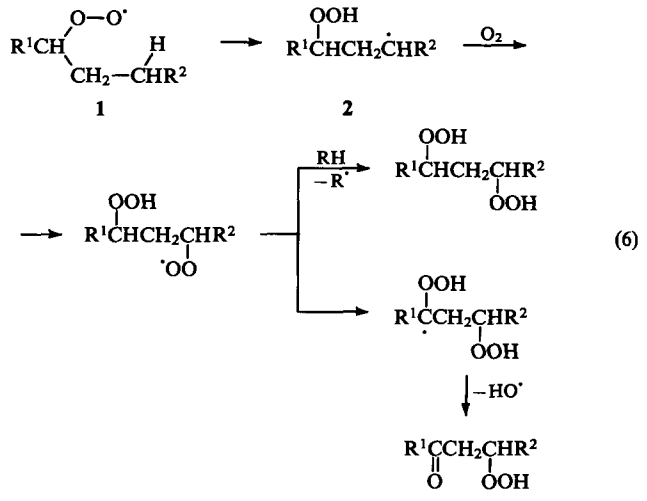
II. Dissociation of C – C bonds in the stages involving the formation and decomposition of hydrocarbon hydroperoxides

The oxidation reactions of hydrocarbons and their oxygen-containing derivatives in the absence of initiating additives are known to include [1,2,21,22] the chain initiation (1), propagation (2, 3), and termination (4) stages:

$$RH + O_2 \longrightarrow R^{\cdot} + HO_2^{\cdot}, \quad (1)$$

$$R^{\cdot} + O_2 \longrightarrow RO_2^{\cdot}, \quad (2)$$

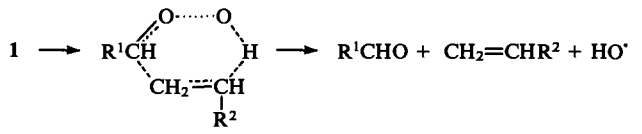
$$RO_2^{\cdot} + RH \longrightarrow ROOH + R^{\cdot}, \quad (3)$$



$$2\,RO_2^{\cdot} \longrightarrow \text{molecular products}. \quad (4)$$

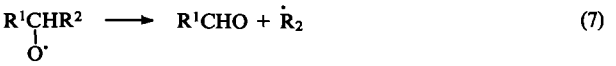
They also involve the degenerate branching stage — unimolecular decomposition of hydroperoxides, i.e.

$$ROOH \longrightarrow RO^{\cdot} + HO^{\cdot}, \quad (5)$$



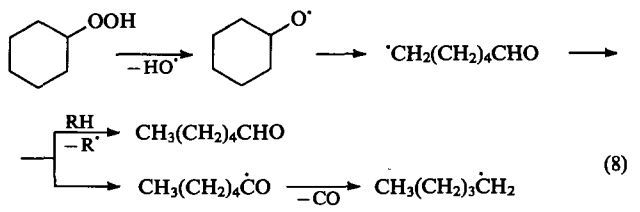
or decomposition with participation of the substrate and the oxidation products, which leads, incidentally, also to the radicals $RO^{\cdot}$. [21,22]

The peroxyl radicals $RO_2^{\cdot}$, formed by reaction (2), are capable of abstracting hydrogen from the substrate molecules [1,2,21–25] [reaction (3)] and of isomerising to type **2** radicals, which are subsequently converted into β- or γ-dihydroperoxides or hydroperoxyketones. [25]



(6)

There are data indicating that the secondary peroxyl radicals can decompose with degradation of the carbon chain.[26]

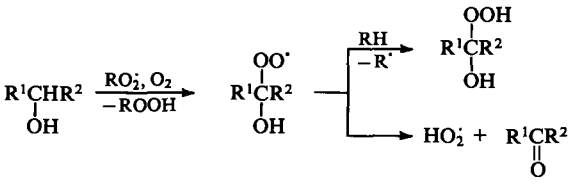


Incidentally, the probability of the degradation via this route is apparently low; it has been shown[26] that, in the sensitised oxidation of pentadecane at 130 °C, the rate of accumulation of unsaturated compounds is only 0.04% of the rate of the radical-chain oxidation.

Secondary monohydroperoxides decompose predominantly without the cleavage of the carbon skeleton, affording approximately equal amounts of alcohols and ketones. The reaction products were then found to include also those whose origin can be explained by the degradative decomposition of oxyl radicals.[27,28]

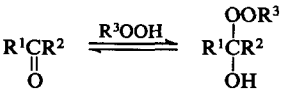
(7)

Thus the cyclohexyl hydroperoxide decomposition pathway leads to caproic aldehyde[27-29] and carbon monoxide.[29]



(8)

It has been shown[29] that 56% of the cyclohexyloxyl radicals generated from *tert*-butyl cyclohexyl peroxide (TBCHP) in cyclohexane are converted into cyclohexanol and only 8% decompose with decarbonylation. This factor as well as data[21] indicating a low contribution of the homolytic pathway to the overall decomposition of hydroperoxides indicate a low contribution of type (7) reactions to the formation of the hydrocarbon chain degradation products in the extensive oxidation process. Incidentally, their role may increase when the radical decomposition of hydroperoxides is stimulated, for example in the presence of cobalt salts,[21] and also with increase in temperature and in an inert solvent.[29]

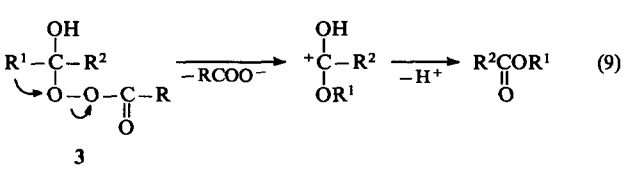


Reliable data concerning the mechanism of the reaction of the dihydroperoxides formed via reactions (6) have apparently not been obtained hitherto. It is postulated that they are less stable than the secondary monohydroperoxides.[30]

III. Degradation of the carbon chain in the oxidation of secondary alcohols and in the interaction of ketones with peroxide compounds

The secondary alcohols formed on decomposition of monohydroperoxides readily undergo the radical-chain oxidation at the α-C–H bonds, the reactivity of which is significantly higher than in hydrocarbons.[1,2,29] The reaction proceeds via the intermediate formation of the α-hydroxyperoxyl radical, which either abstracts hydrogen from a substrate molecule and is converted into a α-hydroxyhydroperoxide or decomposes into a ketone and a hydroperoxyl radical.[2,31]

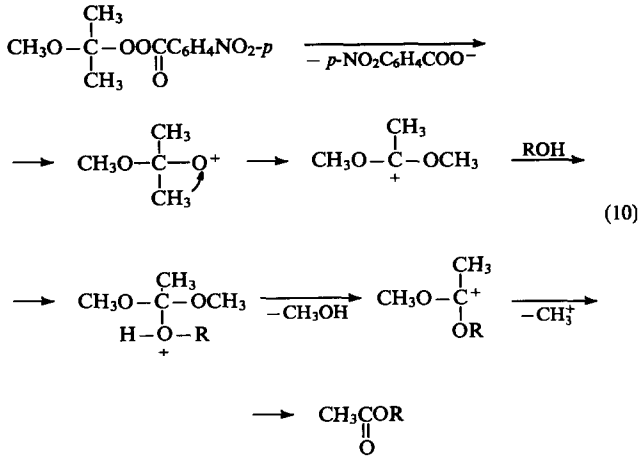
Secondary α-hydroxyhydroperoxides can also be formed as a result of the acid-catalysed reversible nucleophilic addition of H_2O_2 to ketones; in the analogous addition of hydroperoxides or peracids, α-hydroxyperoxides or α-hydroxyperesters are formed respectively.[2]



R^3 = H, Alk, Ac.

The mechanism of the subsequent reactions of the α-hydroxyperesters differs significantly from the mechanisms of the decomposition of α-hydroxyhydroperoxides and α-hydroxyperoxides.

The principal aspects of the oxidation of ketones by peracids (the Baeyer–Villiger reaction), leading to the rupture of the carbon chain, have been considered in reviews.[32-34] The reaction takes place under the conditions of general acid catalysis.[35-37] The peroxide 3 (the Criegee intermediate) formed in the first stage [reaction (9)] undergoes a rapid 1,2-rearrangement. In hydrocarbon solvents, the first stage of the process is rate-limiting.[35] In the oxidation of cyclic ketones by perbenzoic acid, the rate of reaction decreases in the sequence cyclohexanone > cyclopentanone > cycloheptanone, which is consistent with the decrease in the reactivity of the carbonyl groups of the above ketones in the same sequence.[36]

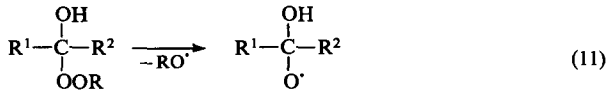


The rearrangement of the Criegee intermediate proceeds via an ionic mechanism[32,37,38] [reaction (9)], which is consistent with data indicating the transfer of the carbonyl oxygen of the ketone to the carbonyl group of the ester.[37]

(9)

3

The ionic nature of reaction (9) has been quite convincingly demonstrated by studying the decomposition of 2-methoxy- and 2-ethoxy-2-propyl *p*-nitroperbenzoates in methanol or ethanol.[38] Methyl acetate is formed in a ~100% yield in the decomposition of 2-methoxy-2-propyl *p*-nitroperbenzoate in methanol, whereas in the case where the reaction is carried out in ethanol up to 93% of ethyl acetate is obtained. Similarly, methyl acetate is formed preferentially from 2-ethoxy-2-propyl *p*-nitroperbenzoate in methanol. It has been suggested[38] that the carbonium ion formed in the stage involving the rearrangement of 2-alkoxy-2-propyl *p*-nitroperbenzoates interacts with the solvent and is converted into an orthoester and then into an ester.

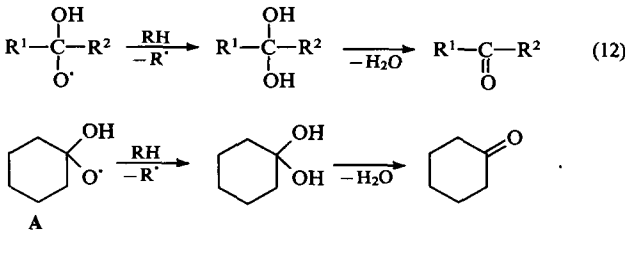


(10)

Robertson and Swelin [39] concluded that the homolytic decomposition of the Criegee intermediate can take place in parallel with the ionic decomposition, but this hypothesis apparently requires an additional experimental test.

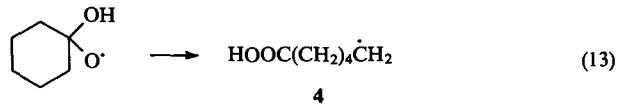
The ability of the radicals to migrate in the Baeyer–Villiger reaction depends on their structure [40–43] and decreases in the sequence *tert*-butyl > cyclohexyl > isopropyl > benzyl > cyclopentyl > neopentyl > ethyl > methyl. [40]

In contrast to α-hydroxyperesters, α-hydroxyperoxides are in all probability incapable of undergoing heterolytic decomposition under the conditions of liquid-phase oxidation in nonpolar media because its products should be, as in reaction (9), esters or lactones which are not formed in appreciable amounts in this instance. [44,45] This factor is evidently associated with the fact that the HO and RO groups are poorer leaving groups compared with RCOO. [46] The heterolysis of the O–O bond in the α-hydroxyhydroperoxide or α-hydroxyperoxide is therefore possible only after the modification of the leaving groups, for example by protonation. Aliphatic carboxylic acids are probably incapable of participating in such a modification. However, it is known that esters or lactones are formed in the oxidation of ketones by hydrogen peroxide in the presence of inorganic acids [32] and also in the oxidation by a hydroperoxide + Lewis acid mixture. [47]



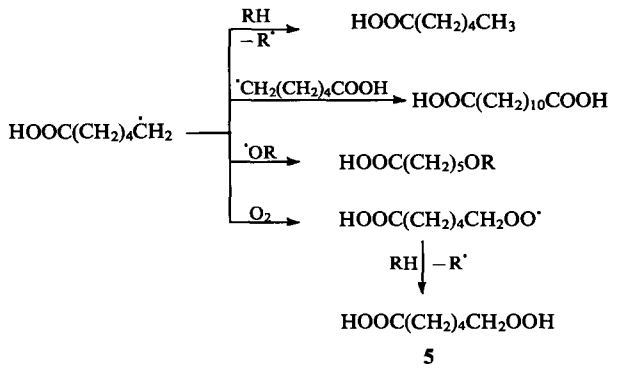
The principal pathway to the formation of products of the degradation of α-hydroxyhydroperoxides and α-hydroxyperoxides involves homolytic decomposition and leads initially to α-hydroxyoxyl radicals.

(11)



The rate constant for reaction (11) is known to be approximately an order of magnitude greater than the rate constant for the homolytic decomposition of hydrogen peroxide or hydroperoxides. [2,48–52]

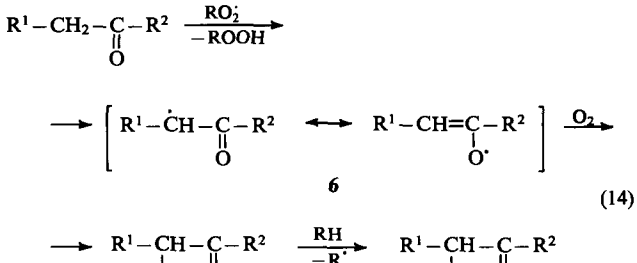
The subsequent reactions of the α-hydroxyoxyl radicals depend on the reaction conditions. [29,53] It has been shown for the 1-hydroxycyclohexyloxyl radical **A** [29] that, in a reactive solvent at a temperature below 80 °C, it is converted preferentially into a ketone via the reaction



(12)

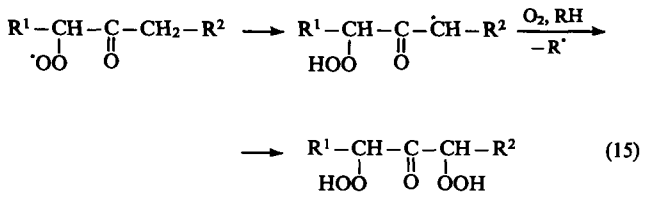
With increase in temperature [29] and in an inert solvent (for example, in benzene), [53] the isomerisation of the radical **A** to the ω-carboxyalkyl radical **4**, occurring with dissociation of the C–C bond, is more probable.

(13)



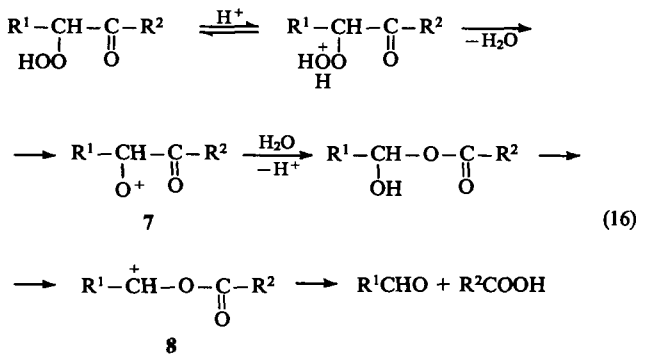
The radical **4** can combine with oxygen, being converted subsequently into the ω-carboxyhydroperoxide **5**, can dehydrogenate the substrate with formation of caproic acid, [54,55] can dimerise to decanedicarboxylic acid [54–56] (which, incidentally, is unlikely under oxidation conditions), and can recombine in a solvent cage with the oxyl radical [52,57] formed simultaneously with the radical **4** via a type (11) reaction.

The role of type (11) reactions should increase on stimulation of the radical decomposition of α-hydroxyperoxides, for example in the presence of variable-valence metal salts. It is significant that this route to oxidative degradation can lead to carboxylic acids, bypassing the ketone formation stage. [53]



IV. Reactions of α-ketohydroperoxides in the radical-chain oxidation of ketones

Apart from the nonchain interactions with peroxide compounds, ketones are capable of undergoing oxidation via a free-radical mechanism preferentially at the α-C–H bonds. [1,2] The reactivity of the α-C–H bonds of ketones is 12–16 times higher than in hydrocarbons, [1,29,58–60] which is due to the resonance stabilisation of the intermediate radical **6** (stabilisation energy ~17 kJ mol^{-1}) [61]



(14)

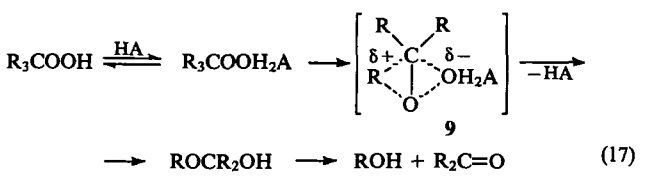
In the oxidation of long-chain aliphatic ketones, [62–65] significant deviations of the composition of the products from that postulated on the basis of the α-mechanism are observed, which is a consequence of the involvement in the oxidation process of C–H bonds remote from the carbon atom of the carbonyl group, and of the isomerisation of α-ketoperoxyl radicals [a type (6) reaction], [1,24] which can also proceed via the intermediate formation of a six-membered reaction ring incorporating the carbonyl group. [24,66–67]

(15)

It was assumed that the α-ketohydroxyperoxides formed via reaction (14) decompose preferentially with degradation of the carbon chain, which leads, in conformity with the familiar acid-catalytic Langenbeck–Pritzkov mechanism, to compounds with functional carbonyl and carboxy-groups.[2,68–76]

(16)

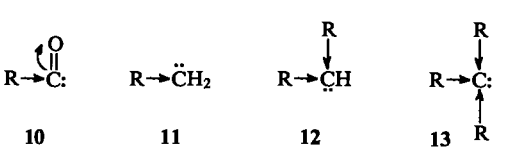
Results casting doubt on the universality of the Langenbeck–Pritzkov mechanism as the principal route to the degradation of the carbon chain in liquid-phase oxidation processes have been obtained comparatively recently. Pritzkov's data[69,70] indicating the preferential formation of 6-oxo-1-hexanoic acid in the decomposition of 2-hydroperoxycyclohexanone were not confirmed in the studies of Perkel' and Freidin[5] and Korsak et al.;[77] the yield of the acid in this reaction did not exceed 15%. The yield of 6-oxo-1-hexanoic acid did not increase also when the reaction was carried out in the presence of cobalt salts[5,77] and acetic acid.[77] These factors are associated with the fact that 2-hydroperoxycyclohexanone is largely converted into 2-hydroxycyclohexanone.[5]



The yield of the ketoalcohol in the thermal decomposition (at 120 °C) of hydroperoxycyclohexanone, obtained by the oxidation of cyclohexanone, depends on the conversion of the ketone and averages 60%.[5] Together with 2-hydroxycyclohexanone (74%), another compound, also formed from the hydroperoxide without the degradation of the carbon chain, namely cyclohexane-1,2-dione (12%), was found among the products of the cobalt naphthenate-catalysed decomposition of 2-hydroperoxycyclohexanone at 80 °C.[5] The conversion of 2-hydroperoxycyclohexanone into 2-hydroxycyclohexanone not only on decomposition of the hydroperoxide under an inert atmosphere but also under oxidation conditions is indicated by the formation, in the initial stages of the noncatalysed and chromium and cobalt salt-catalysed oxidation of cyclohexanone, of a ketoalcohol as the main product.[11,78]

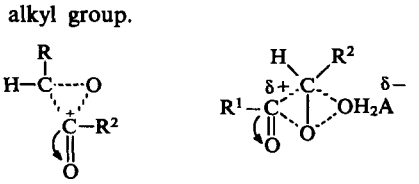
Decomposition without the destruction of C–C bonds is not characteristic solely of 2-hydroperoxycyclohexanone.[6–9] Thus the main products of the thermal reaction of 3-hydroperoxybutanone in oxidised butanone were found to be diacetyl and acetoin.[6] Although the yield of the products (benzoin and benzil) formed without the rupture of the carbon chain in the thermal decomposition of 2-hydroperoxy-1,2-diphenylethanone in oxidised 1,2-diphenylethanone was in fact lower than in the decomposition of 2-hydroperoxycyclohexanone or 3-hydroperoxybutanone, nevertheless it reached 38%–40% in this case also relative to the hydroperoxide which has reacted.[7–9]

It follows from the data presented above that the yield of the products associated with the dissociation of C–C bonds is significantly lower in the decomposition of aliphatic and alicyclic α-ketohydroperoxides than had been supposed earlier. On the other hand, in the decomposition of the hydroperoxides of aromatic ketones the degradation of the carbon chain may predominate.[45,67,79–82]



The mechanism of the degradation of the hydrocarbon chain in the decomposition of α-ketohydroperoxides is apparently obscure. Apart from the acid-catalytic mechanism mentioned above [Eqn (16)] postulated by Langenbeck and Pritzkov, homolytic[3,29,67,79–82] and dioxetane[83–85] mechanisms have been described.

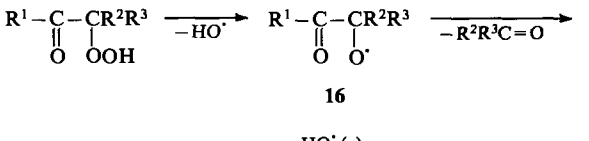
The main evidence in support of the acid-catalytic mechanism is the similarity of the yields of compounds with carbonyl and carboxy-groups observed in the oxidation of a series of ketones and the acceleration of the decomposition of α-ketohydroperoxides in the presence of acids. However, the formation of the oxonium cation **7** has not yet been confirmed experimentally. Yablokov[86,87] demonstrated quite convincingly in relation to cumenyl hydroperoxide that hydrocarbon peroxides do not decompose via the acid-catalytic mechanism [Eqn (16)], since even in a strongly acid medium (HA) the rearrangement of cumenyl hydroperoxide proceeds most probably via the cyclic activated state **9** and not via the type **7** oxonium cation.[86,87]



(17)

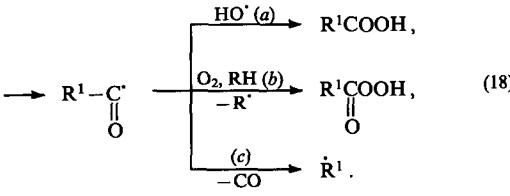
The mechanism (16) presupposes the preferential migration of the acyl carbanion. This hypothesis is controversial for the following reasons. In the mechanisms (16) and (17), the most nucleophilic group, which stabilises most effectively the transition state and the carbonium ion **8** formed after the migration, should migrate to the electron-deficient oxygen atom.[89] However, the acyl carbanion **10** is a weaker nucleophile than the primary, secondary, and especially tertiary hydrocarbon carbanions **11**–**13** respectively, and the probability of its migration should therefore be minimal from the standpoint of nucleophilicity.

The second cause is that the transition states formed on migration of the acyl group are less stable than those formed on migration of the hydrocarbon carbanion, because the sp^2-hybridised carbon atom of the acyl group, the valence bonds of which are disposed at an angle of 120°, produces a greater strain in the reaction ring than the sp^3-hybridised carbon atom in the alkyl group.



Furthermore, the transition state in the rearrangement of α-ketohydroperoxides is less stable than that obtained in the reaction of alkyl hydroperoxides because the oxygen atom increases the partial positive charge on the acyl carbon atom.

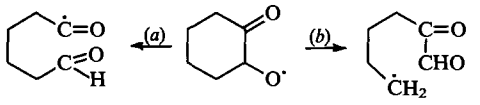
There are three possible types of the 1,2-rearrangement of the oxyl cation **7** which lead to the carbonium ions **8**, **14**, and **15** (Scheme 1).



Examination of the resonant structures **8a, b, 14a–c**, and **15a–c** shows that they can be arranged in the following sequences in order of decreasing stability: **8a** > **14a** ~ **15a**, **14b** ~ **15b** > **8b**, and **14c** > **15c**. At first sight, it appears that the structure **8a** should be more stable than the structures **14a** and **15a**, but the cation **8** is apparently less stable than the cations **14** and **15** because it can have only two limiting structures and there is no structure which would make it possible to stabilise it in the way typical of the allyl carbonium ion, as happens in the cations **14** and **15**.

Thus the existing theoretical ideas [the mechanisms (16) and (17)] concerning the mode of the oxidative degradation reaction of hydrocarbons are in poor agreement with the preferred conversion of the α-ketohydroperoxide into a carboxylic acid and a carbonyl compound. Consequently they are inconsistent with the Langenbeck–Pritzkov mechanism.

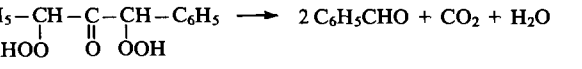
The homolytic mechanism of the degradative reaction of α-ketohydroperoxides has been justified in a number of studies.[29,45,67,79–82] Thus the composition of the products of the oxidation of isopropyl methyl ketone indicates, according to Itoh et al.,[82] the decomposition of the primary reaction product (3-hydroperoxy-3-methylbutan-2-one) via the mechanism



16

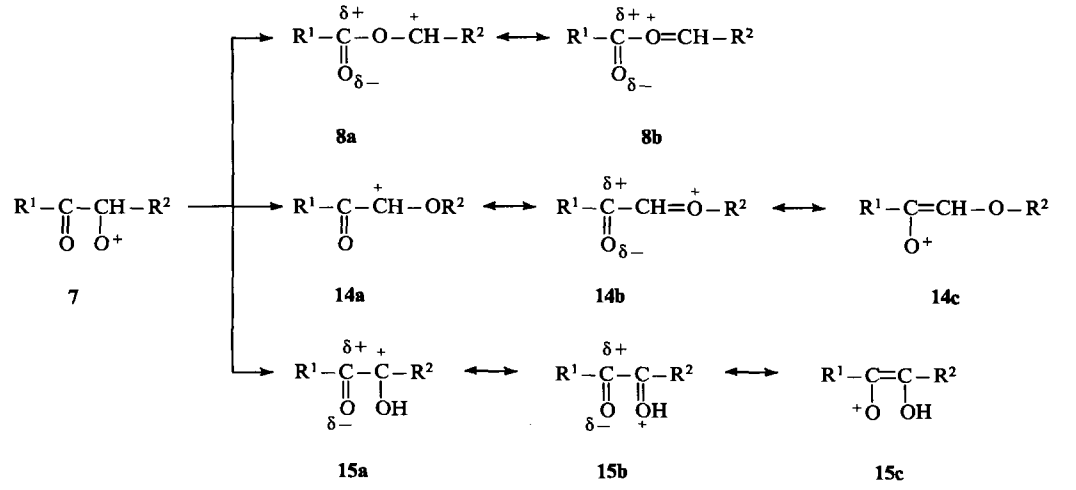
(18)

The reactions of tertiary α-ketohydroperoxides, studied by Ogata and Savaki,[79–81] proceed via a similar mechanism. α-Diketones are then formed in a small amount, probably via the elimination of hydrocarbon groups from the radical **16**. It has been shown that the photolysis of α-ketohydroperoxides in the presence of oxygen leads to a peracid (pathway *b*).[81] The rate of decomposition of α-acyloxyl radicals with destruction of a C–C bond is approximately two orders of magnitude higher than the rate of abstraction of a hydrogen atom from the solvent by this radical with formation of a α-ketoalcohol. This factor is apparently associated with the increased stability of the benzoyl radicals obtained on fragmentation. They are stabilised by the $+E$ effect of the aromatic ring.



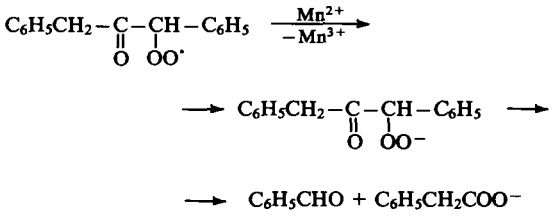
The study of the composition of the products of the oxidation of cyclohexanone led Pritzkov and Hahn[29] to the conclusion that two pathways are possible in the reaction of the 2-oxocyclohexyloxyl radical with degradation of the carbon chain.

(19)



Pathway *a* explains the formation in the oxidation reaction of 6-oxo-1-hexanoic, monoperadipic, and adipic acids,[29] whilst pathway *b* accounts for the formation of glutaric acid, δ-valerolactone, and valeric acid.[29,90]

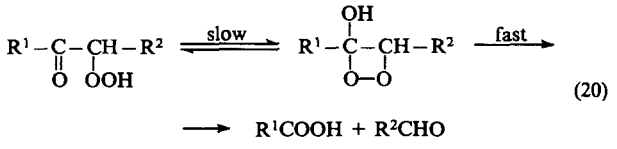
The homolytic decomposition of the secondary α-ketohydroperoxide (the β′-mechanism) has been observed in the oxidation of dibenzyl ketone.[45,67,91] This is indicated by the deviation of the composition of the product from that expected on the basis of the Langenbeck–Pritzkov mechanism (the α-mechanism). The phenylacetyl radical formed via reaction (18) is almost completely decarbonylated to the benzyl radical (pathway *c*); pathways *a* and *b* do not occur. Therefore, on the basis of the ratio of the initial rates of accumulation of phenylacetic acid and of benzyl hydroperoxide together with benzyl alcohol (the benzyl radical reaction products), it is possible to estimate the contribution of the homolytic mechanism to the overall decomposition of the α-ketohydroperoxide. In the noncatalysed oxidation of dibenzyl ketone at 100 °C, the contribution of the homolytic decomposition is not less than 50% according to Perkel' et al.[45] The composition of the products of the decomposition of dibenzyl ketone α-dihydroperoxide, formed in the oxidation of dibenzyl ketone [a type (15) reaction, β″-mechanism],[20,67] also deviates from that expected on the basis of the α-mechanism.



The relative contributions of the different routes to the oxidative degradation of ketones can be altered by introducing catalytic amounts of variable-valence metals.[20,67] According to the data of Perkel' and co-workers,[20,67] the relative contributions of the α-, β′-, and β″-mechanisms (expressed as percentages) in the oxidative degradation of dibenzyl ketone at 100 °C in chlorobenzene are 9 : 49 : 42 in the presence of cobalt(II) naphthenate as the catalyst, 26 : 27 : 47 in the presence of chromium(III) naphthenate, and 40 : 50 : 10 in the presence of manganese(II) naphthenate. Since the contribution of the α-mechanism in the noncatalysed oxidation

Scheme I

under the same conditions is only 18%, the above data demonstrate that chromium and manganese naphthenates increase the selectivity of the dibenzyl ketone oxidation reaction as regards the formation of phenylacetic acid compared with the noncatalysed process.[20,67] In the case of chromium naphthenate, the increase in the contribution of the α-mechanism to the overall process is associated with the decrease in the proportion of the homolytic decomposition of the α-ketohydroperoxide, whilst in the case of manganese naphthenate it is associated with the suppression of reaction (15).[20,67]



The yield of the products of the degradation of α-ketohydroperoxides in conformity with the Langenbeck–Pritzkov mechanism can also be explained satisfactorily by resorting to the dioxetane mechanism. The formation of 1-hydroxy-1,2-dioxetanes (Kohler peroxides[48]) was already postulated in early investigations of the oxidation of the enolic forms of ketones. However, after evidence had been obtained in support of the existence of ketone α-hydroperoxides predominantly in the acyclic keto-form, these ideas were abandoned for a long time.

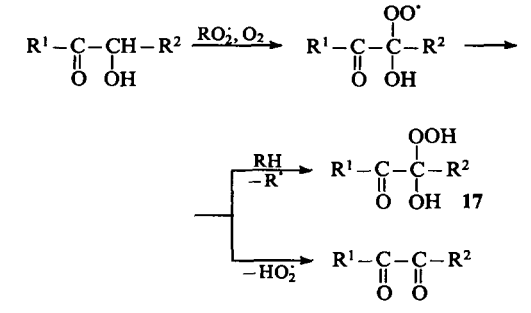
The interest in the dioxetane mechanism was manifested anew in the 1970s–1980s when chemiluminescence characteristic of 1,2-dioxetanes (this class of organic compounds had been well investigated by that time) was observed[83–85] in the base-catalysed oxidation of ketones and in the decomposition of α-ketohydroperoxides in an alkaline medium.[92] These ideas have not gained wide currency as the explanation of the oxidation reaction in a neutral medium.

The dioxetane mechanism of the reaction of α-ketohydroperoxides does not conflict with the available experimental data on the decomposition of these hydroperoxides and it accounts for some of them more satisfactorily than the acid-catalytic and homolytic mechanisms.

The formation of 1-hydroxy-1,2-dioxetanes from α-ketohydroperoxides is energetically unfavourable owing to the ring strain arising under these conditions.[92] The equilibrium in the reversible first stage of the reaction should therefore be displaced towards the keto-form, which is additionally stabilised by an intramolecular hydrogen bond.[93] The sequence of the slow reversible and rapid irreversible reactions should be manifested kinetically as an irreversible first-order reaction,[94] which is in fact usually observed in the decomposition of α-ketohydroperoxides of different structure.[1,2]

(20)

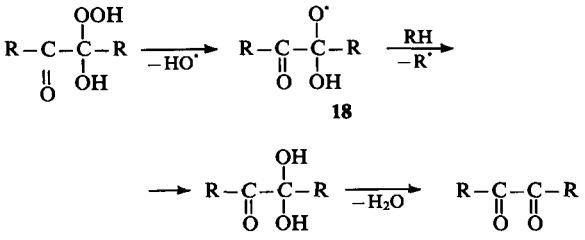
Although the base catalysis in reactions involving nucleophilic addition to the carbonyl group is usually preferred,[46,89] the interaction of carbonyl compounds with hydroperoxides takes place readily also without a catalyst[95] and under the conditions of general acid catalysis by weak acids such as carboxylic acids.[20] Furthermore, the carbonyl group of α-ketohydroperoxides should be significantly activated by the $-I$ effect of the hydroperoxide group and by the intramolecular bond, as happens in the case of α-ketoalcohols.[13]



Evidently, when the dioxetane mechanism operates, a correlation should be observed between the reactivity of the carbonyl groups of the α-ketohydroperoxides and the stability of the latter. Indeed, tertiary α-ketohydroperoxides the carbonyl group of which is linked to an aromatic ring are the most stable (and therefore have been most thoroughly investigated).[3] Aromatic groups are known to reduce the reactivity of the carbonyl group in nucleophilic addition reactions because, when the ketone is converted into the adduct, the stabilisation via delocalisation is disturbed.[46] The presence of substituents at the α-carbon atom also lowers significantly the reactivity of the carbonyl groups owing to steric effects.[46] Evidently this is the reason why 2-hydroperoxy-2,4-dimethylpentanone is much more stable than the α-ketohydroperoxides of normal aliphatic ketones.[2]

In the decomposition of tertiary aromatic α-ketohydroperoxides in the presence of alkoxide ions[96] taken in large amounts, or in the presence of trifluoroacetic acid,[97] 1,2-dioxetanes are not formed. This finding may be associated with the low reactivity of such hydroperoxides in intramolecular nucleophilic addition reactions accompanied by the competing reaction of the carbonyl group with a stronger nucleophile—the alkoxide ion, and also with the suppression of reaction (20) as a consequence of the associative interactions of trifluoroacetic acid with the hydroperoxy- and carbonyl groups of the hydroperoxide. The possibilities of the dioxetane mechanism for the explanation of the characteristic features of the decomposition of α-ketohydroperoxides in autoxidation reactions are apparently still not exhausted.

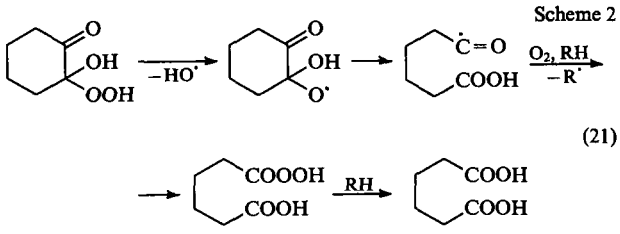
V. Oxidative degradation of α-ketoalcohols



It was noted above that α-ketoalcohols are the principal products of the decomposition of α-ketohydroperoxides not involving the degradation of the carbon chain. The reactions of α-ketoalcohols in hydrocarbons undergoing oxidation involve both a radical-chain process[10,11,13–17,20,98–101] and their interactions with peroxide compounds.[13,17,20]

The mechanism of the radical-chain oxidation of α-ketoalcohols has been investigated in relation to 2-hydroxycyclohexanone,[10,11,13–17,20,98] 11-hydroxy-10-eicosanone,[20] and benzoin.[99–101] As secondary alcohols, α-ketoalcohols are oxidised via the reactive α-C–H bond, which is additionally activated by the carbonyl group. The intermediate α-hydroxy-α-oxoperoxyl radicals in the oxidation of ketoalcohols either abstract hydrogen from the substrate with formation of α-hydroperoxy-α-hydroxyketones **17** or decompose to the radical $HO_2^{\cdot}$ and a diketone.[13,16,20,99–101]

α-Hydroperoxy-α-hydroxyketones dissociate reversibly in their turn into hydrogen peroxide and an α-diketone[15,20,98–101] or undergo degradation via homolytic and nonhomolytic mechanisms[14,17,20,99] with formation of α-diketones, carboxylic acid anhydrides, or free carboxylic acids.

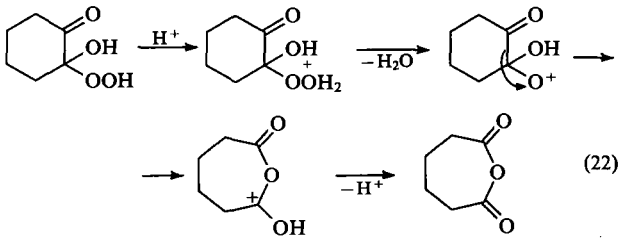


The homolytic decomposition of α-hydroperoxy-α-hydroxyketones proceeds via 1-hydroxy-2-oxoalkoxyl radicals **18**,[14,17,19] the principal pathway in the reaction of which does not involve the formation of a new carbonyl group, as in the case of α-hydroxyalkoxyl radicals (see Section III), but takes place with dissociation of the carbon chain.[14,17,20,99]

18

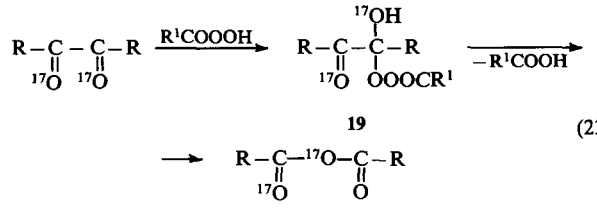
It has been shown in relation to 2-hydroperoxy-2-hydroxycyclohexanone that such degradation in the presence of oxygen leads to adipic acid via a monoperacid (Scheme 2).[14,17,20]

Scheme 2



(21)

By comparing the potential yield of the peracid with the yield of adipic acid formed in the oxidation of 2-hydroxycyclohexanone at 50 °C, it was found that about 50% of the adipic acid is obtained via reaction (21).[17,20]

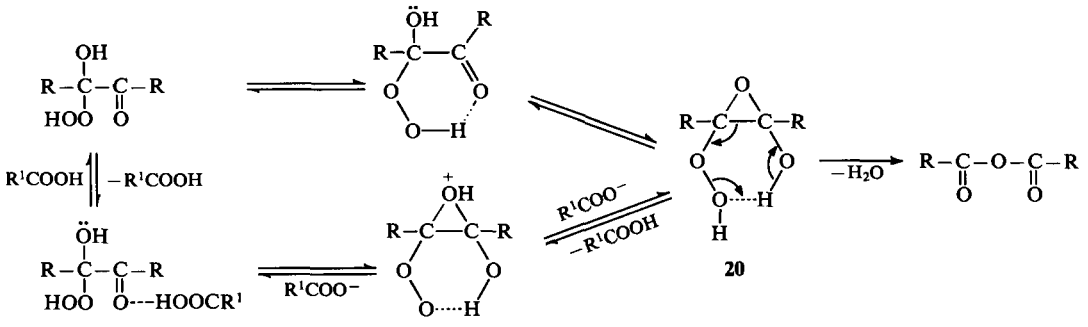


Mechanisms involving both the heterolytic[14,16] and pericyclic[17,20] rearrangements have been put forward to account for the formation of adipic anhydride from 2-hydroperoxy-2-hydroxycyclohexanone.

A heterolytic rearrangement of the Baeyer–Villiger type,

(22)

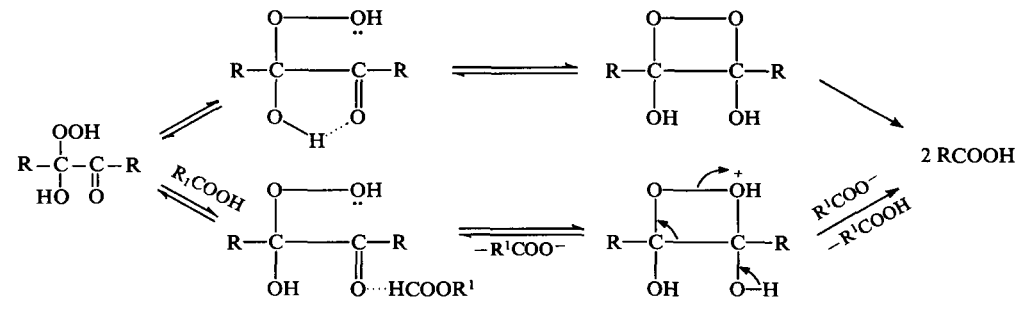
which presupposes the migration of the acyl carbon atom, is unlikely for the same reason as in the acid-catalytic decomposition of α-ketohydroperoxides (see Section IV). Furthermore, there are data[102] showing that, in the oxidation of ^{17}O- or ^{18}O-labelled benzil by *m*-chloroperbenzoic acid, which proceeds via the α-acylperoxy-α-hydroxyketone **19**, one of the carbonyl atoms of the α-diketone becomes the bridging atom of the anhydride, i.e.



19 (23)

which cannot be explained by a Baeyer–Villiger rearrangement [reactions (10) and (22)].

The data on the distribution of the labelled oxygen agree well with the hypothesis that the peroxides **17** and **19** are converted into the anhydride via the slow reversible intramolecular nucleophilic addition of the hydroxy-group to the carbonyl group with subsequent rapid pericyclic rearrangement of the oxirane intermediate **20** (Scheme 3).[17,20]



Reaction (24) takes place under the conditions of general acid catalysis; the effective rate constant for the first-order reaction involving the decomposition of 2-hydroperoxy-2-hydroxycyclohexanone to adipic anhydride in 2-hydroxycyclohexanone undergoing oxidation varies linearly with the concentration of carboxy-groups.[17,20] The mechanism (24) explains fairly satisfactorily the influence of the solvent and of the structure of the α-hydroperoxy-α-hydroxyketone on the yield of anhydrides. It has been established that adipic anhydride is hardly formed in the oxidation of 2-hydroxycyclohexanone in a solvent such as dimethylformamide,[17,20] which suppresses the nucleophilic addition of the hydroxy- and hydroperoxy-groups[17] to the carbonyl group, preventing thereby the formation of the intermediate **20**. One of the causes of the low yield of benzoic anhydride in the oxidation of benzoin may be the reduced reactivity of the carbonyl group of the α-hydroperoxy-α-hydroxyketone linked to the aromatic ring.[46]

Scheme 3

(24)

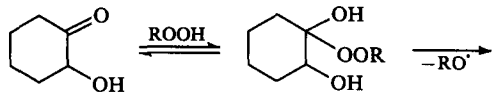
Scheme 4

(25)

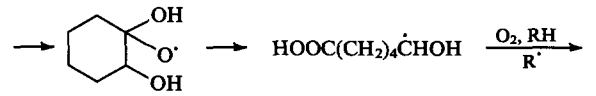
It has been concluded [17,20] that the adipic acid formed in the oxidation of 2-hydroxycyclohexanone is produced mainly not via reaction (21) but as a result of the rearrangement of 2-hydroperoxy-2-hydroxycyclohexanone [reaction (25)] similar to that examined above the α-hydroperoxides [reaction (20)], i.e. the dioxetane mechanism operates (Scheme 4).

The carbonyl group of α-hydroperoxy-α-hydroxyketones is additionally activated (compared with α-ketohydroperoxides) by the $-I$ effect of the hydroxy-group. [17,20] As in reaction (24), carboxylic acids accelerate the conversion of the peroxide. [17,20]

Thus the possibility of the selective preparation of anhydrides from α-hydroperoxy-α-hydroxyketones is determined by the contribution of reactions (24) and (25) to the overall oxidation process. On the grounds that these reactions have stages with similar mechanisms and virtually identical activation energies, [16,17,20] it was concluded that the process selectivity is low. Data on the oxidation of 2-hydroxy-cyclohexanone in chlorobenzene at 95 °C [16] showed that the ratio of the yields of adipic anhydride and adipic acid reaches 2.2 under these condtions, i.e. reaction (24) predominates. An increase in the selectivity of the conversion of α-hydroperoxy-α-hydroxyketones into carboxylic acids can be achieved by stimulating their homolytic decomposition and(or) by suppressing reaction (24). Thus, in the oxidation of 2-hydroxycyclohexanone the significance of reaction (21) increases with increase in the initial concentration of the ketoalcohol, when the reaction is carried out in a reactive solvent, and when variable-valence metal salts are used as catalytic additives. [14-17,20]



When the concentration of 2-hydroxycyclohexanone is varied in the range from 0.24 to 1.47 M (95 °C, chlorobenzene), the ratio of the initial rates of accumulation of adipic acid and its anhydride increases from 0.5 to 1.05. [16,20] In the oxidation of 2-hydroxycyclohexanone in ethylbenzene (95 °C, 1.2 M), this ratio reaches 1.8. [16] The increase in the yield of adipic acid in the cases indicated above is associated with the increase in the contribution of the homolytic decomposition of the α-hydroperoxy-α-hydroxyketone, with participation of compounds R^1H containing reactive C–H bonds, as a result of the occurrence of reaction (26). [16,20,56]

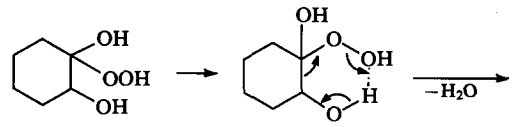


$$ROOH + R^1H \longrightarrow RO^{\cdot} + H_2O + \dot{R}^1 \qquad (26)$$

In the study of the influence of cobalt(II), nickel(II), chromium(III), and iron(III) naphthenates on the oxidation of 2-hydroxycyclohexanone, it was established that the yield of adipic acid in the presence of all the catalysts is higher than in the noncatalysed reaction, while the yield of adipic anhydride is correspondingly lower, especially in the presence of the cobalt salt. [11,20] The results of the decomposition of the peroxide compounds formed in the oxidation of 2-hydroxycyclohexanone under a nitrogen atmosphere showed that the mode of the decomposition and oxidation reactions is as a rule the same. [20] The decrease in the yield of the anhydride with simultaneous formation of the acid in the presence of variable-valence metals has been explained by the increasing role of a type (21) reaction. [20]

An increase in the relative yield of adipic acid has been observed also in the oxidation of 2-hydroxycyclohexanone in dimethylformamide, although the rate of its formation was lower than in the oxidation in chlorobenzene. [17,20] It has been suggested [17,20] that this phenomenon is associated with the suppression of reactions (24) and (25) in dimethylformamide as a consequence of the suppression of the intramolecular nucleophilic addition to the carbonyl group in this solvent. [17,20]

α-Ketoalcohols can not only participate in the radical-chain oxidation but can also interact with peroxide compounds. (The rate of decomposition of peroxide compounds in the presence of ketoalcohols is much higher than in the presence of monofunctional alcohols and ketones. [13,20]) Apart from reactions (26), such interaction can include the addition of the peroxide compounds to the carbonyl group of the α-ketoalcohol, [13,20] which has been observed, for example, in the cooxidation of 2-hydroxycyclohexanone together with ethyl methyl ketone [13] and cyclohexanol [17] and also in the oxidation of benzoin. [99] Thus, when 2-hydroxycyclohexanone is introduced into ethyl methyl ketone undergoing oxidation, ε-caprolactone, ε-hydroxycaproic acid, and 6-oxo-1-hexanoic acid are formed in a yield of about 40% relative to the ketoalcohol which has reacted. The reaction probably proceeds via the following mechanism: [13]



(27)

$$\longrightarrow HOOC(CH_2)_4CH(OH)OOH \xrightarrow{-H_2O_2} HOOC(CH_2)_4CHO.$$

It has been suggested [17] that, in the cooxidation of 2-hydroxycyclohexanone together with cyclohexanol, 6-oxo-1-hexanoic acid is obtained both as a result of reaction (27) and as a result of the pericyclic rearrangement of 1-hydroperoxy-1,2-dihydroxycyclohexane **21**.

21

$$\longrightarrow HOOC(CH_2)_4CHO$$

The formation of benzaldehyde in the liquid-phase oxidation of benzoin is associated with the reaction of the latter with peroxide compounds. [99] This possibility is supported also by data for the oxidation of benzoin by *m*-chloroperbenzoic acid. [103]

VI. Oxidation of α-diketones by peroxide compounds

α-Diketones, which together with α-ketoalcohols are the main products of the reaction of α-ketohydroperoxides without the degradation of the carbon chain (see Section IV), are also capable of interacting with peroxide compounds in hydrocarbons undergoing oxidation.

There are few data on the radical-chain oxidation of α-diketones. The oxidation of diacetyl by oxygen at 80 °C has been investigated. [104] It is suggested that the reaction proceeds via the intermediate formation of acetic anhydride, which, however, was not identified. [104] The main product of the reaction is acetic acid.

In the oxidation of cyclohexane-1,2-dione by oxygen in solution in chlorobenzene, only tarry products were detected. [105] This finding is probably associated with the fact that cyclohexane-1,2-dione exists predominantly as the monoenol (2-hydroxycyclohex-2-en-1-one), [12] which can be readily oxidised at the carbon atom in the α-position relative to the double bond and evidently polymerises under the influence of free radicals. Since there are no data on the enolic form of cyclohexane-1,2-dione in the cyclohexane oxidation reaction, the selection of the latter as a model reaction appears controversial. There is no doubt that

problems concerning the radical-chain oxidation of α-diketones still await solution.

Problems associated with the reactions of α-diketones with peroxide compounds (H_2O_2, hydroperoxides, peracids), used for preparative purposes, have been investigated to a greater extent. A study has been made of the influence of equimolar amounts of added oxygen-containing compounds of different classes on the rate of the thermal decomposition of *tert*-butyl hydroperoxide (TBHP) in benzene at 160 °C under a N_2 atmosphere. The effective rate constants for the decomposition of THBP in the presence of various additives have the following values:[13,20]

Additive	$10^4 k_{eff}/s^{-1}$
Eicosane-10,11-dione	25.0
Cycloheptane-1,2-dione	11.0
2-Hydroxycyclohexanone	10.0
11-Hydroxyeicosan-10-one	5.0
2-Hydroxycyclohex-2-en-1-one	1.27
Cyclohexanone	0.20
Cyclohexanol	0.17
Nonan-5-ol	0.14
Nonadecan-10-one	0.13
Without additive	0.025

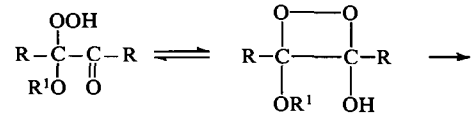
It is seen from the data presented that, in terms of their capacity to decompose hydroperoxides, α-diketones are more effective than not only monofunctional alcohols and ketones but also α-keto-alcohols.

The interaction of α-diketones with peroxide compounds in autoxidation reactions is not only an important route to the conversion of the latter but also serves as a pathway to the formation of degradation products, in particular carboxylic acid anhydrides. It was found that these reactions proceed at fairly high rates even in nonpolar solvents close to room temperature. The first stage of the interaction of hydroperoxides and peracids with α-diketones involves their reversible nucleophilic addition to one of the carbonyl groups of the α-diketone with formation of α-hydroperoxy-α-hydroxy-, α-alkylperoxy-α-hydroxy-, and α-acylperoxy-α-hydroxy-ketones.[12,18,19,32,102,106–110] The rate-limiting stage is the subsequent degradative composition of α-hydroperoxy-α-hydroxy- and α-alkylperoxy-α-hydroxy-ketones.[20,111]

The main products of the oxidation of hexadecane-8,9-dione by hydrogen peroxide are caprylic anhydride and caprylic acid.[18,20] Caprylic anhydride is formed via reaction (24), whilst the acid is formed via reactions (21) and (25).[20] In the interaction of hexadecane-8,9-dione with TBHP, *tert*-butyl caprylate was obtained in addition to caprylic anhydride and caprylic acid.[18,20] The yield of caprylic anhydride is in this case significantly higher than in the reaction with hydrogen peroxide, whilst caprylic acid is formed either in the homolytic decomposition of the peroxide [reaction (21)] or from caprylic anhydride simultaneously with *tert*-butyl percaprylate, and not via reaction (25).[18,20] The effective decomposition rate constants increase linearly under these conditions as the degradation products accumulate,[18] which is apparently associated with the catalytic effect of caprylic acid.

The high equilibrium constants in the interaction of hexadecane-8,9-dione with hydrogen peroxide and TBHP at 23 °C (41.5 and 49.0 litre mol^{-1}) are due to the stabilisation of the adducts by the formation of an intramolecular hydrogen bond.[20,112]

Di-*tert*-butyl peradipate was detected together with mono-*tert*-butyl peradipate among the products of the oxidation of cyclohexane-1,2-dione by TBHP.[12] The formation of the former has been explained by the interaction of the hydroperoxide with a polymeric form of adipic anhydride.[12]

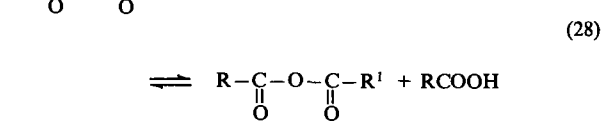


Acetic anhydride is formed selectively in the oxidation of diacetyl by TBHP in solution in acetic acid, while in the case where the reaction is carried out in *tert*-butyl alcohol the acid is formed predominantly.[112] Evidently acetic acid accelerates the conversion of the corresponding α-alkylperoxy-α-hydroxyketone via reaction (24), while *tert*-butyl alcohol has the opposite effect, suppressing this degradation pathway (as a result of the competing interactions of the OH group of the alcohol with the carbonyl group of the α-alkylperoxy-α-hydroxyketone); acetic acid is then formed homolytically via reaction (21).

In the interaction of diacetyl with 2-hydroperoxy-2-methyltetrahydrofuran or 2-hydroperoxytetrahydropyran in chlorobenzene, the homolytic decomposition of α-alkylperoxy-α-hydroxyketones predominates.[106] The reaction products are formed as a result of the recombination of the acyl radical of the α-diketone and oxyl or carbon-centred radicals of the hydroperoxide within a cage.[106] Thus the relative contributions of the different routes to the degradation of α-alkylperoxy-α-hydroxyketones are affected not only by the medium but also by the structure of the α-diketones and hydroperoxides.

In the oxidation of α-diketones by peracids, the rate-limiting stage is the acid-catalysed nucleophilic addition of the peracid to the carbonyl group of the α-diketone. The effective rate constants for the second-order reaction (given in brackets in litre $mol^{-1} s^{-1}$) involving the oxidation of α-diketones by perlauric acid at 23 °C diminish on passing from hexadecane-8,9-dione (0.37) to 1-phenylpropane-1,2-dione (0.036) and then to benzil (0.0071) as a consequence of the decrease in the reactivity of the carbonyl groups of the α-diketones under the influence of aromatic substituents.[20,111] Lauric acid increases the effective rate constant for the reaction of hexadecane-8,9-dione with perlauric acid almost by a factor of 100.[19,20,111] Consequently the importance of such reactions increases at advanced stages in the autoxidation reactions of hydrocarbons.

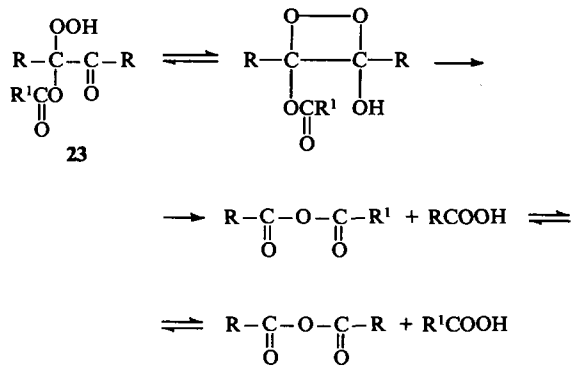
It was first established in Karrer's studies[32,113–117] that the main products of the oxidation of α-diketones by peracids are carboxylic acid anhydrides. It was postulated that such reactions proceed via a heterolytic rearrangement of α-acylperoxy-α-hydroxyketones [reaction (22)][32] or via oxirane intermediates.[20,102,111]



The data[102] indicating the preferential conversion of the α-acylperoxy-α-hydroxyketones into an anhydride [see reaction (23)] cannot be accounted for by resorting to heterolytic rearrangement, but the formation of the anhydride is described satisfactorily by Eqn (24), which involves the oxirane intermediates **20**. The important role of the OH group in the formation of the anhydride is indicated also by the fact that esters and not anhydrides are formed in the decomposition of α-alkoxy-α-hydroperoxyketones **22**.[118] The mechanism (24) does not operate in this case and the ester is formed via a reaction analogous to reaction (25).

22

$$\longrightarrow RCOOR^1 + RCOOH$$



Together with the expected symmetric anhydride [reaction (24)], mixed anhydrides, including acylperacids, were also found in the reactions of hexadecane-8,9-dione and benzil with perlauric acid.[19,20,111] Their formation is associated with the transacylation of the symmetrical anhydride by reaction with lauric acid obtained by the reduction of the peracid.[19]

(28)

The occurrence of reaction (28) leads to a decrease in the selectivity of the overall reaction with respect to the target anhydride. This is probably why the yield of the expected anhydrides did not as a rule exceed 50% in the early studies.[32,113-117]

The formation of symmetrical anhydrides in the decomposition of α-acyloxy-α-hydroperoxyketones **23** is probably associated with transacylation.[119]

23

Thus not only the composition of the products of the reactions of α-hydroperoxy-α-hydroxy-,α-alkylperoxy-α-hydroxy-, and α-acylperoxy-α-hydroxy-ketones, formed in the radical-chain oxidation of α-ketoalcohols and in the oxidation of α-diketones by peroxide compounds, but also the composition of the related peroxides **22** and **23** can be explained on the basis of the mechanisms (21), (24), and (25).

The importance of different mechanisms of the oxidative degradation of the hydrocarbon chain, examined in Sections V and VI, for the hydrocarbon oxidation reactions is still to be assessed. However, there is no doubt that the reactions leading to carboxylic acid anhydrides occupy a special place among them. The formation of the anhydrides was detected not only in the oxidation of the α-ketoalcohols and α-diketones but also in the oxidation reactions of cyclohexane,[10] cyclohexanone,[11,78] ethyl methyl ketone,[120,121] dibenzyl ketone,[45,91] and benzyl phenyl ketone.[7-9,45] Being highly reactive in nucleophilic addition reactions, carboxylic acid anhydrides interact during the autoxidation processes with the water produced in the reaction, alcohols, hydroperoxides, and carboxylic acids[20] and this is why it is usually difficult to establish the amount in which they are actually formed in the reaction. According to the data of Bogomol'nyi and Freidin,[121] not less than 20% of acetic acid is obtained during the oxidation of ethyl methyl ketone as a result of the hydrolysis of acetic anhydride. The problems associated with the participation of the anhydrides in the formation of esters and other oxidation products will be examined in Sections VII and VIII.

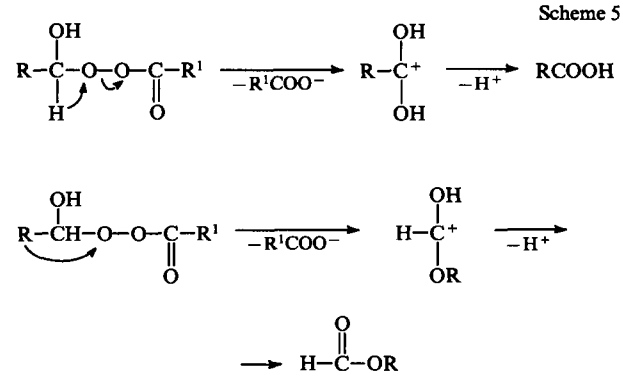
VII. The formation of esters in autoxidation processes

Esters are side products of the reactions involving the autoxidation of hydrocarbons and their oxygen-containing derivatives to carboxylic acids.[1,2] To facilitate the consideration of the mechanisms of the formation of esters, the latter will be divided into three groups.

The first group includes the esters of primary (more rarely secondary) alcohols containing the same total number of carbon atoms as the compound oxidised (for example, ethyl acetate and ε-caprolactone obtained in the oxidation of butane and cyclohexane respectively, or isopropyl acetate, which is a side product in the oxidation of isopropyl methyl ketone,[82] etc.).

The esters of secondary alcohols (with the same number of carbon atoms as in the initial compound) and acids containing as a rule fewer carbon atoms than the alcohols (for example, *sec*-butyl acetate—the product of the oxidation of butane or *sec*-butyl alcohol,[1] the cyclohexyl esters of mono- and di-carboxylic acids—the products of the oxidation of cyclohexane, cyclohexanol,[19] etc.) should be included in the second group.

Finally, the third group incorporates γ- and δ-lactones containing the same or a smaller number of carbon atoms than the initial compound (for example, γ-methyl- and γ-ethyl-butyrolactones obtained by the oxidation of undecan-6-one[24,62] and γ-octyl-butyrolactone and δ-heptylvalerolactone formed in the oxidation of lauric acid[2]).



Since the esters of the first group can be formally obtained by inserting an oxygen atom into the C–C bond closest to the carbonyl group, it was postulated that they are formed in the oxidation of the corresponding ketones by peracids,[44,45,68,82,122] The peroxyl radical,[2] and hydroperoxides[123] and also as a result of the homolytic rearrangement of α-ketohydroperoxides.[1]

The fairly high rate of oxidation of ketones by peracids in nonpolar solvents and at moderate temperatures (see Section III) as well as the existence of theoretical preconditions for the formation of peracids in liquid-phase oxidation processes makes it possible to give preference to the Baeyer–Villiger reaction. An experimental test of the importance of this reaction was achieved comparatively recently for the oxidation reactions of cyclohexanone[44] and aromatic ketones.[45]

In a study of the influence of added diphenyl sulfide and diphenyl sulfone (reagents which reduce peracids) on the composition of the cyclohexanone oxidation products, it was established that the main side product of this reaction—ε-caprolactone—is formed predominantly by the interaction of the ketone with the peracid.[44] It was shown that the alternative mechanisms of the formation of ε-caprolactone, presupposing the oxidation of the ketone by peroxyl radicals or hydroperoxides, as well as the reactions of α-ketohydroperoxides unrelated to the appearance of peracids do not occur on an appreciable scale under the conditions of the process.[20,44] It was found that benzyl benzoate and benzyl phenylacetate are also formed as a result of the oxidation of benzyl phenyl ketone and dibenzyl ketone respectively by the peracid.[20,45]

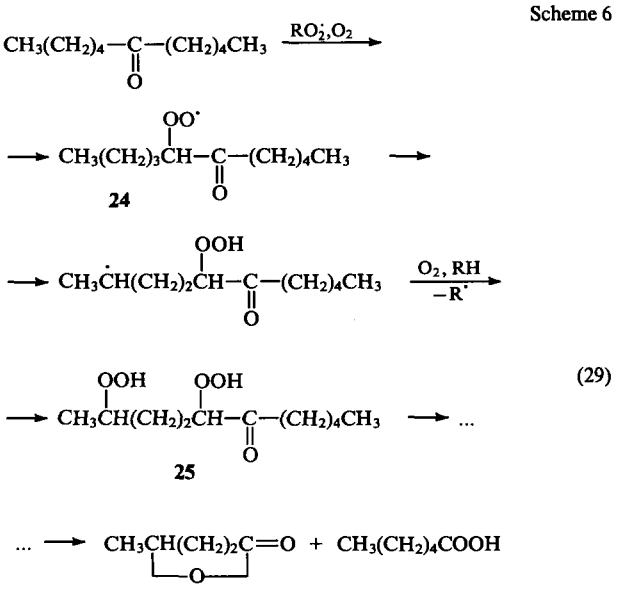
The formation of formic acid esters in the oxidation of aldehydes is apparently also associated with the Baeyer–Villiger reaction. In this case, the 1,2-rearrangement of the α-hydroxyperester may entail the migration of both a hydride ion and of a hydrocarbon group, which lead respectively to an acid and an ester (Scheme 5).[2]

Scheme 5

The mechanism of the formation of the esters of secondary alcohols, which we assigned to the second group, remained obscure for a long time. The esterification of alcohols by carboxylic acids, postulated in a number of studies (see, for example, Emanuel' et al.[1]) as the main reaction, makes only a 10%–25% contribution to the observed rate of accumulation of esters even according to the most optimistic estimates.[126-129] This is evidence in support of the existence of a nonacid (unrelated to carboxylic acids) route to the formation of esters.

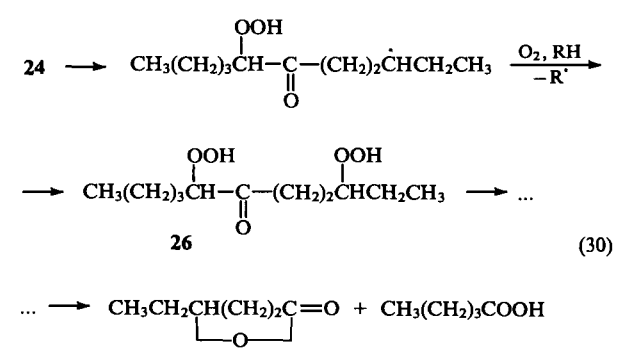
Such a route is apparently provided by the esterification of alcohols by anhydrides. This hypothesis has been tested[10] in relation to the oxidation of cyclohexane. A satisfactory agreement

was found between the rate of accumulation of monocyclohexyl adipate observed in the oxidation of cyclohexane at 150 °C, and the rate of formation of this ester calculated from kinetic data for the reaction of adipic anhydride with cyclohexanol.



The transacylation of the anhydrides with the free acids results in the formation of mixed anhydrides [reaction (28)]. Their interaction with alcohols leads to esters incorporating the acyl residues from the carboxylic acid participating in the transacylation. It has been demonstrated for the oxidation reactions of cyclohexane, cyclohexanol, and cyclohexanone that cyclohexyl or 2-oxocyclohexyl esters of mono- and di-carboxylic acids are formed with participation of adipic anhydride.[19,20]

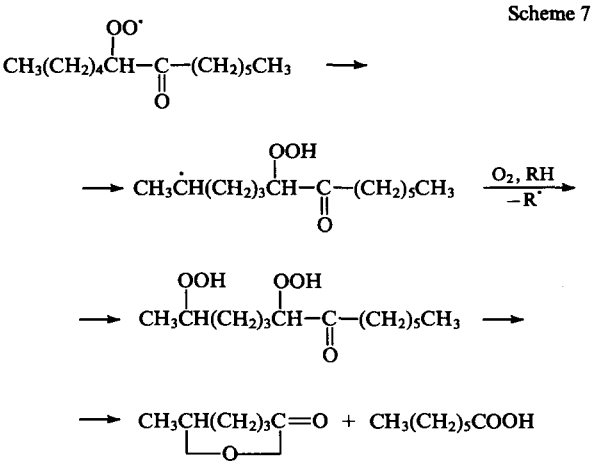
The pathways leading to the formation of γ- and δ-lactones in the oxidation of long-chain hydrocarbons are still insufficiently clear and are apparently associated with the multistage nature of such reactions and with the difficulty of identifying and determining the intermediates. According to the most widely held view, the lactones are formed from the corresponding hydroxyacids.[1,2]



It has been suggested[24,62] that the γ-lactones arise in the stages which follow the formation of the ketones. The products of the oxidation of undecan-6-one were found to contain γ-methyl- and γ-ethyl-butyrolactones, the origin of which has been attributed[24,62] to the intramolecular isomerisation of the ketoperoxyl radical **24** and the subsequent reaction of the dihydroperoxides **25** and **26** (Scheme 6).

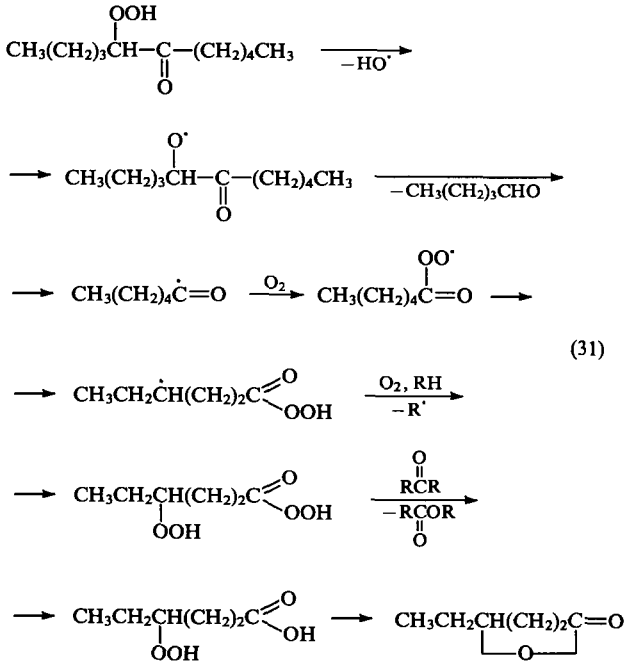
The intramolecular isomerisation of the radical **24** in conformity with reaction (29) is entirely realistic, while the isomerisation of this radical via reaction (30) is improbable.[1] If it is supposed that such isomerisation is possible, then it should lead to δ-lactones in the oxidation of long-chain ketones, for example tridecan-7-one (Scheme 7). However, only γ-lactones were found among the tridecan-7-one oxidation products.[24]

Scheme 6



(29)

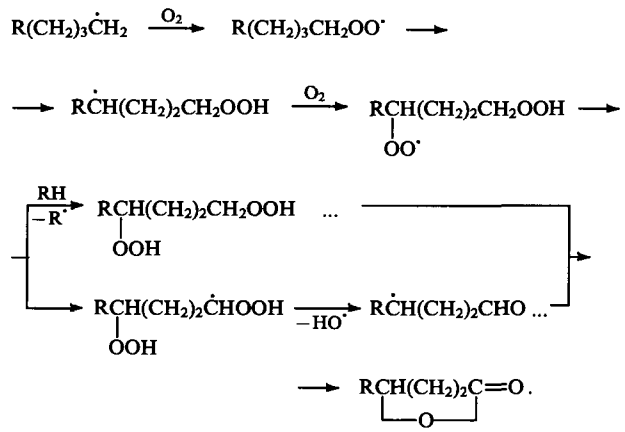
(30)



Scheme 7

The hypothesis has been put forward that the formation of γ-lactones is associated not only with the intramolecular isomerisation of the α-ketoperoxyl radical[24] but also with the oxidation of ketones at the γ- and δ-C–H bonds.[1,2] The possibility of these reaction pathways is not open to doubt, but, in order to achieve the formation of γ- and δ-lactones, it is essentially to subject γ- and δ-ketohydroperoxides to a secondary oxidation at the α- C–H bonds, which is unlikely to occur in the initial stage of the process. Incidentally, the intramolecular isomerisation of the δ-ketoperoxyl radical can also lead to a hydroperoxide of type **25**. The probability of the latter reaction should be fairly high in view of the enhanced reactivity of the α-C–H bonds of ketones.

The oxidation of carboxylic acids at the γ- and δ-C–H bonds can also lead to the formation of γ- and δ-lactones. The reactivities of these bonds are approximately the same[130] and hardly differ from the reactivities of the methylene C–H bonds of hydrocarbons. Indeed, the products of the oxidation of lauric acid were found to contain γ-octylbutyrolactone and δ-heptylvalerolactone.[2] However, the parallel formation of acids and γ-lactones in the oxidation of undecan-6-one and tridecan-7- one[24] as well as the absence of δ-lactones among the tridecan-7-one oxidation products mentioned above cannot be explained by the occurrence of this reaction.



It appears that the formation of γ-ethylbutyrolactone in the oxidation of undecan-6-one can be associated with the

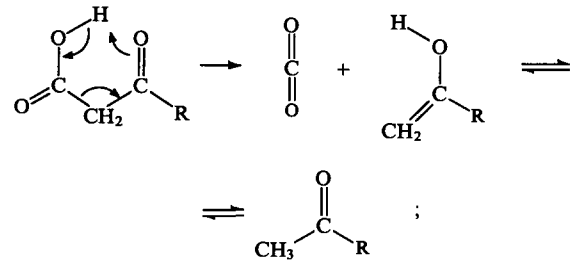
(31)

homolytic decomposition of α-ketohydroperoxide in the presence of oxygen and with subsequent intramolecular isomerisation of the hexanoylperoxyl radical. The fact that the possibility of the occurrence of such a reaction in the oxidation of aldehydes is usually disregarded[1,2] is apparently associated with its suppression in the presence of readily oxidisable substances such as aldehydes. Since acyl radicals may be formed in the oxidation of aldehydes, α-ketoalcohols, and α-diketones (see Sections V and VI), it follows that reaction (31) is an important source of the accumulation of γ-lactones in autoxidation processes.

One cannot rule out the possibility that γ-lactones may be obtained also from primary alkyl radicals via the mechanism

The homolytic decomposition of secondary hydroperoxides and α-hydroxyhydroperoxides [reactions (7) and (13)] as well as decarbonylation and decarboxylation reactions, which will be examined below, lead to primary alkyl radicals.

The experimental data presented show that the structure of the esters formed in the oxidation reactions depends on the method of their synthesis. The esters of primary alcohols (as well as lactones) with the same number of carbon atoms as in the initial hydrocarbon are obtained mainly in the oxidation of ketones by peracids, whereas the esters of secondary alcohols are produced as a result of the esterification of the alcohols by carboxylic acid anhydrides. The formation of γ-lactones is apparently associated with intramolecular isomerisation reactions of the peroxyl radicals.

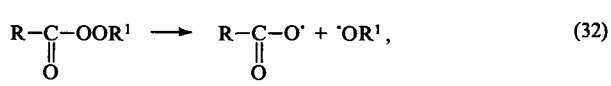


VIII. Certain aspects of the decarbonylation and decarboxylation reactions in the oxidation reactions of hydrocarbons and their oxygen-containing derivatives

The decarbonylation and decarboxylation reactions occur in virtually all the stages of the oxidative degradation of the carbon chain[1,2] and lower the selectivity of the autoxidation processes.

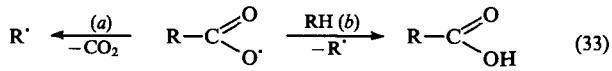
The available literature data permit the conclusion that the decarbonylation process is associated predominantly with the homolytic reactions of the oxidation products.

Under the autoxidation conditions, the acyl radicals formed in reactions (8) (18), and (21) either combine with oxygen [reaction (18, b)] or are decarbonylated [reaction (18, c)] when aldehydes are treated with peroxyl radicals. The relative contributions of these pathways depend both on temperature and on the structure of the hydrocarbon radical.[131,132] Since the activation energy for reaction (2) is close to zero[1] and that for reaction (18, c) involving aliphatic acyl radicals with a normal structure is of the order of 40–91 kJ mol^{-1},[131] one may conclude that the relative importance of the decarbonylation reactions should increase with increasing temperature. The rate constant for reaction (18, c) depends significantly on the stability of the hydrocarbon radicals formed on decarbonylation and increases in the sequence $C_6H_5^{\cdot} \ll CH_3^{\cdot} < CH_3CH_2CH_2^{\cdot} \ll C_6H_5CH_2^{\cdot}$ at 25 °C.[131] The decarbonylation reaction is favoured by the branching of the chain at the α-carbon atom.[132]



With the exception of the cleavage of β-oxoacids and β-dicarboxylic acids, which proceeds readily via a cyclic transition state,[46,89] i.e.

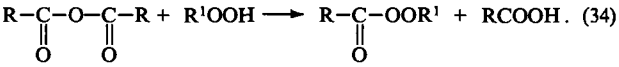
R = Alk, OH;



the decarboxylation reactions in autoxidation processes are mainly associated with the homolytic reactions of the oxidation products.[1,2] Certain features of the decarboxylation resulting from the reactions of peracids, peresters, and carboxylic acids are examined below.

The homolytic decomposition of peracids and peresters leads to acyloxyl radicals,[54] i.e.

(32)



the subsequent reactions of which proceed via two competing pathways—decarboxylation (pathway *a*) and abstraction of hydrogen atoms from the substrate (pathway *b*).[2]

(33)

The relative contributions of these pathways depend on the structure of the radical R$^{\cdot}$, temperature, concentration and the reactivity of the C–H bond of the substrate. Reaction (33, a) is promoted by the stability of the hydrocarbon radical formed on decarboxylation,[21] by unreactive or weakly reactive solvents, and also by a high temperature.[133] Reactive substrates, for example, aldehydes, suppress the decarboxylation reaction.[133]

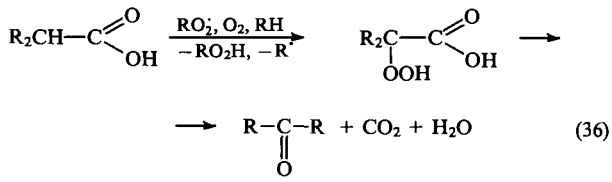
Since peracids are able to oxidise readily carbonyl compounds, being themselves converted into the acids, the role of reactions (32) and (33, a) in decarboxylation processes is probably small. The influence of the perester formation and decomposition reactions on the autoxidation processes is still being elucidated at the present time. Thus the presence in the reaction medium of carboxylic acid anhydrides makes the following reaction probable:

(34)

The study of the kinetics of the accumulation of products in the cyclohexane oxidation reactions and in the interaction of adipic anhydride with cyclohexanol and *tert*-butyl hydroperoxide led to the conclusion that the reaction with the hydroperoxide is an important route to the consumption of the anhydride in the oxidation of cyclohexane. The decomposition of the peresters formed in this process should lead to products with less than 6 carbon atoms.[20] On the hypothesis that peresters are formed in the autoxidation processes, it is possible to account also for the characteristic features of the decarboxylation reactions of carboxylic acids.

Numerous studies, examined in detail in a monograph,[2] have been devoted to the problem of the decarboxylation of carboxylic acids coupled with the oxidation reaction. It was postulated that, in the case of mono- and di-carboxylic acids with a normal structure, the acyloxyl radical, formed on treatment with peroxyl radicals, is decarboxylated.[2]

$$RCOOH + R^1OO^{\cdot} \xrightarrow[-R^1OOH]{} RCOO^{\cdot} \longrightarrow R^{\cdot} + CO_2 \qquad (35)$$



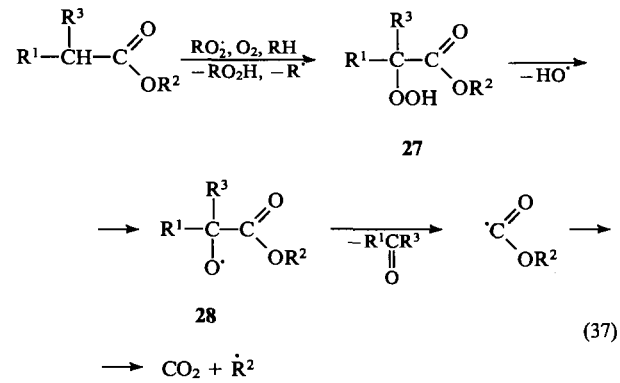
On the basis of the comparatively low values of the kinetic isotope effect (KIE) in the replacement of the carboxyl hydrogen by deuterium and the acceleration observed on the kinetic curves for the evolution of CO_2 in the cooxidation of carboxylic acids together with cumene or other reactive substrates, it was later concluded that the decarboxylation proceeds not only via reaction (35) but also via the intermediate formation of molecular products of the type of hydroperoxyacids and α- or β-oxoacids.[2]

Such a molecular product may be evidently also a perester. The perester can be obtained via reactions (28) and (34). The anhydrides required for these reactions are apparently formed as a result of the oxidative degradation of both the hydrocarbon group of the acid and of the substances employed as the cooxidants.

The hypothesis of the involvement of peresters in the decarboxylation of acids explains satisfactorily a series of experimentally observed facts. The low relative yields of $^{14}CO_2$ in the decarboxylation of acids labelled in the carboxy-group[1,2] may be associated with the possibility of attack by the hydroperoxide on both the initially formed anhydride and on the anhydride incorporating the acyl group of the labelled acid; in the latter case, a perester not containing ^{14}C may also be formed. As nonradioactive acids accumulate in the reaction medium, the probability of the formation of labelled peresters and hence of $^{14}CO_2$ should diminish, as in fact has been observed.[1,2] As was to be expected, the rate of formation of the nonradioactive CO_2 increased under these conditions.[2] The carbon-centred radical obtained by reaction (35) should be readily converted into a carboxylic acid under the oxidation conditions. The similarity of the rates of formation of valeric acid and CO_2 in the oxidation of caproic acid therefore becomes understandable.[2]

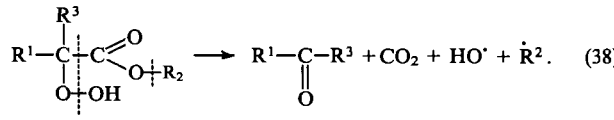
In the transacylation of anhydrides by carboxylic acids, the stage involving the attack on the carbon atom of the anhydride group by the oxygen atom of the acid hydroxyl should be rate-limiting.[44,89] The O–H bond is then ruptured in a nonrate-limiting stage and the replacement of the carboxyl hydrogen by deuterium should not therefore lead to an appreciable kinetic isotope effect, which in fact has been established in the case of acids with a normal structure.[2]

In order to explain the characteristic features of the decarboxylation of acids containing a tertiary hydrogen atom in the α-position, a mechanism involving the oxidation of the acids at the α-C–H bonds and unimolecular decomposition of α-hydroperoxyacids was proposed.[2]



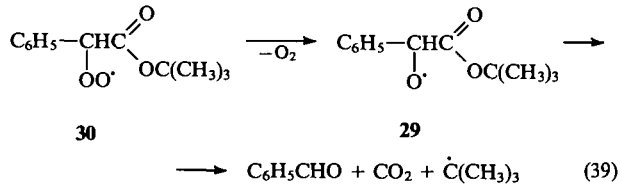
(36)

The proposed mechanism agrees well with the decrease in the rate of decarboxylation of isobutyric acid on replacement of a tertiary hydrogen atom by deuterium (KIE = 6.6).[2] Data indicating a low kinetic isotope effect (1.1) in the replacement of the carboxyl hydrogen by deuterium indicate in their turn an insignificant contribution of the mechanism (35) to the decarboxylation of this acid.[2]



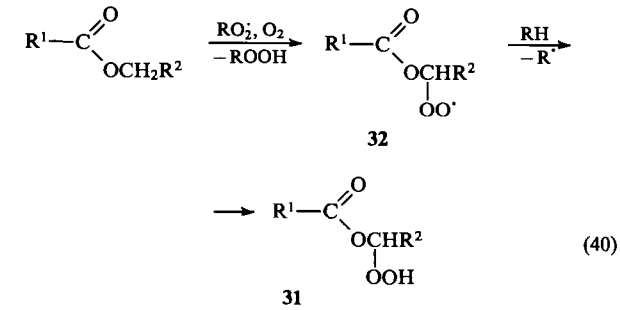
The decarboxylation of isobutyric and trimethylacetic acids apparently proceeds without the participation of peresters, since there are certain difficulties in the formation of anhydrides on oxidation of branched short-chain acids and in addition the probability of the attack on the acyl residues of such acids in the molecules of mixed anhydrides by hydroperoxides diminishes as a consequence of the steric factors mentioned above. The preferential formation of one of the two possible esters in the alcoholysis of mixed anhydrides has been noted.[45,134]

The formation of CO_2 is observed in the oxidative degradation of the ester group.[2,135–139] Carbon dioxide is obtained as a result of the homolytic decomposition of the primary molecular product of the oxidation of the ester at the acyl α-C–H bonds — the α-alkoxycarbonylhydroperoxide **27** [Eqn (37)].



(37)

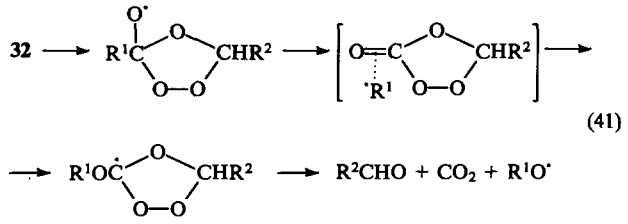
According to Denisov,[21] such a reaction may occur as a result of the concerted dissociation of several bonds in the hydroperoxide molecule [Eqn (38)]



(38)

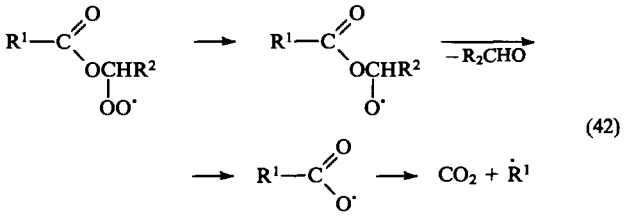
The high relative yield of benzaldehyde in the autoxidation of *tert*-butyl phenylacetate at 140 °C indicates the importance of the homolytic route to the decomposition of the intermediate *tert*-butyl α-hydroperoxyphenylacetate with the degradation of the carbon chain via reactions (37) and (38).[140] The formation of α-*tert*-butoxycarbonylbenzyloxyl radicals **29** and their degradation, leading to benzaldehyde, take place on recombination of the α-*tert*-butoxycarbonylbenzylperoxyl radicals **30** without chain termination.[140]

(39)



The α-acyloxyhydroperoxides **31**, obtained on oxidation of esters,[2,138,141–145] decompose preferentially via a nonhomolytic pathway.

(40)



This was demonstrated in relation to the oxidation of the esters of polyhydric alcohols by Martem'yanov[138,142-145] and was later confirmed in the oxidation of benzyl benzoate[146] and benzyl phenylacetate.[147] The formation of CO_2 from compound **31** in these cases is unlikely.

It has been suggested[138] on the basis of kinetic data and the detection among the ester oxidation products of alcohols of the type R^1OH that CO_2 may be formed in these reactions as a result of the transformations of the α-acyloxyperoxyl radicals **32** [Eqn (41)].

(41)

The formation of CO_2 from compound **31** is also possible as a result of the recombination of the latter without chain termination[146] and the decomposition of the oxyl radicals **33** obtained under these conditions.

(42)

The importance of reactions (37)-(42) for hydrocarbon oxidation processes is still insufficiently clear. There is no doubt that it cannot be considerable because the data on the reactivity of the α-C-H bonds of aromatic esters in relation to the *tert*-butylperoxyl radical[148,149] and of pentaerythritol esters in the reaction with cumenylperoxyl radicals[138,150] indicate the deactivation of the C-H bonds in both α-positions of the ester molecule compared with the hydrocarbon molecule. The oxidation of esters at the C-H bonds remote from the functional group is therefore more probable.[151] In such cases, the degradation of the carbon chain evidently occurs in conformity with the rules examined above for hydrocarbons.

IX. Conclusion

The experimental data obtained during the last 15-20 years permit a fresh look at the importance of the known reaction pathways leading to the rupture of the carbon chain and make it possible to justify new routes to oxidative degradation in autoxidation processes.

When the homolytic decomposition of hydroperoxides is stimulated, for example on catalysis, the degradation of the carbon chain to an appreciable extent can apparently occur already in the stages involving the reaction of the α-hydroxyhydroperoxides formed on oxidation of alcoholic functional groups.

On the other hand, the principal pathways in the oxidative degradation reaction include a stage in which ketones react. The ketones are oxidised by peroxide compounds and are involved in the radical-chain process. The oxidation of ketones by hydroperoxides proceeds via a stage involving the formation of α-hydroxyperoxides, which decompose like α-hydroxy- α-hydroperoxides. When ketones are acted upon by peracids, the carbon chain is degraded with formation of esters. In the radical-chain oxidation of ketones at the most reactive α-C-H bonds, the products are α-ketohydroperoxides, which decompose both with and without the degradation of the carbon chain. The available data show that aliphatic and alicyclic α-ketohydroperoxides react preferentially without the rupture of the carbon chain, affording α-ketoalcohols and α-diketones. The fraction of α-ketohydroperoxides decomposing with destruction of the C-C bonds depends on the reaction conditions and the structure of the α-ketohydroperoxides.

α-Ketohydroperoxides decompose via homolytic and nonhomolytic mechanisms with formation of compounds having functional carbonyl and carboxy-groups. It is not clear what is the principal route to the nonhomolytic degradation of α-ketohydroperoxides. Some preference is given to the dioxetane mechanism, which explains more effectively than the familiar acid-catalytic Langenbeck-Pritzkov mechanism the available experimental data on the characteristic features of the reactions of α-ketohydroperoxides. In the oxidation of ketones at other C-H bonds and also in the intramolecular chain transfer and in the decarbonylation of acyl radicals during the homolytic reactions of α-ketohydroperoxides, the latter do not decompose via the α-mechanism.

In their turn, α-ketoalcohols and α-diketones interact with peroxide compounds in hydrocarbons undergoing oxidation and are themselves subjected to radical-chain oxidation. The influence of these bifunctional compounds on the rate of decomposition of hydroperoxides is much greater than that of monohydric alcohols and monoketones.

The radical-chain oxidation of α-ketoalcohols leads to α-hydroperoxy-α-hydroxyketones, which are also formed on reversible nucleophilic addition of hydrogen peroxide to α-diketones. The interaction of the latter with hydroperoxides and peracids affords α-alkylperoxy-α-hydroxy- and α-acylperoxy-α-hydroxy-ketones, which, like α-hydroperoxy-α-hydroxy-ketones, also decompose with degradation of the carbon chain even at room temperature. The principal products of the degradation of these compounds are carboxylic acid anhydrides and the free acids. The anhydrides are evidently formed as a result of the pericyclic rearrangement of the oxirane intermediate, while the acids are formed via the dioxetane mechanism or on homolytic decomposition of the above peroxides. The relative importance of each of these three main mechanisms for the reactions of α-hydroperoxy-α-hydroxyketones is determined by the relative yields of the corresponding anhydrides and acids and depends on the structure of the peroxide, the medium, and the additives stimulating the homolytic decomposition of the peroxide.

Being extremely reactive, carboxylic acid anhydrides interact during the autoxidation processes with the water produced by the reaction, alcohols, acids, hydroperoxides, and other nucleophiles, participating thereby in the formation of numerous degradation products. In particular, not less than 20% of acetic acid is obtained in the oxidation of ethyl methyl ketone via acetic anhydride, while the cyclohexyl esters of mono- and di-carboxylic acids are formed in the oxidation of cyclohexane predominantly with participation of adipic anhydride. The influence of the homolytic decomposition reactions of the peresters, formed on esterification of hydroperoxides by acid anhydrides, on the rate of initiation and decarboxylation in the autoxidation processes is still to be estimated. However, it is believed that it may be extremely significant.

Abstract. Experimental data on the interaction of phthalodinitriles and bis(phthalodinitriles) with aromatic diamines are surveyed. The dependence of the mechanism of the reaction of phthalodinitriles with diamines on the structure of the diamine and the phthalodinitrile as well as the nature of the reaction medium is examined and general ideas concerning the mechanism of this reaction are formulated. The principal features of the polycondensation of bis(phthalodinitriles) with diamines are specified and the possibility of using this reaction to obtain a series of new classes of heterocyclic polymers with benzopyrrole fragments in the chain is demonstrated. The bibliography includes 70 references.

I. Introduction

A leading aspect of polymer chemistry is the synthesis and study of polyheteroarylenes with a cyclochain structure,[1-7] which have a series of valuable thermal, physicochemical and electrical properties. This review is devoted to a nontraditional approach to the synthesis of heterocyclic polymers, namely the polycondensation of tetracarboxylic acid *o*-dinitriles and aromatic diamines.

Studies on the chemistry of the interaction of *o*-dinitriles of aromatic di- and poly-carboxylic acids with diamines were initiated by the researches of Elvidge and coworkers[8,9] into the condensation of phthalodinitrile with aniline and diamines. Unfortunately, these very interesting reactions did not initially attract the attention of other investigators. It was not until 1967 that Packham and coworkers[10-13] turned their attention to these reactions and attempted to investigate them in greater detail in relation to the interaction of phthalodinitrile with 2,6-diaminopyridine and to use it for the synthesis of polymers with macroheterocycles in the chain. Siegel[14] and Balahura and Purcell[15] studied the mechanism of the condensation of phthalodinitrile with diamines in the presence of metal salts. The condensation of phthalodinitrile with diamines has been used as a preparative method of synthesis of macroheterocyclic compounds.[16,17]

These isolated communications in essence exhaust the studies of the interaction of *o*-dinitriles with the amino-group carried out hitherto.

Studies by Gaumans et al.[18] and Packham and Rackley[19] were devoted to the polycondensation of tetracarboxylic acid tetranitriles and diamines, which results in polymer formation with benzopyrrole fragments in the chain. Fusion of tetracarboxylic acid tetradinitriles with diamines at 300 °C leads to black insoluble and infusible polymers to which a macrocyclic structure has been assigned solely on the basis of IR spectroscopic data.[20] For a long time, there had been no systematic studies whatsoever of the effect of the structure of the starting materials, nature of the reaction medium, and the reaction conditions on the structure and properties of the compounds formed. Clearly, investigation of these problems is essential for the determination of the synthetic possibilities of the reaction, the elucidation of the reaction mechanisms occurring in the interaction of phthalodinitriles and tetracarboxylic acid tetranitriles with diamines, and the determination of the general characteristics of the process.

The few literature data on the model reaction of phthalodinitrile with aromatic diamines,[11,14,15] show that polycondensation of aromatic tetracarboxylic acid tetranitriles with aromatic diamines is an extremely complex process, which may lead to the formation of macrocyclic polymers, polymers without macrocycles, as well as polymers with a mixed structure. Therefore, in order to be able to specify the reaction, it was first essential to investigate in detail the main features of the condensation of phthalodinitriles with aromatic diamines. The macroheterocyclic compounds formed under these conditions in a number of instances were called hexazocyclanes, and polymers containing macroheterocycles with the corresponding structure in the chain were called polyhexazocyclanes.[7,21]

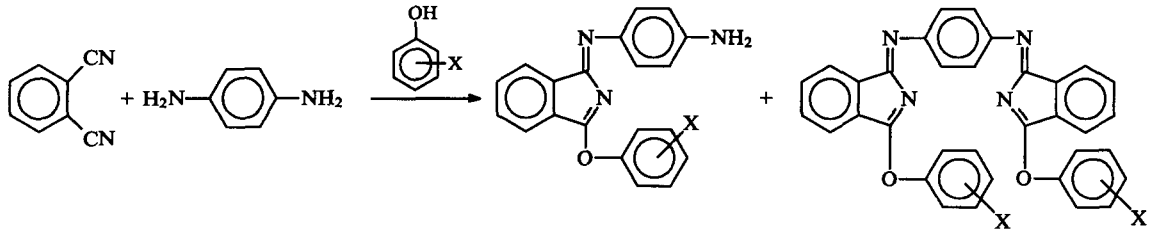
II. Interaction of phthalodinitrile with aromatic diamines

From literature data,[22,23] one may postulate that, when the condensation is carried out in an alcoholic medium, diamines react not with phthalodinitrile but with the product of its interaction with alcohol — 1-alkoxy-3-iminoisoindole. We studied the role of the hydroxylated solvent, and hence also the structure of the 1-alkoxy-3-iminoisoindole on the composition of the products of the condensation reaction between phthalodinitrile and *p*-phenylenediamine.[7,21,24-26] Butyl alcohol, cyclohexanol, phenol, and its derivatives with electron-donating substituents (cresols, dimethylphenol) and electron-accepting substituents (chloro-, bromo-, nitro-, and methoxy-phenols) were used as the reaction medium. The reaction products were investigated by the mass spectrometry and thin-layer chromatography (TLC) with the use of reference substances synthesised by specially developed methods. The results made it possible to put forward mechanisms of the condensation of phthalodinitrile with *p*-phenylenediamine in solvents of different nature.

Thus it was found that chloro- and nitrophenols function not only as the reaction medium but also as one of the reactants and enter into the composition of the reaction products (Scheme 1).

The condensation products of phthalodinitrile with *p*-phenylenediamine in aliphatic and alicyclic alcohols contain a wide range of compounds in which the content of the macroheterocycles **1** is only 50% (Scheme 2).



In the reaction of phthalodinitrile with *p*-phenylenediamine in phenol and its derivatives with electron-donating substituents, the yield of the macroheterocycle increases to 85%. The process is extremely selective and, apart from the macroheterocycle **1**, only compound **2** was found among the reaction products. In the reaction of phthalodinitrile with *p*-phenylenediamine, it was established at various stages of the latter that, when the reaction is carried out in solvents other than phenols with electron-accepting substituents, the intermediates contain compounds with m/z = 236, 327, and 455.

The following expanded mechanism of the reaction of phthalodinitrile with *p*-phenylenediamine in phenol, where the macroheterocycle was obtained in maximum yield, was proposed on the basis of these data (Scheme 3).

The results presented permit the fundamentally important conclusion that one of the decisive factors determining the composition of the products of the condensation of phthalodinitrile with aromatic diamines in hydroxylated solvents is the nature of the reaction medium. Since the condensation of phthalodinitrile with diamines in phenol is the most selective process in the formation of hexazocyclanes, the kinetics and mechanism of this reaction were investigated in detail.

The thermodynamics of the process were investigated for the condensation of phthalodinitrile with *m*-phenylenediamine.[27] Table 1 presents the enthalpies, entropies, and Gibbs free energies as well as equilibrium constants for this reaction at different temperatures. The negative Gibbs free energies indicate that the synthesis of the hexazocyclane is thermodynamically

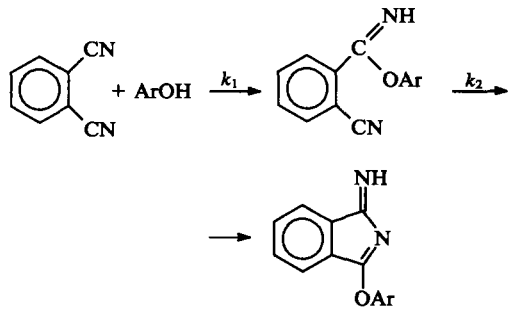
allowed throughout the temperature range investigated. The equilibrium constant of the reaction is $9.3 \times 10^5 - 5.3 \times 10^3$, so that the condensations of phthalodinitrile with diamines are irreversible. In the temperature range 420–500 K, the entropy of reaction is negative. The high negative enthalpy of the process is responsible for its being thermodynamically allowed and for its irreversibilty.

Since the formation of the hexazocyclane is a multistage process, its overall irreversibility does not rule out the reversibility of individual stages. The study of the composition of the products of the reaction of the hexazocyclane with ammonia—a low-molecular-mass product of this reaction—under the conditions of the synthesis[28] made it possible to put forward Scheme 4 for the ammonolysis of the hexazocyclane.

Comparison of the reactions involving the synthesis and ammonolysis of the hexazocyclane provided grounds for the hypothesis that the stages in its formation which take place with evolution of ammonia are reversible, i.e. that the process irreversibility should be attributed to its initial stages.

The kinetics and mechanism of the formation of the hexazocyclane were investigated for the reaction of phthalodinitrile with *p*-phenylenediamine. The process was followed from the decrease in intensity of the C≡N absorption band of phthalodinitrile in the IR spectrum of the reaction solution and

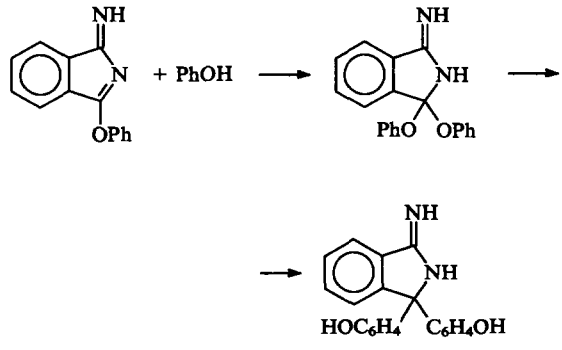


Scheme 4

from the evolution of ammonia. In order to determine the contribution of the individual stages to the formation of the macroheterocycle and to establish the most probable mechanism, mathematical modelling was used with preliminary estimation of the rate constants for those stages where it was possible.

In terms of Scheme 3, the first stage of the reaction is the interaction between phthalodinitrile and phenol. According to literature data,[29,30] there is an excess electron density in the phthalodinitrile molecule on one of the nitrogen atoms and a deficiency on the carbon atoms of the nitrile groups, the positive charge on the carbon atom on one of the nitrile groups being much higher than that on the carbon atom of the other group. This justifies the hypothesis that the reaction begins with nucleophilic attack by the phenol on the carbon atom with the greater positive charge.

The next stage is apparently nucleophilic attack by the nitrogen of the imino-group on the carbon atom of the second nitrile group with subsequent isomerisation and cyclisation.



6

However, it was found that the reaction product is 1-(4-hydroxyphenyl)-1-(2-hydroxyphenyl)-3-iminoisoindoline **7** and not 1-aryloxy-3-iminoisoindole **6**.[31] This gives grounds for the assumption that the 3-imino-1-phenoxyisoindole formed is an unstable compound, which, having combined with a phenol molecule, undergoes a rearrangement, which is consistent with the hypothesis put forward by Bartlett.[32]

Judging from the fact that there is no compound **7** among the products of the reaction of phthalodinitrile with diamines in phenol, the rate of reaction of the aryloxy-group with the amino-group is higher than the rate of its reaction with phenol.

Taking into account the proposed mechanism for the additional polarisation of the nitrile groups, it was decided to employ LiCl as the catalyst (the polarising effect of the Li^+ ion amounts to 1.7).[33]

7

Studies of the kinetics of the interaction of phthalodinitrile with phenol have shown[34] that there is an induction period in the reaction, which becomes shorter after the introduction of LiCl. The fact that the rate of reaction increases as a function of time is extremely important. This justifies the hypothesis that the process is autocatalytic.

Indeed, it was found that, when 1-(4-hydroxyphenyl)-1-(2-hydroxyphenyl)-3-iminoisoindoline is introduced into the reaction mixture, the induction period is markedly shortened. This is apparently associated with the presence in compound **7** of a secondary cyclic amino-group, the interaction of which with the phenolic hydroxyl increases the electron density on the oxygen atom, thereby increasing the rate of the reaction of phenol with the electrophilic carbon atom.

Other cyclic amines exhibit in this reaction a catalytic activity,[34] which increases with increase in the basicity of the amine. When a tertiary amine and LiCl are introduced simultaneously into the reaction, both reagents are activated and the induction period virtually vanishes.

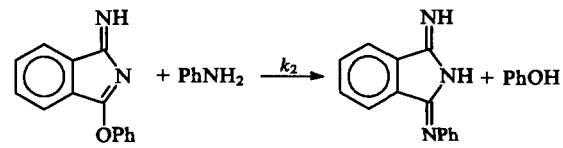
The following reaction rate constants have been obtained from kinetic data with the aid of the mathematical model:

$$k_1/h^{-1} = 0.004 + 1.6\,c_{LiCl} + 7\,c_7,$$

$$k_2/h^{-1} = 5.$$

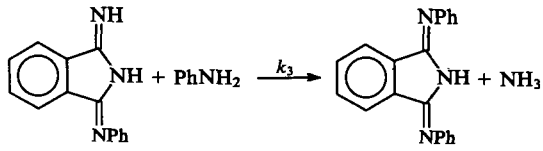
The results show that both LiCl and compound **7** are catalysts of the first stage of the reaction, the catalytic activity of the latter being higher. The cyclisation stage is noncatalytic. The proposed mechanism of the reaction of phthalodinitrile with phenol is confirmed indirectly by the shortening of the induction period with increase in the nucleophilicity of phenols caused by the introduction of electron-donating substituents into the benzene ring.

The product of the reaction of a substituted phthalodinitrile containing an electron-accepting substituent with phenol is 3-imino-1-phenoxyisoindole. The latter compound does not combine with a second phenol molecule and does not rearrange. Kinetic studies have shown[34] that the rate of reaction of phenol with substituted phthalodinitriles depends on the nature of the substituent in the phthalodinitrile and increases as its electron-accepting properties become more pronounced. The equations for the rate constants for the reaction of 4-nitrophthalodinitrile with phenol have the following form:



$$k_1/h^{-1} = 0.075 + 25\,c_{LiCl} + 11\,c_7,$$

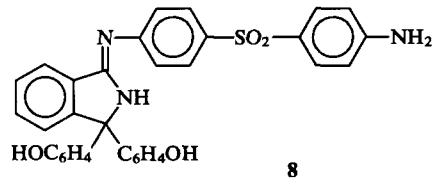
$$k_2/h^{-1} = 9.$$



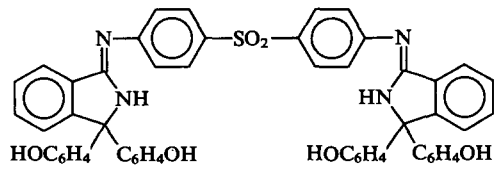
From the above equation for k_1, when the nitro-group is introduced into the phthalodinitrile ring, the contribution of the catalytic reaction increases appreciably (compared with the unsubstituted phthalodinitrile). This is accompanied by a sharp increase also in the catalytic activity of LiCl. Evidently, the increase in the positive charge on the carbon atoms of the nitrile groups facilitates their nucleophilic attack by phenol in the first stage of the reaction by the nitrogen of the free C≡N group in the second stage.

When the electron-donating OH group is introduced into the ring of phthalodinitrile, a sharp decrease in the reaction rate is observed, which is fully consistent with the proposed mechanism.

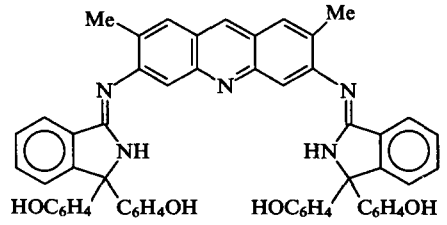
The next stage of macroheterocycle formation, the interaction of 3-imino-1-phenoxyisoindole with the diamine, was investigated for the reaction of phthalodinitrile with aniline at 20–180 °C in view of the complexity of the process.[35] It was found that, at temperatures below 70 °C, 3-imino-1-phenoxyisoindole interacts with aniline via the phenoxy-group.



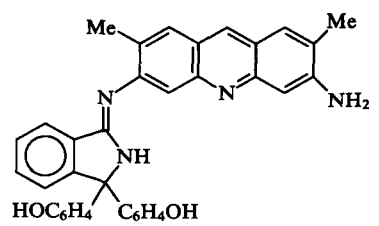
At a temperature above 70 °C, aniline behaves as a nucleophilic relative to the carbon atom of the C≡N group. The reaction of aniline with 1,3-diiminoisoindole results in the evolution of ammonia, which is apparently formed by the addition of the aniline protons to the exocyclic NH group.[36]



Calculation of the reaction rates by means of the mathematical model for the process showed[37] that the rate of reaction of phthalodinitrile with phenol diminishes sharply in the presence of aniline. Comparison of the equations for the rate constants showed that aniline appreciably lowers the catalytic activity of LiCl, apparently due to the formation of the complex $LiCl-PhNH_2$. The rate-limiting stage of the process is the formation of this complex.

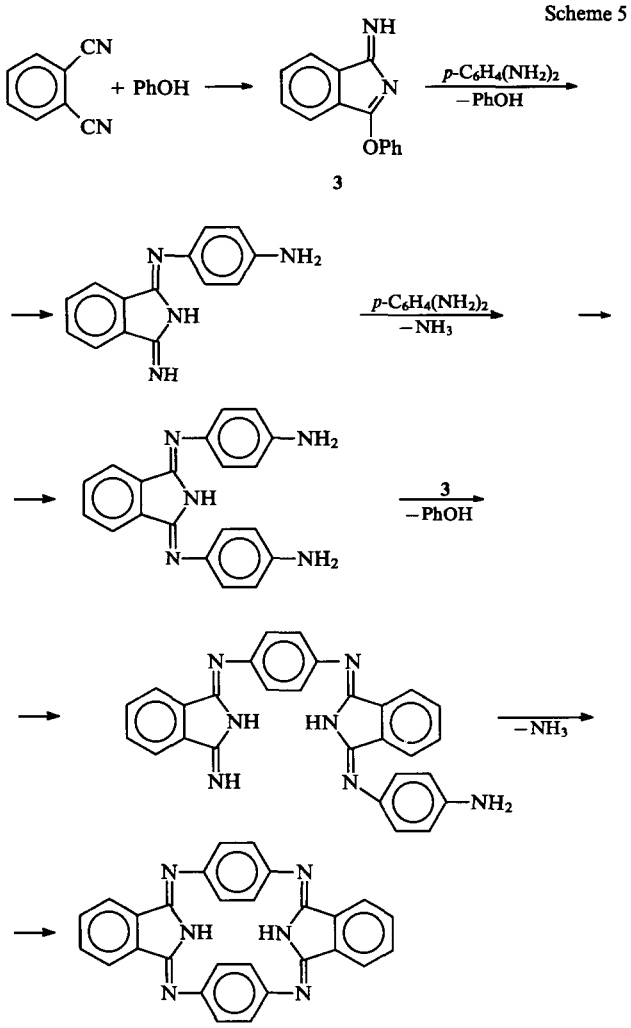


Since the condensation of the amino-group with the phenoxy- and imino-groups takes place via a nucleophilic substitution mechanism, the basicity of the amine should influence significantly the rate and mode of the reactions. The study of the composition of the products of the reaction of phthalodinitrile with 3,6-diamino-2,7-dimethylacridine ($pK_a = 1.5$), di(4,4-aminophenyl) sulfone ($pK_a = 2.7$), 9,9-bis(4-aminophenyl)-fluorene ($pK_a = 3.3$), and *p*-phenylenediamine ($pK_a = 6.2$) in phenol showed that, instead of the macroheterocycles, the corresponding compounds **8–11** are formed in the first two cases.

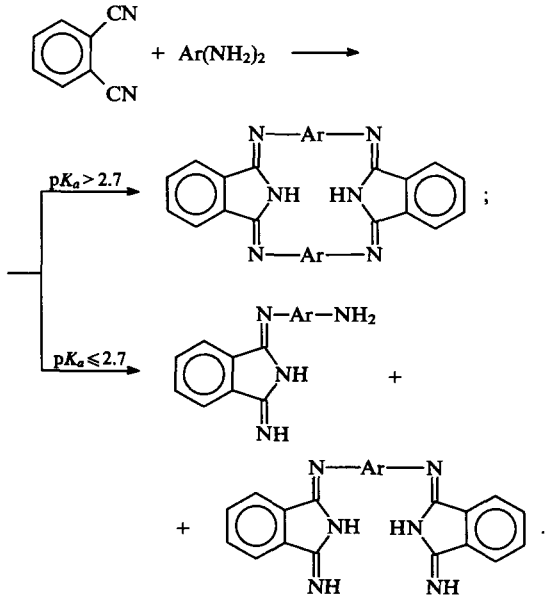


8

9



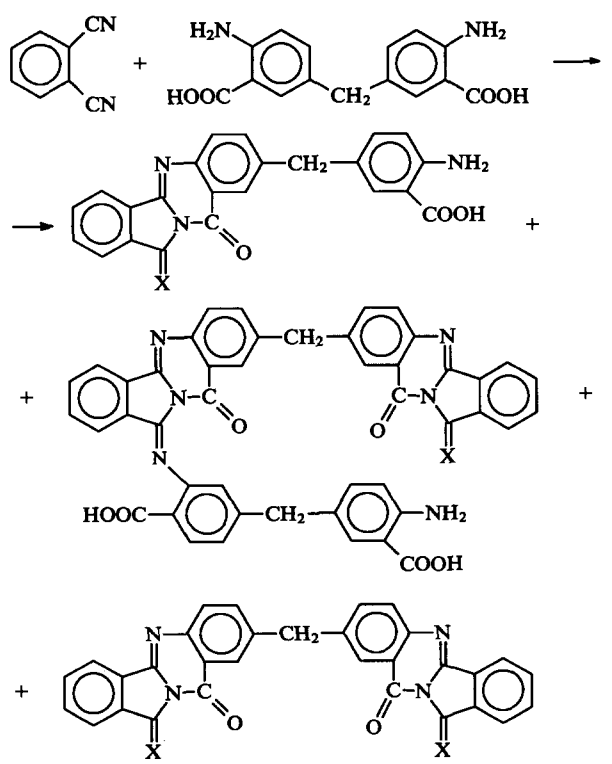
10, $m/z = 835$



11, $m/z = 537$

Scheme 5

Apparently, owing to the low basicity of these diamines, the rate of reaction of the amino-groups with the phenoxy-group in compound **3** (see Scheme 3) is lower than the rate of formation of compound **2**, which actually reacts with the diamine. In all the remaining cases, macroheterocycles are formed. From these data, the interaction of phthalodinitrile with diamines can be represented by the following general scheme as a function of the basicity of the diamines:

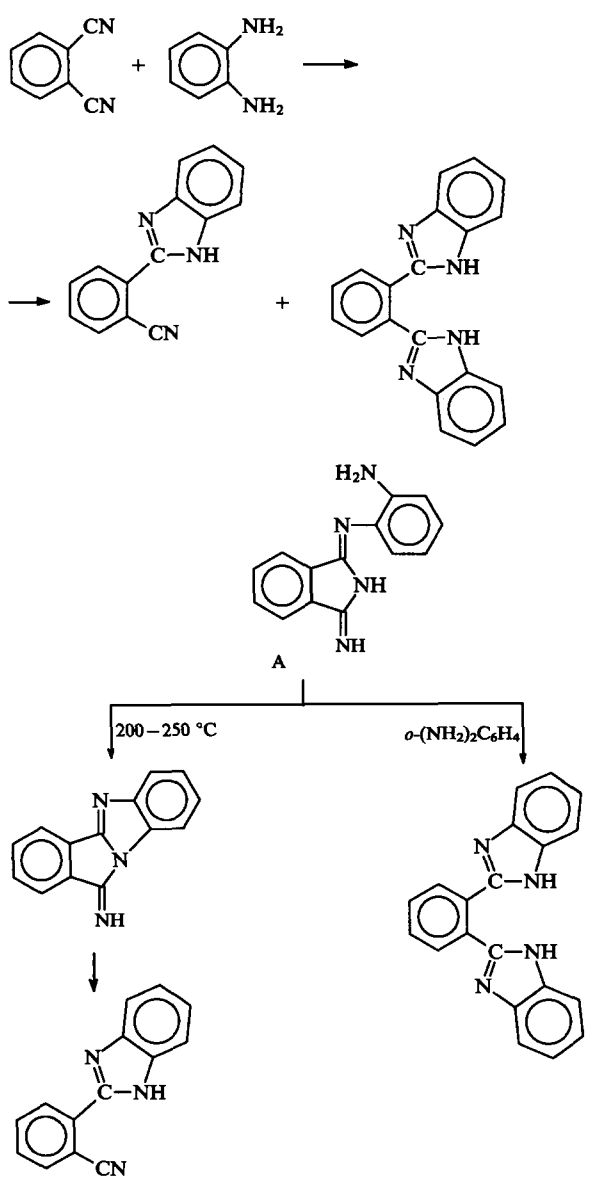


The kinetics of the formation of the macroheterocycle have been investigated for the condensation of phthalodinitrile with *p*-phenylenediamine.[40] The mathematical description of the process made it possible to calculate the rates of all the reactions constituting the formation reaction of the hexazocyclane and to determine its principal aspects (Scheme 5, see previous page).

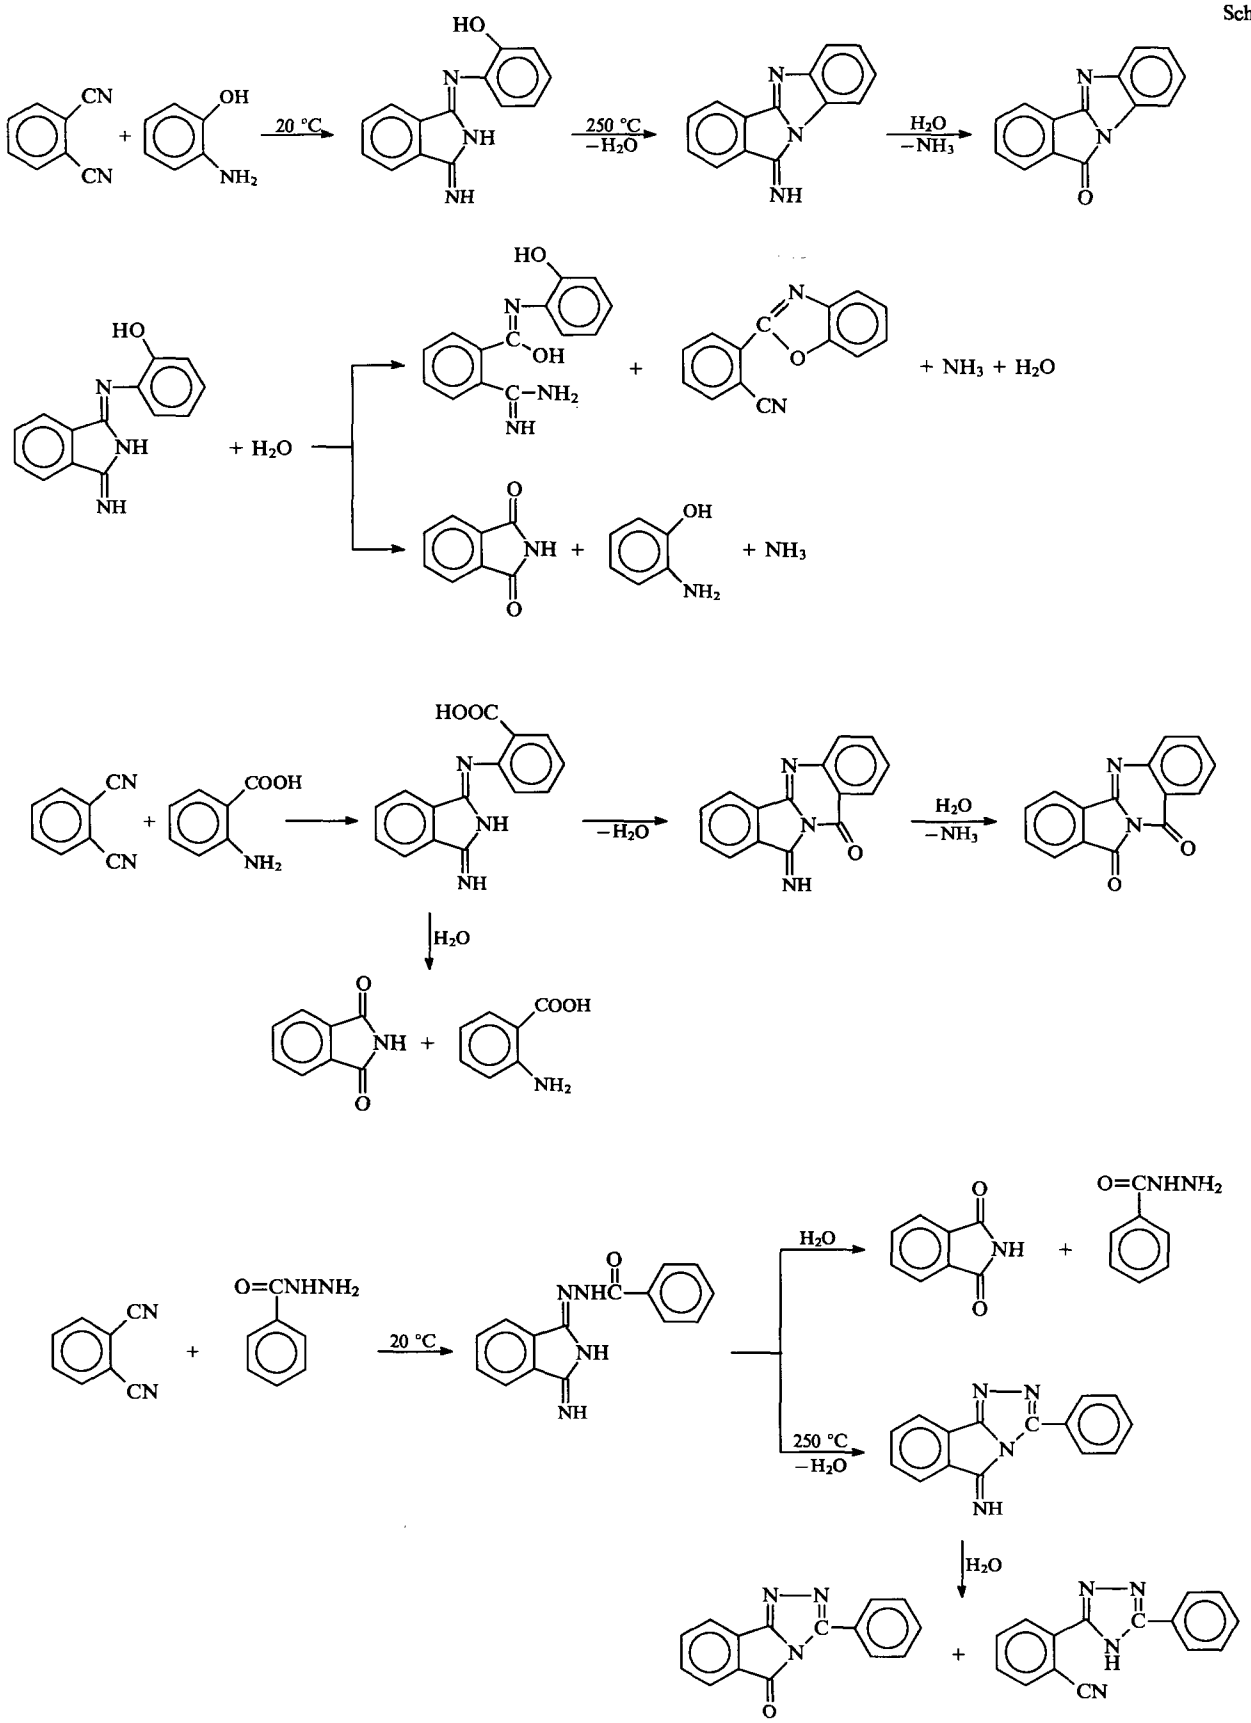
Direct experimental confirmation of the macrocyclic structure of the hexazocyclane was obtained by X-ray diffraction study of the hexazocyclane based on phthalodinitrile and di(4,4-aminophenyl) ether.[31] The geometry of the principal groups of atoms is close to the usual geometry, i.e. the formation of the macroheterocycle hardly requires the distortion of the bond angles and bond lengths. The conformation of the five-membered nitrogen-containing heterocycles is nearly planar (the endocyclic torsional angles do not exceed 4.4°). However, in combination with some twisting about the endocyclic C–N bonds, this proves sufficient for a significant deviation of the conformation of the macrocycle itself from planarity.

Hexazocyclanes contain water in the endocyclic space, i.e. they are clathrate compounds. In contrast to the majority of known clathrate compounds, for hexazocyclanes the guest molecule inclusion cage consists of a single molecule; hexazocyclanes based on mononuclear diamines contain one water molecule in the endocyclic space, whilst the remaining hexazocyclanes contain two such molecules regardless of the size of the macroheterocycle.[41]

III. Macroheterocycles with a system of five- or six-membered heterocycles condensed with the isoindole ring



Macroheterocycles with a system of condensed heterocycles can be formed if a diamine, containing *ortho*-substituents capable of interacting with the secondary amino-groups of the isoindole ring, is used as one of the initial reactants. Such reactions proceed both with the evolution of volatile products and via isomerisation cyclisation. This requires a high reactivity of the *ortho*-substituents. For example, they may contain a labile hydrogen atom, the interaction of which with the NH group of the isoindole ring is accompanied by water or ammonia evolution.

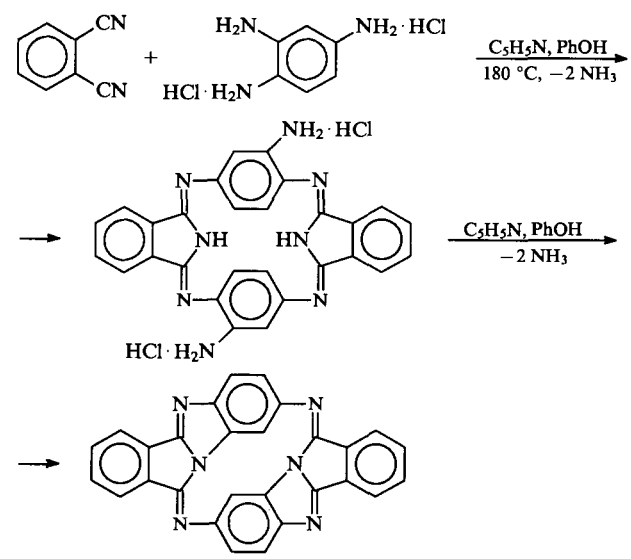


X = O, NH

The mechanism of this process has been studied for the condensation of phthalodinitrile with *ortho*-substituted monoamines—*o*-aminophenol, anthranilic acid, and benzohydrazide.[42] When these diamines interact with the imino-group of the isoindole ring, water is liberated. The thermal cyclisation process was investigated using compounds obtained by condensing phthalodinitrile with a monoamine at room temperature. At 200–250 °C both the formation of compounds with condensed heterocycles and the hydrolysis of the final and intermediate products take place (Scheme 6). Therefore, the possibility of using polyphosphoric acid (PPA) as the reaction medium, which binds the water evolved on cyclisation, was investigated in the condensation of phthalodinitrile with anthranilic acid. The composition and structure of the products of this reaction were found to be determined by the temperature and the order in which the reactants are added. The selectivity of the reaction of phthalodinitrile with anthranilic acid is ensured by introducing the acid at $T > 180$ °C into a solution of phthalodinitrile.

However, the reaction of phthalodinitrile with methylenedianthranilic acid proceeds under these conditions without the formation of a macroheterocycle.[43] (See bottom left.)

Scheme 6

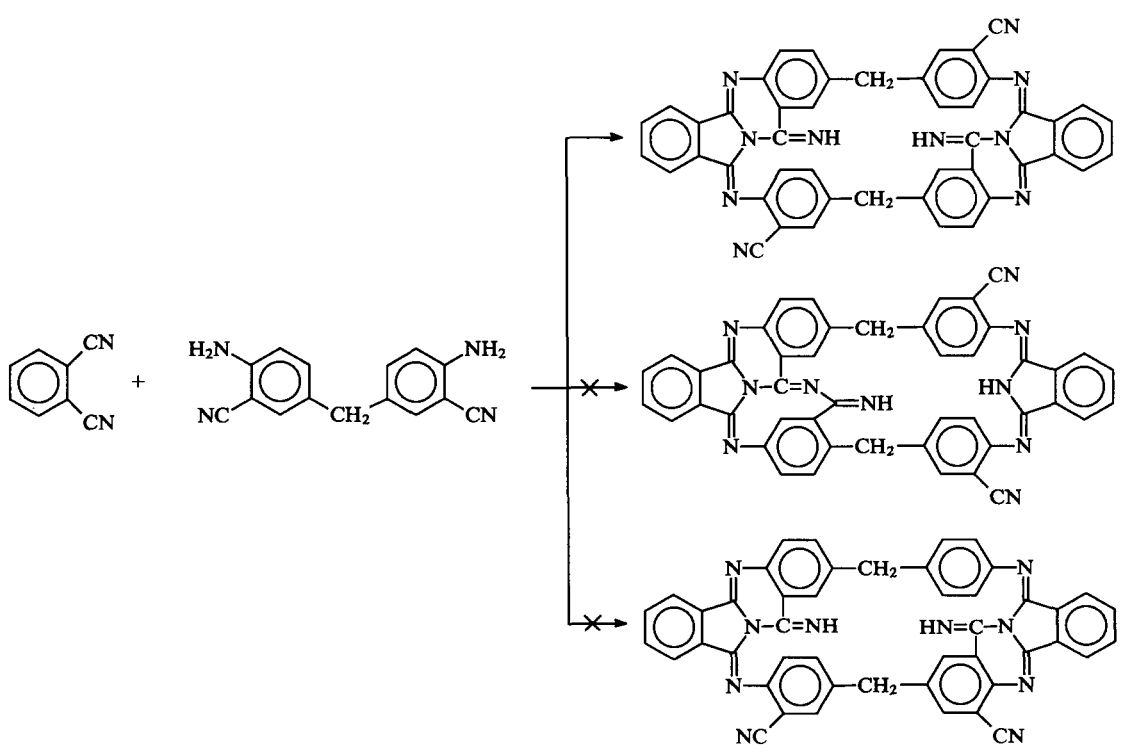


The fact that, instead of the macroheterocycle, only the intermediates in its synthesis are formed in the condensation of phthalodinitrile and *p*-phenylenediamine in PPA is extremely important. The same products, isolated from PPA and then placed in phenol, interact with the latter, affording a hexazocyclane. In the condensation of phthalodinitrile with 1,2,4-triaminobenzene, the formation of a system of condensed isoindole and benzimidazole rings should be accompanied by ammonia evolution. To find out whether such a reaction occurred, a comparison was made of the product composition of the condensation of *o*-phenylenediamine with phthalodinitrile in phenol at 180 °C [44] and of the cyclisation products of 1-*N*-(2-aminophenyl)-3-iminoisoindoline at 200–250 °C in the presence and absence of *o*-phenylenediamine (see page 772, bottom right).

It follows from a comparison of the results that the factors preventing the formation of compounds with a system of condensed isoindole and benzimidazole rings are the isomerisation of compound A with participation of the exocyclic NH group during the cyclisation process as well as the interaction of the intermediate — 1-*N*-(2-aminophenyl)-3-iminoisoindoline — with *o*-phenylenediamine. This required as the initial reactant not *o*-phenylenediamine itself but a derivative with a substituted amino-group. Furthermore, it is necessary that substitution of the exocyclic NH groups should precede formation of the benzimidazole ring.

Therefore, 1,2,4-triaminobenzene in the form of the 1,4-dihydrochloride was used as the amine component for the synthesis of a hexazocyclane with condensed benzimidazole and isoindole rings. During the synthesis, the hydrochloride groups were neutralised in two stages. Judging from literature data,[44] the 4-amino-group is the first to be neutralised, which is the reason for the possibility of macroheterocycle formation. After the neutralisation of the second amino-group, the latter reacts quantitatively with the NH group of the isoindole ring to form condensed heterocycles.[45] (See above right.)

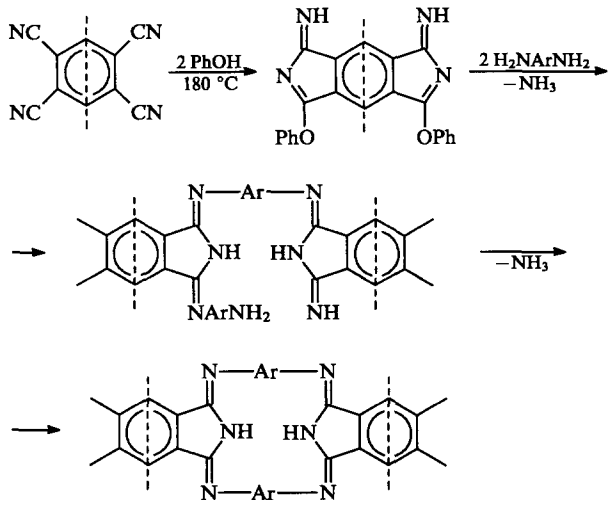
In order to obtain compounds with a system of condensed heterocycles without the isolation of volatile products, the dinitrile of methylenedianthranilic acid was used as the amine component in the reaction with phthalodinitrile in phenol, because in this case the quinazoline ring is formed via isomerisation cyclisation.[46] A quantitative estimate by IR showed that the hexazocyclane



contained two free C≡N groups, which justifies the hypothesis that three isomers of the macroheterocycle differing in the position of the C≡N groups are formed. Studies showed that the reaction proceeds strictly selectively only via a single pathway with formation of a macroheterocycle having the structure presented in Scheme 7.

The selectivity of the reaction is evident because, as a result of the interaction of one of the nitrile groups with the imino-group of the isoindoline ring, the benzene ring incorporating this nitrile group rotates until it coincides with the average plane of the macroheterocycle. The plane of the second benzene ring should then be inclined relative to the average plane of the macroheterocycle. The distance between the nitrile group of this ring and the imino-group of the isoindole ring increases, which rules out the possibility of intramolecular cyclisation.

The data obtained in the study of model reactions of phthalodinitriles with diamines served as a basis for the development of specific methods of synthesis, from tetracarboxylic acid tetranitriles and diamines, of polymers both having a macrocyclic structure and without macroheterocycles.



Scheme 7

IV. Polycondensation of tetracarboxylic acid tetranitriles and unsubstituted diamines in phenol

The data obtained in the study of model reactions of phthalodinitriles with diamines give grounds for the assumption that polymers with the maximum content of macroheterocycles in the chain can be obtained by the polycondensation of tetracarboxylic acid tetranitriles and highly basic ($pK_a > 3.3$) aromatic diamines in phenols ($pK_a > 9.8$). The polycondensation process can be represented by the multistage Scheme 8.

Scheme 8

The polymer chain grows by accumulation in the latter of macroheterocycles, the formation of which is accompanied by ammonia evolution. Hence, the amount of ammonia evolved is used as a measure of the degree of reaction and of the propagation of the polymer chain. The structure of the polymers has been confirmed by ^1H NMR spectroscopic data[26] obtained in the study of a polyhexazocyclane (PHC) based on pyromellitic acid tetranitrile and *p*-phenylenediamine.

Kinetic studies of the reaction of tetracarboxylic acid tetranitriles and diamines show that the polycondensation process is autocatalytic. By analogy with the model reaction, one can postulate that the autocatalysts of the polycondensation process are intermediates containing a cyclic imino-group. The use as the catalyst of a tertiary cyclic amine with LiCl leads to the disappearance of the induction period and to an increase in reaction rate.

The set of monomers which has been used to synthesise PHC made it possible to trace in succession the influence of their structure on the properties of the polymers.

It follows from Table 2 that a high degree of reaction and a high yield are characteristic of all the PHC. The solubility of the polymers is determined by their structure. The introduction into the monomer of a cardo-group and of an oxygen bridge between the benzene rings increases the range of solvents in which the PHC dissolve.[21]

All the PHC possess a high thermal stability and heat resistance. According to dynamic thermogravimetric analyses (TGA), the temperature of the onset of their vigorous decomposition in air exceeds 400 °C. A more complete idea about the thermal transformations of PHC has been obtained in the study of the composition of the products of the thermal and thermohydrolytic degradation of the macrocycle based on phthalodinitrile and *p*-phenylenediamine as well as a series of PHC at 350–600 °C.[47]

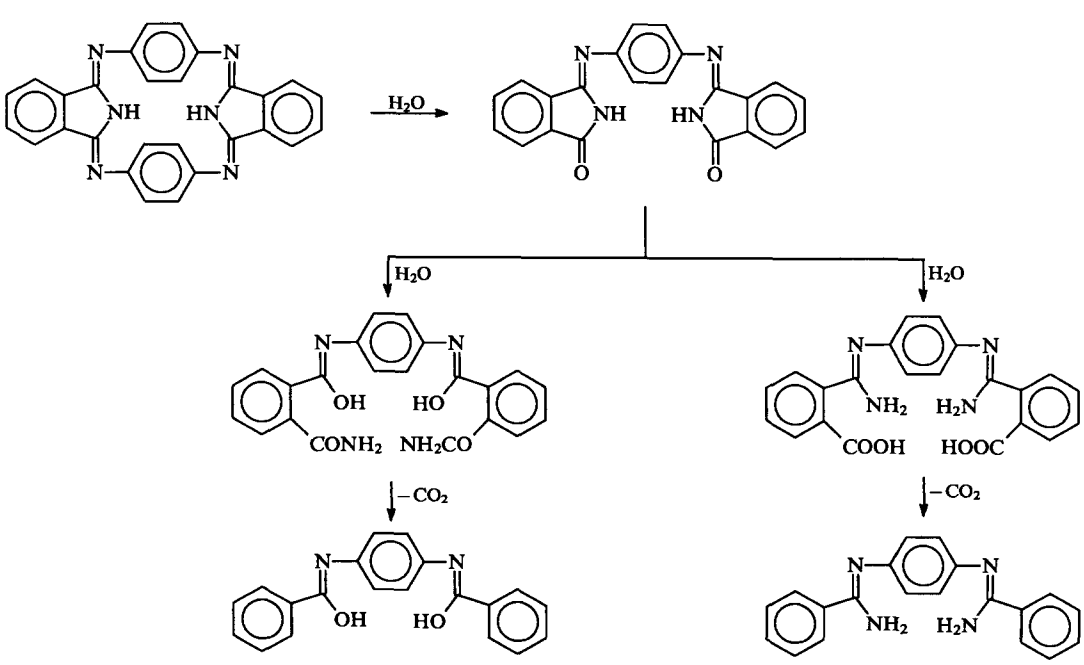
The presence in the thermal degradation products of the macrocycle of carbon oxides, ammonia, phthalimide, and *p*-phenylenediamine suggested that carbon oxides [carbon dioxide only? (Ed. of Translation)] are formed as a result of the hydrolytic cleavage of the hexazocyclane (Scheme 9).

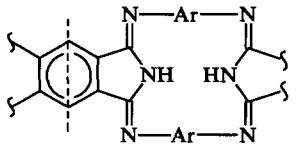
The main hydrolysing agent is apparently the water enclosed in the macroheterocycle. This hypothesis is supported by the finding that the products of degradation (at 400–450 °C) of a hexazocyclane, the endocyclic space within which was occupied by other groups[41] or of a hexazocyclane from which the occluded water had been removed by sublimation, contained only traces of CO_2.

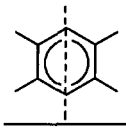
The overall data obtained in the study of the degradation products justified the hypothesis that hydrolytic decomposition processes dominate in the thermal degradation of hexazocyclanes and polymers up to 450 °C, while above 450 °C homolytic decomposition processes assume this role, as indicated by the appearance of hydrogen, methane, and carbon monoxide in the decomposition products.

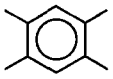
One of the real routes to increasing the thermal stability of the PHC involves the synthesis of polymers the endocyclic part of the space within which is occupied by groups of some kind, which rules out the presence of occluded water. The preparation of polymers containing five- or six-membered heterocycles condensed with the isoindole ring is most promising in this respect.

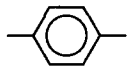
Scheme 9

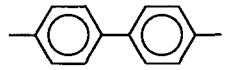


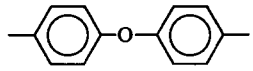


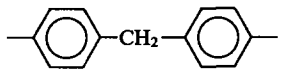


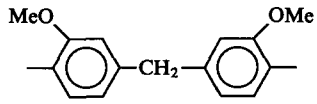


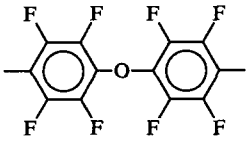


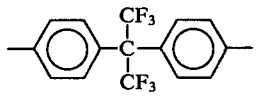


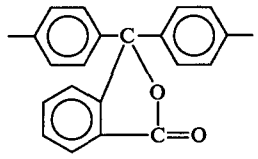


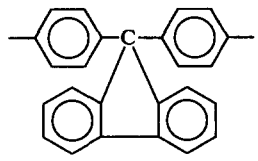


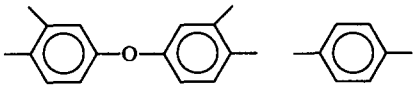












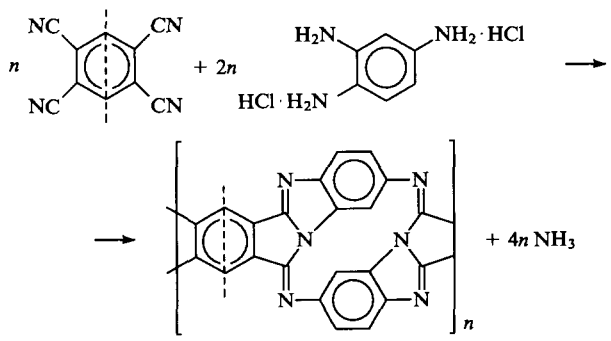


Table 2. The properties of polyhexazocyclanes having the general formula

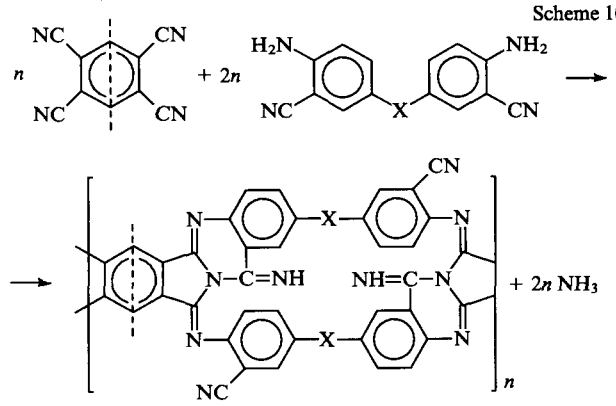
	—Ar—	Degree of reaction (%)	Yield of polymer (%)	Solvents [a] in which polymers dissolve	Temperature of onset of softening [b]/°C	Temperature of onset of decrease in mass [c] in air/°C
		98	99	H_2SO_4	Does not soften	400
		98	99	H_2SO_4	"	420
		95	95	DMF, HMPA, DMSO, *N*-MP	225	400
		98	99	H_2SO_4	370	410
		97	98	DMF, HMPA, DMSO, *N*-MP	180	350
		91	95	DMF, DMA, *N*-MP, DMSO, acetone, dioxane	210	410
		95	95	"	180	380
		98	97	DMF, HMPA, DMSO, *N*-MP	380	410
		99	98	DMF, DMSO, *N*-MP, dioxane	220 (p = 19.6 MPa)	430
		97	92	DMF, DMSO, *N*-MP, HMPA	180	410



[a] DMF = dimethylformamide, HMPA = hexamethylphosphoramide, DMSO = dimethyl sulfoxide, *N*-MP = *N*-methylpyrrolidinone [DMA = dimethylacetamide (Ed. of Translation)].
[b] Rate of temperature rise 10 °C min^{-1}, p = 9.8 MPa.
[c] Rate of temperature rise 4.5 °C min^{-1}.

Polyhexazocyclanes with condensed isoindole and benzimidazole rings have been obtained by polycondensation of tetracarboxylic acid tetranitriles and diamine dihydrochlorides,[48] the latter being neutralised during the synthetic process.

Polyhexazocyclanes with condensed isoindole and quinazoline rings have been synthesised using bis(*o*-cyanoarylamines) (Scheme 10).[48]

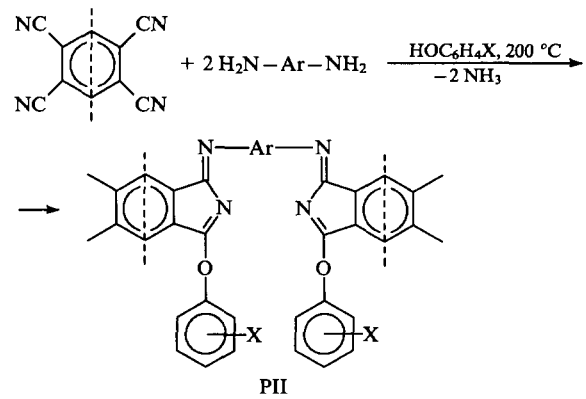
Scheme 10

The thermal stability of such polymers is much higher than that of the usual polyhexazocyclanes.[49] Hydrolytic processes in polymers with condensed heterocycles are extremely slight. The amount of CO_2 evolved during their thermal degradation is smaller by a factor of 4–6 at 450 °C and by a factor of 2–4 at 500–550 °C than in the degradation of the PHC based on *p*-phenylenediamine. In this case, the hydrolysing agent is apparently adsorbed water, the content of which in the polymers, determined by the Fischer method, does not exceed 1%.

V. The properties of solutions of polyhexazocyclanes

The presence of macroheterocycles in the PHC chain determines the specific properties of dilute and concentrated solutions of these polymers.[50] Thus when the degree of reaction is quantitative, the intrinsic viscosity of 0.3%–1.0% solutions of the polymers in *N*-methylpyrrolidinone (*N*-MP) and dimethylformamide (DMF) is low and independent of concentration. Centrifugation results in the complete precipitation of the polymers from the solutions. This provides grounds for the hypothesis that solutions of PHC in aprotic solvents are not true solutions but approach colloidal or are colloidal solutions. This hypothesis has been confirmed by studies of solutions of PHC in *N*-MP by electron microscopy,[51] according to which the polymers in solution exist in the form of aggregates up to 1.5 μm in size, which is evidently associated with a weak polymer–solvent interaction.

In view of the presence in the macroheterocycle of the tertiary amino-group and on the basis of the available data on the solubility of rigid-chain nitrogen-containing polymers,[52,53] it was postulated that the interaction of the polymers with formic acid, which exhibits protogenic properties, is more intense than the interaction with *N*-MP. Indeed, it was found that the absolute intrinsic viscosities of solutions of the polymers in HCOOH are appreciably higher than those of the solutions in *N*-MP. According to electron microscope data, the polymers exist in formic acid in the form of individual 10–20 nm globular particles.



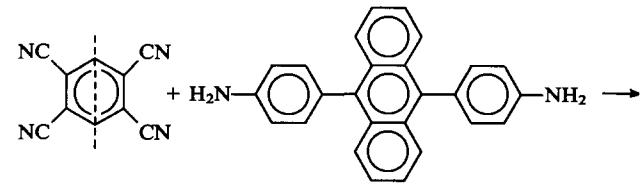
Polymers with charged nitrogen atoms have also been obtained by quaternising them with alkyl halides.[50] The dependence of the viscosity of solutions of such polymers in *N*-MP on the concentration is characteristic of molecularly disperse solutions, while the size of the polymer particles in solution does not exceed 20 nm.

The viscous characteristics of concentrated solutions of PHC are determined by their structure and by the nature of the solvent. Thus, up to a 25%–30% concentration of the PHC in *N*-MP, there is no interaction between the aggregates and the viscosity of the solutions is low and almost independent of concentration. Newtonian flow is characteristic of solutions of PHC in this concentration range. At concentrations above 30% the viscosity rises sharply, evidently at a consequence of the mutual interaction of the aggregates, which leads to a non-Newtonian type of flow.

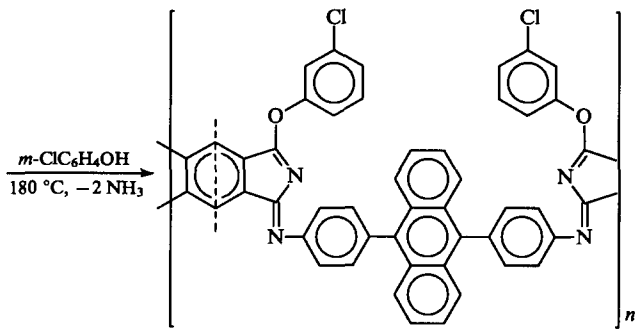
Starting with a 10% concentration of a solution in formic acid of a rigid-chain polymer, the preparation of which is illustrated in Scheme 10, gel formation takes place which is apparently associated with the mutual arrangement of the extended macromolecules. The modulus of elasticity of a 10% solution of the gel is 6.2×10^{-4} Pa. The high elasticity of the gel is due to the presence in the polymer of nitrile side groups, which are additionally polarised as a result of complex formation with the carboxy-group, intensifying the intermolecular interaction. The modulus of elasticity remains constant up to 70 °C, which distinguishes this gel from the usual heat-treated gels produced as a result of the formation of physical bonds.

VI. Polycondensation of tetracarboxylic acid tetranitriles and diamines in phenols with electron-accepting substituents

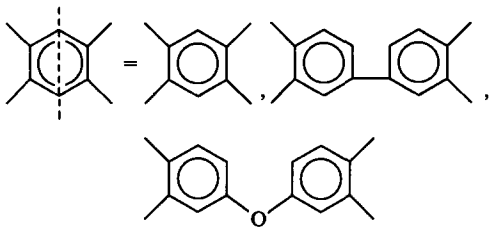
Polymers with side aryloxy-groups in the chain, called polyisoindoxazenes (PII) are formed in the polycondensation of tetracarboxylic acid tetranitriles and diamines in phenols with electron-accepting substituents.[54]



PII



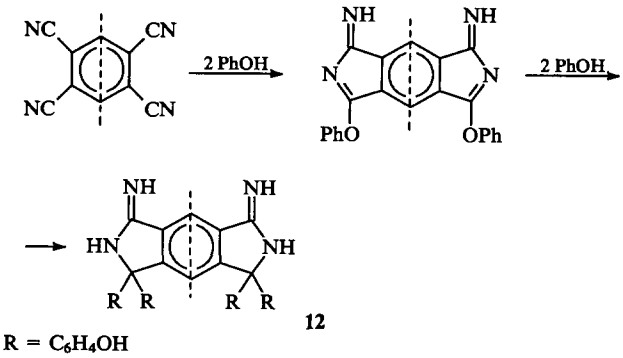
X = Cl, Br, NO_2.



Kinetic studies show that the reaction has an induction period. With increase in the pK_a for a phenol, the duration of the induction period diminishes and the rate of polycondensation rises. From data obtained on model reactions, it is suggested that the process under consideration is autocatalytic, the product of the interaction of the tetranitrile with the phenol playing the role of the autocatalyst. The reaction of the phenol with the *o*-dinitrile is a nucleophilic process, so that the acidity of the phenol determines the rate of formation of the autocatalyst, which is simultaneously a reaction intermediate, and hence the rate of the reaction as a whole.

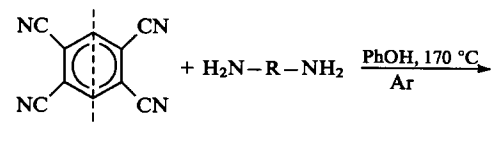
Polyisoindoxazenes have fairly high thermal stabilities and heat resistances, their thermal stabilities being somewhat inferior to those of the PHC. The temperature corresponding to a 5%

decrease in the mass of these polymers in air does not exceed 400 °C according to dynamic TGA data. As a rule, these polymers are readily soluble in organic solvents. The polymer based on pyromellitonitrile and bis(4,4'-aminophenol)anthracene, which precipitates during synthesis and does not dissolve even in sulfuric acid, is an exception.

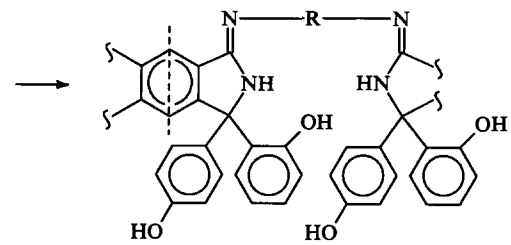


Calculations of the conformational parameters of this PII showed[55] that the rigidity of its macromolecule is such that it cannot form a coil and retains the shape of a straight rigid rod whatever the number of units, which is due to the presence of only a single virtual bond around which rotation is possible. The polymer having this structure has the most rigid chain among all those known at the present time and the concept of the Kuhn segment is not applicable to it. The replacement of pyromellitonitrile by the tetranitrile of oxybis(benzenedicarboxylic) acid results in the appearance in the polymer of additional virtual bonds around which rotation is possible. Under these conditions, the size of the Kuhn segment diminishes to 40 Å and the polymer becomes soluble in organic solvents.

VII. Polycondensation of tetracarboxylic acid tetranitriles and weakly basic diamines



Judging from model reaction studies, in the polycondensation of the tetranitriles and weakly basic ($pK_a < 2.7$) diamines in phenol[56] the first stage in polymer formation is the interaction of the tetranitrile with four phenol molecules and subsequent rearrangement of the phenoxide groups. Compound **12**, formed at this stage, reacts with the diamine.



The polymers obtained in this way have been called polyoxyphenylisoindazenes. Their solubilities are higher than those of PHC and PII, whilst their thermal stabilities are comparable with those of the latter compounds. The presence in the polymers of free hydroxy-groups leads to the possibility of extensive modification of their properties by means of further polymer-analogue reactions.

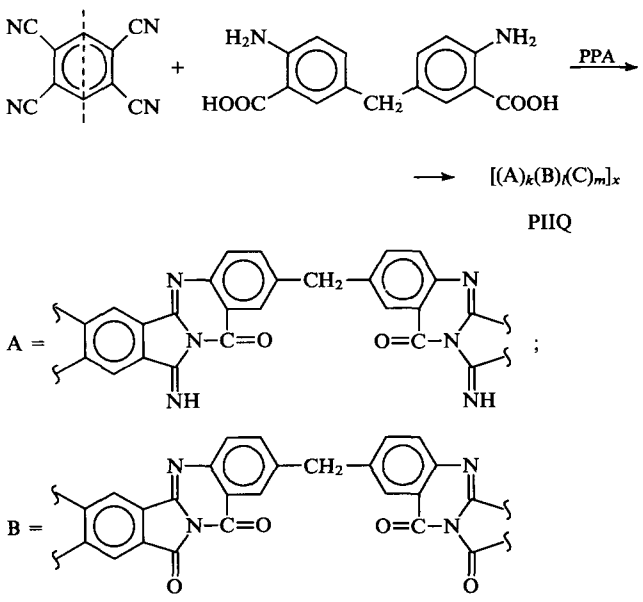
R = C_6H_4OH

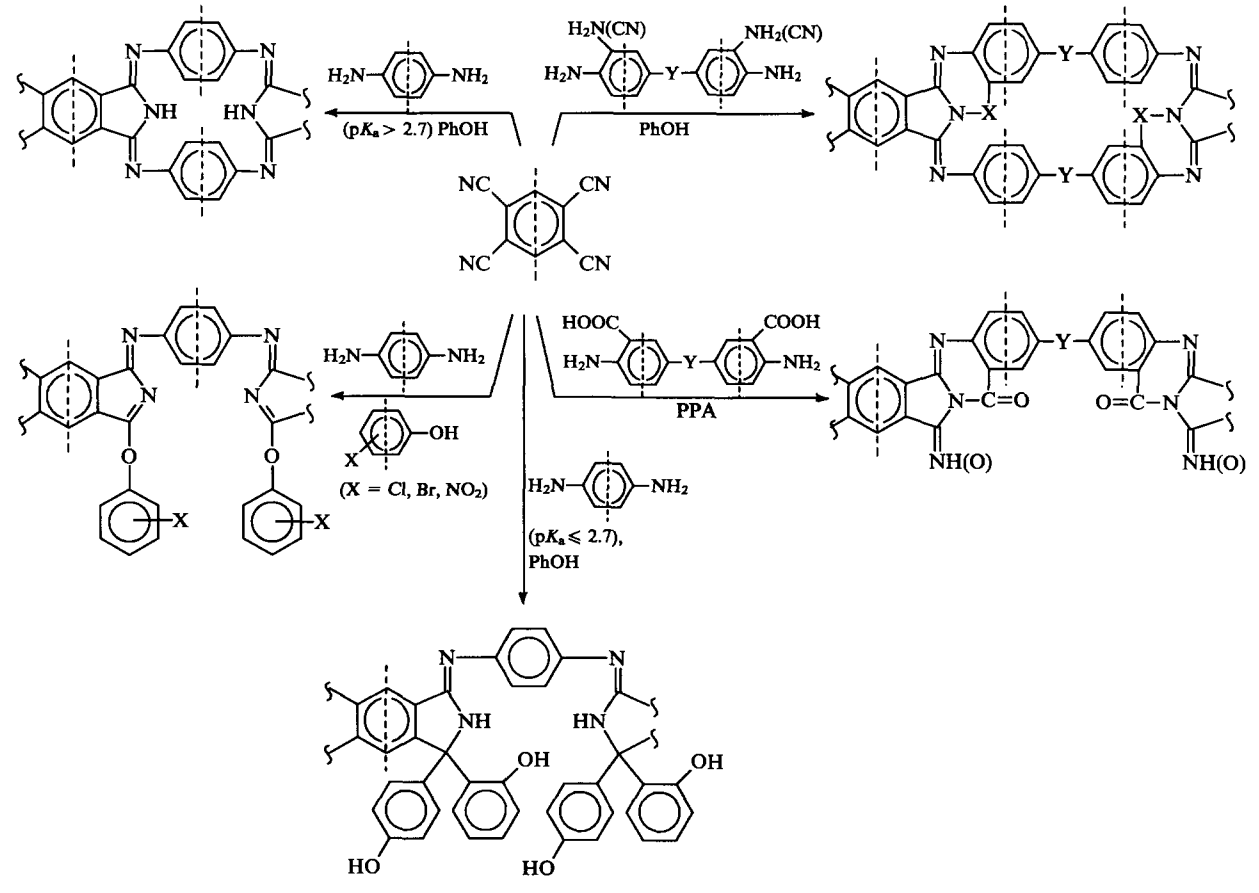


VIII. Polycondensation of tetracarboxylic acid tetranitriles and bisanthranilic acids in polyphosphoric acid

Polymers with a nonmacrocyclic structure, containing condensed isoindole and quinazolinone rings in the chain, have been obtained by the polycondensation of tetracarboxylic acid tetranitriles and bisanthranilic acids in polyphosphoric acid.[42] Such polymers have been called polyisoindolequinazolinones (PIIQ).

Polyisoindolequinazolinonediones, the structure of which is similar to that of the PIIQ, have been obtained by the polycondensation of bis(*o*-aminoamides) [?bis(*o*-aminobenzenecarboxamides) (Ed. of Translation)] with tetracarboxylic acid dianhydrides and also by the interaction of diaminodicarboxylic acids with the dianhydrides and chlorides of tetracarboxylic acid half-esters.[57-61] The possibility of the synthesis of such polymers by polycondensation of derivatives of tetracarboxylic acids with diaminodicarboxylic acids has also been demonstrated.[62,63]

This aspect developed appreciably after the polycondensation of 2,5-dicyanoterephthaloyl chloride with dicarboxy- and bis(methoxycarbonyl)-amines as well as bis(*o*-aminonitriles) had been achieved.[64,65] The use of these compounds made it possible to obtain polyiminoquinazolinepyrrolones via an isomerisation mechanism without the isolation of volatile products.[66]



Polyisoindolequinazolinones are readily soluble in organic solvents and in inorganic acids. Their thermal stability is high: according to dynamic TGA data, the temperature of a 5% decrease in their mass in air is 420–440 °C. Carbon monoxide is completely absent from the products of the degradation of the polymers in vacuo at 400 °C, while at 450 °C its amount is insignificant, which indicates the virtually complete cyclisation of the polymer under the conditions of the synthesis.

At 500 °C, gas evolution is greater by a factor of 4–5 for polyisoindolequinazolinones than for PHC, indicating an appreciable contribution of the macrocyclic structure to the thermal stability of the polymers (Scheme 11).

Thus the study of the condensation and polycondensation of phthalodinitriles and bis(phthalodinitriles) with diamines demonstrated the extensive synthetic possibilities of these reactions. The determination of the physicochemical characteristics of the processes made it possible to formulate general ideas concerning the mechanisms of these reactions, which provided a basis for the synthesis of a series of new classes of polymers.[6,7,21,42,43,48,67–70]

Abstract. The transfer of the ideas and methods of nuclear physics and nuclear chemistry to the study of structural biology has led to the creation of a new method of studying the accessible surface and the three-dimensional structure of biological materials. We shall review the papers which have formed a basis for the tritium planigraphy method and the main directions in which the method has developed in its applications to molecular biology problems. The bibliography includes 129 references.

I. Introduction

Recent advances in the study of many biological phenomena at the molecular level have stimulated the search for and development of new approaches to the study of the structure of supermolecular systems, to the determination of the size and composition of the surface of the interacting components in the system, and to the study of the mechanism of specific protein–protein and protein–nucleic acid interactions.

High-resolution (1–2 Å) X-ray structural analysis is the only experimental method capable of giving wide-ranging data on the three-dimensional structure, and therefore also on the surface area of the object. However, its range of applications is limited to a relatively narrow choice of materials, available as highly ordered crystals. In addition to the purely technical problems associated with the growth of these crystals (especially in the case of large and labile complexes) there are difficulties in the interpretation of their complex diffraction patterns. Furthermore, demonstrating the identity in structure of a given compound in a crystalline sample and in solution (the natural working medium of biological systems) remains an unsolved problem.

Because of these difficulties methods such as NMR are still used in studies of relatively low-molecular peptides and proteins.[1]

In the case of large-scale objects (100 nm or more) structural information can be obtained by electron microscopy methods, which (in conjunction with the most recent data processing techniques) offer a resolution of the order of 20 Å, increasing to 5 Å in cryoelectron crystallographic studies.[2,3] This method allows the molecular architecture of complexes to be studied, together with the distribution of the component masses in the complex, the relative localisation of the molecules, and the quaternary structure of the protein (see, for example, Holzenburg et al.[4]).

The new scanning electron microscopy method, which offers the highest reported resolution (~1 Å), must also be mentioned among the methods of studying the surface, but it has not yet achieved the status of a generally usable method. So far its application to biological materials is mainly in general illustration of areas of interest, but we may well find that with some further development the method will provide information at the level of localisation of individual atoms.[5]

Traditional approaches, based on the introduction of various types of probe and of modifier, are widely used in studies of the surface topography and the structure of biological systems. The recently produced low-frequency ESR spectrometers have allowed whole cells and even fragments of tissue to be studied *in vivo*.[6] However, the structural information obtained in this way applies exclusively to local fragments of the object, or (in the most favourable case) to the nearest surroundings of the tracer species, and is totally unrelated to the structure of the sample as a whole. Perturbations which can seriously alter the native structure of the object can be induced by the introduction of probes of various kinds, and should not be ignored when this information is interpreted.

In all the studies listed above the use of modifying agents labelled with radioactive isotopes increases the sensitivity of the detection by a large factor. Successful studies of the selective iodination of surface proteins in cell membranes[7] and of intact hepatitis A virus particles[8] are good examples of this effect.

However, there is also another group of methods based on the use of radioactive indicators. In these methods structural data are obtained directly from the method used to introduce the label, which establishes the accessibility of the various groups in the three-dimensional structure to the particular test label.

A good example of this approach is the study of the surface of specific protein-transfer RNA complexes, in which the label was introduced into the H-8 position of the purine bases of RNA by exchange with HTO water.[9] Of course, there are many cases in

which both groups of methods can be applied: in these, the steric accessibility of the reactive group is established (from the yield of the labelled product) together with its structural surroundings (for example, from the spectral characteristics).

The tritium planigraphy method belongs essentially to the second group. It is characterised by lack of selectivity of the labelling. As will be shown below, it can be used to determine the steric accessibility of the hydrocarbon groups ($-CH$, $-CH_2$, $-CH_3$) to attack by a hot tritium atom under free flight conditions. The result of this attack is the replacement of ^1H hydrogen by its radioactive isotope tritium, which takes place in all the sterically accessible fragments of the object with approximately equal probability and does not affect their properties: the labelled product and the unlabelled initial molecule are chemically identical. The range of application of this method is quite wide, since practically all the biological molecules are derivatives of hydrocarbons. It should be pointed out that the small size of the tritium atom results in a higher level of structural discrimination than can be achieved by using larger probes or labels.

In this review we shall not discuss the various methods of introducing the tritium label: interested readers are referred to the monograph by Neiman et al.[10] We shall instead confine the discussion to the tritium planigraphy method, in which the hot tritium atoms are generated by thermal dissociation of molecular tritium.

II. Fundamentals of the method

The tritium planigraphy method is based on chemical reactions involving fast particles (the so-called hot-atom chemistry), which began to be studied in the 1950s and 1960s. The most important result of these studies was the concept of the excitation function of a chemical reaction, i.e. the dependence of the probability (or cross-section) of the reaction on the energy of the particles. It was shown that in many cases this function has a limiting character, and the cross-section of the reaction increases from zero over a relatively narrow range of energies. Obviously, if several reactions (with different thresholds) can occur together in a given system the process can be shifted in the required direction by varying the energy. Thus, if the particles X and Y can interact by three channels having activation energies E_1, E_2, and E_3, where $E_1 < E_2 < E_3$, all three products can be formed in the system when $E > E_3$. However, if $E_2 < E < E_3$ only two channels are available to the reaction, and lastly for $E_1 < E < E_2$ only one reaction is possible (Fig. 1).

The most important chemical process taking place during the interaction of hot hydrogen atoms with saturated hydrocarbons is the substitution reaction, which (according to the energy of the atoms) can proceed by the direct substitution mechanism (activation energy 1.5 eV)[11,12]

$$RH + \overset{*}{H} \longrightarrow R\dot{H} + H, \quad (1)$$

or through a free radical formation stage

$$RH + \overset{*}{H} \longrightarrow \dot{R} + H_2, \quad (2)$$

$$\dot{R} + \dot{H} \longrightarrow RH, \quad (3)$$

where the asterisk denotes a hot atom and the dot denotes a free radical. The limiting step is the removal of the hydrogen atom, whose activation energy lies between 0.3 and 0.4 eV (depending on the bond type).[13] The recombination reaction (3) has a zero activation energy, and takes place with the participation of hot hydrogen atoms. The nonreactive collision is accompanied by loss of energy (thermalisation) of the hot atom:

$$RH + \overset{*}{H} \longrightarrow (RH)' + H, \quad (4)$$

where $(RH)'$ is an excited molecule. The probability of the collision and the amount of energy transferred in a single collision depend on the velocity of the incident particle, and also on the structural and energy characteristics of the partner molecule. When ordinary hydrogen is replaced by its isotope (tritium) the product of the substitution reaction is labelled. As a method of studying the accessible surface and the three-dimensional structure of the object tritium planigraphy is applicable only under conditions in which the chemical substitution reaction leading to the incorporation of the label occurs at the first collision between the hot atom and the hydrocarbon molecule. Obviously, this requires a source of atoms having energies which satisfy the condition $0.3 < E < 1.5$ eV and $E - \Delta E < 0.3$ eV, where ΔE is the loss of energy accompanying a nonreactive collision. In this case one nonreactive collision makes the subsequent reaction impossible, and only reaction (2) (hydrogen removal) is observed in the system.

The ideal variant would seem to be the presence of a source of monoenergetic particles having energies in the required range, but this is extremely difficult to realise in practice. The tritium planigraphy method relies on the atomisation of diatomic gases on heated metal filaments, first studied by Langmuir.[14] On the surface of an incandescent filament the gas molecules dissociate into atoms, which are emitted from the surface with an energy corresponding to the temperature of the filament. This method was used in studies[15,16] of the reactions between oxygen and hydrogen atoms.

At a filament temperature of 2000 K the average energy of the emitted atoms is 0.17 eV, and in the Maxwell spectrum of the atomic beam ~25% of the atoms have an energy sufficient to displace hydrogen ($E \geqslant 0.3$ eV).[17] The proportion of the particles having energies of 1.5 eV, and therefore able to replace hydrogen by the direct substitution mechanism [reaction (1)], is small (<3%), and therefore reaction (1) can be ignored.

Attempts to use the thermal activation method to prepare labelled compounds began in the middle 1960s. Moser et al.[18] bombarded films of sugars with tritium atoms, and obtained labelled products, but the high yield of decomposition products even then raised serious doubts as to the practical value of the method. For the same reason other similar studies (for example, early attempts to label whole granules of starch)[19] have not been developed further. It was found that the main decomposition mechanism was the use of excessively thick targets, which suppressed the removal of heat from the reaction zone. The surface of the target became heated by absorbing the luminous radiation of the filament, by heat transfer through the molecular gas, and also by the heat evolved by the reaction of the tritium atoms with the substance. It was subsequently shown that by using effective heat removal procedures almost 100% of the substance

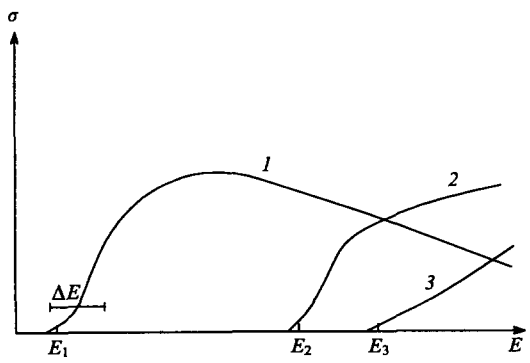

Figure 1. Dependence of the probability of a chemical reaction (σ) on the energy of the interacting particles (E) for three possible channels with thresholds E_1, E_2, and E_3: ΔE is the loss of energy for a single nonreactive collision.

could be preserved.[20] This required working with thin layers of organic materials and cooling the target with liquid nitrogen. Even after a long exposure the temperature of the target was not more than 10–15 K higher than the liquid nitrogen temperature.[21] A low target temperature (77 K) suppresses the mobility of the free radicals formed by hydrogen removal, and therefore the main path for their disappearance is the recombination with thermalised tritium atoms with formation of the labelled initial molecule [reaction (3)].

The possibility of studying the accessible surface and the three-dimensional structure of the macromolecules is due to the small penetration depth of the tritium atoms which are able to react with the target atoms. The direct measurement of the depth of penetration of the reactive tritium atoms is experimentally difficult. However, this quantity can be calculated by making certain assumptions, and it can also be obtained from some indirect results. The calculations show that for tritium hot-atom initial energies close to the threshold energy of the removal reaction even a single nonreactive collision is sufficient to transfer the particle to a region in which hydrogen removal becomes impossible. Fig. 2 shows the dependence of the fractional number of tritium atoms with an energy $E \geqslant 0.3$ eV upon the depth of penetration into a layer of organic compound. It can be seen that whereas at X = 0 (i.e. at the surface of the object or at the first collision of the tritium atom with the molecule) the fractional number of reactive atoms is 26% this value decreases to 0.4% when the atoms have penetrated within the layer to a depth of only 6 Å. In practice the free path of the reactive atoms (the thickness of the reaction layer) is even smaller, since their number in the beam passing through the target is lowered also by a chemical reaction whose cross-section is comparable to the collision cross-section in the case of atoms with an energy higher than the threshold value.[10] This means that if a macromolecule is used as the target the distribution of the label over its fragments becomes a measure of its steric accessibility for a collision with the primary bombarding particle, i.e. it characterises the surface area of the macromolecule accessible to the tritium atoms. The thickness of the reaction layer can also be estimated from the results of experiments on the introduction of a tritium label into adsorption layers of surface-active substances with hydrocarbon chains of different lengths

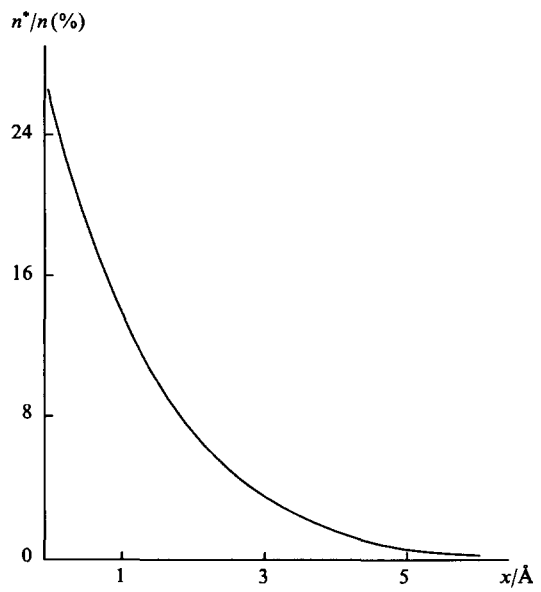

Figure 2. Decrease in the relative number of reactive particles during the passage through a layer of thickness x in a condensed organic substance (calculated for atoms with a temperature of 2000 K under conditions of elastic retardation, $E_{act} = 0.3$ eV).

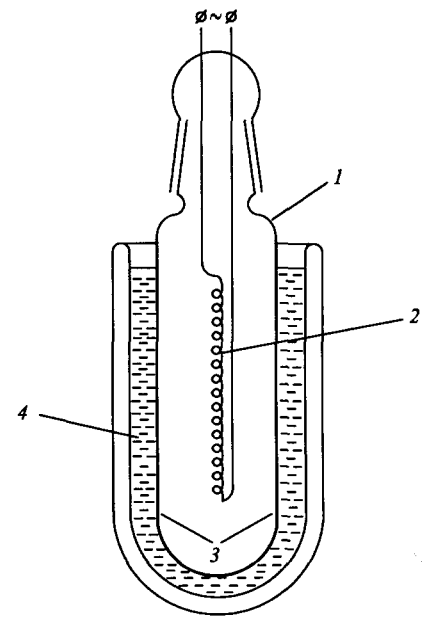

Figure 3. Glass reactor for tritium bombardment.

(from C_1 to C_{16}).[22] From the dependence of the yield of labelled product (incorporation of the label) on the length of the molecule and on its orientation at the interface it was concluded that a change in layer thickness by one methylene group, i.e. by ~3 Å, has a marked effect on the yield of labelled product. This length can be used as a quantitative characteristic of the thickness of the reaction layer. A similar value is suggested by experiments on the incorporation of tritium into myoglobin, which will be discussed below.

The apparatus used in all the experiments on tritium labelling is shown in Fig. 3. The central part of the apparatus (the reactor) is a cylindrical glass vessel (*1*) fitted with an axial tungsten wire (*2*) heated by an electric current. The target material (*3*) is deposited as a thin film on the side wall of the vessel, which is cooled in liquid nitrogen (*4*). The reactor is evacuated to a residual pressure of 10^{-5} Torr, and gaseous tritium is then admitted into the system. In the reaction vessels used in the majority of experiments (60 mm in diameter) the pressure of molecular tritium was 5×10^{-3} Torr. When the filament was heated to 2000 K the tritium was atomised on its surface, and the resulting atoms (formed under conditions of free flight to the target) were allowed to bombard the walls of the reactor. Experimental details and the sequence of operations have already been discussed in some depth,[10] and in this review we shall confine ourselves to examining the methods of preparation of the target and the general methodology adopted for analysing the distribution of the label.

The simplest method is the lyophilisation of a solution of the substance. However, if this method is chosen it is essential to ensure that the resulting film is firmly attached to the reactor walls over the whole of its internal surface. Furthermore it should not be forgotten that the lyophilic drying process may itself influence the structure of the substance under study.

In order to study the structure of the macromolecule in solution a target can be prepared by 'smearing' the experimental solution as a thin film by rapidly rotating the reactor immersed in liquid nitrogen. In many cases this method gives good results, but there are at least two aspects which limit its application. The first is the crystallisation of the water induced by the relatively low rate of cooling. When the vessel is immersed in liquid nitrogen the latter boils, forming a layer of gas bubbles close to the wall which slows down the cooling. This effect can be avoided by choosing other cooling agents (for example, liquid ethane), but working with this

gas has some undesirable features. The formation of a crystalline phase of ice must be avoided in work with materials containing 'internal' water, such as macromolecules and their complexes (including clusters) including more than 10 water molecules, liposomes, and whole cells.

The second limitation is due to the specific features of the method. Since the incorporation of the label is confined to a zone accessible to the first collision of the tritium atom incident from the gas phase, i.e. to the surface of the target, and in practical experiments the specific radioactivity is measured, it is essential to know, or at least to be able to control, the concentrations of the solute at the surface and in the bulk of the sample. In the method of target preparation described above a liquid solution exists for a certain time, giving a water–air interface. Therefore the bombardment by atomic tritium is experienced by an adsorption layer of molecules, whose parameters are determined by the adsorption process. The concentration of solute molecules in this layer is described by the adsorption isotherm. It is most convenient to work under conditions of complete saturation of the surface layer: these offer adequately reproducible results even when the surface concentration of the substance is not known. Calculations show that for solutions of macromolecules the time of formation of the saturated layer is a few minutes ($\sim 2-5$ min), which is of the same order as the time of preparation of the sample. The formation of a saturated layer is confirmed by the observed dependence of the time on the concentration of the solution.[22] In the case of amphiphilic substances the use of this method of target preparation can lead to the orientation of the molecules with respect to the phase separation boundary, and in this case the distribution of the label will represent the character of the orientation rather than the structural features of the object. In substances of low-molecular mass the orientation effects are especially clearly displayed. The orientation of macromolecules requires long times, and their amphiphilicity is weaker.

Both these difficulties (crystallisation of the water and the contribution from adsorption processes) can be avoided by rapidly freezing the solution using a 'spraying' technique. The solution is sprayed as very small droplets onto the inner surface of the reactor previously cooled in liquid nitrogen by using a specially designed nebuliser. The lifetime of each drop, and therefore also of the water–air interface, is small (equal to the time of flight from the nozzle of the nebuliser to the wall), and adsorption cannot take place. However, the rate of cooling of the drop incident on the reactor surface at 77 K is so high that the solution solidifies as a glass. Under these conditions we find a state of affairs similar to that which exists on a freshly cleaved solid surface. The concentration of molecules on the cleaved surface can be related to that in the bulk by the simple expression $C_s = C_v^{2/3}$. The dependence of the activity taken up by the sample on the concentration ($I = C_v^{0.67}$) is found to be consistent with the above relationship in experiments with both substances of low-molecular mass and solutions of proteins.[10,22,23].

Yusupov and Spirin[24] proposed an original method of target preparation which avoided the artefacts associated with the crystallisation of water and with the adsorption of the solute on the phase separation surface. A solution or suspension of the sample was introduced dropwise into liquid nitrogen. The very small particles of ice formed in this way were crushed directly in the liquid nitrogen, and this 'slurry' was deposited on the reactor walls. The liquid nitrogen quickly boiled off, and the ice particles were left firmly adhering to the reactor wall. The results obtained confirm the effectiveness of the proposed method, but its practical application requires special skills.

When considering the technique of the method we must particularly note the special factors which determine the reproducibility of the results obtained. Among customary factors, such as the precision of radioactivity measurement and of the determination of temperature of the wire, of the pressure of molecular tritium, of the exposure time, and also of the errors introduced by the chosen method of analysis, we should include the reproducibility of the total surface area of the target bombarded by the tritium atoms. When the techniques of solution spraying or evaporation from a suspension are used it is difficult to achieve good reproducibility of the total target area. To ensure a correct comparison of the results of independent experiments we must normalise the reported values with respect to the total flux of tritium atoms reacting with the target surface. Obviously, the latter quantity corresponds to the total radioactivity of the sample, including the activity of the sample itself and that of the solvent. If all the other standardisation conditions are observed (for example, the mass of the label attached to the C–H bond) the assignment of the radioactivity of the substance under study to the flux of tritium atoms should be constant for a given substance. An additional method (in some cases, the only possible method) of standardising the experiment is to use a different kind of monitor: organic substances placed at a fixed distance from the filament. Monitors of this type include various polymer films, cellulose or paper filters, etc.

In studies of proteins the transition from the amount of label included to the determination of the steric accessibility (or, in other words, of the accessible surface area) requires an allowance for the probability of the incorporation of tritium into aminoacid residues of different types under identical exposure conditions. These calibrating coefficients are needed also in all other cases of experimental samples consisting of components of different chemical nature. Several attempts have been made to determine the relative reactivities of aminoacid residues by comparing free aminoacids[25] and short peptides,[23] and determining the inclusion of the label in the aminoacid residues and in proteins with known three-dimensional structures in which the accessibility (exposure response) of the residues could be calculated from X-ray structural analysis results. Though the results of different workers, obtained for different systems, show some discrepancies they can be summarised as follows:

(1) in proteins we find a linear relationship between the amount of label incorporated and the accessible surface area calculated for the hydrocarbon fragments of the aminoacid residue;

(2) the nature of the neighbouring residue on the polypeptide chain does not affect the amount of label which is taken up (if normalised for unit area of accessible surface); this amount is also independent of the site on which the residue is located (the N or the C end of the peptide);

(3) the inclusion of the label in the residues of different aminoacids has almost equal probabilities when calculated for a single C–H bond or for unit area of accessible surface.

The results obtained by Gedrovich and Badun[23] deserve a special mention: these workers found that in the composition of di- and tripeptides the relative reactivities of three aminoacids (valine, leucine, and isoleucine) are several times higher than those of other aminoacids. This effect was ascribed to the presence (in the side group) of tertiary carbon atoms, from which the removal of hydrogen is substantially easier than in other configurations.[26] Table 1 shows the probabilities of including the label into the residues of aminoacids, established experimentally for the model protein lysozyme. We consider these results to be among the most reliable.

In conclusion we should dwell briefly on the general methodology used in the analysis of the distribution of the label in the experimental object. It varies according to the particular problem being studied, and it is determined by the required level of 'resolution'. Even the first stage [the determination of the overall amount of label remaining in the sample after removal of the labelled solvent, i.e. the sum of the labile (exchangeable) and of the stable labels (held in the C–H bond), and also the labelled water strongly bound to the surface of the macromolecule] allows us to determine the total area of accessible surface of the sample. Since the overall amount of label is usually 2–3 orders of magnitude

Table 1. Probability of including the label (K) in the aminoacid residues of lysozyme, normalised for unit area of accessible surface of the hydrocarbon fragment ($C_\alpha - H$, side groups).[45]

Aminoacid residue	K[a]	Aminoacid residue	K[a]
Lys	0.12	Pro	0.11
His	0.16	Ala	0.12
Arg	0.10	Val	0.11
Asx	0.10	Ile	0.10
Glx	0.20	Leu	0.08
Thr	0.10	Tyr	0.07
Ser	0.10	Phe	0.09
Gly	0.09		

[a] Standard deviation 20%.

greater than the amount of stable label in the C–H bonds the differences between the probabilities of interaction of tritium with aminoacids of different types are quite unimportant.

Preliminary estimates can be made, and a fairly wide range of problems whose solution requires a knowledge of the total aminoacid content of the solvent can be examined, by determining the label incorporated in aminoacids of different types. To this end the protein freed from the labile label (by dialysis, chromatography, electrophoresis, etc.) is hydrolysed, and the inclusion of the label in individual aminoacids is determined by analysing the hydrolysates and at the same time measuring their radioactivity.

Often we need to know the distribution of the label along the polypeptide chain of a protein. In this case the protein is fragmented into peptides, the mixture of peptides is separated, the peptides are identified and hydrolysed, and lastly the inclusion of label in each aminoacid is determined. Obviously, in an ideal situation, peptides in which each aminoacid occurs only once are produced by the fragmentation of the protein. In practice this state of affairs is very seldom met, but every effort is made to minimise the number of repeat occurrences. Lastly, a sequence of peptides with an analysis of the activity in each of the aminoacids removed is also possible.

Thus, by correctly preparing the target, labelling the sample, and choosing an appropriate strategy for analysis of the distribution of the label, the latter parameter can be used to construct a model of the three-dimensional structure. This possibility was first demonstrated in a study of labelled myoglobin.[27] According to the X-ray structural analysis results the N end of the protein fractions is an α-helix A, including the residues 3–18 (Fig. 4) and oriented so that part of its surface is directed outwards, and part is in the 'shadow' produced at its contact with the G and H helices where A connects them with a chain fragment.[28] The distribution of the label in the N end of the protein (aminoacid residues 1–20) shows that the label is incorporated only in the aminoacid residues pointing outwards, and not in those localised in the region of contact and therefore not accessible to the tritium. A reasonably good correlation was obtained in comparisons of the incorporation of the label with the area of the accessible surface in the same residues, calculated by the method of Lee and Richards[29] from X-ray structural analysis data. This experiment confirmed earlier reports of the dependence of the take-up of the label on the three-dimensional structure in peptides, and predicted the possibility of developing a new experimental method of studying the structure and the topography of the accessible surface of macromolecules and of supermolecular systems: the tritium planigraphy method.

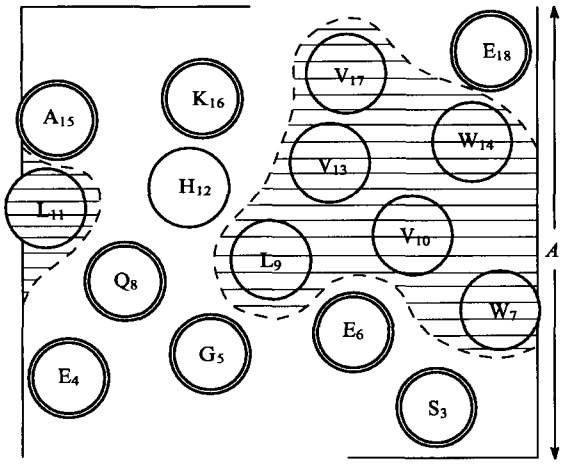

Figure 4. Schematic of the 'unfolding' of the surface of the α-helix region A of the whale myoglobin protein (residues 4–18). The one-letter code is used for the aminoacids. The cross-hatched regions are aminoacid residues sterically inaccessible to the tritium atoms (regions of 'shadow').

III. Study of the accessible surface of proteins. Limits of application of the method

The interaction of polymeric molecules takes place through groups of atoms localised on their surface. Methods proposed to describe the surface (Fig. 5) include determining the area of the macromolecule surface accessible to water molecules: this was found to be a very important concept, because this surface plays a fundamental role in the formation, stabilisation, and operation of the native structure of biopolymers. A new term was created by Lee and Richards[29] to describe it: the 'accessible surface'. It denotes the surface which can accommodate the centres of spherical test species (probes) with a radius of 1.4 Å (approximately equal to the radius of water molecules) in contact with the van der Waals surface of the macromolecule. The macromolecule itself is treated as an assembly of atoms approximating van der Waals spheres, and the coordinates of their centres are determined by high-resolution (1–2 Å) X-ray structural analysis. Lee and Richards obtained a quantitative description of the accessible surface by applying a specially developed computational algorithm, which they used to calculate the accessible surface area of three globular proteins: lysozyme, ribonuclease A, and myoglobin.[29] These calculations were subsequently applied to a series of other globular proteins, whose three-dimensional structure was thus determined with an acceptably high resolution.

The great functional importance of the surface of macromolecules, and its relationship with the characteristics of their three-dimensional structure, stimulated a large number of studies (mainly theoretical) of various aspects of the correlation of the area, composition, and topography of the surface with the globule

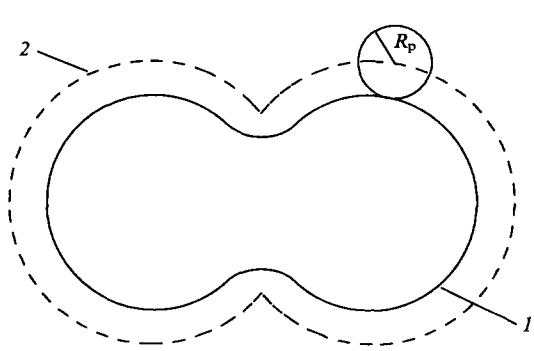

Figure 5. Description of the 'surface' by testing with a spherical probe of radius R_p in a two-centre system.[30] (*1*) contact surface; (*2*) accessible surface.

volume, the molecular mass of the protein, its packing density, and other parameters of the three-dimensional structure (see, for example, Refs 31–36).

In recent years the surface of macromolecules has been analysed increasingly by the molecular cartography method, which allows almost the whole of the protein surface to be 'viewed' simultaneously.[37] By using these charts Barlow and Thornton[38] studied the distribution of charged groups, and Fanning et al.[39] and Novotny et al.[40] studied the topography of the protein surface with the aim of localising the antigenic centres. An analysis of the surface features can be carried out by super-imposing three different charts.[41] This analysis of the nature of the accessible surface provided an unambiguous interpretation of the hydrophobic properties of proteins, calculated exclusively from their aminoacid composition. The concept of an accessible surface has proved very fruitful in the construction of models of the self-organisation of the polypeptide chain.[42–44]

Without belittling the value of the computational methods of determining the accessible surface we note that all the calculations are based on high-resolution X-ray structural analysis results. There is no doubt that the tritium planigraphy method now offers the fullest possible information on the accessible surface of the object. As stated above, this method relies on establishing the steric accessibility of the hydrocarbon groups (CH, CH_2, and CH_3) of all the component units (in the case of proteins, the aminoacid residues) in the substance under study, and provides information on its surface. As could have been expected, a simple relationship has been observed between the specific radioactivity (A) and accessible surface area calculated by the Lee and Richards algorithm (S): $A = kS$, where k is the probability of finding the label in the aminoacid residue of a given type, normalised for the accessible surface area. By using model proteins with known three-dimensional structures it was shown that this relationship applies for the majority of protein residues.[27,45] In most cases the results corresponded to those given by calculations of the accessible surface by the Lee and Richards algorithm.[29] However, some discrepancies were noted: these were associated with special features of the mechanism chosen to introduce the label and with the difference in size between the tritium atom and the water molecule. A new model, proposed to eliminate these contradictions, describes the accessibility to tritium atoms of fragments of the sample on the assumption that any scattering event must result in loss of reactivity.[46] A calculation by this model for the 20 N end residues of myoglobin gave a better agreement with previously reported[27] experimental data. The effective radius of the tritium atom (1.1 Å) was found, as expected, to be smaller than the radius assumed for a water molecule.

It should not be forgotten that the surface defined by the tritium planigraphy method differs in principle from the accessible surface in its generally accepted sense. In the surface accessible to the incorporation of the label there are no atoms not directly linked to hydrogen atoms (in the proteins these are the oxygen atoms of the carbonyl groups, =C=O, in disulfide bonds and in methionine they are the sulfur atoms). There are also no groups from which the label is readily removed by exchange with water (the −OH, −SH, $-NH_2$, =NH, and −COOH groups). The fragments which are sterically inaccessible to reactions with tritium atoms incident on the surface with a rectilinear trajectory are also not included. As a result, the surface determined by tritium planigraphy includes breaks associated with the regions containing the atoms and groups of atoms listed above, whereas the surface calculated by the Lee and Richards algorithm is free from discontinuities.

It is legitimate to ask to what extent and between what limits the tritium planigraphy data can be correlated with calculations of the accessible surface by the 'sliding' probe method. To answer this question the radius of the probe approximating the tritium atom, for which the calculation by the algorithm which assumes 'lining' of the van der Waals surface agrees most accurately with experiments on the incorporation of the label, had to be determined. It was also necessary to determine the limits between which these data can be extrapolated to test probes having other radii. These studies were carried out with the model protein lysozyme, for which high-resolution X-ray structural analysis data are available, and the accessibility profile of the aminoacids towards the introduction of the tritium label was established.[47]

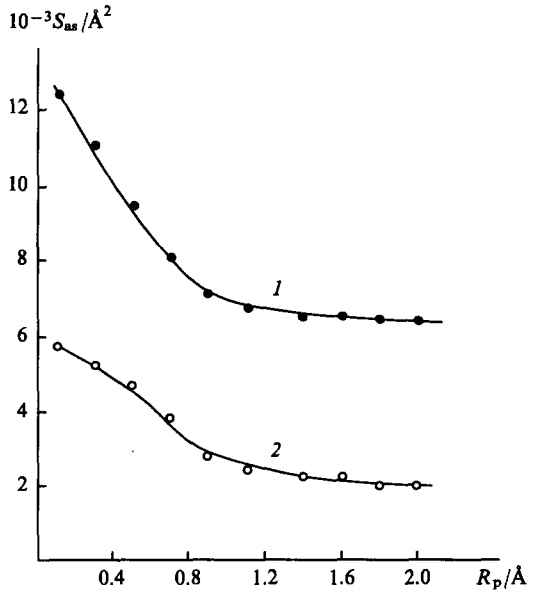

Figure 6. Dependence of area of accessible surface in a lysozyme globule upon the radius of the test probe (R_p). (*1*) Accessible surface of the globule (S^{Σ}_{as}), (*2*) accessible surface of the hydrocarbon fragments (S^{CH}_{as}).

By using a slightly modified algorithm (as compared with that proposed by Lee and Richards) the surface area of the protein accessible to probes with radii between 0.1 and 2.0 Å (and even 10.0 Å) was calculated for each aminoacid residue and for the protein globule as a whole. The calculation was carried out separately for each residue, including the 'labile' hydrogen-containing groups (S^{Σ}_{as}), and only for the hydrocarbon fragment (S^{CH}_{as}) of the aminoacid. Fig. 6 shows the dependence of the accessible surface area of the protein globule upon the radius of the test probe. It can be seen that for low radii (from 0.1 to 1.0 Å) the accessible surface decreases sharply (by ~40%) as the radius is increased, an effect ascribed to the smoothing of the surface topography. For probe radii greater than 1.0 Å the S^{Σ}_{as} value stays almost constant until it begins to increase again for the largest probes (10 Å) as a result of the increased radius of the 'sliding' trajectory. For a probe with a radius of 1.4 Å (the water molecule) the calculated value of S^{Σ}_{as} stays practically constant at the level of 6510 Å^2, which is close to the value of 6710 Å^2 obtained by Lee and Richards.[29] The best agreement between experiment and calculation is obtained by assuming a sphere with a radius of 0.9 Å as an approximation to the tritium atom (Fig. 7).

Fig. 8 shows experimental and calculated accessibility profiles for the peptide chain of the protein. Data on the inclusion of the label are presented as the ratio A/K, which is equivalent to the accessible surface area (in Å^2). It can be seen that on the whole the correlation between the two distributions is acceptably good. Accessibility calculations for probes having different radii showed that the results obtained for a tritium atom assumed to have a radius of 0.9 Å can be extrapolated with reasonable assurance to probes having radii of up to 2 Å for aminoacid residues with a high (> 50%) or a moderately high (20% – 50%) average level of accessibility if the ratio of the residue areas (in the composition of the protein molecule) to the area of a hypothetical fully unfolded

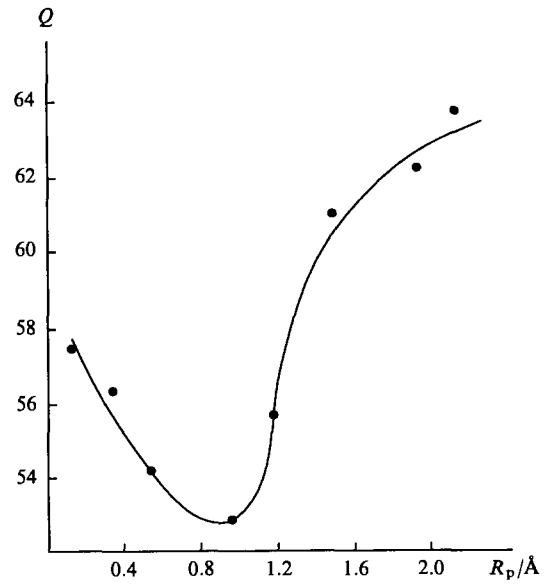

Figure 7. Deviation function Q, describing the discrepancy between calculated and experimental data for test probes having different radii. The minimum of the function corresponds to an effective radius of the tritium atom of R = 0.9 Å.

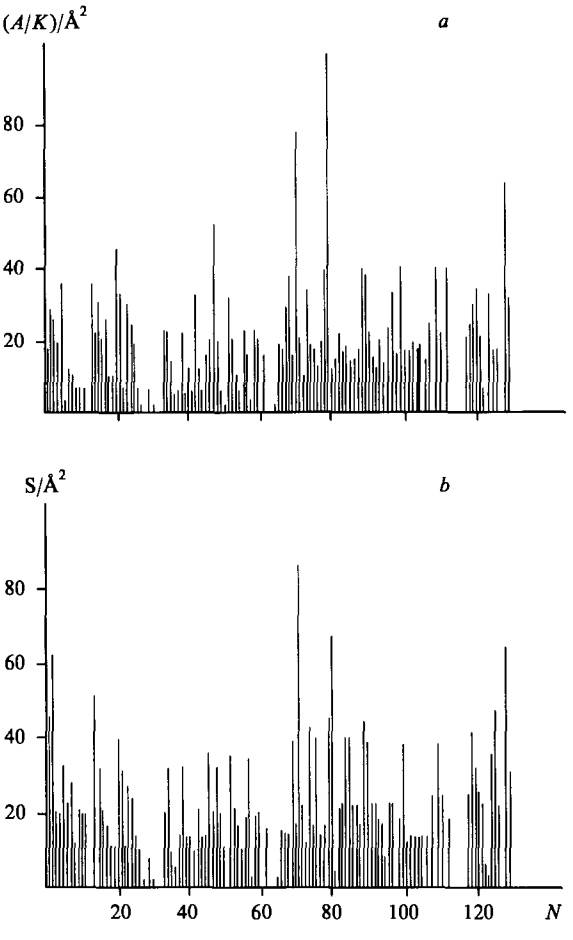

Figure 8. Accessibility profile of the polypeptide chain in lysozyme, obtained experimentally by introducing the label (*a*) and calculated for a test probe of radius 0.9 Å (*b*). A/K is the specific activity of the aminoacid residues, normalised for the probability of incorporating the label, S is the accessible surface area in Å², N is the number of the aminoacid residue in the protein sequence.

polypeptide chain for a probe with a radius of 1.4 Å is taken as a measure of the accessibility (the *trans*-peptide Ala–X–Ala is a suitable model compound). In the case of poorly accessible residues (< 20%) the data on the incorporation of the label should be interpreted with some caution. However, the proportion of these residues on the surface of the macromolecule is not large, and it cannot introduce a significant error into the final result. In the determination of the total area of the protein their contribution balances out.

In the same investigation the coefficients needed to convert the accessible surface area of the hydrogen fragment into the total area of the residue ($S_a^{CH} = \gamma S_{as}^{\Sigma}$) were determined. It was found that the parameter γ depends not only on the nature of the residue (which is not surprising) but also on its level of accessibility in the tertiary structure. However, at the level of the entire globule this quantity remains constant over a wide range of probe radii (0.4 ± 0.06). We note that according to Chothia[81] the fractional amount of accessible surface formed by nonpolar atoms (mainly, the hydrocarbon fragments) depends on the molecular mass of the protein: it decreases as the latter increases. In the work of Lee and Richards[29] this fraction was 0.392 for lysozyme, which corresponded to the value obtained by Bogacheva et al.[47]

Gedrovich et al.[55] suggested an approach which allows quantitative estimates of the total accessible surface area of the protein from the amount of label included in the aminoacid residue groups which are free to exchange and in the water molecules firmly bound to the surface (hydration shell). They examined a group of proteins having known three-dimensional structures (lysozyme, ribonuclease S, myoglobin, papain, subtilisin, and α-chymotrypsin), and obtained a linear dependence in $\lg I - \lg S$ coordinates. The straight line thus obtained can be treated as a calibrating plot, and used to determine the accessible surface area of globular proteins of unknown structure (Fig. 9). Calculations of this type carried out for the globular protein parvalbumin III found in the pike gave an accessible surface area of 5700 ± 900 Å². Using the empirical dependence of the accessible surface area on the molecular mass of the protein gave[34] an area of 5800 Å².

The results of experiments with proteins whose three-dimensional structure had been determined by high-resolution X-ray structural analysis allowed the method to be extended to objects on which structural information was inadequate or totally absent.

Thus an analysis of the specific labelling of aminoacids in the overall hydrolysate of the protein led to reasonable conclusions on various parameters of the periphery of human serum albumin,[45,49] for which available X-ray structural analysis data had a resolution of 6 Å which was insufficient for the calculation.[48] It was found that (as compared with that of lysozyme) the accessible surface of the albumin was enriched in hydrophobic aminoacid residues, which accounted for 63% of the total aminoacid content

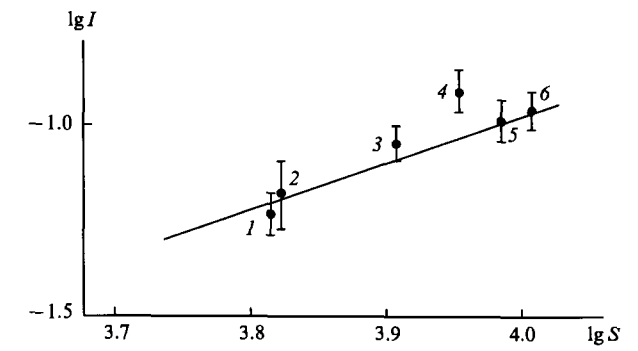

Figure 9. Dependence of the reduced radioactivity on the accessible surface area of proteins. (*1*) Lysozyme, (*2*) ribonuclease S, (*3*) myoglobin, (*4*) papain, (*5*) subtilisin, (*6*) α-chymotrypsin. The I value includes the label in the C–H bonds, in the labile groups, and in the strongly held water, normalised for the flow of tritium atoms.

of the surface (whereas in lysozyme the amount was 18%). Summing the accessible surface areas in the aminoacids and allowing for the number of residues of each type gives[45] a total area $S_{as}^{CH} = 19\,900$ Å^2. Using the ratio $S_{as}^{CH}/S_{as}^{\Sigma}$, whose value is 0.4 for lysozyme, gave a total area of 49 000 Å^2 for the protein. Using the empirical dependence of the accessible surface area of a fully unfolded polypeptide chain on the molecular mass gave a coefficient of 0.48 for the degree of unfolding of the polypeptide chain. By treating the albumin globule as an ellipsoid of revolution with axes of 140:40:40 Å important structural parameters of the surface were determined:[50] for example, the 'roughness coefficient' of the native protein was found to be 2.7. For the lysozyme molecule the corresponding unfolding and roughness coefficients were 0.68 and 1.7. From these results we may conclude that the packing is less compact (and the surface topography is more broken) in the polypeptide chain of human serum albumen than in lysozyme, in good agreement with the known physicochemical properties of this protein and above all with its strong hydrophobicity.[51] The openwork appearance of its three-dimensional structure is confirmed by many data on the capacity of albumin to bind low-molecular hydrophobic substances (for example, fatty acids), and is consistent with reports of the presence of several hydrophobic cavities in the molecule of this protein.[52] The rough packing of the albumin globule is also consistent with views on the flexibility of this molecule and on its tendency to undergo volume fluctuations.

Bobkova et al.[53,54] reported a comparative study of the surfaces accessible to label introduction in two important enzymes of protein biosynthesis (aminoacyl-tRNA-synthetase). The two enzymes (phenylalanine-tRNA-synthetases from *E. coli* and *Thermus thermophilus*) have complex quaternary structures. The similarity in structure (at least, in the region of the active centres of these enzymes) suggests that the thermophilic enzyme catalyses the aminoacylation reaction of tRNA from *E. coli*, whereas the enzyme from *E. coli* can catalyse the aminoacylation of the thermophilic tRNA. The enzyme from *Thermus thermophilus* was obtained in the form of crystals suitable for use in X-ray structural analysis, but attempts to prepare crystalline phenylalanine-tRNA-synthetase from *E. coli* were unsuccessful. In these circumstances the tritium planigraphy method is one of the few methods available for studying the surface structure of the enzyme from *E. coli* and for comparing it with that of its thermophilic analogue. Fig. 10 shows the diagrams defining the surface areas of the aminoacid residues for the two proteins, obtained from data on the specific activity of the aminoacids and of the total hydrolysates of the proteins. We note a fairly high level of hydrophobicity in the surface of the proteins (60% for the enzyme from *E. coli* and 67% for the thermophilic protein). Comparing the data for the degree of hydrophobicity and for the overall sum of hydrophobic residues in the two proteins shows that this distribution is approximately the same for the mesophilic and the thermophilic synthetase being studied. The proportionate increase in hydrophobicity on the surface and in the inner parts of the protein globule on passing from the mesophilic to the thermophilic enzyme is a very interesting effect. However, the possibility of identifying the difference in the aminoacid residues localised on the surface of the protein is even more important. The increased accessibility of the arginine residues in the identifiable composition of the aminoacyl-tRNA-synthetase led to an explanation[53,54] of the increased sensitivity to exposure of the charged residues on the globule surface in terms of the tendency of the thermophilic tRNA-synthetase to compensate the destabilising action of the high temperature by using additional electrostatic interactions with the substrate.

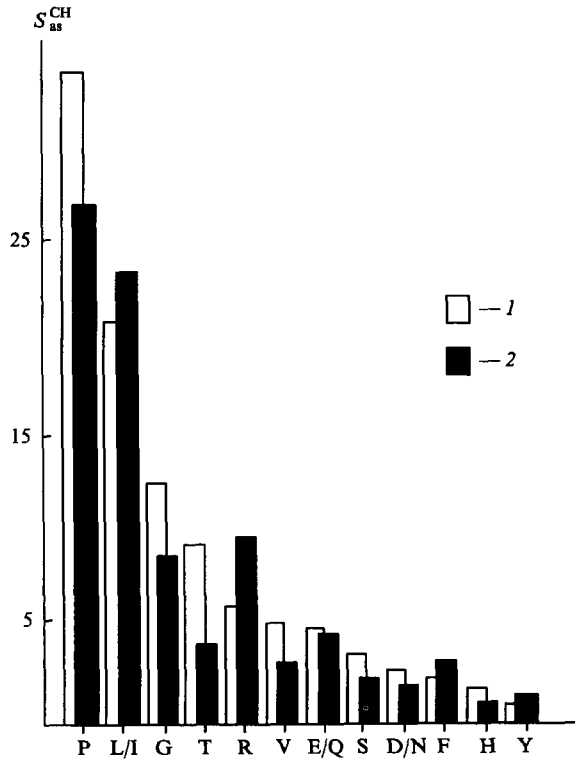

Figure 10. Aminoacid composition of the accessible surface phenylalanine–tRNA–synthetase from *E. coli* (*1*) and from *Thermus thermophilus* (*2*) expressed as a percentage of the total area of the globule.

Similar studies had been previously carried out with the Fe- and MoFe-proteins of the azotobacter nitrogenase.[10] Without discussing these results in detail we shall only point out that they yet again confirm the possibility of obtaining valuable structural information from a relatively simple experiment.

IV. Conformational transitions in proteins

Obviously, any changes in the three-dimensional structure of a macromolecule must affect the topography of its accessible surface. This suggests very promising applications of the tritium planigraphy method in studies of conformational transitions. Volynskaya et al.[56,57] demonstrated this prospect in a study of the denaturation of lysozyme by 8 M urea with reduction of the disulfide bonds. Distribution of the label on the aminoacid residues in the denatured form differs markedly from the native distribution and approaches random distribution. The latter was calculated by using the tripeptide Ala–X–Ala as a model,[29] allowing for the probability of incorporating the label. Of course, this model can only be accepted as a crude approximation. In the analysis of the real structure of the denatured state we must allow for the mutual screening of the residues by their nearest neighbours, and also for the possible orientation of the polypeptide chain on the surface of the target. Nevertheless the calculated and the experimental distribution of the label in the fully denatured form are reasonably close.

We note that, under the influence of 8 M urea only, a state having a well-defined structure is formed without breaking the S–S bonds. It is characterised by an accessibility of the hydrophobic aminoacid residues greater than in the native material, coupled with a small change in the accessibility of the hydrophilic groups. This is interpreted[56,57] as a breakdown of the hydrophobic contacts although the globular structure as a whole is retained. The interpretation is consistent with independent data on the viscosity of the protein solutions in the presence of 8 M urea, on the circular dichroism (CD) spectra, and on optical rotary dispersion.[58,59]

The high sensitivity of tritium planigraphy led to the detection of intermediate states of the protein, formed as a result of weak denaturing interactions and not revealed by traditional

methods.[56] One of these states can be induced by adding 1 M lithium chloride and is characterised by an accessibility of the polar aminoacid residues substantially lower than in the native conformation, while the accessibility of the hydrophobic residues is almost unchanged. This transition can be treated as a 'compression' of the globule. Conversely, another state is characterised by an increased accessibility of all the types of aminoacid residue, and is induced by the addition of 1 M urea and guanidine·HCl. This transition is similar to an unfolding of the globule while retaining all the other structural characteristics (viscosity, CD spectra, etc.). Obviously, in this case we are dealing with a slight 'loosening' of the packing of the elements in the secondary structure without dissociation and without changes in the overall architecture of the globule. A similar type of intermediate state was detected also in ribonuclease.[60]

The conformational transitions observed in lysozyme have been compared with the changes in enzyme activity. By using the rate of lysis of *Micrococcus lysodecticus* as a test it was shown that the 'compression' and the 'loosening' of the lysozyme globule result in a decreased enzyme activity, the 'compression' effect being the stronger. Similar changes were observed in ribonuclease A.[60] Low salt concentrations (0.1–0.2 M) produced compression of the protein globule, accompanied by a rapid decrease in the enzyme activity. Under these conditions the intramolecular mobility of the protein, monitored as its mean-square deviation $\langle X^2 \rangle$ from Rayleigh scattering data for the Mössbauer radiation, is also substantially lowered. Unlike the addition of salts, low concentrations of urea produce a loosening of the protein globule also accompanied by a decrease in the enzyme activity. In this case complete loss of enzyme activity was observed only in the presence of 8 M urea.

The results of studies by tritium planigraphy of pH-dependent conformational transitions in proteins call for a detailed discussion. These changes often play a key role in the functioning of macromolecules, and in this case changes in the pH of the medium are one of the factors which control their biological activity.

Human serum albumin is one of the most important proteins in blood plasma, whose function is mainly to control the transport of various kinds of biologically active substances. It is known to undergo various pH-dependent conformational changes, of which the most striking are the N–F and the N–B transitions, taking place in acid (pH 3.5–4.5) and in alkaline media (pH 7.0–9.0) respectively.[61,62] In spite of extensive studies the nature of these structural transitions is not well understood.

A comparative study by tritium planigraphy of the accessible surface of a protein in the N, F, and B form produced some valuable structural information.[63,64] It was found that in the N–F transition the total accessible surface is increased 2-fold, in good agreement with the change in size of the molecule, determined by low-angle scattering and by viscosity measurements.[65,66] Broadening of the globule in the F form is indicated by an increase in the ratio of the molecular axes[67] from 3.3 to 5.8, and also by a 50% increase in the hydration of the molecules.[68] In the F form of the protein the hydrophobic residues are more accessible to labelling than in the N form. This effect is well correlated with the greater hydrophobicity of the protein in the F form as compared with the native form. An analysis of the distribution of the label in the B form of the protein indicates a greater accessibility of the aminoacid residues in this form than in the native state, but the scale of this increase and the number of residues undergoing a change in accessibility are much smaller than in the N–F transition.

Unfortunately in all the above studies the label incorporated in the sum of the aminoacids of various types was determined, and no attempt was made to analyse the distribution of tritium over the chain of the protein. This allowed the occurrence of a conformational transition to be established, and the most general characteristics of the states thus produced to be identified, but none of the information was helpful in identifying the detailed structure.

Interesting results were obtained in studies of pH-dependent conformational transitions in hemagglutinin, a functionally important protein of the virus membrane group. It is now firmly established that the fusion of the viral and of the endosomal membrane induced by pH changes (the most important contribution to the infection of the cell) takes place with the participation of this protein.[69] However, in spite of wide-ranging studies by biochemical, biophysical, genetic, and immunologic methods,[70] the molecular mechanisms and the intermediate states of the fusion of the membranes are still a problem to be solved. Glushakova et al.[71] proposed a sensitive experimental model for studying pH-dependent conformational changes in proteins leading to their interaction with the membrane.[71]

The model system consisted of liposomes with the ionophore nigericine attached to the lipid membrane and containing hemagglutinin in their bulk. Lowering the pH of the surrounding medium produced a corresponding change in the pH within the liposome and induced a transition of the protein to a conformation able to interact with the liposomal membrane. Tritium labelling was used to visualise the outer surface of the liposomes. By comparing the specific labelling of the protein and the distribution of radioactivity in the aminoacids in control samples (at a neutral pH) and in the experimental samples (at the fusion pH) of the liposomes the authors were able to explain the nature of the protein–membrane interaction. It was found that in an acid medium the specific activity of the protein is increased (the activities of the hydrophobic aminoacids Ile, Phe, and Tyr increased 2–3-fold). This indicates the introduction of a protein molecule (or a part of it) into the membrane, and possibly also that part of the molecule is exposed on the outer surface, and it confirms the widely held opinion that the hydrophobic N-end peptide in a small subunit of the protein (the so-called fusion peptide) is responsible for the interaction of the membranes. An analysis of the intramolecular distribution of the label along the protein chain from control and from experimental liposomes should unambiguously establish the detailed pattern of the lipid–protein interaction. The model can be treated as universal for studies of lipid–protein interactions of any type, since any protein (and even an entire virus) can be incorporated within the liposome.

The tritium planigraphy method has been used to study the pH-dependent conformational change of hemagglutinin in the composition of the whole virus, leading to its inactivation. So far attempts have been made to calculate the change in the conformation of the hemagglutinin after acid preincubation of the virus from the change in the antigenic properties of the protein, in its sensitivity to proteinases, and above all from changes in the exposure of its 'fusing peptide'. An attempt to study this phenomenon by tritium planigraphy was reported by Ksenofontov et al.,[72] who showed that on the one hand the small subunit of hemagglutinin in the virus inactivated in an acid medium is readily accessible, as shown by the approximate doubling of its specific labelling as compared with the active virus; on the other hand inactivation in an acid medium of the target without membrane does not produce a strong exposure of the 'fusion peptide'. These results led the authors to propose a new model of the conformation of hemagglutinin in the composition of the inactive virus.

V. Accessible surface and intramolecular dynamics of proteins

Several published papers suggest a relationship between the intramolecular dynamics of biopolymers and their functional properties.[73] Clearly, the intramolecular mobility (at least the large-scale segmental mobility) should be reflected by the structure of the accessible surface. However, only a few calculations aiming to demonstrate this relationship have been published so far. In particular, Levit[74,75] showed by a computer modelling experiment that in dynamic calculations the accessible surface of several aminoacid residues may differ from the static value by

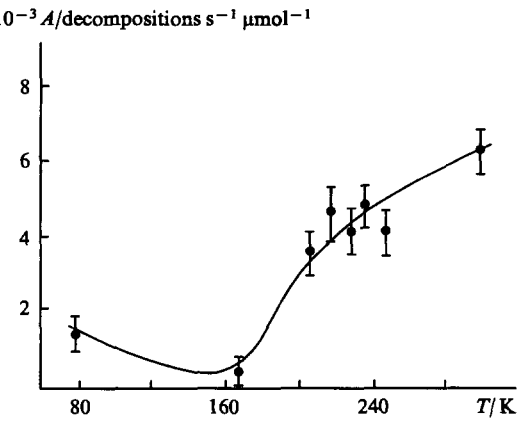

Figure 11. Temperature dependence of the inclusion of the label in lysozyme. *A* is the radioactivity of the protein normalised for the activity of the monitor.

50%–60%. No direct experimental data on the relationship between the accessible surface and the dynamic parameters have been published so far.

We know that the intramolecular mobility of biopolymers is substantially dependent on two parameters: the water content of the sample and its temperature.[76,77] This suggests the possibility of studying the relationship between the accessible surface and the molecular dynamics by the tritium planigraphy method by analysing the distribution of the label for different target temperatures and a constant humidity, or vice-versa.

A similar attempt was reported by Bogacheva et al.,[78] who chose the protein lysozyme as the model substance and determined the temperature dependence of the incorporation of the label in both the protein as a whole and the aminoacid residues of each type. The target temperature was varied between 77 K and room temperature.[79] In Fig. 11 we show the temperature dependence of the specific radioactivity of the protein, normalised for the flux of tritium atoms (*A*) in the temperature range 77–293 K. Two regions can be distinguished in the curve: a decreasing incorporation of the label at 77–163 K followed by an increase at 163–293 K. The increased level of labelling above 163 K cannot be explained in terms of the temperature dependence of the rate constant of the reaction leading to an increased incorporation of the label, since the temperature of the hot tritium atoms incident on the target surface (2000 K) is much higher than the temperature of the sample. An increase in temperature from 77 to 293 K can increase the incorporation of the label by not more than a factor of 1.2, but the observed increase in activity is 3-fold. According to data on the Rayleigh scattering of the Mössbauer radiation, and by using paramagnetic probes, it was shown[76,80] that an 'unfreezing' of the intramolecular mobility takes place at 170 to 190 K. This observation is well correlated with the observed[78] increase in the accessibility. The greater incorporation of the label (corresponding to an increased accessible surface area) upon lowering the temperature from 163 to 77 K is inexplicable in terms of dynamic effects. It may be due to a change in the three-dimensional structure of the protein as a result of the freezing of the internal water, firmly bound to the protein, which destroys the balance of forces stabilising the three-dimensional structure and leads to its breakdown.

The temperature dependence of the probability of incorporating the label was studied also at the level of the individual aminoacid residues. According to the features of this dependence all the residues can conveniently be divided into three groups. Most of the residues of the first group, whose accessibility increases in the range of 170–293 K, lie outside the region of enhanced mobility of the polypeptide chain. They are usually located on the N and C ends of the structured regions, near the sites of rotation of the polypeptide chain. The residues of the second type have a lower accessibility, independent of the temperature in this region. As a rule they are found in the middle of α-helix regions, in the immediate vicinity of the residues forming the inner region of the protein globule. Lastly 70% of the residues, which form the regions of enhanced mobility, are residues of the third type. Their accessibility changes only slightly in the range 160–270 K, but increases steeply at 293 K.

Unfortunately these results, like the results of the studies of conformational transitions discussed above, are averaged over the types of aminoacid and do not allow a detailed picture to be established. We are only at the first stage in the attempt to show that the accessible surface is a function of the molecular dynamics and that this relationship can be studied by applying the present method.

VI. Modelling the three-dimensional structure of proteins

As was stated above, X-ray structural analysis and the NMR method are laborious and have a number of fundamental limitations which seriously hinder the study of the three-dimensional structure of macromolecules. These shortcomings stimulated numerous attempts to develop theoretical predictions of the tertiary structure of proteins on the basis of data on the primary structure, of a statistical and evolutionary analysis of objects having a known structure, etc.[82–85] Unfortunately we must conclude that (in contrast to the methods of predicting the secondary structure) the theoretical modelling of the three-dimensional structure is still an unresolved problem, even at the level of predicting the general outline of the polypeptide chain.

Clearly, the most promising approaches are those which use, in addition to the theoretical predictions, parameters obtained directly from experiments (for example, data on the topography of the accessible surface). In fact, since an unambiguous linkage exists between the three-dimensional structure and the accessible surface, and since this linkage can be calculated from the coordinates of atoms, it is legitimate to formulate the inverse problem, namely to construct a model of the three-dimensional structure of the protein molecule from the accessibility of the constituent aminoacid residues. The algorithm for the solution of this problem can be defined in the following general form:

(1) determine the accessibility profile of the aminoacid residues of the protein molecule labelled with tritium;

(2) predict the elements of the secondary structure of the protein by using existing theoretical approaches;

(3) find a method of packing together the elements of the secondary structure while ensuring their surface localisation on the model of the chain fragments accessible to the tritium atoms, and (conversely) identify the inaccessible regions within the model of the globule.

Modelling greatly facilitates the acquisition of additional information: for example, data on the number and localisation of disulfide bonds, on the binding sites of ligands, substrates, and metals, on the localisation of individual functional groups, and antigenic mapping data. Taken as a whole this information may be sufficient for the choice of the optimum method of packing the elements of the secondary structure at all stages in the assembly of the model.

The first attempt to construct a model of the three-dimensional packing of a polypeptide chain was undertaken for the protein in the shell of the tobacco mosaic virus.[86] The simplicity of the object, containing only four α-helix portions, made it easy to construct a three-dimensional model satisfactorily consistent with the X-ray diffraction analysis data.[87]

More recently the scope of this approach was tested on the globular protein, pike parvalbumin, belonging to the family of Ca^{2+} binding proteins[88] (a relatively small protein containing 108 aminoacids). Two widely used methods were used to calculate the elements of the secondary structure: those of Chow and Fasman[89]

and Lim.[90] The five-predicted α-helices included 69 aminoacids, corresponding to 64% of the whole number of aminoacids. This feature greatly facilitated the modelling. Models of the three-dimensional structure of the protein were constructed by the method of Ptitsyn and Rashin,[91] which includes as an essential step a search for the contacts between neighbouring α-helices (using rigid cylinders as an approximation to the α-helices in this case). The stacking of the polypeptide chain was carried out by first searching for the contacts between the inner C and D helices (classified as inner from the standpoint of their accessibility to tritium labelling), and then successively adding to the resulting complex the helices E, F, B, and A. The choice of the relative orientation of the helices was helped by a knowledge of the calcium binding regions, which imposes strict limitations on the mutual disposition of the residues which coordinate the calcium ions.[92] The model of the three-dimensional structure of pike parvalbumin (Fig. 12) was found to be very similar to that of the homologous protein carp parvalbumin.[93]

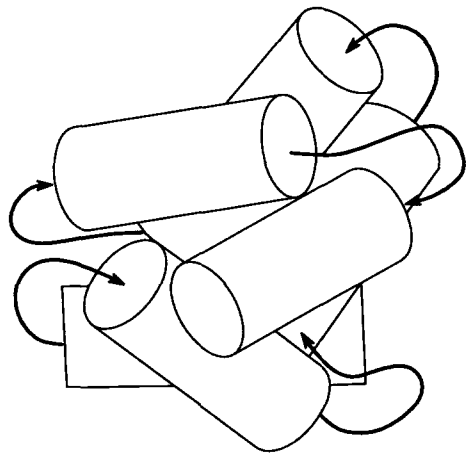

Figure 12. Model of the three-dimensional structure of the protein, pike parvalbumin III.

The similarity in structure of these two proteins is seen also in the similar topographies of their accessible surfaces, observed by comparing calculated data for carp parvalbumin with experimental data for pike parvalbumin.[87]

The results examined in this section cannot be treated as a complete concept, allowing three-dimensional models of proteins to be constructed from a combination of experimental data on the topography of the accessible surface and of theoretical predictions of the elements of the secondary structure. However, there are good reasons to hope that the further development of this approach and the application to it of the appropriate elements of computer modelling will provide researchers with a new and fruitful method of obtaining information on the three-dimensional structure of macromolecules.

VII. Three-dimensional organisation of supermolecular systems

The relationship between label distribution and structure of the accessible surface demonstrated above for proteins is seen even more clearly in studies of supermolecular systems, in which the mutual screening effects of the components play a substantial role. Depending on the experimental plan, information was obtained on the most general characteristics of the structure (general architecture of the complex, relative distribution of the components of the system in three dimensions, localisation of the contact surfaces, etc.) as well as on structural details such as determining the accessibility of the individual monomer units of the protein in the composition of the complex system.

As far as can be established the first attempt to use the tritium planigraphy method to study the three-dimensional structure of a complex supermolecular object was the tritiation of the ribosome from *E. coli*. As we know, a ribosome is a nucleoprotein complex which contains two molecules of highly polymeric RNA: 16S-RNA in the smaller moiety and 23S-RNA in the larger. The composition of the large 50S-subparticle also includes the low-molecular 5S-RNA. In the small 30S-subparticle, 21 proteins are associated with the 16S-RNA, and the large subparticle contains 32 different proteins.

By comparing the amounts of label incorporation in the proteins of the isolated subparticles of the 30S and 50S ribosomes and in the whole 70S ribosome, the proteins exposed on the surface could be identified and the absence of proteins on the contacting surface of the subparticles was demonstrated.[24,94-96] As was shown in separate experiments, under these conditions the RNA molecules retain their integrity and their ability to undergo specific interactions with proteins.[97] However, when considering the absence of proteins from the contacting surface of ribosomal subparticles, we should not forget that in practice the contact of two ribosomal subparticles is not very tight and cannot prevent the incorporation of tritium in the protein in the region between the subunits.

An interesting attempt to determine the accessibility of a polypeptide chain synthesised on the ribosome has been reported.[98,99] It has been suggested that the first units of the growing peptide are accommodated in a channel whose geometry allows the polypeptide chain to unfold into a helix. However, experimental approaches aimed at demonstrating the existence of the channel mostly relied on large macromolecules (protease and its antibody) as test reagents applied to the proteins synthesised by the ribosome. It was found that the small size of the tritium atom offers information with the required detail. The data on the inclusion of the label showed that a polypeptide chain already three or more residues long is exposed on the ribosome surface. Unfortunately these workers used a synthetic poly-(Y)-dependent cell-free translation system, i.e. they did not allow for the initiation of the translation in the form found in the translation of natural mRNAs. This may account for the discrepancy between the results and current views on the presence of a channel.

Another example of a nucleoprotein complex which has been studied by tritium planigraphy are the chromosomes from mouse fibroblast.[100] It was found that in the metaphase chromosomes both the chromosome proteins and the RNA are accessible to tritium. An analysis of the take-up of label by the protein showed that the 'scaffold' proteins are the most exposed, which suggests that they are located on the outer surface of the metaphase chromosomes.

A substantial volume of work has been devoted to applying the tritium planigraphy method to studies of the three-dimensional architecture of protein complexes having many subunits. Thus, Mironov and coworkers[101,102] tried to determine the relative accessibility of the protein subunits in the composition of cytochrome oxidase and in its complex with cytochrome C. Cytochrome oxidase is the terminal enzyme of the respiratory chain of living cells. It is a transmembrane protein, consisting (in the higher mammals) of 12 different subunits. Tritiation of the free enzyme and of the enzyme incorporated in the complex was carried out in order to establish, confirm, and add some detail to the existing model of the structural organisation of the subunits in cytochrome oxidase, and also to identify the regions of interaction of the enzyme with cytochrome C. Comparing the specific labelling values of the subunits showed that in the formation of the complex the cytochrome molecule is partially screened by the subunits I, II, VIc, and VIIa–VIIc of the protein, which agrees with previous reports.[103]

Applications of tritium planigraphy to the study of membrane structures (in particular to the study of the topography of transmembrane proteins) are of special interest because the presence of a lipid bilayer should lead to marked differences in

the accessibility to tritium between the exposed and the intramembrane parts of the polypeptide chain. In fact, as was shown in the experiments with liposome loaded with hemagglutinin discussed above, the bilayer lipid membrane weakens the flow of tritium atoms by a factor of 10.[72] The cell membrane almost completely screens the contents of the cell from the incident tritium atoms. Thus, in the case of erythrocytes it was observed that the level of incorporation of the label into the hemoglobin within the cell is more than two orders of magnitude lower than the same level in the free protein.[104]

The first example of the study of membrane structures by tritium planigraphy was applied to bacteriorhodopsin.[104-106] This is one of the best characterised membrane proteins, for which the type of three-dimensional organisation has been established in general traits and various exposed residues have been identified (see, for example, Ovchinnikov et al.[107]). This work allowed the prospects of the method to be assessed, and (in the case of favourable results) it also allowed additional experimental data, needed for checking and more detailed characterisation of existing models of the protein location in the membrane, to be obtained. A packing scheme (Fig. 13) was proposed by analysing the incorporation of label in the aminoacid residues of the protein in the membrane composition, and shown to agree satisfactorily with the model constructed from theoretical predictions.[108] As a result of this work the positions of the tryptophan residues were accurately established (positions 10 and 12), and shown to lie near the surface rather than within the membrane, as had been suggested earlier.[109,110] The new model allows for the partial screening of the fragments not included in the composition of the intramembrane α-helix segments.[111]

The fact that residues within the membrane, at least 5 Å distant from the surface (i.e. at a distance greater than the mean free path of the tritium atoms), nevertheless include some tritium can be attributed to the number of lipids in the purpuric membrane (10 molecules per molecule of protein[112]) being insufficient to make the inner part of the polypeptide chain wholly inaccessible to tritium.

Ostrovskii et al.[113] tritiated the intact cells and the protoplasts of *Micrococcus luteus* bacteria with the aim of localising the components of the membrane (potential antigens) exposed on the cell envelope. It was shown that over 90% of the non-exchanged tritium is included in cytoplasmatic membranes, and that 98% of this amount is associated with lipids, suggesting good prospects for studying the asymmetric distribution of lipids in the cell membrane. It was also found that in the case of protoplasts the tritium is incorporated preferentially in three membrane proteins, but in the case of cells in a single protein.

In most of the work discussed above the information on the structure of the supermolecular object was limited to the determination of the accessibility of whole molecular complexes (with the exception of bacteriorhodopsin). A more detailed study was carried out with the tobacco mosaic virus (TMV). Data for the virus from an X-ray diffraction analysis[114,115] with a resolution of 3.6 Å, and a detailed antigenic characterisation of the virus capsid,[116] show that this object can be used as the ideal model system.

Whole virus particles were exposed to tritium bombardment.[117-119] In Fig. 14 we show the distribution of the label over the aminoacid residues of the polypeptide chain of the protein.

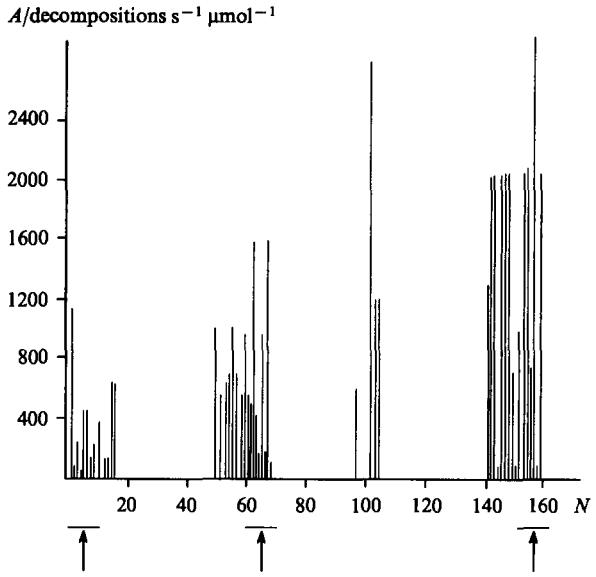

Figure 14. Experimental accessibility profile of the polypeptide chain in the protein of the tobacco mosaic virus shell in the virion composition. *N* is the number of the aminoacid residue in the polypeptide chain.

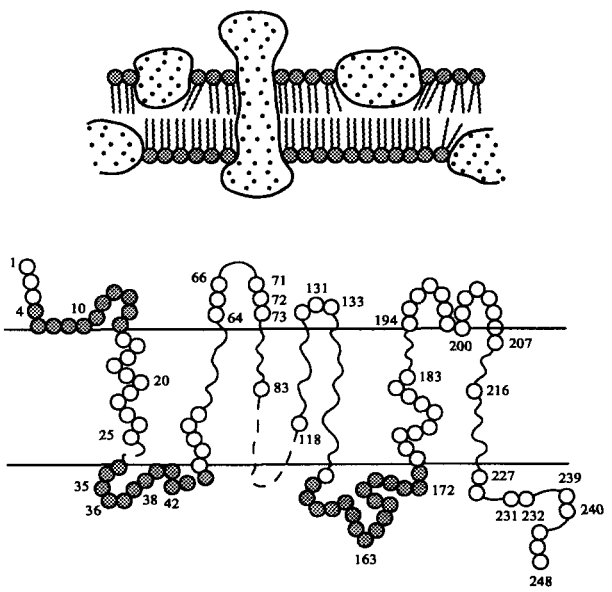

Figure 13. Schematic diagram of the 'placement' of the polypeptide chain of bacteriorhodopsin in the membrane. Filled circles denote aminoacid residues in which incorporation of the label has been observed. The sections 25-33, 66-71, 83-118, 207-231, 232-239, and 240-246 have not been analysed.

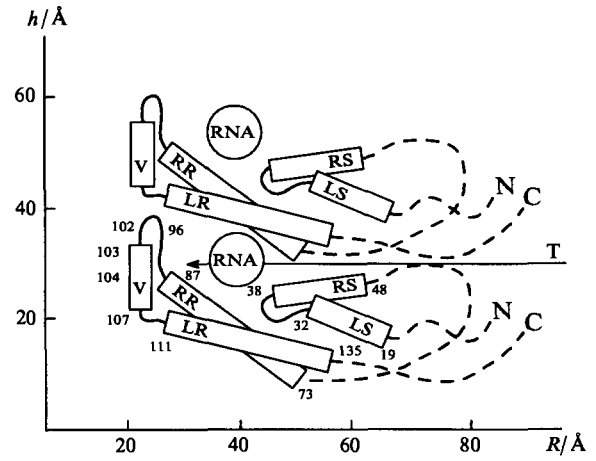

Figure 15. Schematic diagram of the placement of protein subunits in the TMV virion, demonstrating the possibility of penetration by the tritium atoms into the inner region of the virion.[115]

Relatively extensive regions can be observed, in which the amino-acid residues are not accessible to the tritium atoms. Fig. 15 shows a schematic view of the packing of the polypeptide chain for the protein coat of the virus. Comparing the experimental results on the distribution of the label in the protein with those given by this scheme shows that the N and C end fragments of the protein, located on the outer side of the virus particle, are the most accessible; the part of the protein not accessible to the labelling is found in the contact region between subunits. Surprisingly, at first sight the label was found to be included in residues 93–112 of the polypeptide chain, which (according to the X-ray structural analysis data) is remote from the surface of the virus and in contact with the RNA molecule. The authors suggested that channels are present at the 'joint' between three shell protein subunits, and that the tritium atoms can penetrate into the bulk of the virion and interact with the 93–112 residues and the virus RNA located on its 'bottom'. On the X-ray diffraction pattern these regions, 3–5 Å in diameter, appear as regions of low electron density.[114–116] It appears that channels of this type have been observed by Neiman et al.[120] in a study of the structure of the MS2-phage. According to their results 25% of the label is combined with RNA within the bacteriophage, which also suggests the presence of a relatively large number of 'pores' in the capsid of the phage between the protein molecules, through which the tritium atoms can interact with the internal regions of the phage.

It is of interest to compare the information on the surface of the virion obtained in this way with data on the localisation of the antigenic determinants. In Fig. 14 we have marked the regions 1–10, 62–68, and 153–158, which are the antigenic determinants of the protein in the composition of the virus.[116] It can be seen that they all fall among the fragments accessible to labelling by tritium. There can be no doubt that the tritium atoms are not the best indicator of the location of antigenic determinants. The small size (~1 Å) of the tritium atoms allows them to 'see' too much. However, a knowledge of the surface regions undoubtedly helps this work by narrowing the circle of possibilities.

The results obtained for the model object stimulated studies of a virus on whose structure (mainly the conformation of the subunits of the shell protein and their packing in the virion) very little was known. This was the X potato virus (XPV), one of the most widespread members of the potato virus group. Its flexible rod-like virion contains single-chain RNA, and the capsid of the virion is composed of identical protein subunits containing 236 aminoacid residues. When this work was begun data on the surface of the virion were scarce, and to some extent contradictory. Immunological studies indicated the localisation of the N-end region of the protein on the virion surface.[121] By predicting the elements of the secondary structure of the protein in the shell of XPV, using the three-dimensional structure of TMV as a first approximation, Sawyer et al.[122] were able to postulate a certain generality in the formation of the architecture of virions, namely the surface localisation of the N and C end regions in all the rod-like vegetable viruses. Subsequently Schukla et al.[123] suggested that the deflection of the polypeptide chains in proteins was a general phenomenon, leading to surface localisation of their N and C end regions in all the rod-like vegetable viruses.

In a comparative study by tritium planigraphy of intact XPV particles and of XPV degraded in situ (lacking the first 19 aminoacids through the action of the protease in the cell sap[126]) it was shown that the distribution of the label (Fig. 16*a*) differs

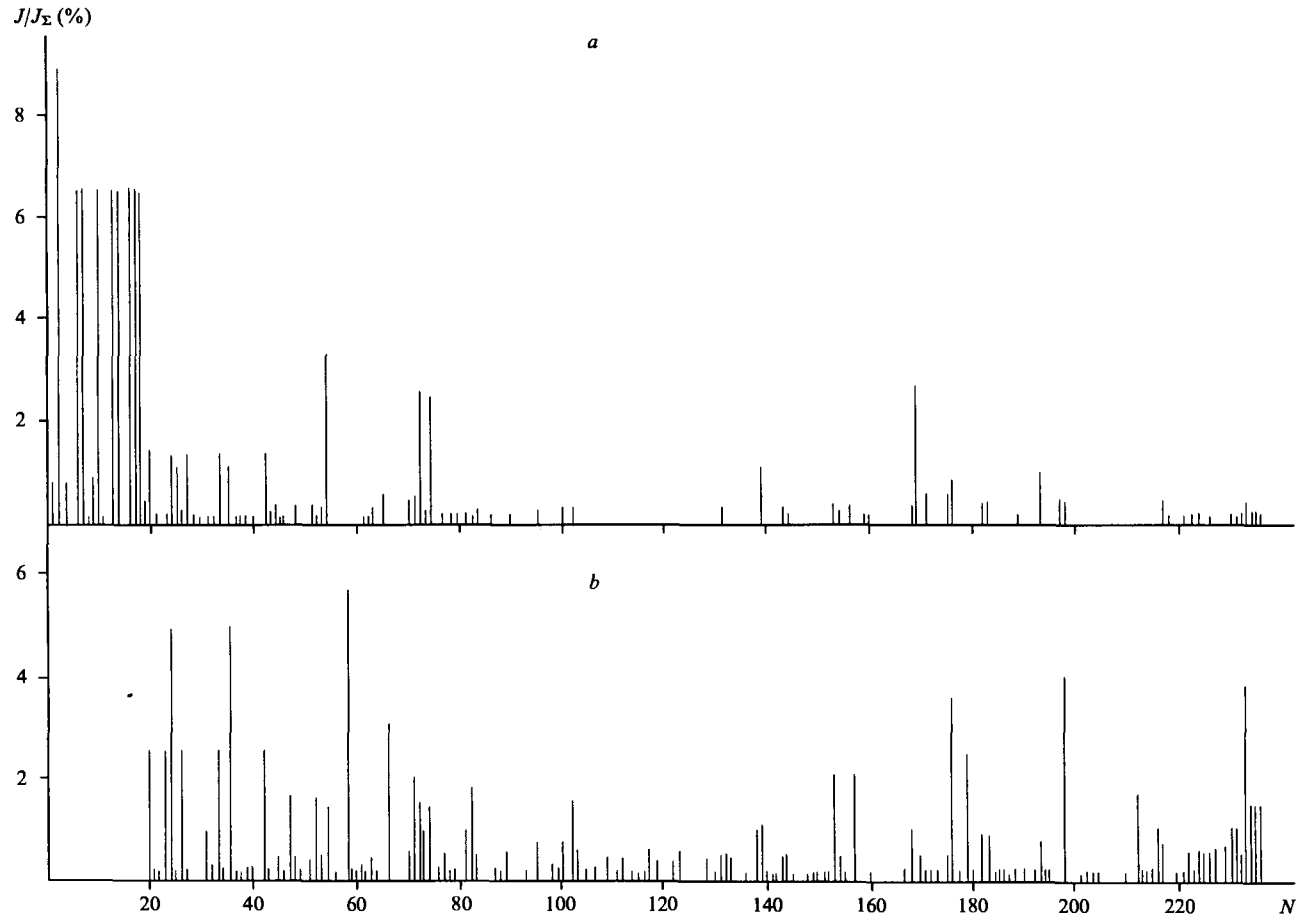

Figure 16. Experimental accessibility profile of the polypeptide chain in the X potato virus (XPV) in the native form (*a*) and partially degraded by proteases of the cell sap (*b*). J/J_Σ is the portion of the activity attributable to the respective aminoacid residue; N is the number of the aminoacid residue in the polypeptide chain.

from the distribution observed for TMV (see Fig. 14): the sharp boundaries between accessible and inaccessible regions have disappeared. This suggests that XPV has a much 'rougher' surface than TMV.[124,125] We note that 85% of the total amount of label incorporated by the preparation is located in the first 19 amino-acids in the intact virus: this shows that the entire N-end region of the protein is exposed on the virus surface. The absence of the first 19 end aminoacids (Fig. 16*b*) in the coat protein of the virus preparation degraded in situ produces a qualitative change in the labelling process. Evidently, the C-end region of the protein, which apparently had been previously 'covered' by the N-end part of the protein in the coat, has become accessible to the tritium atoms.

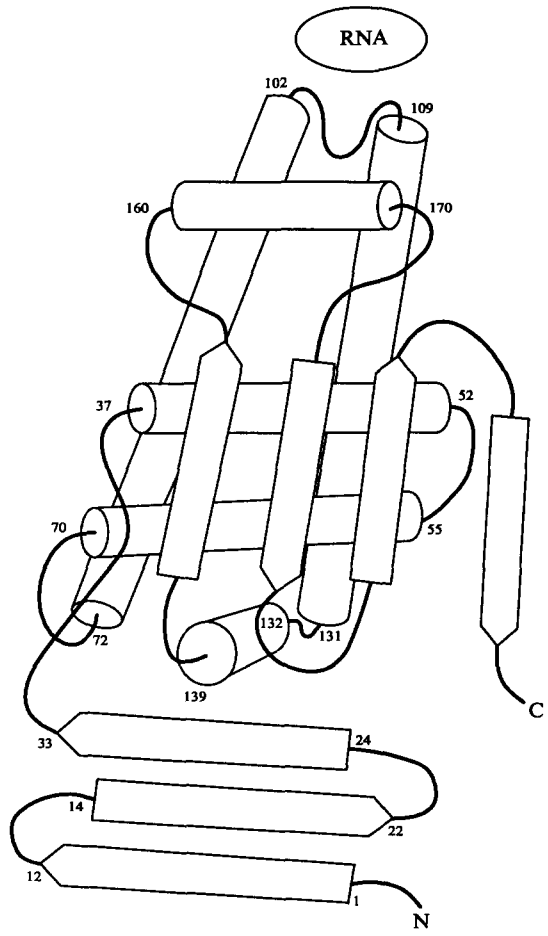

Figure 17. Model of the three-dimensional packing of the polypeptide chain in the protein of the XPV shell. The α-helices are shown as cylinders; the β structural regions are indicated by arrows. The numbers denote the boundaries of the structured regions.

On the basis of the result obtained by tritium planigraphy, of existing biochemical and immunological data, and also of the basic principles governing the packing of the predicted elements of the secondary structure in globular proteins Baratova et al.[125] proposed a model of the tertiary structure of the protein in the coat of XPV (Fig. 17). In this model one β group, containing the β structural regions 1–12, 14–22, and 24–33, lies alongside the molecule and forms the outer surface of the virus particles.

To conclude this review we shall briefly mention another group of problems which could be solved effectively by the application of tritium planigraphy. The concept of linear or conformational antigenic determinant proteins is widely adopted in modern immunology and immunochemistry. It is assumed that linear determinants are composed of several aminoacid residues, amounting to a substantial proportion of the residues in the protein sequence, whereas the conformational determinants contain aminoacid residues from different parts of the sequence, lying close together in the native structure of the protein globule.

However, recent work suggests that all the antigenic determinants are conformational.[127,128] Thus, the surface of the protein obtained from X-ray structural analysis data is always complex and has a very broken outline. Even a visual analysis of any structure shows that most of the residues on the protein surface have neighbours which are quite removed in the primary structure of the protein. Furthermore the most 'unbroken' parts are mostly loops and/or projecting regions. This explains why surface properties such as hydrophilicity, accessibility, and mobility can be used to predict possible antigenic determinants. This concept is well illustrated by the correlation between the accessibility to tritium atoms and the antigenic properties of these parts of the structure, observed in the TMV and XPV viruses and (earlier) in globular proteins. By describing the structure of the object in terms of data on its surface (provided by an analysis of the tritium labelling), and also by a comparative analysis of the surfaces of the free protein and of the protein complexes with a monoclonal antibody, it should be possible, we believe, to identify the conformational determinants. So far this possibility has been realised only at the level of the X-ray structural analysis of structures such as complexes with site-directed mutagenesis.[129]

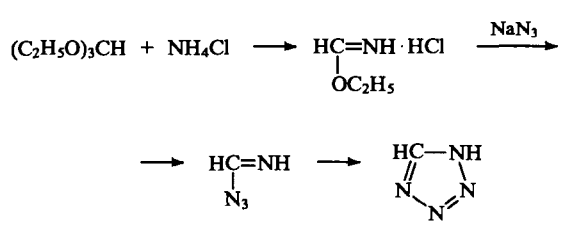
VI. Conclusion	809

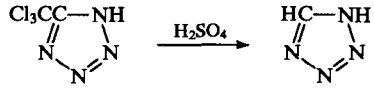
Abstract. A systematic account is given of the latest data on the methods of synthesis, physicochemical properties, and practical applications of tetrazoles. New results obtained in the study of the electronic structures, acid–base properties, tautomerism, reactivities, and thermal stabilities of tetrazoles are discussed. The bibliography includes 369 references.

I. Introduction



The development of the chemistry of tetrazoles during the last decade has been largely associated with the wide-scale employment of these compounds in medicine,[1–12] biochemistry,[13–17] agriculture,[18–20] and photography,[21,22] and also as components of systems for the recording of information.[23–25] Novel[26–29] methods of synthesis of substituted tetrazoles have been developed during these years and existing methods have been significantly improved.[30–35] As a result of this, tetrazoles, which had been difficult to obtain and were rather exotic, became the subject of detailed investigation and in many instances their practical applications were recommended. New results obtained in the study of the electronic structures,[36–40] acid–base properties,[41–43] tautomerism,[44] reactivities,[45–47] and thermal stabilities[48–50] of tetrazoles are of great interest. Original studies published up to 1981 have been described schematically in other reviews.[46,51] The latest data on methods of synthesis, physicochemical properties, and practical applications of tetrazoles are discussed below.

II. Methods of synthesis of tetrazoles



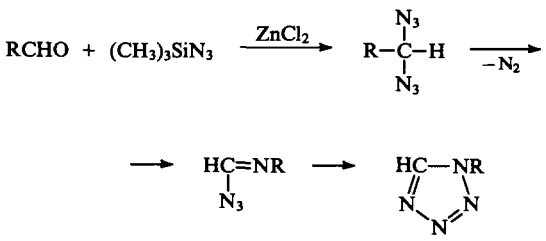
1. Tetrazole

Several methods of synthesis of tetrazole are known: the interaction of hydrocyanic acid with hydrazoic acid, the interaction of ethyl formate with sodium azide and ammonium chloride in acetic acid, the diazotisation of 5-aminotetrazole in the presence of reductants, the oxidative degradation of mono- and di-substituted tetrazoles, and certain others.[51]

Among these methods, the commonest involve the diazotisation of 5-aminotetrazole and the interaction of ethyl orthoformate with sodium azide. In the latter case, the reaction evidently proceeds via the formation of the iminoester hydrochloride and its subsequent conversion into tetrazole on treatment with sodium azide.[52]

The electrochemical reduction of 5-trichloromethyltetrazole is known to afford a low yield of tetrazole (~16%).[53] On the other hand, according to our data, tetrazole is formed in 75% yield on heating 5-trichloromethyltetrazole in 85% sulfuric acid.

The synthesis of a tetrazole containing a ^{13}C carbon isotope atom in the ring has been described recently.[54]



2. 1-Substituted tetrazoles

The choice of synthetic methods for 1-substituted tetrazoles is limited. The main procedure again involves addition of hydrazoic acid to isonitriles. Together with this procedure, use is also made of coupling reactions between diazonium salts and diformylhydrazine or the interaction of imidoyl chlorides, obtained from monosubstituted formamides, with hydrazoic acid.[51] Among the new methods of synthesis of 1-substituted tetrazole, mention should be made of the reaction of aldehydes with trimethylsilyl azide (TMSA)[55] and of amines with ethyl orthoformate and sodium azide.[56–59] In the former case,[55] the interaction of an aldehyde with TMSA leads to the initial formation of a diazide which is then converted into an imidoyl azide by scission of a nitrogen molecule and a rearrangement.

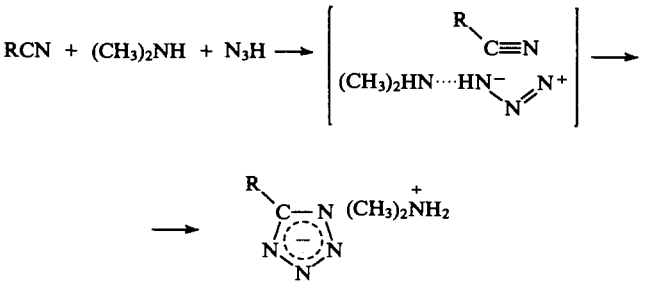
The imidoyl azide cyclises to the 1-substituted tetrazole.

The mode of reaction depends on the aldehyde : TMSA ratio. In the presence of a threefold excess of TMSA, 1-substituted tetrazoles are formed, while for a reactant ratio ranging from 1 : 1 to 1 : 1.5 the products are disubstituted tetrazoles.

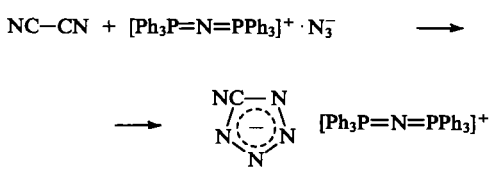
One of the most promising methods of synthesis of 1-substituted tetrazoles involves the reaction of amines with ethyl orthoformate and sodium azide. This method may be regarded as universal, since aliphatic and aromatic amines having different structures can be used for the preparation of tetrazoles. It is believed[58] that 1-substituted tetrazoles are formed in accordance with the following scheme:

1-Substituted tetrazoles can also be obtained by alkylating tetrazole. This reaction will be examined in detail in the discussion of the chemical properties of tetrazoles.



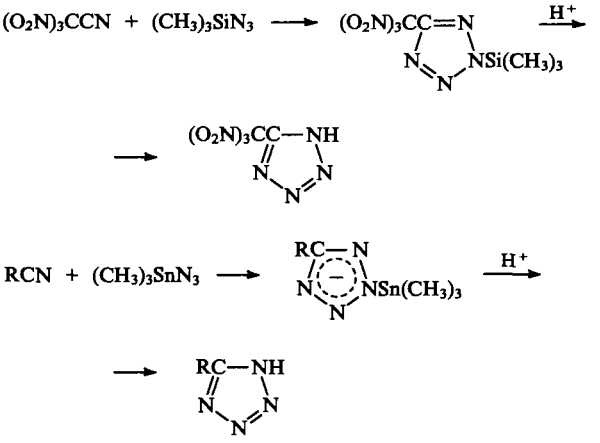
3. 2-Substituted tetrazoles

The development of simple and effective methods of synthesis of 2-substituted tetrazoles is one of the problems in the chemistry of tetrazoles of greatest current interest. As before, the only method of synthesis of 2-substituted tetrazoles involves the alkylation of tetrazole.[47,51] On the other hand, we should bear in mind that, although a wide variety of 2-substituted tetrazoles may be obtained in the alkylation of tetrazole, the application of this method usually entails difficulties in the separation of the isomeric 1- and 2-substituted tetrazoles formed as a result of the reaction.

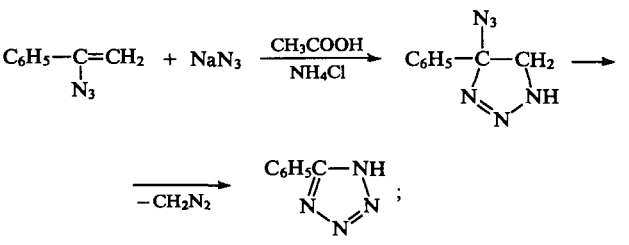


4. 5-Substituted tetrazoles

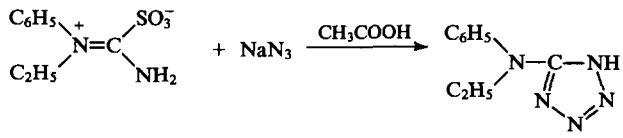
The commonest method of synthesis of 5-substituted tetrazoles involves the reaction of nitriles with salts of hydrazoic acid.[51] Both the simplest aliphatic and aromatic nitriles and nitriles with a complex structure, including those containing N-, O-, and S-heterocyclic substituents, may be used for such purposes.[60-68] The most suitable solvents for such reactions are dimethyl formamide[51] and butanol.[69]



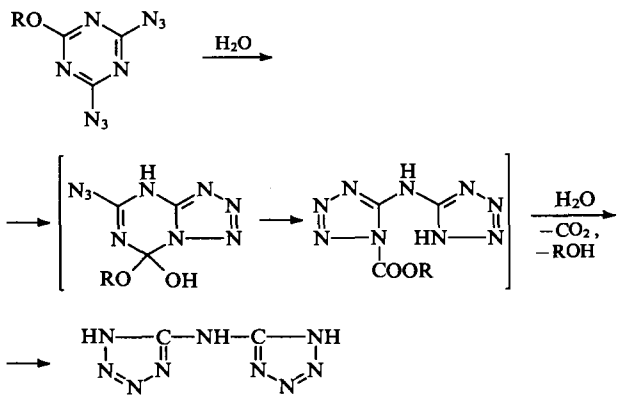
It was postulated previously that the interaction of nitriles with ammonium azides is accompanied by the formation of an imidoyl azide as a result of nucleophilic attack of the azide ion on the carbon atom of the nitrile group; the imidoyl azide cyclises to the tetrazole.[70] However, subsequently it was established in the study of the kinetics of this reaction that 5-substituted tetrazoles are formed via a 1,3-dipolar cycloaddition mechanism. In this process, the dipolarophile is the nitrile, while the hydrogen-bonded complex of the amine with hydrazoic acid serves as the 1,3-dipole.[71,72]



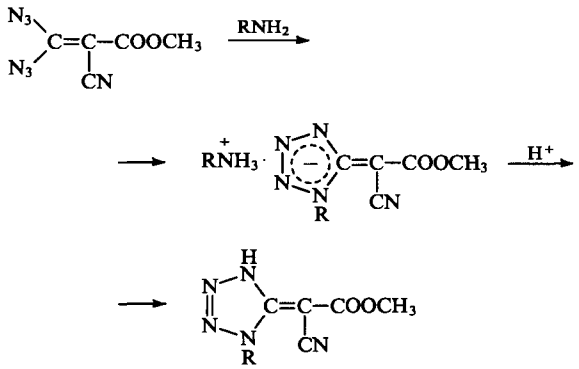
On the other hand, the possibility of the formation of 5-substituted tetrazoles via a two-stage mechanism is not ruled out. This mechanism apparently operates for substrates in which the nitrile group is linked to a powerful electron-accepting substituent, for example for trifluoro- and fluorodinitroacetonitriles[73-75] and also for oxalodinitrile.[76] It is therefore appropriate to note that oxalodinitrile reacts at a high rate with $[Ph_3P=N=PPh_3]^+N_3^-$ affording 5-cyanotetrazole in 96% yield.[76]



Instead of the salts and complexes of hydrazoic acid, trimethylsilyl azide[29,74] as well as trimethyl- and tributyl-stannyl azides[77,78] may be employed in the reaction with nitriles. In such cases, 1-trimethylsilyl- and 1-trimethyl(butyl)stannyl-5-R-tetrazoles are formed in the first stage, being converted into 5-R-tetrazoles on acid hydrolysis.

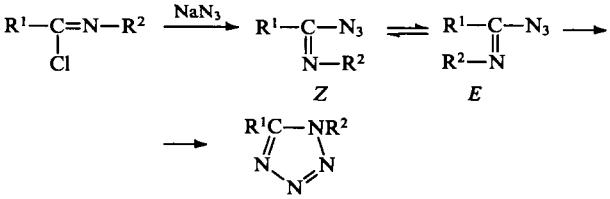


One should include among the novel methods of synthesis of 5-substituted tetrazoles the reaction of 1-azido-1-phenylethene with sodium azide in acetic acid or in dimethylformamide (DMF),[27] i.e.

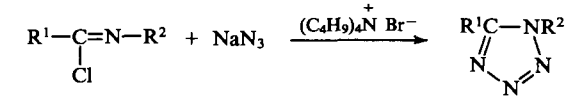


as well as the interaction of aminoiminomethanesulfonic acids with sodium azide in acetic acid.[28]

An interesting method of synthesis of di(tetrazol-5-yl)amine has been proposed.[79] When 6-alkoxy-2,4-diazido-1,3,5-triazines are heated in water, a ring carbon atom and the alkoxy-group linked to it are eliminated, which leads to di(tetrazol-5-yl)amine.

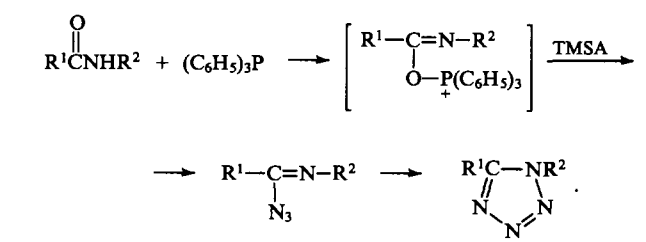


The synthesis of 5-substituted 4,5-dihydrotetrazoles from methyl 3,3-diazido-2-cyanoacrylate and ammonia or amines in a satisfactory yield has been reported recently.[80,81]

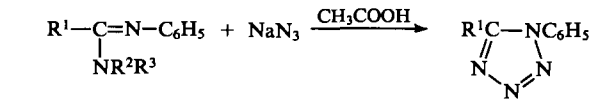


R = H, Alk

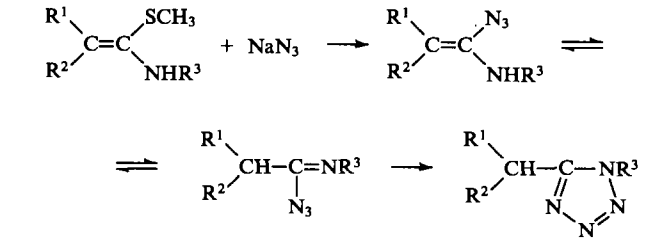
5. 1,5-Disubstituted tetrazoles



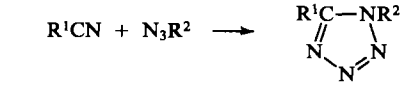
The reactions of imidoyl chlorides with hydroazoic acid or inorganic azides is again one of the most commonest methods of synthesis at 1,5-disubstituted tetrazoles. This method is universal and can be used to synthesise 1,5-disubstituted tetrazoles containing a wide variety of functional groups.[82-91] The kinetics and mechanism of this reaction have been investigated.[92,93] It has been shown that the interaction of an imidoyl chloride with sodium azide involves the formation in the first stage of a mixture of the (*Z*)- and (*E*)-conformers of the imidoyl azide in which only the (*E*)-conformer is converted into the tetrazole.



In the synthesis of 1,5-disubstituted tetrazoles from imidoyl chlorides and hydrazoic acid, one should bear in mind that certain precautions must be taken in working with hydrazoic acid, which is highly toxic and explosive. The use of inorganic azides instead of hydrazoic acid enables these difficulties to be avoided to a large extent, but, owing to the limited solubility of these reagents, the reaction must be carried out in DMF.[94,95] Other solvents—dry dioxane, ethanol, or acetone—are less effective.[96-99] The addition of water to the reaction mixture makes it possible to increase somewhat the solubility of alkali metal azides, but, owing to the hydrolysis of the imidoyl chloride, the yield of 1,5-disub-stituted tetrazoles diminishes.[100] This conflict was resolved with the aid of phase transfer catalysis. It was shown that imidoyl chlorides react at a high rate with sodium azide in the methylene chloride (chloroform)–water two-phase system in the presence of phase transfer catalysts (tetrabutylammonium bromide, 5-butyl-2,3-diphenyltetrazolium bromide, or hexa-decyltributylphosphonium bromide). Under these conditions, tetrazoles are formed in 87%–92% yields.[33-35]

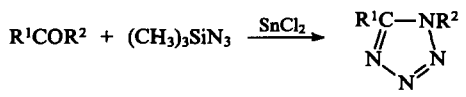


It has recently been reported that trimethylsilyl azide may be used in the reaction with imidoyl chloride instead of hydrazoic acid or inorganic azides.[101] It has been stated[78] that trimethylsilyl azide has been used successfully in the synthesis of 1,5-disub-stituted tetrazoles from amides and triphenylphosphine. The reaction evidently proceeds in accordance with the following mechanism:

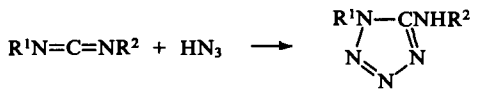


A convenient method of synthesis of 1,5-disubstituted tetrazoles has been proposed by Gaponik et al.,[102] who found that the reaction of amidines with sodium azide in acetic acid results in the formation of the corresponding tetrazoles in a high yield.

Finally, 1,5-disubstituted tetrazoles may be obtained from *S,N*-acetals of ketene on heating the latter with sodium azide in dimethyl sulfoxide.[26]

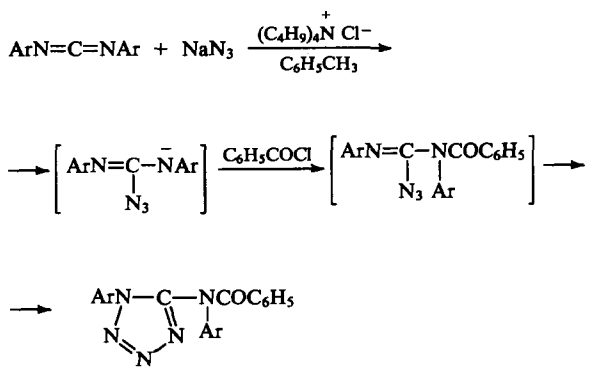


One of the fairly thoroughly investigated methods of synthesis of 1,5-disubstituted tetrazoles involves the reaction of nitriles with aliphatic and aromatic azides.

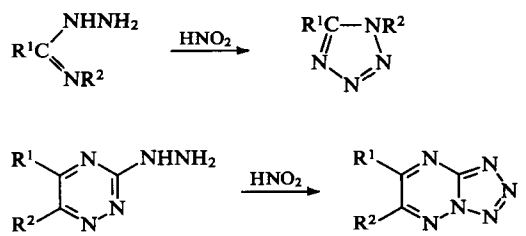


Nitriles having different structures have been used to obtain 1,5-disubstituted tetrazoles.[103-105] The process is significantly accelerated when the reaction is carried out at an increased pressure (10 kbar).[30,31,106,107]

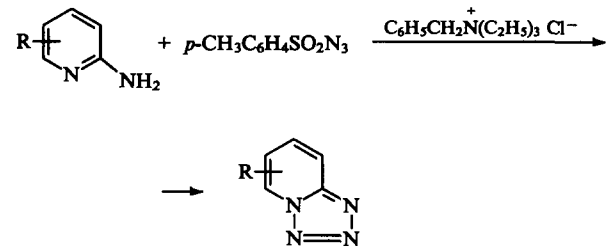
The transition state in the reaction of nitriles with organic azides is formed by the interaction of the HOMO of the azide and the LUMO of the nitrile.[108] This conclusion agrees with experimental data and also accounts for the influence of steric factors on the reactivity of nitriles and organic azides.



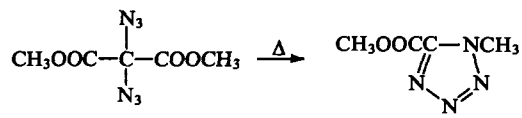
The reaction of ketones with hydrazoic acid is very important for the synthesis of 1,5-disubstituted tetrazoles.[51] The mechanism and synthetic possibilities of this reaction have been investigated in very great detail. It has been shown that ketones of various structures, including steroid ketones, may be used in the synthesis of 1,5-disubstituted tetrazoles. The reaction is carried out in the presence of catalysts such as sulfuric or trichloroacetic acids,[109,110] boron trifluoride etherate,[111,112] and titanium tetrachloride.[113] For a long time, the principal limitation of the method was the need to use hydrazoic acid. These difficulties were overcome by using trimethylsilyl azide with tin chloride[114] or trifluoroacetic acid[115] instead of hydrazoic acid.



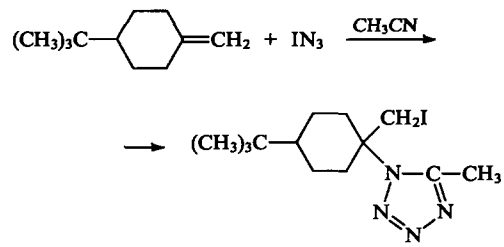
Yet another common method of synthesis of 1,5-disubstituted tetrazoles involves the reaction of carbodiimides with hydrazoic acid.[116-118]



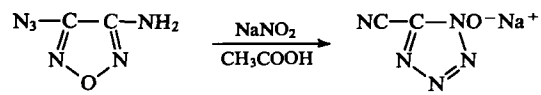
If the reaction is carried out under the phase transfer catalysis conditions in the presence of benzoic acid chlorides, then sodium azide may be used instead of hydrazoic acid.[32]



1,5-Disubstituted tetrazoles may be obtained by treating hydrazides,[119] 4-hydrazino-1,2,3-triazines,[120] or 3-hydrazino-1,2,4-triazines[121] with hydrazoic acid.

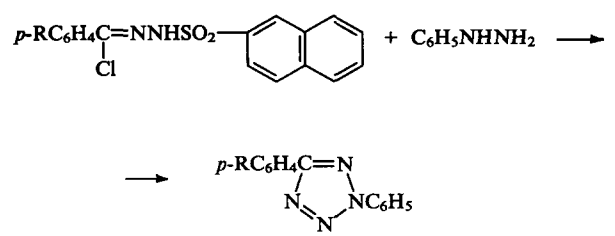


An interesting method of synthesis of annelated tetrazoles by the interaction of 2-aminopyridine or 2-aminoquinoline with toluene-*p*-sulfonyl azide under phase transfer catalysis conditions has been proposed.[122]



Finally, mention should also be made of a series of methods of synthesis which have so far been used to a limited extent. In the first place, this includes the reaction of isocyanates with sodium azide[123] or trimethylsilyl azide[124] and the thermal rearrangement of 5-azido-1,2,3-triazoles[125,126] and the diesters of 3,3-diazidomalonic acid.[127]

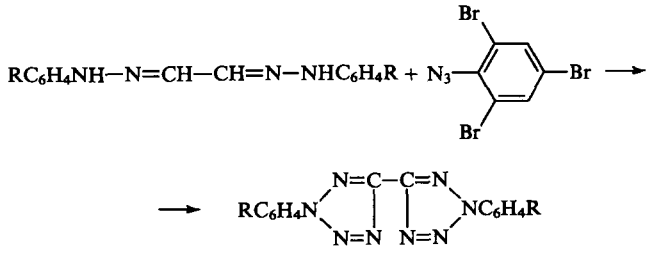
This group of syntheses also includes the addition of iodine azide to norbornene[128] and 4-(*tert*-butyl)-1-methylenecyclohexane[129] acetonitrile.



Several further methods of synthesis of 1,5-disubstituted tetrazoles have been proposed recently: the reaction of 1,3-oxazinium salts with sodium azide,[130] the reaction of benzotriazole with glyoxal and sodium azide,[131] and the diazotisation of 3-amino-4-azido-1,2,5-oxadiazole.[132]

6. 2,5-Disubstituted tetrazoles

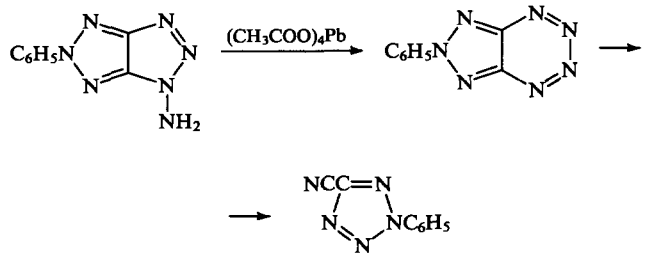
The methods of synthesis of 2,5-disubstituted tetrazoles have been developed inadequately. Not even one fundamentally new method of synthesis of these compounds of a general character has been proposed during the last decade. Nevertheless, the reaction of imidoyl chlorides with phenylhydrazine is noteworthy.[133]



R = H, CH_3, OCH_3, NO_2

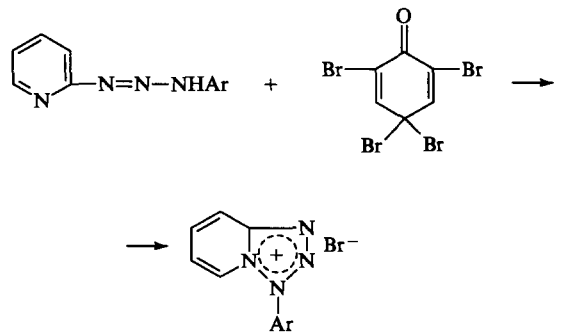
N-(Naphthalenesulfonyl)benzohydrazides were used to synthesise the imidoyl chlorides.

A novel method of synthesis of 2-aryl-5-(2-aryltetrazol-5-yl)tetrazoles, based on the reaction of glyoxal bisarylhydrazones with 2,4,6-tribromoazidobenzene, has been proposed (Scheme 1).[134]



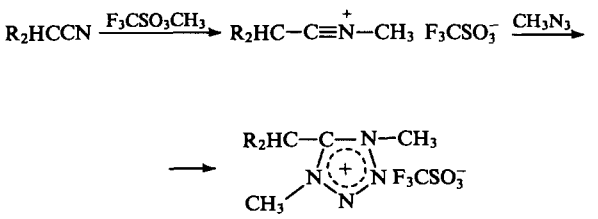
Scheme 1

R = H, OCH_3, Br, Cl



Finally, mention should be made of an interesting example of the conversion of condensed 4-amino-2-phenyl-1,2,3-triazolo-[4,5-*d*]-1,2,3-triazole into 5-cyano-2-phenyltetrazole on treatment with lead tetraacetate (Scheme 2).[135]

Scheme 2



7. Tetrazolium salts

Isomeric 1,2,5-, 1,3,5-, 1,4,5-, and 2,3,5-trisubstituted tetrazolium salts are known. The synthesis of these compounds has been reviewed.[136] Studies published after 1986 are considered below. The syntheses of a series of 1,2,5-trisubstituted tetrazolium salts by oxidising 3-aryl-1-(2-pyridyl)triazenes with 2,4,4,6-tetrabromocyclohexa-2,5-dien-1-one have been described.[137,138]

The alkylation of 1,5- and 2,5-disubstituted tetrazoles is a convenient method of synthesis of tetrazolium salts.[136] It has been shown recently[139] that 1,4,5-trisubstituted tetrazolium salts are formed in a satisfactory yield in the alkylation of 1,5-disubstituted tetrazoles by dialkyl sulfates or alkyl iodides. The above tetrazolium salts have also been obtained by the successive treatment of nitriles with methyl trifluoromethanesulfonate and methyl azide.[140]

The oxidation of formazans having different structures with potassium permanganate in an organic solvent–water two-phase system leads to the corresponding tetrazolium salts in a high yield. A significant feature of this reaction is the fact that the role of the phase transfer catalyst is assumed by the tetrazolium hydroxide formed in the first stage of the reaction—in the oxidation of the formazan at the interface.[34,141,142]

The synthesis of mesoionic tetrazoles has been described.[143–145]

III. Physicochemical properties

1. Electronic structure

Nonempirical quantum-chemical methods have been used successfully during the last decade to study the electronic structure of tetrazoles. Attention has been concentrated on the problem of prototropic tautomerism in the solution of which an ab initio method was employed. The total energies of 1*H*- and 2*H*-tautomers of tetrazoles have been calculated in terms of the 6-31G** and 6.311+G(2*d*, 2*p*) basis sets. It follows from these data that the 2*H*-tautomer is more stable in the gas phase.[146,147] The vertical ionisation potential of the 2*H*-tautomer of tetrazole, calculated by quantum-chemical methods, agrees with the experimental value obtained by photoelectron spectroscopy.[148] It is noteworthy that the higher stability of the 2*H*-tautomer in the gas phase is indicated by the results of quantum-chemical calculations for the radical-cations of the two prototropic tautomers, carried out by the semiempirical CNDO/2 method, and also by mass-spectrometric data.[149,150] On the other hand, calculations by the modern semiempirical MNDO method indicate a greater stability of the 1*H*-tautomers of tetrazole and 5-fluorotetrazole in the gas phase.[36,37]

Objectively, the choice of the basis set does not play a fundamental role in the analysis of the prototropic tautomerism of tetrazole by a nonempirical method. However, the situation changes on passing to the protonated tetrazole (the tetrazolium cation). Here one should bear in mind that, in the calculation of the energy of the protonation of tetrazole in terms of a minimal basis set, unduly high values are obtained. It follows from the calculation that the tetrazolium cation containing protons in the 1- and 4-positions in the heterocycle is the most stable and that the relative stability of this tautomer diminishes by 29.3 kJ mol^{-1} on passing from the STO-3G basis set to the 6-31G**/6-31G basis set.[38,151] A similar analysis has been carried out for the protonation of 1-methyl- and 2-methyl-tetrazoles, in which the basicity centre is also the N(4) atom of the heterocycle according to the ab initio (6-31G) calculation.[152]

The extensive application of quantum-chemical methods made it possible to obtain valuable information not only about the prototropic tautomerism of tetrazoles but also about many other interesting questions. Thus a topological analysis of the structures of complexes of tetrazole with Li^+, Na^+, K^+, and Al^{3+} has been carried out by an ab initio method. The possibility of different relative dispositions of the heterocyclic ligand and the metal ion in space has been demonstrated.[40]

Modern semiempirical methods have also been used successfully in the analysis of the electronic structures of tetrazole and its derivatives. It has been shown that the MNDO method describes adequately the electronic structures of tetrazoles and that the application of this method is sometimes preferable to the use of the ab initio method in terms of a minimal basis set.[153]

At the same time, it has been noted that the method yields enthalpies of formation which are too low by 83.8 kJ mol^{-1}: 230.5 and 248.0 kJ mol^{-1} for 1*H*- and 2*H*-tetrazoles respectively.[36]

We may list a further several studies in which the electronic structures of tetrazoles have been investigated. Thus a study has been made[154,155] of the electronic structures of various alkyl- and alkenyl-tetrazoles (MNDO). The proton affinities of tetrazole and substituted tetrazoles have been calculated.[156] The azidoazomethine–tetrazole equilibrium has been analysed[36] and the structure of a dipolar diazonium tetrazolate has been considered in another study.[157] One should include here also the recently published results of an ab initio calculation of the potential energy profile for the Dimroth rearrangement of 1-substituted 5-aminotetrazoles[158] and the stability of the relatively unstable electronic states of tetrazole[159] as well as the results of semiempirical calculations of the electronic parameters of the reactants and products in the alkylation reactions of salts of 5-substituted tetrazoles (CNDO, CNDO/2),[160,161] the exhaustive alkylation of isomeric *N*-alkyltetrazoles,[162] and the aminomethylation of *N*-alkyl-5-aminotetrazoles (CNDO/2).[163]

Quantum-chemical calculations have been used effectively for the interpretation of the UV spectra of 1,4-dihydro-5*H*-tetrazoles (CNDO/S-CI),[164] the ^{15}N NMR spectra of tetrazole (MNDO), *N*-alkyltetrazoles (INDO/S-SOS),[165,166] *N*-aminotetrazoles (INDO),[167,168] and tetrazolopyridines (INDO/S-SOS),[169] and also of the mass spectra of the isomeric methyltetrazoles (CNDO, CNDO/2).[150,170]

The joint analysis of experimental data and results obtained by quantum-chemical methods will probably persist.

2. Electronic, photoelectron, and vibrational spectra

Communications concerning the application of UV spectroscopy as an analytical method in the study of protolytic equilibria, reactivities, and compositions of multicomponent mixtures of tetrazoles have occupied a leading position among publications of recent years. Thus UV spectroscopy has been used successfully to determine the acidity and basicity constants of 5-(*o*-, *m*-, and *p*-carboxyphenyl)tetrazoles in aqueous solutions of different acidity,[171] in the study of the rates and regioselectivities of the reactions of tetrazolate anions with dimethyl sulfate,[172,173] ethyl bromoacetate,[174] and methyl vinyl ketone,[175,176] and also in the study of equilibria involving ion pairs of the salts of 5-aryltetrazoles in acetonitrile.[174] Finally, bearing in mind the sensitivity of the UV spectra of the tetrazolate anions to the addition of small amounts of water, one may investigate quantitatively the specific solvation of tetrazolate ions in binary systems and also estimate the reactivities of specifically solvated tetrazole substrates.[173]

The luminescence spectra of 5-aryltetrazoles have been discussed.[177]

The photoelectron spectra (PES) of tetrazoles have their specific features and differ from those of other azoles, which is associated with the high ionisation potentials of tetrazoles by virtue of the enhanced stabilisation of the π levels.[178] According to photoelectron spectroscopic data, tetrazole exists in the gas phase almost exclusively as the 2*H*-tautomer.[148,179] A satisfactory agreement between spectroscopic data and the results of non-empirical calculations has been noted.[148,179] A publication[180] on the photoelectron spectra of certain condensed tetrazoles should be added to the studies quoted above.

Finally, we shall consider investigations of the vibrational spectra of tetrazoles. Thus the frequencies and the normal modes of vibration of 1-methyl- and 2-methyl-tetrazoles, 1-vinyl- and 5-vinyltetrazoles, 2-methyl-5-vinyltetrazole, and 5-phenyltetrazole have been analysed.[181,182] Detailed studies have been made of the vibrational spectra of the hydrazides of tetrazolylacetic acids[182] and tetrazole-containing polymers[183] and also of the IR and Raman spectra of 5-aminotetrazole.[184,185] Levchik et al.[185] interpreted the bands due to the stretching-deformation vibrations of 5-aminotetrazole (1000–1100 cm^{-1}) in terms of Fermi resonance. These data permit a reliable interpretation of the experimental spectra of tetrazoles, which extends the possibilities of vibrational spectroscopy as a method for the identification of compounds containing the tetrazole ring. Vibrational spectroscopy and ^{1}H and ^{13}C NMR spectroscopy can be used jointly in the analysis of tetrazoles having a complex structure. This approach has been demonstrated successfully in the analysis of polyvinyltetrazoles.[186]

3. NMR spectra

NMR spectroscopy has been used widely for the identification, structural study, and the prediction of the properties of tetrazoles. In a number of recent investigations the exceptional possibilities of ^{15}N NMR spectroscopy as a promising method for the investigation of polynitrogen heterocycles, and in particular tetrazoles, have been clearly demonstrated. This method proved extremely effective in the study of the prototropic tautomerism of tetrazole, since the chemical shifts of the ^{15}N nuclei of the pyrrole [N(1)] and pyridine [N(2)] atoms differ significantly.[187] According to Woffold et al.[187] and Bojarska-Olejnik et al.,[188] tetrazole in solution in DMSO-d_6 and $CDCl_3$ exists predominantly as the 1*H*-tautomer. The study of the ^{15}N NMR spectra of tetrazole and isomeric *N*-alkyltetrazoles led to the same conclusion.[189] It was shown that, for solutions of tetrazoles in DMSO or dioxane at concentrations not exceeding 0.5 M, it is possible to identify reliably the 1*H*- and 2*H*-tautomers and the isomeric *N*-alkyltetrazoles[166,189] and to demonstrate convincingly that 5-mercapto- and 5-hydroxy-tetrazoles exist mainly as the thiono- and oxo-derivatives respectively.[189] The structures of mono- and di-alkyl(alkenyl)tetrazoles,[190,191] complex condensed systems incorporating the tetrazole ring,[169] and also tetrazolium salts[191,192] have been established with the aid of ^{15}N NMR spectroscopy. The results of these investigations agree well with X-ray diffraction and gas electron diffraction data.[193] Interesting results have been obtained in a study[194] of tetrazoles by ^{15}N NMR spectroscopy. ^{15}N chemical shifts for a series of mono- and bicyclic tetrazoles and also for the salts and complexes of 5-substituted tetrazoles were determined. Together with the solution of the traditional problem — the determination of the individuality of the N(1)- and N(2)-isomers — ^{15}N chemical shifts were obtained for the tetrazolate anions taking into account data on the NH acidity of 5-substituted tetrazoles. A later study[190] dealt with the influence of the protonation of the tetrazole ring at the N(4) atoms on the ^{15}N chemical shift.

^{13}C NMR spectroscopy has also been used widely for the solution of structural problems in the chemistry of tetrazoles. The available information about the ^{13}C NMR spectra of isomeric *N*-substituted tetrazoles and other azoles has been surveyed and the data have been compared.[195] The torsional angles between the phenyl and azolyl fragments in *N*-aryltetrazoles have been estimated from ^{13}C NMR spectroscopic data,[196,197] and the electronic constants of the *N*(1)-tetrazolyl group have also been found.[196,198] ^{13}C NMR spectroscopy has been used in the study of 5-aryltetrazoles,[199] derivatives of 5-furyltetrazole,[200] and isomeric vinyltetrazoles[154,201,202] and also in the analysis of complex amino-imino equilibria involving 5-alkylamino-1-phenyltetrazoles.[203]

The most complete information about the structure of tetrazoles can be obtained by the joint application of ^{1}H, ^{15}N, and ^{13}C NMR spectroscopy. The tendency to carry out such studies is clearly manifested in recent publications.[154,168,169,191] It is noteworthy that the spin–spin coupling constants $J(^1H, ^1H)$,[204] $J(^{15}N, ^1H)$,[205] and $J(^{13}C, ^{13}C)$[206] as well as the nuclear Overhauser effect[207] are used together with the ^{1}H, ^{15}N, and ^{13}C NMR chemical shifts for the solution of structural problems, including the problem of the prototropic tautomerism and the identification of the isomeric *N*-alkyl(aryl)tetrazoles.

4. Thermolysis, combustion, and detonation

Tetrazoles possess extreme thermochemical characteristics among the azoles. The enthalpies of formation of tetrazole in the crystalline and gaseous states are ΔH_f(cr) = 236.1 kJ mol^{-1} and ΔH_f(g) = 327.2 kJ mol^{-1} respectively,[208,209] while the enthalpy of formation of crystalline 5-(tetrazol-5-yl)tetrazole is ΔH_f(cr) = 532.1 kJ mol^{-1}.[210] The standard enthalpies of combustion ΔH_c of tetrazole and 5-(tetrazol-5-yl)tetrazole are −916.1 and −1605.6 kJ mol^{-1} respectively.[208,210] The thermal decomposition of tetrazoles takes place in the temperature range 150–250 °C with dissociation of the N–N bonds.[211] According to the results of thermogravimetric analysis, the intense decomposition of tetrazoles is accompanied by an exothermic effect and a marked decrease in mass.[185] The thermal stability of tetrazoles is determined by the nature and location of the substituents in the heterocycle.[212–214] Thus an increase in the number of nitro-groups in nitroaryltetrazoles lowers their thermal stability.[214] The decomposition of the tetrazole ring is usually accompanied by the evolution of molecular nitrogen. However, the routes to the fragmentation of isomeric tetrazoles differ significantly. The thermolysis of 1,5-disubstituted tetrazoles leads to intermediate nitrenes,[215] while nitrile imines are formed from 2,5-disubstituted tetrazoles.[216,217] In all cases, the elimination of nitrogen proceeds via a highly polar transition state.[218] The rate-limiting stage of the thermal decomposition of 1,5- and 2,5-disubstituted tetrazoles is the homolytic dissociation of the N(1)–N(2) and N(2)–N(3) bonds respectively. The activation energies for these processes are in the range E_a = 162–200 kJ mol^{-1}. There is a linear relation between the logarithms of the rate constants for the thermal decomposition of tetrazoles and the Coulombic component of the perturbation energy (E_N). This makes it possible to predict the rate constants for the homolytic thermal decomposition of tetrazoles of different structure.[219] The characteristic features of the thermal decomposition of amino- and nitroamino-tetrazoles have been considered.[220,221]

It has been established that the rate-limiting stage in the thermolysis of poly-1-vinyltetrazole is the opening of the tetrazole ring. The activation energy for this process is 140–148 kJ mol^{-1}.[222] The thermal decomposition of the salts of 5-alkyl-2,3-diaryl- and 2,3,5-triaryl-tetrazolium salts has been discussed.[34,141]

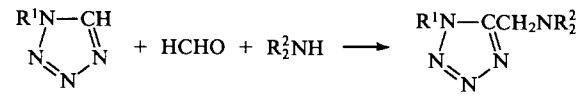
In conclusion, it is essential to note that the fragmentation reactions of the tetrazole ring under the influence of a thermal pulse and electron impact have common features.[51] Joint examination of the thermal decomposition and mass spectra of tetrazoles yields valuable information about the nature of the reacting and intermediate species and about their reactivities.[223–227]

The characteristic features of the structure of the high-energy tetrazole ring predetermine the specific features of the combustion processes involving tetrazole and tetrazole-containing substances. These processes sometimes take place with unusual external effects, as happens in the combustion of mixtures of tetrazole and sodium tetrazolate.[50,228–230] A detailed study of the combustion of tetrazole has been carried out[231] and it has been shown that the process proceeds mainly in the condensed phase.

The characteristics of the transition of the combustion of the tetrazoles to detonation have been investigated in relation to the isomeric 1-methyl- and 2-methyl-5-nitrotetrazoles. Moulded 2-methyl-5-nitrotetrazole has much more effective detonation characteristics. The average time required for the transition from combustion to detonation is longer for 2-methyl-5-nitrotetrazole than for lead azide but shorter than for lead styphnate.[232] The capacity for detonation of complexes of 5-cyano-, 5-nitro-, and 5-nitroamino-tetrazoles as initiating explosives has been investigated experimentally.[233–235] Theoretical predictions of the detonation properties of tetrazoles have been made[236] and the methods for the analysis of the explosive properties of tetrazole derivatives have been discussed in a monograph.[237]

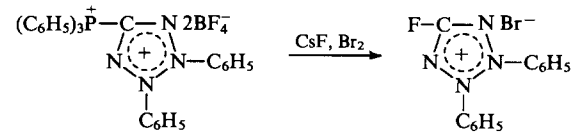
5. Acid–base properties

Tetrazole and 5-substituted tetrazoles are NH acids and weak organic bases, the acidity and basicity constants of which vary within wide limits depending on the nature of the substituent. Thus, on passing from 5-methyl to 5-nitro-tetrazole, the acidity constant increases while the basicity constant decreases approximately by seven orders of magnitude. The results of an experimental study of the acid-base properties of tetrazoles published up to 1990 have been surveyed in reviews[41,42] and in a monograph.[43] The same publications present tabulated acidity and basicity constants for a large number of tetrazoles. Among the studies in recent years, mention must be made of those in which the acidity and basicity have been investigated by various quantum-chemical methods and the proton affinities PA and PA^- of tetrazole and monosubstituted tetrazoles have been calculated.[160,168,238] The values of PA^- for the tetrazolate anion, calculated by the MNDO, AM1, and PM3 methods, are respectively 1567.5, 1351.3, and 1325.7 kJ mol^{-1}.[238]



The calculations by Ostrovskii et al.[160] and Claramunt et al.[168] agree with the earlier experimental data for the basicity of tetrazoles. The protonation of tetrazoles of different structure at the nitrogen atom in the 4-position has been explained by the greater stability of the corresponding tetrazolium cation. It has also been shown[160] that there is a linear correlation between the calculated (MNDO) affinities PA and the experimental pK_{BH^+} for 5-substituted tetrazoles: pK_{BH^+} = 0.323PA − 49.01.

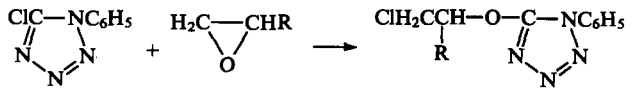
Unfortunately there have been as yet no experimental studies of the acidity and basicity of tetrazoles in the gas phase.



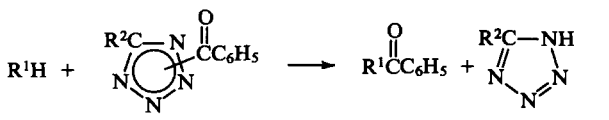
IV. Reactions of tetrazoles

1. Electrophilic substitution at a ring carbon atom

The reactions involving electrophilic substitution at a ring carbon atom in tetrazoles have been inadequately investigated. It has been shown recently that 1-alkyltetrazoles are smoothly iodinated by iodine in solution in sulfuric acid in the presence of potassium permanganate.[239] The corresponding 1-alkyl-5-iodotetrazoles are formed in 55%–75% yield. It has also been established that, when 1-methyltetrazole is treated with *tert*-butyllithium in tetrahydrofuran (THF), the hydrogen atom at a ring carbon atom in substituted by lithium.[240] The hydrogen at a ring carbon atom in 2,3-diaryltetrazolium salts is also substituted on treatment with *tert*-butyllithium in hexane.[241,242] 1-Substituted tetrazoles react with formaldehyde and amines under mild conditions, affording aminomethylation products.[59,243]

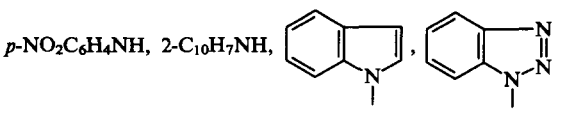


Finally, it is noteworthy that the triphenylphosphonium group in 2,3-diaryl-5-triphenylphosphoniotetrazolium is substituted by fluorine on treatment with caesium fluoride in the presence of bromine.[241]

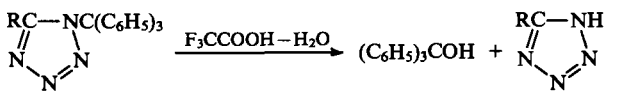


2. Nucleophilic substitution

The chlorine atom in 5-chloro-1-phenyltetrazole is readily substituted by treatment with alkali metal phenoxides in acetonitrile.[244] Similarly the chlorine atom in 5-chloro-1-phenyltetrazole is substituted by the SeH group on interaction of the tetrazole with sodium selenide in DMF at 100 °C.[245] Under phase transfer catalysis conditions, the corresponding ethers are formed in a satisfactory yield from 5-chloro-1-phenyltetrazole and various epoxy-compounds.[246]



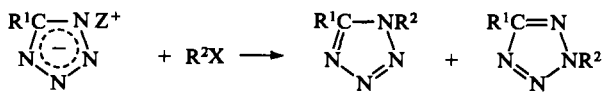
The bond between the sulfur and carbon atoms in 1-aryl-5-mercaptotetrazoles is cleaved on alkaline hydrolysis, which leads to the formation of 1-aryl-5-tetrazolols.[245]



The tetrazole ring in 5-aryl-1-benzoyl- and 5-aryl-2-benzoyltetrazoles is readily substituted by various nucleophiles.[247] *N*-Benzoyltetrazoles are mild acylating agents, which are effective in reactions with primary and secondary aliphatic and aromatic amines as well as alcohols, benzimidazoles, and benzotriazole.

R^1 = C_2H_5O, C_6H_5O, *p*-$NO_2C_6H_4O$, 2-$C_{10}H_7O$, C_6H_5NH,

Compared with the widely used acylating agents *N*-benzoylimidazole and *N*-acylimidazoles,[248] 5-aryl-*N*-benzoyltetrazoles have significant advantages. The reactivity of *N*-benzoyltetrazoles is superior to that of *N*-acylimidazoles and these compounds also have a higher selectivity towards primary and secondary hydroxy- and amino-groups.[249] The use of *N*-benzoyl-tetrazoles is especially effective when the reactants and products are sensitive to acids and alkalis and are also thermally relatively unstable. The tetrazole ring in 1-triphenylmethyl-5-R-tetrazoles is readily substituted on treatment with trifluoroacetic acid in aqueous tetrahydrofuran.[78]

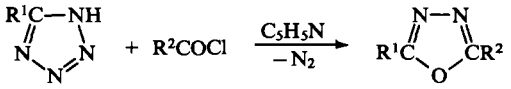


3. Alkylation

Alkylation belongs to the group of reactions of tetrazoles which have been investigated in greatest detail. It constitutes a simple method of synthesis of mono- and di-substituted tetrazoles of different structure, the preparation of which by other procedures is frequently impossible. Theoretically this reaction is of great interest, since it can serve as a convenient model for the study of heterocyclic substrates with dual reactivity.

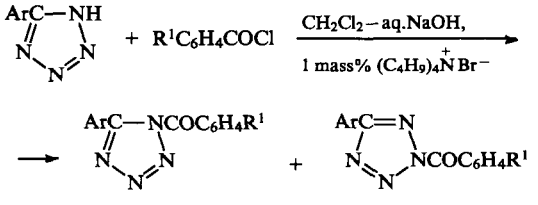
Depending on the properties of the reaction medium, tetrazole, 5-substituted tetrazoles, as well as their salts enter into the alkylation reaction. Alkyl halides,[250-255] esters of sulfuric and aromatic sulfonic acids,[254] the acetates of nitroaminoalcohols,[256] and compounds containing activated double bonds [175,176,257,258] are used as the alkylating agents. Data on the application of alcohols, [259-262] unsaturated compounds (propene and isobutene),[263] certain nitrylium ions,[264] and vinyl ethers [265] for such purposes have been published recently. Separate mention should be made of the reactions of 5-substituted tetrazoles with aldehydes (formaldehyde) and amines, which result in the formation of *N*-aminomethyl(*N*-hydroxymethyl) derivatives of tetrazoles.[266-269]

It was postulated previously that, regardless of the nature of the alkylating agent and the properties of the reaction medium, the alkylation of tetrazole and 5-substituted tetrazoles always results in the formation of the corresponding 1- and 2-substituted tetrazoles.



Z^+ = cation.

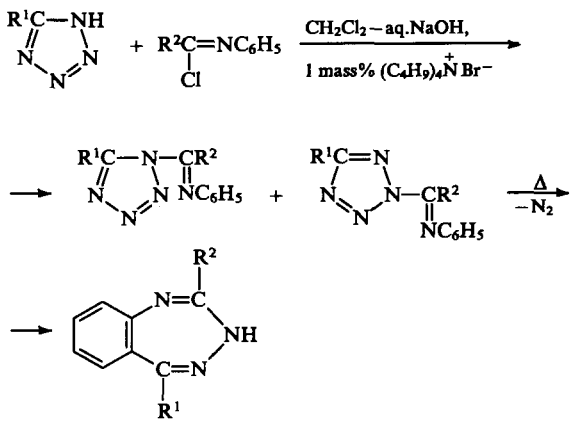
It was noted that the electronic nature of the substituents in the 5-position in the tetrazole ring exerts the main influence on the selectivity of this reaction—electron-donating and electron-accepting substituents promote respectively an increase and a decrease in the fraction of the *N*(1)-isomer in the alkylation products.[51] However, according to the latest data, exclusively 2-substituted tetrazoles are formed in the alkylation of tetrazole and 5-substituted tetrazoles by *tert*-butyl, isopropyl, or cyclohexyl alcohols in 96% sulfuric acid regardless of the nature of the substituent in the 5-position in the tetrazole ring.[262] Consequently, the selectivity of the alkylation of the tetrazoles depends also on the form (neutral or ionised) in which the substrate reacts with the alkylating agent. The high selectivity of the alkylation of the triethylammonium salts of 5-aryltetrazoles by methyl vinyl ketone in aprotic dipolar solvents [only the corresponding 4-(5-aryltetrazol-2-yl)butan-1-ones are formed] can be explained by the steric blocking of the N(1) atom of the tetrazole ring.[175,176]



In the alkylation of tetrazoles under conditions of phase transfer catalysis and in homogeneous media, appreciable differences between the reaction selectivities were not discovered.[162] On the other hand, alkylation employing phase transfer catalysis is preparatively an extremely promising method, which makes it possible to obtain a wide variety of *N*-mono- and *N*,*N*′-disubstituted tetrazoles under mild conditions and in high yields using simple and readily available reagents and solvents.[270]

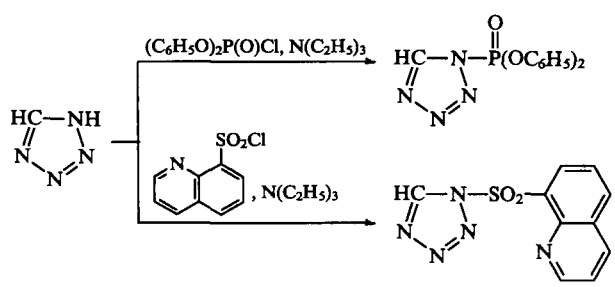
4. Acylation and imidoylation

Reactions of tetrazoles with acylating agents and imidoyl chlorides have recently acquired special importance, mainly because 2,5-disubstituted 1,3,4-oxadiazoles of different structure [142,247,270-273] as well as the previously unavailable 3*H*-1,3,4-benzotriazepines [274-277] can be obtained with their aid. Thus tetrazole and 5-substituted tetrazoles are converted into the corresponding 1,3,4-oxadiazoles in high yields on acylation by the chlorides of organic acids in the presence of organic bases at 100–120 °C.



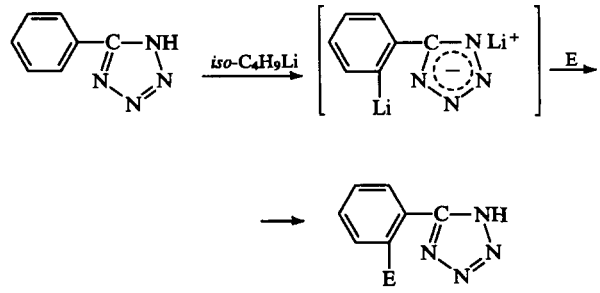
Previously it had been assumed that the first stage of this reaction involves the formation of an unstable 2-acyltetrazole, the cleavage of which with evolution of a nitrogen molecule leads to 1,3,4-oxadiazole.[278] However, subsequently it was demonstrated as a result of the application of phase transfer catalysis that the acylation of 5-aryltetrazoles by substituted benzoic acid chlorides affords not only 2-benzoyltetrazoles but also the isomeric 1-benzoyltetrazoles.[247,271]

The formation of oxadiazoles from 1-benzoyltetrazoles is preceded by isomerisation of the latter to 2-benzoyltetrazoles. It is suggested that, as a result of thermal cleavage and the elimination of a nitrogen molecule, 2-benzoyltetrazole is converted into an acylnitrile imine, the cyclisation of which leads to the oxadiazole.



The results obtained in the study of the acylation of 5-substituted tetrazoles by carboxylic acid anhydrides are of greatest practical interest.[273] This reaction can be regarded as one of the most effective and simple methods of synthesis of 2(5)-mono- and 2,5-disubstituted 1,3,5-oxadiazoles.

During the last 30 years, it has come to be assumed that the reaction of 5-substituted tetrazoles with imidoyl chlorides, leading to 3,4,5-trisubstituted 1,2,4-triazoles, proceeds via a mechanism similar to that of the acylation reaction.[279] It was postulated that, on heating 5-substituted tetrazoles with imidoyl chlorides in pyridine, an unstable 2-imidoyl tetrazole is formed initially and is then converted into an imidoylnitrile imine as a result of thermal cleavage and elimination of a nitrogen molecule. The subsequent cyclisation of the imidoylnitrile imine leads to the 1,2,4-tetrazole. The study of this reaction under phase transfer catalysis conditions established that not only 2-imidoyltetrazole but also the isomeric 1-imidoyltetrazole is formed in the first stage. It is of fundamental importance that heating of the isomeric imidoyltetrazoles thus obtained in solutions in toluene, *m*-xylene, or dioxane and also in the absence of solvents results in the formation of the previously unknown 3*H*-1,3,4-benzotriazepines instead of the expected 3,4,5-trisubstituted 1,2,4-triazoles.[276,277]



5. Silylation, phosphorylation, and sulfonylation

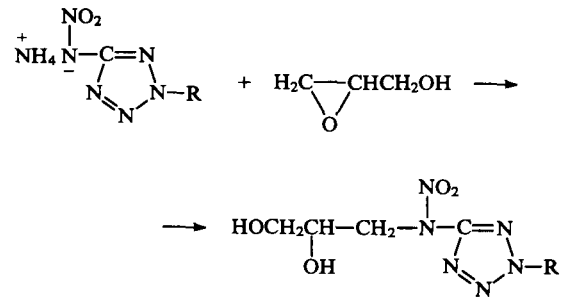
The interaction of the sodium salts of tetrazole with chlorotrimethylsilane results in the formation of trimethylsilyltetrazole in 85% yield.[47] The best solvent for this reaction is methylene chloride, while acetonitrile and DMF are virtually unsuitable. Begtrup and Larsen[47] do not discuss the problem of the selectivity of the silylation reaction, but one cannot rule out the possibility of the formation of two isomers — 1- and 2-trimethylsilyltetrazoles. It is surprising that the problem of regioselectivity has also not been discussed in the study of the phosphorylation[279] and sulfonation[280] of tetrazole. It is assumed that these reactions result in the formation of only 1-substituted tetrazoles.

6. Reactions of electrophiles with substituted tetrazoles

The reactions of 5-aryltetrazoles as well as 1-alkyl- and 2-alkyl-5-phenyltetrazoles with electrophiles of different nature have been investigated.[240,281–284] For example, it has been shown that, when 5-phenyltetrazole is treated with isobutyllithium in THF at −35 to −30 °C in the presence of tetramethylethylenediamine, the corresponding ionic intermediate is formed and reacts in situ with methyl iodide, acetaldehyde, or acrolein.[284]

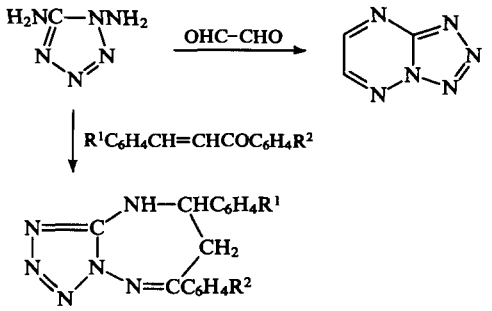
It is striking that electrophilic substitution takes place only in the benzene ring and does not involve the tetrazole ring.

It is interesting that, when 5-alkyl-*N*-methyltetrazoles react under similar conditions, electrophilic substitution takes place in both *N*-methyl and *C*-alkyl groups.[285]

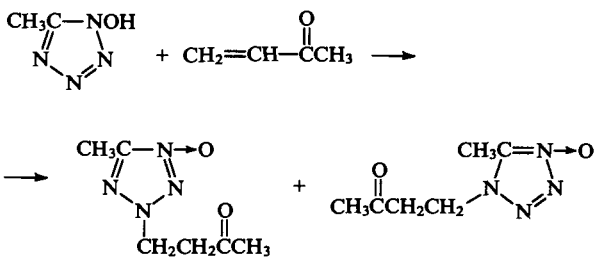


The nitration of 5-aminotetrazole and also of 1-alkyl- and 2-alkyl-5-aminotetrazoles by tetranitromethane in an alkaline medium leads to the corresponding 5-nitroaminotetrazoles.[286,287] Data exist on the nitration of condensed systems—5,6-dihydro-7*H*-imidazolo[1,2-*d*]tetrazole, 7,8-dihydrotetrazolo-[1,5-*b*]1,2,4-triazine, and 5,6,7,8-tetrahydrotetrazolo-[1,5-*b*]-1,2,4-triazine[288]—as well as certain tetrazolium salts.[289]

Treatment of 5-aminotetrazoles with orthoesters results in the formation of the corresponding iminoesters,[290] whilst heating with nitriles in the presence of organoboranes affords amidines.[291] On treatment with thionyl chloride, 1-alkyl-5-aminotetrazoles are unexpectedly converted into 1,2,4-thiadiazoles.[292]



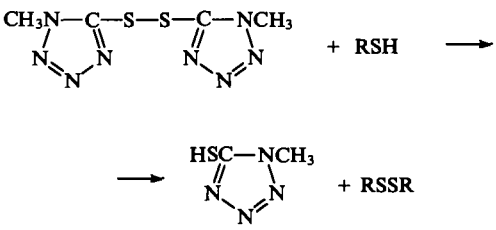
The acylation of 5-aminotetrazole at the amino-group by the chlorides of aromatic carboxylic acids[293,294] as well as the interaction of 5-aminotetrazole with *p*-cyanophenylcarbonylimidoyl chloride[295] have been described. In the latter case, the reaction also involves the exocyclic amino-group.



The salts of 2-alkyl-5-nitroaminotetrazole are alkylated by glycidol under mild conditions.[296] The tetrazole ring is not involved in this case.

1,5-Diaminotetrazole is an interesting reagent in the synthesis of heterocycles of various structures. Thus the interaction of 1,5-diaminotetrazole with glyoxal or unsaturated ketones leads to the formation of tetrazolo[1,5-*b*]-1,2,4-triazines and 5,7-disubstituted 5,6-dihydro-4*H*-tetrazolo[1,5-*b*]-1,2,4-triazepines respectively.[288,296]

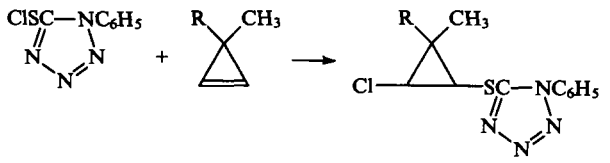
When 1-hydroxy-5-phenyltetrazole is treated with epoxyalkanes, the reaction involves both the hydroxy-group and the tetrazole ring.[297] On the other hand, the reaction of 1-hydroxy-5-methyltetrazole with methyl vinyl ketone affords the corresponding isomeric *N*-oxides.[298]



The tetrazole ring is not involved in the alkylation of bis(1-aryltetrazol-5-yl)methanes by methyl iodide,[299] in the arylation and alkylation of 1-phenyltetrazole-5-thiol by 1-chloro-2,4-dinitrobenzene[300] and *tert*-butyl isonitrile[301] respectively, and in the interaction of tetrazole-containing glyoximes with bromocyanogen.[302]

7. Reactions of nucleophiles with substituted tetrazoles

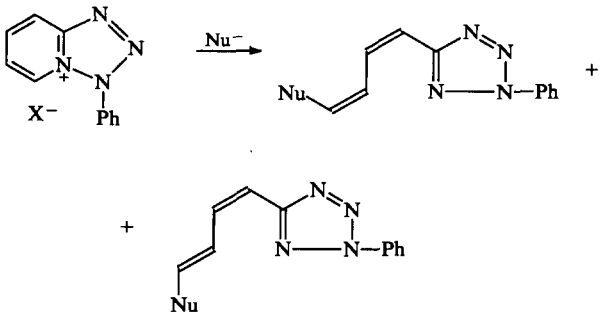
The interaction of tetrazole-5-diazonium chloride with substituted anilines affords a high yield of 3-aryl-1-(tetrazol-5-yl)triazepines.[302] Treatment of 1-alkyl- and 2-alkyl-5-chloroethyltetrazoles with an alcoholic solution of sodium hydroxide led to the formation of the corresponding 5-vinyltetrazoles.[303]



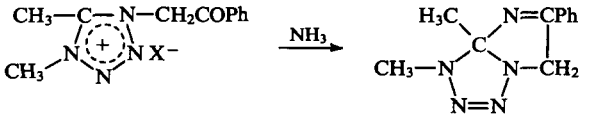
The reactions of 1-alkyl(aryl)tetrazole-5-thiols with nucleophiles (thiols, alcohols) have attracted continuous attention. This is because they can be used to synthesise substances with biological activity.[304] Thus it has been observed that bis(1-methyltetrazol-5-yl) disulfide exhibits an exceptionally high reactivity in relation to thiols.[305-307]

This reaction[306] is a convenient method of synthesis of both symmetrical and asymmetric disulfides.

S-Heteroaryl derivatives of 1-phenyltetrazole-5-thiols are also readily cleaved by potassium hydroxide in the water–acetonitrile system.[245]



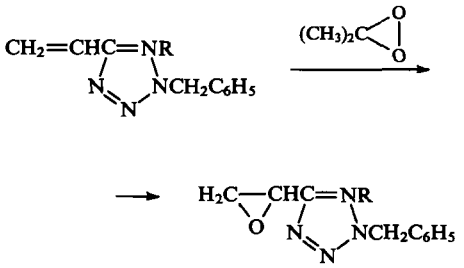
3,3-Disubstituted cyclopropenes interact with 1-phenyltetrazole-5-sulfenyl chloride in solution in methylene chloride at −20 °C.[308]



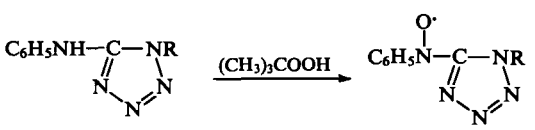
On treatment with unsaturated alcohols in the presence of tertiary amines, *S*,*S*′-bis(1-phenyltetrazol-5-yl) dithiocarbonate is hydrolysed under mild conditions.[309,310]

Grignard reagents may be used to obtain a series of tetrazole derivatives with functional group substituents.[311-313]

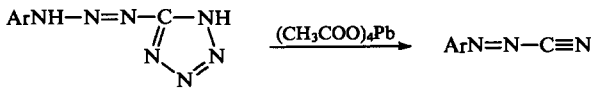
Finally, it is noteworthy that treatment of tetrazolylpyridinium salts with nucleophiles entails the dissociation of the N–C bond in the six-membered heterocycle.[314]



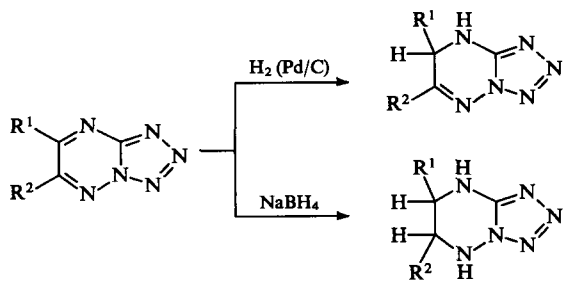
On the other hand, 2,3-dimethyl-4-benzoylmethyltetrazolium salts are converted into dihydro-3*H*-imidazo[1,2-*d*]-tetrazoles on treatment with ammonia.[315]



8. The effect of oxidants and reductants



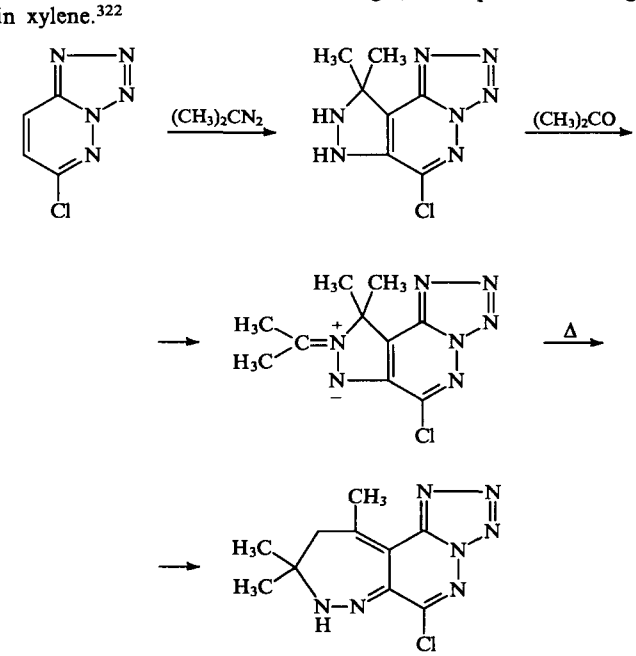
The tetrazole ring is resistant to the action of oxidants. The nature of the reactions between tetrazoles and oxidants depends on the nature and position of the substituent in the heterocycle. Thus interaction of 2-benzyl-5-vinyltetrazole with dimethyldioxirane results in the formation of the corresponding epoxide.[316]



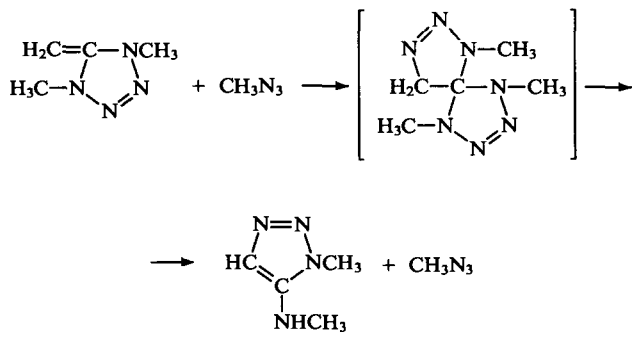
while the oxidation of 5-arylaminotetrazoles by *tert*-butyl peroxide afforded stable nitroxyl radicals.[317]

On the other hand, treatment of 1-aryl-3-(tetrazol-5-yl)triazenes with lead tetraacetate results in the degradation of the heterocycle.[318]

The ring is usually not involved in the reactions with reductants. It has been shown[288] that the reduction of tetrazolo-[1,5-*b*]-1,2,4-triazines by hydrogen (Pd/C) entails only partial hydrogenation of the six-membered ring, whereas in the reduction by sodium tetrahydroborate in methanol the corresponding 5,6,7,8-tetrahydrotetrazolo[1,5-*b*]-1,2,4-triazines are formed in a high yield.



Satisfactory results have been obtained in the catalytic (Pd) reduction of 5-(2-naphthoxy)-1-phenyltetrazole by tetrabutylammonium hypophosphite in the benzene–water two-phase system.[319]

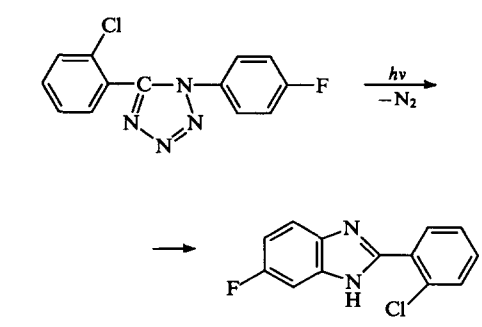


A small number of studies on the electrochemical reduction of tetrazoles have been published in recent years. It has been found that the electrochemical reduction of 1-vinyl- and 5-vinyltetrazoles in acetonitrile proceeds with the transfer of one electron.[320] The electrochemical reduction of 5-trichloromethyltetrazole leads to the formation of tetrazole and 5-chloromethyl- and 5-dichloromethyl-tetrazoles in 16%, 5%, and 28% yields respectively.[53]

9. Cycloaddition reaction

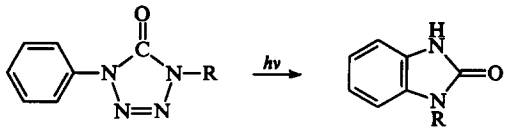
In connection with the active search for methods of synthesis of new heterocyclic systems, there has been an appreciable growth of interest in cycloaddition reactions with participation of tetrazoles as dipolarophiles.[321] It has been shown that the interaction of 6-chlorotetrazolo[1,5-*b*]pyridazine with diazoalkanes results in the formation of the corresponding cyclic adducts. The interaction of the latter with acetone leads to stable azomethine imines, which are converted into tetrazole-containing 1,2-diazepines on heating in xylene.[322]

On treatment with methyl azide, 4,5-dihydro-1,4-dimethyl-5-methylenetetrazole isomerises to 1-methyl-5-methylamino-1,2,3-triazole.[140] It is believed[140] that an unstable cyclic adduct is formed in the first stage of this reaction and then decomposes to the corresponding triazole and methyl azide.



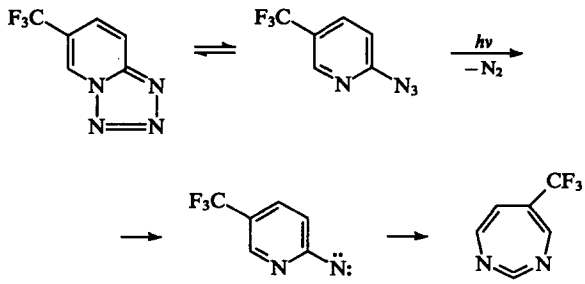
The formation of a stable cyclic adduct can be detected in the reaction of phenyl azide with 4,5-dihydro-1-methyl-5-(1-methylethylidene)-4-phenyltetrazole in cyclohexane.

10. Polymerisation of vinyltetrazoles

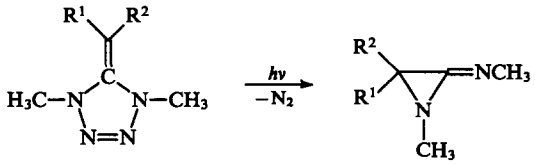


Vinyltetrazoles polymerise fairly readily in solution or in bulk in the presence of radical catalysts, for example azobisisobutyronitrile. Important data for the understanding of the mechanism of the polymerisation of vinyltetrazoles and for the prediction of the polymers formed have been obtained in a study of the polymerisation of 1-vinyl-, 5-methyl-1-vinyl-, and 2-methyl-5-vinyltetrazoles in aqueous solutions of sodium thiocyanate.[323] It was shown that the polymerisation of these compounds is in many respects similar to the polymerisation of acrylonitrile under similar conditions and is apparently of a complex-radical type. The use of sodium thiocyanate solutions as the reaction medium makes it possible to obtain tetrazole-containing polymers with a high molecular mass and the polymerisation process is much faster than in organic solvents. Together with the homopolymerisation, a study was made of the copolymerisation of 1-vinyl- and 2-methyl-5-vinyltetrazoles with acrylic and methacrylic acids, their derivatives, and styrene.[324–326] It was established that very long blocks of homopolymer units may be formed in the copolymer macrochain in the copolymerisation of 2-methyl-5-vinyltetrazole with acrylonitrile, which indicates a tendency by vinyltetrazole to undergo homopolymerisation. On the other hand, the probability of the formation of copolymer blocks is higher in the copolymerisation of 2-methyl-5-methylenetetrazole with methacrylic acid and its esters.

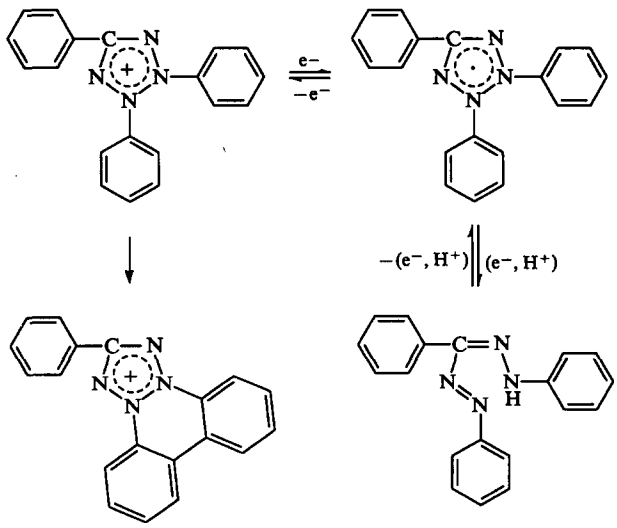
11. Photochemical reactions



The photolysis of tetrazoles entails their fragmentation with liberation of a nitrogen molecule and the formation of a new heterocyclic system. Thus satisfactory yields of the corresponding benzimidazoles can be obtained from 1,5-diaryltetrazoles.[327]



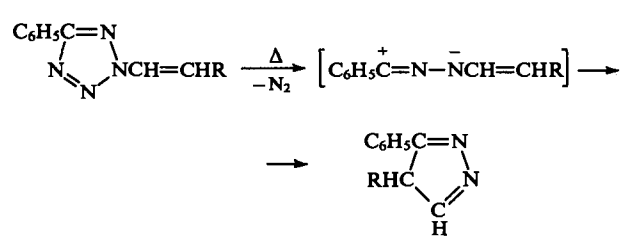
1,4-Disubstituted 4,5-dihydrotetrazol-5-ones undergo similar reactions.[328-330]



Interesting results have been obtained in a study of the photolysis of tetrazolopyridines containing the trifluoromethyl group in the six-membered ring.[331] This reaction can be regarded as a method of synthesis of 1,2-didehydro-1,3-diazepines, which are difficult to obtain.

The mechanism of the photolysis of 2,5-disubstituted tetrazoles has been investigated.[332] It has been shown that the corresponding nitrile imines are intermediates in these reactions. The formation of iminoaziridines has been detected in the photolysis of 5-alkylidene-4,5-dihydrotetrazoles.[333]

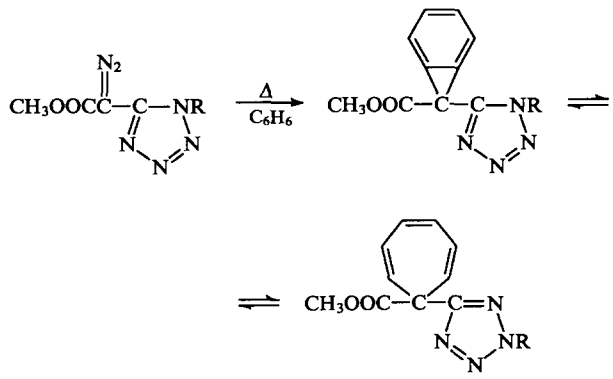
The mechanism of the photochemical reduction of 2,3,5-triphenyltetrazolium chloride has been investigated in aqueous solutions at pH 9–11.5 by the method of flash photolysis. A mechanism involving the formation of an intermediate tetrazolium radical has been proposed for this reaction.[334]



12. Metal complexes of tetrazoles

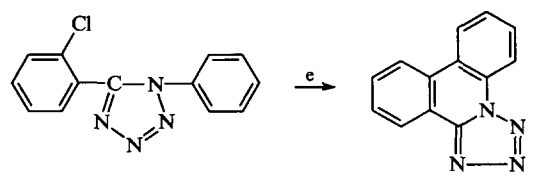
Systematic studies on the structures and properties of metal complexes of tetrazoles and also the capacity for complex formation of the corresponding heterocyclic ligands were not initiated until the beginning of the 1980s.[335-338] The unsubstituted tetrazole readily forms complexes with cobalt(II), nickel(II), copper(II), and cadmium(II) chlorides.[335] It has also been shown that 1- and 2-monoalkyltetrazoles interact with copper(II) chloride and thiocyanate, affording crystalline complexes. Regardless of the reactant ratio and the nature of the tetrazole ligand (T), complexes having the general formula CuT_2X_2 are formed.[339,340] Tetrazoles substituted in the 1- and 2-positions are monodentate ligands which are coordinated to the central copper atom via one of the nitrogen atoms. It is significant that 1-alkyltetrazoles show a greater tendency to form complexes than the 2-isomers.[336] The cobalt(II) and cobalt(III) complexes of 5-substituted tetrazoles have been investigated in detail.[341-343] It has been shown that the interaction of 5-aminotetrazole with pentamminecobalt nitrate results in the formation of the complex $[Co(NH_3)_5T](NO_3)_3$.[343] The indium(III) and iron(III) complexes PMT, where P is the octaethylporphyrin dianion and M the corresponding metal ion, have been obtained by the reaction of azidoporphyrins with nitriles.[344,345] Numerous complexes of 1,5-disubstituted tetrazoles with cobalt(II), nickel(II), copper(II), and iron(III) chlorides have been obtained. It has been shown that the crystalline complexes $CuTCl_2$ are formed in a high yield in the interaction of 1,5-disubstituted tetrazoles with $CuCl_2$ in organic solvents at 25–30 °C.[340] The molecules of the 1,5-disubstituted tetrazoles apparently serve as bridging ligands in such complexes. Each molecule of the tetrazole ligand is bound simultaneously to two neighbouring Cu^{2+} ions linked to one another by Cl^- bridging ions. Barium complexes of 1,5-disubstituted tetrazoles have been described.[346] 1,5-Disubstituted 4,5-dihydrotetrazoles proved to be effective siderophores.[347,348] When the methyl esters of 2-(1-R-4,5-dihydrotetrazol-5-yl-alphaidene)cyanoacetic esters are treated with iron(III) chloride ether, blue cryptocrystalline complexes FeT_3 are formed. Each of the three molecules of the tetrazole ligand in such complexes is coordinated to the central Fe^{3+} ion via a nitrogen atom of the heterocycle and the carbonyl oxygen atom. When iron(III) chloride is replaced by $FeSO_4$, the polymeric complex $(FeT_2)_n$ is produced.

The complexes of 2,5-disubstituted tetrazoles have been investigated to a much lesser extent. The complexes of 2-methyl-5-vinyltetrazoles with chromium(III), nickel(II), cobalt(II), and palladium(II) chlorides have been recently described. It has been shown that the metal ion in such complexes is coordinated to the N(4) atom of the tetrazole ligand.[349,350] The mercury(II) and palladium(II) complexes of tetrazolium salts have been described.[351,352]



13. Other reactions

In this section, it is necessary to mention primarily the conversion of 2-alkenyl-5-phenyltetrazoles into the corresponding 4-alkenyl-3-phenylpyrazoles.[282] The alkenyltetrazoles are fragmented on heating in 1,2-dichlorobenzene, the yield of pyrazoles being 79%–98%.



This reaction can be regarded as a method of synthesis for 3,4-disubstituted pyrazoles which are difficult to obtain.

The isomeric *N*-substituted 5-(methoxycarbonyldiazomethyl)tetrazoles undergo interesting reactions on heating.[353] The different influences of the isomeric tetrazolyl substituents on the functional groups in the side chain can be clearly traced in this example.

The electrochemical cyclisation of 5-(*o*-chlorophenyl)-1-phenyltetrazole to tetrazolo[1,5-*a*]phenanthridine has been investigated.[354]

Finally, it has been shown recently that trichloroacetonitrile adds smoothly to 1-methyl- and 2-methyl-5-vinyltetrazoles,[355,356] that 4,6-dinitrotetrazolo[1,5-*a*]pyridine forms stable adducts with alkoxide anions,[357] and that the acid hydrolysis of 5-diazomethylazotetrazole results in the formation of 5-hydrazinotetrazole.[358]

V. Applications of tetrazoles

There has been a steady growth of publications devoted to the applications of tetrazoles during the last decade. A systematic analysis of this problem, involving the examination of 700 patents published in 20 countries, has been carried out.[359] It follows from this analysis that the main applications of tetrazoles are in medicine, biochemistry, agriculture, analytical chemistry, information recording systems, and energy consuming processes as corrosion inhibitors and energy consuming materials. The most significant results have been obtained in the synthesis of tetrazole-containing β-lactam antibiotics of the cephalosporin series.[1,3,360,361] Such antibiotics exhibit a high antimicrobial activity, a prolonged action, and a low toxicity. Highly effective antiviral preparations have been found among tetrazoles.[362] 3-Tetrazole analogues of azidothymidine (AZT) have been obtained recently. It has been predicted that they should be active against the AIDS virus.[118] *C*-Glycosyltetrazoles—potential inhibitors of *E. coli* dehydrokinase-synthetase—have been described.[68] Preparations possessing antitubercular activity have been widely investigated.[4,6,8] Studies devoted to the creation of tetrazole-containing antihypertensive (losartan) and antiangina preparations, which belong to the new generation of regulators of cardiovascular activity, merit special attention.[7,11] Certain tetrazolium salts exhibit a high radioprotecting activity. The use of these compounds ensures the survival of up to 60% of animals irradiated with a lethal dose.[363]

Tetrazole is a condensing agent in the synthesis of oligonucleotides and also in systems for the automated synthesis of polynucleotides. In a number of instances, it is superior to other nitrogen-containing heterocycles used for these purposes.[16,17,364,365] Date have been published recently concerning the preparation of new generation herbicides on the basis of tetrazole-containing compounds.[20] Tetrazolium salts are widely used in analytical chemistry as extractants for the lanthanide metals[366] and in information recording systems, including their use as components of low-silver photographic materials.[21,25] 5-Mercapto-1-phenyltetrazole is a DIR component in modern photoprogramming systems and is one of the best antifogging agents.[22] Finally, highly effective corrosion inhibitors,[367] components of pyrotechnic and gas-generating compositions, and explosives[368,369] have been found among tetrazoles.

VI. Conclusion

Little more than a hundred years have elapsed since the discovery of tetrazoles. Interest in these compounds was aroused at the beginning of the 1950s when the principal methods of synthesis of tetrazoles were developed and studies on their physicochemical properties were initiated. Some diminution of interest in tetrazoles towards the end of the 1960s was rapidly replaced by its rearousal, and active studies on the chemistry of these compounds have been continued to the present.

Tetrazoles are exceptionally important in synthetic chemistry. They are used in the syntheses of many nitrogen-containing heterocycles—pyrazoles, imidazoles, 1,2,4-triazoles, 1,3,4-oxadiazoles, and what is especially important, the previously unavailable 3*H*-1,3,4-benzotriazepines.

Unfortunately no new advances have been made recently in the development of new general methods of synthesis of tetrazoles. This problem still awaits solution.

There have been considerable achievements in the practical application of tetrazoles, especially in medicine and biochemistry. An increase in the production of tetrazoles in industrially developed countries has been noted.

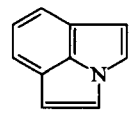
Abstract. The methods of synthesis of isomeric pyrroloindoles are surveyed. The characteristic features of electrophilic substitution reaction of the pyrroloindole ring and certain side chain reactions are discussed. The bibliography includes 60 references.

I. Introduction

Pyrroloindoles are striking representatives of indole-containing condensed systems. Chemically they are the closest analogues of indole. A wide variety of bifunctional analogues of biologically active indole derivatives have been obtained from pyrroloindoles.



Substances with bactericidal, antimicrobial, and antitumour activities as well as other properties of value for medicine and the national economy have been found among pyrroloindole derivatives.[1–3] The highly active antitumour antibiotic CC-1065, the principal structural fragment of which is the pyrroloindole system, was isolated in 1987 from *Streptomyces zebensis*. Its antitumour activity in vitro is many times greater than that of other known preparations.[4] This stimulated further development of synthetic methods for the preparation of pyrroloindoles. Research on these lines is being continued.

Pyrroloindole is a typical representative of heteroaromatic systems. Its molecule consists of three conjugated rings with 14π electrons which satisfy the aromaticity rule ($4n + 2$) in Dewar's treatment. Like indole itself, the pyrroloindoles **1–4** belong to systems with an excess of π electrons, since the total number of π electrons of the aromatic system exceeds the number of atoms in the ring.[35] In contrast to indole, there are two nitrogen atoms in the molecules of the pyrroloindoles **1–4** which contribute four π electrons to the aromatic system. Simple calculations have shown that the number of π electrons corresponding to each ring atom is 1.17 in the pyrroloindoles **1–4** and 1.11 in indole. Thus the excess of π electrons in pyrroloindoles is greater than in indole. Approximately the same relation between their reactivities with respect to weak electrophiles may be expected.

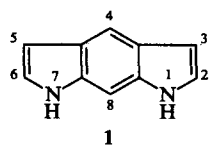
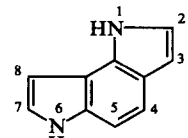
The pyrroloindoles described in the literature can be divided into three groups. Those in the molecules of which pyrrole is condensed with indole via the benzene ring (type I) or the carbon atoms in the pyrrole ring (type II) and also pyrroloindoles in the molecules of which there is one common nitrogen atom and all three rings are linked directly to one another (type III), for example as in the following formula:

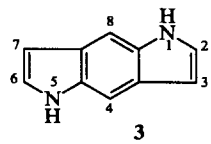


The properties of type I pyrroloindoles differ from those of type II and III compounds, which will not be considered in the present review.

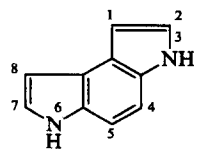


Type I pyrroloindoles are particularly interesting because they contain two reactive centres in the β-positions in the pyrrole rings. This makes it possible to obtain bifunctional analogues of the known physiologically active indole compounds.

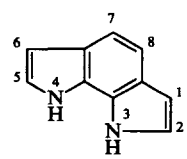
II. Methods of synthesis of pyrroloindoles



The following pyrroloindole systems are known at present:



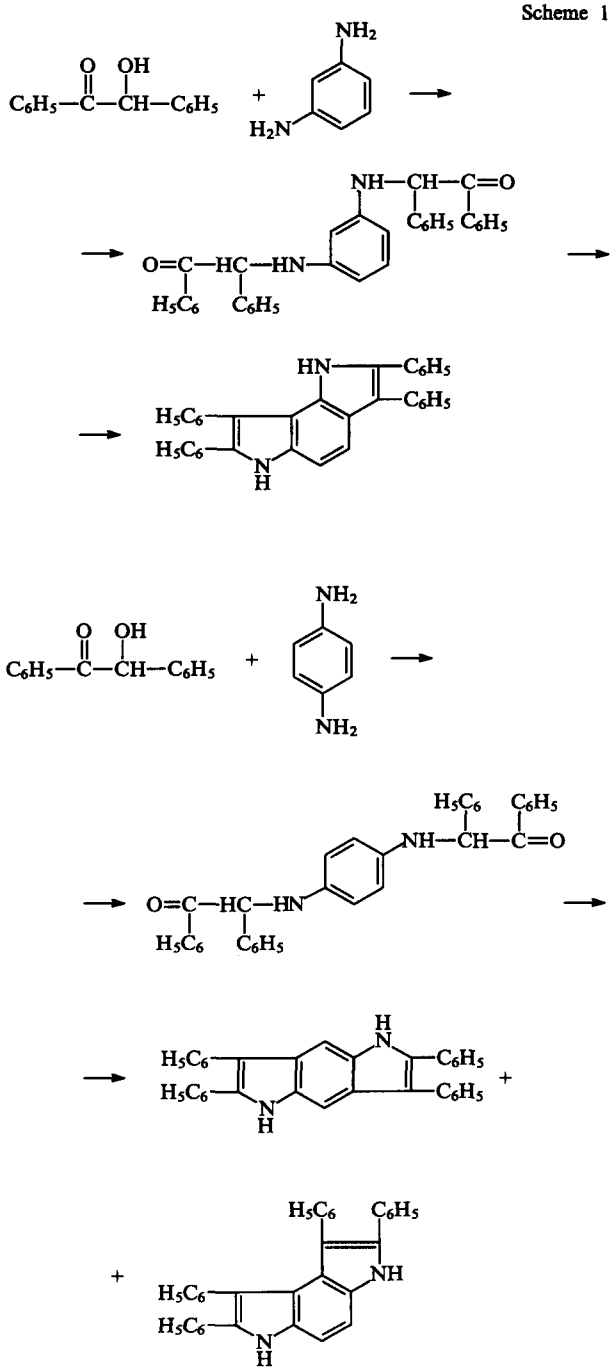
1



2

3

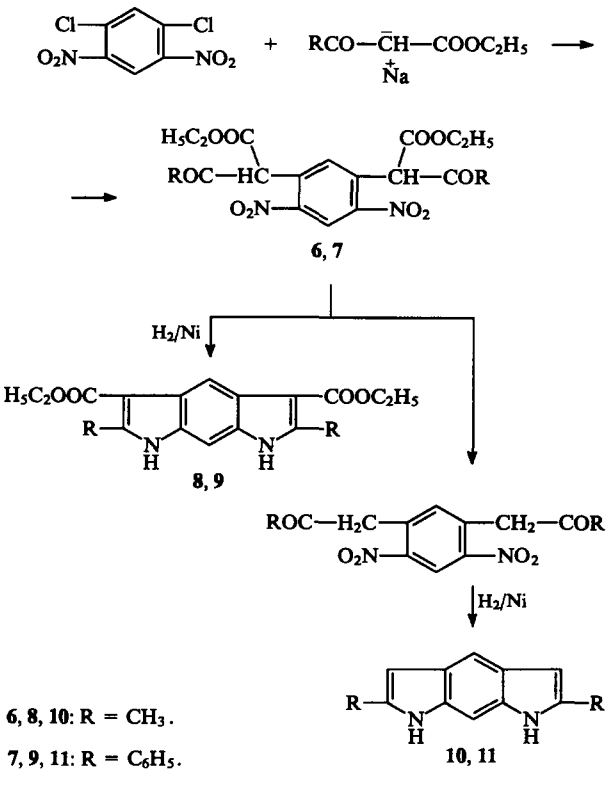
4



5

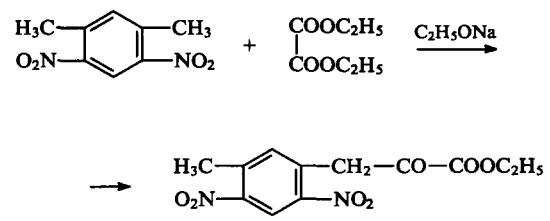
Pyrroloindoles may be synthesised in two ways: the first procedure involves simultaneous closure of both pyrrole rings, the second involves the attachment of a pyrrole ring to the benzene ring of indoline or indole.

The first pyrroloindoles were obtained as early as the past century. Thus Japp and Meldrum[5] synthesised tetraphenylpyrroloindoles from *m*- and *p*-phenylenediamines and benzoin by the Bischler reaction (the yields are not indicated) (Scheme 1).



Scheme 1

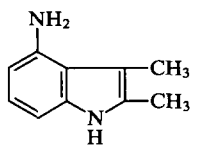
Another scheme for the synthesis of pyrroloindoles using the Bischler method involves the condensation of 4-, 5-, 6-, and 7-aminoindoles with benzoin and subsequent cyclisation. Various isomeric pyrroloindoles obtained in accordance with this scheme are listed in Table 1.

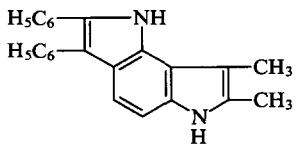


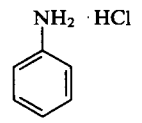
However, these reactions are only of historical significance: they are restricted because only aryl- or arylalkyl-substituted derivatives can be obtained and the yields of the cyclisation products are low.

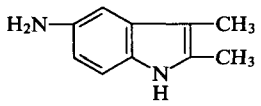
The German investigator Ruggli and his students[7,8] used a different method for the synthesis of pyrroloindoles, which is based on a modified Reissert reaction.

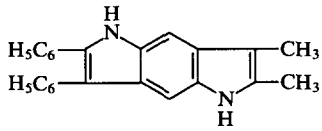
The condensation of 2,4-dichloro-1,5-dinitrobenzene with the enolates of certain ketoacid esters takes place stepwise; the substitution of the second chlorine atom is difficult. The reductive cyclisation of the diketones **6** and **7** in the presence of 'Ni Rupe' (a mixture of the crude catalyst with clay powder) under a hydrogen atmosphere leads to the pyrroloindoles **8** and **9**. Ketonic cleavage of compounds **6** and **7** and subsequent reduction afford the pyrroloindoles **10** and **11**. It is noteworthy that the target products were obtained in low yields owing to the considerable losses of these compounds during isolation and purification.

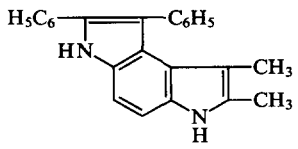


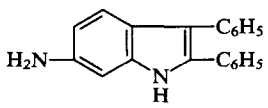


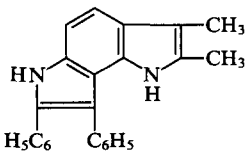


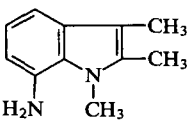


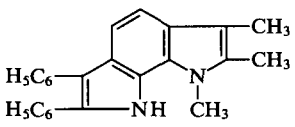


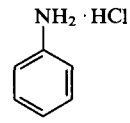




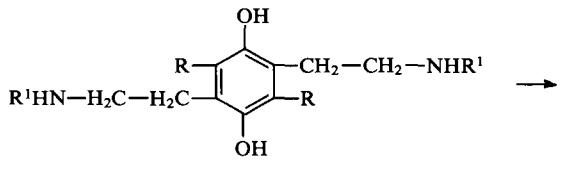








A disadvantage of the synthesis of pyrroloindoles by the Reissert reaction is also the fact that it cannot be used to obtain the unsubstituted pyrroloindole with a linear structure, since it has been established that in the condensation of diethyl oxalate with 4,6-dinitro-*m*-xylene only one methyl group reacts.



In 1973, Baird, Baxter, and coworkers[9] discovered a new method of synthesis of pyrroloindoles. It was found that the dihydrobromide of 2,5-bis(β-aminoethyl)hydroquinone **12a** is converted spontaneously into the dihydropyrroloindole **13a** in aqueous solution in air. The synthesis of compound **13a** was not the authors' aim, but they nevertheless investigated this process and put forward an hypothesis concerning the reaction mechanism. They also dehydrogenate compound **13a** to give the fully aromatised pyrroloindole **3**.

It was established subsequently[9] that the hydroquinones **12b** and **12c** undergo bicyclisation under similar conditions, forming respectively the dihydropyrroloindoles **13b** and **13c**. Compound **13c** was dehydrogenated to compound **14c**.

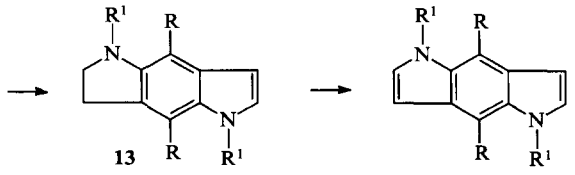


Table 1. Pyrroloindoles obtained from the products of the condensation of aminoindoles with benzoin.[6]

Initial aminoindole	Pyrroloindole	Cyclising agent	Yield (%)

R = R^1 = H (**a**);
R = Br, R^1 = H (**b**);
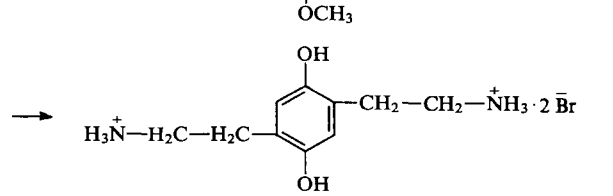
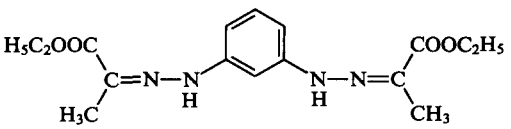
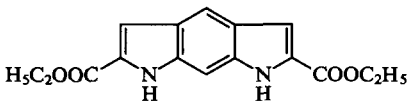
R = H; R^1 = CH_3 (**c**).

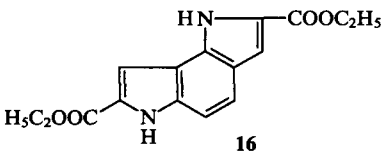


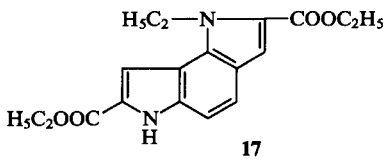
3: R = R^1 = H;

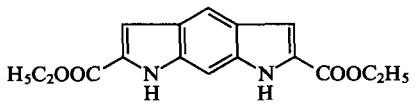
14c: R = H, R^1 = CH_3.

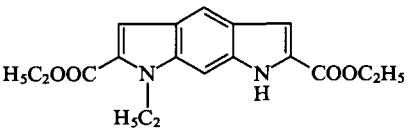


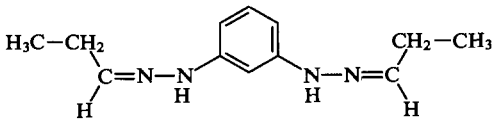


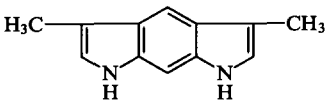


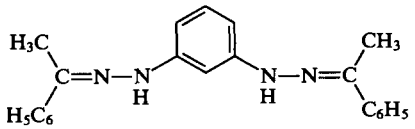


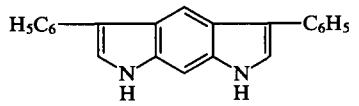


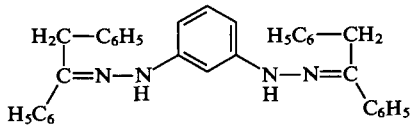


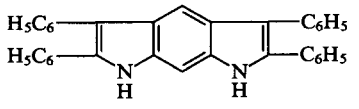


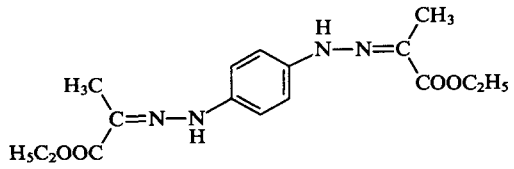


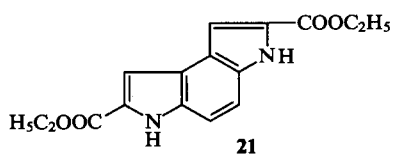












The initial hydroquinone **12a** was synthesised from 1,4-di(chloromethyl)-2,5-dimethoxybenzene.

Table 2. Pyrroloindoles obtained by cyclising certain *m*- and *p*-phenylhydrazones.

Hydrazone	Pyrroloindole	Cyclising agent	Yield (%)	Ref.
 **15**		12% H_2SO_4/C_2H_5OH	—	10
	 **16**	—	65	11–13
	 **17**	—	1	11–13
	 **18**	—	8	11–13
	 **19**	—	1	11–13
		5% H_2SO_4/C_2H_5OH	—	10
		12% H_2SO_4/C_2H_5OH	3	14
		H_2SO_4/ C_2H_5OH	50	14
 **20**	 **21**	EEPPA	6–9	15

Compound **12b** was obtained by brominating the hydroquinone **12a** and compound **12c** was synthesised by methylating it.[9]

However, in view of the low availability and instability of the initial compound and the large number of stages, this method cannot be regarded as preparative for the synthesis and further study of unsubstituted pyrroloindoles.[3]

The Fischer reaction has also been used in the synthesis of pyrroloindoles. The pyrroloindoles obtained by the cyclisation of certain *m*- and *p*-phenylenedihydrazones by the Fischer reaction are presented in Table 2.

It was found subsequently[11] that the first syntheses[10,14] suffered from significant disadvantages: the optimum reaction conditions were not selected (certain dihydrazones did not react even on prolonged refluxing, which indicated the low effectiveness of the catalyst employed); the cyclisation process was accompanied by appreciable charring and the reaction products were difficult to purify; the yield of the reaction products was very low. Furthermore, the cyclisation products were not characterised either by further reactions or by spectroscopic methods and a linear structure was attributed to them without proof. For example, when the cyclisation reaction of the dihydrazone **15** was reproduced under the conditions described by Giuliano and Leonardi[10] and the reaction product was investigated spectroscopically, it was found that it had an angular structure.[11]

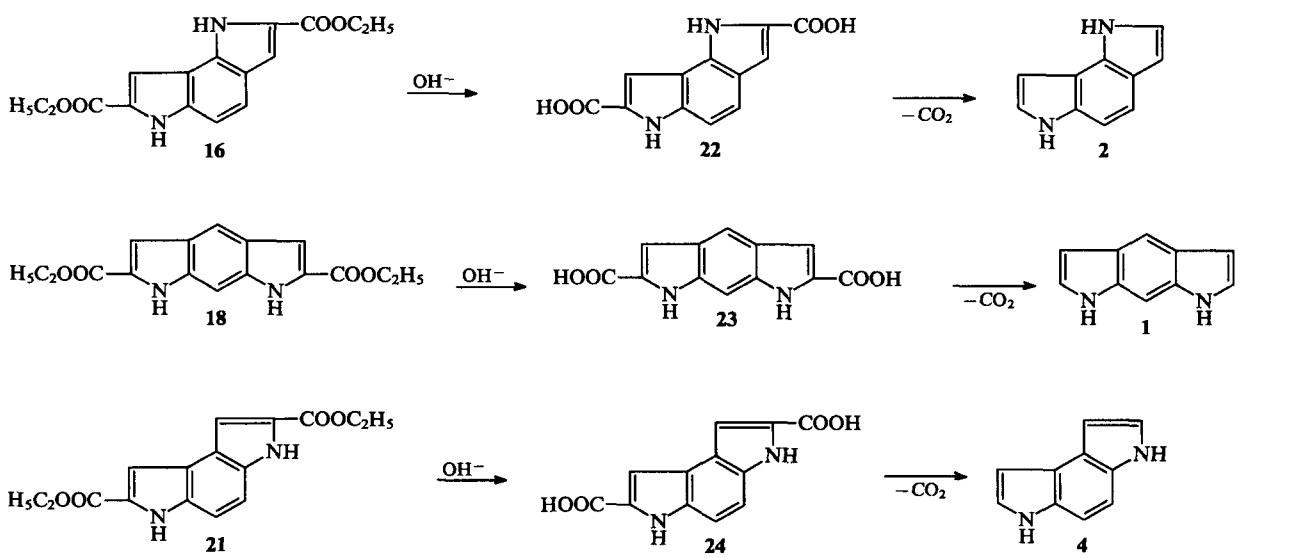
For these reasons, there was a need for a detailed investigation of the Fischer reaction of phenylenedihydrazones, since this reaction was and remains the most convenient method of synthesis of indole and its analogues.

Studies were carried out on the cyclisation of ethyl pyruvates and *p*-phenylenedihydrazones and the optimum reaction conditions were selected.[11-13,15]

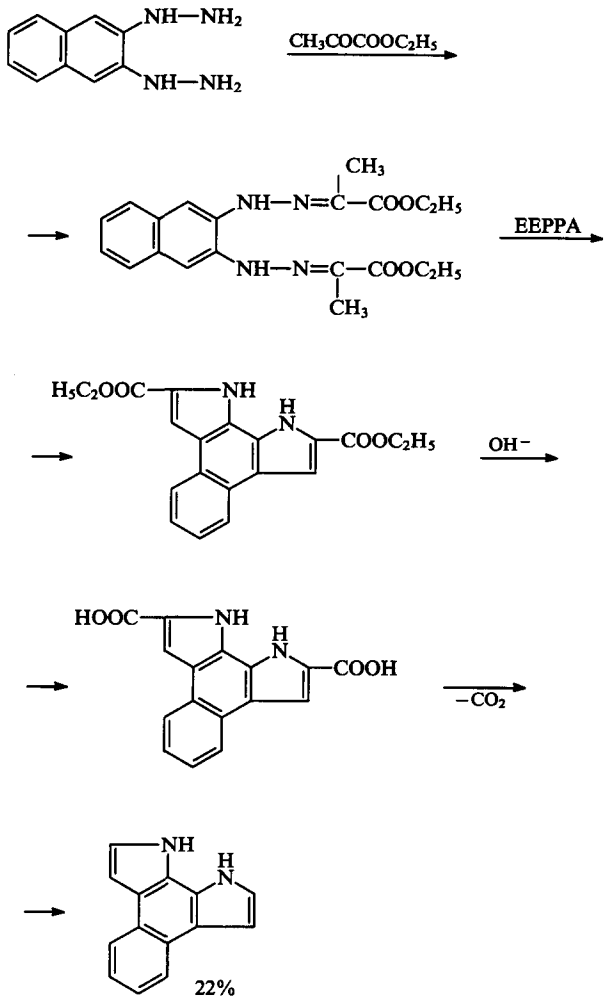
In the bicyclisation of *m*-phenylenedihydrazones, the formation of pyrroloindoles of two types, differing in the condensation of the rings, is theoretically possible. The cyclisation described above gives a mixture of the pyrroloindoles **16** and **18** having angular and linear structures, the angular isomer **16** predominating (yield 65%).[12,13] This can be explained by the fact that the angular structure is energetically more favourable than the linear structure in the formation of polynuclear condensed aromatic systems.[16] The *N*-ethyl derivatives **17** and **19** were also isolated from the cyclisation products in yields less than 1%.[13]

The conversion of various stereoisomers of the *m*-phenylenedihydrazone of ethyl pyruvate into indole derivatives takes place in virtually identical yields.

It is noteworthy that the development of convenient methods of synthesis of 2,7-diethoxycarbonyl-1*H*,6*H*-pyrrolo[2,3-*e*]indole **16** in high yields is a very important task, since this compound opens the way to the subsequent synthesis of the unsubstituted heterocycle.



The ethyl ester of polyphosphoric acid (EEPPA) proved to be the most effective cyclising agent for the conversion of the *p*-phenylenehydrazone of ethyl pyruvate **20** into an indole derivative. However, in this case the yield of 2,7-diethoxycarbonyl-3*H*,6*H*-pyrrolo[3,2-*e*]indole **21** was only 6%–9%. In the remaining cases, charring of the reaction mass was observed.[15] The low yield of products in the cyclisation reaction can probably be explained by the fact that a crude dihydrazone **20** was employed, its purification involving considerable difficulties.[15]

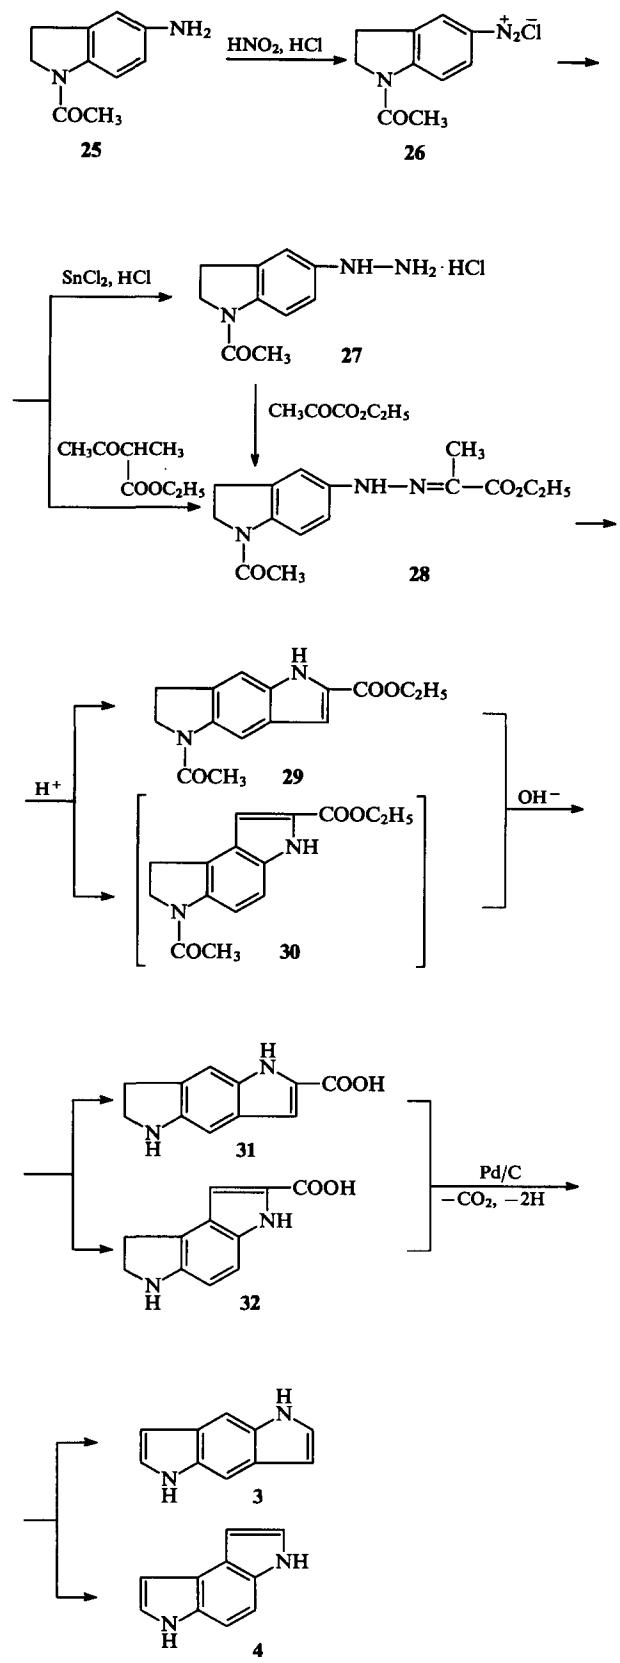


The hydrolysis of the diesters **16**, **18**, and **21** afforded high yields of the corresponding dicarboxylic acids **22**–**24** (Scheme 2).[11,12,15]

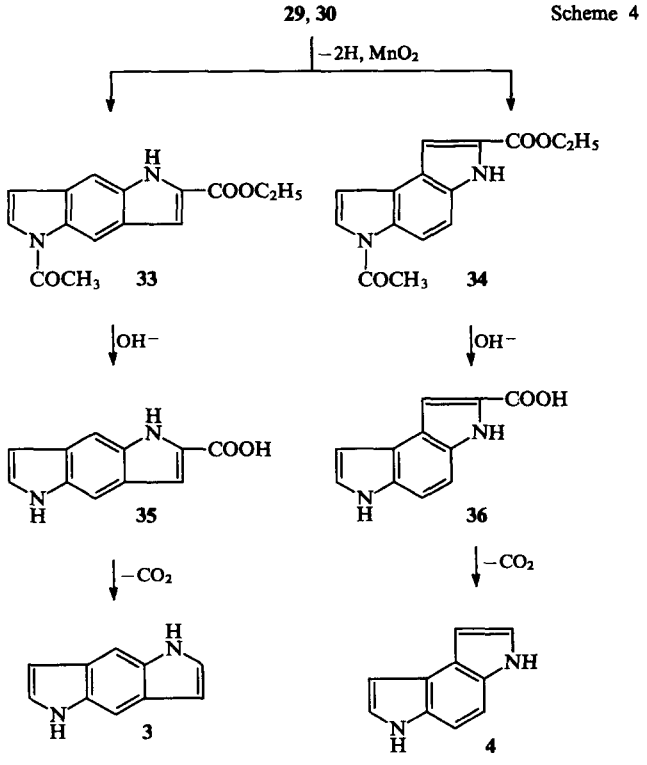
However, the methods for the bisdecarboxylation of dicarboxylic acids described in the literature (heating in quinoline or in dimethylacetamide in the presence of powdered copper[17] or copper salts[18]) proved unsuitable. The desired results were achieved only on thermal decarboxylation of the dicarboxylic acids **22**–**24** in a stream of an inert gas. The unsubstituted pyrroloindoles **1**, **2**, and **4** corresponding to compounds **22**–**24** were then obtained in 20%, 30%, and 25% yields respectively.[11,12,15]

The cyclisation of 2,3-naphthylenedihydrazone to 2,9-diethoxycarbonyl-1*H*,10*H*-benzo[*e*]pyrrolo[3,2-*g*]indole was achieved in 1984. Hydrolysis and subsequent decarboxylation of the dicarboxylic acid afforded the unsubstituted 1*H*,10*H*-benzo[*e*]-pyrrolo[3,2-*g*]indole.[19] The yields of the products were high in all the stages of the synthesis except the last.

Scheme 2

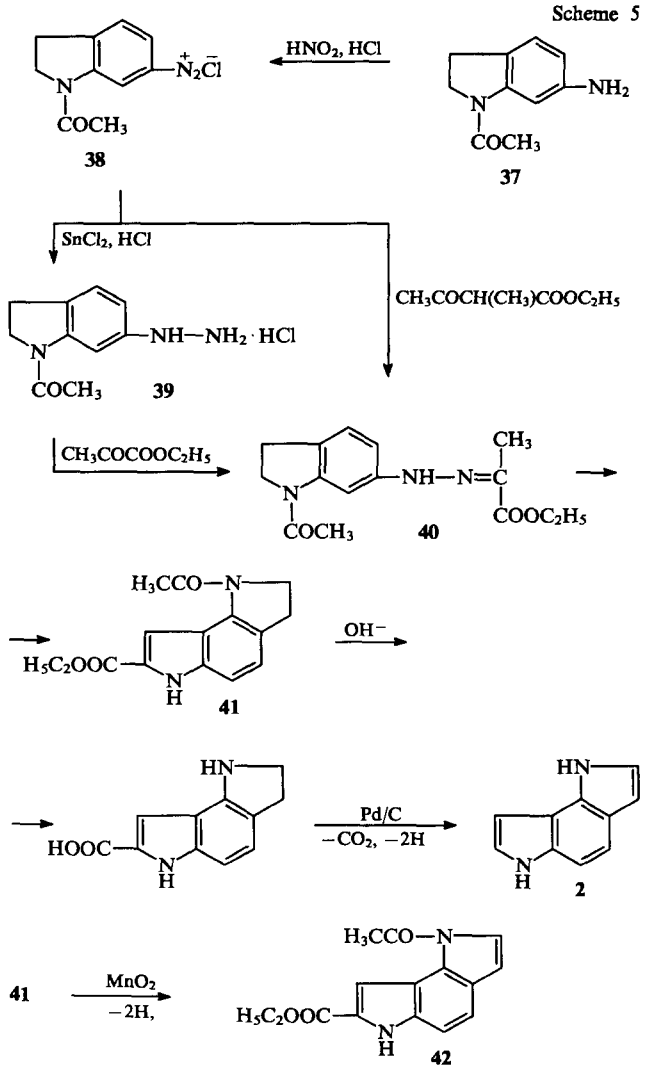


Thus it is seen that the unsubstituted pyrroloindoles **1**–**4** may be obtained with the aid of the Fischer reaction and the reaction of Baird and Baxter. However, these methods enable only 1*H*,6*H*-pyrrolo-[2,3-*e*]indole **2** to be synthesised in an amount sufficient for further study. The remaining three heterocycles **1**, **3**, and **4** are obtained in very low overall yields. Furthermore, the synthesis of the pyrroloindole **3** is complicated by the low availability and instability of the initial compound.



Continuing the search for convenient methods of synthesis of pyrroloindoles, Samsoniya, Suvorov, Kadzhrishvili, and coworkers[20] used a new procedure for the construction of the pyrroloindole system — the addition of the pyrrole ring to the benzene ring of the indoline system. The initial compounds chosen were 5- and 6-aminoindolines. The first of these was synthesised from indoline by the method of Terent'ev and Preobrazhenskaya[21] in acetic anhydride using nitric acid as the nitrating agent (yield 70%), while the second was obtained by nitration with a mixture of nitric and sulfuric acids (quantitative yield). The nitroindolines were acetylated with acetic anhydride and were reduced with hydrazine hydrate in the presence of Raney nickel (yield 95%) by the general method recommended for aromatic nitro-compounds.

The syntheses of 1*H*,5*H*-pyrrolo[2,3-*e*]indole **3**, 3*H*,6*H*-pyrrolo[2,3-*e*]indole **4**, and 1*H*,6*H*-pyrrolo[2,3-*e*]indole **2** are presented in Schemes 3–5.[20]



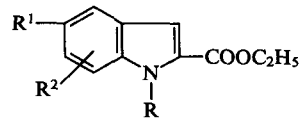
Scheme 3

Scheme 4

Scheme 5

Different compounds were tried as cyclising agents in the conversion of the hydrazones **28** (Scheme 3) and **40** (Scheme 5) into indole derivatives. The best results were obtained when EEPPA was used.

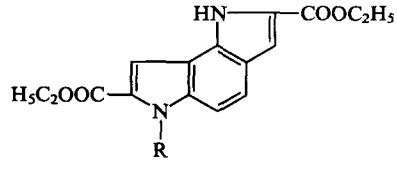
The cyclisation of the hydrazone **28** results in the formation of a mixture of pyrroloindolines having linear (compound **29**) and angular (compound **30**) structures (yield 74%). The main reaction product is the linear isomer. The attempts to separate the mixture of the isomers **29** and **30** were unsuccessful, but compound **29** can be isolated and characterised by means of column chromatography.



Hydrolysis of the mixture of esters **29** and **30** with aqueous alkali is very rapid and leads to a mixture of the acids **31** and **32** in 93% yield. The decarboxylation and simultaneous dehydrogenation of the acids in the presence of 10% Pd/C afforded a mixture of the isomeric pyrroloindoles **3** and **4** (yield 20%). The latter were separated by column chromatography.

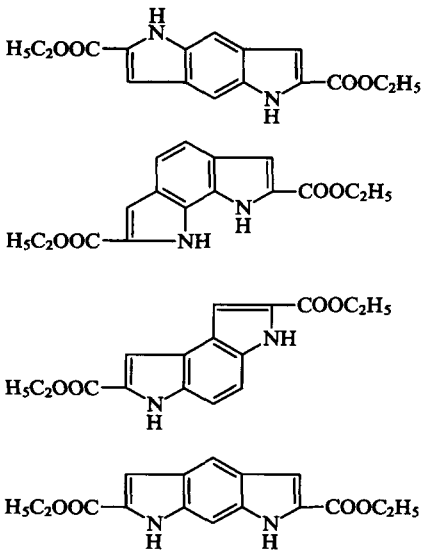
The dehydrogenation of a mixture of the isomeric esters **29** and **30** by manganese dioxide in boiling xylene was also achieved (Scheme 4); compounds **33** and **34** were obtained in 75% yield. Separation of this mixture by column chromatography affords the angular ester **34** and the linear ester **33** in proportions of 1 : 6.

Hydrolysis of the esters **33** and **34** with aqueous alkali leads to high yields of the corresponding acids **35** and **36**, the thermal decarboxylation of which afforded the unsubstituted pyrroloindoles **3** and **4** in 20% and 26% yields respectively.[20]



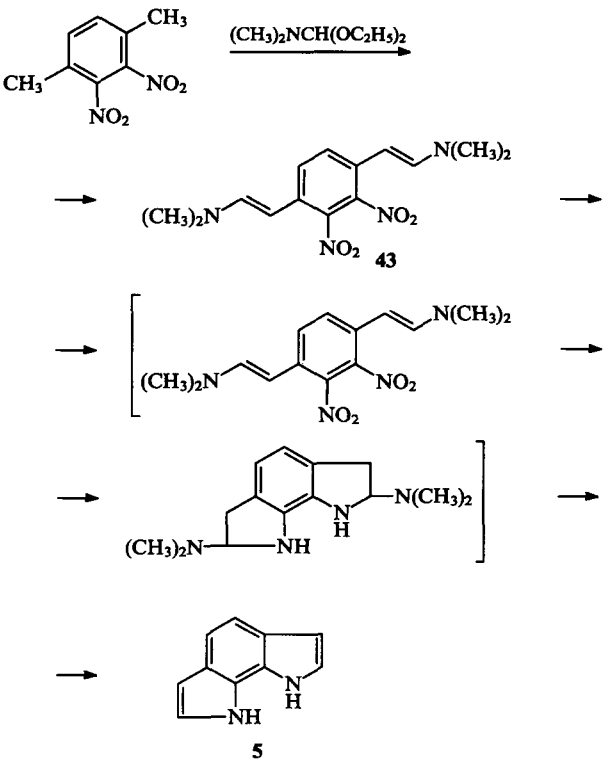
The unsubstituted pyrroloindole **2** was obtained similarly from the hydrazone **40** (Scheme 5) after the corresponding transformations. The dehydrogenation of the ester **41** gives the pyrroloindole **42**. The yields of the products of these reactions are approximately the same as in the previous syntheses.

Later (in 1983) Katti and Siddappa[22] achieved the synthesis of various pyrroloindole systems from *o*-, *m*-, and *p*-nitroanilines by the stepwise closure of one and then the other pyrrole rings using the familiar Fischer scheme. The 4-, 5-, 6-, and 7-nitroindoles obtained in this way are reduced with Raney nickel, diazotised under mild conditions, and coupled with methylacetoacetic ester. The diesters of the isomeric pyrroloindoles are obtained by cyclising the corresponding hydrazones. The overall yields of the pyrroloindoles are low. The subsequent reactions of the heterocycles were not described by the authors.



R = H, CH_3; R^1 = H, CH_3;

R^2 = NO_2, NH_2, —NH—N=C(CH3)COOC2H5.

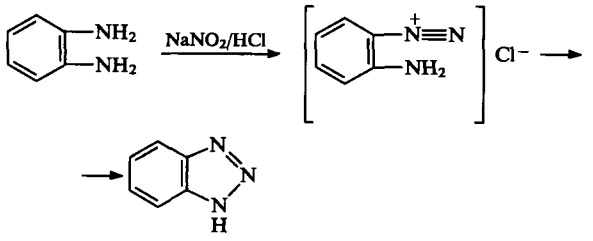


R = H, CH_3.

(continued over)

A convenient method of synthesis of certain pyrroloindoles has been proposed by Berlin et al.[23]

The synthesis was carried out by the Leimgruber – Batcho reaction and involved the following processes: the condensation of dinitro-*p*-xylene with the diethyl acetal of dimethylformamide and subsequent reductive cyclisation of the dinitroenamine **43**, obtained in the condensation reaction (yield 75%), to the unsubstituted pyrroloindole **5** (yield 70%).



The linear pyrroloindole **1** was obtained similarly from 4,6-dinitro-*m*-xylene (yield 55%), while the isomer **3** was synthesised from 2,5-dinitro-*p*-xylene (yield 39%).

Only pyrroloindoles unsubstituted in the pyrrole rings can be obtained by this method, which limits its applications.

1. Synthesis of the initial hydrazones

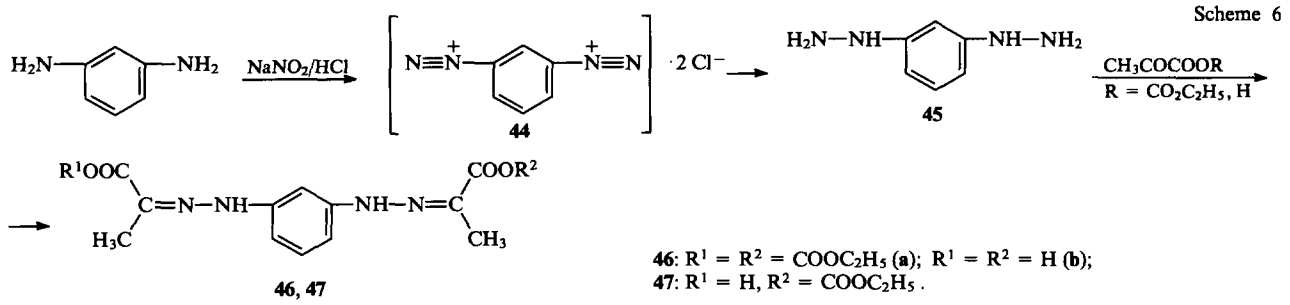
The initial compounds for the Fischer reaction (arylhydrazones) are obtained by condensing arylhydrazines with the corresponding carbonyl compounds; the Japp – Klingemann reaction is sometimes used for this purpose. In both cases, it is necessary to have sufficiently pure aryldiazo-compounds.

The synthesis of benzene-1,2-bisdiazonium salts by the usual diazotisation of phenylenediamines is known to involve appreciable complications. Thus the diazotisation of *o*-phenylenediamine results in the initial formation of the *o*-aminobenzenediazonium salt, which is converted into a cyclic azimine (benzotriazole).

The diazotisation of *p*-phenylenediamine is accompanied by appreciable oxidation to quinone or quinone imine, while *m*-phenylenediamine readily couples during the diazotisation process with the mono- and bis-diazonium ions formed, affording the corresponding azo-dyes.[24-26]

Special diazotisation methods are used in the synthesis of the benzene-1,2-diazonium salt. Thus comparatively pure benzene-1,2-diazonium and benzene-1,4-diazonium chlorides are synthesised by diazotising the corresponding diamines with nitrosylsulfuric acid in the presence of concentrated phosphoric acid.[26,27] Since the synthesis of pure benzene-1,4-diazonium involves considerable difficulties, a two-stage process is employed as a rule in the synthesis of dyes — diazotisation and coupling of the amino-groups of *p*-phenylenediamine.[24]

In the diazotisation of *m*-phenylenediamine, the excess HCl and the brief contact between the reactants suppress the coupling reaction indicated above. The yield of benzene-1,3-diazonium chloride then increases.[24,28] The same result was achieved by introducing polyhydric alcohols or carbohydrates into the reaction.[29]



Thus only the *meta*-isomer is obtained in a high yield from all the isomeric benzenebisdiazonium chlorides, which makes it convenient to use it in the synthesis of phenylenedihydrazones.

The reduction of benzene-1,3-bisdiazonium **44** with tin dichloride in an excess of HCl leads to the corresponding dihydrazine **45**. However, the product is highly contaminated by tin salts, which creates difficulties for subsequent reactions. The purification of dihydrazine **45** is also difficult. It is carried out by passing gaseous H_2S through an aqueous solution of the compound.[10] However, the present authors were able to solve this problem by simple recrystallisation of compound **45** from water.[11] The *m*-phenylenedihydrazine purified in this way is entirely suitable for further reactions (Scheme 6).

The condensation of *m*-phenylenedihydrazine **45** with ethyl pyruvate in a weakly acid medium leads to a high yield of the *m*-phenylenedihydrazone of ethyl pyruvate **46a**. The mixed hydrazone **47**, containing both ester and acid groups, is formed as a side product of this reaction. It is apparently obtained as a result of the hydrolysis of the ethoxycarbonyl group of the initial ethyl pyruvate or of the dihydrazone **46b** formed.

p-Phenylenedihydrazine, which is suitable for the synthesis of *p*-phenylenedihydrazone, cannot be obtained in a pure form. It contains an appreciable amount of *p*-phenylenediamine.[15] Owing to the difficulty of separating this mixture and also the instability of *p*-phenylenedihydrazine, the latter could not be identified either in the form of a base or in the form of the dihydrochloride.

Scheme 6

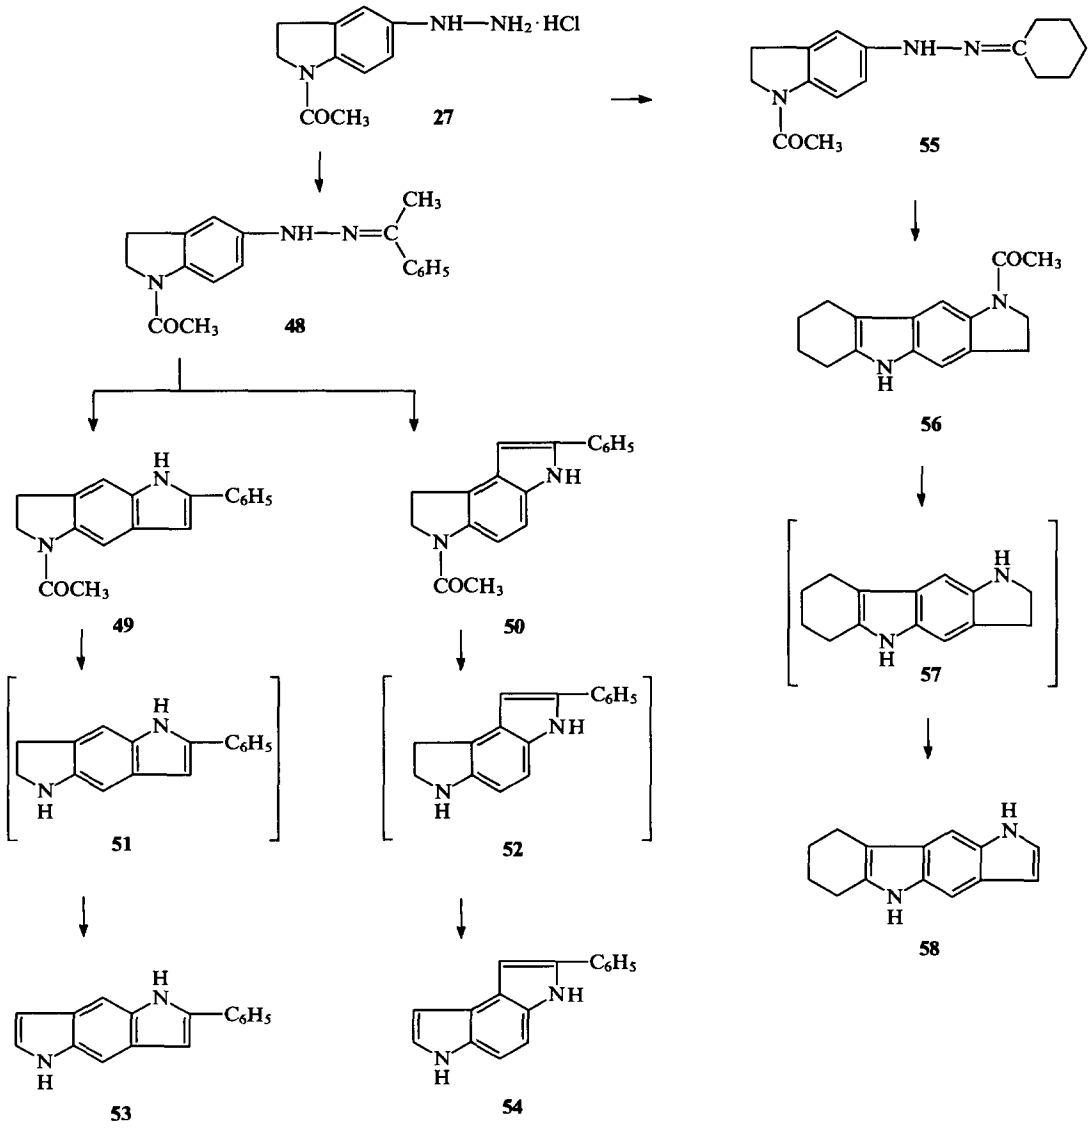
46, 47

46: $R^1 = R^2 = COOC_2H_5$ (a); $R^1 = R^2 = H$ (b);
47: $R^1 = H$, $R^2 = COOC_2H_5$.

The m-phenylenedihydrazone of ethyl pyruvate is formed as a mixture of geometrical isomers having the *syn,syn-*, *syn,anti-*, and *anti,anti*-configurations. These isomers were separated by column chromatography and their structures were established from spectroscopic data. [11]

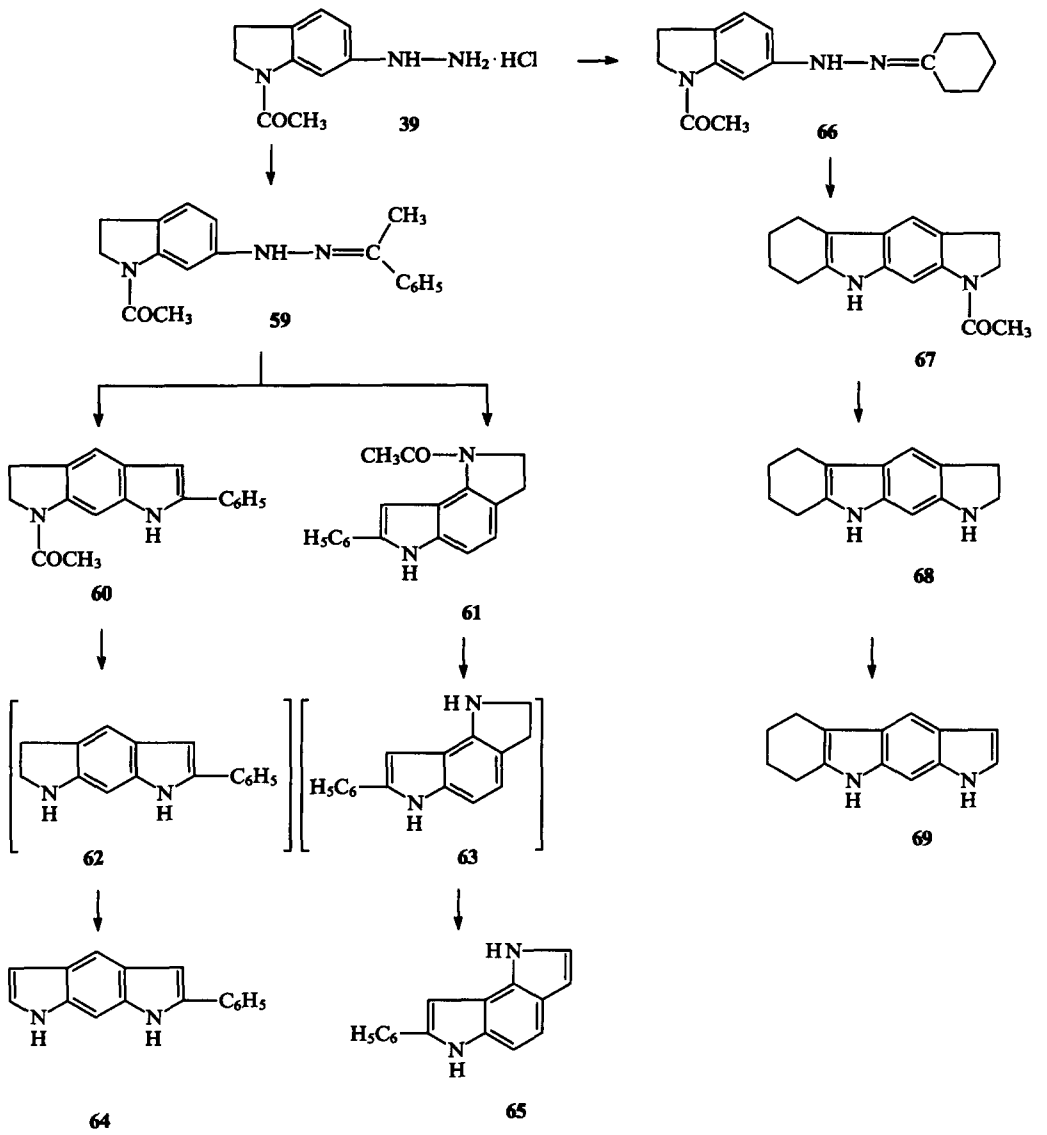
The usual diazotisation of 1-acetyl-5-aminoindoline **25** and 1-acetyl-6-aminoindoline **37** and the subsequent reduction of the diazonium salts **26** and **38** by tin(II) chloride lead to the hydrochlorides of 1-acetyl-5-hydrazinoindoline **27** and 1-acetyl-6-hydrazinoindoline **39**. The hydrazones **28** and **40** have been obtained in high yields by condensing the hydrazines **27** and **39** with ethyl pyruvate. [20]

The coupling of the diazonium salts **26** and **38** with methylacetoacetic ester via the Japp–Klingemann reaction also affords the hydrazones **28** and **40**.



2. Synthesis of substituted pyrroloindoles from acetophenone and cyclohexanone

Apart from the cyclisation of the hydrazones of ethyl pyruvate, the conversion of the hydrazones of acetophenone and cyclohexanone into indole derivatives (Schemes 7 and 8) has been used to obtain pyrroloindole structures. [30]



Condensation of compounds **27** and **39** with acetophenone and cyclohexanone yielded the corresponding hydrazones **48**, **55**, **59**, and **66**.

When the hydrazones were converted into indole derivatives, the best results were achieved using EEPPA as the cyclising agent.

Scheme 7

Scheme 8

It was established from spectroscopic data on the cyclisation products that conversion of the acetophenone hydrazones **48** and **59** into indole derivatives gives a mixture of the linear pyrroloindolines **49** and **50** and the angular pyrroloindolines **60** and **61**, while the conversion of the cyclohexanone hydrazones **55** and **66** into indole derivatives afforded only the linear isomers (compounds **56** and **67**). This has been explained by steric factors.[30] Hydrolysis of the pyrroloindolines **49**, **50**, **55**, **60**, **61**, and **66** leads to compounds **51**, **52**, **57**, **62**, **63**, and **68** and their subsequent dehydrogenation gives rise to the pyrroloindoles **53**, **54**, **58**, **64**, **65**, and **69** respectively.

III. Electrophilic substitution reactions of pyrroloindoles

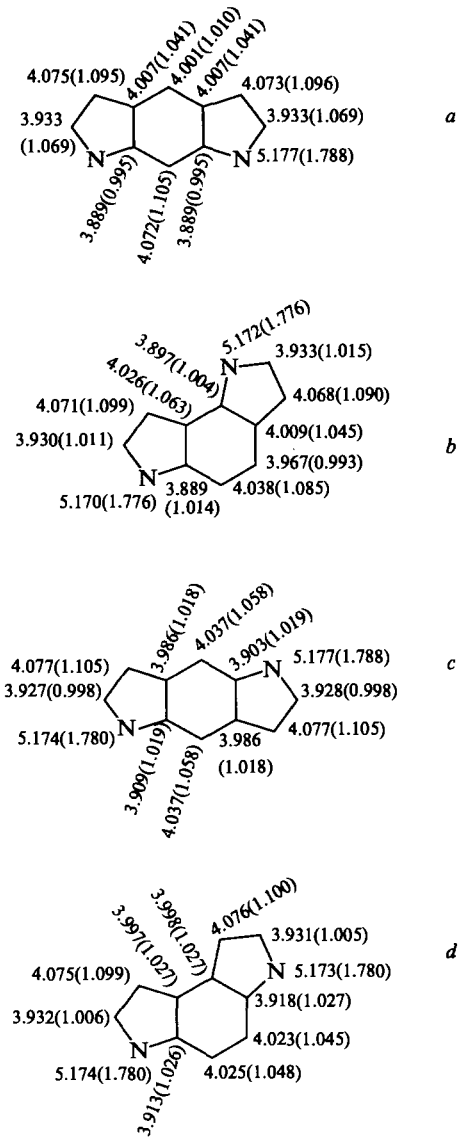
The preparative methods described above have enabled the pyrroloindoles **1**–**4** to be obtained in amounts sufficient for various electrophilic substitution reactions to be studied in this series of compounds. The classical electrophilic substitution reactions characteristic of indoles were investigated: the Mannich, Vilsmeier, azo-coupling, and acetylation reactions.[13,31–34]

The effect of different types of condensation of the pyrrole and indole rings on the specific features of electrophilic substitution was of definite interest. Furthermore, the study of the above reactions was also of practical importance, since some of the pyrroloindole derivatives themselves possess physiological activity or can be used in the syntheses of other physiologically active substances.

The distribution of electron densities in the substrate is known to determine the mode of attack by electrophiles in electrophilic substitution reactions, although the site of preferential substitution depends greatly also on other factors promoting the stabilisation of the corresponding transition state.

In order to predict the most preferable directions of electrophilic attack in pyrroloindole molecules, quantum-chemical calculations were performed for compounds **1**–**4** in accordance with Maslov's program[36] on a BESM-6 computer by the SCF-MO method in the CNDO/2 approximation (Fig. 1).[37]

It is seen from the molecular diagrams that the highest overall ($\sigma + \pi$)- and π-electron densities are observed for atoms in the β-positions in the pyrrole rings. It was postulated that initial attack by electrophiles should take place at these sites. In the molecules of the pyrroloindoles **1**–**4**, there are also other reaction centres having fairly high electron densities. Nor can one rule out also the influence of other factors, especially steric factors, on the site of the initial electrophilic attack in these electrophilic molecules.



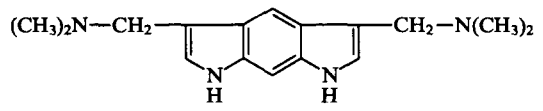


Figure 1. Molecular diagrams for the pyrroloindoles **1**–**4** (*a*–*d*); the overall ($\sigma + \pi$) charges are presented; the (σ^{**}-π)-electron densities are indicated in brackets.

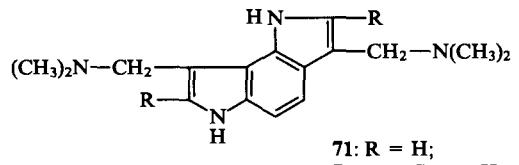
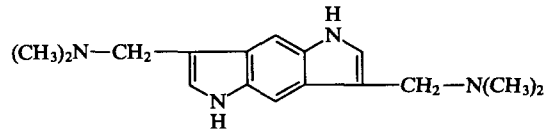
1. The Mannich reaction

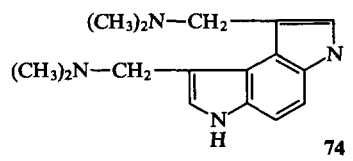


The great importance of the Mannich reaction for compounds of the indole series arises from the possibility of using the products of this reaction in the synthesis of a wide variety of biologically important compounds (tryptophan, heteroauxin, the series of tryptamines, etc.).

Among the indole Mannich bases, the alkaloid gramine (3-dimethylaminomethylindole) and its substituted derivatives have found the most extensive applications. The study of the Mannich reaction for the pyrroloindoles **1**–**4** is therefore of interest both from the standpoint of the possibility of obtaining bifunctional gramine analogues and for the investigation of their biological activity.



The aminomethylation of the unsubstituted pyrroloindoles **1**–**4** by freshly prepared Mannich bases (dimethylamine, formaldehyde, acetic acid) affords, apart from the bisgramine analogues **70**, **71**, **73**, and **74**, also compounds which are insoluble in the majority of organic solvents, which greatly reduces the yield of the target product.[31–33]



70

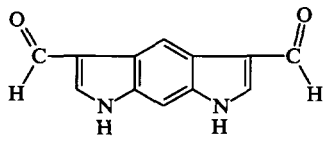
71: R = H;
72: R = $COOC_2H_5$.

73

74

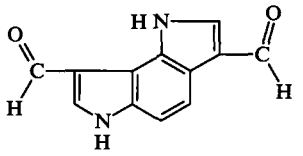
The formation of side products can probably be accounted for by the interaction of the heterocycles with formaldehyde, similarly to the situation which obtains in the condensation of indole and its derivatives with formaldehyde in an acid medium with formation of bis(3-indolyl)methanes.[38,39]

This undesirable process is hindered in the case of 2,7-di-(ethoxycarbonyl)-1*H*,6*H*-pyrrolo[2,3-*e*]indole, apparently owing to the presence of the electron-accepting α-ethoxycarbonyl groups and their steric influence. The bisgramine **72** is formed in a high yield.



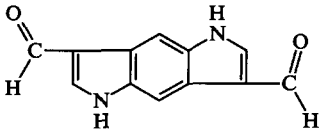
In the syntheses of the unsubstituted bisgramines **70**, **71**, **73**, and **74**, the desired result was achieved using as the electrophile *N*,*N*-dimethylmethyleneammonium chloride [$CH_2=N^+(CH_3)_2 . Cl^-$], synthesised from $[(CH_3)_2N]_2CH_2$ and CH_3COCl.[40] Best results were obtained when acetonitrile was used as the solvent. In this case, side products are not formed and the bisgramines **70**, **71**, **73**, and **74** were isolated in high yields.[31–33]

In order to investigate their physiological activity, the bifunctional gramine analogues synthesised were converted into the corresponding dihydrochlorides.[1]

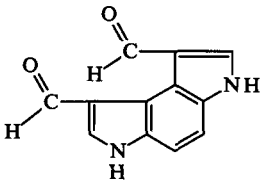


The blocking effect of the bisgramines on neuromuscular transmission was investigated by quaternising the tertiary nitrogen atoms in their molecules, which was achieved by converting them into the corresponding dimethosulfates.[1,2] The synthesis of the dimethosulfates is accompanied by formation of polyadducts as a result of interaction of the quaternary salts with the gramines. In order to suppress side reactions, the process is carried out in an acid medium. In the synthesis of the dimetho-sulfates of the diaminomethyl derivatives of the pyrroloindoles containing ethoxycarbonyl groups in the α-positions in the pyrrole rings, the formation of side products was not observed even in the absence of acetic acid, owing to the presence of electron-accepting groups.

2. The Vilsmeier reaction

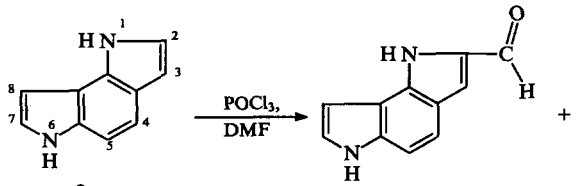


The formylation of the pyrroloindoles **1**–**4** by the dimethylformamide–$POCl_3$ complex proceeds readily at room temperature. When the reaction is carried out in the presence of a threefold excess of the Vilsmeier reagent, the hydrogen atoms in the β-positions in the pyrrole rings are substituted, as expected, and the dialdehydes **75**–**78** are formed in high yields.[31–33,41]

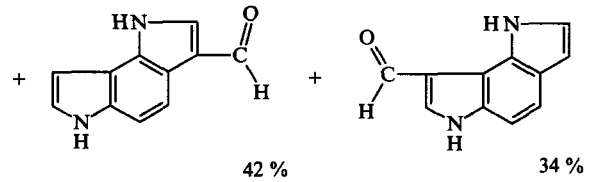


75

76



77

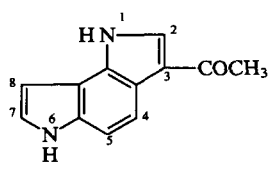


78

In the pyrroloindole **2**, the reactivities of the β-positions in the two different pyrrole rings are not the same. It follows from the model of the molecule of this compound that substitution in the 8-position is difficult owing to shielding by the neighbouring pyrrole ring. It was interesting to elucidate how these factors influence the electrophilic substitution reaction for an equimolar reactant ratio. It was established that three monosubstituted products are formed: 2-, 3-, and 8-formylpyrroloindoles.[42]

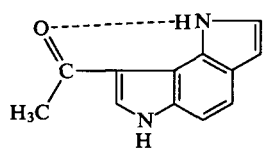
2

5 %



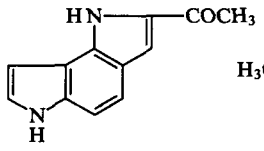
42 % 34 %

The ethoxycarbonyl groups in the α-positions in the pyrrole rings of the pyrroloindole **2** lower its reactivity, as expected. In this case, only the 3-substituted product is formed (yield 41%) and even then a fivefold excess of the Vilsmeier complex is required.[42]

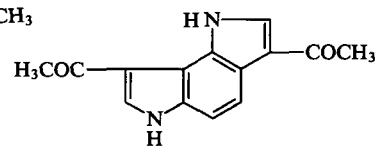


The formylation of 2,6-diethoxycarbonyl-1*H*,7*H*-pyrrolo-[3,2-*f*]indole under these conditions proceeds anomalously. Mainly the hydrogen atoms of the benzene ring are substituted (Scheme 9).[43]

In order to compare the reactivities of the β-positions of 1*H*,6*H*-pyrrolo[2,3-*e*]indole in the Vilsmeier reaction, a more selective electrophile was employed—a complex based on dimethylacetamide and $POCl_3$. This complex is known to react only with highly nucleophilic substrates. Certain indole-containing polynuclear heterocycles altogether fail to react with it,[44] while indole itself does react, affording 3-acetylindole in only 22% yield.[45]

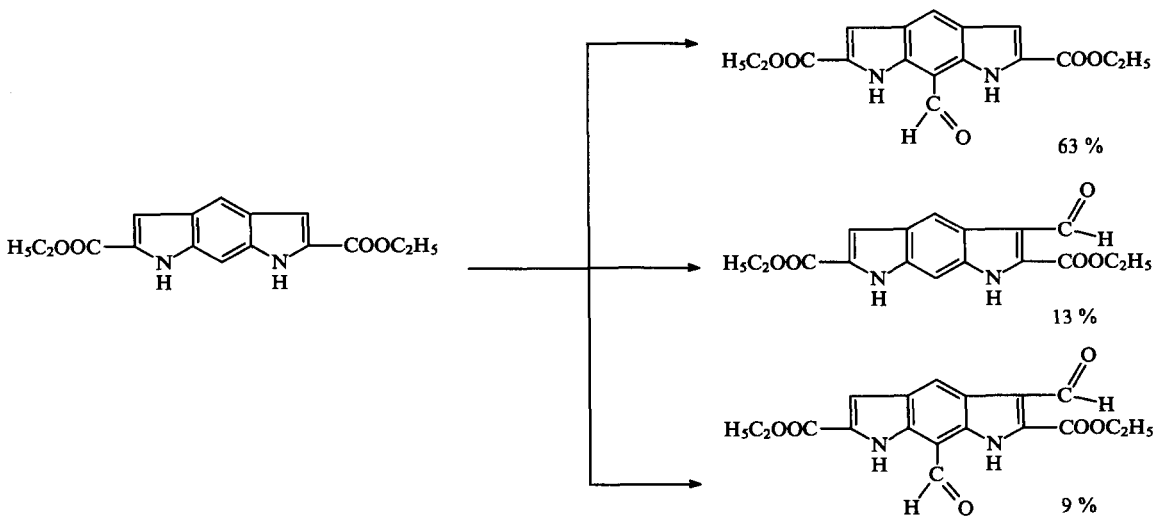


The pyrroloindole **2** has been acylated under the same conditions as those employed in the acetylation of indole. Four reaction products were isolated.[34] The main one is 3-acetyl-pyrroloindole **79**, which is formed at room temperature immediately after mixing the initial compounds. On heating the reaction mixture, the 8- and 2-acetyl-substituted derivatives **80** and **81** were also obtained and after some time 3,8-diacetyl-pyrroloindole **82** was produced. The overall yield of products is ~40%.

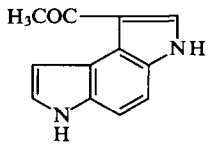


79

80



81



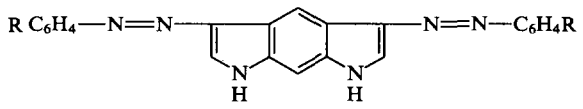
82

Scheme 9

As regards the remaining isomeric pyrroloindoles (compounds **1**, **3**, and **4**), the Vilsmeier reaction could be carried out only for compound **4**. 1-Acetyl-3*H*,6*H*-pyrrolo-[2,3-*e*]indole **83** is formed in 60% yield. In the remaining cases (compounds **1** and **3**), the reaction takes place with charring.[41]

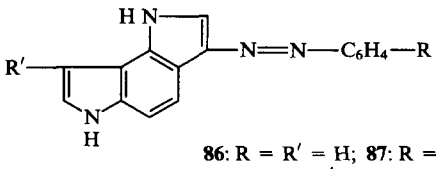
83

Thus the acetylation of pyrroloindoles by the Vilsmeier complex showed that the angular structures are more stable than the linear isomers.



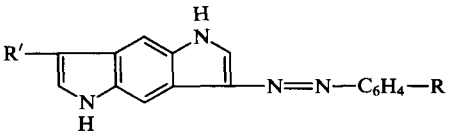
The reduced electrophilicity of the complex based on *N*,*N*-dimethylacetamide and $POCl_3$ compared with the dimethylformamide–$POCl_3$ complex makes it necessary to carry out the reaction at elevated temperatures, which leads to charring of the products of the reaction of linear pyrroloindoles.

3. The azo-coupling reaction

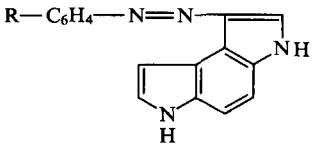


Arenediazonium salts are typical weak electrophiles. They are sensitive to small differences in the reactivities of substrates.

Benzenediazonium and *p*-chloro- and *p*-nitro-benzenediazonium chlorides have been used as the diazo-components in the azo-coupling of pyrroloindoles. Complex mixtures are formed in all cases, from which it has been possible to isolate by preparative column chromatography one product (probably the main one) in each case.



The azopyrroloindoles **83**–**93** are relatively unstable compounds which readily decompose during purification on a chromatographic column and on recrystallisation, which greatly hinders their isolation.



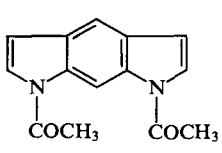
83: R = H; **84**: R = Cl; **85**: R = NO_2.

86: R = R′ = H; **87**: R = Cl, R′ = H;
88: R = Cl, R′ = N=N–C_6H_4–Cl.

89: R = NO_2, R′ = H;
90: R = H, R′ = N=N–C_6H_5;
91: R = Cl, R′ = N=N–C_6H_4–Cl.

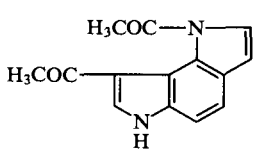
92: R = Cl;
93: R = NO_2.

In the azo-coupling of the linear compounds **1**–**3**, mainly the formation of disubstituted products is observed.[32,33]



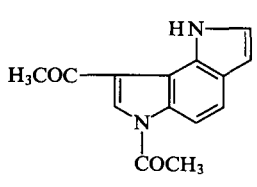
After the azo-coupling of the angular pyrroloindoles **2** and **4**, mainly monosubstituted products were isolated. In this case, the neighbouring pyrrole ring probably exerts a steric influence.[31,32]

4. The acetylation reaction

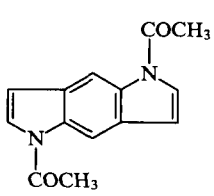


The acetylation of the pyrroloindoles **1**–**4** has been carried out without using the typical Friedel–Crafts catalysts: because these heterocycles are acidophobic, the use of strong catalysts induces the charring of the reaction mixture and lowers the yield of products.

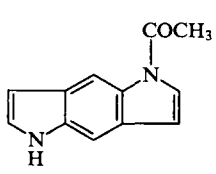
The acetylation of the pyrroloindoles **1**–**4** under the conditions proposed for indole itself[46] leads to the formation of a mixture of the *N*- and *C*,*N*-acetylated derivatives **94**–**102**. The low yield of the reaction products (not more than 40%) can be explained by the partial charring of the reaction mixture.[31–33]



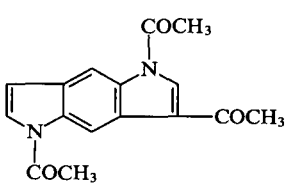
Thus electrophilic substitution reactions in the pyrroloindoles **1**–**4** take place mainly in the β-positions in the pyrrole rings, which agrees with the results of quantum-chemical calculations. In the Vilsmeier acetylation of the pyrroloindole **2**, the formation of 2-substituted products, for which there is no analogous reaction involving indole, is due to the increased excess of π electrons and hence the increased reactivity of the pyrroloindole compared with indole.



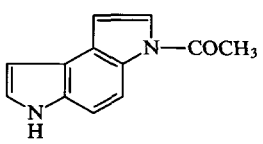
94



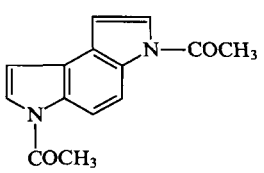
95



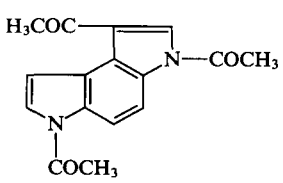
96



97



98



99

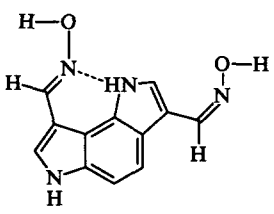
100

101

102

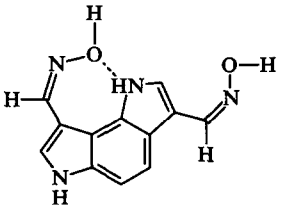
It has been established that the β-positions of both pyrrole rings in linear pyrroloindoles are equally reactive, which cannot be said of the angular isomers. In the interaction of the latter with weaker electrophiles (the azo-coupling reaction and the Vilsmeier acetylation), mainly monosubstituted products are formed, probably as a consequence of steric factors and of the reduced reactivity of the system due to the introduction of an electron-accepting substituent.

IV. Side chain reactions of derivatives of 1*H*,6*H*-pyrrolo[2,3-*e*]indole



1. The condensation reactions of 3,8-diformyl- and 3-formyl-1*H*,6*H*-pyrrolo[2,3-*e*]indole

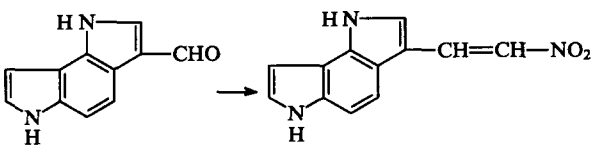
Among nucleophilic addition–elimination reactions, the condensation reactions with nitromethane, nitroethane, acetone, malonic and barbituric acids, aniline, and thiosemicarbazide have been investigated (for 3,8-diformyl-1*H*,6*H*-pyrroloindole) (Scheme 10).[47–49]



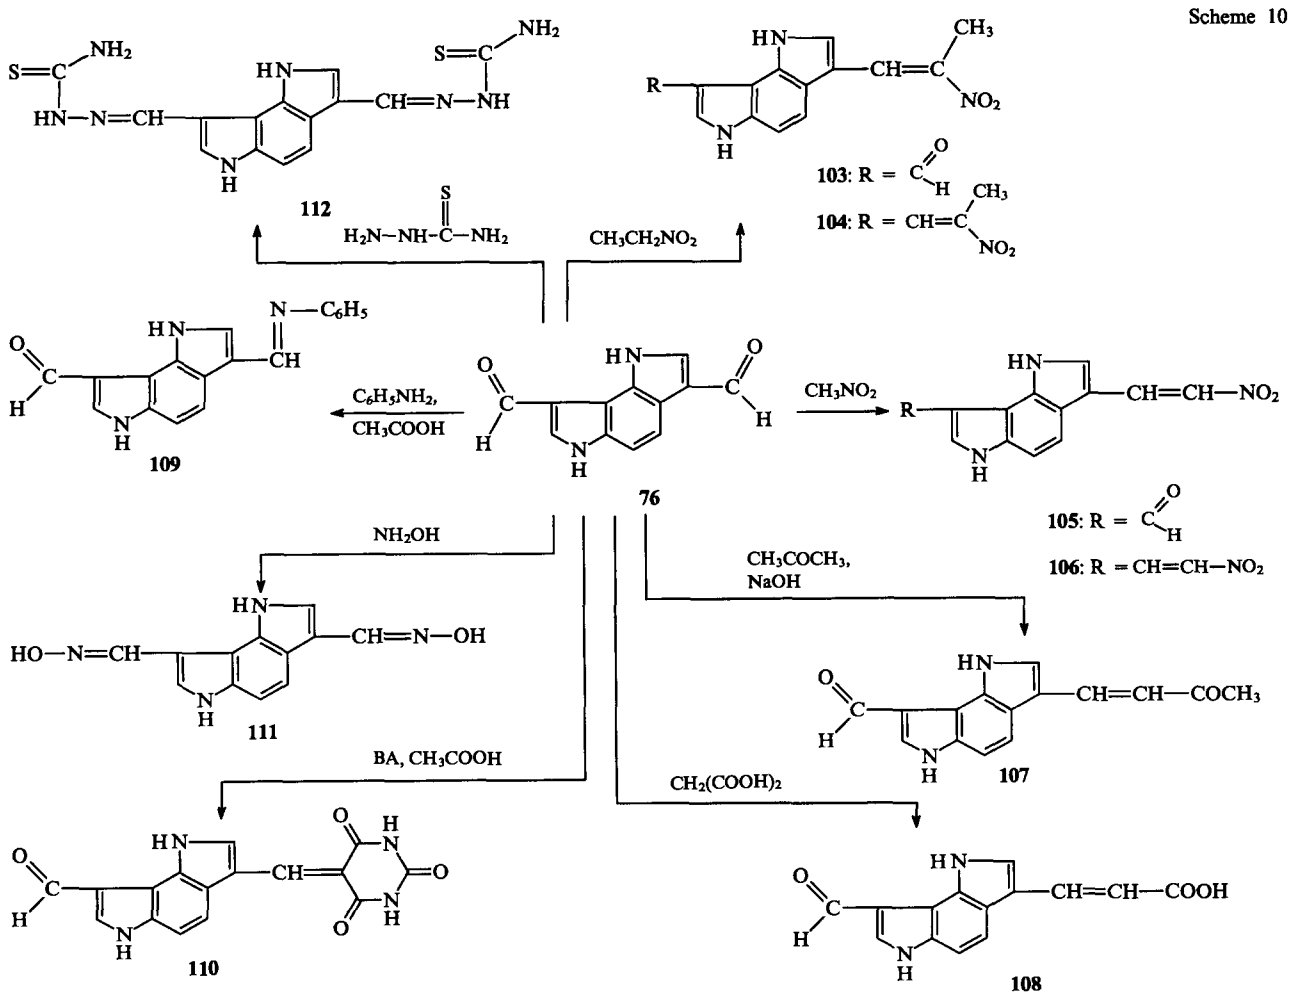
Under the conditions described,[47,48] the dialdehyde **76** reacts with CH acids mainly via one formyl group. The monocondensation products **103, 105**, and **107–110** are formed in high yields. The reduced reactivity of the formyl group in the 8-position can apparently be accounted for by the presence of an intramolecular hydrogen bond and also by steric factors.

In order to develop a convenient method of synthesis of the dinitrovinylpyrroloindoles **104** and **106**, various catalysts were employed (ammonium acetate, liquid ammonia, 50% NaOH solution, pyridine, $KHSO_4$). The desired result was achieved only when dimethylformamide was used as the solvent, in which the dialdehyde **76** is readily soluble.

The disubstituted products **111** and **112** are obtained when the dialdehyde **76** is condensed with hydroxylamine and thiosemicarbazide in a weakly acid medium. The dioxime **111** was formed as a mixture of geometrical isomers which were separated by column chromatography. It has been established by ^1H NMR spectroscopy that these isomers have the *anti,syn*-configuration (compound **111a**) and the *syn,syn*-configuration (compound **111b**) and the cisoid-transoid conformation of the side chains.[49]



111a



111b

In the reaction of the monosubstituted 3-formyl-1*H*,6*H*-pyrrolo[2,3-*e*]indole with nitromethane in the presence of ammonium acetate, 3-nitrovinyl-1*H*,6*H*-pyrrolo[2,3-*e*]indole is formed in a high yield.

Scheme 10

BA = barbituric acid.

2. Certain syntheses based on 3,8-bis(dimethylaminomethyl)-1*H*,6*H*-pyrrolo[2,3-*e*]indole and its diethoxycarbonyl derivative

3-Indolylacetonitrile (a natural product), is an effective stimulator of plant growth.[50] It has been used successfully in the syntheses of certain physiologically active indole derivatives.

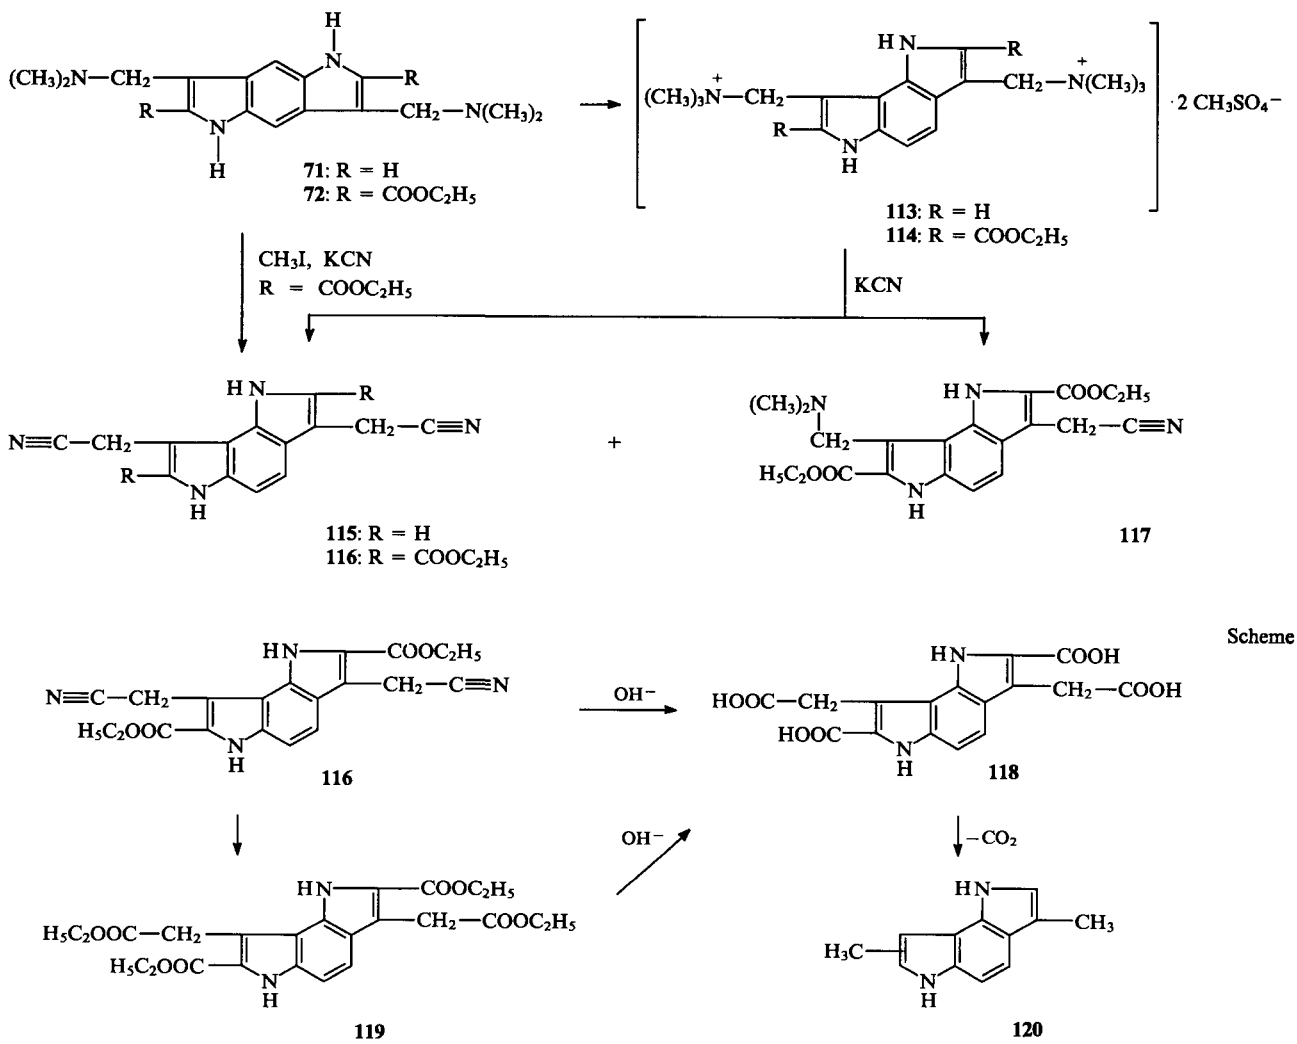
3-Indolylacetonitrile can be conveniently obtained from quaternary salts of gramine and alkali metal cyanides. The use of a quaternised amino-group instead of a free amino-group facilitates the reaction and increases the yield of the target product.[51]

The bisgramines **71** and **72** were converted into the corresponding quaternary salts **113** and **114**. The subsequent reaction of these salts with KCN at 40 °C leads to the corresponding dinitriles **115** and **116**.[52] In the case of the salt **114**, the monosubstituted product **117** is also formed in a low yield. Its yield increases appreciably at high temperatures, accounted for, probably, by the increase in the rate of hydrolysis of KCN.[52]

Further studies showed that the dinitrile **116** can be more conveniently synthesised without the preliminary isolation of the quaternary salt, by adding solutions of KCN and CH_3I to the reaction mixture containing the Mannich base **72**. The application of this method in the synthesis of the dinitrile **115** did not yield positive results.[52]

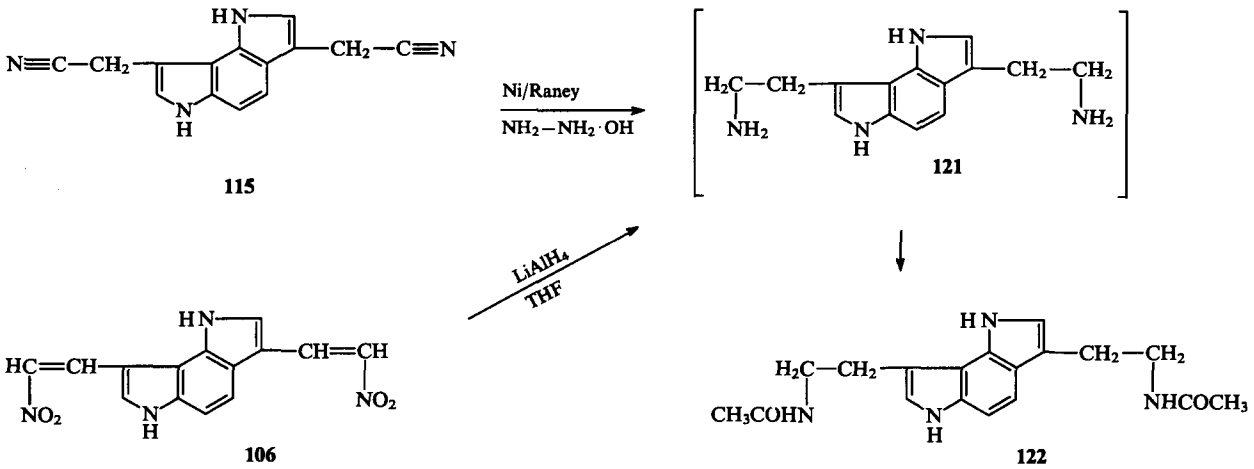
The tetracarboxylic acid **118** is formed readily in the alkaline hydrolysis of the dinitrile **116**. Its structure was established by spectroscopic methods and by specific synthesis from the corresponding tetraester **119**.

The skatole analogue **120** has been synthesised by decarboxylating the acid **118**; acid alcoholysis of the dinitrile **116** in 33% alcoholic HCl afforded the tetraester **119** (Scheme 11).[52]



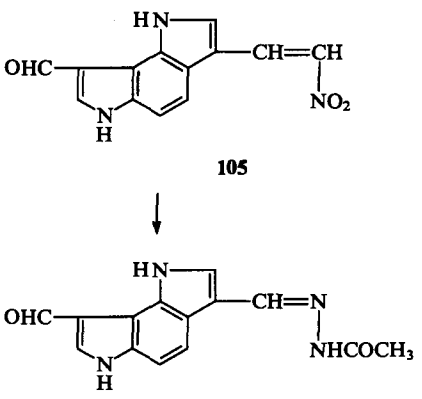
3. Synthesis of a tryptamine analogue from 1*H*,6*H*-pyrrolo[2,3-*e*]indole

It has been shown[48] that the bistryptamine **121** cannot be obtained by the direct reaction of the corresponding Grignard reagent, 1*H*,6*H*-pyrrolo[2,3-*e*]indolebismagnesium halide, and ethyleneimine.[48]



The bistryptamine **121** has been obtained in a high yield by reducing 3,8-di(cyanomethyl)-1*H*,6*H*-pyrrolo[2,3-*e*]indole **115** and 3,8-di(nitrovinyl)-1*H*,6*H*-pyrrolo[2,3-*e*]indole **106**. The product was purified by conversion into the diacetyl derivative **122** and was characterised in this form.[48]

In order to obtain the *N*-unsubstituted tryptamine in a pure form, 8-formyl-3-nitrovinyl-1*H*,6*H*-pyrrolo[2,3-*e*]indole **105** was used as the starting compound. However, the reaction took a completely different route. It was found that the reduction of compound **105** with diimide (hydrazine hydrate and Raney nickel) and subsequent acetylation of the product afford only the 3-*N*-acetylhydrazone of 3,8-diformyl-1*H*,6*H*-pyrrolo[2,3-*e*]indole **123**[48] (see over).



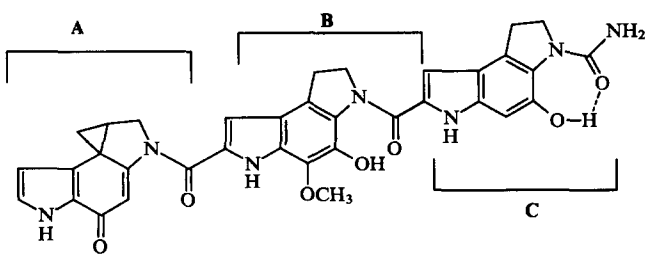
The reduction of the pyrroloindole **105** with lithium tetrahydroaluminate and subsequent acetylation lead to the formation of a gel-like mass, the components of which are difficult to isolate and identify. This is apparently associated with the formation, after the reduction of the aldehyde group, of an analogue of the unstable 3-indolylmethanol,[53] which is capable of both dimerising and of conversion into an oligomer in an acid medium or on standing.[48]

Scheme 11

115 121 106 122

105 123

4. Some syntheses based on 1*H*,10*H*-benzo[*e*]pyrrolo-[3,2-*g*]indole



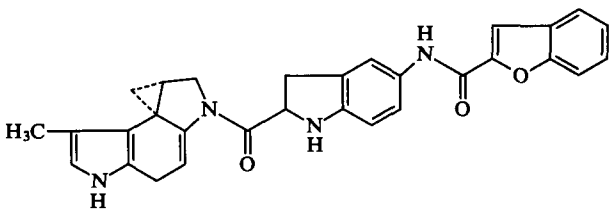
As expected, 1*H*,10*H*-benzo[*e*]pyrrolo[3,2-*g*]indole forms products disubstituted in the β-positions of the pyrrole rings in the Vilsmeier and Mannich reactions. In reactions with weaker electrophiles (azo-coupling reactions), only monosubstituted products are formed.[54]

Certain reactions of 2,9-di(carbohydrazido)-1*H*,10*H*-benzo-[*e*]pyrrolo[3,2-*g*]indole **124** have been described (Scheme 12).[55]

The reactions of the acid dichloride of 2,9-dicarboxy-1*H*,10*H*-benzo[*e*]pyrrolo[3,2-*g*]indole **125** merit attention. It has been obtained in a quantitative yield by refluxing the corresponding dicarboxylic acid with thionyl chloride. The condensation of the acid dichloride **125** with amines and phenols leads to various diamides and diesters.[56] In addition, high-molecular-mass compounds containing benzopyrroloindole fragments have been obtained from the pyrroloindole **125**.[57]

5. The antibiotic CC-1065 and its analogues

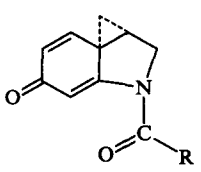
In the Introduction, we noted that the molecule of the powerful antitumour antibiotic CC-1065 contains the pyrrolo-indoline fragments **B** and **C**.[4]



It was shown that this compound is bound covalently via the cyclopropane ring to the *N*(3)-position of adenine in a specific nucleotide sequence and is located within the limits of the small groove of DNA, suppressing selectively its synthesis. On the other hand, the antibiotic is not an intercalator; the cytotoxicity of the compound CC-1065 is approximately 400 times higher than that of adriamycin, which has been used successfully in the treatment of oncological diseases.[4] Unfortunately the antibiotic CC-1065 is also highly toxic, which precludes its clinical application.[58]

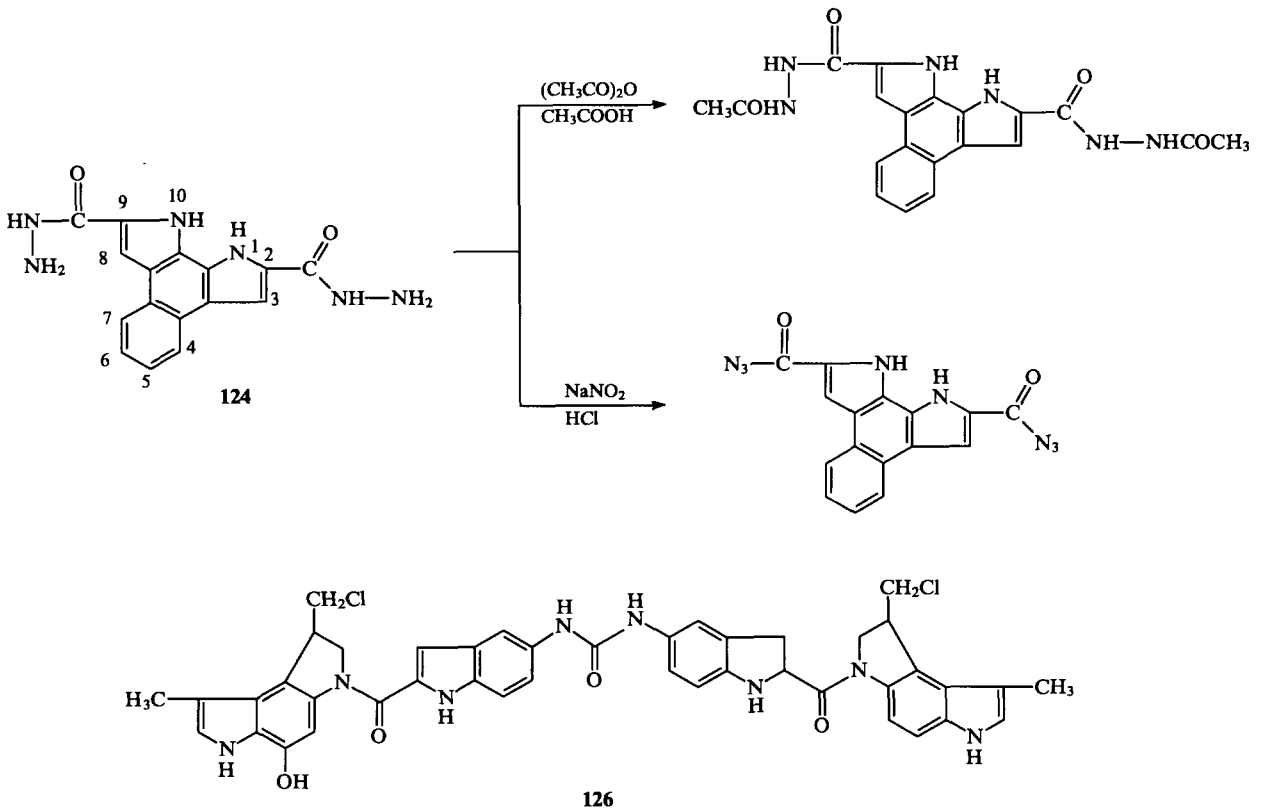
The data of Rawal et al.[4] initiated studies, directed towards the synthesis of the individual components (**A**, **B**, and **C**) of compound CC-1065. These investigations have been described in detail in the above review by the American investigators Rawal et al.[4]

A classical strategy was used in the synthesis of the pyrroloindole fragments **B** and **C** of the compound CC-1065. Indoline was obtained from substituted benzene and then the corresponding pyrroloindoline was obtained by the Fischer method or the pyrrole rings were attached stepwise to the benzene ring and the resulting pyrroloindole was hydrogenated to the corresponding pyrroloindoline.



These skillfully performed complex syntheses include 14 stages each and the yields of the target products are < 7%.

An enormous amount of work was carried out on the synthesis of analogues of the antibiotic CC-1065. The benzofuran analogue I-73975 is promising.



This compound is also a monoalkylating agent containing a cyclopropane ring in its structure. A highly active dialkylating agent, having the structure **126**, has also been synthesised.[59] However, it is not altogether clear whether the mechanism of its action is identical with that of the natural antibiotic.[59]

It was later observed,[60] that a whole class of antibiotics exist—duocarmycins—which are structurally and chemotherapeutically similar to CC-1065. They are all characterised by a common pharmacophore.[60]

Scheme 12

It is evident from the data presented that pyrroloindoles are extremely promising as regards the search for new antitumour preparations and merit further study.

Polyarylates. Synthesis and properties

S V Vinogradova, V A Vasnev, P M Valetskii

Contents

I. Introduction 833
II. Synthesis of polyarylates and their properties 833
III. Applications of polyarylates 846

Abstract. Data on the synthesis and properties of various types of polyarylates, including cardo-, self-coloured, self-protecting, carbaborane-containing, stereoregular, and block-polyarylates, etc., are examined and surveyed. It is shown that polyarylates represent a promising class of polymers with a valuable set of properties, which can be altered specifically by an appropriate design of the polymer chain. Certain aspects of the practical use of polyarylates are considered. The bibliography includes 320 references.

I. Introduction

In terms of their theoretical and practical importance, heterochain polyesters occupy an important place among synthetic high-molecular-mass compounds. The first representatives of these polymers had already been obtained in the last century.[1–4] Since then, there has been a continuous development of this field in polymer chemistry.

The study of the interrelation between the structure and properties of heterochain polyesters has led to the idea that the most interesting properties, and especially enhanced thermal characteristics, may be expected from polymers based on aromatic components. Thus the syntheses of a series of polyesters of aromatic dicarboxylic acids and aliphatic glycols have been achieved. Among these compounds, poly(ethylene terephthalates) and poly(butylene terephthalates) are of undoubted practical interest. The aromatic ring can be introduced into the polyester chain also via the diol component.

Polyarylates are heterochain polyesters of dihydric phenols. The first representatives of polyesters of this type were polycarbonates, i.e. polyarylates of dihydric phenols and carbonic acid, which were synthesised in 1898 by Einhorn[5] by the interaction of phosgene with resorcinol and hydroquinone. The study of polycarbonates developed during the 1960s because polymers of practical value were discovered among them, in particular the polycarbonate of 2,2-bis(4-hydroxyphenyl)propane.[6,7]

In 1957–1958 publications on the polyarylates of aromatic dicarboxylic acids, with a series of valuable properties, began to appear almost simultaneously in Belgium, the USSR, and the USA.[8–10] The studies on these polymers have continued to this day.

II. Synthesis of polyarylates and their properties

Polyarylates can be obtained by the interaction of dicarboxylic acids with dihydric phenols (method I), of the diacetates of dihydric phenols with dicarboxylic acids (method II), and of dihydric phenols with dicarboxylic acid esters (method III), but the synthesis of polyarylates using the chlorides of dicarboxylic acids as the acid reagents (method IV) has assumed the greatest importance.

In the synthesis of polyarylates by the first three methods,[4,10–31] the polycondensation is usually carried out in the melt in an inert gas stream; in the final stage, the reaction mixture is heated in vacuo. A disadvantage of these methods is their unsuitability for the synthesis of polyarylates with high softening temperatures. Furthermore, the polyarylates obtained by polycondensation in the melt frequently acquire a colour during the reaction.[32]

The last method is best for the synthesis of high-melting polyarylates as well as polyarylates containing reactive groups in their chains. The employment of highly reactive dicarboxylic acid chlorides makes it possible to carry out successfully the polycondensation in solution. This method is of great importance in the synthesis of high-melting polyarylates, since it is then possible to achieve successful polycondensation up to a high degree of reaction without the decomposition of the polymer formed.

The polycondensation of dicarboxylic acid chlorides with dihydric phenols can be achieved in several versions: (1) at an elevated temperature in a high-boiling solvent; (2) as interfacial polycondensation; (3) as acceptor-catalytic polyesterification.

The characteristics of the polycondensation of dicarboxylic acid chlorides with dihydric phenols in a high-boiling solvent have been investigated in a number of studies.[4,11,14,33–40] It was established that the reactivity of the starting materials is greatly influenced by their structure.[33,37–45]

For example, when the condensation is carried out in dinyl (azeotropic mixture of diphenyl ether with biphenyl) in the temperature range 150–210 °C, it was found that isophthalic acid chloride reacts with 2,2-bis(4-hydroxyphenyl)propane at a higher rate than terephthalic acid chloride (at 170 °C, the rate constants are 10.7×10^{-5} and 6.6×10^{-5} litre mol^{-1} s^{-1} respectively). At 170 °C, dihydric phenols can be arranged in the following sequence in terms of the rate of their reaction with terephthalic acid chloride: hydroquinone > resorcinol > 2,2′-dihydroxybiphenyl > 2,2-bis(4-hydroxyphenyl)propane.[41]

The study of the kinetics of the polycondensation of terephthalic acid chloride with bis(4-hydroxyphenyl)methane, 2,2-bis(4-hydroxyphenyl)propane, 2,2-bis(4-hydroxyphenyl)-hexafluoropropane, bis(4-hydroxyphenyl)phenylmethane, 2,2-bis(4-hydroxyphenyl)-2-phenylethane, bis(4-hydroxyphenyl)-trifluoromethylphenylmethane, and bis(4-hydroxyphenyl)-diphenylmethane in ditolylmethane in the temperature range 160–200 °C showed that the nature of the substituents at the central carbon atom of the bisphenol sometimes exerts a significant influence on the rate of polycondensation.[39] Thus the replacement of the electron-donating methyl groups in 2,2-bis-(4-hydroxyphenyl)propane by the strongly electron-accepting trifluoromethyl groups makes the rate of polycondensation of 2,2-bis(4-hydroxyphenyl)hexafluoropropane with terephthalic acid chloride higher by a factor of 2–2.5 than the rate of polycondensation of 2,2-bis(4-hydroxyphenyl)propane.

The introduction of side groups by substitution into the aromatic rings of the dihydric phenol in the *ortho*-position relative to the hydroxy-group diminishes the rate of reaction with aromatic dicarboxylic acid chlorides.[40,43] For example, when the extents of reaction of aromatic dicarboxylic acid chlorides with 2,2-bis(4-hydroxyphenyl)propane and 2,2-bis(3-allyl-4-hydroxyphenyl)propane are compared, it is found that the process is slower in the case of the diallyl-substituted bisphenol. Thus, whereas the degree of reaction of isophthalic acid chloride with 2,2-bis(4-hydroxyphenyl)propane at 220 °C (in dinyl) is 0.89 after only 1 h, in the case of the diallyl-substituted bisphenol the extent of reaction over the same period is only 0.34 and reaches 0.83 only after 9 h. Hence it follows that it is desirable to carry out the polycondensation of the diallyl-substituted bisphenol with terephthalic and isophthalic acid chlorides at an elevated temperature of the order of 220 °C over a long period.[43]

The rate of polycondensation of dicarboxylic acid chlorides with dihydric phenols containing substituents in the *ortho*-position relative to the hydroxy-group is influenced not only by the size but also by the chemical nature of the substituent. Thus the rate constants of the polycondensation of terephthalic acid chloride with 2,2-bis[3-methyl(propyl, chloro)-4-hydroxyphenyl] propanes are lower at the corresponding temperatures than the rate constants for the unsubstituted dihydric phenol in the same reactions.[40]

We shall also consider the synthesis of mixed block-polyarylates by high-temperature polycondensation in solutions of dicarboxylic acid chlorides, bis-phenols, and various low-molecular-mass polymers with terminal hydroxy-groups.[33,46–51] The block components employed were poly(ethylene oxide) $HO(CH_2CH_2O)_nH$, poly(propylene oxide) $HO[CH(CH_3).CH_2O]_nH$, poly[3,3-bis(chloromethyl)trimethylene oxide] $HO.[CH_2C(CH_2Cl)_2CH_2O]_nH$, and a silicon-containing oligomer having the structure $\{HOC_6H_4C(CH_3)_2C_6H_4[OSi(CH_3).(C_6H_5)]\}_2O$, i.e. polymers without reactive bonds in their chains with the exception of reactive terminal functional groups. Since the ether group is inert with respect to exchange reactions, such block components, used as one of the initial diols for the synthesis of the polyester, were introduced without change into the polymer chain of the final product, modifying it significantly. The properties of such mixed block-polyarylates are determined both by the composition and structure of the initial components and by the process conditions because the reactivities of the block component and of the dihydric phenol differ from one another. Comparative study of the kinetics of the polycondensation of terephthalic acid chloride with 2,2-bis(4-hydroxyphenyl)propane and the bifunctional block components listed above in ditolylmethane at 220 °C showed that these diols can be arranged in the following sequence in terms of their reactivity towards the acid chloride: poly(ethylene oxide) > poly(propylene oxide) > 2,2-bis(4-hydroxyphenyl)propane > poly[3,3-bis(chloromethyl)-trimethylene oxide] > silicon-containing oligomer.[47]

Apart from the synthesis of linear thermoplastic polyarylates, thermoreactive polymers can also be obtained by polycondensation in a high-boiling solvent. These include, for example, polyarylates containing free hydroxy-groups in the chain, obtained by the polycondensation of aromatic dicarboxylic acid chlorides with dihydric phenols and polyhydric aliphatic alcohols [glycerol, tris(hydroxymethyl)propane, pentaerythritol, tris(hydroxymethyl)ethane, etc.].[37,52–54]

Comparative study of the kinetics of the polycondensation of terephthalic and isophthalic acid chlorides with 2,2-bis(4-hydroxyphenyl)propane and tris(hydroxymethyl)ethane in dinyl showed that aromatic dicarboxylic acid chlorides react with polyhydric aliphatic alcohols much more vigorously than with dihydric phenols.[37] The extent of reaction is greatly influenced by the chemical nature of the diol component. Thus the extent of reaction of isophthalic acid chloride with tris(hydroxymethyl)-propane at 150 °C is 0.74 after 9 h, whereas in the case where 2,2-bis-(4-hydroxyphenyl)propane is used as the diol component it is only 0.21. In the latter case, the extent of reaction can be raised to 0.74 after 8 h only by carrying the polycondensation at 210 °C, i.e. at a higher temperature. In the polycondensation of isophthalic acid chloride with 2,2-bis(4-hydroxyphenyl)propane at 220 °C, the extent of reaction is 0.89 after only 1 h.

The above data show that it is desirable to synthesise mixed polyarylates containing free hydroxy-groups in the chain in two stages. The first stage — the polycondensation of the dihydric phenol with a dicarboxylic acid chloride — should be carried out at an elevated temperature (up to 220 °C). The second stage (after the entire dihydric phenol has reacted) — the polycondensation of the polyarylate formed with an aliphatic polyhydric alcohol — must be performed at lower temperatures (110–150 °C), which makes it possible to attain a fairly high degree of reaction without premature hardening of the product.[37,55]

Much attention has also been devoted to the study of processes occurring in the synthesis of polyarylates with the aid of interfacial and acceptor-catalytic polyesterification.[4,11,13,15,56–70]

Using all three variants, polymers with high molecular masses [for example up to 150 000 for the polyarylates obtained from 2,2-bis(4-hydroxyphenyl)propane and the chlorides of terephthalic and isophthalic acids by interfacial polycondensation, 60 000–100 000 for the polyarylates obtained by the high-temperature polycondensation in solution of phenolphthalein and aromatic dicarboxylic acid chlorides] can be obtained in nearly quantitative yields from dicarboxylic acid chlorides and dihydric phenols.[33,56]

The polycondensation of dicarboxylic acid chlorides with dihydric phenols has been used successfully for the synthesis of polyarylates having a wide variety of chemical structures.

As early as the 1930s, mention was made of the use of phenolphthalein for the synthesis of polyesters in a list of initial compounds published in an American patent.[71] Data on the synthesis of alkyd polymers using fluorescein and phenolphthalein were published in 1946.[72] However, a characteristic feature of these studies is that phenolphthalein was used simply as one of the representatives of the enormous number of diols without taking into account its specific contribution to the properties of the polymers.

Polyarylates derived from phenolphthalein and aromatic dicarboxylic acids were first obtained in 1961 and attention was turned to the specific contribution of the phthalide side group to a valuable set of properties of these polymers: the combination in the latter of an increased thermal stability with an effective solubility in organic solvents.[73,74] It was subsequently suggested that polymers of this type, i.e. those containing in the repeat unit at least one element entering into the composition of the cyclic side group, be called cardo-polymers,[75] from the Latin word 'cardo', which means loop, because such groups can be regarded as loops in relation to the main chain of the macromolecule. In subsequent years, the studies in the field of cardo-polyarylates developed extensively.[11,12,33,56,57,73–113]

In the synthesis of cardo-polyarylates, various dihydric phenols containing closed cyclic groups at the central carbon atom were used as the starting materials: phenolphthalein, phenolfluorene, phenolanthrone, phenolacenaphthylene, phenolphthalein imide, its *N*-β-hydroxyethyl and allyl derivatives, etc. The acid chlorides of aromatic dicarboxylic acids of the cardo-type, for example diphenylnaphthalide-4,4′-dicarboxylic acid, have also been used in a number of cases. For example, phenolphthalein polyarylates with a high molecular mass (up to ~100 000) have been obtained successfully by acceptor-catalytic polyesterification in an organic solvent at moderate temperatures (up to ~50 °C) in the presence of a tertiary amine or by polycondensation in an inert medium at an elevated temperature (100–200 °C) in a high-boiling solvent. Since the process takes place in the absence of a catalyst in the latter case, its completion requires approximately 10 h.

An interesting feature was discovered in the study of the formation reactions of phenolphthalein polyarylates in a high-boiling solvent. It was established that the properties of the polyarylate obtained from isophthalic acid and phenolphthalein varied appreciably depending on the nature of the solvent in which the process was carried out.[114]

The chemical structure of the polyarylates obtained from phenolphthalein and aromatic dicarboxylic acids ensures a high rigidity of their macromolecules. For this reason, in the synthesis of such polyarylates in ditolylmethane, which is not a solvent for the polymer obtained, the free energy of formation of the coiled macromolecules should be smaller than the free energy of formation of the uncoiled macromolecules. This results in the selection, during the synthesis, of globular forms of the macromolecules and ensures the globular type of supermolecular structure of the phenolphthalein polyarylates synthesised in ditolylmethane. On the other hand, in the synthesis of the phenolphthalein polyarylate in α-chloronaphthalene or nitrobenzene, which are solvents also for the polymer formed, uncoiled (extended) macromolecules are formed preferentially. Fibrillar supermolecular structures arise as a result of this. The polymers with such supermolecular structure have a better set of physicochemical properties. This follows from Table 1, which presents the characteristics of the isophthalic–phenolphthalein polyarylates synthesised in various media.

Table 1. The properties of phenolphthalein–isophthalic acid polyarylate.

Properties of polyarylate	Medium in which the polyarylate has been synthesised			
	ditolyl-methane	α-chloro-naphthalene		nitro-benzene
Molecular mass	28 000	28 000	48 000	26 000
Softening temperature/°C	270	290	300	275
Tensile strength/ kgf cm^{-2}	640	740	780	650
Elongation at rupture (%)	10–20	80	100	40–70
Specific impact strength/ (kgf cm) cm^{-2}	2–3	10	20	14

The synthesis of polyarylates based on 2-(β-hydroxyethyl)-3,3′-bis(4-hydroxyphenyl)phthalimidine or phenolphthalein imide at elevated temperatures is nonspecific, since infusible and insoluble polymers with a three-dimensional structure are then formed owing to the trifunctional nature of the initial bisphenols. At the same time, the interfacial polycondensation of these bisphenols with dicarboxylic acid chlorides, carried out under mild conditions, leads to linear high-molecular-mass polyarylates containing free hydroxy- or NH groups in the chain,[81,82,115] which do not interact with the acid chloride groups under the conditions of the given reaction.

The use of such bisphenols in the synthesis of polyarylates in a mixture with the usual bisphenols leads, for example, to the possibility of a clear-cut regulation of the content of the reactive group along the polymer chain. Such polymers have advantages over the widely known alkyd polymers because of their linear structure, high softening temperature, high molecular mass, and a uniform distribution of the free functional groups NCH_2CH_2OH or NH along the chain.

The development of the theory of nonequilibrium (irreversible) polycondensation and the advances in the field of its preparative methods of synthesis have created broad preconditions for the synthesis of block-copolymers of the polycondensation type. This applies in the first place to acceptor-catalytic polycondensation,[33,68,116,117] the mild conditions of which make it possible to synthesise block-copolymers with virtually complete suppression of exchange reactions. When the process characteristics are known adequately, this makes it possible to produce block-copolymers directly from the monomers.[68] Even greater prospects for controlling the microstructure of the polymer chain in block-copolymers and hence their properties arise when oligomers and polymers with terminal functional groups are used as the starting materials for their synthesis.[116–148]

At least three methods of synthesis of polycondensation block-copolymers are realistic, for example the synthesis of polyarylate-arylene sulfone oxide block-copolymers.

(1) The synthesis in two reaction volumes of oligomers, having different chemical structures, with a specified molecular mass and heterofunctional groups followed by their copolycondensation (Scheme 1).

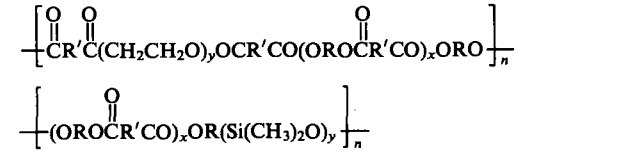
(2) The synthesis in two reaction volumes of oligomers, having different chemical structures, with a specified molecular mass and homofunctional end groups and their copolycondensation with the aid of an intermonomer (a chain lengthening agent) (Scheme 2).

Scheme 2

(3) The synthesis of an oligomer having a specified molecular mass and its copolycondensation with a low-molecular-mass monomer and an intermonomer, the interaction of which gives rise to polymer blocks having a different chemical structure (Scheme 3).



Scheme 3

Naturally, depending on the method of synthesis of the block-copolymers, the chemical structure of the monomers and the block components, their molecular mass, the length of blocks having different chemical structures and their distribution along the macrochain all vary, i.e. the nonuniformity of the composition of the block-copolymer and hence its properties vary. It follows from the three schemes presented above that the block-copolymers having the most regular structure are obtained as a result of acceptor-catalytic polyesterification in accordance with Scheme 1.

The polycondensation method makes it possible to vary widely the position of the block-copolymers. Thus various block-copolymers containing both polymer blocks having similar chemical structures (for example, polyarylate-arylene sulfone oxides [119-123, 136, 137]) and polymer blocks differing appreciably in their structure and properties from polyarylates [for example, polyarylate-ethylene oxides [120, 131, 137, 140, 141] or polyarylate-organosiloxanes [125-129, 137-139] (Scheme 4)] have been obtained (and investigated) on the basis of cardo-polyarylates incorporating terephthalic and isophthalic acids (polyarylate F-1 in the case of isophthalic acid) and the polyarylate obtained from 2,2-bis-(4-hydroxyphenyl)propane and terephthalic and isophthalic acids (polyarylate D).

Scheme 4

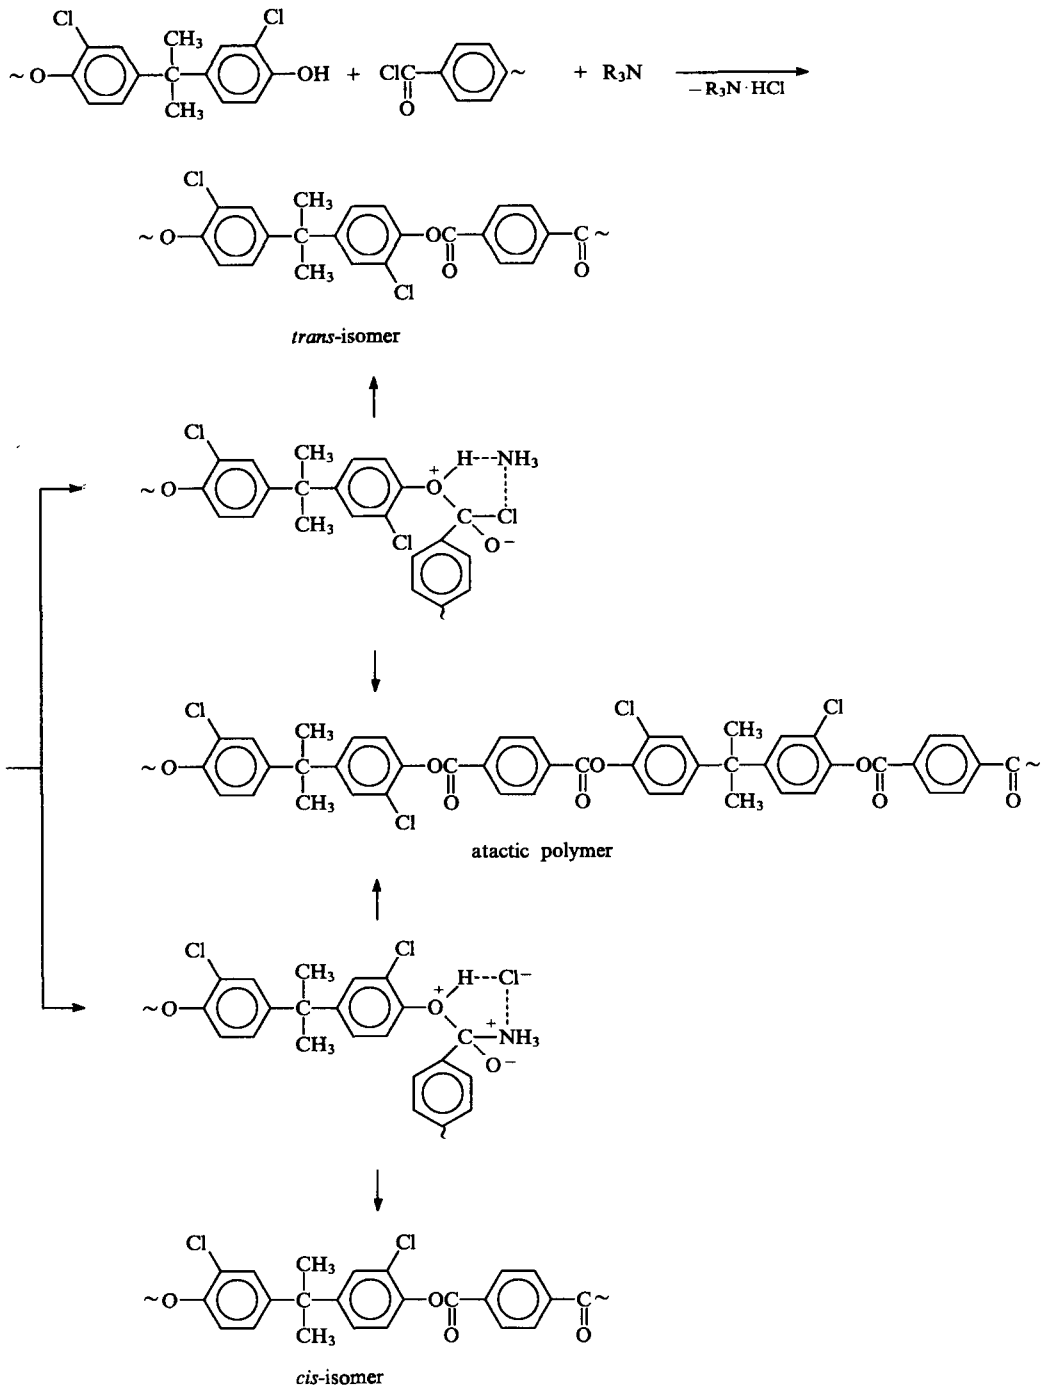
Deeper study of nonequilibrium condensation processes, especially acceptor-catalytic polyesterification, created theoretical preconditions for the synthesis of stereoregular polyarylates the molecules of which contain regular sequences of stable rotational isomers. [68, 145, 149-160]

The fundamental novelty of the synthesis of conformationally regular polyarylates consists in the fact that their regular steric microstructure is formed directly during the growth of the macromolecule when monomers which are neither conformational nor configurational isomers but their molecules contain fragments with hindered internal rotation are used in the reaction. An example of polyarylates of this kind is provided by the stereoregular polyterephthalates based on disubstituted 2,2-bis-(4-hydroxyphenyl)propanes, for example 2,2-bis(3-chloro-4-hydroxyphenyl)propane.

Comparison of the stereotacticities of the polymers obtained with the conditions of their synthesis made it possible to formulate a series of rules governing the formation of such macromolecules. Thus in the presence of weakly basic heterocyclic tertiary amines (nucleophilic catalysis), mainly polyarylates with the *cis*-disposition of the substituents in the bisphenol fragment are formed, whereas in the presence of highly basic trialkylamines (general base catalysis) polyarylates with the *trans*-isomers are produced, which is associated with the different geometries of the transition complexes. The presence of regular sequences of isomeric forms in the macromolecules of polyarylates influences significantly their properties. In particular, an increase in the stereotacticity of the polymers increases the degree of their crystallinity and their softening temperatures and diminishes their solubility. The synthesis of stereoregular polyarylates is illustrated schematically (Scheme 5).

A special series of studies have been carried out on the so called 'self-coloured' polyarylates. [161-166] Aromatic polyesters are known to be extremely difficult to dye. [161, 166] It has been found that in the case of polyarylates this problem can be solved by synthesising polymers the macromolecules of which contain chemically bound dye molecules.

The construction of such a polymer chain is achieved by employing chromophore-containing dihydric phenols and dicarboxylic acid chlorides together with the usual phenols and acids for the synthesis of polyarylates. Thus homogeneous and mixed polyarylates, containing anthraquinone residues or azo-groups in the chain, have been synthesised, and their properties investigated, from compounds such as the chlorides of azobenzene-3,3'- and azobenzene-4,4'-dicarboxylic acids, 2,2' and 4,4'-dihydroxy-, 4,4'-dihydroxy(ethoxy), and 4,4'-dihydroxy-(propoxy)-azobenzenes, quinizarin, alizarin, and Alizarin Blue. The use of fumaric acid chloride as the acid reagent in the synthesis of such polyarylates made it possible to obtain coloured polyarylates capable of copolymerising with various monomers. Table 2 (page 838) presents examples of the polymers obtained.



All these polyarylates are substances having colours corresponding to that of the starting material. It is noteworthy that, as part of the coloured component in the homopolyarylate is replaced by a colourless monomer, the colour of the polyarylate is usually retained and the intensity of the absorption in the visible region varies in proportion to the concentration of the coloured component in the polymer. The relatively high intensity of the absorption in the visible spectra of self-coloured polyarylates with even small amounts (for example 0.1-0.05 mole) of coloured chromophore-containing monomers in the mixture of the initial components suggests a technologically extremely simple solution of the problem of dyeing the known polyarylates. [163, 166]

The fact that molecules of the coloured substance in the self-coloured polyarylates are covalently linked to other components renders their colour stable towards various influences, including the action of light, which is one of the most important characteristics of the colour. For example, in the case of self-coloured homopolyarylates and copolyarylates containing only 0.05 mol.% (2-3 mass%) of a chromophore-containing substance, the photostability proved to be satisfactory.

It has been observed that the introduction of even small amounts of a chromophore-containing monomer into the polyarylate chain appreciably increases the resistance of solutions and films of these polymers to the action of UV radiation. [161]

Transparent coloured films, the tensile strength of which in the nonoriented state at room temperature varies in the range from 800 to 1300 kgf cm^{-2}, have been obtained from a series of coloured polyarylates containing different amounts of a chromophore-containing substance. Tests on these films at

Scheme 5

elevated temperatures showed that at 250 °C they retain up to 40% of the initial strength. The coloured polyarylates can be worked to produce cast and moulded articles. The specific impact strength of moulded specimens of the 4,4′-dihydroxyazobenzene polyarylate is 25 (kgf cm) cm^{-2}.[166]

A series of coloured polyarylates containing fumaric acid fragments in their macromolecules are satisfactorily compatible with various monomers (styrene, methyl methacrylate, diallyl isophthalate), forming with the latter under appropriate conditions coloured copolymers in the form of transparent coloured monolithic substances. Compositions comprising self-coloured unsaturated polyesters with unsaturated monomers have been used successfully in the preparation of yellow and red vitreous plastics possessing a high photostability and an effective chemical stability in addition to good mechanical parameters.[161,166]

Thus chromophore-containing bisphenols and dicarboxylic acids are of interest not only from the standpoint of the synthesis of new heat-resistant coloured polyesters but also from the standpoint of imparting a predetermined colour with a specified intensity to colourless polyarylates most interesting from the practical point of view and of an appreciable improvement of the photochemical stability of these polymers.[161]

In order to find polyarylate structures with an increased photostability, a study has been made of the effect of ultraviolet radiation on specifically synthesised homogeneous and mixed polyarylates based on phenolphthalein, phenolsulfophthalein, bis(4-hydroxyphenyl) sulfone, phenolphthalein anilide, phenolphthalein imide, phloroglucinol, and the chlorides of terephthalic, isophthalic, and methylphosphinic acids, bis(4-carboxyphenyl)-methyl ether, and a number of others.[167-174]

It has been found that the partial or complete replacement of the lactone ring by a lactam ring in phenolphthalein polyarylates as well as the presence of a cyclic substituent with a conjugated bond system (for example, the fluorenyl substituent) at the central

Table 2. Certain properties of coloured polyarylates.

Starting material		Temperature/°C		Colour of powdered polymer
acid chloride	dihydric phenol	softening	onset of decomposition[a]

[b] Softening takes place with decomposition.

carbon atom in the bisphenol residues appreciably increase the resistance of the polymer to the action of light. The inclusion of small amounts (~1%) of sulfur, phosphorus, and free phenolic groups in the polyarylate chain afforded polyarylates with increased resistance to light-induced ageing.

As shown above, the photostability of polyarylates can be increased also by introducing into their polymer chain the residues of bifunctional chromophore-containing substances (for example, 1,3-dihydroxyanthraquinone). It is also noteworthy that the high photostability of polyarylates, exhibited when their solutions are irradiated, may be due to the occurrence under these conditions of the Fries rearrangement, which leads to the appearance in the polymer chain of hydroxyketone groups stabilising the polymer.

The introduction of sulfur and phosphorus into the structure of phenolphthalein polyarylates increases not only the photostability of the polymers but also their thermal stability and in the case of phosphorus their fire resistance.

Thus polymers with 'self-protecting' properties as regards the action of light and heat can be obtained with the aid of specific design of the polyarylate chain.[174]

Polyarylates containing reactive groups in their chain, for example hydroxy-groups, and double bonds possess thermoreactive properties. They are capable of long-range chemical reactions and of undergoing a transition to an infusible three-dimensional state as a result of both heat treatment and various chemical reactions.

Thus polyarylates based on polyhydric alcohols containing free hydroxy-groups in their chain are capable of undergoing a transition to a three-dimensional state on additional heat treatment and as a result of their interaction with pyromellitic, maleic, and phthalic anhydrides, diisocyanates, metal derivatives, and other reagents,[52-54,175,176] whereupon the properties of the polymers are modified significantly, for example their thermal characteristics are improved.

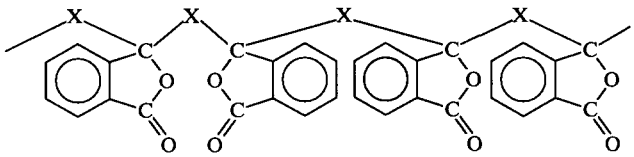
The double bond-containing polyarylates based on 2,2-bis(3-allyl-4-hydroxyphenyl)propane (with added 2-allylphenol) and fumaric acid may be hardened on heating or as a result of copolymerisation with other unsaturated compounds.[177-186] This made it possible to modify within wide limits the properties of the polymers, in particular to improve their thermal characteristics. For example, high elastic deformation over a wide temperature range is characteristic of the hardened polyarylate obtained from isophthalic acid and 2,2-bis(3-allyl-4-hydroxyphenyl)propane; the decomposition of this polymer is observed at temperatures exceeding 500 °C.[11]

Polyarylates derived from aromatic dicarboxylic acids possess a valuable set of properties: high heat resistance and thermal stability, effective insulating properties over a wide temperature range, and resistance to the action of many chemical reagents, UV light, and ionising radiation.

The physicochemical properties of these polymers are closely related to their structure and depend on the disposition of the functional groups in the initial components and also on the presence and nature of substituents. The highest melting points are observed for polyarylates whose monomers contain functional groups in the *para*-positions and have no aliphatic units. Thus poly(hydroquinone terephthalate) and *o*-hydroxybenzoic acid polyarylate (econol) do not melt up to 500 °C, and the softening temperatures of phenolphthalein–terephthalic acid and phenolphthalein–isophthalic acid polyarylates are 340 and 275 °C respectively.

The high heat resistance of cardo-polyarylates[11,12,56,76-79,82,92,99,102] greatly exceeds that of polyarylates with similar chemical structures but not containing cardo-groups. For example, the softening temperatures of polyarylates of terephthalic acid combined with phenolphthalein, phenolfluorene, and phenolanthrone are 340, 350, and 360 °C respectively, whereas that of poly[bis(4-hydroxyphenyl)diphenyl methane terephthalate] is 280 °C. The heat resistance of polyarylates increases significantly with increase in the number of aromatic rings in the initial components.

The presence of alkyl substituents in the *ortho*-positions relative to the hydroxy-group of the bisphenol as it were promotes the 'internal' plasticisation of the polyarylates based on them.[187-191] Polyarylates obtained from terephthalic acid and such bisphenols have lower softening temperatures [for example, the softening temperature of the 2,2-bis(4-hydroxy-3-methylphenyl)propane polyarylate is 180 °C] and a greater impact resistance and they can be more readily worked to form monolithic articles than the polyarylates derived from the corresponding ring-unsubstituted bisphenols.

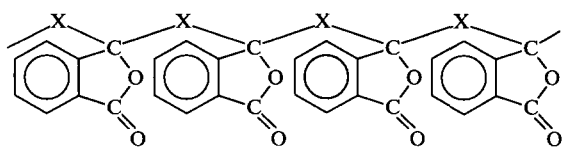


The properties of polyarylates are also closely related to the nature of the side substituents at the central carbon atom of the dihydric phenol.[192-199]

The decrease in the packing density of the polymer chains as a consequence of the presence of functional groups in the initial components in the *meta*- or *ortho*-positions rather than *para*-positions and the presence of side substituents in dihydric phenols promote the formation of amorphous polyarylates. The tendency of polyarylates to crystallise also diminishes with the appearance of an asymmetric substituent at the central carbon atom of the bisphenol.[4,11]

Since polyarylates based on phenolphthalein and an acid such as terephthalic it had always been obtained in the amorphous form, the impression was created initially that this is a specific feature of the cardo-polymers due to the large bulk of their cyclic substituents. However, deeper study of polyarylates with different cardo-groups made it necessary to revise this idea. It was found that, despite the large bulk of the cardo-group, these polymers are capable of crystallising. The conditions facilitating their crystallisation are the symmetry of the shape of the cardo-group (fluorene and anthrone groups) and the presence in the polymers of polar components (the anthrone group).

This made it necessary to look again at the lack of capacity for crystallisation in cardo-polyarylates containing cardo-groups with an asymmetric shape (phthalide and acenaphthene groups) and to attempt an explanation of this feature in terms of the atactic nature of the polyarylates obtained. As a consequence of the asymmetry of their shape and the statistical nature of the polycondensation reaction, the cardo-groups in such polymers are arranged in different nonordered ways relative to the main axis of the macromolecule (Scheme 6).



Scheme 6

Subsequently it was demonstrated for polyarylates with phthalimidine groups that polyarylates with asymmetric cardo-groups can also crystallise. This is apparently achieved by virtue of the presence of hydrogen bonds promoting a definite disposition and orientation of the macromolecules. A greater crystallinity can be achieved when the orientational mobility of the hydrogen is facilitated to the maximum extent (the H atom at the nitrogen atom is replaced by the CH_2CH_2OH group).[82]

The crystallisation of polyarylates with phthalimidine groups gives rise to the hope that, by an appropriate selection of the conditions in the synthesis or by subsequent treatment of the finished polymer, it may be possible to achieve the crystallisation also of polyarylates containing asymmetric cardo-groups such as the phthalide group. It is quite logical to suppose that this would be promoted by a regular disposition of the groups along the polymer chain (Scheme 7).

Scheme 7

The possibility of a deliberate change in structure is undoubtedly an important factor which will make it possible to achieve the desired modification of the properties of the polymers. For example, the heat resistance of the polyarylate obtained from phenolanthrone and terephthalic acid may be varied by altering the conditions in the synthesis and in the subsequent treatment of the polymer.[84,85,99] It increases significantly on passing from an amorphous polymer to one with an ordered structure: the amorphous polyarylate softens at ~340–360 °C, whilst the crystalline one does not soften before decomposition.[86]

Polyarylates with a definite structure also exhibit liquid crystal properties.[200–211]

The solubility of polyarylates is likewise associated with their chemical structure. Polyarylates derived from aromatic dicarboxylic acids such as terephthalic and isophthalic acids and biphenyl-4,4'-dicarboxylic acid and bisphenols such as hydroquinone and resorcinol are almost insoluble in organic solvents. The presence of side substituents in the bisphenol increases the solubility of the polyarylates. The polyarylates obtained from isophthalic acid, on the one hand, and 2,2-bis(4-hydroxyphenol)-propane, 2,2-bis(4-hydroxyphenyl)butane, and bis(4-hydroxy-phenyl)diphenylmethane, on the other, are soluble in cresol and chlorinated hydrocarbons. Compared with noncardo-polymers, cardo-polymers are much more readily soluble in organic solvents.[11,102] For example, the polyarylates obtained from phenolphthalein and aromatic dicarboxylic acids dissolve readily in methylene chloride, chloroform, dichloroethane, *sym*–tetra-chloroethane, tetrahydrofuran, cyclohexanone, etc., forming highly concentrated (> 25%) solutions.

The presence of mobile hydrogen atoms in the cardo-groups (for example, in the polyarylates of phenolphthalein imide), which are capable of involvement in the formation of hydrogen bonds, narrows the range of solvents. Such polyarylates no longer dissolve in chlorinated solvents but are readily soluble in solvents capable of forming hydrogen bonds with the mobile hydrogen atoms in the polyarylates (in dimethylformamide, tricresol, etc.).[81,82] Mixed polyarylates are more soluble than the homopolymers.[11]

Polyarylates possess film- and fibre-forming properties. In order to exhibit film-forming properties, the polymers must have an intrinsic viscosity (η_{int}) (in dichloroethane or tetrachloro-ethane) of the order of 0.4–0.5 dl g^{-1}, while the value required for fibre formation is approximately 1.0 dl g^{-1}. The breaking stress on extension of nonoriented polyarylate films is 600–1000 kgf cm^{-2}. The orientation of films in both directions can increase this value to 1500–2000 kgf cm^{-2}.

A valuable property of polyarylate films is their ability to retain effective mechanical parameters after prolonged heating at elevated temperatures. The breaking stresses on extension of nonoriented films of the cardo-polyarylates obtained by the reaction of diphenylphthalide-4,4'-dicarboxylic acid with phenol-phthalein and phenolphthalein anilide at 300 °C are 330 and 250 kgf cm^{-2} respectively. Films of mixed polyarylates obtained from 2,2-bis(4-hydroxyphenyl)propane and terephthalic and isophthalic acids withstand prolonged heating (for 1000 h) at 150–200 °C, retaining satisfactory mechanical parameters.

Polyarylates have effective dielectric parameters which do not change over a wide temperature range.[4,11,212,213] The relative permittivity of films of 2,2-bis(4-hydroxyphenyl)propane–phenolphthalein polyarylates is close to that of poly(ethylene terephthalate). The advantage of polyarylates over poly(ethylene terephthalate) and poly[2,2-bis(4-hydroxyphenyl)propane carbonate] consists in a smaller change in the dielectric loss angle and in the specific resistance of the bulk-phase material in the temperature range from −60 to 200 °C and above. The dielectric loss angle does not exceed $(4-5) \times 10^{-3}$ for 2,2-bis(4-hydroxy-phenyl)propane polyarylates and $(5-8) \times 10^{-3}$ for phenol-phthalein polyarylate in the same temperature range. Whereas the maximum in the dielectric loss angle is observed at 140 °C for poly(ethylene terephthalate) and at 200 °C for poly[2,2-bis-(4-hydroxyphenyl)propane carbonate], in the case of phenol-phthalein polyarylates it has not been observed even at 300 °C. The bulk-phase value of the resistivity of 2,2-bis(4-hydroxy-phenyl)propane and phenolphthalein polyarylate films is about $(1-3) \times 10^{13}$ Ω cm at 200 °C, which is 1.5–2 orders of magnitude higher than for poly(ethylene terephthalate) and the polycarbonate.

Polyarylates are resistant to the prolonged action of inorganic and organic acids (with the exception of sulfuric acid), oxidants, and dilute alkalis, but are inadequately resistant to the action of concentrated solutions of alkali and ammonia.[214]

The polyarylates of aromatic dicarboxylic acids are char-acterised by high thermal stability.[43,215] The polyterephthal-ates of 2,2-bis(4-hydroxyphenyl)propane, phenolphthalein,

phenolanthrone, and phenolfluorene under an inert atmosphere begins to lose mass at 350–360 °C for a heating rate of 5 °C per minute. The decrease in the mass of the phenolphthalein–biphenyl-4,4'-dicarboxylic acid polyarylate during isothermal heating in air at 400 °C for 1 h is about 7%.

Polyarylates burn but do not support combustion. The polymers containing chlorine (up to 13%) and phosphorus in the macromolecule exhibit an enhanced fire resistance and also a high resistance to the action of ionising radiation. The radiation yield of the gaseous products of the radiolysis of these polymers, obtained by the polycondensation of isophthalic acid chloride with 2,2-bis(4-hydroxyphenyl)propane and hydroquinone, is of the order of 0.02 of a molecule per 100 eV, which is appreciably less than the yield of gases on irradiation of poly(ethylene terephthalate) and the polycarbonate. The molecular structure of polyarylates does not change significantly for doses of the order of 10^{23} eV cm^{-3}.[216]

Table 3 presents certain properties of the phenolfluorene–terephthalic acid polyarylate. Evidently high heat resistance, thermal stability, and dielectric parameters are characteristic of this polymer over a wide temperature range.[108,109] Films of this polymer retain an appreciable strength even at 350 °C.

The cardo-polyarylates based on polycyclic bisphenols containing norbornane groups at the central carbon atom also possess a high heat resistance, effective physicomechanical and dielectric parameters, and a high solubility.[78,87,88]

The synthesis of mixed polymers based on several dicarboxylic acid chlorides or bisphenols as well as the synthesis of block-copolymers with polyarylate fragments in the chain have given rise to extensive possibilities for specific regulation of the properties of polyarylates. One of the methods for synthesis of the block-copolymers with polyarylate fragments involves, as mentioned above, their preparation from oligomers, previously synthesised, with a specific molecular mass and functional groups of different nature. By varying the molecular mass of the initial block components and their chemical nature, it is possible to regulate within wide limits the properties of such block-copolymers. We shall consider certain examples.

It is of interest that, despite the polyblock nature of their construction, polyarylate–siloxane block-copolymers possess a distinct microheterogeneous structure ensuring the retention of the high-temperature properties of the rigid block and the low-temperature properties of the flexible block. All the polyarylate–dimethylsiloxane copolymers have two glass points corresponding to the polydimethylsiloxane (−120 °C) and the polyarylate (for example, 320 °C in the case of the phenolphthalein–terephthalic acid polyarylate) and combine the properties of both homopolymers (strength, elasticity, gas-separating properties, etc.). Nonvulcanised films of such block-copolymers retain high ultimate strengths and relative elongations over a wide temperature range, which is related to the glass point of the rigid block and the phase incompatibility of the two blocks in the polyblock system. Table 4 shows that, after exposure to air at 250 °C for 10 h, the films of the block-copolymers remain elastic.[124]

Table 4. Mechanical properties of the polyarylate-siloxane block-copolymers $-[OROC(O)R'CO]_{10}ORO[Si(CH_3)_2O]_y-$.

[a] After ageing for 10 days at 250 °C.

In the case of polyarylate–arylene sulfone oxides,[119–123,136,137] microphase separation is difficult and a monotonic variation of the properties takes place over a wide range of compositions, as happens in the case of statistical copolymers. However, it has been found that, when the polyarylate–arylene sulfone oxide contains 10–15 mass% of arylene sulfone oxide blocks, a seemingly abrupt change in properties takes place, being manifested, in particular, by a sharp increase in the viscosity of their concentrated solutions and melts. This decrease reaches several orders of magnitude, the viscosity approaching the value for the poly(arylene sulfone oxide) melt. Thus, whereas the viscosities are $10^{4.0}$ P for the poly(arylene sulfone oxide) melt, $10^{7.0}$ P for the polyarylate F-1, and $10^{6.0}$ P for the polyarylate D, the viscosity of the block-copolymer based on the polyarylate F-1 and poly(arylene sulfone oxide) [obtained from 2,2-bis-(4-hydroxyphenyl)propane and bis(4-chlorophenyl) sulfone], in which the content of the latter is 10 mass%, amounts to $10^{4.5}$ P and that of the block–copolymer based on the polyarylate D and the same polysulfone for a content of the latter of 12 mass% is 10^4 P. This leads to the possibility of successful working of such block-copolymers by casting under pressure (which constitutes their advantage over homopolyarylates) whilst retaining a higher heat resistance than that of the initial polysulfone.

Table 5. Properties of polyarylate-arylene sulfone oxide block-copolymers.

Parameter	Brand of block-copolymer

Table 5 shows that polyarylate-arylene sulfone oxides have effective mechanical and electrophysical properties.[136] The properties of these block-copolymers can be altered specifically by varying the microstructure of the polymer chain and its chemical structure and composition.

A complex transformation of the phase composition from single-phase to three-phase takes place in polyblock polyarylate-ethylene oxide block-copolymers containing relatively short individual blocks with a definite compatibility.[140] In contrast to the block-copolymers with full phase separation, such as polyarylate-dimethylsiloxanes,[126,128] the phase separation in polyarylate-ethylene oxide block-copolymers depends on the mass ratios of the individual blocks and also on their molecular masses.[140]

Table 6 presents certain mechanical properties of polyarylate-ethylene oxide block-copolymers.[141] They show that, by varying the ratio of block sizes, it is possible to vary the properties of the block-copolymers within wide limits. Thus the strength of the films varies from 90 to 1000 kgf cm^{-2}, the deformation at rupture varies from 30% to 700%, and the modulus of elasticity varies from 400 to 17 000 kgf cm^{-2}. It is also noteworthy that the ratio of the reversible and irreversible deformations of the films likewise varies significantly under these conditions. For example, the high elastic deformation reaches 50% in the block-copolymer having the composition $x:y = 5:91$ (the molecular mass ratio is 2500:4000) and in terms of all their properties the block-copolymers having this composition approach an elastomer.[141]

Together with the synthesis of polycondensation block-copolymers containing block sequences of various heterochain polymers, block-copolymers based on block components comprising carbochain polymers have been synthesised. In particular, polyarylate-butadiene and polyarylate–arylene sulfone oxide–butadiene block-copolymers have been obtained and investigated using oligobutadiene and its derivatives as one of the block components.[142–144,147,148] Such construction of the polymer chain leads to new possibilities for the modification of polyarylate polymers. Thus it is known[12] that the deformation of

polyarylates takes place without the formation of a 'neck'. The appearance of a 'neck' has been observed in the deformation of polyarylate-butadiene block-copolymers containing up to 30% of polybutadiene blocks, which is associated with the increased mobility of the polyarylate phase owing to a kind of plasticisation of the latter by the polybutadiene blocks.[142]

We shall consider yet another type of polymer—carbaborane-containing polyarylates. The most interesting carbaborane-containing polyarylates have been synthesised from 1,2- and 1,7-bis(4-carboxyphenyl)carbaboranes combined with various bisphenols[216-229] or from 1,2-bis(4-hydroxyphenyl)-carbaborane (phenolcarbaborane) combined with the chlorides of various aromatic dicarboxylic acids.[230-233] These polyarylates have been synthesised by acceptor-catalytic and high-temperature polyesterification in solution.

Table 7 presents as an example data on the polyarylates derived from 1,2- and 1,7-bis(4-carboxyphenyl)carbaboranes. Polyarylates with diphenylcarbaborane fragments in the chain dissolve in a wide range of organic solvents. It must be emphasised that, in contrast to the usual cardo-polyarylates which are also readily soluble, many carbaborane-containing polyarylates exhibit a high solubility in solvents such as aromatic hydrocarbons (benzene, toluene, xylene), polyarylates derived from the less symmetrical and more polar isomer of bis(4-carboxyphenyl)-*o*-carbaborane being somewhat more soluble.[219] Like the usual polyarylates, strong colourless films can be obtained from the carbaborane-containing polyarylates by casting from solutions.

The softening temperatures of the polyarylates obtained from the *ortho*- and *meta*-isomers of bis(4-carboxyphenyl)carbaborane and dihydric phenols having the same composition are virtually identical under the conditions of a comparable phase state. The polyarylates derived from dihydric phenols of the cardo-type have the highest softening temperatures (340–360 °C).

In the case of a mononuclear dihydric phenol of the type of hydroquinone or a dinuclear one of the type of bis(hydroxyphenyl)propane the structure of the polyarylates derived from the more symmetrical *meta*-isomer of bis(4-carboxyphenyl)carbaborane is more ordered than that of the polyarylates of the *ortho*-isomer. Thus, whereas the polyarylate obtained from 1,2-bis-(4-carboxyphenyl)carbaborane and 2,2-bis(4-hydroxyphenyl)propane by acceptor-catalytic polycondensation is amorphous, the corresponding polymer based on the *meta*-isomer has a crystalline structure with a high degree of order. The polyarylates synthesised from 1,7-bis(4-carboxyphenyl)carbaborane and dihydric phenols of the cardo-type differ little from the analogous polymers based on the *ortho*-isomer as regards the degree of order. According to X-ray diffraction data, these polyarylates have a crystalline structure with an average degree of order.

The thermal properties of the polyarylates with the diphenylcarbaborane fragments in the chain described above have been considered in a number of studies.[217-219,221-225] According to the results of thermogravimetric analysis, in air the mass of the carbaborane-containing polyarylates begins to change at a temperature higher by 20–60 °C than for the usual polyarylates. Slower degradation processes are characteristic of the carbaborane-containing polyarylates and in a number of cases sections corresponding to the retardation or cessation of the degradation in the temperature range between 600 and 650 °C are observed on the thermogravimetric curve. The high 'coke' residue (from 50%

Table 7. The properties of polyarylates obtained by the acceptor-catalytic (A) and high-temperature (B) polycondensation of 1,2-bis-(4-carboxyphenyl)carbaborane (*ortho*) and 1,7-bis(4-carboxyphenyl)carbaborane (*meta*) with various dihydric phenols.

Remarks. All the polymers A were obtained in the presence of triethylamine in acetone over a period of 1 h at 45–50 °C. The polymers B were obtained in α-chloronaphthalene over a period of 10–16 h at 220 °C. The yields of the polymers were nearly quantitative. All the properties other than η_{int} are quoted for polymers obtained by method A.

[a] The temperature corresponding to the point of intersection of the tangents to the thermomechanical curve in the region of the onset of flow for a load of 0.8 kgf cm^{-2} was adopted as the softening temperature.

[b] The temperature was determined from the thermogravimetric curve at a heating rate of 4.5 °C per minute in air.

[c] Isothermal conditions in air over a period of 3 h.

[d] The molecular mass, determined by the light scattering method, was 116000.

to ~90% relative to the initial mass of the polymer), characteristic of the bis(4-carboxyphenyl)carbaborane polyarylates when the latter are heated in air to 900 °C should also be mentioned, as the usual polyarylate burns completely at 650–700 °C.

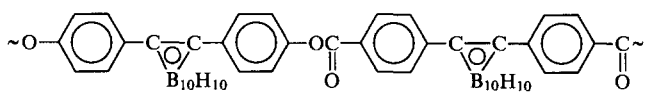
This difference is manifested even more clearly when carbaborane-containing polyarylates and the polyterephthalate of phenolfluorene are heated under isothermal conditions in air. Thus, after being heated at 400 °C for 3 h, the mass of the carbaborane-containing polyarylates (Table 7) diminishes by 2%–15%, whereas the polyterephthalate of phenolfluorene begins to decompose even before 400 °C is attained and the degree of decomposition increases monotonically, reaching 35% of the initial mass after 3 h.

Under an inert atmosphere, the mass of all the bis(4-carboxyphenyl)carbaborane polyarylates begins to change at the same temperature as in air, while the 'coke' residue amounts to ~80%–90% after thermal degradation, in many instances actually at higher temperatures than on heating in air.[219]

An appreciably lower content of carbon oxides and a high content of hydrogen in the gaseous products together with a lower degree of decomposition are characteristic of the thermal degradation processes involving polyarylates with diphenylcarbaborane fragments (compared with the usual polyarylates).[217,223,224] This difference is more striking for polyarylates with *o*-carbaborane groups in the chain. The evolution of hydrogen at comparatively low temperatures and with a low activation energy (~20 kcal mol^{-1}) and the results of the analysis of the thermal behaviour of compounds modelling fragments of the molecules of carbaborane-containing polyarylates and the products of the possible reactions led to the assumption that this phenomenon is due to heterolytic and not homolytic processes. The carbaborane ring exerts a stabilising influence on the thermal stability of the ester linkage. It has been noted that the thermal decomposition of the polyarylate obtained from bis-(4-carboxyphenyl)-*o*-carbaborane and phenolfluorene proceeds via two mechanisms: heterolytic reactions predominate up to 450 °C, whilst radical processes predominate at higher temperatures.[223]

Derivatives of dicarbaundecaborate have been detected in the products of the thermal degradation of carbaborane-containing polyarylates and the corresponding model systems in the presence of nucleophiles, including water.[221,223] This suggests that water, a certain amount of which is always present in polymers, behaves as a nucleophile disrupting the carbaborane ring to form the dicarbaundecaborate anion in the first stage of the degradation of the carbaborane-containing polyarylate. The consumption of water in this reaction with the carbaborane ring rules out the hydrolysis of the ester linkage, which plays the main role in the initial stage of the degradation of the usual polyarylates. This promotes in the case of the carbaborane-containing polyarylates the retention of the weak polyarylate link (the ester group) at higher temperatures.

Comparative study of the thermal and thermooxidative degradation of the 1,2-bis(4-carboxyphenyl)carbaborane–phenolfluorene polyarylate and the polyterephthalate of phenolfluorene revealed yet another characteristic feature of the behaviour of these polymers.[222] In vacuo, the onset of gel formation occurs sooner in the case of the *o*-carbaborane-containing polymer and a 100% degree of reaction is attained already at 350 °C, whereas the gel content in the case of the terephthalic acid polyarylate is only 2.7%. Under oxidation conditions, the *o*-carbaborane-containing polyarylate begins to lose its solubility much sooner and is fully cross-linked already at 275 °C, whereas the terephthalic acid polyarylate contains only 30% of the gel even at 350 °C.



In the synthesis of polyarylates based on phenolcarbaborane and the chlorides of terephthalic, isophthalic, biphenyl-4,4′-carboxylic oxybis(benzene-4-carboxylic), and diphenylphthalide-4,4′-dicarboxylic acids, polyarylates with relatively high intrinsic viscosities were obtained only in the last two cases (0.92 and 0.62 dl g^{-1} respectively in tetrachloroethane).[230] Regardless of the conditions in the synthesis, the polyarylates derived from these dicarboxylic acids have an amorphous structure, whereas the terephthalic and biphenyl-4,4′-dicarboxylic acid polyarylates, obtained by high-temperature polycondensation, have a crystalline structure with a high degree of order according to X-ray diffraction data and are insoluble. The polymer obtained from isophthalic acid, which is less ordered and more soluble, occupies an intermediate position, but it too was obtained with low intrinsic viscosities of the solutions (0.20–0.31 dl g^{-1} in tetrachloroethane). In all cases, these polymers precipitated during polycondensation even for low degrees of conversion and subsequent polycondensation could take place only under heterogeneous conditions. The limited solubility, caused by the crystallisation of the polymers during their formation, is apparently the reason for their low molecular mass.

In comparing the properties of polyarylates derived from phenolcarbaborane polyarylates based on its carboxyl analogue — 1,2-bis(4-carboxyphenyl)carbaborane — one should note that the latter are readily soluble and are amorphous or are comparatively little ordered when dihydric phenols such as hydroquinone, 2,2-bis(4-hydroxyphenyl)propane, and bis(4-hydroxyphenyl) ether are used. Conversely, they are more ordered when dihydric cardo-phenols are employed: phenolphthalein, phenolfluorene, and phenolanthrone.[231] The softening temperatures of the amorphous polyarylates obtained by the polycondensation of phenolcarbaborane with oxybis(benzene-4-carboxylic) and diphenylphthalide-4,4′-dicarboxylic acids are 275 and 330 °C. The isomeric amorphous polyarylate obtained from 1,2-bis(4-carboxyphenyl)carbaborane and bis(4-hydroxyphenyl) ether softens at 290 °C, i.e. whether the *o*-carbaborane group is linked to the hydroxyphenyl or carboxyphenyl residues is immaterial as regards the softening temperatures of the amorphous polyarylates with an isomeric structure.

Under the conditions of dynamic thermogravimetric analysis, the mass of phenolcarbaborane polyarylates begins to change at 350–400 °C in air and at 360–410 °C in an inert medium. All these polymers contain a large 'coke' residue on heating to 900 °C both in air (70%–85%) and in an inert medium (85%–90%).

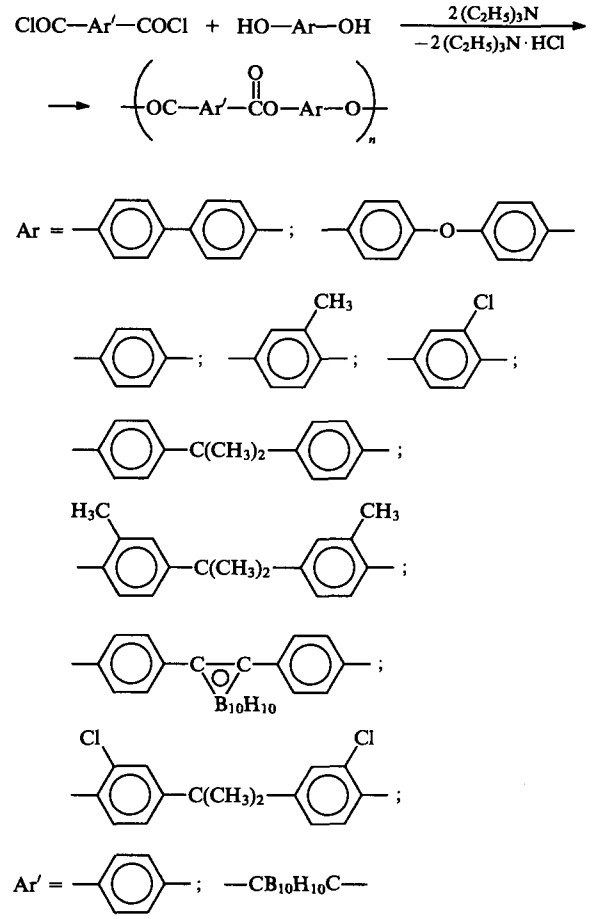
A polyarylate the polymer chain of which was made up only of alternating ester and 1,2-diphenylcarbaborane fragments has been synthesised by the polycondensation of 1,2-bis(4-hydroxyphenyl)-carbaborane with the acid chloride of 1,2-bis(4-carboxyphenyl)-carbaborane (Scheme 8).[232]

Scheme 8

It was found that, regardless of whether the polymer was synthesised by acceptor-catalytic polycondensation in acetone in the presence of triethylamine or by high-temperature polycondensation in chlorinated biphenyl or α-chloronaphthalene, the polymer formed had a crystalline structure (degree of crystallinity is 35%–55%) and was insoluble in any of the solvents known for polyarylates with the exception of tetrahydrofuran. The polymers obtained by high-temperature polycondensation in α-chloronaphthalene at 220 °C over a period of 15–18 h have the highest crystallinity. As already mentioned, by varying the polycondensation condition and also the subsequent treatment of the polymer, it is possible to alter its physical structure. Thus it has been observed that, after reprecipitation from solution in tetrahydrofuran in cold water or methanol, the polymer becomes amorphous and soluble in solvents such as chloroform, tetrachloroethane, cyclohexanone, and benzene. Depending on the degree of conversion into the amorphous form, the polymers soften at 260–290 °C, whereas the crystalline specimens do not melt up to 400 °C. Above this temperature, their thermal degradation begins.

Interesting results have been obtained in the study of the thermal stability of the polyarylate obtained from phenolcarbaborane and 1,2-bis(4-carboxyphenyl)carbaborane with different degrees of crystallinity [232,233] under the conditions of dynamic thermogravimetric analysis in air, under an inert atmosphere, and also under isothermal conditions at 400 °C for 3 h.

The highest-melting specimen usually has the highest thermal stability among polymers of the same or similar chemical structure which pass to the highly elastic or fused state at different temperatures. This can be accounted for by the diffusional inhibition of the degradative processes in the solid phase of the polymer. The opposite behaviour has been observed for the carbaborane-containing polyarylate considered: under the conditions of both dynamic (in the temperature range 400–500 °C) and isothermal (400 °C, 3h) thermogravimetric analysis, the specimen converted into the amorphous form exhibits the smallest weight loss.

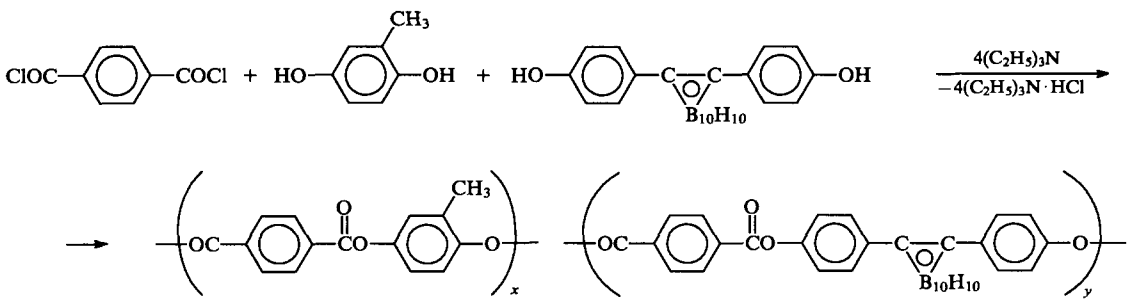


With increase in the degree of crystallinity of the polymer, the weight loss increases in all cases. Thus the mass of the specimen converted into the amorphous form does not change up to 650 °C, while the mass of the crystalline polymers diminishes already at 400 °C. It has been suggested that the different types of behaviour on heating of the crystalline carbaborane-containing polyarylate specimen and the specimen converted into the amorphous form may be caused by the difference between their molecular mobilities in the range 280–380 °C. [233] The increased thermal stability of the amorphous polymer with a relatively low softening temperature is caused either by the enhanced stabilising influence of the carbaborane groups in the polymer melt or by the formation of thermally more stable secondary structures as a result of the interaction of the carbaborane groups, the occurrence of which in the melt or in the highly elastic state is facilitated. In highly crystalline polymers with a high melting point, the manifestation of these effects is evidently hindered. [232]

The possibility of obtaining organoelement liquid crystal polymers from carbaborane-containing polyarylates has recently attracted the attention of investigators. [146,210,211,234]

Thus the polyarylates whose structures are presented in Schemes 9 and 10 have been obtained [146,234,235] by acceptor-catalytic polycondensation from bis(4-hydroxyphenyl)-*o*-carbaborane, the chloride of carbaborane-*m*-dicarboxylic acid (as the carbaborane-containing components), terephthalic acid chlorides, and various bisphenols.

The properties of carbaborane-containing polymers such as retarded thermal and thermo-oxidative degradation, effective mechanical properties, and high yields of the 'coke' residues in the products on heating, due to the involvement of the carbaborane fragments in the formation of three-dimensional structures, constitute a positive factor in the creation of thermostable and heat resistant materials. [229] Therefore one of the approaches to the preparation of new copolyarylate liquid crystal carbaborane-containing structures with an improved thermal stability involves the introduction of carbaborane-*m*-dicarboxylic acid and phenylcarbaborane fragments into the structures of various homo- and copolyarylates.



Scheme 9

The study of the properties of the polymers and copolymers obtained showed that, on passing from the high-melting polyterephthalate of 4,4′-dihydroxybiphenyl (does not melt up to 500 °C) to the carbaborane-*m*-dicarboxylic acid copolyarylates (i.e. on replacing some of the terephthalic acid units by the carbaborane-*m*-dicarboxylic acid units in the polyarylate structure), the softening temperature of the polymer falls appreciably (to 140 °C). A solid–liquid crystal transition (the temperature range of the mesophase is 260–350 °C) then appears in the copolymer with a molar content of the carbaborane-*m*-dicarboxylic acid (relative to the sum of the dicarboxylic acids) of 90 mol.% at 260 °C. On the other hand, the complete replacement of terephthalic acid residues by carbaborane-*m*-dicarboxylic acid residues in the polyester structure leads to the formation of poly(4,4′-dihydroxybiphenyl carbaborane-*m*-dicarboxylate) with a softening temperature of 240 °C and lacking liquid crystal properties.

The introduction of carbaborane-*m*-dicarboxylic acid fragments into the structure of the polyterephthalates of 2,2-bis-(4-hydroxyphenyl)propane, hydroquinone, or their chloro- or

Scheme 10

methyl-substituted derivatives leads to an appreciable decrease in the softening temperatures of the polymers. The presence or absence of the mesophase in the three-component copolyarylate structures depends on their quantitative content of carbaborane-*m*-dicarboxylic acid fragments. For example, the copolyarylate based on chlorohydroquinone and the chlorides of terephthalic and carbaborane-*m*-dicarbocyclic acids, introduced into the reaction in molar proportions of 1:0.8:0.2, has a softening temperature of 220 °C and the temperature range of the mesophase is 250–350 °C. In the case of four-component copolyarylates containing hydroquinone, 2,2-bis(4-hydroxyphenyl)-propane, and their chloro- or methyl-substituted derivatives, the introduction of small amounts of carbaborane-*m*-dicarboxylic acid (for example, 20 mol.%) leads to the loss of liquid crystal properties by the copolyarylates.

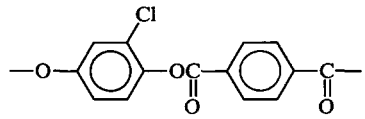
Table 8 presents as an example data on the homo- and co-polytetraphthalates of chlorohydroquinone and bis(4-hydroxyphenyl)-*o*-carbaborane.

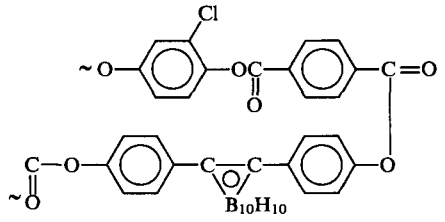
It is noteworthy that the copolyterephthalates based on chlorohydroquinone and hydroxyphenylcarbaborane have lower softening temperatures than the copolyterephthalate of hydroquinone and hydroxyphenylcarbaborane owing to the introduction into the polymer structure of asymmetrically constructed fragments in the form of chlorohydroquinone residues. The transition to the mesophase occurs at a higher temperature the smaller the amount of hydroquinone introduced into the copolymer structure.

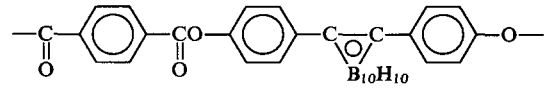
The temperature corresponding to the formation of the mesophase in carbaborane-containing copolyarylates based on hydroxyphenylcarbaborane shifts towards higher values (by 70–80 °C) compared with the copolyarylates containing carbaborane-*m*-dicarboxylic acid fragments.

The liquid crystal properties of carbaborane-containing copolyarylates based on asymmetric monomers having, as it were, a 'head' and a 'tail', in particular chlorohydroquinone and methylhydroquinone, are influenced not only by the ratio of the initial components in the copolymer structure but also by the microstructure of the copolymer: the sequence in which the comonomers alternate in the polymer chain and the direction in which the 'heads' and 'tails' of the asymmetric monomer are arranged. Thus, among the copolymers obtained from methylhydroquinone and the chlorides of terephthalic and carbaborane-*m*-dicarboxylic acids in molar proportions of 1.0:0.4:0.6[146] only those with a block structure are capable of undergoing a transition to a liquid crystal melt.

In order to investigate the effect of thermal influences on the structure and properties of copolymers containing carbaborane-*m*-dicarboxylic acid units, the copolyterephthalate of chlorohydroquinone carbaborane-*m*-dicarboxylate, containing 20 mol.% of carbaborane-*m*-dicarboxylic acid, was heated in air at 200 °C for 6 h. It was then found that the specimen retained its original composition, structure, and properties after the heat treatment.[146]







According to the results of a thermogravimetric study, chlorohydroquinone polyterephthalate decomposes totally in air at 600 °C (heating rate 5 °C min^{-1}), while the copolyarylate containing 20 mol.% of carbaborane-*m*-dicarboxylic acid affords a 65% yield of the 'coke' residue at the same temperature; the 'coke' residue of the copolyarylate containing 60 mol.% of carbaborane-*m*-dicarboxylic acid is 80%. Thus the presence of the carbaborane nucleus has a positive effect on the thermal properties of the liquid crystal copolyarylates obtained.

Together with their influence on the thermal characteristics, the carbaborane fragments in the macromolecules also alter the solubilities of the polymers. Thus the presence of 20 and 50 mol.% of carbaborane-*m*-dicarboxylic acid fragments (relative to the total acids) in the structure of the insoluble methylhydroquinone polyterephthalate led to the formation of soluble copolyarylates. Similarly, the introduction of bis(4-hydroxyphenyl)-*o*-carbaborane fragments into the structure of insoluble polyterephthalates of hydroquinone and its chloro- and methyl-substituted derivatives promotes an improvement in solubility and all the copolyarylates indicated are soluble in organic solvents.[146,234]

Thus the presence of carbaborane-containing fragments in the polymer structures lowers the softening temperatures of the copolyarylates and the temperatures corresponding to the transition to the liquid crystal state, improves their thermal properties, and helps to make them soluble.

It is useful to carry out further studies on carbaborane-containing liquid crystal polyarylates in order to establish the possibility of detecting the mesophase in the polymer on heating to 250 °C and above as a result of the thermal transformations of the *o*- and *m*-carbaborane nuclei which lead to the formation of a three-dimensional cross-linked structure.[229]

Table 8. The results of the synthesis and of the study of the properties of homo- and co-polyterephthalates of chlorohydroquinone and bis(4-hydroxyphenyl)-*o*-carbaborane.

Structure of homo- and co-polyarylates	Molar monomer ratio	η_{int}/dl g^{-1}	X-Ray diffraction data	T_{decomp}/ °C	Temperature range of mesophase/ °C
	1.0:1.0	insoluble	crystalline	160	none
	0.6:1.0:0.4	0.34	weakly-crystalline	195	230–400
	0.5:1.0:0.5	0.37	"	200	235–400
	0.4:1.0:0.6	0.40	"	210	245–400
	1.0:1.0	0.15	amorphous	215	none

The syntheses and properties of polyarylates of different structure were examined above and it was shown that the most promising method for their synthesis is the polycondensation of dicarboxylic acid chlorides with bisphenols carried out in different versions. However, attempts have been made to obtain polyarylates also in other ways.[146]

The new methods for synthesis of polyarylates include their preparation by the method of 'carbonylation' polycondensation resulting from the use of carbon monoxide and aromatic dihalocompounds combined with bisphenols in the presence of palladium catalysts, in place of the traditional dicarboxylic acids or their derivatives, as the acid component in the polycondensation process. Thus polyarylates with average intrinsic viscosities have been obtained by the reaction of 2,2-bis-(4-hydroxyphenyl)propane (or other bisphenols), bis(4-bromophenyl) ether, and carbon monoxide in the presence of palladium catalysts at 115 °C in chlorobenzene.[236-241]

The synthesis of polyarylates was also tried by comparatively new polycondensation methods such as 'direct',[69,146,242-258] 'activated',[69,146,259,260] and 'silylated'[146,261-271] polycondensation.

The 'direct' polycondensation leads to the possibility of carrying out the polycondensation process directly between the dicarboxylic acid (and not its derivatives) and the bisphenol in solution at a moderate temperature by employing special condensing agents (for example, triphenylphosphine dichloride, arenesulfonyl chloride, or hexachlorocyclotriphosphazene frequently in combination with other compounds).

The 'activated' polycondensation is based on the activation of the process by employing in the latter monomers having the appropriate structure [for example bis(2,5-dinitrophenyl) isophthalate or adipate, bis(pentachlorophenyl) isophthalate, etc.], containing groups which activate the terminal functional groups of the monomer in the part of the molecule which enters into the composition of the low-molecular-mass product during polycondensation and does not participate in the construction of the chain. This method makes it possible to carry out the process under comparatively mild conditions and is characterised by little tendency towards side reactions.

The 'silylated' polycondensation is based on the use of silylated nucleophilic monomers, in particular bisphenols and carboxylic hydroxyacids, as the starting materials in the polycondensation process. The silylation of the monomers leads to the possibility of altering their reactivity, frequently increasing it appreciably. The employment of silylated monomers instead of 'free' monomers makes it possible in a number of instances to carry out the polycondensation process under milder conditions, avoiding undesirable side reactions. However, in many cases the new methods do not lead to the desired results. There is no doubt that they still require further development and improvement.

III. Applications of polyarylates

Polyarylates are worked to produce articles by cast moulding, moulding under pressure, extrusion, vortical sputtering and, in the case of soluble polyarylates, also by employing their solutions.[11,56,214,272-278]

It was found that an infusible and insoluble polyarylate such as econol, can be used successfully to produce monolithic articles by sintering at 425–450 °C under a pressure of 350–1400 kgf cm^{-2} and also by high-speed forging. Econol coatings can be obtained by a plasma method (in a helium atmosphere).

The high heat resistance of polyarylates combined with their effective strength parameters have led to extensive possibilities for the use of these polymers as constructional articles (components for automation and other mechanisms); by virtue of their effective insulating properties, they are used successfully in radio engineering and electrical engineering (shells for coils, plugs, disconnecting devices, etc.) and in the electronic industry.[11,56,273,277,279,280]

Heat-resistant polyarylate films are obtained by extrusion or casting from solution and are used as electrically insulating materials. Polyarylates are also employed for the preparation of varnishes. By virtue of their high solubility and compatibility with various polymers, cardo- and other polyarylates are used successfully for the preparation of valuable composite materials.

For example, oligoepoxide-polyarylate compositions are used as casting compounds, sealing coatings, binders for reinforced plastics, etc. They exhibit enhanced heat resistance (~250 °C); the ultimate compressive strength of such systems reaches 800 kgf cm^{-2} and the ultimate bending strength is up to 1700–2000 kgf cm^{-2}, which is almost twice as high as the analogous parameters of systems hardened without using polyarylates.[309] In terms of their properties, such compositions are not inferior to materials containing mineral fillers and, in terms of a series of parameters, they are superior to them. Thus they are distinguished by a significantly higher specific gravity (by ~40%) and a high capacity to resist repeated thermal shocks following changes in temperature from −60 to 250 °C.

The introduction of a polymer such as the terephthalic acid–phenolphthalein polyarylate into an epoxide composition leads to the formation of not only strong and lighter materials but also of materials capable of being employed over a wide range of temperatures and loads.[310,311] The study of the properties of oligoepoxide-polyarylate compositions has demonstrated the extensive possibilities for the regulation of the mechanical properties of these network systems, including those associated with vibroabsorption.[310,312,313] Materials based on oligoepoxide polyarylate compositions exhibit a low creep when subjected to high loads.[313]

Filled materials such as antifriction products, which have a low coefficient of friction and can be employed for a long time without a lubricant at high temperatures (250 °C), *in vacuo*, and for high velocity gradients between friction surfaces (sliding and roller bearings) are also obtained from polyarylates. It has been suggested that highly heat-resistant antifriction self-lubricating coking plastics, ensuring the operation of dry friction units at temperatures in the range 350–500 °C, be prepared by employing in such plastics carbaborane-containing polymers including carbaborane-containing polyarylates which can be converted during preparation into a high-strength coke, constituting a sterically structured polymeric system, without altering the initial mass and shape of the article.[229,314-316]

For example, heat-treated materials comprising carbaborane-containing polyarylates [obtained from the acid chloride of 1,2-bis(4-carboxyphenyl)carbaborane and phenolfluorene or 1,2-bis(4-hydroxyphenyl)carbaborane] and graphite have the following physicomechanical parameters: coefficient of friction 0.05–0.09, intensity of linear wear $(2.5-5) \times 10^{-9}$, and limiting working temperature 500 °C.

It has been noted that compositions containing polyarylate, polyester imide, and a filler are technologically suitable for moulding and the preparation of impact-resistant articles.[281] The glass-reinforced polyarylates based on 2,2-bis(4-hydroxyphenyl)-propane and mixtures of terephthalic and isophthalic acid chlorides containing also a mineral filler possess a valuable set of properties.[290] Impact-resistant compositions with improved low-temperature properties (worked on a casting machine), which are used to manufacture motorcar components, are obtained from mixtures of polyarylates with poly(alkylene terephthalates) and other polymers.[292] Electrically conducting transparent polymer compositions have been developed. They were obtained by the crystallisation in situ of tetraselenatetracene chloride in a polyarylate matrix.[299]

It is noteworthy that filled polyarylate materials can be obtained not only by processing finished polyarylates with a filler but also directly during the synthesis of the polymer by polycondensation in the presence of fillers, which may play the role of a homogeneous or heterogeneous matrix.[270,317-320] For example,

mixtures of polyterephthalates of 2,2-bis(3-chloro-4-hydroxyphenyl)propane with graphite, obtained by polycondensation, are superior to blends obtained by the mechanical mixing of a finished polyarylate with a filler in terms of many properties (thermal characteristics, specific impact stength, specific electrical resistance, and a lower coefficient of friction).

The solubility of cardo-polyarylates leads to the possibility of their successful conversion from a solution into films and fibrous materials, which are used for the purification of gases and liquids and for the trapping of aerosols. Depending on the operating conditions, such filter materials can be employed at temperatures up to 300 °C.[11,56]

Polycondensation block-copolymers with a polyarylate base also possess useful properties.[56,145,146] Thus films of polyarylate-siloxane block-copolymers of the Silar type have a valuable set of physicomechanical and gas-separating properties. Their tensile strength reaches 500 kgf cm^{-2} in many cases. They possess a high elasticity and permeability to gases, the latter approaching that of polydimethylsiloxane, but their mechanical strength is higher than that of the latter material. This leads to the successful employment of such polymers in engineering and medicine (for example, as membrane gas oxygenators).

Polyarylate-arylene sulfone oxides with a small content of arylene sulfone oxide (~15%) exhibit a high heat resistance, which is close to that of polyarylates, but the viscosity of their melts is appreciably lower than that for the latter compounds, which significantly facilitates the working of such block-copolymers. Heat-resistant (prolonged heat resistance at 200–230 °C) polyarylate-arylene sulfone oxide cast thermoplastics, designed for constructional and electrical insulating purposes, can be used for the manufacture of articles for electronic engineering electrically insulating materials, and components subjected to appreciable loads at elevated temperatures.[136]

* * *

The foregoing review shows that polyarylates constitute an extremely promising class of polymers, which can be used successfully in many branches of engineering where a high heat resistance, photostability, and effective electrical insulating, mechanical, etc. parameters are needed.

The knowledge of the characteristic features of the formation of polyarylates and of the relation between their structure and properties leads to extensive prospects for the specific design of the polyarylate chain and hence for imparting a set of desired properties to such polymers.

This review has been written with the financial support of the Russian Fundamental Research Fund (grant 94-03-4288).

Abstract. We review the quantitative relationships between the degradation kinetics of the main classes of polymers (polyolefins, polyesters, polyamides, elastomers) used as implants. Their biocompatibility criteria and the reactions of the organism on the implants are considered, and the catalytic activity of biological media (water, salts, enzymes) are discussed together with problems in the metabolism and conjugation of the degradation products. The bibliography includes 127 references.

I. Introduction

The problem of producing special synthetic polymers to be used in contact with biological media first arose in the 1950s. It was created by the need by biology and medicine for synthetic polymeric materials to be used in the manufacture of various endoprostheses. This led to the development of a completely new area in technology: the production of polymers for medical applications.[1–3]

Both in the case of testing existing polymers for medical applications and when modified materials are used, the minimisation of the undesirable interactions between the material and the tissue of the living organism in implants of short or long duration as a function of the properties of the material is the most urgent problem.

Bioengineers who produce articles from these materials and doctors who use them in practice are interested in the biocompatibility of the polymers and in the retention time of desirable properties (mechanical, diffusional, optical, etc.).

When in contact with biologically active media (tissues) most polymers undergo two mutually related processes: degradation under the influence of the biologically active substances and interaction of the degradation products with the biological media responsible for the degradation (i.e. an influence of the metabolic and of the conjugation products on the life processes of the organism).

The study of the macrokinetic aspects of these processes ultimately allows the prediction of the lifetime of the polymer under stated operating conditions.

II. Reaction of the organism on the polymer

1. Initial reaction of the organism

A polymer in contact with the tissues of a living organism not only undergoes changes in its physical and chemical properties but also stimulates (as a foreign body) a corresponding reaction from the organism.

As a result of the damage produced in the tissues, the implantation of polymers into a living organism is accompanied by an inflammatory process.[4] This reaction consists, in the first stage of damage to the tissues, in a decrease in pO_2 and in pH, a decrease in the concentration of potassium, sodium, calcium, and magnesium ions, an accumulation of physiologically active substances resulting from the breakdown of the cell membranes and the evolution of circulating lymphocytes, and an increased accessibility of the microvessels.

In the second stage of the inflammatory process different forms of cell (neutrophils, monocytes, basophils, macrophages, etc.) are accumulated as a result of the directed motion of cells towards the inflammation region stimulated by the chemical irritants (chemotaxis). Chemical irritants include the physiologically active substances released by damaged cells and tissues (Table 1, see over), and also substances released by the polymeric materials (degradation products, residues of catalysts, stabilisers, fillers, etc.).[5]

Thus in this stage polymers can actively influence the progress of the inflammatory process.

If the process is not complicated by the onset of infections this stage of the inflammatory process is completed (on average) in three days, and the neutrophils (which were the predominant species initially) are replaced by monotcytes, plasma cells, lymphocytes, and macrophages.[6]

2. Formation of capsules round the polymer

After 4 to 5 days of contact the macrophages begin to predominate round the polymer, but lymphocytes, plasma cells, and fibroblasts are also present.[7]

If the polymer is biocompatible the number of macrophages decreases steeply after 1 or 2 weeks, and the fibroblasts form a collagen-like capsule on the surface of the polymer (Fig. 1). If the polymer is only partially biocompatible the microphages can

Table 1. Physiologically active substances contributing to inflammation reactions.

Substance	Chemical nature	Origin	Special features of the action
Histamine	β-Imidazolylethylamine	Fat cells, basophils, thrombocytes	Increased penetrability of the microvessels
Serotonin	5-Oxytryptamine	"	"
Catecholamines	Noradrenaline	"	"
Kinins	Polypeptides (metabolic products)	Plasma	Increased penetrability of the microvessels, pathogenic reactions
Hageman factor	Protease, globulin	"	"
Plasmin	Protease	"	"
Complement	Plasma proteins and metabolic products	Endothelium cells	Chemotaxis
Leucokinins	Polypeptides	Leucocytes	Increased penetrability of the microvessels
Lysosomal enzymes	Within-cell proteins	Neutrophils, macrophages, fat cells	Chemotaxis, phagocytosis
Lymphokinins	"	Lymphocytes	Immune reactions in the organism
Low-molecular regulators	Prostaglandins	Precursors present in all cells except erythrocytes	Increased penetrability of the microvessels, modulation of the inflammation, chemotaxis

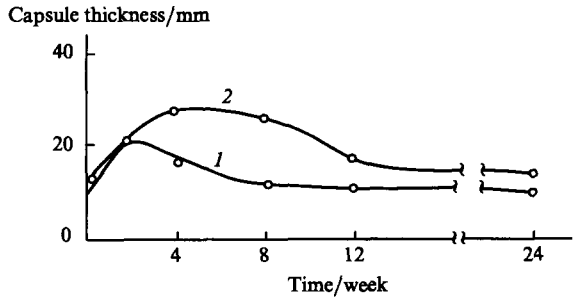

Figure 1. Plots of the thickness of the capsule against implantation time.[14] (*1*) Polydimethylsiloxane; (*2*) polystyrene coated with polydimethylsiloxane.

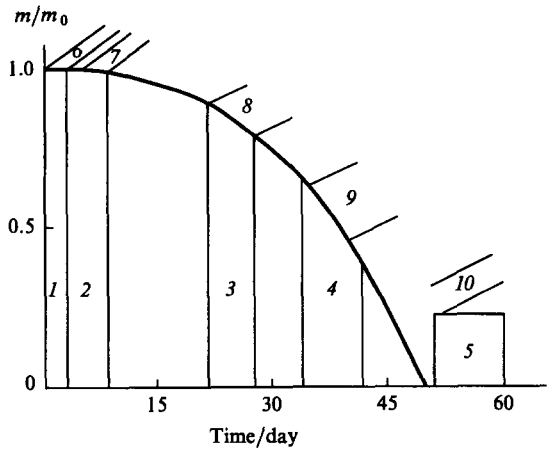

Figure 2. Dependence of the mass of the implant on time, and on its histoformological surroundings during the degradation of a polymer with satisfactory compatibility (polyglactin). (*1*) Macrophages round the implant: (*2*) macrophages containing phagocytes, fibroblasts; (*3*) giant cells and active macrophages; (*4*) macrophages and giant cells surrounding the polymer filaments with mitochondrial regions; (*5*) macrophages and giant cells surrounding the residues of the polymer fragments; (*6*) reaction on the polymer structure; (*7*) reaction to an operational trauma and healing, synthesis of collagen; (*8*) participation in the hydrolysis of the implant through the enzyme system; (*9*) participation of the cells in the metabolic process (increase in the respiratory functions); (*10*) complete resorption.

survive for longer times round the implanted polymer, and under these conditions giant cells can be formed.[8]

The thickness of the capsule depends on the biocompatibility of the polymer.[9] If the species responsible for the inflammation (for example, the degradation products) are produced at steady state we observe a chronic inflammation leading, after a long period, to the complete degradation of the polymer.

Being the main phagocyte cells of the organism the macrophages actively contribute to the degradation of most polymers. The macrophages contain lysosomes, which act as the 'alimentary canal' of the cell.[10] The lysosomal enzymes, mainly hydrolases, can destroy the polymer (phagocytosis) by two mechanisms. The first is exocytosis, in which liposomal enzymes are produced by the macrophage and the degradation takes place on the polymer surface. The second is endocytosis, in which the degradation process within the cell is preceded by the absorption of polymer particles by the macrophages. For example, Winter[11] detected metal particles within the macrophages by spectroscopic methods.

The dynamics of the morphological changes taking place on the surface of the polymer after implantation are illustrated in Fig. 2.

III. Biocompatibility of polymers

1. General definitions

We shall examine in general terms the response of the organism to a polymer after implantation, with special emphasis on the problems of biocompatibility.

When implanted into the organism polymers used in medical applications can fulfil special prosthetic or other functions (diagnostic, surgical or therapeutic) without undesirable interactions with the surrounding tissues or with the organism as a whole. At present we have no clear definition of biocompatibility, since there are no material parameters or biological tests which could be used as a quantitative measure of this property of polymers.[12]

Biocompatibility means that the polymer can exist in contact with blood and enzymes without undergoing degradation or causing thrombosis, breakdown of the tissues, or harmful immunological, toxicological, or allergenic effects.

Pure polymers with a high molecular mass usually have a low toxicity.[13] The degradation of the macromolecules produces fragments of lower molecular mass, down to the final degradation products (which could be the pure monomers). We know that the toxicity of the polymers of a given homologous series is inversely proportional to their molecular mass.[13]

Depending on the rate of degradation of the polymeric implant in the biological medium, its biocompatibility is found to change. In general the biocompatibility of the polymeric material is defined not only by the initial interactions but also by its chemical stability towards the surrounding biological medium.

2. Methods of determining the biocompatibility

A group of papers describing quantitative tests of the biocompatibility in various series of polymers has been published in the last few years.[14-18]

The in vitro experiments were mostly done by the 'tissue culture' method, which consists in growing cells on the surface of the experimental material. Two forms of the method are known: (1) depositing a layer of agar on the polymer, and observing the multiplication of the cells in the medium;[18-21] (2) depositing cells (usually fibroblasts) on the polymer and immersing the polymer inoculated with cells in the feed medium.[22,23]

The effect of the polymer on three functions of the cells is usually studied: their adhesion, survival, and multiplication.

Eleven phenomena were observed in a microscopic study.[15] Table 2 lists the polymers, the phenomena which were observed, and the doubling parameter (P_D) of the resulting fibroblast cells:

$$P_D = \frac{\lg(N/N_0)}{0.69}, \quad (1)$$

where N is the number of cells after 48 h incubation and N_0 is the initial number of cells deposited on the polymer.

From the results obtained in vitro all the polymers were divided into three arbitrary toxicity classes.

The in vivo measurements included 6 tests of the biocompatibility: (1) the extent of damage to the cells; (2) the thickness of the capsule; (3) the total number of cells; (4) the number of multinuclear leucocytes and erythrocytes; (5) the number of eosinophils, lymphocytes, and giant cells; (6) the number of fibrocytes from mononuclear phagocytes.

The number of cells is usually determined microscopically by defining a standard area.

An eight-point scale was adopted for each test.[16] The average index for each test (M) was found by adding the data obtained after two implantation cycles:

$$M_{STS} = (STS_{7\,\text{days}} + STS_{28\,\text{days}}) \times 10^{-1}, \quad (2)$$

where STS is the average sum of the marks on the scale for the tests.

The M_{STS} values for various polymers determined after implantation in the subcutaneous cellular tissues of the rat and their arbitrary assignment to the toxicity classes are shown in Table 3.

Table 2. Cytotoxicity of polymers in vitro.

Polymer	Phenomenon[a]	P_D	Toxicity class
Polypropiolactone	1	2.7	I
Polyhexamethylenediamine	1	1.9	I
Teflon	1	2.1	I
Polylactide	1	1.6	I
Poly(ethylene oxide)	1	2.1	I
Polyacrylamide	1	2.0	I
Polycaprolactone	1	2.1	I
Polyacrylonitrile	1	2.1	I
Polyglycollide	1	2.0	I
Poly(methyl methacrylate)	1, 11	–	II
Polymethyllactyl-2-cyano-acrylate	7, 8, 10	–	II
Polyisobutyl-2-cyanoacrylate	1	2.0	II
Poly(1,2-isopropylidene)-glycerolcyanoacrylate			
high-molecular	4	0.4	II
low-molecular	2, 5, 6, 7	–	III
Poly(acrylic acid)	5, 8, 9	–	III
Polydimethyl-2-cyanoacrylate	5, 7, 8	–	III

[a] The numbers refer to the following phenomena: 1, normal adhesion and multiplication of cells; 2, adhesion of a small number of cells; 3, normal growth of a small number of adhering cells; 4, the number of cells adhering after 48 h is negligible; 5, all cells in the medium have died; 6, all cells adhered to the growing surface have died after 48 h; 7, cells form a clump; 8, cells are not attracted to the surface; 9, sudden change in pH to 5.2; 10, there are some changes in the cells in the medium after 48 h; 11, the polymer adheres to the cells.

Table 3. Toxicity of polymers.

Polymer	M_{STS}	Toxicity class
Gelatin	2.1	I
Polyacrylamide	10.3	I
Polyglycollide	19.6	I
Polyacrylonitrile	52.0	I
Poly-α-lactide	34.7	I
Poly-β-propyllactone	69.1	I
Polycaprolactone	37.3	I
Poly(ethylene oxide)	21.8	I
Polymethyl-α-lactylcyanoacrylate	56.7	II
Poly(methyl methacrylate)	49.2	III
Polydimethyl-2-cyanoacrylate	59.1	III
Polyisobutyl-2-cyanoacrylate	49.7	III

IV. Catalytic activity of biological media

At the contact between polymers and biological media the latter usually show a catalytic activity towards the chemically unstable bonds in the polymers. Biological media contain a large number of low-molecular and high-molecular mass substances of different chemical nature, which interact with different polymers to different extents.

An analysis of published papers showed that the following substances should be considered from the standpoint of catalytic activity: water, salts, and enzymes. The choice of these substances was made partly because they are the most widespread and partly because their catalytic activity is now generally accepted.

1. Water

The water content of biological media is high. For example, the human organism contains approximately 75% of water, mainly in the intracellular fluid of the tissues and in the plasma. Thus polymers implanted into any part of the organism must be in contact with water.

Abundant information on the sorption and diffusion of water in various polymers is available. In Table 4 we show accepted data for the polymers used in medicine. As can be seen, water readily diffuses in all the polymers, but the amount of sorbed water varies widely as between the polymers. Three characteristic features can be noted.

In amorphous-crystalline polymers the sorbed water is located mainly in the amorphous regions. A dual sorption takes place in hydrophobic polymers at temperatures below the glass transition: volume filling of the micropores and dissolution in the polymer matrix.[28,29] Heterochain polymers and some carbon-chain polymers with heteroatoms in the side radicals are unstable towards water. Carbon-chain polymers without heteroatoms in the side chains are stable towards water.

Table 4. Values of the sorption ($c^0_{H_2O}$) and of the diffusion coefficient (D) of water in various polymers used in medicine.

Polymer	T/°C	$c^0_{H_2O}$/ g (100 g)$^{-1}$	$10^9 D$/ cm^2 s^{-1}
Segmented polyurethanes			
Avcotan-51	37	1.2	400
Biomer	37	1.0	700
Polyacrylonitrile [a]	25	7.5	
Poly(vinyl alcohol) [a]	25	4.0	0.051
Poly(vinyl chloride) [a]	30	0.5	23
Polydimethylsiloxane [a]	35	0.07	70000
Polydodecaneamide [b]	30	2.0	3.9
Poly(2-hydroxyethyl methacrylate), hydrone	37	40	100
Polyglycollide	37	8	5.0

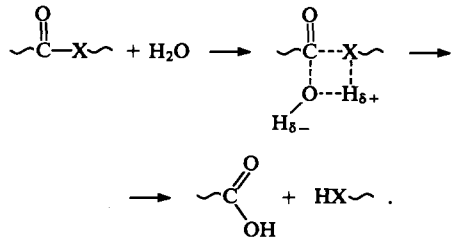
Polycarbonate	37	0.3	66
Polyglactin (copolymer of lactic and glycollic acids)	37	8.0	7.0
Poly(methyl methacrylate) [a]	50	1.2	130
Polypropylene [a]	25	0.007	240
Polytetrafluoroethylene [a]	20	0.01	–
Polyethylene (ρ = 0.923) [a]	25	0.006	230
Poly(ethylene terephthalate)	25	0.3	3.9

[a] Data from Ref. 26.
[b] Data from Ref. 27.

In the majority of polymers water diffuses relatively fast, and is sorbed in quite large quantities. Thus, in filaments and thin plates we can expect the degradation processes to take place in the inner kinetic region.

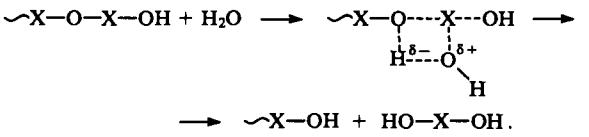
Table 5 shows the $k_{eff} c^0_{H_2O}$ values at 37 °C (where k_{eff} is the effective rate constant of the polymer degradation), and also the activation energy of the degradation for different heterochain polymers.

Partially cross-linked polydimethylsiloxane sorbs very small amounts of water, and its degradation takes place mainly in the outer diffusion-controlled kinetic region. The k_{eff} value at 37 °C and the activation energy are 2×10^{-5} g cm^{-2} day^{-1} and 14 kcal mol^{-1} respectively for this material.[35]



Thus in many polymers [for example polyglycollide, polygalactin, and poly(dimethylsiloxane)] degradation in water is relatively fast, and this must be allowed for when considering the overall kinetics of the resorption of these polymers in biological media, and also when choosing a sterilisation procedure (these polymers cannot be sterilised in steam).

Table 5. Values of $k_{eff} c^0_{H_2O}$ at 37 °C and activation energies for the degradation of various heterochain polymers.



Polymer	$k_{eff} c^0_{H_2O}$/ min^{-1}	E_{H_2O}/ kcal mol^{-1}	Ref.

[a] Reviewers' experimental results.

The hydrolytic degradation of carbonyl-containing polymers (polyamides, polyesters, polycarbonates) takes place by the bifunctional catalytic mechanism

The hydrolytic degradation of polymers containing oxygen (for example, polydimethylsiloxane) takes place only at the end of the chain (depolymerisation), and apparently by the following mechanism:[36]

2. Salts

Salts are found in large quantities in biological media. In Table 6 we show the ionic composition of liquids in the human organism.[37] The plasma and the intracellular liquid contain proteins present in the anionic form, because they include carboxylate groups. Detailed studies of the diffusion and sorption of salts in various polymers have been carried out in our laboratory.[24, 38] We shall mention only some of the most characteristic results.

In the diffusion of electrolytes in hydrogels [poly(2-hydroxyethyl dimethacrylate), poly(vinyl alcohol), etc.] the kinetic parameters (for example, the diffusion coefficient D) are close to the corresponding values for solutions. In hydrophilic polymers with only a moderate solubility for water the sorbed water does not form a continuous aqueous medium in the polymer matrix, and the ions diffuse by activated jumps between polar groups. This leads to a large decrease in the c^0 and D coefficients of the electrolyte as compared with the same parameters for the solution.

Electrolytes diffuse in hydrophobic polymers by a mechanism analogous to the transport of gases and vapours. Therefore in the case of electrolytes with a high vapour pressure (for example, hydrochloric acid) the c^0 and D values are close to the corresponding values for water in these polymers. For electrolytes with a low vapour pressure (for example, chlorides and phosphates) we find very low values of c^0 and D, i.e. these electrolytes are not sorbed on hydrophobic polymers to a significant extent.

Table 6. Ionic composition of the liquids in the human organism, mequiv l^{-1}.

Ion	Plasma	Liquid in tissues	Intracellular liquid
Na^+	138	141	10
K^+	4	4.1	150
Ca^{2+}	4	4.1	40
M^{2+}	3	3	40
Cl^-	102	115	15
HCO_3^-	26	29	10
PO_4^{3-}	2	2	100
SO_4^{2-}	1	1.1	20
Organic acids	3	3.4	–

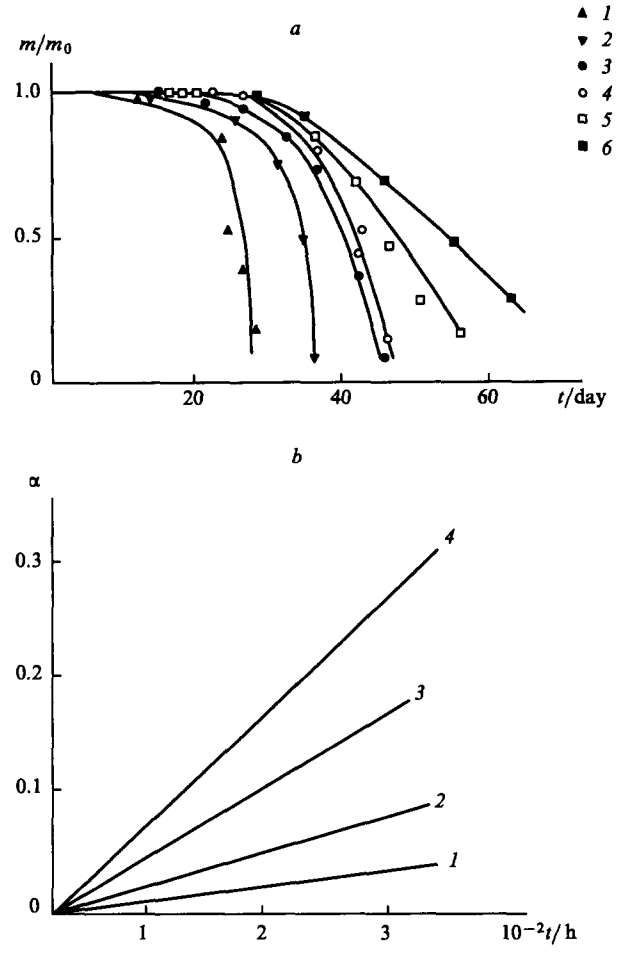

Figure 3. Plots of the relative mass of polyglycollide filaments against time since implantation and of exposure to model media (*a*) and change in the degree of conversion of the molecular mass of polycaproamide filaments incubated in a phosphate buffer solution (*b*). (*a*) pH 7.4, $T = 37$ °C; (*1*) 1 M phosphate buffer; (*2*) organism (subcutaneous tissue of rabbit): (*3*) 0.5 M phosphate buffer; (*4*) 0.1 M phosphate buffer; (*5*) 1 M salt solution; (*6*) water; (*b*) $M_{PCA} = 15000$, pH 7.4, $T = 37$ °C; concentration of phosphate buffer, M, (*1*) 0.1; (*2*) 0.3; (*3*) 0.6; (*4*) 0.1.

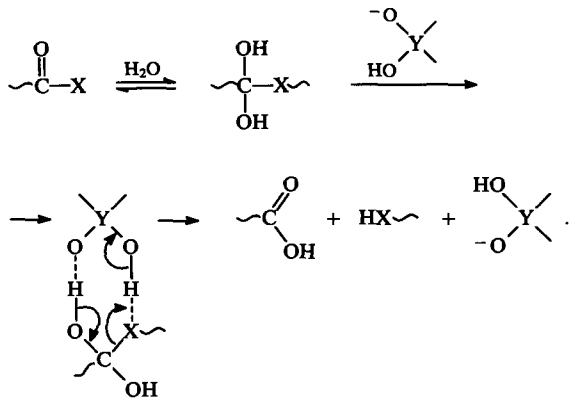

Thus all polymers can be nominally classified into two groups: those that dissolve water and those that do not. Polymers with $c^0_{H_2O} > 1\%$ are assigned to the first group; those with $c^0_{H_2O} < 1\%$ are assigned to the second.

Studies of the catalytic action of salts towards polymers are only just beginning. The effect of the salts listed in Table 6 on some polymers has been examined in our laboratory.

The degradation of moderately hydrophilic polymers (polyglycollide and polycaprolactam is markedly accelerated by an increase in the concentration of acid phosphates, bicarbonates, and bisulfates in buffer solutions of constant pH (Fig. 3). On these same polymers the salts of monobasic acids have a much smaller catalytic effect.[39]

Thus the ions so far examined can be arranged in the following sequence: the anions of polybasic acids are potentially catalytically active, the anions of monobasic acids and the cations listed in Table 6 are catalytically inactive.

The following overall scheme can be suggested for the catalysis by salts of the processes leading to the degradation of polymers containing carbonyl groups:[24]

Clearly, this bifunctional catalysis is impossible in polymers not containing carbonyl groups: for example polydimethylsiloxane.[35]

Thus salts (especially phosphates) have a strong catalytic influence on the degradation process in polymers containing carbonyl groups.

3. Enzymes

Enzymes play an active role in the degradation of polymers implanted in the organism. However, until very recently there was no clear experimental evidence of the reality of these effects. Typical results reported for medical polymers are shown in Table 7. Similar results have been obtained for some other polymers.[42]

Table 7. Rate of change of the relative intensity of the IR absorption bands ($10^2 W/\text{day}^{-1}$) of the polyurethane adhesive KL-3 in model media and in the subcutaneous tissue of rats.[40]

Medium	1110 cm^{-1}	1230 cm^{-1}	1730 cm^{-1}
Physiological solution	0.13	0.05	0.04
Ringer–Lock solution	0.13	0.04	0.03
Rabbit liver extract	0.10	0.04	0.02
Rabit muscle extract	0.10	0.02	0.03
Rabbit kidney extract	0.12	0.02	0.02
Trypsin solution (0.01%)	0.11	0.01	0.02
Chymotrypsin solution (0.01%)	0.12	0.01	0.02
Living organisms	0.59	0.39	0.34

We may conclude from these figures that the chosen media do not adequately model the high rate of degradation of polymers in the living organism. This can be explained by noting that the enzymes which catalyse the degradation are dissolved in a capsule and are essentially lysosomal enzymes produced by macrophages and other cells.

Salthouse[6] determined by quantitative histoenzymology the activity of various enzymes in a capsule on the surface of materials after implantation for different times into rats (Table 8, see over). An increase in the enzyme activity takes place in all the materials after 14 days, associated with an increased phagocytosis in the implantation region. After the healing of the surgical incision and the formation of a capsule from the connective tissue a stationary concentration of enzyme is apparently reached on the polymer surface.

Enzymes diffuse easily in the capsule, and are adsorbed on the surface of polymers in different concentrations. The surface concentration of catalytically active enzymes is determined not only by the number of enzyme species in the bulk of the capsule but also by the competitive adsorption of other proteins (catalytically inactive plasma proteins), lipids, etc. The mechanism of the action of enzymes on polymers is

Table 8. Activity of enzymes in the capsule on the surface of various materials.

Notes. The following symbols are used: – no activity; ± very low activity; + moderately high activity; + + substantial activity; + + + high activity; + + + + abnormally high activity.

[a] Combined activities of succino- and lactodehydrogenase and of cytochromeoxidase.

extremely complex because the majority of polymers are not specific substrates for the enzymes.

We have the results of experiments in vitro which confirm the action of enzymes on polyglycollide. Fig. 4 shows the kinetic curves for the evolution of glycollic acid during the degradation of polyglycollide fibres in solutions with different activities of β-glucouronidase.[43] The initial rate of degradation increases in proportion to the activity of the enzyme; if an inhibitor (iodoacetamide) is added to these solutions the catalytic effect of the β-glucouronidase is almost totally suppressed. Williams[44–46] studied the stability of polyglycollide filaments in solutions of various enzymes, and showed that carboxypeptidase A, physin, and leucineaminopeptidase can strongly accelerate the degradation of this polymer. In the case of other polymers catalytically active enzymes have not been identified beyond doubt, though they are often suggested as a possibility in published papers.

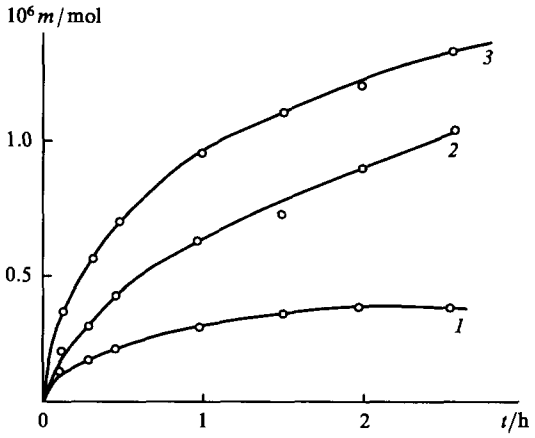

Figure 4. Kinetics of the production of glycollic acid during the incubation of polyglycollide filaments in a solution of the enzyme β-glucouronidase at a concentration of 1 mg ml^{-1} without inhibitor (*1*) and in the presence of the inhibitor iodoacetamide at concentrations 0.5 (*2*) and 1.8 mg ml^{-1} (*3*).

Thus enzymes, like water and the phosphates, are important catalytic agents in the degradation of polymers in biological media.

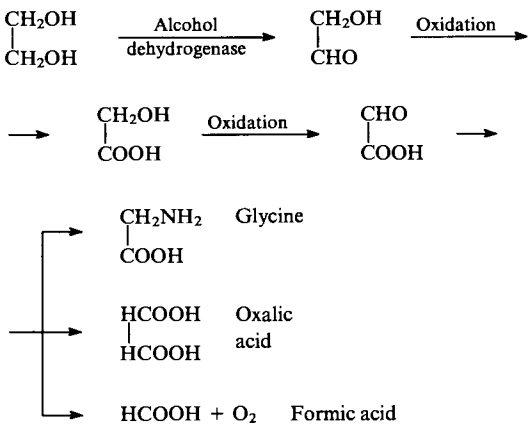
V. Products of the degradation in the organism

The degradation products are removed from the organism by a two-phase process: metabolic transformation and conjugation. This produces metabolites and conjugates, which are excreted with the urine and the bile or breathed out into the air.[47]

Metabolic transformations are reactions as a result of which the degradation products undergo one or more conversions (oxidative, hydrolytic, etc.) leading to the formation of functional groups which increase the polarity of the molecules.

Conjugation is a reaction which allows the degradation products or their metabolites to combine with biologically active substances in the organism, making the molecules more polar and less fat-soluble and therefore easily eliminated.

Table 9 shows the main heterochain medical polymers, the degradation products identified in model media, and their characteristic properties.



All the degradation products can be divided into three groups.

(1) Degradation products which contribute directly to the metabolic processes (cycles) of the organism: for example, lactic acid in the Corey cycle. These degradation products are almost nontoxic.

Table 9. Heterochain polymers used in medicine, their degradation products, and their characteristics.

Polymer	Degradation products	$10^5 k_{dis}$	Solubility in water
Polyglycollide	Glycollic acid	15	Good
Polyglactin	Glycollic and lactic acid	14	"
Polydodecaneamide	Aminoundecanoic acid	14	Poor
Polycaproamide	α-Aminocapronic acid	14	Good
Polydimethylsiloxane	Mixture of silols and their cyclisation products	–	–
Poly(ethylene terephthalate)	Terephthalic acid, ethylene glycol	29 35	Poor Good

(2) Degradation products able to undergo metabolic or conjugative transformations. For example, ethylene glycol is transformed in the organism by the scheme[47]

The toxic effect of the ethylene glycol is seen first of all in the kidneys, where oxalates are deposited in the channels.

(3) Degradation products eliminated from the organism in an unchanged form. For example, terephthalic acid ($k_{diss} \approx 3 \times 10^{-4}$) has a fairly high polarity and cannot easily penetrate into the tissues, and is therefore rapidly eliminated through the kidneys. It should not be forgotten that terephthalic acid can form a complex with albumin through the amino group of aspartic acid, and in this form it can be carried by the blood circulation system of the organism. Metabolically inert and nonpolar compounds such as vinyl chloride are eliminated with difficulty and tend to accumulate in the fatty tissues.

VI. Biocompatibility and biodegradation of polymers of different classes

Work on the biocompatibility and biodegradation of the main classes of polymers of medical importance is being currently reported. Various approaches to the study of these processes and the most important results obtained by various workers will be discussed below.

1. Polyamides

a. Polycaproamide

Polycaproamide (PCA) is one of the polymers first used for medical purposes. Its structure is similar to that of a polypeptide chain. At present this polymer has only limited applications, mainly as suture filaments (produced by the Ethicon Company, USA: a similar filament is produced in Russia as A122). Polycaproamide can be considered to be biocompatible as a polymer: histological data suggest a very slight inflammation round the implant.[48,49]

PCA has a moderately high resolution time in the organism. From this standpoint it can be used as a model for in vitro studies. For this reason detailed data are now available on the microkinetics of the decomposition of PCA not only in the organism but also in model media.[39,40,42] It follows from those data that the degradation of PCA takes place by a mixed mechanism: both on the surface and in the bulk of the polymer. The catalytic action of water and salts (phosphates, carbonates) on the degradation process should be examined first. In the organism the degradation of PCA takes place with a change in weight and in the molecular mass, due to the dissociation of the accessible amide bonds in the amorphous regions of the polymer (Fig. 5).

A remarkable feature of the degradation of PCA is the fact that the total surface of the polymer remains practically constant during the degradation as a result of the compensation of the normal decrease in diameter of the filaments by the increase in surface area produced by roughness and cracks on the surface.

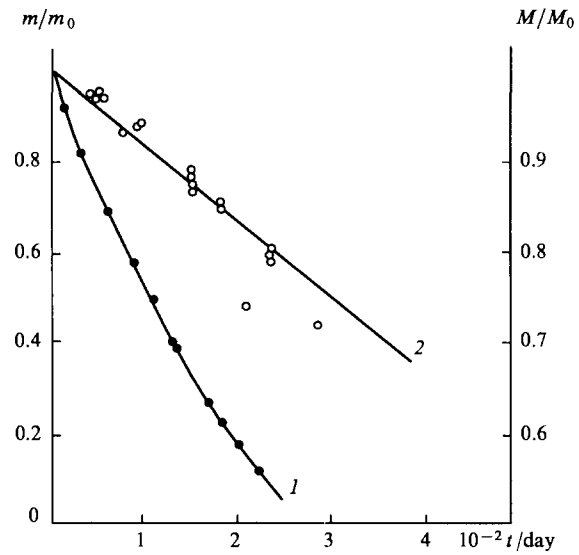


Figure 5. Change in the mass (*1*) and in the molecular mass (*2*) of PCA A122 (diameter = 24±2 μm, M = 15 000) after implantation for various times in the subcutaneous tissues of rabbits.

The change in mass of the polymer is described by the equation

$$m = m_0 - k_{eff}^S t .$$

Here m_0 and m are the initial and final mass respectively, and k_{eff}^S is the rate constant for the degradation of the polymer on the surface,

$$k_{eff}^S = kc_{cat} S ,$$

where c_{cat} is the concentration of catalyst and S is the area of the polymer surface.

The constant k_{eff}^S was determined by experiments on rabbit, and found to be $(1.6 \pm 0.2) \times 10^{-3}$ g day^{-1}. The rate constant of the decomposition of the amide linkages in the polymer matrix, determined by the law of chance [$k_{eff(l.ch.)}$] from data on the titration of the terminal amido groups in the implanted samples, was $(5.4 \pm 0.5) \times 10^{-5}$ day^{-1}.

An analysis of the action of catalytic agents showed that the bulk degradation of PCA takes place under the influence of water, whose solubility in PCA is 5.5% ± 0.5%. The large water content of the polymer allows the penetration of salts into the PCA with a diffusion coefficient[51] of 10^{-9} cm^2 s^{-1}. The rate constant of the decomposition of the amide bonds in the amorphous region in the presence of water at 37 °C is 1×10^{-7} day^{-1}; with this value of the rate constant only 0.5×10^{-4} of the amide bonds are dissociated in a year, which is much less than the rate constant for the decomposition in the organism.[32] This shows the important contribution made by salts to the degradation of polymers in the bulk. Model experiments in 0.1 M NaH_2PO_4 (the concentration of the liquid within the cells) at 37 °C gave

$$k_{eff(l.ch.)} = (0.5 \pm 0.1) \times 10^{-5} \text{ day}^{-1} .$$

Special experiments have shown that enzymes cannot penetrate effectively into films of PCA of thickness equal to the diameter of the filaments even over a period of 100 days. It is assumed that enzymes can contribute to the degradation process only from the surface. Thus the decomposition in the bulk of the polymer (V-type) takes place under the influence of water and salts, whereas the decomposition on the surface (S-type) takes place under the influence of enzymes in the organism.

These quantitative results allow us to predict the stability of PCA in the organism. In spite of the satisfactory compatibility with the tissues of the organism the use of PCA in suture threads is not very widespread; the prospects of using this material as rapidly resorbed threads have suffered from the more recent development of materials such as Dexon and polyglactin.

b. Polydodecaneamide

Polydodecaneamide (polyamide 12) is used as an endoprosthesis. This polymer is fairly stable in terms of its rate of resorption in the tissues of the organism, and therefore it is of interest as the foundation of various structural modifications aimed at preparing new materials for endoprosthetic purposes.[52-55]

The mechanism of the degradation of polyamide 12 was shown to be similar to the mechanism found in polycaproamide: implantation results in a decrease in molecular mass, in mass of the sample, and in the stability and diameter of the elementary filament, accompanied by the appearance of cracks on the polymer surface. As could have been expected the degradation mechanism is identical to that of the decomposition of PCA in the organism, i.e. the degradation takes place in the amorphous regions of the polydodecaneamide (according to IR spectroscopy and to X-ray structural analysis data[54]) under the influence of the same catalytic agents as in the case of PCA: salts and enzymes.

2. Polyesters

a. Polyglycollide

Polyglycollide (PGL), the polycondensation product of glycollic acid, was the first polymer specially synthesised for medical applications (in the late 1960s) by the American Cyanamid Company (USA). The principles of the synthesis and the structural features of PGL have been widely studied.[56-60] Polyglycollide is used in various fields of medicine: in orthopaedics and traumatology (pins, plates, pegs, needles, bone replacements), and in opthalmology as threads, fibre materials, sponges, and powders for wounds and burns. The principal advantage of PGL is its suitability for use in two-component systems as the resorbed member of the prosthesis.

The widespread use of PGL is explained by the good compatibility of the polymer at the initial implantation irrespective of its form (blocks, powders, filaments), and also by the fact that the only decomposition product, glycollic acid, contributes actively to the metabolism in the organism, breaking down[6] to H_2O and CO_2. Histological studies of this material (see Tables 2 and 3) in the initial, intermediate, and final stages of the implantation failed to detect any trend towards an increase in the size of the cells, characteristic of specific inflammation reactions. A well-formed capsule of connective tissue is found round the implant.[61-63]

Since the synthesis of PGL many studies of its degradation have been reported. The most detailed studies were made of suture threads of PGL commercially available under the name of Dexon produced by the firm Chek and Devis Cyanamid (USA).[8,46,64-66]

Some recent papers[43,46,67-71] discuss the kinetics of the decomposition of PGL in the organism and in model media. They include studies of the macrokinetics of the decomposition in the organism and in vitro and determinations of the main catalytic components of the medium in the living organism, and also of the relative contribution of each component to the degradation process.

Studies of the macrokinetic features of the degradation of the material in the living organism and in the separate components of the biological medium, coupled with quantitative studies of the contribution of each component of the medium allowing for the structural properties of the PGL filaments (established by electron microscopy and by X-ray diffraction analyses), led these workers[68,70] to propose a mechanism for the decomposition of PGL in the organism. The most significant results of this work are the following.

The filaments decompose by an unusual mechanism in the organism. After 15-18 days implantation the micrographs show a transverse distribution of the filaments on regions ~1 mm wide, without any change in the diameter of the elementary threads. However, a loss in mechanical strength of the PGL is observed.

The curves describing the loss in mass (Fig. 6) have a complex form: a slight change in the initial stages of the implantation followed by a rapidly increasing loss of mass after 20 days.

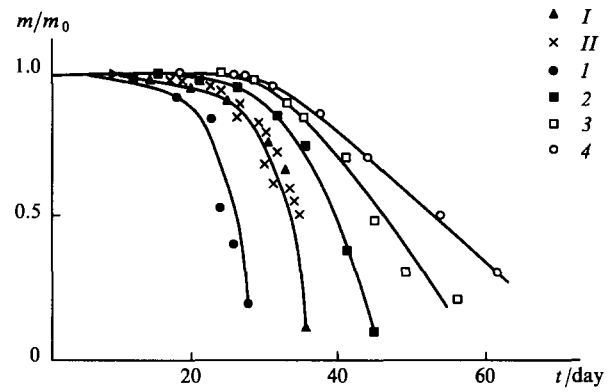

Figure 6. Changes in the relative mass of PGL filaments against time of implantation in the subcutaneous tissues of rabbits and time of treatment in a phosphate buffer of pH 7.4 at 37 °C. (*I*) In the organism, (*II*) theoretical curve for the organism as a medium; concentration of phosphate buffer, M: (*1*) 1; (*2*) 0.3; (*3*) 0.1; (*4*) water.

The kinetic weight loss curves in water, in phosphate buffer, and in carbonate buffer at pH 7.4 and 37 °C are similar to those observed in the organism, the salts of strong monobasic acids having practically no effect on the kinetic parameters whereas in the presence of phosphates we find a marked increase in the rate of degradation (curve *1* of Fig. 6).

In buffer solutions of pH 4.05 and 2.01 the PGL filaments are degraded at a rate close to that observed in water, i.e. in this range of pH the acid medium does not markedly affect the hydrolysis of the ester bonds.

In vitro experiments on the incubation of PGL in proteolytic enzyme solutions showed that the enzyme β-glucouronidase is active towards this reaction. The following values of the effective decomposition rate constant for the dissociation of esters bonds in PGL under the influence of the main components of the medium in the organism at 37 °C were reported.

Constant	$k \times 10^2$
$k^V_{H_2O}$	5.0
$k^{S-V}_{H_2O}$	4.2
$k^V_{H_2PO_4}$	5.0
$k^{S-V}_{H_2PO_4}$	4.2
k^{S-V}_{enz}	1.0

Here k^V is the effective rate constant for the decomposition of the ester bonds in PGL in the amorphous regions of the polymer under the influence of water and salts; k^{S-V} is the effective constant for rate of dissociation of ester bonds on the surface of the crystallites, depending on the type of decomposition of the fragments of the PGL macromolecule on the crystallite surface and on the adhesion and solubility in the surrounding medium of the decomposition products.

An analysis of these results suggests a two-stage mechanism for the degradation of PGL (a highly crystalline polyester, with an amorphous fraction of ~0.2 and a crystalline fraction of 0.8). In the initial period of the implantation water is sorbed in the amorphous regions, and the polymer degrades slowly, mainly under the influence of water. Then, after a conversion of the polymer of 0.2, the rate of degradation in the organism increases rapidly. This can be attributed to the breakdown of the crystallites on the surface under the influence of the sorbed water, salts, and enzymes. From in vitro experiments we can obtain the effective rate constants for the dissociation of the ester bonds under the influence of water, salts, and enzymes.

The general equation for the change in mass, obtained from the above results, is

$$\frac{m}{m_0} = 0.2 - v_i[1 - \exp(-k^V_{H_2O}\, c^V_{H_2O}\, t)]^2 + (1 - v_i)\left(1 - \frac{k^{S-V}_{H_2O}\, c^{S-V}_{H_2O}\, t}{Nb_0\rho}\right)^2 - v_i[1 - \exp(-k^V_{H_2PO_4^-}\, c^V_{H_2PO_4^-}\, t)]^2 + (1 - v_i)\left(1 - \frac{k^{S-V}_{H_2PO_4^-}\, c^{S-V}_{H_2PO_4^-}\, t}{Nb_0\rho}\right)^2 + (1 - v_i)\left(1 - \frac{k^{S-V}_{enz}\, c^{S-V}_{enz}\, t}{Nb_0\rho}\right)^2,$$

where m_0 and m are the initial and the time-dependent mass of the polymer, N is the number of crystallites in the transverse section, ρ is the density of the polymer, b_0 is the transverse dimension of the crystallites, $c^V_{H_2O,\,H_2PO_4^-}$ is the average concentration of water and of phosphate ions in the amorphous part of the polymer, 0.2 is the volume fraction of amorphous regions in the PGL, $c^{S-V}_{H_2O,\,H_2PO_4^-}$ is the average concentration of water and of phosphate ions on the side surface of the crystallite.

A computer solution of the inverse problem which used the above rate constants and a range of enzyme concentrations in the subcutaneous tissue of rabbits, undertaken because of the lack of accurate published data, gave a satisfactory agreement with the experimental curve for the weight loss in the organism.

The above quantitative analysis allows the kinetic curves for the decomposition and lifetime of PGL filaments of various diameters to be predicted for different parts of the organism (containing different enzymes and salts). The prospects for the application of this polymeric material in medicine are exceptionally good because of its good mechanical properties and biocompatibility and of its controllable resorption times.

b. Polyglactin

Polyglactin (PGLA) is a copolymer of glycollic and lactic acid produced by the Ethicon Company (USA). The decomposition products of this polymer in the organism are glycollic and lactic acid, which take part in the metabolic processes. Histomorphological tests on PGLA items in the form of suture threads or tablets show a good compatibility with the tissues of the organism.[6, 72–76]

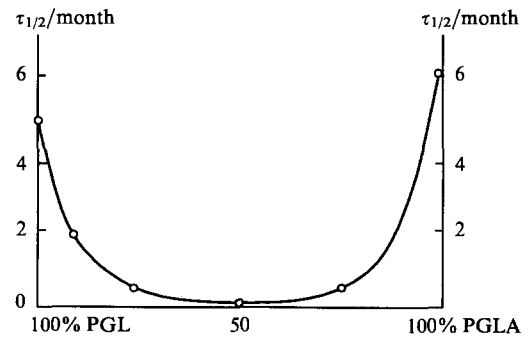

Figure 7. Plot of the time of half-decomposition of tablets of the copolymers PGL and PGLA implanted in rats.

The decomposition mechanisms and the rates of degradation of PGLA and its copolymers are identical. The homopolymer of lactic acid decomposes more slowly than PGL in the subcutaneous tissue of rats, evidently because of the lower solubility of water in the polylactide.[77] Tablets of the copolymer with different concentration ratios of glycollic and lactic acid have different half lives (measured from the concentration of ^{14}C in the organs of the rats), ranging from several months for the homopolymers to one week for the polymer with a concentration ratio of 50 : 50 (Fig. 7).

Salthouse and Matlaga[78] published a detailed study of the degradation of PGLA 910 in the subcutaneous tissues of rats, aimed at clarifying the role of cell enzymes in the resorption of the polymer. They concluded that in the initial stages the enzymes do not contribute to the degradation. A slight increase in the dehydrogenase and cytochrome oxidase activity after 40 days is explained by the participation of these enzymes in the breaking down of the dissociation products to metabolites by the scheme

PGLA 910 + water ⟶

⟶ Lactic and glycollic acids $\xrightarrow{\text{Oxyreductase}}$

⟶ $CO_2 + H_2O$.

We should stress that PGLA is the only polymer for which the decomposition kinetics and the metabolism of the degradation products have been investigated.

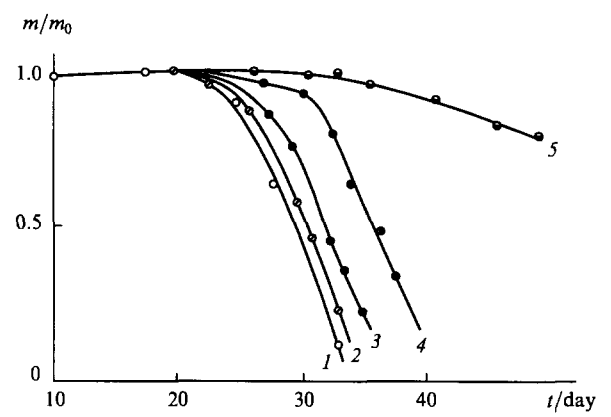

Figure 8. Changes in the relative mass of PGLA filaments with time of implantation in the subcutaneous tissues of rabbits and with the time of treatment in buffer systems of pH 7.4 at 37 °C. (*1*) 1 M carbonate buffer; (*2*) organism; (*3*) 1 M phosphate buffer; (*4*) 0.5 M phosphate buffer; (*5*) water.

The weight loss curves in the organism, in water, and in various buffer solutions are similar to the kinetic curves for PGL (Fig. 8).[68] We note a slight acceleration of the decomposition of PGLA as compared with the PGL filaments.[77] This can be explained by a slight disordering of the crystalline regions of the polymer due to the difference in the parameters of the unit cell of the copolymer.

Copolymers of this type have good prospects of applications in medicine because suture materials made from them offer a wider spectrum of resorption times than the materials made from PGL.

c. Poly(ethylene terephthalate)

Items made of poly(ethylene terephthalate) (PETP) as gauzes, suture threads, and vessel prostheses have a well established place in surgical practice because of their ability to retain their functional prosthetic properties over long implantation times as well as because of their good biocompatibility.[79–82]

Abundant information is available on its histological compatibility: it is well established that PETP implants always produce the smallest reaction from the tissues, consisting of a thin capsule and a normal connective tissue round the prosthesis for extended time periods (up to 5 years).[83-85] However, macrophages have been detected after long implantation times, apparently due to the influence of terephthalic acid on the surrounding tissues.[86]

There are reports of macroscopic observations of differences in the properties of vessel prostheses in the human organism implanted for different times, and it has been shown that periods in the organism of up to 5 years make effectively no difference to these properties.[81] After 8 and 11.5 years of residence in the organism cracks appears on the surface of the polymeric prosthesis, and the filaments becomes thinner.

Systematic studies of the degradation processes in PETP gauzes produced in Russia and implanted in the muscle tissues of rabbits, dogs, and humans have been aimed at establishing the lifetimes of the prostheses.[87-89]

As was pointed out above, at 37 °C PETP is stable towards hydrolysis in water, but it undergoes *S*-type decomposition in basic media (when the reaction rate is much greater than the rate of diffusion of the aggressive medium) and *V*-type decomposition in acid media (when the reaction rate is much smaller than the rate of diffusion of the aggressive medium). An analysis of data on the degradation of prostheses made from PETP used in soft tissues showed that both types of degradation can take place, depending on the conditions existing in the organism.

When the pH of the surrounding medium is between 7.0 and 7.4 the breaking load can be determined by the formula

$$P = P_0\left(1 - k_{\text{eff}}^{S}\,\frac{t}{r_0\rho}\right)^2,$$

where P_0 and P are the initial and the final breaking loads and r_0 is the radius of the elementary filaments. The linear dependence of $P^{1/2}$ on the time t allows the time for a 50% loss of strength under these conditions to be predicted (Fig. 9*a*).

The *V*-type decomposition of PETP was first detected in an analysis of the properties of prostheses implanted in the organism under conditions of strong inflammation. The medium had a pH of 4.8–6.8, and it appeared that these values were controlled by the action of bacteria observed on the prostheses and near them.[80] Under these conditions the samples completely lost their strength after 2 or 3 months in the organism, and their molecular mass fell steeply as a result of the dissociation of the ester bonds in the amorphous regions (Fig. 9*b*). The change in the molecular mass is described by the equation[90]

$$\frac{1}{M} - \frac{1}{M_0} = k_{\text{eff}}^{V}\,t,$$

where M_0 and M are the initial and the time-dependent number-average molecular masses, and k_{eff} is the effective rate constant of the dissociation of the bonds in the amorphous regions of the polymer.

As regards the participation of the catalysts present in the organism water does not appear to have any catalytic effect in the case of PETP: k_{eff} for water in PETP at 37 °C is 10^{-9}–10^{-10} min^{-1}, and after 10 years 0.1% of the ester bonds are decomposed.[24] Phosphate ions penetrate into the polymer matrix to a negligible extent, and therefore the degradation induced by these species is confined to the surface. The enzymes found in the organism should contribute (as in the case of PGL and PCA) to the degradation starting from the surface. Therefore under the conditions normally experienced by the prosthesis (pH 7.0–7.4) the degradation of the PETP will take place from the surface under the influence of salts and enzymes.

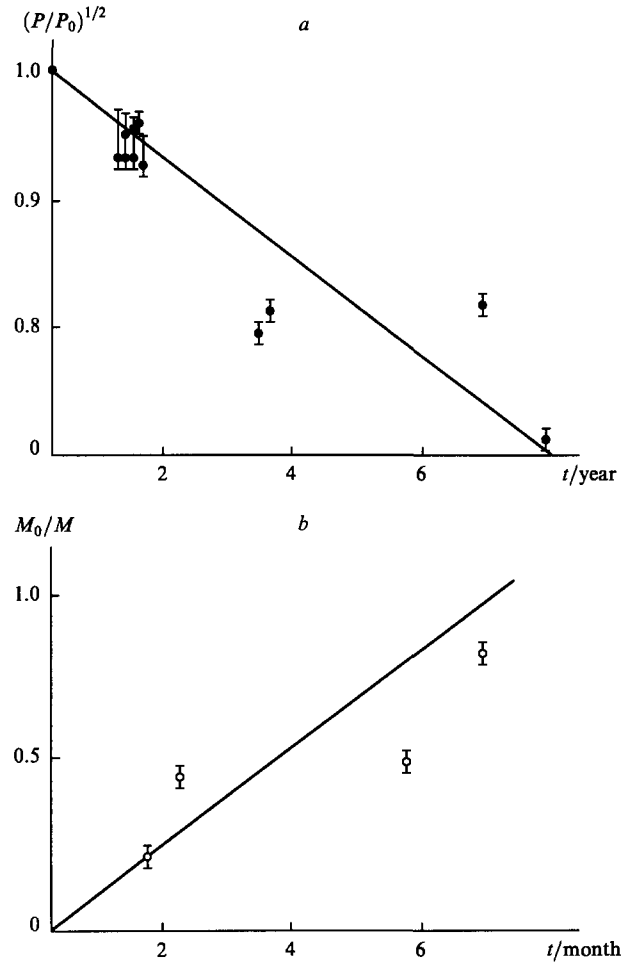

Figure 9. Changes in the breaking strength of elementary filaments of PETP recovered from the human organism for different times of residence of the prosthesis in the organism at pH 7.0–7.4 (*a*) and dependence of the relative molecular mass for samples of prostheses of PETP recovered from the human organism under infectious conditions, pH 4.8–6.8 (*b*).

In the case of a prosthesis in pathological surroundings (acidic medium) enzymes and acids can become catalytically active. Acids are the only really active substances able to induce degradation in the volume of the PETP because of the ability of volatile acids to diffuse in the polymer matrix. In this case the effective rate constant for the degradation of PETP in the organism[91] is 1.1 ± 0.5 year^{-1}.

These observations can explain the report[46] that PGL is degraded in the presence of bacteria. In fact, PGL (unlike PETP) dissociates in an acid medium at a rate close to its rate of decomposition in water (see Fig. 6). As reported,[89,92] the active degradation agents in a bacterial medium are mainly the enzymes produced by the bacteria, and various low-molecular products (mainly acids) which lower the pH of the medium. In the light of the main parameters of this material (biocompatibility and biodegradation) we may suggest that PETP will achieve a wide exploitation in medical practice for the fabrication of prostheses and other articles and materials.

3. Polyolefins

a. Polypropylene

Polypropylene (PP) was first used in medical practice because of its high chemical stability and favourable mechanical properties. In the early 1970s it was used for lining the valves of artificial hearts, and for ball joint prostheses. It is now commercially available as suture threads from the Ethicon Company (USA).

Histological results show that PP of 'medically pure' grade stimulates only a moderate reaction from the tissues of the living organism [6, 8, 93] as compared with PP containing traces of catalysts and stabilisers.[94]

Polypropylene can undergo only oxidative degradation. Therefore in the tissues of the living organism PP should be stable, and decompose slowly only under the influence of oxidative enzymes and oxygen dissolved in the living medium.

The overall picture of the degradation of PP filaments and films in the organism is characterised by the following phenomena: a worsening of the mechanical properties (a decrease in the breaking load and in the relative elongation);[84] crack formation in the initial stages of the implantation and fragmentation of the polymeric implant at longer times (the fragmentation being observed sooner in PP samples without an antioxidant);[84] constant molecular mass at all times during the implantation; appearance in the IR spectra of the PP samples after implantation of an absorption band corresponding to the C=O group;[95] an increased activity of oxyreductase and cytochrome oxidase in the capsule surrounding the implant.[6]

It follows from the above experimental observations on the degradation of PP in the organism that this polymer undergoes the *S*-type of degradation under the influence of oxidising enzymes, which cannot penetrate into the polymer matrix. As is well known, oxidative degradation is accompanied by the breaking of the main chain of the polymer and should lead to a decrease in the molecular mass, but since the catalytic agents are unable to penetrate into the bulk of the polymer the surface bond breaking produces a negligibly small decrease in the molecular mass of the whole article. The accumulation of carbonyl compounds as a result of oxidation also takes place on the surface of cracks rather than over the whole volume of the sample.

Special experiments with PP incubated in a solution of cytochrome oxidase did not produce the expected result because of the rapid inactivation of this enzyme in experiments in vitro. Therefore experiments with bacteria which produce oxidative enzymes able to open the C – C bond are needed to account for the role of these enzymes in the oxidation of this polymer.

b. Polyethylene

Articles made of polyethylene (PE) have been used in surgery for the past 30 years: for example, high-pressure polyethylene (HPPE) is used for fabricating pelvic joint prostheses. As a stable, undecomposed polymer this material has been used in emergency medical technology as packing and as circulatory vessels.

Histomorphological studies of PE have attracted extensive interest. It has been reported that the overall reaction of the organism to this polymer is favourable.[98–100]

The biodegradation of PE was established by solving the inverse problem with the aim of exploiting the polymeric by-products with the aid of microorganisms and bacteria. It was found that commercial polyethylenes (especially HPPE) undergo practically no biodegradation by the radical mechanism.[101, 102]

The following features of the biodegradation of PE have been established.

(1) The main condition for the biodissociation is an increase in the specific surface of the polymer (for example by using powders).[103]

(2) The dissociation process takes place with a decrease in mass, accelerating during the initial stages of incubation and then slowing down.

(3) Samples of low-pressure polyethylene (LPPE) incubated with microorganisms are found to include carbonyl groups, especially in the presence of fillers, which are sensitive to oxidases and esterases.[104, 105]

PE specially labelled with ^{14}C was used in studies of the rate of biodegradation of slowly decomposed PE.[105] Samples incubated with microorganisms for different times (up to 3 years) were irradiated with UV light in order to accelerate the degradation, and the weight loss caused by the action of the bacteria and microorganisms was determined. Extrapolation to zero time of irradiation gave the weight loss due to the biodegradation. The loss of mass of the powders determined by this method was 0.5% in 3 years.

It follows from these data that PE (like PP) is degraded by the *S*-type of mechanism, and that the decomposing species can be oxidative enzymes generated by bacteria and microorganisms, for which the PE acts as a carbon feed medium.

By combining the data for the degradation of PP and PE we may conclude that although these polymers decompose slowly the rearrangement of their structure during the oxidation process can lead to undesirable consequences for the organism.

4. Elastomers

a. Polydimethylsiloxane

Articles made from polydimethylsiloxane (PDMS) are used successfully in medicine. Its inertness, its favourable mechanical properties, and the ability to produce articles of almost any shape for introduction into the organism opened a wide range of applications for polyorganosiloxanes in various fields of medicine (in surgery as prostheses for various bone structures and for soft tissues, and as auxiliary items such as tubes, catheters, bypasses, medicine carriers). In the 1960s this polymer was industrially adopted for the production of various articles, now available under the trade name Silastic, by the Dow Corning Corporation (USA).

The good biocompatibility of PDMS is confirmed by the results of many quantitative studies. Histological and histochemical data obtained for silicone polymers are often used as tests for the biocompatibility in the evaluation of new polymers.[106–110]

In spite of the extensive studies and experimentation aimed at the practical application of siloxane polymers very few quantitative data on their degradation in the organism have been published. Systematic studies of the degradation of

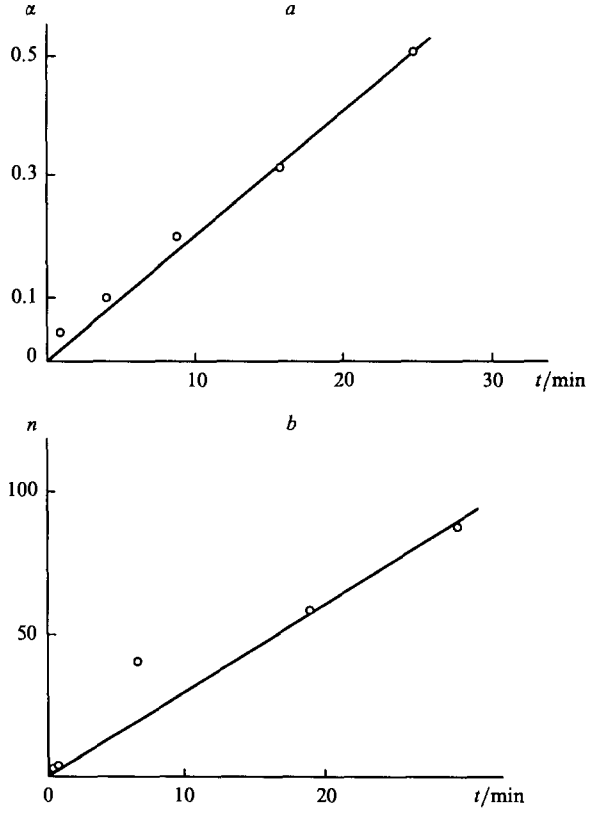

Figure 10. Plots of the extent of mass conversion of PDMS (*a*) and of the number of broken silanol bonds (*b*) against time during hydrolysis at 300 °C.

vulcanisates from dimethylsiloxane rubber of low molecular mass (SKTN) in living tissues have been carried out during the last 20 years at the Vishnevskii Surgery Institute.[109,111,112]

Fragments containing Si–O bonds can decompose in water.[113,114] Reported data[115] on the decomposition of SKTN at high temperatures in water vapour (Fig. 10) can be analysed quantitatively by postulating two simultaneous processes:
(1) decomposition by the laws of chance (with a rate constant $k_{l.ch.}$) with formation of silanol end groups

$$\frac{dn}{dt} = k_{l.ch.}(n_0 - n),$$

where n_0 is the initial concentration of silanol bonds, and n is the concentration of broken bonds at time t;
(2) depolymerisation at the silanol bonds (with a rate contant k_{dep}), resulting in loss of mass of the polymer

$$\frac{dm}{dt} = k_{dep} n .$$

On the assumptions that these two processes take place with comparable rates, that the decomposition by the laws of chance proceeds only to a small extent, and that the reaction itself is under activation control, the overall change in mass can be described by the equation

$$\Delta m = k_{dep} k_{l.ch.} t^2 .$$

Data on the degradation of PDMS are shown in Fig. 11.

The degradation of PDMS at temperatures below 100 °C has been discussed.[35] At these temperatures we can expect, in addition to the decomposition in the inner activation-controlled region, an active contribution from decomposition at the surface, since the concentration of water in the bulk of the polymer is extremely small. These types of degradation can be identified as follows. If a change in strength is observed the process is taking place mainly in the bulk, and conversely if the strength remains unchanged the surface decomposition is predominant. It was found that at high temperatures, when the water is in the vapour phase, the reaction is of the *V*-type, whereas at lower temperatures it is of the *S*-type.

Experiments on the degradation of PDMS in a phosphate buffer failed to detect a catalytic influence from the phosphate ions, thus excluding the possibility of a bifunctional catalysis reaction under the influence of the ions present in the organism.

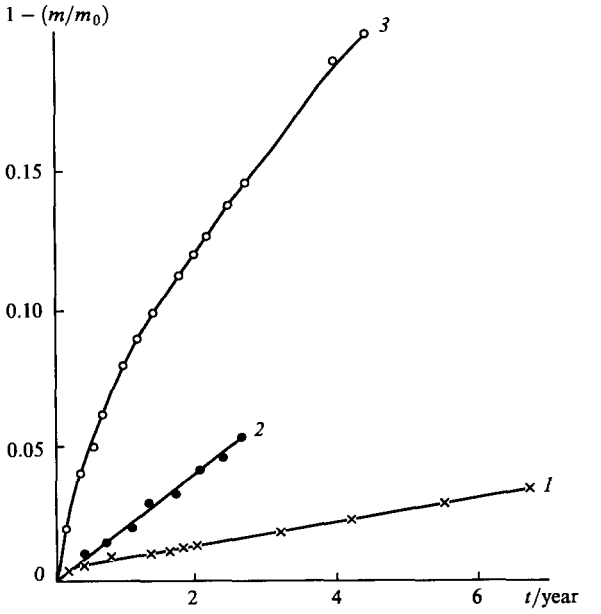

Figure 11. Plots of the extent of mass conversion of PDMS at 37 °C against time. (*1*) air; (*2*) water; (*3*) organism (subcutaneous rabbit tissue).

Therefore the contribution of water to the degradation of PDMS in the organism should manifest itself in the activation of the reaction leading to the depolymerisation of the end groups on the surface of the PDMS. However, the rates of degradation in the organism and in water are very different (see Fig. 11). This difference can be ascribed to the contribution from the enzyme component to the surface depolymerisation reaction. Unfortunately enzymes capable of breaking siloxane bonds have not so far been identified, and it is difficult to attempt a quantitative analysis of the contribution from enzymes.

The thinning of a PDMS plate owing to loss of mass (for example, during degradation in the organism) amounts to ~ 40 μm year^{-1}. Therefore the fabrication from PDMS of articles having a strictly prescribed form for long-term implantation is not recommended.

The prospects of articles based on polyorganosiloxane polymers in medicine are assured, especially in the solution of medical technology applications. Polydimethylsiloxane is also often used as an essential component for the modification of other polymers.

b. Polyurethanes

Polyurethane materials have found applications in medical practice because of their physicochemical properties, which can be varied over wide limits.

The polymer chain of polyurethanes (PU) contains the urethane group, whose structure is close to that of the peptide group in proteins: this may account for the successful application of this class of synthetic materials as biological plastics. Articles based on segmented PU with ether bonds are used as clot-resistant materials, catheters, intra-aortal bulbs, and components of artificial hearts.

Widely used items made from PU foam with ester bonds include adhesives and various alloplasts. Extensive studies have been devoted in our country as well as abroad to problems of biocompatibility and biodegradation in articles made from PU, especially adhesive compositions.[41,116–118] This work led to the conclusion that the main reaction is the hydrolysis of esters bonds, which results in the degradation of adhesives and other PU items in the tissues of the living organism.[119] These workers deny the involvement of enzymes in the degradation process on the basis of model experiments in solutions of trypsin, chitotrypsin, and elastase. Their results showed that in every case there was no difference between the rates of decomposition of PU in these media and in a physiological solution (the rates being determined from the change in molecular mass and from the strength of the IR absorption bands).

Enzymes which are found in a capsule of the given polymer must be used for experiments in vitro. In particular, aminopeptidase and acid phosphatase were found in the PU capsule.[6] This explains the negative effect reported[119] when using proteolytic enzymes, which often have an inhibiting action.

An analysis of kinetic data for PU with ester bonds showed that the degradation is caused by the hydrolytic dissociation of these bonds in water over the whole volume, as shown by the change in molecular mass of the polymer. The difference in the rates of decomposition can be explained by the participation of enzymes in the degradation from the surface of the polymeric material theough the breaking of the urethane bonds under the laws of chance, as was shown in the case of PGL.[68]

A systematic study of the degradation of low-molecular polyurethanes labelled with ^{14}C under the influence of a range of enzymes (from esterase to oxidative enzymes) also indicated a nonspecific degradation, mainly dependent on the molecular mass of the polymer. This work was done at a qualitative level.[120]

The role of the cell components in the degradation of PU foams from the surface (the so-called 'cell participation') has also been reported.[121,122] The cell involvement in the degradation of polymers is specially striking in polymers with a developed surface, such as PU, but nevertheless the active groups are the ultimate degradation agents.

Table 10. Main parameters of biocompatibility and biodegradation of polymers.

Polymer	Toxicity class of polymer	Toxicity of decomposition products	Type of decomposition and main catalyst	Notes
Polycaproamide	–	Moderately high	*S*, enzymes *V*, salts	$m/g = m_0/g - 1.6 \times 10^{-3} t/day$; a filament 24 ± 4 μm in diameter decomposes in 500 ± 50 days in the subcutaneous tissues of rabbits
Polydodecaneamide	–	Moderately high	*S*, enzymes *V*, salts	$m/g = m_0/g - 1 \times 10^{-3} t/day$
Polyglycollide	I	Very low	*S*, enzymes *V*, salts, water	$m/m_0 = 0.2 - 0.2[1 - \exp(-k_{H_2O}t) - \exp(-k_{salt}t)] + 0.8[(1 - k_{H_2O}t/A)^2 + (1 - k_{salt}t/A)^2] + (1 - k_{enz}t/A)^2$, where $A = Nb_0$. For a filament with a diameter of 18 ± 1 μm $P = 0$ after 20–25 days (subcutaneous rabbit tissues)
Polyglactin	I	Very low	*S*, enzymes *V*, water, salts	Similar equations apply to PGL
Poly(ethylene terephthalate)	–	Moderately high	*S*, enzymes, salts	$m/g = m_0/g - 4.0 \times 10 (t/day)(S/cm^2)$ $P = P_0[1 - 4.0 \times 10 (t/day)(S/cm^2)]^2$ After 30 ± 7 years a filament with a diameter of 19 ± 2 μm is completely decomposed and $P \approx 0$ (clinical data)
Polypropylene	–	Not determined	*S*, enzymes	–
Polyethylene	–	"	*S*, enzymes	$m/g = m_0/g - 2 \times 10^{-6} t/day$
Polydimethylsiloxane	I	"	*S*, water, enzymes	$m/g' = m_0/g - 1.5 \times 10^{-5} (t/day)(S/cm^2)$

5. Cyanoacrylate adhesives

Synthetic adhesive compositions based on cyanoacrylates have found wide applications in surgery for the sutureless connection of tissues. Cyanoacrylates, including the well known ethyl ester of α-cyanoacrylic acid, were first used in medical technology, but they were then modified for applications in medicine. At present adhesives based on alkyl(aryl)-α-cyanoacrylates are generally used in experimental and clinical surgery. A recent review [120] listed the main conclusions on the properties of cyanoacrylate adhesives. In general, according to a large group of results, cyanoacrylate adhesives are degraded rapidly (~60%–80% by weight in the first few months).[120] It is pointed out that the degradation products do not cause toxic of allergenic reactions in the organism,[120] and that the adhesives based on n-alkyl-α-cyanoacrylates are nontoxic, nonimmunogenic, biodegradable polymers.[121, 122] According to other workers (for example, Lipatova and Pkhakadze[123]) the degradation products of cyanoacrylate adhesives can induce local toxic reactions.

Unfortunately many studies of the biodegradation of cyanoacrylate adhesives do not include a quantitative analysis. Some interesting results were obtained [124] for the heterogeneous in vitro degradation of poly(n-alkyl-α-cyanoacrylates) of different molecular masses at 37 °C and different pH values (6–8). Under these conditions the degradation proceeds from the surface, and the experiments were made with films of sample having identical surface areas. The main product of the degradation is formaldehyde, and the dependence of the mass dissociation constant on the pH, molecular mass, and nature of the radicals (ethyl, butyl, hexyl) is linear.

Salts present in the organism catalyse the degradation, and therefore we expect the degradation of cyanoacrylate adhesives in the tissues of the living organism to proceed mainly from the surface.

Other polymers, such as polytetrafluoroethylene, poly(vinyl chloride), polycarbonate, poly(methyl methacrylate), cyanoacrylates, poly(vinyl alcohol), and poly(ethylene oxide) are used in medicine in addition to those mentioned above. The possibility of medical applications has been examined for polymers such as polydodecaneamide, polyglycollide, polyglactin, hydrogels, and segmented polyurethanes.

VII. Conclusion

At present polymers used in medicine cannot (unfortunately) be fully characterised in terms of their biocompatibility and biodegradation parameters (see Table 10). For PGL, PETP, and PDMS the lifetime and the mass durability in the organism can be determined with adequate precision. For PP and PE accurate data are not available at present, and must be obtained in the current research. Biocompatibility problems are the less well understood. With the exception of polymers specially synthesised for medical purposes, for which we may confidently expect that the degradation products cannot cause any complications in the organism, unambiguous and well founded conclusions on the biocompatibility of other polymers should become possible in the near future from a generalisation of the results of implantations and of experiments now in progress in many medico-biological research centres.

Levoglucosenone: the properties, reactions, and use in fine organic synthesis

M S Miftakhov, F A Valeev, I N Gaisina

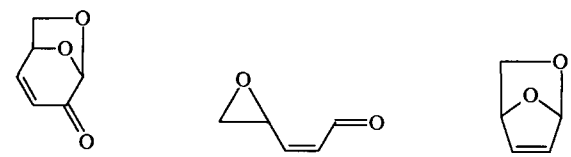
Contents

I. Introduction	869
II. The synthesis, structure, and mechanism of the formation of levoglucosenone	869
III. Chemical syntheses of levoglucosenone	871
IV. Reactions of levoglucosenone and its derivatives	871
V. The use of levoglucosenone in the synthesis of natural products	877

Abstract. The review deals with the synthesis, structure, chemical properties, and use of 1,6-anhydro-3,4-dideoxy-β-D-pyranosen-2-one (levoglucosenone) in the synthesis of natural products. The bibliography includes 67 referencces.

I. Introduction

Levoglucosenone (1,6-anhydro-3,4-dideoxy-β-D-pyranosen-2-one) is a sugar enone obtained in the acid-catalysed pyrolysis of cellulose and related materials which has attracted the attention of investigators by the unique nature of its structure and as a means for the introduction of chiral centres in the stereospecific synthesis of natural products. The 6,8-dioxabicyclo[3.2.1]octane skeleton, an enone system, and a highly activated keto-group and an acetal centre are combined in the structure of levoglucosenone. The effective facial differentiation of the attack by the reactants, induced by the 1,6-anhydro-bridge, as well as the coordinating and 'cooperative' effects of the 'chelate' acetal oxygen atoms ensure ease of occurrence and the high regio- and stereo-selectivity of the majority of the reactions involving levoglucosenone. Levoglucosenone is 'self-protected' in the form of an internal acetal, is thermally stable, and distils without appreciable decomposition. It forms readily dimeric and oligomeric condensation products and under certain conditions can generate highly reactive oxidopyrylium ylides. Levoglucosenone has proved useful as an effective Michael acceptor and as a powerful dienophile in Diels–Alder reactions, in dipolar cycloaddition, etc.



Although levoglucosenone has been known for more than 20 years,[1] it has still found only limited applications in organic synthesis. This is apparently associated with certain difficulties in the synthesis, purification, and handling of this compound and also with the lack of reviews on this topic. We hope that the data presented in this review will stimulate research by Russian chemists in this field.

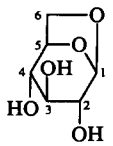
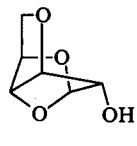
II. The synthesis, structure, and mechanism of the formation of levoglucosenone

Since the 1970s, the attention of investigators has been directed to the study of the structure, mechanism of the formation, and the properties of levoglucosenone **1**, which is one of the principal volatile products of the acid-catalysed thermolysis of cellulose and related carbohydrates.[1] Other empirical and structural formulae were initially attributed erroneously to this compound; 4,5-epoxy-2(*Z*)-pentenal ($C_5H_6O_2$) **2**,[2] 1,5-anhydro-2,3-deoxy-β-D-pent-2-enofuranose ($C_5H_6O_2$) **3**,[3] etc. The principal difficulties in the determination of the structure **1** were associated with the incorrect interpretation of mass-spectrometric data; the *m/z* 98 peak, corresponding to the formula $C_5H_6O_2$, was assumed to be due to a molecular ion.



1 **2** **3**

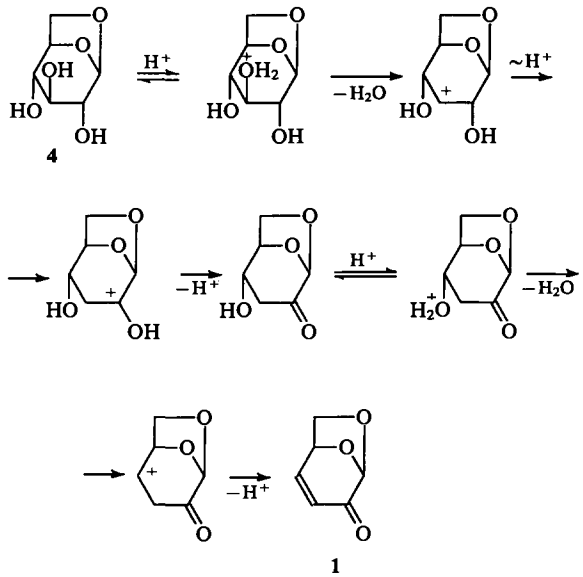
Having investigated by NMR, UV, and IR spectroscopy as well as mass spectrometry and osmometry the products of the thermolysis of cellulose obtained under analogous conditions, Halpern et al.[4] concluded that it has the molecular formula $C_6H_6O_3$ and is 1,6-anhydro-3,4-dideoxy-β-D-pyranosen-2-one **1**, which was given the trivial name levoglucosenone.



The structure of levoglucosenone was subsequently confirmed and adopted also by other investigators.[5–10] In particular, the exact mass of the molecular ion was determined[11] in 1985 as 126.0327, which corresponds to the empirical formula $C_6H_6O_3$, with the aid of chromatograph-linked mass spectrometry using both electron impact and chemical ionisation. The ion with *m/z* 98.0381 proved to be secondary and was produced as a result of fragmentation of levoglucosenone with ejection of CO. On the basis of ^1H and ^{13}C NMR spectroscopic data, it was also established that the six-membered ring of levoglucosenone has the envelope conformation.[12]

The pyrolysis of cellulose is a complex process, which leads to various products depending on the conditions.[13–18] Thus pyrolysis in vacuo (300–500 °C) affords a high yield of levoglucosan — 1.6-anhydro-β-D-glucopyranone **4**; at atmospheric pressure, levoglucosenone **1** and 1.4:3,6-dianhydro-β-D-glucopyranose **5** are formed as a result of the combination of

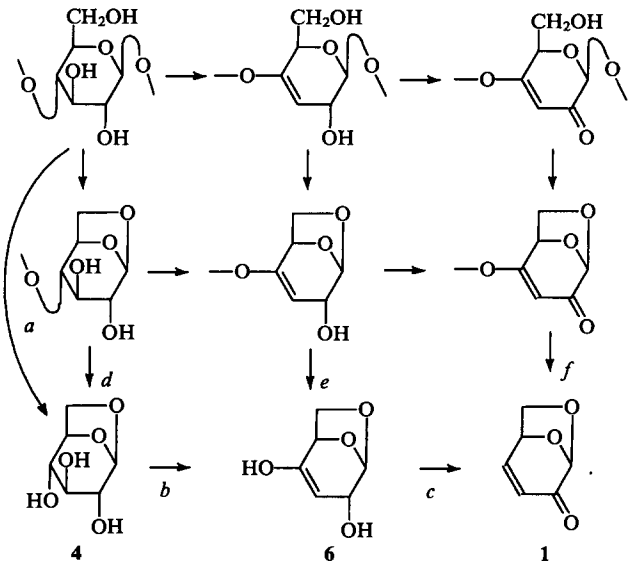
the reactions involving transglycosylation and dehydration of the D-glucose residues of cellulose.[17] The rapid removal of levoglucosan and other anhydrosugars prevents their further transformations into oligosaccharides, their decomposition into other volatile components, and salt formation. The presence of an acid catalyst promotes dehydration and charring accompanied by the formation of levoglucosenone, other unsaturated compounds, and carbon.[18]



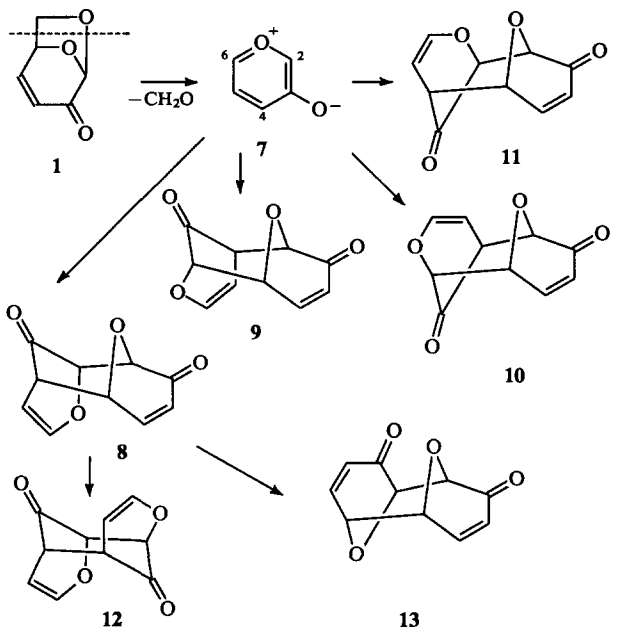
4

5

Studies of the influence of reaction conditions on the yield of levoglucosenone[17-21] led to the discovery of the optimum process parameters: 300 °C, atmospheric pressure, and 1% phosphoric acid concentration.



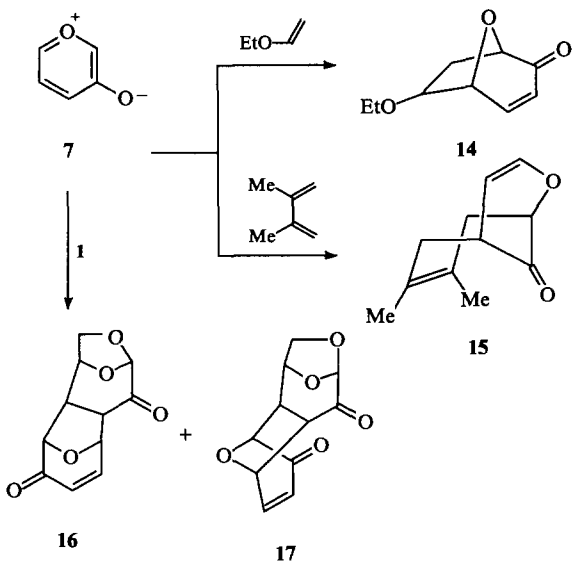
A mechanism has been proposed for acid-catalysed isotypical thermal decomposition reactions of cellulose, D-glucose, and levoglucosenone.[22] The C(1) and C(5) chiral centres of levoglucosan **5** are not involved in the transformations but the levoglucosenone obtained from the optically active levoglucosan {$[\alpha]_D^{25} = -55°$, $c = 0.5$, H_2O} is chiral {$[\alpha]_D^{25} = -52.7°$, $c = 1.0$, $CHCl_3$}.



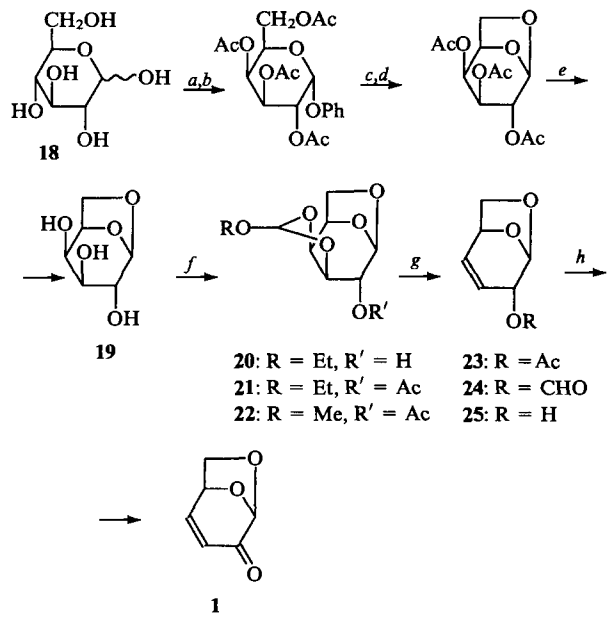
The third stage of the proposed mechanism, involving a 1,2-hydride shift from the C(2) atom to the carbenium centre C(3) and the formation of a more stable hydroxycarbenium ion, is the most important. The alternative 1,2-hydride shift leading to a hydroxycarbenium ion at C(4) apparently does not occur, since the corresponding levoglucosenone isomer was not found in the pyrolysate.[23]

The method involving pyrolysis at the Curie point was used subsequently to identify the primary products of the decomposition of cellulose and related compounds.[7] In this procedure, the specimen was heated briefly to a fixed temperature under an inert carrier gas atmosphere. As a result of the relatively low temperature, the reactions of the primary products were ruled out. The pyrolysis mechanism (top right) was proposed.[7]

Compounds **1**, **4**, and **6** can be formed not only via routes *a*, *b*, or *c* but also via polymeric anhydro- and deoxy-sugar units (stages *d*–*f*). However, direct evidence for this has not yet been obtained.



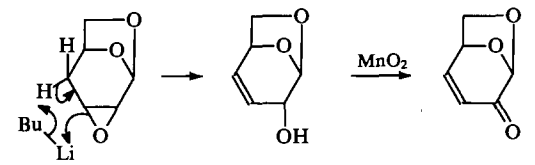
Levoglucosenone can undergo pyrolytic deformylation, affording the 3-oxidopyrylium intermediate **7**.[25] The highly reactive ylide **7** readily dimerises via a [6π + 4π] mechanism to form four regioisomeric adducts — the *endo*-compounds **8** and **9** and the *exo*-compounds **10** and **11** respectively. The situation is complicated by the fact that each of these adducts undergoes allyl rearrangements in its turn, affording two new dimers in each case. Thus the dimers for the primary adduct **8** are the bisvinyl ether **12** and the bisenone **13**.



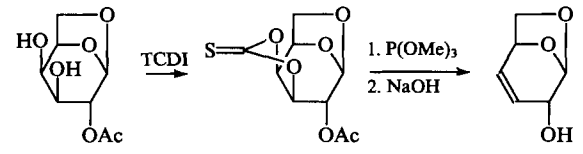
In thermal cycloaddition reactions, the 3-oxidopyrylium derivative **7** behaves both as a 4π-electron system (addition of ethyl vinyl ether and the formation of the bicyclic enone **14**) and as a 6π-electron component (addition in the 2- and 4-positions in the reaction with 2,3-dimethylbutadiene and the formation of the bicyclic vinyl ether **15**). In addition, the ylide **7** enters into a [4π + 2π]-cycloaddition reaction with levoglucosenone, affording the adducts **16** and **17**.

Thus the 3-oxidopyrylium intermediate **7** can condense with itself, with alkenes, and with dienes in electrocyclic reactions permitted by thermal conditions. All these factors are responsible for the diversity of the pyrolysis products.

III. Chemical syntheses of levoglucosenone



The synthesis of levoglucosenone from D-galactose **18** has been described.[26]



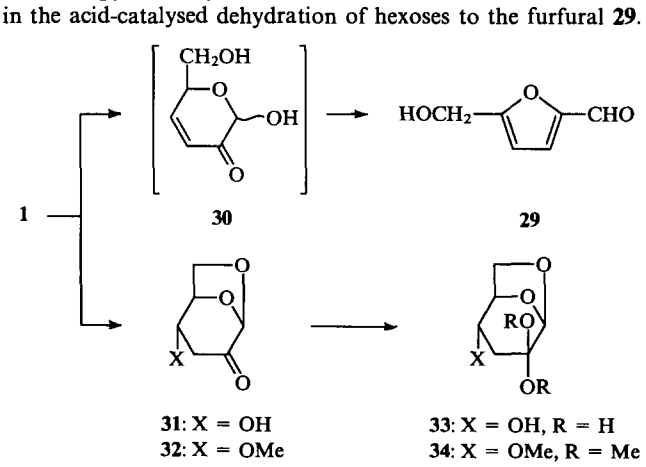
(*a*) AcONa–Ac_2O; (*b*) H^+, PhOH; (*c*) NaOH–H_2O; (*d*) Ac_2O, Py; (*e*) NaOMe; (*f*) $(RO)_3CH$, H^+, DMF; (*g*) Ac_2O, Cat; (*h*) MnO_2.

1,6-Anhydro-β-D-galactopyranose **19**, obtained from D-galactose, was mixed with 4 equivalents of triethyl orthoformate in solution in *N*,*N*-dimethylformamide in the presence of catalytic amounts of H_2SO_4 and was allowed to stand for 12 h. After appropriate treatment of the reaction mixture, the 3,4-ethoxyacetal of 1,6-anhydro-β-D-galactopyranose **20** was isolated in 95% yield. In the key reductive decarboxylation stage, the ethoxyacetal **20** or its acetyl derivatives **21** and **22** were refluxed in solution in acetic anhydride containing the catalyst. The highest yield of 2-acetyl-1,6-anhydro-3,4-dideoxy-β-D-*erythro*-hex-3-enopyranose **23** (in the absence of Ac_2O, the corresponding 2-formyl derivative **24** may be formed) was achieved when an aqueous solution of zirconium oxide was used (the yield of the alkene **23** was 88%). In the concluding stage, levoglucosenone was obtained as a result of the allylic oxidation of compound **25** by MnO_2.

Köll et al.[27] developed a scheme for the synthesis of levoglucosenone the key stage of which is the rearrangement of the epoxide **26**[28] to the allyl alcohol **25**.

The same workers proposed a more practical route to the enone **1** starting with the groundnut galactomannan. Pyrolysis of this polysaccharide followed by acetonation affords a monoisopropylidene derivative of 1,6-anhydro-β-D-galactopyranose. Its acetylation and treatment with aqueous acid lead to compound **27**. The crystalline thionocarbonate **28** was obtained from the latter by reaction with *N*,*N*′-thiocarbonyldiimidazole (TCDI) in boiling 2-butanone. On heating compound **28** with trimethyl phosphite for many hours and on treatment with alkali, the allyl alcohol **25** is produced.

A method for the synthesis of levoglucosenone from glucose has been described.[29] The reaction is carried out in dimethylformamide at 70–120 °C in the presence of concentrated H_2SO_4.

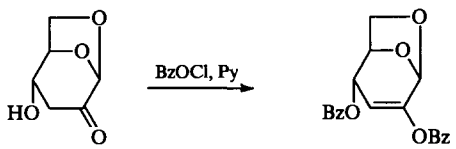


We may note that none of the methods of synthesis of levoglucosenone listed above can compete with the pyrolysis of cellulose, which remains the most economical and effective method for its preparation despite disadvantages such as the low yield of the product and the need to work with relatively large volumes of solid cellulose materials.

IV. Reactions of levoglucosenone and its derivatives

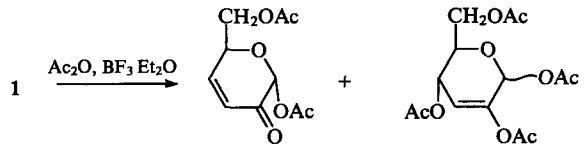
1. Acid- and base-catalysed reactions of levoglucosenone

Levoglucosenone has three reaction centres: the carbon–carbon double bond, the keto-group, and the glycosidic anhydro-linkage. Depending on the process conditions, each of these groups can react selectively.



When levoglucosenone is heated with aqueous solutions of inorganic acids, 5-hydroxymethylfurfural **29** is formed.[17] This entails the initial rupture of the 1,6-anhydro-linkage of levoglucosenone and the formation of 3,4-dideoxy-D-*glycero*-hex-3-enopyranos-2-ylose **30**, which is in fact an intermediate in the acid-catalysed dehydration of hexoses to the furfural **29**.

Heating of levoglucosenone in aqueous acetic acid affords an intermediate resulting from the addition of water of the double bond — 1,6-anhydro-3-deoxy-D-*erythro*-hexopyranos-2-ylose **31**. Compound **31** can be readily separated from levoglucosenone **1** by extracting the latter with chloroform. The high solubility of compound **31** in water is due to the hydration of the keto-group and the formation of the *gem*-diol **33**, which has been confirmed by ^{1}H NMR spectroscopy.

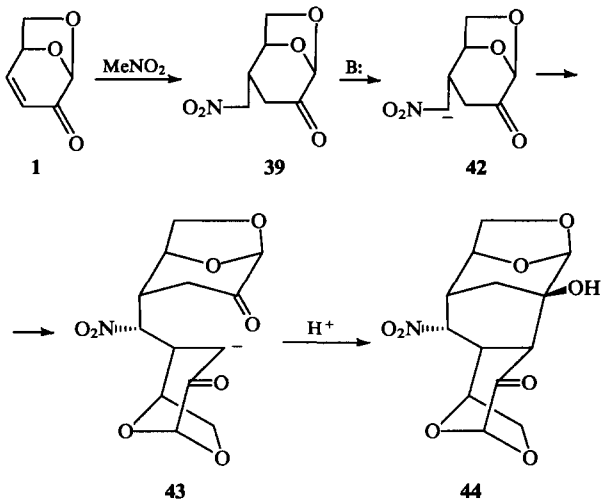


The acid-catalysed addition of methanol to the double bond of levoglucosenone using the MeOH – HCl system initially affords 4-*O*-methyl-2-ylose **32**, which is then rapidly converted into the dimethyl acetal **34** in an almost quantitative yield. Hydrolysis of compound **34** again leads to 4-*O*-methyl-2-ylose **32**.

The attempts to benzoylate the 4-hydroxy-group in compound **31** by benzoyl chloride in pyridine led to 1,6-anhydro-2,4-di-*O*-benzoyl-3-deoxy-β-D-*erythro*-hex-2-enopyranose **35** (via stages involving the successive enolisation and benzoylation of the keto-group).

31 **35**

The 1,6-anhydride ring of levoglucosenone is readily opened under acetolysis conditions in the presence of $BF_3.Et_2O$ as catalyst, which leads to the diacetate **36**. The anomeric tetraacetates **37** and **38** are formed in smaller amounts as a result of the exhaustive acetylation of the enone.



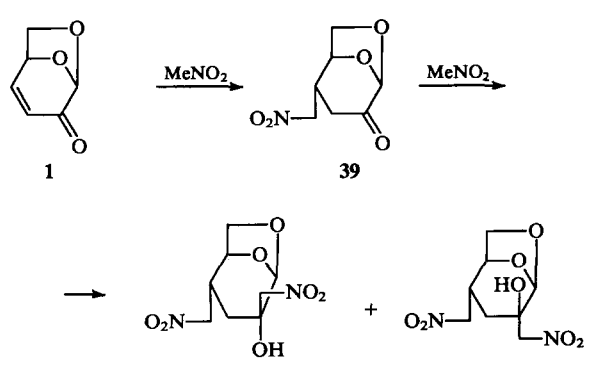
36 **37(α), 38(β)**

Reactions involving addition to the 3,4-double bond of levoglucosenone are also catalysed by bases. In the presence of small amounts of triethylamine, levoglucosenone affords satisfactory yields of the adducts **31** and **32** in water and anhydrous methanol respectively.

2. Michael addition

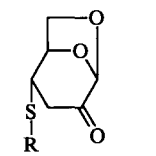
The reactions in which levoglucosenone serves as a Michael acceptor merit special attention.[30–33] Treatment of levoglucosenone with an excess of nitromethane in the presence of catalytic amounts of tetramethylguanidine gave rise to a mixture of two isomeric 2 : 1 adducts in an overall yield of 98%.[30] The reaction involves the initial 1,4-addition to the enone [the nitronate anion $^-CH_2NO_2$ adds to the C(4) atom of levoglucosenone from the side opposite to that of the 1,6-anhydro-bridge]; the subsequent base (B)-catalysed addition of a second nitromethane molecule to the carbonyl group of compound **39** leads to the formation of the diadducts **40** and **41** in proportions of 10 : 1.

When the reaction is carried out with an excess of levoglucosenone, 1 : 2 adducts are formed. The proposed mechanism of the formation of compound **44** represents the Michael addition of the nitromethyl anion **42** to levoglucosenone accompanied by the intramolecular aldol condensation of the intermediate diketone **43**. The high yield of the product **44** (95%) shows that each of the reaction stages is highly selective and that in each case the attack on the nucleophilic centre is directed exclusively to the *exo*-position.



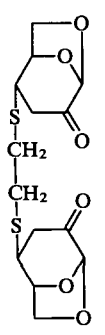
1 **39** **42**

43 **44**



1,6-Anhydro-4-butylthio-3-deoxy-β-D-hexopyranos-2-ylose **45** has been obtained in a quantitative yield by the addition of butane-1-thiol to levoglucosenone.[31] Steric hindrance generated by the 1,6-anhydro-bridge interferes so much with equatorial attack on the thiol that the axial sulfide is formed exclusively. Other thiols behave similarly, affording the adducts **46**–**51**.

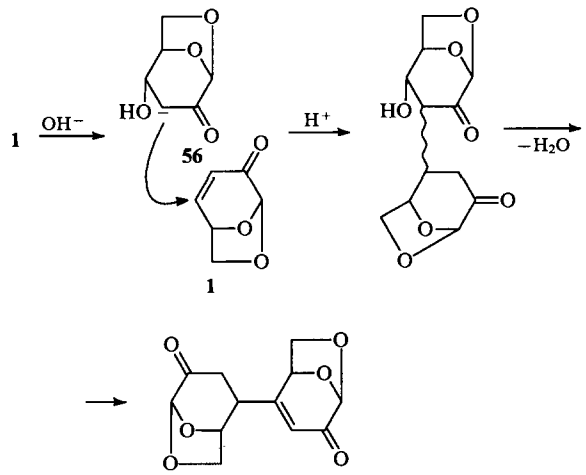
The same workers investigated the possibility of cross-coupling two levoglucosenone molecules via dithiols. Ethane-1,2-dithiol was chosen as the binding component, its reaction with levoglucosenone affording two products. The structure of one of them (compound **52**), obtained in 47% yield, was established by spectroscopic methods. The other reaction product could not be identified because of its instability (the compound decomposed rapidly at room temperature and it was shown by thin-layer chromatography that it afforded highly polar secondary products). Its ^{1}H and ^{13}C NMR spectra indicated the presence of three levoglucosenone molecules in its structure. The monoadduct was not detected.



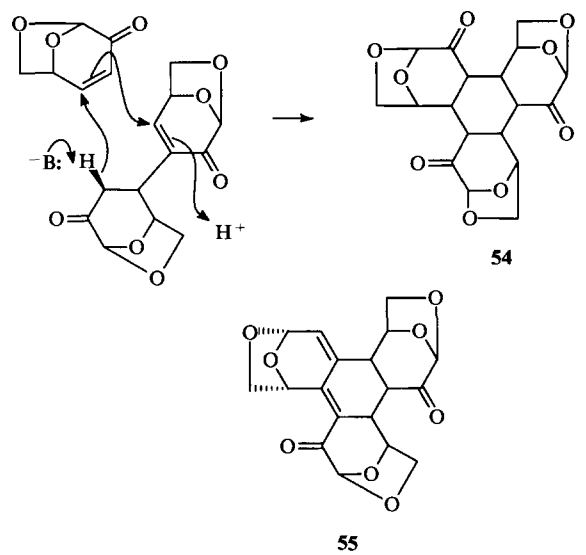
1 **39**

40 **41**

45: R = $(CH_2)_3CH_3$
46: R = $(CH_2)_5CH_3$
47: R = $(CH_2)_9CH_3$
48: R = $(CH_2)_{11}CH_3$
49: R = $CH_2CH(CH_3)_2$
50: R = $C(CH_3)_3$



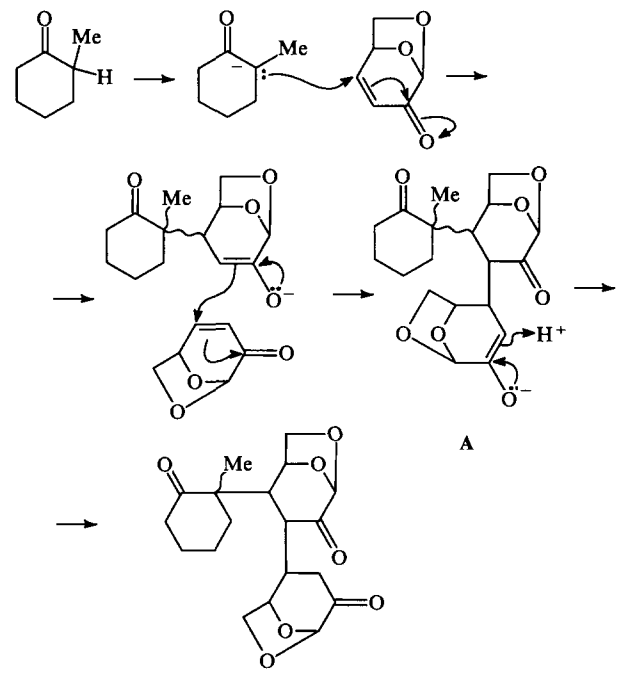
51: R = 



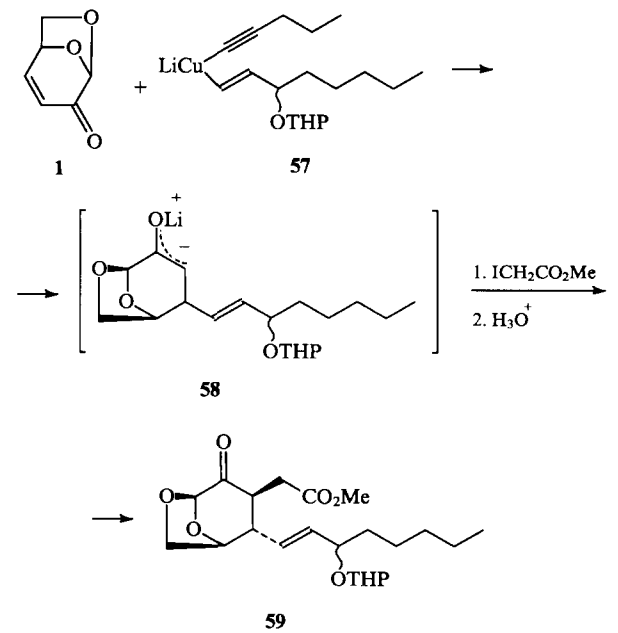
52

Heating levoglucosenone in aqueous triethylamine gives three principal oligomers: the dimer **53**, the saturated trimer **54**, and the unsaturated trimer **55**.[32]

The mechanism of the dimerisation of levoglucosenone is presented below. The base-catalysed hydration of compound **1** leads to the α-keto-stabilised carbanion **56**, which attacks a second levoglucosenone molecule in the *exo*-position. Subsequent dehydration affords the dimer **53**.

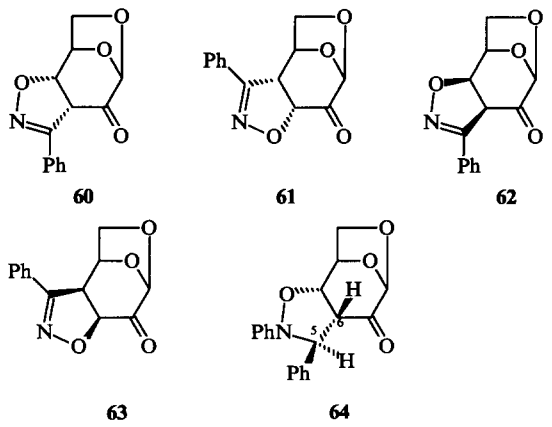


The mechanism of formation of the trimer **54** involves the condensation of three levoglucosenone molecules. The intramolecular condensation of the α-keto-stabilised carbanion **56** with a molecule of compound **1** is then accompanied by intramolecular cyclisation.



The formation of the alkene trimer **55** from compound **1** in aqueous triethylamine proceeds mainly via a similar mechanism. The crystal structures of the cyclic levoglucosenone trimers have been confirmed by X-ray diffraction.[33]

The Michael additions of diethyl malonate, ethyl cyanoacetate, 2-nitropropane, and 2-methylcyclohexanone to levoglucosenone using various catalysts have also been investigated.[34] The reaction of levoglucosenone with 2-methylcyclohexanone was carried out in *tert*-butyl alcohol in the presence of equimolar amounts of potassium *tert*-butoxide. The structure **A** was attributed to the product on the basis of spectroscopic data.

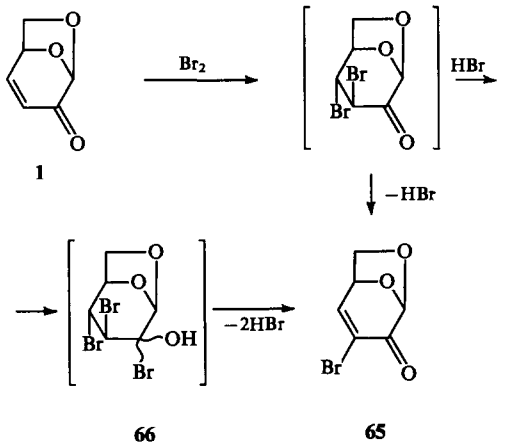


In order to obtain thromboxane-like structures, a study was made[35] of the coupled 1,4-addition of the racemic cuprate reagent **57** to levoglucosenone with subsequent alkylation of the intermediate enolate **58** by ethyl iodoacetate. The 'triple convergent coupling' sequence achieved ultimately led to compound **59** in 35% yield.

3. 1,3-Dipolar cycloaddition reactions

Levoglucosenone readily enters into cycloaddition reactions with benzonitrile oxide ($PhC{\equiv}N^{+}-O^{-}$) and with *C*,*N*-diphenylnitrone [$PhCH=N^{+}(Ph)-O^{-}$].[36] It was shown that, of the four possible adducts of levoglucosenone with benzonitrile oxide (the two *endo*-isomers **60** and **61** obtained when 1,3-dipolarophile is attacked from the side opposite to that of the 1,6-anhydro-bridge and the two alternative *exo*-isomers **62** and **63**), the *endo*-adduct **60** (yield 71%) and trace amounts (0.6%) of the *exo*-isomer **62** are formed.

60 61 62



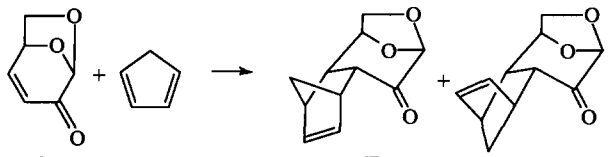
63 64

In the case of the *C,N*-diphenylnitrone, there is a possibility of the formation of eight adducts: the *exo*- and *endo*-isomers for each pair of regioisomers. However, refluxing of levoglucosenone with *C,N*-diphenylnitrone in toluene afforded only one 1 : 1 adduct in 68% yield. The absence of an appreciable Overhauser effect (< 2%) between the H(5) and H(6) protons is evidence in support of the *endo*-structure **64**, which was subsequently confirmed by X-ray diffraction. Thus the reaction also proved to be regio- and stereo-specific.

4. Bromination of levoglucosenone

The crystalline monobromo-derivative **65**, characterised by spectroscopic methods, has been obtained by brominating levoglucosenone with two equivalents of Br_2 in $CHCl_3$ and the subsequent removal of excess bromine by washing the organic phase with sodium hydroxide.[37]

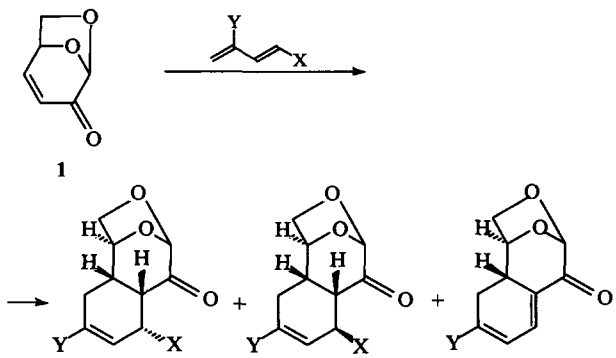
The change in the type of treatment, i.e. the removal of the excess bromine by evacuation at 20 °C, led to the unstable crystalline tribromo-derivative **66**. In all probability, this anomalous course of the reaction is caused either by the presence in the reaction mass of HBr, formed owing to the presence of moisture in bromine, or by the radical reaction between bromine and chloroform. On heating in the solution, compound **66** splits off two HBr molecules, affording 3-bromolevoglucosenone **65**.



1 66 65

5. Levoglucosenone in the Diels–Alder reaction

The Diels–Alder reaction of levoglucosenone with cyclopentadiene, carried out in an excess of boiling dicyclopentadiene, affords a 47.8% yield of the crystalline adduct **67** and insignificant amounts of an unidentified carbohydrate.[38] Other investigators[39,40] carried out the reaction in boiling chlorobenzene and isolated the syrupy isomer **68** (in 16.5% yield) in addition to the crystalline compound **67** (in 65% yield).



The structure of the adducts follows from spectroscopic data. Thus the absence of an appreciable interaction between H(4) and H(5) indicated by the ^1H NMR spectra of compounds **67** and **68** is evidence that these protons are diequatorial (the β-D-*ribo*-configuration) and that both adducts are formed when the diene is attacked 'from below'. The main adduct **67** is an *endo*-alkene (established with the aid of X-ray diffraction of the transformed product), while the minor adduct **68** is an *exo*-alkene (the configuration relative to the norbornene fragment is indicated).

1 67 68

The $ZnCl_2$-catalysed low-temperature Diels–Alder reaction of the above components, which makes it possible to obtain compound **67** in 75% yield without an admixture of the second isomer, is preparatively preferable.[41]

Subsequently various derivatives of cyclopentadiene, buta-1,3-diene, hexa-1,3-diene, and furan were tried as the diene component in the [4 + 2]-cycloaddition reactions of levoglucosenone.[38–40,42] In particular, in connection with the development of approaches to the synthesis of the indole alkaloid reserpine,[42] a study was made of the reaction of levoglucosenone with substituted buta-1,3-dienes. Unsubstituted buta-1,3-diene afforded a 98% yield of the adduct **69a**. In the case of 1-acetoxybuta-1,3-diene, the product of the elimination reaction **71** was formed together with the main product **69b** (in proportions of 3 : 1), whilst prolonged heating led to compound **71** as the only product formed in a quantitative yield. The reaction of levoglucosenone with 1-trimethylsiloxybuta-1,3-diene led to the formation of a mixture of the *endo*- and *exo*-adducts **69** and **70** in proportions of 2 : 1 in a 91% overall yield. the introduction of 5-benzyloxy-2-methoxypenta-1,3-diene, necessary for the formation of the basic reserpine synthons, into the reaction led to a stereoisomeric mixture of products in an overall yield of 38%.

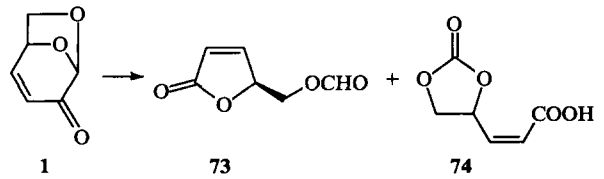
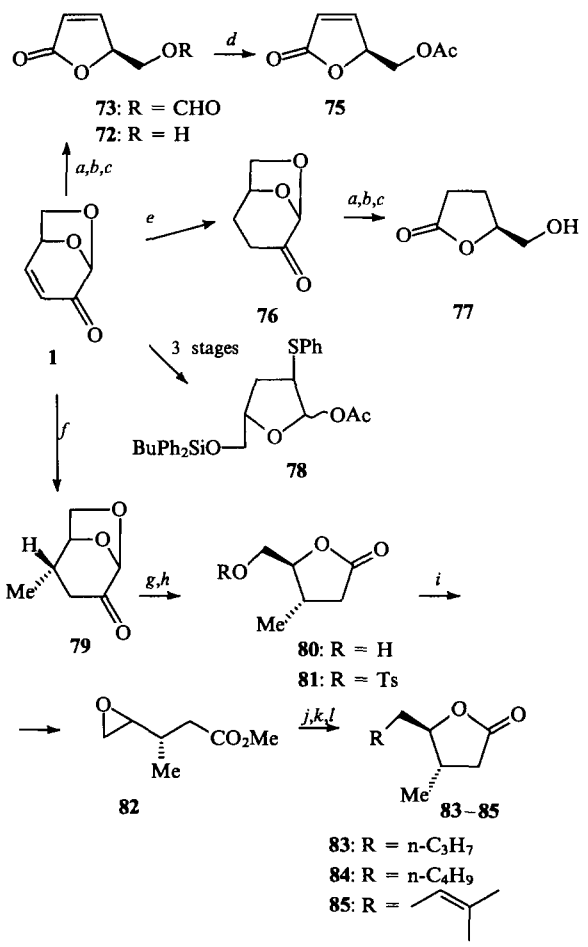
6. The oxidation reactions of levoglucosenone and some of its derivatives



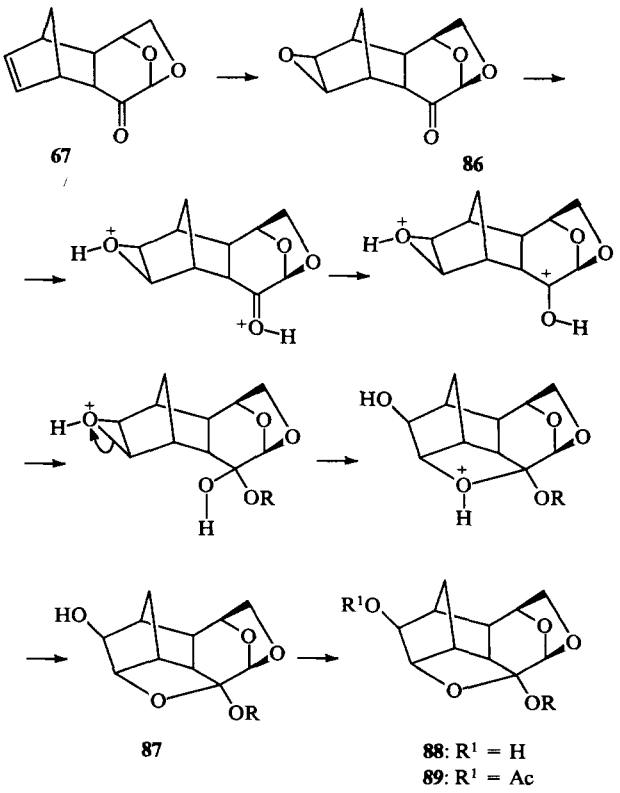
The unsaturated γ-lactone (*S*)-5-hydroxypent-2-en-4-olide **72**, containing one chiral centre, has found extensive applications in the manufacture of various medicinal drugs (burseran and isostegan), the antibiotic lasalocid A,[43] pheromones, aromatisers for whisky and cognac,[44] and also preparations suppressing the growth of the AIDS virus.[45]

In contrast to the approaches to the synthesis of the lactones **72** proposed previously and based on expensive and multistage syntheses using D-ribose and L-glutamic acid as the starting materials, the method developed by Koshi et al.[46] is extremely convenient and simple. The lactone **72** is obtained in one stage by oxidising levoglucosenone with *m*-chloroperbenzoic acid (MCPBA) by the Baeyer–Villiger method.

Shafizadeh and Furneaux,[17] who investigated the oxidation of levoglucosenone by *m*-chloroperbenzoic acid, demonstrated on the basis of spectroscopic data that the product of this reaction is either compound **A** or compound **B**, the formation of the enol-lactone **B** being most probable.

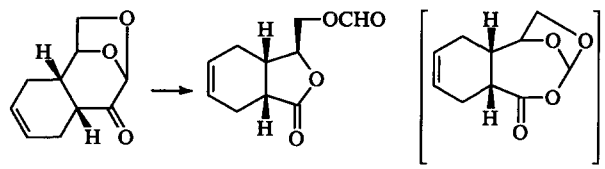


However, a more correct study of the oxidation reaction carried out by Koshi et al.,[46] established that the main reaction product is the formate **73** (yield 59%), while the cyclic carbonate **74** is a side product (yield 16%).



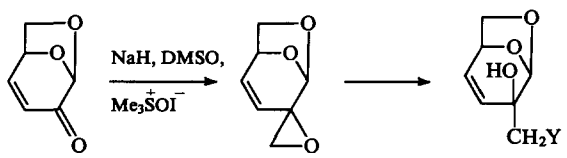
Subsequently peracetic acid was used to avoid oxidative rearrangements as side processes. After methanolysis and acetylation, the acetate **75** was synthesised as a result in 65% yield relative to levoglucosenone. (*S*)-5-Hydroxypentan-4-olide **77**[46,47] as well as 2-α-phenylthio-2,3-dideoxyribose **78** were obtained similarly from dihydrolevoglucosenone **76**.[48]

3,4-Dibsubstituted γ-lactones have been synthesised by the same procedure.[44] The methyl ketone **79** was oxidised to the lactone **80** and tosylated, the key epoxide **82** being obtained after the treatment of the tosylate **81** with alkali. The regioselective opening of the epoxide ring in compound **82** by means of appropriate cuprate reagents led to the 4-substituted γ-lactones **83**–**85**.



The oxidation of the principal cyclic [4 + 2]-adduct of levoglucosenone and cyclopentadiene **67** by *m*-chloroperbenzoic acid has been investigated.[43] The reaction afforded the *exo*-epoxide **86** in 86% yield. Its stereochemistry was elucidated by means of chemical reactions. Thus the hydrolysis of compound **86** does not entail the formation of a nonclassical ion characteristic of the norbornyl epoxide. Instead intramolecular cyclisation takes place and leads to the pentacyclic product **87**. Chemical proof of the involvement of the carbonyl group at the C(2) atom in the acid-catalysed solvolysis of compound **86** has been obtained by changing the solvent (water replaced by methanol). In order to determine the position of the hydroxy-group, compound **88** was acetylated. The spectra of the resulting acetate **89** indicated unambiguously that the hydroxy-group is at the C(9) atom while the methoxy-group is at the C(2) atom in compound **88**.

(*a*) AcOOH, AcOH; (*b*) Me_2S; (*c*) MeOH–HCl, 45 °C; (*d*) AcCl, Py, CH_2Cl_2; (*e*) H_2, Pd/C; (*f*) Me_2CuLi; (*g*) AcOOH, AcOH; (*h*) *p*-TsCl, Py; (*i*) K_2CO_3, MeOH; (*j*) Pr^n_2CuLi; (*k*) Bu^n_2CuLi; (*l*) $Me_2C{=}CHMgBr{-}CuBr$.

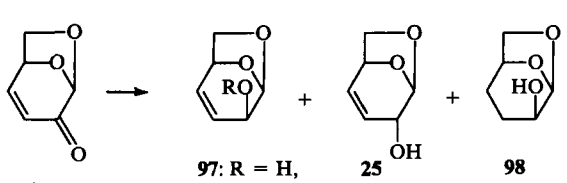


The Baeyer–Villiger oxidation of the tricyclic ketone **69a** afforded a high yield of the formyloxy-γ-lactone **90** with a *cis*-junction.[50] It was postulated that the formation of the formate is associated with the acid-catalysed rearrangement of the intermediate mixed inner orthoester **91**.

69a **90** **91**

7. Reactions involving the keto-group of levoglucosenone

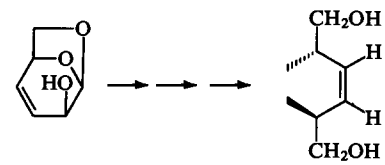
In the course of the nucleophilic attack on the carbonyl group, the 1,6-anhydro-bridge of levoglucosenone exercises steric control, directing the approach of the reagent 'from below' the plane of the pyranose ring. Thus the interaction of the levoglucosenone with Cory's reagent, obtained by the reaction of NaH with $Me_3S^+OI^-$ in dimethyl sulfoxide, afforded a 50% yield of the epoxide **92**, which is obtained exclusively as a result of the *endo*-attack on the bulky reactant from the side of the levoglucosenone less shielded by the 1,6-anhydro-bridge.[51,52]



1 **92** **93–96**

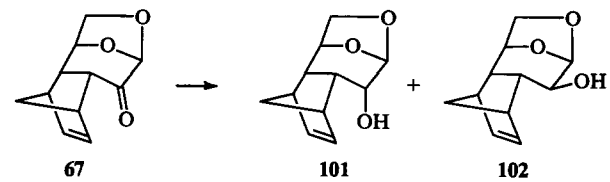
Y = OH (**93**), H (**94**), N_3 (**95**), NH_2 (**96**).

Alkaline hydrolysis of the epoxide **92** by aqueous NaOH leads to the crystalline diol **93** in 71% yield. X-Ray diffraction of the specimen confirmed the structure **93** and hence also the structure of the epoxide **92**. Next the derivative **94** was obtained from the epoxide **92** by reduction with $LiAlH_4$, while azidolysis gave rise to the azide **95**, the reduction of which with $LiAlH_4$ led to the crystalline aminoalcohol **96**.



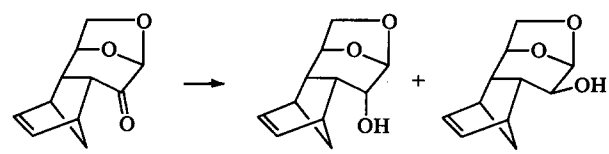
Thus the opening of the ring in the spiroepoxide **92** takes place entirely regiospecifically via an S_N2 mechanism.

It has been shown[13,27,53] that the double bond of levoglucosenone can be selectively hydrogenated. On the other hand, the reduction of the keto-group by $NaBH_4$ affords the allyl alcohols **97** and **25** as the main products, although the formation of minor unsaturated alcohols of type **98** is also possible depending on the reaction conditions.



1 **97**: R = H, **99**: R = Ts. **25** **98**

On the basis of preliminary data obtained in Shafizadeh's laboratory,[13] the D-*erythro*-configuration (compound **25**) was attributed incorrectly to the product of the reduction of levoglucosenone by $LiAlH_4$. Subsequently the product was characterised as the D-*threo*-isomer **97** by comparing the alcohol obtained and its tosylate with authentic specimens[53,54] and also by the stereospecific conversion into (*Z*)-3,4-dideoxy-D-*threo*-hex-3-enitol **100**[17] with a known absolute configuration.



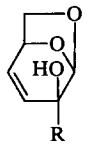
97 **100**

The reduction of the adduct **67** by sodium tetrahydroborate in 95% ethanol at 25 °C led to a mixture of the *endo*-alcohol **101** and the *exo*-alcohol **102** in 53% and 39% yields respectively.

67 **101** **102**

68 **103** **104**

Similarly the reduction of the minor adduct **68** with $NaBH_4$ afforded a mixture of the *exo*-alcohol **103** (yield 74%) and the less polar *endo*-alcohol **104** (yield 22%), the structures of which were established by spectroscopic methods. Axial attack on the *endo*-alkene **67** by the BH_4^- anion is more difficult, since in this case the carbonyl group occupies the *syn*-position relative to the bicyclo[2.2.1]hept-2-ene system.



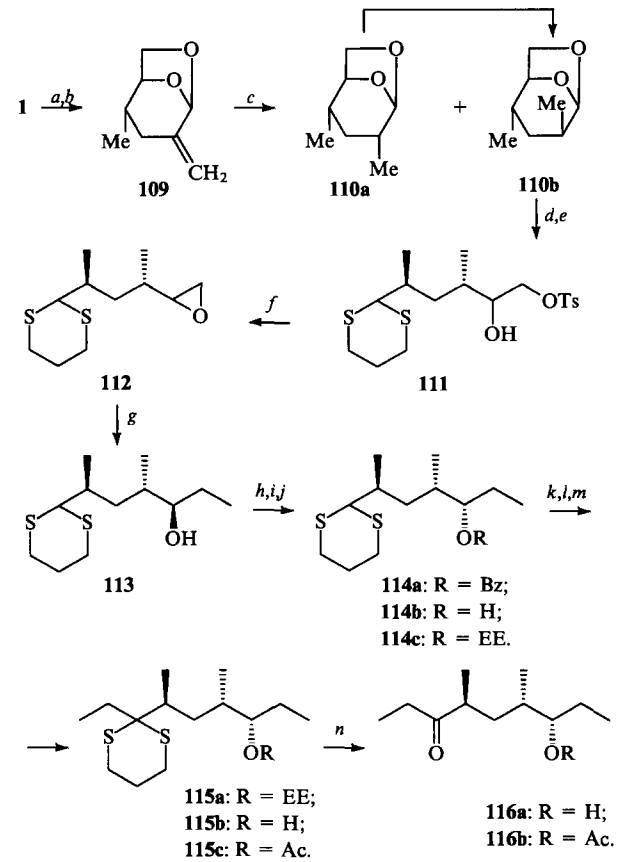
It had been reported earlier[13] that 1,2-adducts were obtained by the reaction of levoglucosenone with methylmagnesium iodide: 1,6-anhydro-3,4-dideoxy-2-*C*-methyl-β-D-*erythro*-hex-3-enopyranose **105** in 56% yield, its C(2)-epimer (1,6-anhydro-3,4-dideoxy-2-*C*-methyl-β-D-*threo*-hex-3-enopyranose **106**) in 6% yield, and the 1,4-adduct (1,6-anhydro-3,4-dideoxy-4-*C*-methyl-β-D-*erythro*-hexopyranos-2-ylose **79**) in 6% yield. When the reaction was carried out in the presence of Bu_3PCuI at −78 °C, the 1,4-adduct **79** was formed exclusively. The small spin–spin coupling constant between the H(4) and H(5) atoms obtained from the ^1H NMR spectrum of the adduct **79** indicated the *erythro*-configuration of the chiral centres. However, subsequently this claim was recognised as erroneous and, by analogy with the hydride reduction reaction, the D-*threo*-configuration was assigned to the main product of the Grignard reaction of levoglucosenone with methylmagnesium iodide.[17]

105: R^1 = Me, R^2 = OH. **106**: R^1 = OH, R^2 = Me. **79**

In order to attach long hydrocarbon chains, the reactions of levoglucosenone with tetradecyl- and octadecyl-magnesium bromides were carried out. Despite the fact that the target products **107** and **108** were obtained in 20% and 11% yields, the main products proved to be higher hydrocarbons formed via the

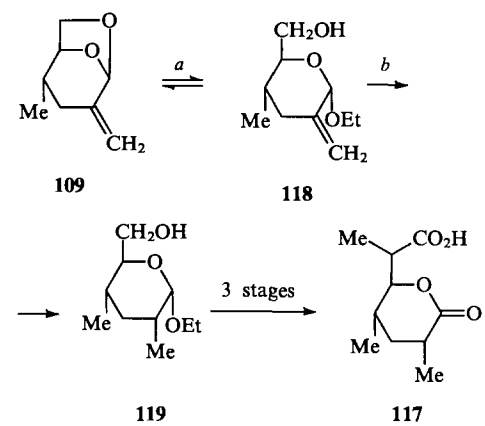
Wurtz reaction; the replacement of the Grignard reagent by alkyllithium reagents in order to suppress side reactions did not lead to the desired results.

107: R = $(CH_2)_{13}CH_3$;
108: R = $(CH_2)_{17}CH_3$.



V. The use of levoglucosenone in the synthesis of natural products

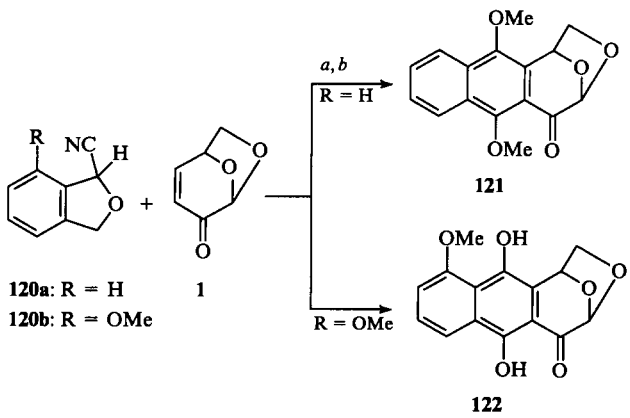
The employment of sugars in the total syntheses of natural products has attracted the attention of investigators by the ready availability of the starting material with chiral centres and the universality of the approach, which are ensured by the diversity of the monomeric carbohydrates with a known configuration of the chiral centres. In contrast to other monosaccharides, levoglucosenone, which is a 1,6-anhydro-sugar, has a greater synthetic potential in view of its unusual structure and the conformational rigidity of the molecule. The characteristic features and advantages of levoglucosenone, noted in the Introduction and in the previous sections, were subsequently demonstrated on specific examples.

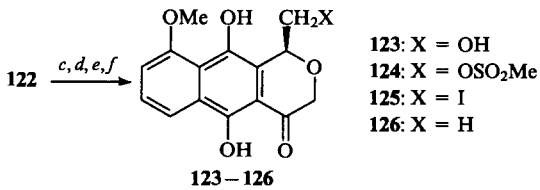


The stereoselective synthesis of serricornine, which is a sex pheromone of the tobacco beetle (*Lasioderma serricorne*—a pest on tobacco leaves), has been described.[55] Levoglucosenone was used as the starting material, its 1,6-anhydro bridge controlling unambiguously the stereoselective introduction of the methyl group at the C(4) atom. After the methylenation of the keto-group and hydrogenation of compound **109** in the presence of Pd/C, the 2,4-dimethyl derivatives **110a** and **110b** were obtained in proportions of 4:1. Compound **110b** (95% diastereoisomeric purity) was converted into the dithiane **111** and was then tosylated and the epoxide **112** was obtained after treatment with alkali. The epoxide reacted smoothly with 5 equiv. of Me_2CuLi in diethyl ether, affording the alcohol **113**. In order to obtain the alcohol having the desired configuration, Mitsunoba's method was used, the benzoate **114a** being hydrolysed to the alcohol **114b**. Compound **114b** was converted into acetylserricornine **116b** by a standard procedure: via stages involving the alkylation of dithiane, the replacement of the protecting group, and the hydrolysis of the dithiane **115c** with the aid of the $HgCl_2$–$CaCO_3$–aqueous MeCN system. The deacylated product **116a** exhibited the expected biological activity.

The *exo*-methylene derivative **109** proved to be a convenient starting material in the synthesis of the chiral synthon for the Prelog–Djerassi lactonoacid **117**.[56] Heating of the allyl glycoside **109** with trifluoroacetic acid in ethanol afforded an equilibrium mixture of compound **109** and the transglycosylation product **118**, isolated chromatographically. The stereoselective hydrogenation of the α-anomer **118** on a platinum catalyst led to ethyl 2,3,4-trideoxy-2,4-dimethyl-α-*ribo*-hexopyranoside **119** and its C(2) epimer in proportions of 6:1. Spectroscopic data confirmed the identity of compound **119** and of the key intermediate used in the synthesis of the Prelog–Djerassi lactonoacid. The method proposed makes it possible to reduce significantly the number of stages in the synthesis of the target lactone.

Pyranonaphthoquinones are compounds containing the naphtho[2,3-*c*]pyran ring system, which exhibit fungicidal, antibacterial, and anticancer activities. The fungal metabolite nanomycin A, altersolanol A, and the anthracycline antibiotic β-rhodomycinone are the best known representatives of these compounds.



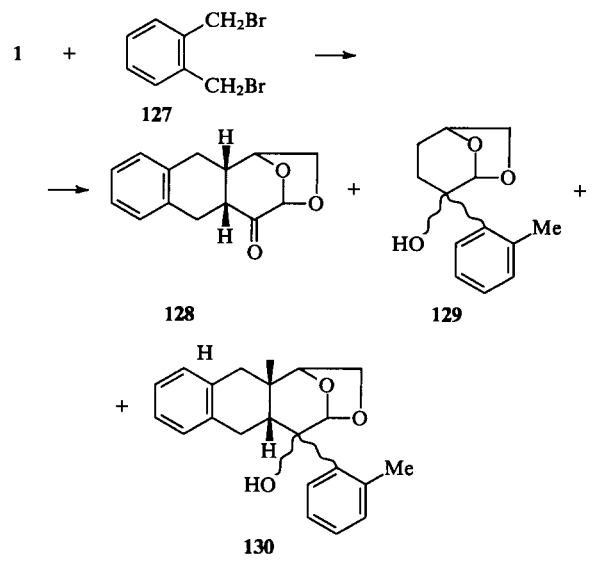


(*a*) Me_2CuLi, Et_2O; (*b*) Ph_3PCH_2, Et_2O; (*c*) H_2, Pd/C; (*d*) $HS(CH_2)_3SH$, $BF_3.Et_2O$, CH_2Cl_2; (*e*) *p*-TsCl, Py; (*f*) KOH, MeOH; (*g*) Me_2CuLi, Et_2O; (*h*) Ph_3P, BzOH, Et_2O; (*i*) KOH, MeOH; (*j*) EVE (EtOCH=CH_2), *p*-TsOH, CH_2Cl_2; (*k*) BuLi, TMEDA ($Me_2NCH_2CH_2NMe_2$), THF–EtI; (*l*) *p*-TsOH, EtOH; (*m*) Ac_2O, Py; (*n*) $HgCl_2$, $CaCO_3$, MeCN.

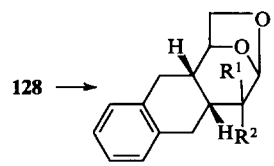
(*a*) 0.5% CF_3COOH–EtOH, 50 °C; (*b*) H_2, PtO_2, Et_2O.

The development of a new method for the construction of the rings of the naphthopyran ring system, which constitutes the central component of the above antibiotics, has been reported.[57] Levoglucosenone, which has the same stereochemistry as the dihydropyran fragments of the above antibiotics, was condensed with cyanotetrahydroisobenzofuran **120a**, affording an unstable naphthohydroquinone derivative, which was converted by methylation into compound **121** in 40% yield.

(*a*) $MeSCH_2Li$; (*b*) $Me_2SO_4.OH^-$; (*c*) Zn–Cu; (*d*) $MeSO_2Cl$; (*e*) NaI; (*f*) Zn–Cu.



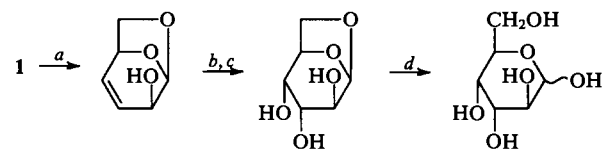
On the other hand, the reaction of compound **120b** with levoglucosenone gave rise to the stable crystalline naphthohydroquinone **122** in 65% yield. Its ring was subjected to reductive opening by the Zn–Cu couple in tetrahydrofuran. Having synthesised the chiral unit **123**, it was possible to construct in two stages the ring system of naphtho[2,3-*c*]pyran-5,10-quinones.



After several unsuccessful attempts to remove the primary hydroxy-group from compound **123**, the latter was converted via the methanesulfonate **124** into the iodide **125** and the required compound **126** was obtained by treatment with the Zn–Cu couple in moist THF. It is also noteworthy that the attachment of the lactone ring opened an easy route to calafungin, while the synthesis of the enantiomers **123–126** provided a short pathway to intermediates for the synthesis of nanomycin and its analogues. Overall, the sequence of reactions described above constitutes a promising method of synthesis of a series of substituted derivatives **123–126**, the hydroxyphthalides required for the synthesis of compound **120** being readily available.

It has been observed [57,58] that the interaction of levoglucosenone with the dibromo-derivative **127** in 1,4-dioxane in the presence of zinc powder in an ultrasonic bath affords compounds **128–130** in 53%, 3%, and 14% yields respectively.

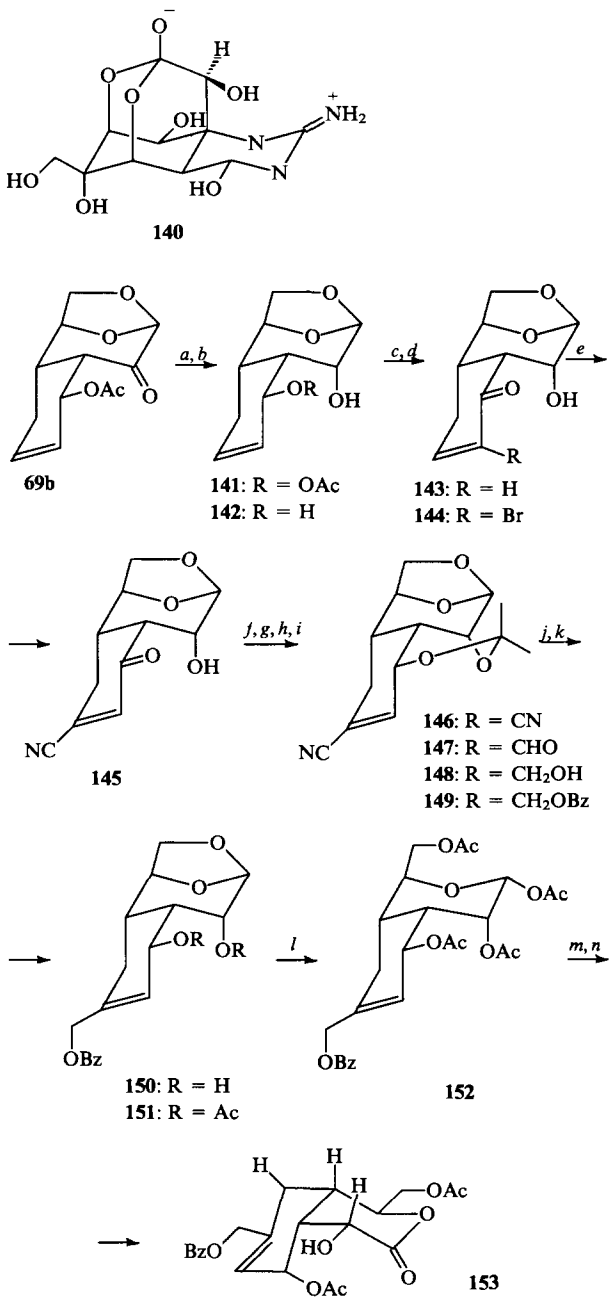
The ^1H and ^{13}C NMR spectra of the main product **128** agree with the structure ascribed to it. The reduction of the ketone **128** with sodium tetrahydroborate leads to the epimeric alcohols **131** and **132**, which were isolated in 35% and 50% yields respectively. They were characterised as the acetates **133** and **134**; the H(4) and H(4a) atoms in compounds **131** and **133** are axial (according to ^1H NMR data), so that the compounds have the D-*altro*-configuration established by the *exo*-addition of the reagent to the double bond.



Compound **128** — a potential synthetic precursor of a series of representatives of pyranonaphthoquinone antibiotics — has been obtained by the Barton deoxygenation via the alcohols **131** and **132** and their thionocarbonates **135** and **136**. The side products **129** and **130** are believed tentatively to be formed from compound **127** via the Reformatskii reaction with participation of an organozinc intermediate, which attacks the carbonyl groups of the main product and levoglucosenone.

D-Altrose **139** is a rare sugar, for the preparation of which there is no readily available natural raw material. All the known syntheses of this compound consist of many stages. The method of synthesis of D-altrose via D-altrosan — 1,6-anhydro-β-D-altropyranose **138** — proposed by Chew and Ferrier [59] includes three stages and the overall yield is 29.1%.

1,6-Anhydro-3,4-dideoxy-β-D-*threo*-hex-3-enopyranose **97** has been synthesised from levoglucosenone by reduction using a standard method. [60] The *cis*-dihydroxylation of the double bond of the pyranose **97** by the OsO_4–*N*-methyl-morpholine *N*-oxide system proceeds stereoselectively, affording D-altrosan **138** in 86% yield; when stoichiometric amounts of $KMnO_4$ were used for the oxidation, the yield of the triol **138** was only 32.7%. Acid hydrolysis of compound **138** leads to D-altrose **139**.

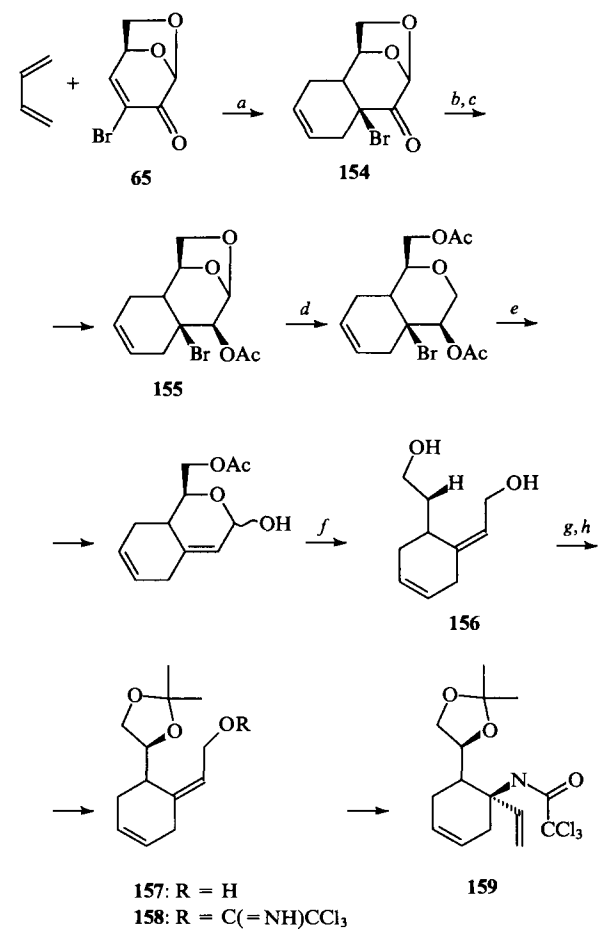


(*a*) $LiAlH_4$; (*b*) OsO_4–*N*-methylmorpholine *N*-oxide, Me_2CO, H_2O; (*c*) Na_2SO_3; (*d*) HCl–1,4-dioxane.

The same investigators obtained D-allosan and D-allose in six stages from levoglucosenone in 45% and 30% yields respectively. [61,62]

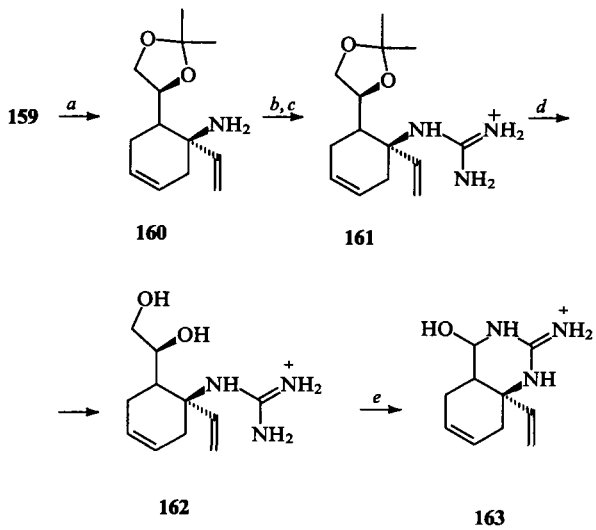
The key aspect of the approach to the synthesis of tetrodotoxin **140**, one of the best known of the food toxins, is the stage involving formation of the structure of the chiral cyclohexane via cycloaddition of acetoxybutadiene to the chiral dienophile — levoglucosenone. [63]

For this purpose, adduct **69b** was transformed into enone **143** via compounds **141** and **142**. The bromo-derivative **144** was obtained from the enone **143** by reaction with 1 equiv. of bromine in dichloromethane and subsequent treatment with triethylamine.



The addition of 2 equiv. of KCN at room temperature in the presence of ammonium chloride to the bromo-derivative **144** afforded the crystalline compound **145**. The reduction of the keto-group in compound **145** with sodium tetrahydroborate and protection of the diol group by 2,2-dimethoxypropane in camphorsulfonic acid (CSA) led to the acetonide **146**. Next followed the two-stage reduction of the nitrile group to the hydroxymethyl group via the aldehyde **147**. The alcohol **148** obtained was converted into the benzoate **149** and after acid hydrolysis the diacetate **151** was obtained from the diol **150**. The tricyclic compound **151** was solvolysed in the trifluoroacetic acid–acetic anhydride system. The yield of compound **152** was 96%.

(*a*) $NaBH_4$; (*b*) NaOMe; (*c*) MnO_2; (*d*) Br_2, CH_2Cl_2, Et_3N; (*e*) KCN–NH_4Cl; (*f*) $NaBH_4$, $Me_2C(OMe)_2$, CSA; (*g*) Bu^i_2AlH (DIBAL-H); (*h*) $LiAlH_4$; (*i*) BzCl–Py; (*j*) AcOH–THF–H_2O; (*k*) Ac_2O–Py; (*l*) Ac_2O–CF_3COOH; (*m*) $NH_2NH_2 \cdot H_2O$–DMF; (*n*) Jones reagent.

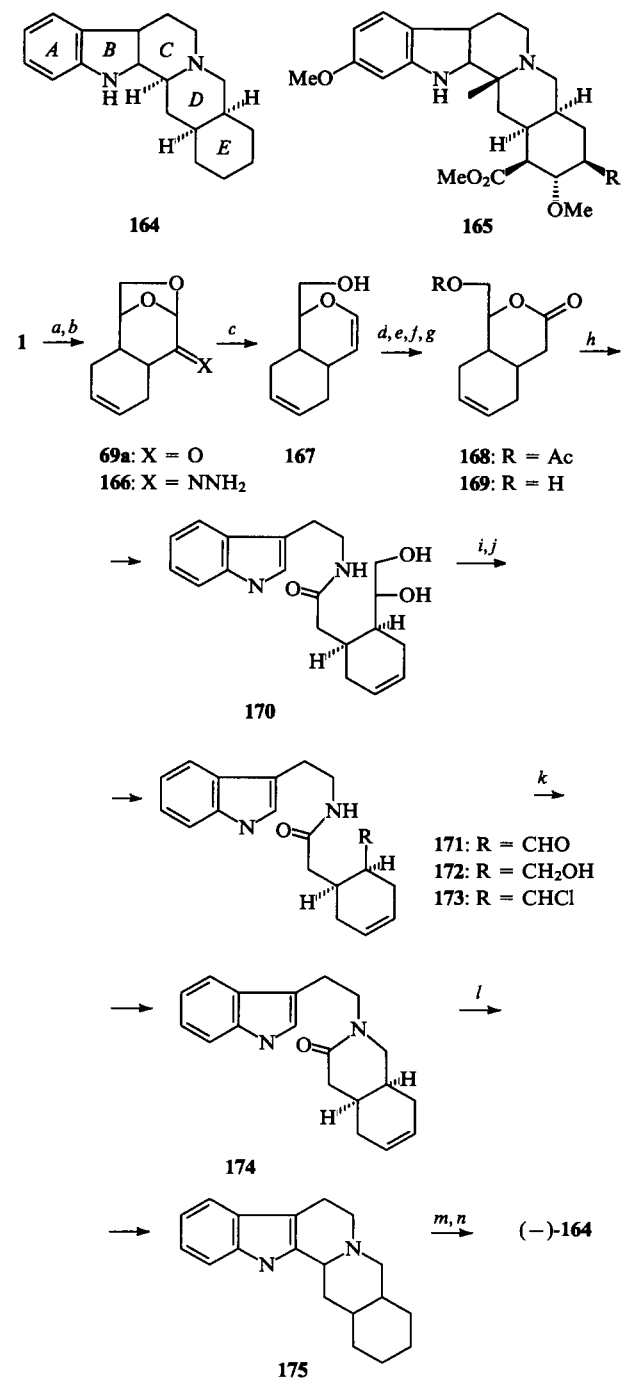


Acid hydrolysis of the anomeric acetate gave rise to the corresponding hemiacetal in a maximum yield of 70%, but this was accompanied by the formation of a side product. The hydrolytic stage was optimised by employing hydrazine (1.2 equiv. of $NH_2NH_2.H_2O$ in DMF at 60 °C). Oxidation of the hemiacetal by the Jones reagent completes the stage involving the formation of the cyclohexane unit **153**, into which suitable functional groups have been introduced.

The guanidine-containing part of tetrodotoxin was synthesised from the bromoketone **154**.[64] By opening the 1,6-anhydro-bridge and subsequent treatment with $NaBH_4$, the bromohydrin acetate **155** was transformed into the triol **156** and further into the *exo*-allyl alcohol **157**. The latter was treated with trichloroacetonitrile and NaH, the imide **158** formed was heated for 12 h in xylene, and the trichloroamidate **159** was obtained as a result of the successful Overman rearrangement.

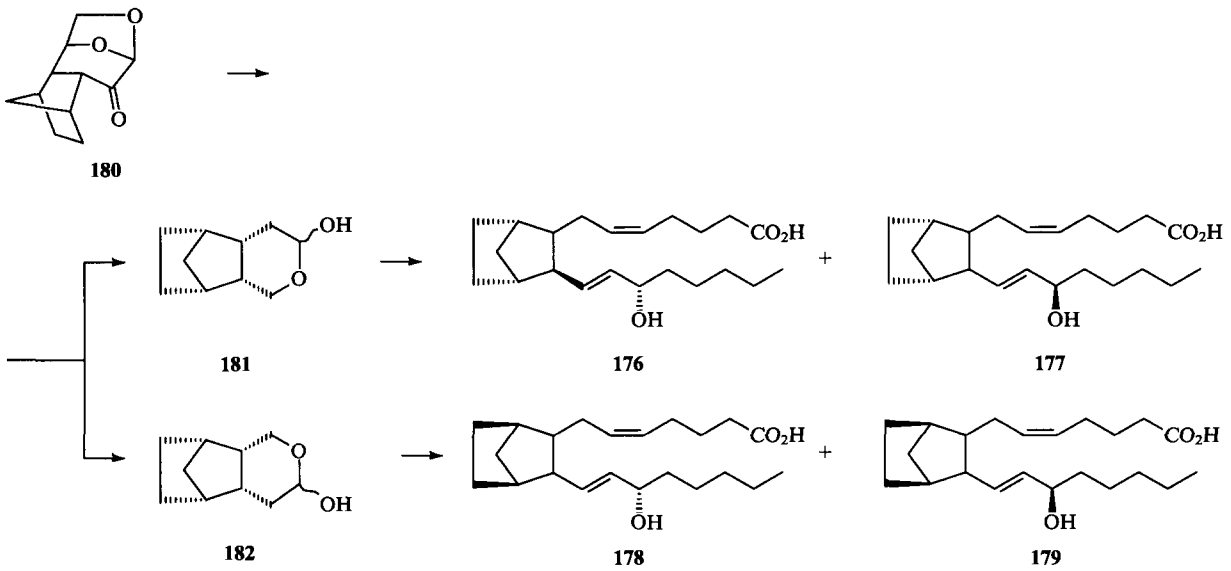
(*a*) 110 °C, 12 h; (*b*) $NaBH_4$–MeOH; (*c*) Ac_2O, Py; (*d*) CF_3COOH, AcOH; (*e*) Zn–Cu; (*f*) $LiAlH_4$–THF; (*g*) $Me_2C(OMe)_2$, CSA; (*h*) Cl_3CCN, NaH, Et_2O; (*i*) 110 °C, 12 h.

The subsequent stages involved the hydrolysis of the trichloroacetamide group of compound **159** and the successive treatment of the amine **160** with bromocyanogen and ammonia, which led to the formation of the guanidine **161**. Next the acetonide protecting group was hydrolysed with trifluoroacetic acid, the glycol **162** was cleaved with periodic acid, and the guanidine derivative **163** was obtained in a satisfactory yield. Thus the optically active model tetrodoxin units **153** and **163** were synthesised from levoglucosenone.



(*a*) KOH, EtOH, 50 °C; (*b*) BrCN–$NaHCO_3$; (*c*) NH_3, 100 °C; (*d*) CF_3COOH; (*e*) HIO_4.

The syntheses of the related optically active alkaloids alloyohimbane **164** and reserpine **165** from levoglucosenone have been described.[65] The crystalline Diels–Alder adduct of levoglucosenone with buta-1,3-diene **69a** was converted into the hydrazone **166**, the treatment of which with NaH in dimethyl sulfoxide (DMSO) afforded the vinyl ether **167**. Next followed stages involving acetylation, hydrolysis, and oxidation with the Jones reagent. The lactone **168** obtained was treated with MeONa in MeOH and compound **169** was heated with three equivalents of tryptamine in a 6:11 tetrahydrofuran–ethyldiisopropyl amine mixture. The glycol **170** produced was cleaved with HIO_4 to the aldehyde **171**. The reduction of the latter with $NaBH_4$ in methanol afforded the amidoalcohol **172**. The alcohol **172** was then converted by standard methods into the chloro-derivative **173**. Since compound **173** proved to be unstable, it was rapidly introduced into the reaction with lithium bis(trimethylsilyl)amide and the lactone **174** was obtained. In the concluding stage, cyclisation was achieved by heating compound **174** with $POCl_3$ and reduction of compound **175** with tetrahydroborate led to the target compound **164**.

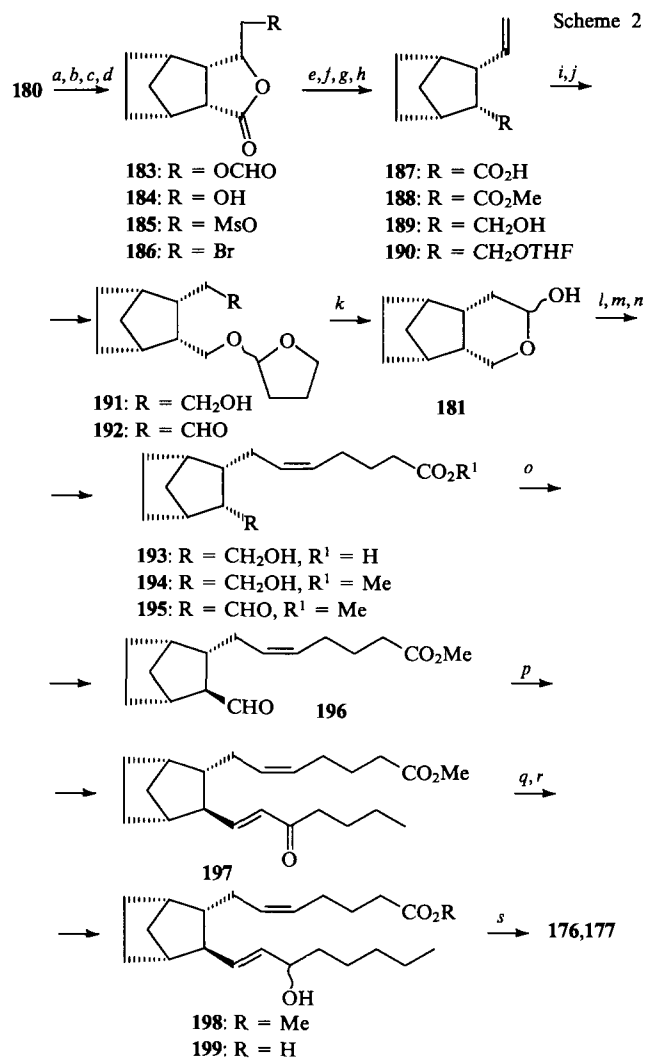


The enantiodivergent approach to the synthesis of the 9,11-ethano-analogues of the prostaglandin *endo*-peroxides (PGH_2) **176–179**, developed on the basis of the single chiral unit **180**, ensures a rational synthesis of the structures of both key enantiomeric precursors of the target compounds — the lactols **181** and **182** (see Scheme 1).[66,67]

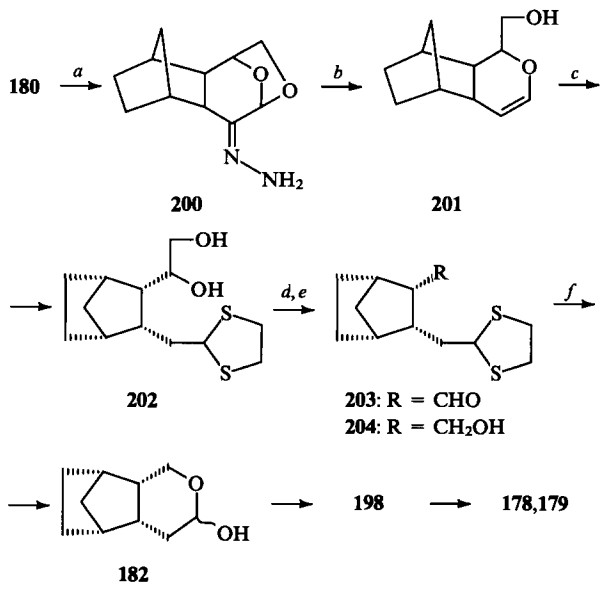
The synthesis of nat-9,11-ethano-PGH_2 **176** and of its (15*R*)-diastereoisomer **177** is presented in Scheme 2. As can be seen from the latter, the transition **180** → **181** requires deoxygenation at the C(1) atom and the cleavage of the C(8)–C(9) bond in compound **180**. For this purpose, the ketone **180** was introduced into the Baeyer–Villiger reaction and the intermediate formate **183** was obtained in a high yield. It was hydrolysed to the alcohol **184**. The subsequent methanesulfonation, bromination (giving rise to compounds **185** and **186**), and then dehydrobromination with zinc

(*a*) $CH_2=CH-CH=CH_2$, 140 °C; (*b*) $NH_2NH_2 \cdot H_2O$, Et_3N; (*c*) NaH, DMSO; (*d*) Ac_2O–Py; (*e*) HCl–THF; (*f*) Jones reagent, 0 °C; (*g*) NaOMe–MeOH; (*h*) tryptamine, Pr^i_2EtN, THF; (*i*) HIO_4; (*j*) $NaBH_4$; (*k*) Ph_3P, CCl_4–LiN(SMe_3); (*l*) $POCl_3$, 100 °C; (*m*) $NaBH_4$; (*n*) H_2, Pd/C.

Scheme 1



in Pr^iOH-H_2O led to the acid **187**. The latter was converted into the methyl ester **188** and treated with $LiAlH_4$ to form the alcohol **189**. After blocking the hydroxy-group in compound **189** by formation of the tetrahydrofuryl ether, the terminal double bond in compound **190** was functionalised with the aid of 9-bora-bicyclo[3.3.1]nonane (9-BBN) and the resulting diastereoisomeric mixture of alcohols **191** was oxidised with the Collins reagent and the acetal **192** was deblocked to form the lactol **181**. In view of its lability, the lactol **181** was converted, without purification, into an alkene by treatment with a phosphorane reagent and the alkene **193** was converted into the stable hydroxyacid **194** [the content of the 2'-(*Z*)-isomer was ~95%]. After methylation and oxidation by the P_2O_5-DMSO system, the hydroxyacid **194** afforded the *cis*-aldehyde **195**, which isomerises smoothly to the *exo*-aldehyde **196** on refluxing in toluene containing 1,5-diazabicyclo-[5.4.0]-undec-5-ene (DBU). Next the enone **197** was synthesised by the reaction of the aldehyde **196** with dimethyl 2-oxoheptyl-phosphonate under the conditions of the Wittig–Horner reaction. In the concluding stages, tetrahydroborate reduction of the enone **197** and hydrolysis of the ester **198** afforded a mixture of the 15α,β-epimeric alcohols **199** in proportions of ~1 : 1, which were separated by high performance liquid chromatography (HPLC).



The synthesis of ent-9,11-ethano-PGH_2 **178** and of its (15*S*)-diastereoisomer **179** requires the C(8)-deoxygenation of the ketone **180**, which was achieved by the Huang–Minlon method. The conversion of the ketone **180** into the hydrazone **200** and then into the unsaturated ether **201** was achieved with an overall yield of 50% (see over). The following stages involved the conversion of compound **201** into the dithioacetal **202**, the cleavage of its diol group by $Pb(OAc)_4$, the reduction of the resulting *cis*-aldehyde **204** with sodium tetrahydroborate, and the Hg^{2+}-induced hydrolysis of the mercaptal **204** to the lactol **182**, which was transformed into the enone ent-**198** and further into substances of the ent-series **178** and **179**, as had been done in the case of compound **181**.

Thus the data presented demonstrate the extensive possibilities for the employment of levoglucosenone as a chiral precursor in the complex stereospecific synthesis of natural products and their analogues.

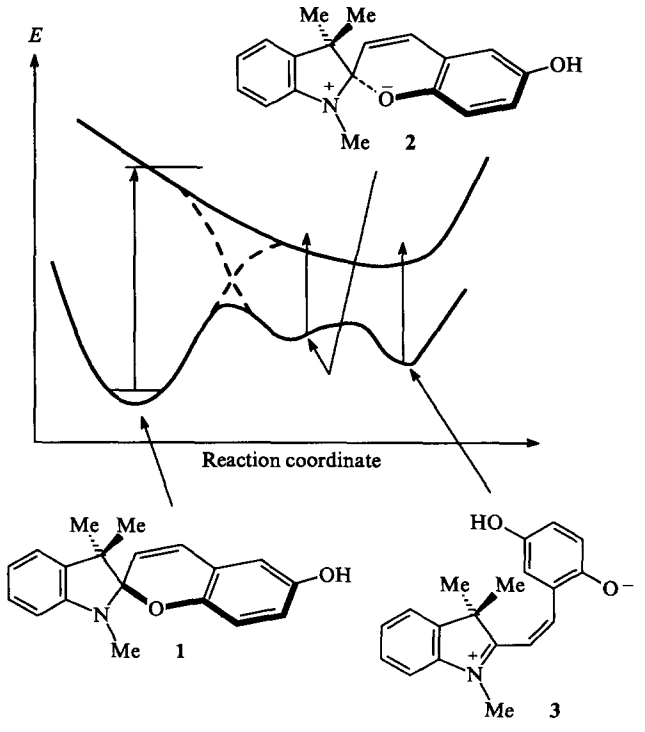
Abstract. We show that the path of a chemical reaction on the potential energy surface of a chemical system can only be a gradient line between two critical points. Existing rules of symmetry conservation along the reaction path are analysed to establish their consistence with published experimental data and with ab initio calculations. In some systems the possible existence of reaction paths consisting of several gradient lines (both equivalent and nonequivalent) has been demonstrated. The relationship between the reaction mechanisms and the corresponding paths on the potential energy surface is discussed. The bibliography includes 238 references.

I. Introduction

The dynamics of chemical reactions on the appropriate potential energy surfaces (PES) are currently being studied in depth.[1–4] However, many problems relating to the structure of the PES and to the paths of chemical reactions on this surface are still controversial,[4–7] and in many cases have not yet been clearly and precisely formulated. Thus, studies of the dynamics of the thermo- and phototransformation of molecules (both in a gas and in a condensed medium) require a correct definition of the topology of the PES for both the ground and the excited state, as well as of their relative disposition over a reasonably wide range of changes in the intrinsic coordinates. Currently used one-dimensional models of various photoprocesses are far from offering a solution of these problems. A good example is provided by a study[8] of the dynamics of the photochromic behaviour of the indoline spiropyran **1** (1′,3′,3′-trimethyl-6-hydroxyspiro[2*H*-1-benzopyran]2,2′-indoline) in solution by nano- and femtosecond spectroscopy methods (Fig. 1). When the compound **1** is irradiated ($\lambda \approx 300$ nm) the C–O bond breaks in less than 100 fs with formation of the metastable compound **2**, which then isomerises to the merocyanine form **3**. The whole process is represented schematically by a one-dimensional energy diagram. This model cannot account for the many motions of a chemical system as complex as molecule **1** on the multidimensional surface of the ground and the excited state.

The dynamic behaviour of chemical systems in the classical or the quantum approximation is now being studied mainly in the one-channel approximation, although many examples of reactions taking place along several equivalent paths are



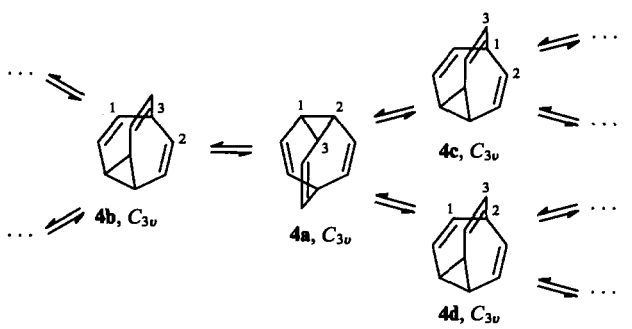


Figure 1. Scheme of the photochemical opening of 1′,3′,3′-trimethyl-6-hydroxyspiro[2*H*-1-benzopyran]-2,2′-indoline (**1**) (see Ref. 8). (**2**) initial metastable product, corresponding to the structure with a broken C–O bond but retaining the configuration of the fragments lying in perpendicular planes; (**3**) merocyanine form, which follows the reac-tion path along the diabatic surfaces (broken lines). Only one of the vari-ous possible merocyanine isomers (**3**) is shown in the figure as a product.

known,[9-22] for example the isomerisation of bulvalene **4** (Scheme 1),[9-12] the internal rotation of two or several groups in various systems,[13-19] the opening of cyclopropane[20,21] and ozone rings,[22] and other systems.[23-25] Clearly, changing to a multichannel representation of the reaction dynamics requires the development of new approaches to the description and the treatment of the PES, and also to the study of the system dynamics on such a surface.

Scheme 1

As shown by recent work,[26-37] the effect of a solvent on the mechanism and rate of the reaction is not so much a static effect as the effect of the direct participation of one or several solvent molecules in the reaction as discrete species. This undoubtedly requires the inclusion of the solvent molecules into the PES being considered for the chemical systems.

Studies of the structure of a solid surface,[38] of its interaction with adsorbed molecules, and of the chemical reactions taking place on the surface are impossible without a detailed knowledge of the structure of the PES for a combined system consisting of the adsorbed molecule and a model of the solid surface.[38-45] Configurational transitions of the solid from one symmetry group to another can be treated as transitions from one minimum to another in the appropriate PES.

The development of molecular devices for use in molecular electronics is greatly dependent on studies of the complex motion of the chemical system along the appropriate PES.[46,47] The problem of the transformation of one form of energy into another is far from solved,[48,49] and therefore studies of the direct molecular conversions of solar energy are important.[49-52] The search for molecular systems capable of storing solar energy, concentrating it, and converting it into forms convenient for practical applications relies on the study of the structure of the adiabatic PES of the appropriate chemical systems.[49]

A deeper understanding of the nature of biological systems and of their operating principles obviously requires a detailed study of the PES of model chemical systems simulating the totality of active centres and their collective properties.[53-56]

It follows from the above considerations that the study of the global PES is only beginning. The solution of many key theoretical and experimental problems is associated most closely with the study of the structure of the appropriate PES.

With the exception of the report by Bazilevskii and Ryaboi[4] there have so far been no reviews of the problems associated with the global structure of the PES in the Russian literature. Therefore the main aim of the present paper will be to fill this gap by stressing the many examples of inadequate studies of the PES, and thus to promote a wider understanding of the reaction path.

II. Path of a chemical reaction on the potential energy surface

The path of a chemical reaction on the PES,[57-59] which determines its mechanism, is one of the most important concepts in chemistry. This concept, first introduced[57] in the late 1930s immediately following the establishment of the concept of an adiabatic PES for the molecule,[60] is still controversial.[4-7,61-77] There are several different definitions of the reaction path, of which the most important are the minimum energy reaction path,[57-59,71-73] the path of steepest descent,[67-69,72,76] and the intrinsic reaction coordinate.[61,63,68]

The minimum energy path (MEP) is a line following the bottom of the reaction valley and connecting the energy minima of the reactants and products through the appropriate saddle point (transition state[78,79]) on the PES. The path of steepest descent is a gradient line originating at the saddle point and pointing towards the energy minima of the reactants or of the products. When mass-weighted coordinates are used the path of steepest descent becomes the intrinsic reaction coordinate (IRC).[61,63,68] In the construction of a topological PES structure, when the reaction valley connects the energy minima of reactants and products through a high saddle, all the above definitions of the reaction path are described by the same line on the PES (Fig. 2). In more complex topological structures of the PES the minimum energy path, the gradient line, and the IRC can be different, and therefore the mechanisms predicted for a given reaction may also differ. Of course, it becomes essential to choose the definition of the reaction path on the PES which is most appropriate to the physics and chemistry of the process being studied. Without denying the possible validity of the MEP or of the IRC this review will be concerned mainly with the gradient reaction path.[7,80] The choice of this definition of the path is most convenient in the case of a PES having a complex topological structure. We shall discuss only the PES of the electronic ground state, although the methodology developed in this review is equally applicable to the PES of any electronic state.

The potential energy surface $E(X)$ and its first and second derivatives are assumed to be finite and continuous functions at any point X (X_1, X_2, ..., X_{3N}) of the configurational space R^{3N} except at the poles (the points where the coordinates of two or more atoms in the molecule coincide). The chemically most important regions of the PES are the so-called nondegenerate critical (stationary or extremal) points, i.e. the points X_{cr} on the PES where the following relationships are satisfied simultaneously;

$$\nabla E(X_{cr}) = \operatorname{grad} E(X_{cr}) = 0\,, \tag{1}$$

$$\operatorname{rank}(H_{ij})_{X_{cr}} = \operatorname{rank}\left\|\frac{\partial^2 E}{\partial X_i \partial X_j}\right\|_{X_{cr}} = 3N-6\,, \tag{2}$$

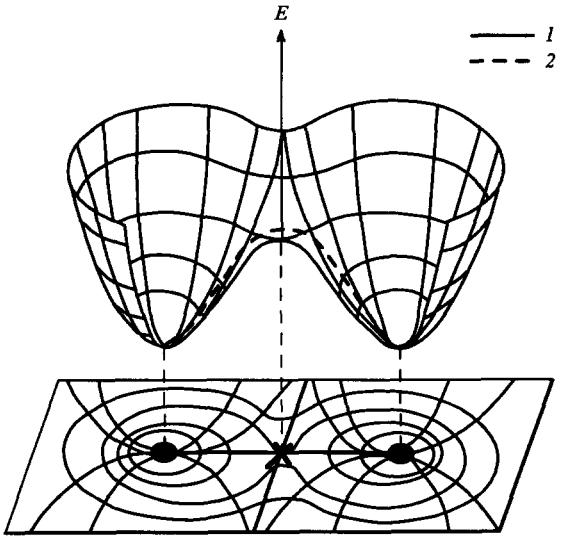

Figure 2. Potential energy surface of the molecule and its two-dimensional projection on the configurational space. (*1*) Path of the reaction on the PES, (*2*) projection of the reaction path on the configurational space. The curves emerging from the minima are gradient lines, the closed curves are equipotential lines.

where X and N are (respectively) the Cartesian coordinates of the nuclei and the number of atoms in the molecule.[64,65,78,79] Eqn (2) states that the Hessian (H_{ij}) has only six zero eigenvalues corresponding to the motion of the molecular system as a whole (three translations with respect to the three axes and three rotations round these same axes).

The point $X \in R^{3N}$, where the relationship (1) is not obeyed [$\nabla E(X) \neq 0$], is called a regular[81,82] (noncritical or normal[61,65]) point. All the critical points are characterised by the index λ (the number of negative eigenvalues of the Hessian). Thus, for a minimum $\lambda = 0$, for a saddle point $\lambda = 1$, for a critical point $\lambda = 2$, etc.[65]

The reaction path of the chemical system[57-59,61,83] is defined by a line on the PES which originates from the energy minimum for the reactant, passes through the saddle point corresponding to the transition state, and terminates at the energy minimum for the product (see line *1* of Fig. 2). The reaction path is defined in $(3N+1)$-dimensional R^{3N+1} space (the direct sum of the configurational space and of the energy coordinate $R^{3N+1} = R^{3N} \oplus E$),[81] which we shall call the entire space. A mutually single-valued correspondence exists between the points (and therefore also the curves) on the PES and in the configurational space. Thus the line in the configurational space directly defines the line on the PES, and vice versa. The orthogonal projection of the reaction path on the configurational space gives a curve in the R^{3N} space which is also called the reaction path (see line *2* in Fig. 2). We shall in most cases refer to the reaction path in the entire space.

In the adiabatic approximation[60] the PES is independent of the nuclear masses, and therefore any lines lying on the PES and its projection on the R^{3N} space are also independent of the nuclear masses. An infinitesimally small displacement along the PES from any point X_0 (produced by motion at an infinitesimally small speed) can only follow the direction of the gradient vector.[61,67,69] The result is that under conditions of infinitesimally small displacement the molecular system can slide on the PES only along the gradient lines between any two critical points.[61,63,68,69] Therefore of all the lines on the PES only the gradient line can act as the reaction path. In this case in order to identify the line on the PES corresponding to the path of the chemical reaction we must solve a system of ordinary differential equations defining the gradient lines on the PES, which can be written in Cartesian coordinates not weighed for mass in the well-known form,[61,63,68,81,82]

$$\frac{dX_1}{\partial E/\partial X_1} = \frac{dX_2}{\partial E/\partial X_2} = \cdots = \frac{dX_{3N}}{\partial E/\partial X_{3N}} = \text{const}, \qquad (3)$$

with the initial conditions $X_0 = (X_1, X_2, ..., X_{3N})_0$, and from the family of solutions of this system we must choose those which connect the appropriate critical points. Eqn (3) in mass-weighted coordinates was first used by Fukui[61] (in 1970) as a means of finding the reaction path. However, we should note that in studies of the dynamics of chemical systems it is convenient to work with mass-weighted coordinates,[61] though we shall not consider these in the present review, leaving interested readers to consult the original publications.[1-4,61,63,68]

For our purpose Eqn (3) is conveniently written as a system of $3N$ ordinary differential equations[4,61,67-69,80]

$$\frac{dX_i}{dt} = -\frac{\partial E[X_1(t), ... X_{3N}(t)]}{\partial X_i}, \quad i = 1, 2, ..., 3N, \qquad (4)$$

with the initial conditions $X(t_0) = (X_1, X_2, ..., X_{3N})_0$. The quantity t is a parameter for the length of the curve. The minus sign on the right-hand side of Eqn (4) means that the potential decreases as t increases. The integral curves of Eqn (4) are called the gradient lines $X = X(t)$ of the adiabatic potential.[68,69]

Thus under conditions of infinitesimally small displacement the molecular system can move on the PES only along gradient lines connecting any two critical points.[61,63,68] Only a gradient line can act as the reaction path among the lines belonging to the PES.

According to Ostgood's theorem[85,86] the system (4) with a right-hand side satisfying the Lipshits condition

$$\left| \frac{\partial E(X')}{\partial X_i} - \frac{\partial E(X'')}{\partial X_i} \right| \leqslant K \sum_i^{3N} |X_i' - X_i''|,$$

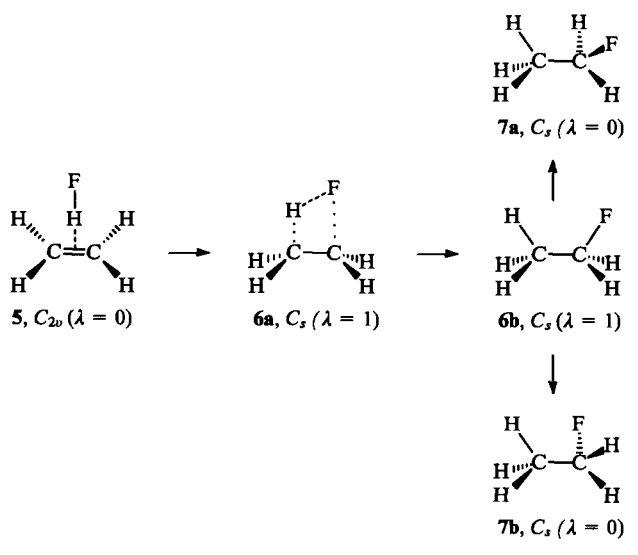
where X', $X'' \in R^{3N}$ and K is a positive constant, has a unique solution which passes through the given initial point X_0. Obviously the condition imposed on the PES ensure that the Lipshits conditions are obeyed by the right-hand side of (4), and therefore that for these condition the Ostgood theorem applies. Thus there is only one solution of the system (4), $X = X(t)$, which passes through the given regular point.[69,70,80,85,86] This means that the gradient line can neither disappear at nor emerge from a regular point, i.e. that gradient lines can have no bifurcations on the slopes of the PES.

The vector-gradient field ∇E behaves like an ordinary electrostatic field, whose integral lines of force do not intersect[84] (see also the quantum topology theory[87]).

In curvilinear coordinates $Q(X) \in R^{3N-6}$ (where R^{3N-6} is the configurational space of the intrinsic coordinates) the Eqns (4) can be written in the tensor form[4,6,68,74,88]

$$\frac{dQ^k}{dt} = -\sum_{l=1}^{3N-6} g^{kl} \frac{\partial E[Q^1(t), ..., Q^{3N-6}(t)]}{dQ^l}, \qquad (5)$$

$$k = 1, 2, ..., 3N-6,$$



where the metric tensor g^{kl} (see Refs 81 and 88) is defined by the equation[4,74]

$$g^{kl} = \sum_{i=1}^{3N} \left[\frac{\partial Q^k}{\partial X_i}\right] \left[\frac{\partial Q^l}{\partial X_i}\right], \quad k = l = 1, 2, ..., 3N-6.$$

It is important to note that the functions $E(X)$ and $E(Q)$ define the same adiabatic PES, and the equations (4) and (5) give the same system of gradient lines.[4,6,67,74] The tensor form (5) ensures the invariance of the gradient lines for any transformation of the coordinates with a nonzero Jacobian. Thus the gradient lines, like the PES, are defined only by the given molecular system and are independent of the choice of coordinates.

A system of gradient lines connecting the energy minima of reactants and products and passing through one or several saddle points is called a gradient reaction path.[7,80] Thus in order to obtain the gradient reaction path we must have the solutions of Eqns (4) and (5), but this cannot be done in an explicit form since the functions $E(X)$ and $E(Q)$ are not known in an analytic form even

Scheme 2

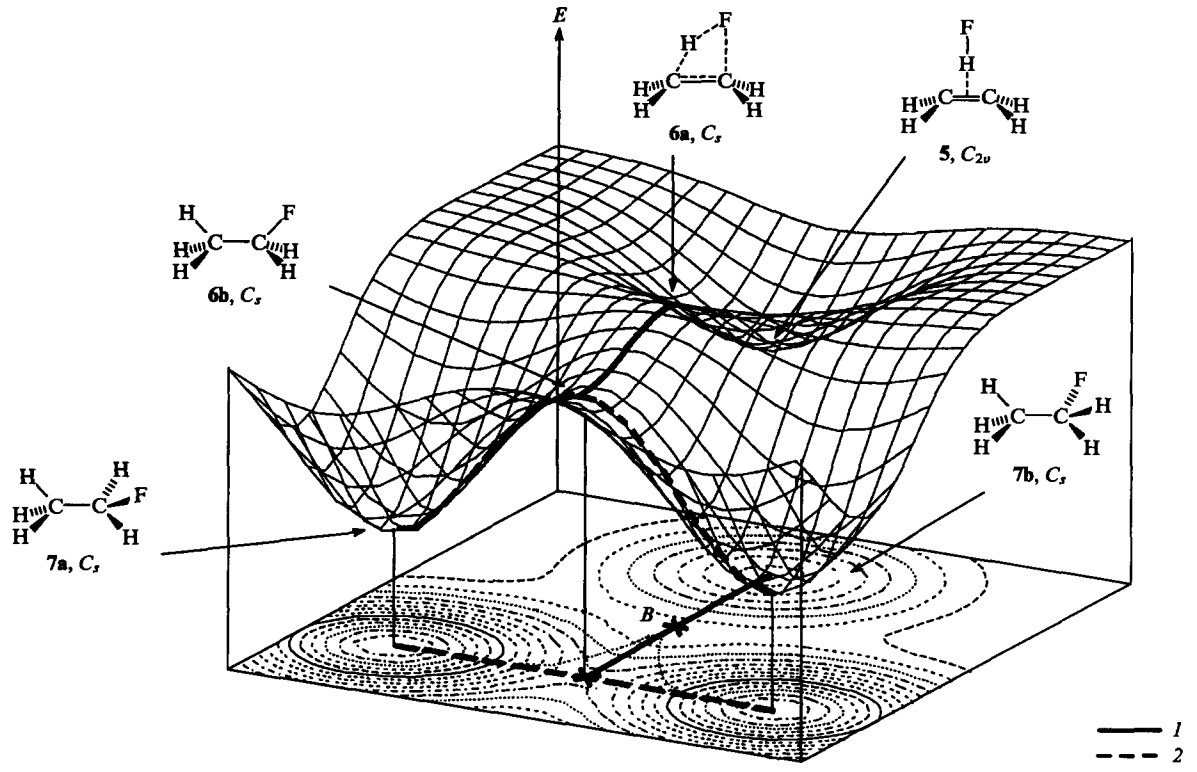


Figure 3. Potential energy surface for the electrophilic addition of HF to the C=C double bond of ethylene.[7] The line *1* corresponds to the initial part of the reaction **5** → **6a** → **6b**. The line *2* corresponds to the reaction **7a** ⇄ **6b** ⇄ **7b** for the internal rotation in the substituted ethane; the lines emerging from the bifurcation point *B* define the minimum energy path; the transition states are shown by crosses.

for the simplest triatomic systems.[71] However, numerical approximations to the gradient lines can now be obtained without great difficulty. We shall consider, as an example, the gradient path of the electrophilic addition of HF to a molecule of ethylene.[7] Nonempirical calculations (MP2/DZP) have predicted[7] that this reaction can be represented by the Scheme 2.

The structure of the PES for this reaction is shown in Fig. 3. The reaction, which begins with the formation of the metastable π-complex **5**, is described by the gradient line *1* in the region **5** → **6a** → **6b**. This line passes through the saddle point corresponding to the transition state **6a** and reaches the neighbouring saddle point corresponding to the other transition state **6b** for the internal rotation round the C–C bond.

At the point on the PES corresponding to the state **6b** the gradient path of the reaction changes direction in the configurational (entire) space and passes from the first gradient line to the second (line *2* of Fig. 3), reaching the minima of the states **7a** and **7b** along the two branches of the second line.

If the gradient line connects two critical points all the eigenvectors of the Hessian $\vec{q}_i$ of one critical point should smoothly change at the point of descent along the gradient line into the accompanying Frenet polyhedron,[81,82] which should itself be transformed into the appropriate eigenvectors of the Hessian for the other critical point.

In this case it is sufficient to consider the evolution of the two eigenvectors of the Hessian $\vec{q}_1$ and $\vec{q}_2$ along the first gradient line from the state **6a** to the state **6b** (see Fig. 4). The transition vector $\vec{q}_1$ of the state **6a** at the point of descent is converted into the tangential vector $\nabla E/|\nabla E|$ ($\vec{q}_1$ at the point *B*), which is further converted (for the state **6b**) into the eigenvector of the Hessian corresponding to the first positive eigenvalue ($\vec{q}_1$ at the point **6b**). At the same time the perpendicular vector $\vec{q}_2$, corresponding to the eigenvector of the Hessian for the first positive eigenvalue at the point **6a**, is continuously transformed along the gradient line, becoming the transition vector $\vec{q}_2$ for the structure **6b**.

Thus the gradient path of the addition of HF to ethylene consists of two nonequivalent gradient lines of which the first connects the points **5** → **6a** → **6b**, and the second the points **7a** → **6b** → **7b**. A characteristic feature of the PES is shown in Fig. 3: the first gradient line emerging from **6a** does not reach either of the minima at **7a** or **7b**. Along this gradient line and beyond the point *B* a shift in a perpendicular direction lowers the energy, i.e. a reaction valley develops beyond the bifurcation point *B* and therefore the MEP splits into two (broken lines in Fig. 3). The minimum-energy path begins at the point **6a** and leads to the minimum **7a** (or **7b**), missing the point **6b**. Thus the bifurcation point *B* exists only for the MEP, but not for the gradient line (∇E does not vanish at the point *B*, and therefore only one gradient line can pass through this point).

Gradient lines can be generated or disappear only at critical points,[85,86] and therefore the behaviour of the gradient lines in the infinitesimally small surroundings of the critical point denotes a relationship between the symmetry properties of the system on the reaction path and the symmetry properties of the system at a critical point (in particular, at the minimum points and at the saddle point).[80]

In the immediate surroundings of any critical point Q_{cr} the potential energy surface $E(Q)$ can be approximately represented by the quadratic term alone of a Taylor series[82]

$$E(Q) = \frac{1}{2}\sum_{l=1}^{3N-6}\left[\frac{\partial^2 E}{(\partial Q^l)^2}\right]_{Q_{cr}} \qquad (Q^l)^2 = \frac{1}{2}\sum_{l=1}^{3N-6}\alpha_l (Q^l)^2 . \qquad (6)$$

For this type of potential the equations (5) are easily integrated, giving solutions of two types:[67,69,74,80]

trivial

$$Q^k = 0, \quad k = 1, 2, ..., 3N-6 , \qquad (7)$$

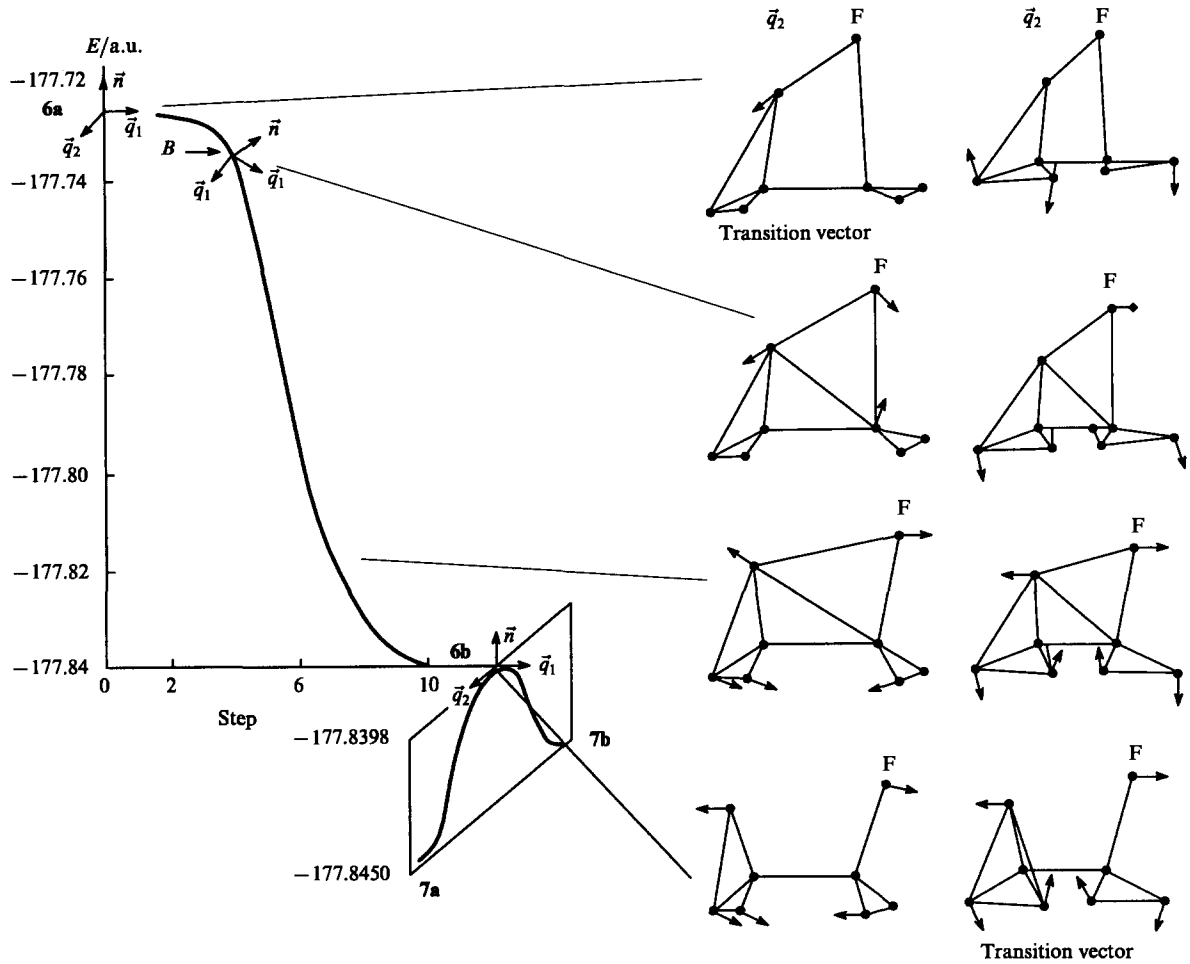

Figure 4. Evolution of the eigenvectors $\vec{q}_1$ and $\vec{q}_2$ of the Hessian along the gradient lines from the point **6a** (see Fig. 3) to the point **6b**. The vector $\vec{q}_1$ is the transition vector at the point **6a**, and the vector of the first positive eigenvalue of the Hessian at the point **6b**. The vector $\vec{q}_2$ is the vector of the first positive value of the Hessian at the point **6a** and the transition vector at the point **6b**. The forms of these vectors are shown on the right, $\vec{n}$ is the vector of the normal to the gradient line, and coincides with the direction of the E axis at the critical points.

and nontrivial

$$Q^k = (Q^k)_0 \exp(-\alpha_k t), \quad k = 1, 2, ..., 3N-6, \qquad (8)$$

where $(Q)_0$ is the initial point, corresponding to $t = 0$.

These curves are shown in Fig. 5 for the infinitesimally small surroundings of a minimum ($\lambda = 0$) and of a saddle point ($\lambda = 1$). They are asymptotic gradient lines for the total potential $E = E(Q)$ in an infinitesimally small region surrounding the nondegenerate critical points. Thus the gradient lines of any potential $E = E(Q)$ are described by the solution (7) or (8) as they approach the critical point.

For the quadratic potential (6), as for the total potential $E = E(Q)$, only one gradient line can exist in the infinitesimally small surroundings of the critical point. It passes through the given regular point Q_0 (the point X_0 in Fig. 5), and this line [a curve described by Eqn (7) or (8)] enters (or issues from) the critical point tangentially to one of the eigenvectors of the Hessian $\vec{q}_i$ ($i = 1, 2, ..., 3N-6$). In the special case of a saddle point we always find only one gradient line issuing from this point and tangential to the transitional eigenvector[79] corresponding to a negative eigenvalue of the Hessian.[67]

The eigenvectors of the Hessian $\vec{q}_i$ ($i = 1, 2, ..., 3N-6$) at the critical point are classified by irreducible representations of the symmetry point group of the molecular configuration corresponding to this critical point. It is important to note that whether or not the symmetry point group of this molecular configuration contains multidimensional representations the

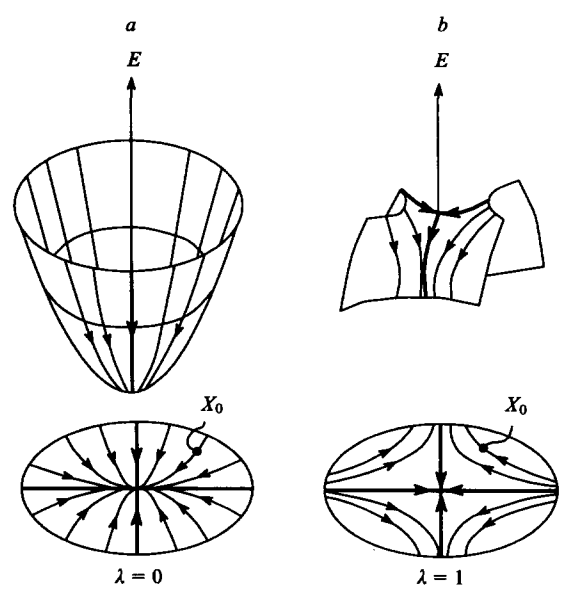

Figure 5. Principal (thick) and secondary gradient lines (thin) in the immediate vicinity of the minimum ($\lambda = 0$) and of the saddle point ($\lambda = 1$) in the entire space (*a*) and in the configurational space (*b*). X_0 are the initial points of the secondary gradient lines; the arrows on the gradient lines show the directions of decreasing potential.

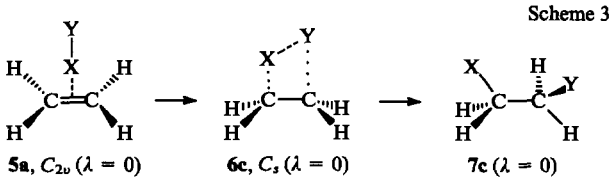
gradient lines defined by the solution (8) can be tangential only to a vector belonging to a one-dimensional (nondegenerate) irreducible representation.[80]

The situations discussed above correspond to nondegenerate critical points, and in particular to minimum points and saddle points. However, there may be cases (said[4, 65] to be fairly rare) of degenerate critical points appearing on the PES, i.e. points where the condition (2) is not satisfied and one or several zero eigenvalues are found in the Hessian in addition to the six listed above. The study of the behaviour of the gradient lines in the immediate vicinity of degenerate points is one of the most important problems in the topological structure of the PES.[69, 70]

III. Symmetry of the reaction path



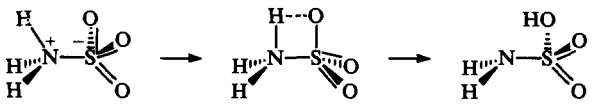
The conditions for symmetry conservation of the system along the reaction path are controlled by a theorem established by Pearson[89] in 1970, which states that the reaction path between two critical points (which are not included in the discussion) is strictly totally symmetric, i.e. that the symmetry point group of the molecular configuration is conserved over the whole length of the reaction path. It was later shown by Pechukas[67] that in practice the symmetry is conserved along the line of steepest descent (the gradient line) and that under these conditions the symmetry point group of the molecular structure of the transition state is conserved, i.e. the saddle point (upper critical point) is included in the discussion. However, Pechukas could not explain why in degenerate reactions (i.e. in reactions in which the reactant and the product are equivalent) this symmetry point group can vary at the critical points, and he was forced to treat these reactions as exceptions. Subsequently Rodger and Schipper[90, 92] also studied the conservation of symmetry along the reaction path by using the expression

$$G_q = G_R \cap G_T = G_P \cap G_T \subseteq G_R \cap G_P , \qquad (9)$$

where G_q, G_R, G_T, and G_P are respectively the symmetry point groups for the reaction, the reagent, the transition structure, and the product. Eqn (9) shows that the symmetry elements conserved along the reaction path should be symmetry elements of the reagent, of the product, and of the structure of the transition state. The expression was used[90] to formulate a hypothesis called the principle of maximum symmetry: all the symmetry relationships between reactants and products are conserved along the whole of the allowed reaction path, i.e. all the symmetry elements included in the symmetry groups of both the reactants and the products are conserved. However, examples have been reported of both degenerate and nondegenerate reactions on whose path the symmetry of the molecular configuration of the transition state can be perturbed and which do not satisfy the Pearson–Pechukas[67, 89] and the Rodger–Schipper[90] symmetry rules.

For example, as indicated by many quantum-chemical calculations in various approximations,[64, 93–102] the electrophilic addition of the XY molecule to the C=C double bond takes place according to the Scheme 3:

Scheme 3



5a, C_{2v} ($\lambda = 0$) **6c**, C_s ($\lambda = 0$) **7c** ($\lambda = 0$)

where XY = HF (Refs 93–96, 98, 99), HCl (Refs 95, 96), F_2 (Ref. 97), Cl_2 (Ref. 97), HCN (Ref. 100), H_2O (Ref. 101), and MeLi, MeCu (Ref. 102).

This reaction begins with the formation of the metastable pre-reaction π-complex **5a**, followed by the transition structure **6c** with a C_s symmetry, and it ends at the minimum of the product **7c**.

It can be seen from Scheme 3 that the mirror plane of symmetry, which passes through the atoms X and Y and through the C=C bond and is retained in the initial part of the reaction (**5a** → **6c**), disappears in the final part **6c** → **7c**. But since no intermediate minima are found in the whole of the path (**5a** → **6c** → **7c**) this behaviour is inconsistent with both the Pearson[89] and Pechukas[76] theorems and the Rodger–Schipper relation.[90] A similar state of affairs has been observed[103] in the intramolecular proton transfer reaction of sulfamic acid from the zwitterion form **8** to the neutral form **10**, passing through the transition state **9** (Scheme 4):

Scheme 4

8, C_{3v} ($\lambda = 0$) **9**, C_s ($\lambda = 1$) **10**, C_1 ($\lambda = 0$)

Other examples of reactions on whose path the initial symmetry is altered through an intermediate state have been reported.[66, 104–112]

It has been shown[80] that the symmetry of a chemical system is preserved only during motions along gradient lines, and that this symmetry is determined by the symmetry of the eigenvectors of the Hessian $\vec{q}_i$ ($i = 1, 2, ..., 3N-6$) at the minimum and at the saddle point of the PES. Let us examine this problem in some detail.

The gradient lines entering an energy minimum[80] can be classified into two types: principal and secondary (see Fig. 5). The principal gradient lines define the main directions of the curvature[81, 82] at the minimum of the PES. By definition they are characterised exclusively by the eigenvectors of the Hessian $\vec{q}_i$ ($i = 1, 2, ..., 3N-6$) at the minimum, i.e. by the curvature properties of the PES in the infinitesimally small surroundings of the minimum, and they are independent of the initial conditions [the points $X_0(Q_0)$]. Evidently there are only $2(3N-6)$ principal gradient lines if allowance is made for the positive and the negative directions of each of the $\vec{q}_i$ vectors. The secondary gradient lines enter the minimum tangentially to $\vec{q}_i$ (corresponding to the lowest eigenvalue of the Hessian), and form an infinite series of gradient lines defined by the initial points $X_0(Q_0)$.

The symmetry point group of the molecular configuration at some point X on the gradient line defines the symmetry point group of the tangential vector $\nabla E(X)/|\nabla E|$, and this symmetry group (according to Pearson's theorem) is conserved over the entire length of the gradient line. Thus the symmetry of the gradient line, defined as the symmetry group of the vector $\nabla E/|\nabla E|$, is uniquely determined by this vector.

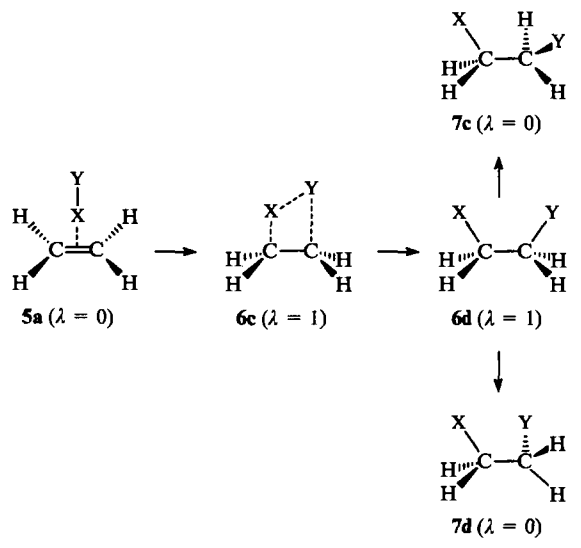
The direction of the principal gradient line in the configurational space coincides with that of one of the vectors $\vec{q}_i$ ($i = 1, 2, ..., 3N-6$) in the infinitesimally small surroundings of the minimum point. This means that the tangential vector $\nabla E(X)/|\nabla E|$ at the point X ($X \neq X_{min}$), which belongs to immediate surroundings of the minimum, has the symmetry of the corresponding vector $\vec{q}_i$. The symmetry point subgroup of the vector $\vec{q}_i$ is defined as the plurality of symmetry elements of this vector.

Thus the symmetry of the principal gradient line is given by the symmetry group of the Hessian vector $\vec{q}_i$, to which it is tangential at the minimum point. A similar analysis of the symmetry of a gradient line emerging from the saddle point tangentially to a transition vector shows that its symmetry group is determined by that of the transition vector. If the gradient line emerging from the saddle point enters the minimum along a principal direction the symmetry group of the transition vector coincides with that of the corresponding vector $\vec{q}_i$.

The direction of the secondary gradient lines in the configurational space does not coincide with the direction of the vector $\vec{q}_1$ in the infinitesimally small surroundings of the minimum

point. Therefore arguments similar to those used above for the principal gradient lines are not applicable to secondary lines. For the secondary gradient lines we may only conclude that the symmetry group cannot be higher than the symmetry group of the vector $\vec{q}_1$ to which they are tangential.

The rules for the conservation of symmetry along the reaction path can be formulated as follows.



(1) The symmetry point group of the structure vector of the transition state is conserved along a gradient line. This symmetry group can either coincide with the symmetry group of the corresponding eigenvector of the Hessian for the minimum (if the gradient line enters the minimum along a principal direction) or it can have a lower value (if the gradient line enters the minimum along a secondary direction).[80]

(2) A change in the symmetry point group of the molecular configuration of the system is possible only at the critical points.[67, 113, 114]

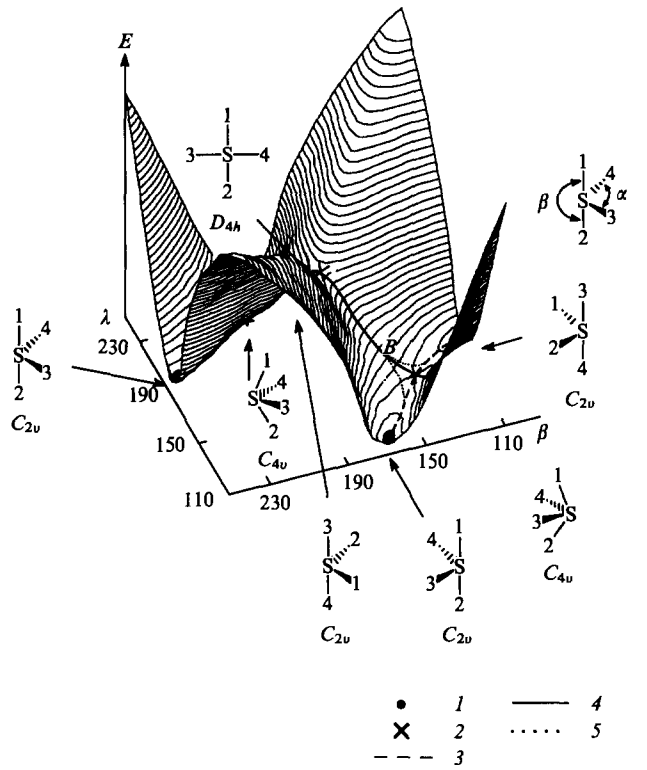
(3) The symmetry point group of the transition vector, which is conserved along the gradient line, should also be a subgroup of the symmetry point groups of the reactant, of the transition state structure and that of the product, or of all three critical points connected by the given gradient line.[113]

The first rule states that the symmetry is conserved along the gradient line, and not along the MEP, and therefore we must first of all identify all the gradient lines which contribute to the reaction path of the given reaction by analysing the conservation of symmetry along each gradient line.

Scheme 5

Thus, if the reaction path consists of two gradient lines[7] (see Scheme 5, and also Scheme 3 and Fig. 3), the appropriate symmetry is retained along each of these lines. In the initial stage **5a** → **6c** → **6d** the reaction path is defined by the gradient line along which the mirror plane of symmetry passing through the atoms X and Y and through the two carbon atoms is conserved (C_s symmetry). In the final stage **7c** → **6d** → **7d** the reaction path is defined by the other gradient line (corresponding to internal rotation round the C–C bond, along which the symmetry conservation conditions are different from those which apply to the first gradient line.

The PES of sulfur tetrafluoride SF_4 has a more complex structure (Fig. 6). For this system the path of the enantiomerisation reaction consists of three nonequivalent gradient lines. The gradient line passing through the saddle point (corresponding to the planar transition structure with D_{4h} symmetry) connects three neighbouring saddle points (transition structures corresponding to two pyramidal structures with C_{4v} symmetry and one planar structure with D_{4h} symmetry).



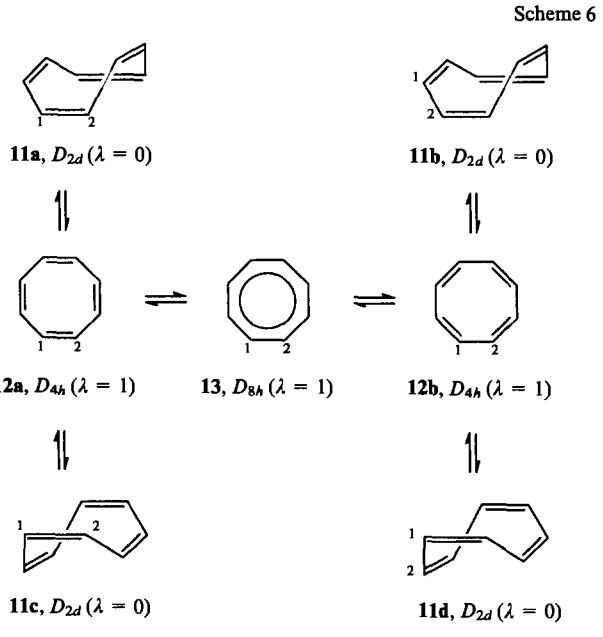


Figure 6. Potential energy surface of the enantiomerisation reaction of the sulfur tetrafluoride molecule in α, β coordinates according to ab initio calculations (STO 6-31G*).[108] The angles α and β are defined on the right of the figure.[108] (*1*) Minima; (*2*) saddle points (transition states); (*3*) Berry pseudorotation; (*4*) inversion of the C_{4v} structure of SF_4; *B* is the bifurcation point where the minimum energy path (*5*) breaks into two and diverges from the gradient line.

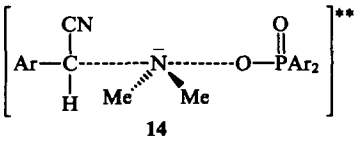
We should note that at the point *B* the minimum energy path is split into two and diverges from the gradient line. The other two gradient lines correspond to Berry's pseudorotation reaction[115] in sulfur tetrafluoride. A similar structure is observed in the PES for the 1,3 proton shift reaction in the zwitterion **8** (see Ref. 103) and in other reactions.[104, 105]



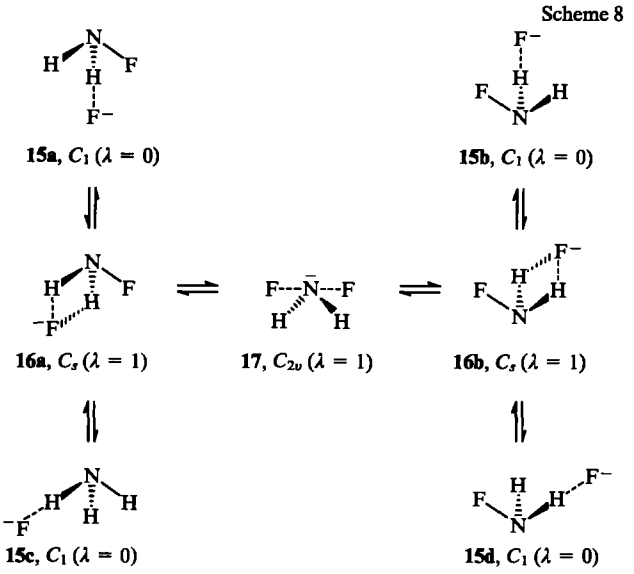
Scheme 6

The isomerisation of the cyclooctatetraene (COT) molecule,[116-121] first synthesised[118] by Willstätter in 1913, is a remarkable example of a reaction whose path consists of several nonequivalent gradient lines (Scheme 6). An unusual stereochemical lability (the fast valence isomerisation **11a** ⇄ **11b**, taking place through the planar structure **13** with an activation barrier of 14 kcal mol^{-1}) was detected by NMR more than 30 years ago.[112] Later studies[123,124] by dynamic NMR detected a lower-energy conformational transition in this system: the ring inversion **11a** ⇄ **11c**, with a barrier of ~10 kcal mol^{-1}. The transition structures in this process could be either the planar structure **12** (D_{4h}) or various nonplanar structures. The planar configuration **13** (D_{8h}) is a classical example of an antiaromatic system.[64,119] If the structure **12** corresponds to the transition state the difference in energy between the structures **12** and **13** will be the energy of the antiaromatic destabilisation (delocalisation) in the molecule. Therefore establishing the nature of the stationary points on the PES of cyclooctatetraene corresponding to the structures **12** (D_{4h}) and **13** (D_{8h}) has stimulated the interest of theoretical chemists for many years.[106,125-127] It was established relatively recently[106] by accurate ab initio calculations (CAS SCF/3-21G* and 6-31G* + ΔZPE) with full allowance for the force constants that these two planar structures are transition states ($\lambda = 1$) for the ring inversion and the valence isomerisation reaction respectively. In this case the structure of the PES is similar to that shown in Fig. 6. Surprisingly, however, though the vector of the transition state **13** shows unambiguously that the reaction path (gradient line) issuing from the PES point corresponding to **13** (D_{8h}) should arrive at the point **12** (D_{4h}), the authors[106] assume that the reaction path of the valence isomerisation misses this structure by branching on the slope of the PES.

The nucleophilic substitution (S_N2) at the nitrogen atom[128-133] is an interesting example of a reaction with a complex path. By using two isotopic labels it was shown experimentally[133] that the nucleophilic substitution reaction on the nitrogen atom of *N*, *N*-dimethyl-*O*-(diarylphosphinyl) derivatives passes through the structure of a transition state of the type **14**, which is similar to the transition structure of the S_N2 reaction at a carbon atom. This confirms the generality of the Walden inversion in tetrahedral or pseudotetrahedral configurations (in which the unshared pair of the central atom plays the role of a phantom ligand) in nucleophilic substitution reactions (Scheme 7).

Scheme 7

14



Ab initio calculations[107] (SCF TZP+/CISD) carried out with adequate precision within a year of the previous work[133] on the model reaction (Scheme 7)

$$F^- + H_2NF \rightleftarrows FNH_2 + F^-,$$

confirmed the original conclusions[133] and showed that the reaction begins with the formation of the nondipolar complex **15** having a linear F$^-\cdots$H–N bond and passes through the transition state **17** with a C_{2v} symmetry and an activation barrier of 24 kcal mol^{-1} (Scheme 8). This barrier is higher than the corresponding activation barrier for the S_N2 reaction on the carbon atom, calculated (by SCF DZDP/CISD methods) to be 17.1 kcal mol^{-1} (see Ref. 134). According to the proposed mechanism the fluoride ion can be transcoordinated between two NH bonds through the transition state **16** (C_s) by surmounting an activation barrier of 4.6 kcal mol^{-1}.

Thus, according to published calculations,[107,135] the general reaction path outlined in Scheme 6 is very similar to that of the sulfur tetrafluoride enantiomerisation and the cyclooctatetraene valence isomerisation reactions, and can be represented by the

Scheme 8

PES shown in Fig. 7. The gradient line issuing from the saddle point **17** transition state with C_{2v} symmetry) enters the neighbouring saddle point **16a** (or **16b**, transition state with C_s symmetry) corresponding to the peak of the activation barrier for the transcoordination of the fluoride ion from one NH bond to the next. At the point on the PES corresponding to the state **16a** the system passes from one gradient line to the next, and reaches the minima **15a** and **15c** (or **15b** and **15d**) along both branches of the line.

The conclusion that two (or more) saddle points cannot exist on the same gradient line follows from the Fernandez–Sinanoglu theorem.[136] It also follows that the reaction path must split into two before the second saddle point (the second transition state). The proof of the Fernandez–Sinanoglu theorem is based on the hypothesis that the reaction path always consists of a single gradient line connecting the saddle point with a minimum. However, there are no logical or physical reasons for this condition to be satisfied in general. As can be seen from the examples discussed above, the reaction path may consist of several gradient lines which the system follows sequentially. This means that the Fernandez–Sinanoglu theorem does not apply in general, and that there are no limitations (other than the Morse expressions,[137] which establish strict relationships between the numbers of nondegenerate critical points of different order in a defined region of the PES) on the character of the critical points lying on one gradient line (see also Refs 25 and 66).

According to the first rule of symmetry conservation along the reaction path (see above), the symmetry point group conserved along a gradient line is not that of the molecular configuration of the transition structure as had been suggested,[64,67,75,90-92,113,114] but that of the transition vector. This important difference from previously formulated rules[67,90] removes existing discrepancies in our understanding of the conservation of symmetry along the reaction path, including the exceptions from the Pechukas rules.[67] We shall illustrate this conclusion with two examples: the inversion in the ammonia molecule and the internal rotation in ethane. As can be seen from Fig. 8, the symmetry point groups of the vector of the rotational mode at the minimum and of the transitional vector at the saddle point coincide in the ethane molecule, and are equal to D_3. Similarly, in the ammonia molecule the symmetry point group C_{3v} is conserved. These symmetry groups do not change during the transition from the minimum of the reactants through the transition state to the minimum of the products. However, the corresponding point groups of the molecular configurations change from D_{3d} to D_{3h} and back to D_{3d} for ethane, and for ammonia they change in the sequence C_{3v}–D_{3h}–C_{3v}.

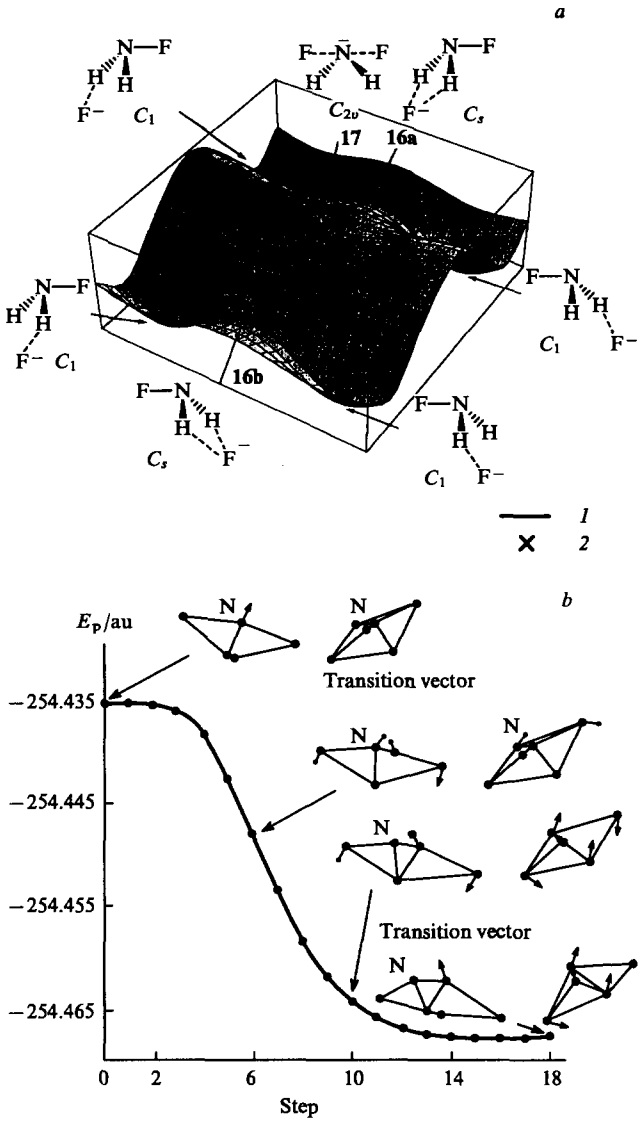


Figure 7. Potential energy surface (*a*) of the nucleophilic substitution reaction $F^- + H_2NF \rightleftarrows FNH_2 + F^-$ and evolution (*b*) of two eigenvectors of the Hessian along the gradient line (*1*) from the saddle point **17** to the neighbouring saddle point **16a** according to SCF/DZP ab initio calculations;[135] (*2*) are the saddle points.

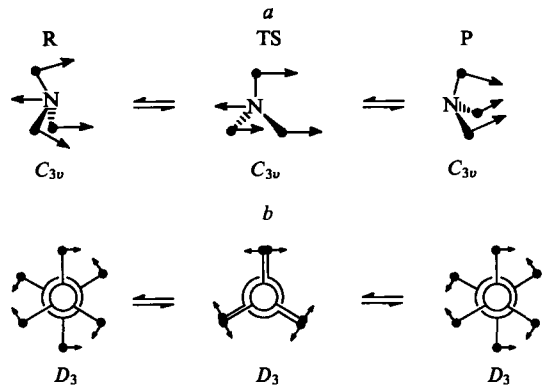
Rule (2) [like rule (3)] is a corollary of rule (1). Unless used in conjunction with rule (1) it confuses our understanding of the principle of symmetry conservation along the reaction path.

We shall interpret the symmetry of a point on the PES (including a critical point) as the symmetry point group of the corresponding molecular configuration. The symmetry subgroup of each vector $\vec{q}_i$ is unambiguously determined by the symmetry point group of the molecular configuration at the critical point. Obviously, the inverse statement is equally valid: the symmetry subgroups of all the $\vec{q}_i$ vectors uniquely define the total symmetry group of the molecular configuration. In this case we may conclude that the symmetry of any critical point is determined by the symmetry of all the gradient lines entering or emerging from that point.[80] In other words each gradient line contributes to the given critical point its own symmetry subgroup, and the symmetry point group of the molecular configuration in the same critical point is determined by the combined symmetries of all three gradient lines. Therefore when the molecular system has reached a critical point (including a minimum) the order of its symmetry group can only rise.[114]



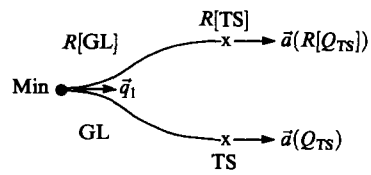


Figure 8. Reactions producing inversion of the pyramidal configuration of bonds in the ammonia molecule (*a*) and internal rotation around the C–C bond in ethane (*b*). The arrows show the components of the normal and of the transition vectors at the minima. R are the reactants, P are the products, TS is the saddle point.

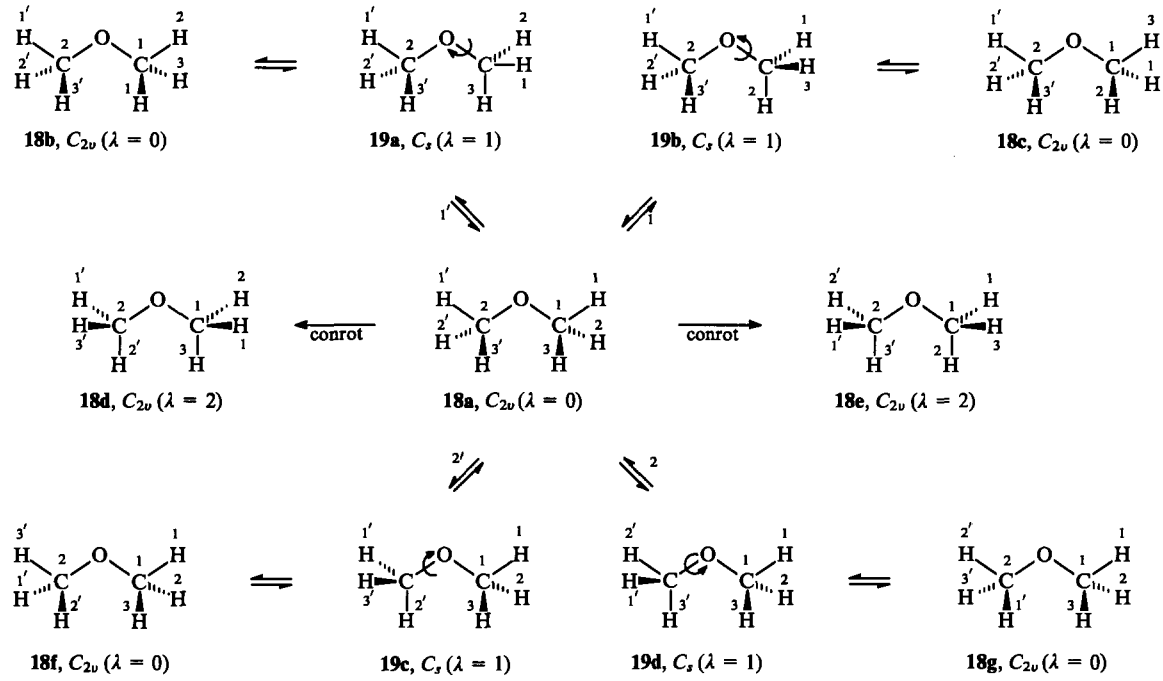
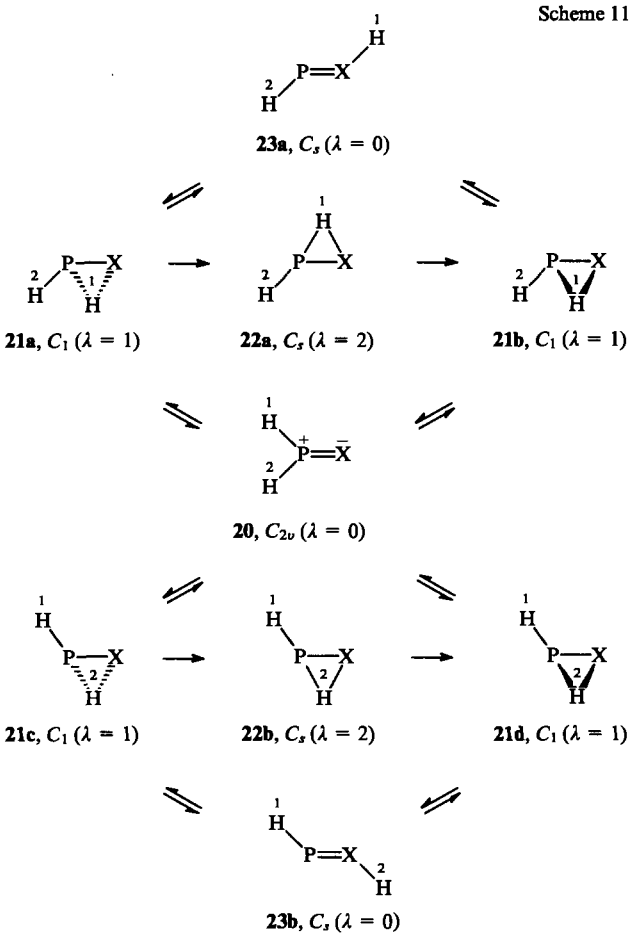
IV. Reaction paths consisting of several equivalent gradient lines

1. Reaction paths consisting of two equivalent secondary gradient lines



Unlike the symmetry group of principal gradient lines (see above) the symmetry group of a secondary gradient line entering a minimum can either coincide with the symmetry group of the Hessian vector $\vec{q}_1$ (corresponding to the lowest eigenvalue) or be its subgroup.[80] Therefore, if a secondary gradient line connects the minimum with any transition state the symmetry group of the transition state [according to the rule (1), see above] can either coincide with the symmetry group of the vector $\vec{q}_1$ at the minimum point or be its subgroup. We shall assume that $\vec{q}_1$ has at least one nontrivial symmetry element R, and that the transition state TS with the transition vector $\vec{a}(Q_{TS})$ is found on one of its secondary gradient lines. In this case the symmetry conditions require that in addition to the transition state TS an equivalent state R[TS] with a transition vector $\vec{a}(R[Q_{TS}])$ must exist. Then the minimum point is coupled with the two equivalent transition states TS and R[TS] by the two symmetry-equivalent secondary gradient lines GL and R[GL], as illustrated in Scheme 9.

Scheme 9



In this case the gradient path of the chemical reaction consists of two equivalent (physically indistinguishable) gradient lines. Various combinations are possible: each of the equivalent gradient lines leads to a different minimum (Figs 9*a* and 9*b*, see over), the lines lead in pairs to the same minimum (Figs 9*c* and 9*d*), etc. Examples of reactions whose equivalent paths lead to the same minimum[14,23,130,139] or to different minima[14–21,139–141] have been reported. If the molecule contains two stereochemically equivalent nonrigid groups which can independently undergo a conformational rearrangement (for example, rotation around single bonds, Scheme 9) we may observe a gradient reaction path consisting of two equivalent gradient lines. For example, in propane,[15] dimethyl ether,[16,17] and other molecules[18,19,138–141] two methyl groups can rotate independently of each other. Under these conditions each line in the gradient reaction path leads to a different minimum (see Fig. 9*b*). In particular, for the dimethyl ether molecule[16] this type of gradient reaction path can be illustrated by Scheme 10 (see over).

Scheme 10

Each of the methyl groups in this molecule can rotate independently. Four equivalent gradient lines, each passing through its own transition structure **19a–19d** and leading to a separate minimum **19b–19g**, emerge from the minimum **18a**. The routes 1 and 2 form one gradient reaction path, the routes 1′ and 2′ form another.

Scheme 11

An example of a reaction corresponding to the case shown in Fig. 8*c* is the 1–2 shift of the hydrogen atom in the $H_2P{=}N$ and $H_2P{=}P$ molecules (Scheme 11). Ab initio calculations[23] allowing for the correlation energy of the electrons in the $H_2P{=}N$ and $H_2P{=}P$ molecules show that in the migration process **20** ⇄ **23** the hydrogen atom moves out of the (initially) planar molecule. The out-of-plane (inversion) mode of the normal vibration of the structure **20** corresponds to the lowest frequency. In these reactions the transition states are the states **21a–21d**. The states **22a** and **22b** corresponds to a critical point with $\lambda = 2$ (see Refs 23 and 142). The potential energy surface of the system is shown in Fig. 10. The two secondary gradient lines emerging from the minimum **20** tangentially to the vectors $+\vec{q}_1$ and $-\vec{q}_1$ (out-of-plane inversion mode), which pass through the two saddle points **21a** and **21b** and terminate in the same neighbouring minimum **23a**, form two equivalent gradient reaction paths.

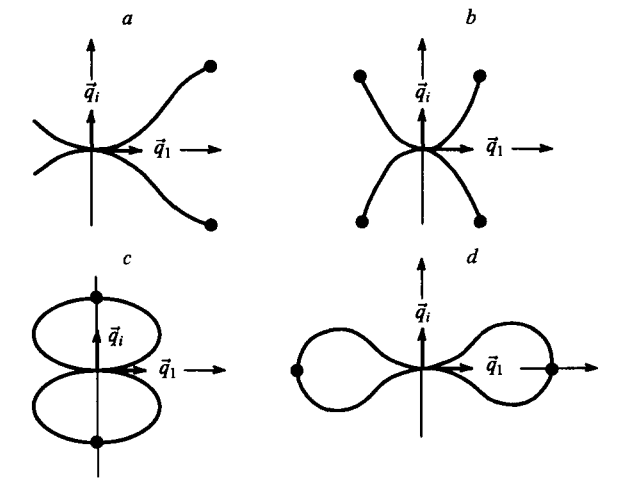


Figure 9. Variants of the two-line reaction paths. (*a*) Two branches of two equivalent secondary gradient lines enter two minima; (*b*) each of the branches of two gradient lines enters its own minimum; (*c*) two branches of one gradient line enter the same neighbouring minimum; (*d*) the branches of two different gradient lines enter the same neighbouring minimum.

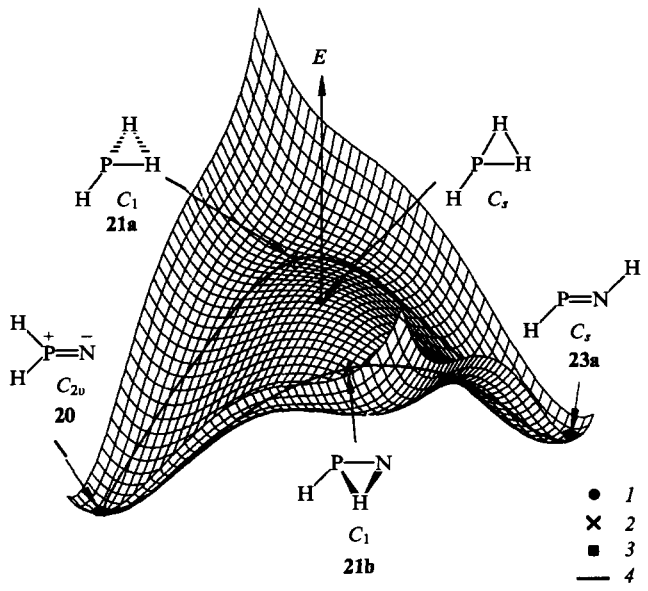

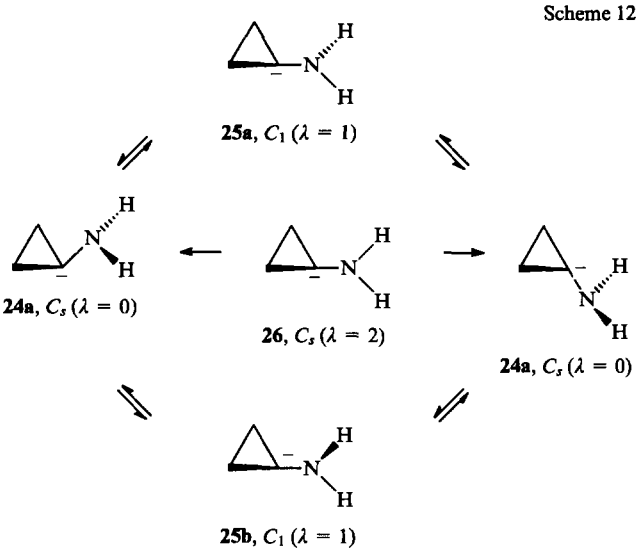

Figure 10. Potential energy surface of the 1,2 hydrogen atom shift in the H_2PN molecule (**20**) according to ab initio calculations.[23] (*1*) minima; (*2*) saddle points (transition states); (*3*) critical points with $\lambda = 2$; (*4*) gradient reaction path consisting of the two gradient lines **20** ⇄ **21a** ⇄ **23a** and **20** ⇄ **21b** ⇄ **23a**.

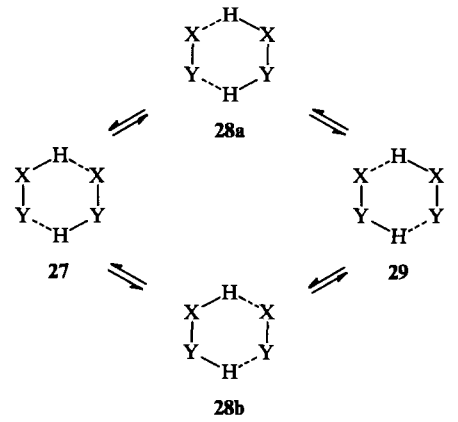
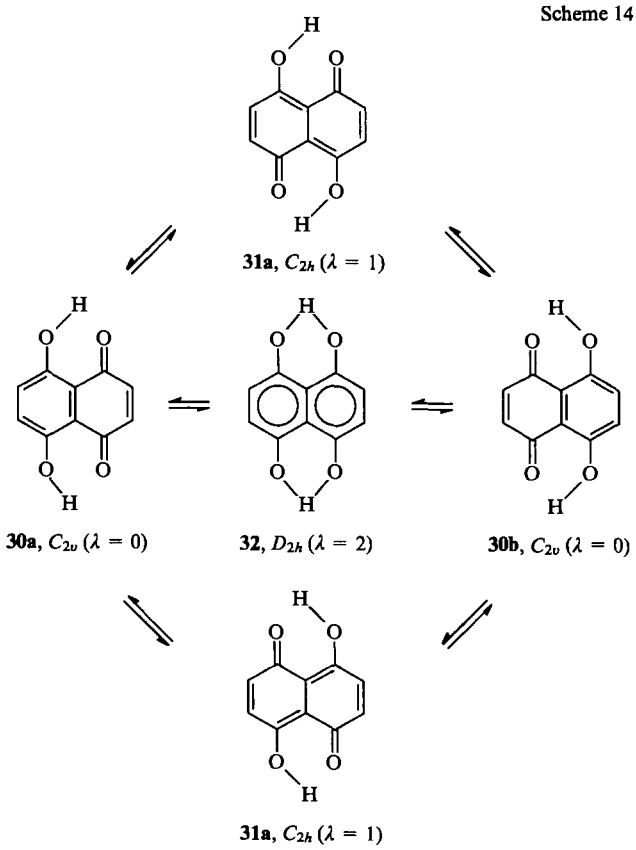
The principal gradient line issuing tangentially to $\vec{q}_2$ (the mode corresponding to the 1,2-H shift) passes through the critical point with $\lambda = 2$ (structure **22a**) and enters the minimum **23a**. This topology of the PES is consistent with the correlation of the atomic shift vectors along the whole length of the gradient line between two minima.[142]



Scheme 12

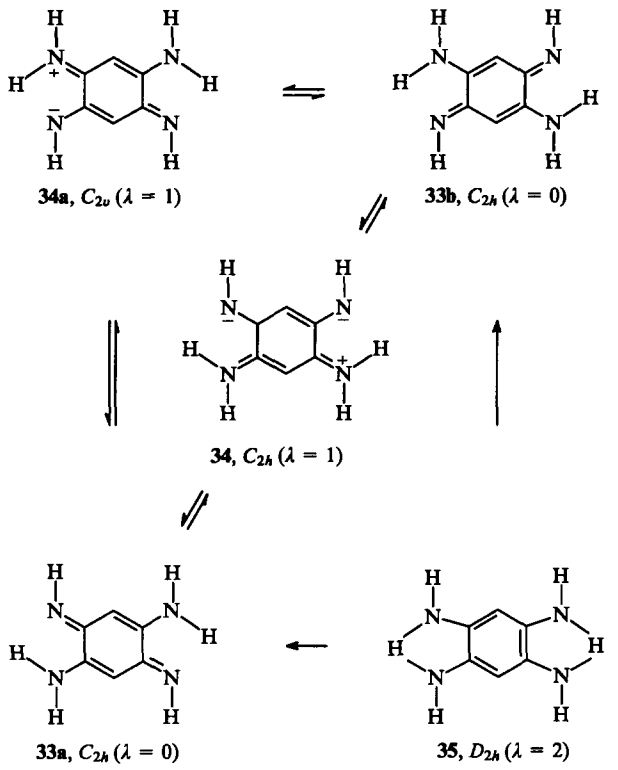
The inversion reaction at the carbanion centre of the aminocyclopropyl anion **24** (Scheme 12) is an interesting example. Ab initio calculations [MP2/6-31 + G(d)//6-31 + G(d)][138] predict that the inversion reaction passes through two enantiomeric asymmetric (C_1) transition states **25a** and **25b** with an activation barrier of 30.1 kcal mol^{-1}. This means that the gradient path of the reaction is described by two equivalent gradient lines. The state **26** (C_s or C_{2v}), which unfortunately was not studied by Chou et al.,[138] should correspond to a critical point with $\lambda = 2$ on the PES of the carbanion.



An important class of reactions described by two equivalent lines includes the double proton transfer reactions in various organic compounds,[143–167] such as porphyrin,[143–147] tetraphenylchlorin,[149] oxalamidine,[150,151] azophenone,[150–155] naphthazarin,[156–161] and the dimer of formamidine.[162–164] In all these systems the transfer of two protons occurs[149] by the general Scheme 13.

Scheme 13

The states **28a** and **28b** on the PES can be transition states (concerted process) or they can correspond to intermediate minima (multistage process). Nevertheless in both cases the chemical reaction **27** ⇄ **29** is described by two equivalent routes, **27** ⇄ **28a** ⇄ **29** and **27** ⇄ **28b** ⇄ **29**, along which the chemical system can decompose with equal probabilities. Thus, the double proton transfer in the naphthazarin molecule **30a** ⇄ **30b** (Scheme 14) passes through the transition state **31** with an activation barrier of 25 kcal mol^{-1}, calculated by an ab initio method in an STO-3G basis.[156] As was shown by the calculation[156] the symmetrical structure **32** (D_{2h}) corresponds



Scheme 14

to a critical point with $\lambda = 2$. These results agree with NMR data[158,159] and with IR spectroscopy results.[161] However, the small energy difference (3 kcal mol^{-1}) observed[156] between the structures **32** and **31**, which may be strongly affected by allowing for the correlation energy,[14] calls for a more careful examination of these results.

The next example of a reaction which has been studied in reasonable depth is the double proton transfer in the azophenine molecule **33** (Scheme 15).[150–155] The automerisation of this molecule was explained (from measurements[150] of the kinetic and isotopic effects in derivatives of azophenine) by the simultaneous synchronous (concerted) transfer of two protons through the transition state **35** with an activation barrier of 10 kcal mol^{-1}.

Scheme 15

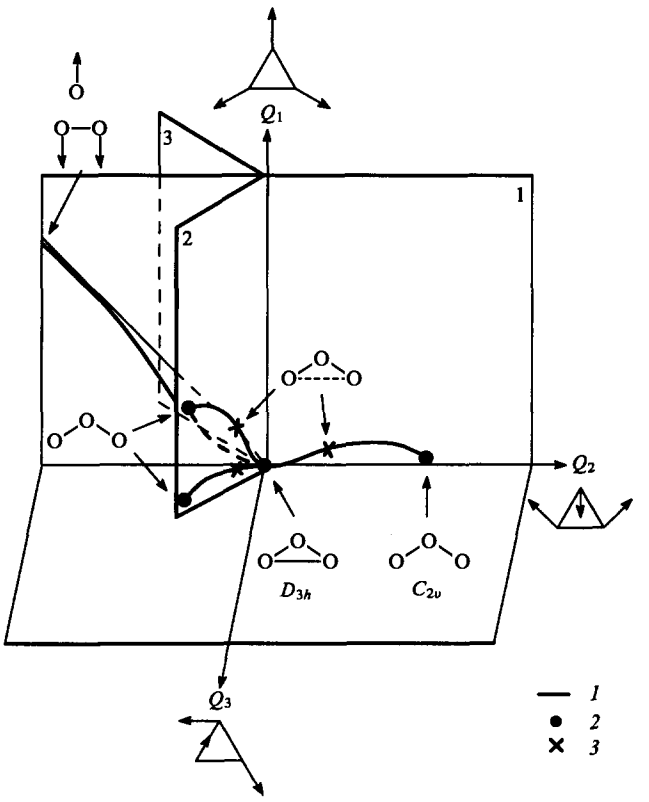
However, later calculations by AMI[153] and by ab initio methods[155] (MP2/3-21G//3-21G) showed that the reaction **33a** ⇄ **33b** takes place in stages through the zwitterion intermediate structure **34** ($\lambda = 0$) with an activation barrier of 17.3 kcal mol^{-1}, which exceeds the experimental value by 7.3 kcal mol^{-1}. Under these conditions the structure **35** (D_{2h}), as in the case of naphthazarin, corresponds according to the calculations[153,155] to a critical point with $\lambda = 2$. The observed discrepancy between experimental and theoretical data stimulated a careful re-examination of the experimental measurements.[152] New experiments[152] carried out immediately after the theoretical calculations[155] confirmed the conclusion[153,155] that the reaction **33a** ⇄ **33b** takes place in stages through the zwitterion intermediate structure **34**. However, the difference between the theoretical height[155] of the activation barrier (17.3 kcal mol^{-1}) and the experimental value[150] (~10 kcal mol^{-1}) is attributed to the choice of an insufficiently broad basis[155] and to the failure to allow for the effect of substituents on the barrier height.

Thus the path of the reactions discussed above (Schemes 9–15) and of some other reactions consists essentially of two equivalent gradient lines along which the chemical system can move with equal probabilities.

The existence of these reaction paths was first predicted by Salem,[168] who used the term narcissistic to describe them.

2. Reaction paths consisting of three or more equivalent gradient lines

A chemical reaction gradient path consisting of three or more equivalent gradient lines can be realised for chemical systems having a point group symmetry containing a triad (or higher) symmetry axis.[80] In this case the gradient lines approach the minimum in a radial direction in the space generated by the $\vec{q}_k$ vectors from a multidimensional representation. Two situations may be realised in this way: in the first each equivalent gradient line leads to its own minimum, and in the second all the equivalent gradient lines enter the same neighbouring minimum. Good examples of the first case are the isomerisation (topomerisation) of bulvalene,[9] mentioned in the Introduction, and the opening of the three-membered ring of the ozone molecule.[22]



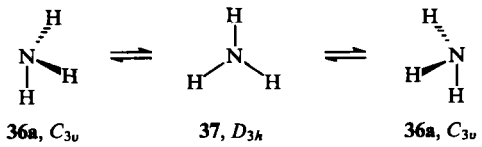


Figure 11. Equivalent gradient lines (*1*) leading to three equivalent transition states in the ring opening reaction of the D_{3h} form of the ozone molecule. The normal Q_i coordinates (i = 1, 2, 3) of the cyclic D_{3h} form are used as coordinates.[22] (*2*) Is a minimum; (*3*) is the transition state. The components of the normal $\vec{q}_i$ vectors (i = 1, 2, 3) are shown on the side of the coordinate axes.

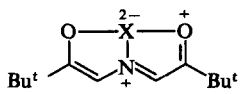
Let us consider in more detail the opening of the three-membered ring (D_{3h}) of the ozone molecule. The gradient path of this reaction consists of three equivalent gradient lines connecting the central minimum (D_{3h}) with three equivalent minima (C_{2v}) corresponding to the open form of ozone (Fig. 11). In this case the global coordinates were taken to be the normal coordinates of the D_{3h} form. Unlike the local coordinates, which give an adequate description of the system only in a small region of the configurational space, the global coordinates fully describe the configurational space of the molecular system over the whole range of internal coordinates. The figure also shows how the gradient line corresponding to a motion opposite to that of the ring-opening reaction leads to the removal of an oxygen atom from the ozone molecule. Along this line the normal mode is converted into the local mode.[169,170] The theory of local modes was developed to explain the breaking of individual chemical bonds, for which the theory of normal modes could not account.



An example of a reaction in which all three gradient lines connect two neighbouring minima is provided by the inversion of the pyramidal bond configuration in the trifluorophosphine molecule.[24,25] The history of the discovery of this uncommon reaction path is instructive and we shall briefly dwell on it. We know[14,171-175] that the inversion of the ammonia molecule **33a** ⇄ **33b** takes place through a planar (D_{3h}) transition state **37** (Scheme 16).

Scheme 16

36a, C_{3v} **37**, D_{3h} **36a**, C_{3v}

It has long been assumed that a planar (D_{3h}) structure of the type **37** is the only possible transition state for the inversion of various three-coordinated pyramidal (C_{3v}) structure. This hypothesis is confirmed by the many published studies of inversion processes in different systems, and no exceptions to it have so far been reported.[13,14,171-175] However, the synthesis[176-178] of the compound **38**, containing a planar T-shaped bond configuration on the pnictogen atoms (P, As, Sb, and Bi) suggested that the T configuration may act as the transition state in the inversion of the XF_3 molecule (where X = P, As, Sb, Bi):

38

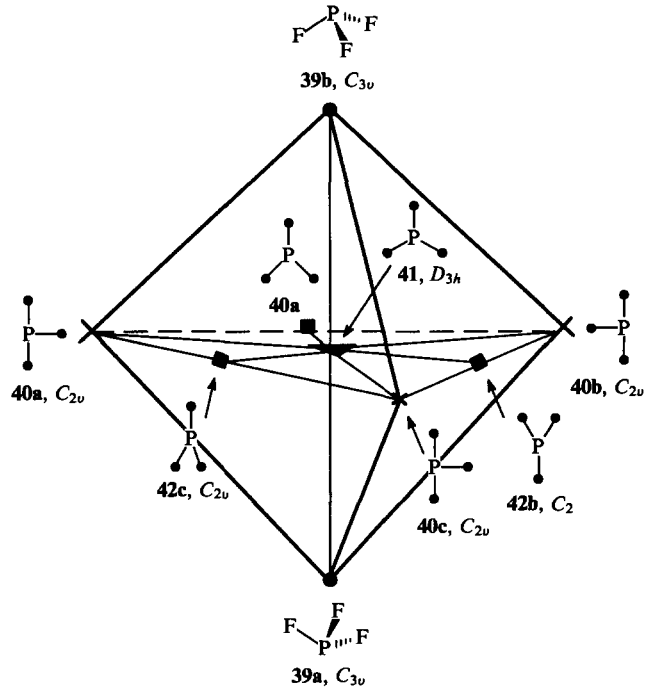
X = P, As, Sb.

In this way it was shown by ab initio calculations[179,180] that in the pyramidal molecules[179] PF_3 and SbF_3^+, and AsF_3 and SbF_3 (see Ref. 100) having a C_{3v} symmetry, the inversion takes place through the T-shaped C_{2v} form rather than through the planar (D_{3v}) form. This difference in the structure of the transition state between PF_3 and the ammonia molecule is unexpected. It can be attributed to the fact that the electrostatic repulsion between the unshared pair and the ligands is much smaller in the T-shaped form of the PF_3 molecule than in the D_{3h} form, whereas in the ammonia molecule (and in the other systems which invert through a planar D_{3h} state) the opposite is true.[179]

The appearance of a T-form as the transition state on the inversion path of the XF_3 molecule (X = P, S^+, As, Sb) requires the inversion mechanism to be reconciled with the microscopic reversibility principle,[181] according to which the path of the inversion reaction should contain three equivalent (topomeric) T-shaped transition structures[24] through which pass three equivalent gradient lines which form the gradient path of the reaction.

In the region between the two stable pyramidal C_{3v} forms the potential energy surface of PF_3 has a D_{3h} symmetry. The potential energy surface can be represented as a diagram of the gradient lines which connect the critical points (Fig. 12).[24]

The two axial corners of this bipyramid correspond to the two stable pyramidal structures **39a** and **39b** (C_{3v}), the three equatorial corners to the three T-shaped transition states **40a** – **40c** (C_{2v}). The centre of the bipyramid corresponds to the planar structure **41** (D_{3h}). All the lines in this figure are gradient lines issuing from a critical point with $\lambda \geq 1$ (structures **40**–**42**) in the direction of one of the imaginary frequency vectors. The gradient lines emerging from the transition structures **39a**–**39c** form (as a combined path) the gradient paths of the inversion reaction. In Fig. 12 they are shown as the edges of the pyramid. The axial line passing through the two axial corners and the centre of the bipyramid corresponds to the usual inversion (as in the ammonia molecule).



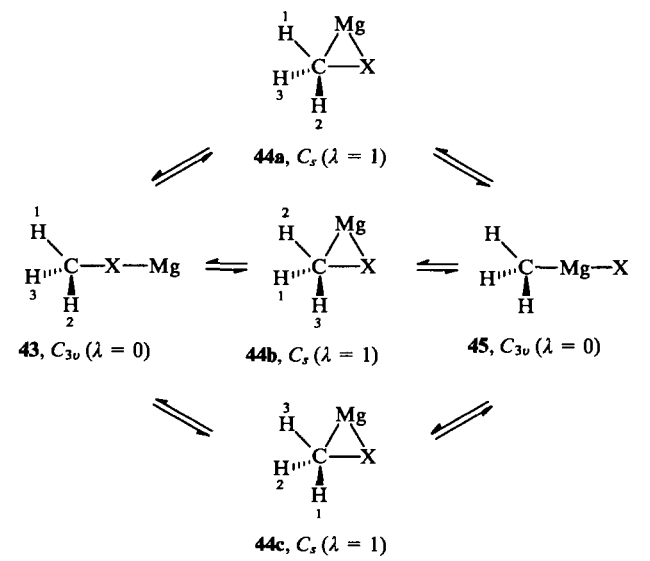


Figure 12. Diagram of the inversion reaction in the PF_3 molecule.[24] The thick lines denote three equivalent gradient lines passing through three equivalent transition states **40a**–**40c** (shown by crosses). The rectangles and the triangle show respectively the critical points of the second ($\lambda = 2$) and of the third order ($\lambda = 3$).

The lines joining the centre of the bipyramid with its equatorial corners correspond to three gradient lines on which the structure **41** (D_{3h}) becomes distorted into **40** (C_{2v}). All the transition structures are connected by a gradient line corresponding to the 'internal pseudorotation' of the T-shaped structure, simulating the true pseudorotation in ClF_3 (see Ref. 182) and other AX_3 systems (see Ref. 183).

Another interesting example of a reaction whose path consists of three equivalent gradient lines connecting two neighbouring minima is provided by the insertion of a magnesium atom into the C–X bond (X = F, Cl) of the halogenomethanes H_3C-X with formation of a Grignard reagent (Scheme 17). This reaction begins[184] with the formation of the complex **43**, after which

Scheme 17

44a, C_s ($\lambda = 1$)

43, C_{3v} ($\lambda = 0$) **44b**, C_s ($\lambda = 1$) **45**, C_{3v} ($\lambda = 0$)

44c, C_s ($\lambda = 1$)

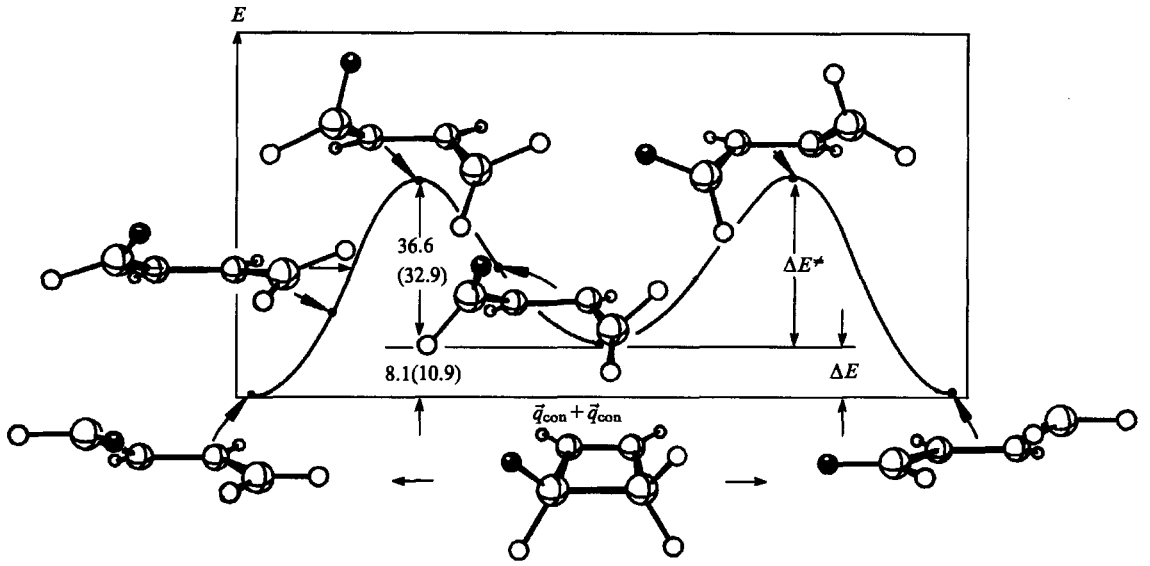

Figure 13. Mechanism of the pericyclic transformation reaction of the cyclobutene molecule into the gauche structure of 1,3-butadiene along the allowed conrotational path. The Figure shows the geometrical transformation of the water molecule along both directions of motion $+\vec{q}_{con}$ and $-\vec{q}_{con}$. Experimental [199-201] and calculated [188,193] values of the activation barrier and of the heat of reaction are given (numbers in parentheses and without parentheses respectively, kcal mol^{-1}).

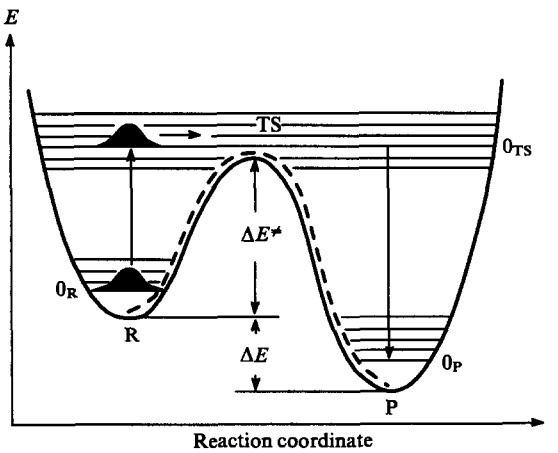
[according to MP4 SDTQ/6-311G(dp) ab initio calculations [184]] the gradient path of the reaction passes simultaneously in three directions through the three equivalent transition states **44a–44c** and terminates at the minimum **45**. The activation barriers calculated for the reaction of (25) with X = F and Cl are 31.2 and 39.4 kcal mol^{-1} respectively.

V. Unimolecular reaction mechanisms

The term mechanism of a chemical reaction is usually applied to the totality of the elementary steps which contribute to the conversion of the reactants into the products.[185,186] For the purpose of this discussion it is more convenient to use the concept of the mechanism of an elementary reaction step,[187] which denotes the totality of the electronic–nuclear transformations of the molecular system on the reaction path from the given minimum to the neighbouring minimum. In Fig. 13 we show the mechanism of the pericyclic ring opening reaction of the cyclobutene molecule, including the geometric transformation of the system along the reaction path, established by various methods.[188-202] During the reaction the system moves along two equivalent gradient lines, which emerge from the minimum tangentially to the vectors $+\vec{q}_{con}$ and $-\vec{q}_{con}$ corresponding to the allowed[185] conrotation of the methylene end groups. These lines terminate in two different (enantiomeric) minima. If a substituent is introduced into the third position of cyclobutene these two paths become nonequivalent and we observe the so-called rotational stereoselectivity.[193,196]

If the elementary step of the reaction corresponds to two (or several) equivalent gradient lines connecting two minima the mechanism of the elementary step includes the transformations which the molecular system undergoes along all these equivalent gradient lines (see, for example, Fig. 12).

The mechanism of the elementary step is more complex in the case of the valence isomerisation reaction of the cyclooctatetraene molecule. As can be seen from Scheme 6 there is only one transition state **13** between the four equivalent minima **11a–11d**. The reaction in the chemical system takes place only when the latter is thermally excited to an energy corresponding to the transition state (ignoring the possibility of tunnelling), i.e. it is transferred from the zero vibrational level to an excited energy level located above the transition state (Fig. 14). If there are two equivalent transition states the reaction can take place through either. Therefore in order to induce the isomerisation of the cyclooctatetraene molecule from one of the minima (**11a**) into another (for example, **11b**) the system must be promoted to a vibrational energy level lying above the transition state **13**. However, in this case the system will rapidly become delocalised on this hypersurface with equal probabilities for the four minima **11a–11d**, and it can then relax to the zero vibrational level in each minimum. Therefore in this case the elementary step is described by three gradient lines: **11a** ⇄ **12a** ⇄ **11c**, **11b** ⇄ **12b** ⇄ **11d**, and **12a** ⇄ **13** ⇄ **12b** (see Scheme 6), and hence the mechanism of the elementary step is the totality of the transformations of the system along the three gradient lines. However, if we are concerned only with the inversion of the ring, the mechanism of the elementary step now becomes the totality of the transformations along only one of the lines, **11a** ⇄ **12a** ⇄ **11c** or **11b** ⇄ **12b** ⇄ **11d** (Scheme 18).



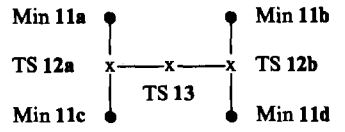


Figure 14. Classical reaction path (broken line joining the minima of the reactant R and of the product P through the saddle point of the transition state TS) and quantum transition (vertical arrows) from the vibrational ground state of the reactant (0_R) to the vibrational state (0_{TS}) lying above the energy of the transition state, and beyond to the vibrational ground state of the product (0_P).

Scheme 18

It is often assumed[61,75,203] that any unimolecular reaction begins along the 'softest mode', i.e. along the vector $\vec{q}_1$ corresponding to the minimum frequency. It is evident from the above discussion that this assertion is not entirely accurate, since in addition to the very large number of secondary gradient lines tangential to the vector $\vec{q}_1$ we have $2(3N-7)$ principal gradient lines tangential to the vectors $\pm\vec{q}_i$ ($i = 2, 3, ..., 3N-6$), which may also contain transition states. Of course, the chemical system can take part in all the reactions corresponding to these transition states, but the number of transition states which may be found on the secondary gradient lines entering a given minimum is still an unsolved problem. Therefore the problem of listing all the reaction mechanism available to a molecular configuration corresponding to a given minimum is also still unsolved. Obviously, the number of such mechanisms must be finite.

As was pointed out above, the chemical system can move away from a minimum only along the appropriate gradient line. This means that it can begin to move from the minimum only along one of the $\vec{q}_i$ vectors ($i = 1, 2, ..., 3N-6$), i.e. the chemical reaction can start only along a normal (collective) mode.[80] The idea of using a normal mode to describe a motion with a large amplitude was stimulated by the discovery by Pitzer and Kemp[204] (in 1937) of the restricted internal rotation in ethane. The idea was later developed and used to explain the mechanism of the internal pseudorotation in cyclopentane[205-209] and other molecules.[13,14,115] The same idea was recently extended to pericyclic reactions in the outstanding studies of Woodward and Hoffmann.[185] The case of unimolecular reactions of an arbitrary type has been discussed by the writer.[80]

The motion of the system from a minimum along a gradient line tangential to one of the $\vec{q}_i$ vectors ($i = 1, 2, ..., 3N-6$) helps us to understand the nature of the departure of the gradient path from the shortest path (in which the reaction follows the shortest path of each atom in the molecular system from the reactants to the products), proposed by Rice and Teller[210] in 1938 (see also Ref. 62). If the direction of the $\vec{q}_i$ vector coincides with that of the shortest distance path the reaction follows this path. However, the gradient path of the reaction may not coincide with the shortest distance path. For example, the transformation of the cyclobutene molecule into the gauche form of 1,3-butadiene (see Fig. 13) follows a path close to the shortest distance path, as can easily be seen by superimposing the structures along the reaction path. In this case the motion of each atom from its initial position (cyclobutene) to the final position (butadiene) is almost a straight line. In contrast to this reaction the elimination of a hydrogen molecule from 1,4-cyclohexadiene (according to MCSCF ab initio calculations in 6-31G and 6-31G** bases)[211] follows a path markedly different from the shortest distance path. As can be seen from Fig. 15, during the reaction the atoms follow fairly complex trajectories strongly different from straight lines. The normal vibration vector, shown by arrows in Fig. 15 and tangential to the reaction path, corresponds to the distortion of the planar structure into a bathtub conformation and does not agree (in this case) with the direction of shortest travel. An interesting characteristic of this process is the observation (in experimental studies of the distribution of vibrational and rotational energy in the products of the elimination reaction)[212] that a hydrogen molecule being removed from the benzene begins to rotate in a plane parallel to the benzene ring, which cannot be explained by the calculated[221] characteristics of the PES. In order to reconcile the experimental[212] and the theoretical data[211] we must postulate a second transition state on the reaction path (the point A in Fig. 15) with a structure of C_{2v} symmetry, corresponding to the rotation of the hydrogen molecule in a plane parallel to that of the benzene ring.

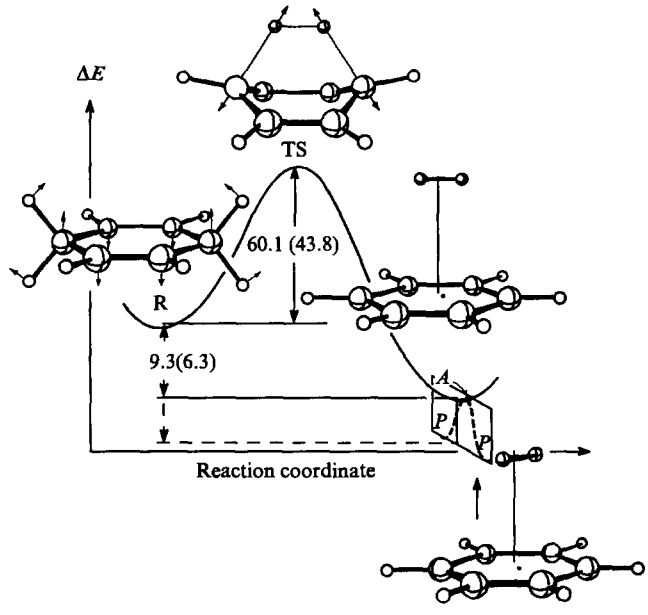

Figure 15. Transformation of the 1,4-cyclohexadiene molecule along the reaction path of the reaction for the removal of a hydrogen molecule according to ab initio calculations[211] (numbers without parentheses, kcal mol^{-1}). Experimental data for the activation barrier[213] and for the heat of the reaction[214] are given (numbers in parentheses). In order to reconcile the calculated PES [211] with the experimental data[212] we must assume that the point A corresponds to the second transition state on the path of the elimination reaction and that this structure is the transition state for the internal rotation of the hydrogen molecule in a plane parallel to the benzene molecule (broken line). The arrows show the components of the normal vibration vector at the minimum and of the transition vector at the saddle point.

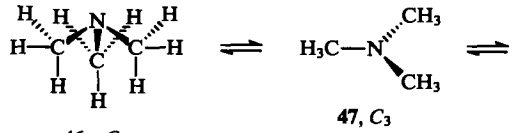
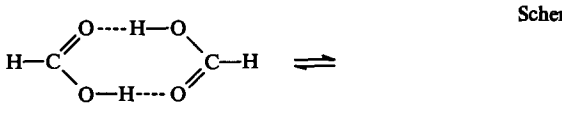


At the second transition state the translational motion of the hydrogen molecule with respect to the benzene becomes a rotational motion. In this case the gradient reaction path becomes analogous to the reaction path proposed in Scheme 2.

This approach also makes clear the nature of the strictly correlated conrotational or disrotational motion of the methylene end groups in the pericyclic ring opening reactions of polyenes,[185] and answers a number of other questions. For example, how does one methylene group at the beginning of the reaction 'sense' that another methylene group has started to move, and how does it establish the direction of this motion so as to align itself correctly with it? Why is the character of this correlated motion often different in similar systems? Answers to these questions can be given relatively simply by using existing data.[80] At a minimum point the molecular system initially has a limited choice of vibrational modes, corresponding only to the conrotational and the disrotational modes of the methylene group (see, for example, the calculations[215] of the rotational spectra of the *cis*- and *gauche*-conformers of 1,3-butadiene). Therefore in this system the gradient path of the reaction begins at a minimum tangentially to the vectors of these modes.

VI. Collective processes

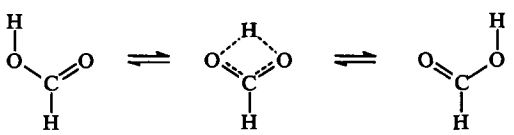
Any single-stage process can be treated as a collective process. The most important collective processes are those consisting in the correlated (coordinated) motion of two or several groups (especially between not covalently bound fragments) with relatively minor changes in the other geometric parameters of the system. Equally important are the conditions under which the independent motion of these groups (multistage reaction) becomes single-stage. Let us make these statements clearer by considering some examples.



Scheme 19

46a, C_{3v} **47**, C_3 **46b**, C_{3v}

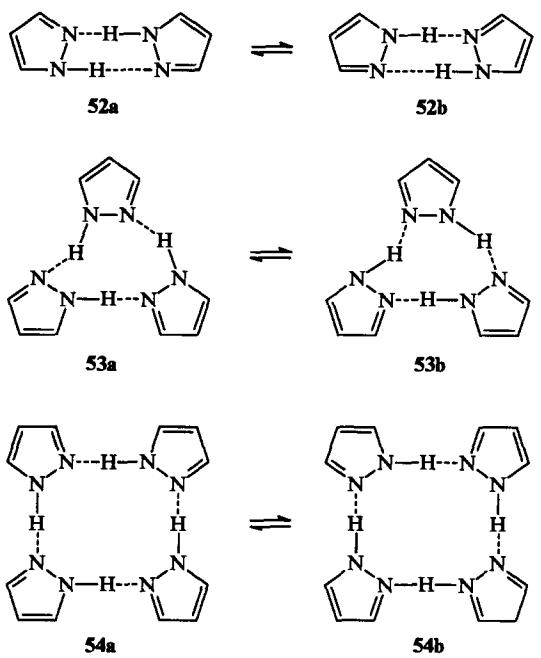
We shall discuss as a first example the inversion reaction of the trimethylamine molecule $(CH_3)_3N$ (Scheme 19). In the ground state this molecule has a C_{3v} symmetry.[216] In the transition structure during the inversion through a planar configuration of N–C bonds surrounding the nitrogen atom the molecule acquires the C_3 configuration. This means that all three methyl groups rotate simultaneously and synchronously during the reaction, so that a collective process of simultaneous and strictly correlated motion of all the stereochemically labile groups can take place in this reaction, i.e. the inversion of the bonds on the nitrogen atom induces a synchronous internal rotation of the methyl groups. A similar inversion process occurs in the $(CH_3)_3O^+$ (see Ref. 217) and the $(CH_3)_3S^+$ cations (see Ref. 216).



Scheme 20

48a **49** **48b**

We shall discuss as a second example the intermolecular double proton exchange in the dimers of formic acid[163,218,219] and pyrazole,[220–222] and the triple (in the trimer) and the four-fold proton transfer (in the tetramer) of pyrazole[220–222] (Scheme 20). As shown by theoretical and by experimental studies of the formic acid dimer[163,218,219] a double proton transfer takes place simultaneously in this system through the symmetrical transition structure **49** with an activation barrier of ~8 kcal mol^{-1} (see Ref. 163). At the same time the intramolecular transfer of a proton between oxygen atoms (Scheme 21) in the monomer **50** takes place, according to ab initio calculations,[223] with a much higher activation barrier: about 40 kcal mol^{-1}.

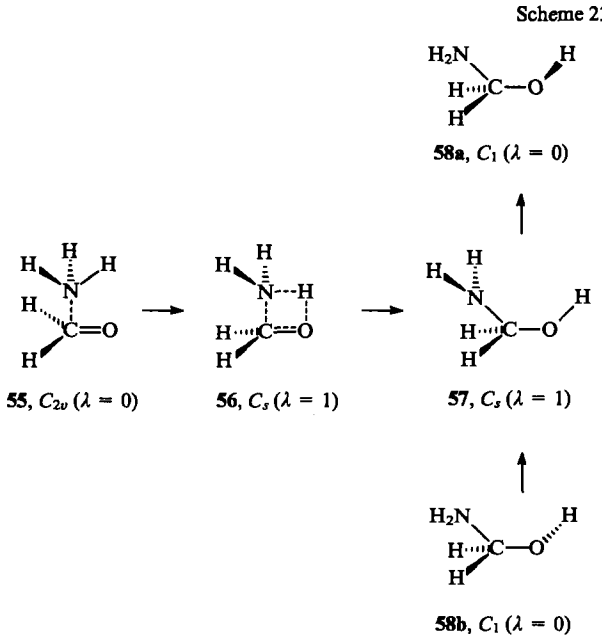


Scheme 21

50a **51** **50b**

Similar studies of the pyrazole dimers,[220,222] trimers,[220] and tetramers[222] showed that fast, reversible low-barrier proton transfer processes are possible in these systems. On the other hand the intramolecular proton transfer in pyrazole, as in formic acid, involves overcoming a substantially higher activation barrier (Scheme 22).

Scheme 22



52a **52b** **53a** **53b** **54a** **54b**

According to experimental data[220–222] the rate of the proton transfer reaction in the series of compounds **52**–**54** decreases at first (on going from the dimer **52** to the trimer **53**), and then increases again in the tetramer **54**. This can be ascribed to the replacement of the concerted proton transfer in **52** by a multistage process in **54**.

The low activation barriers to the intermolecular double and triple proton transfer processes in these systems are due to two factors: the almost ideal stereochemical conditions found by the proton transfer[224–226] and the catalytic (acid–base) action of the second hydrogen bond, which greatly assists the reaction.[64]

Scheme 23

58a, C_1 ($\lambda = 0$) **55**, C_{2v} ($\lambda = 0$) **56**, C_s ($\lambda = 1$) **57**, C_s ($\lambda = 1$) **58b**, C_1 ($\lambda = 0$)

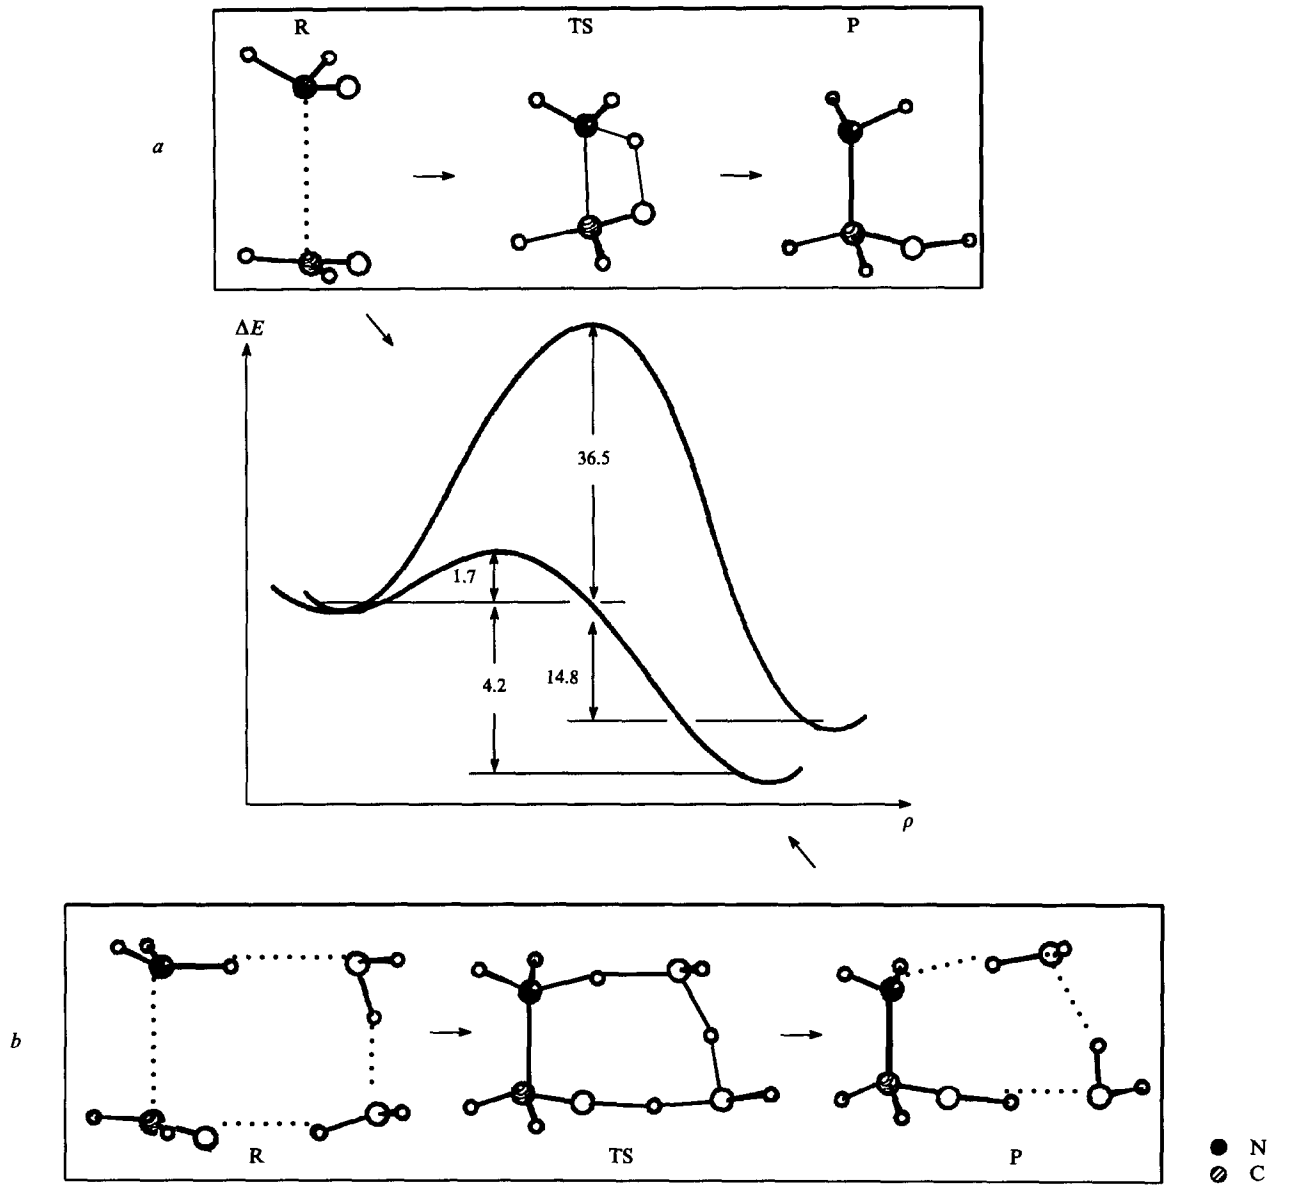


Figure 16. Mechanism of the addition of an ammonia molecule to formaldehyde according to ab initio calculations.[26] (*a*) Not allowing for solvation; (*b*) allowing for solvation by two water molecules. The relative energies are given in kcal mol^{-1}; ρ is the reaction coordinate.

Small differences in the distance between the hydrogen-bonded monomers lead to marked changes in the mechanism of the transfer process. Thus, the transition from the dimer of formic acid [163] to the dimers of formamide and of formamidine converts the proton transfer mechanism from single-stage (synchronous) to multistage (non-synchronous) as a result of the increased length of the H bond.

Our third example is the nucleophilic addition reaction of an ammonia molecule to formaldehyde with formation of aminomethanol and solvation by two water molecules (Scheme 23),[26,227] which is a model of the formation of peptide bonds in proteins.[228] The reaction begins with the formation of the complex **55**, in which the nitrogen atom of the ammonia molecule is oriented towards the carbonyl group. The reaction proceeds by the synchronous motion of all the atoms in the system through the multicentre transition state **56**. The energy profile of the reaction and its geometric evolution are shown in Fig. 16, together with data for the system which allow for the solvation by two water molecules. A comparison of the solvated and the nonsolvated system leads to the following conclusions.

First, in the nonsolvated system the reaction takes place along two gradient lines. Initially, from the pre-reaction complex **55** through the transition state **56** to the following transition state **57**, the system slides along a single gradient line. At the point corresponding to the structure **57** the system passes from the first line to the second, corresponding to the internal rotation of the O–H bond round the C–O single bond. In this way the two enantiomeric forms **58a** and **58b** appear as products in the nonsolvated system. Solvation with two water molecules lowers the initial symmetry C_s of the system to C_1, and the second (enantiomeric) reaction channel disappears.

Second, as the nitrogen atom approaches the carbon atom of the carbonyl group three protons are collectively transferred over the three hydrogen bridges in the system.

Third, in the pre-reaction solvated complex all the constituent single molecules are oriented in such a way that the stereochemical conditions most favourable to four simultaneous reactions [224–226,229–232] are satisfied: the nucleophilic addition to the carbonyl group [229–232] and three proton transfers over the hydrogen bridges.[224–226]

VII. Biological systems

The examples of various chemical reactions examined above have revealed some extremely branched (multichannel) mechanisms. Conversely, chemical reactions in living organisms follow strictly single paths.[228,233-236] This is because all living organisms (including the living cell) are essentially molecular machines,[233,235,236] and (accordingly) they function as machines, in a strictly determined rather than a random way. In this case the 'global' thermodynamics of biochemical processes (in particular the path of the reaction and its energy profile along this path) should be 'machine like'.[235,236]

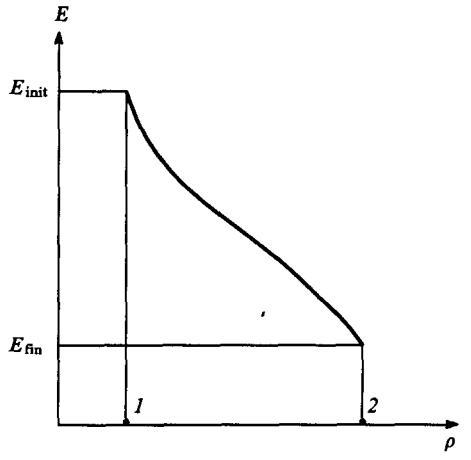

Figure 17. Energy profile of a living organism as a macroscopic body as a function of the internal reaction coordinate ρ. (*1*) and (*2*) are the initial and the final point of the motion along the reaction coordinate respectively. The reaction coordinate ρ is the length along the reaction path constructed in the coordinate system of the centre of mass.

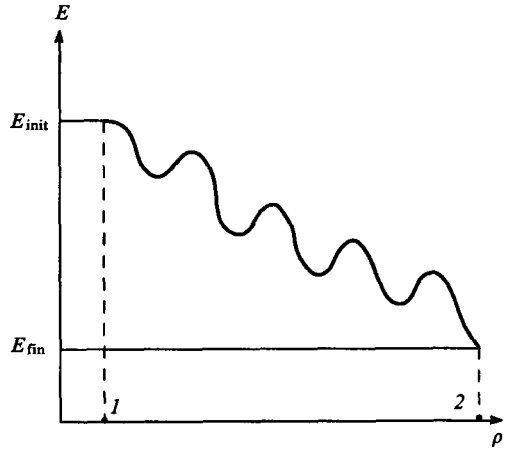

Figure 18. Energy profile of the system of a living organism as the combination of all the biochemical reactions along the reaction coordinate ρ. The points *1* and *2* correspond to those defined in Fig. 17.

The global energy profile of a living system is determined by examining its motion over a small enough time interval, during which the system can be treated as closed.[237] The motion of a system such as a macroscopic body as a whole is determined by the law of energy conservation (the first law of thermodynamics) irrespectively of the internal structure or of the nature of the internal interactions taking place in it.[237] The motion of the body over a small time interval satisfies the inequality

$$E_{init} > E_{fin},$$

where E_{init} and E_{fin} are the total energies of the system at the initial and the final moments. Therefore the dependence of the total internal energy of the system on the internal reaction coordinate (corresponding to a small time interval) is shown as a falling curve (Fig. 17). At the same time, any biological system is a plurality of chemical reactions strictly correlated in time and space. We know that the energy profile of the elementary step of any chemical reaction is defined by the Arrhenius curve.[59,83,238] A very large number of these elementary steps can occur in living cells. If they are mutually indepen-dent[228,238] the overall profile of the biological system consists of the independent profiles of the separate elementary chemical reactions, and it can be represented by the curve shown in Fig. 18. In this respect the profile of biological systems (interpreted as the combined profiles of many chemical reactions) does not coincide with the energy profile of Fig. 17. Thus we meet a difference in principle between the very complex energy profile of processes in biological systems and the energy profile of the macroscopic body (including biological bodies). In order to reconcile the profiles of biosystems (as macroscopic objects and as biochemical systems consisting of chemical reactions following microscopically separate paths) we must assume that the profile shown in Fig. 17 consists of a large number of separate parts corresponding to separate chemical reactions in the biosystem. This is possible if the final point of the previous reaction occurs after the activated barrier of the subsequent reaction, i.e. if the energy profile can be represented by the curve shown in Fig. 19. Only this reconciliation of the profiles of the elementary chemical reactions in the biological system can allow the development of functional systems such as molecular machines. Of course, this description is strictly schematic and oversimplified, and it cannot be offered as the final picture, but the arguments used above make clear the essential difference between chemical reactions and their biochemical analogues in the living organism. This difference suggests one possible direction for further studies of collective reactions.

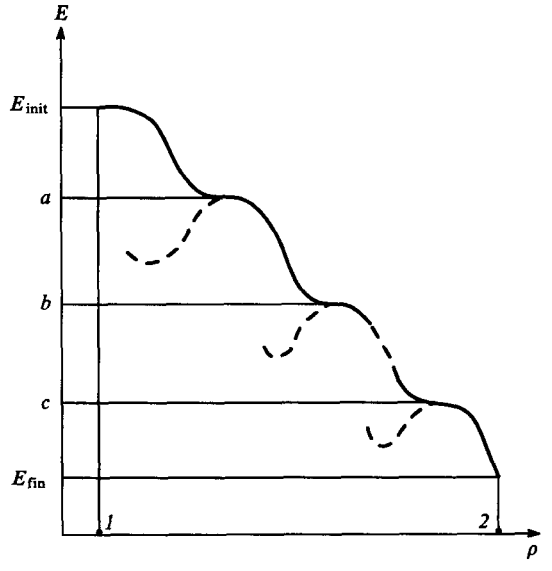

Figure 19. Full energy profile (thick line) of the system of a living organism as the combination of separate biochemical reactions (broken line) strictly correlated in space and time. Each reaction terminates at a point lying beyond the transition state of the 'next' reaction. E_{init} denotes the 'first' reaction (corresponding to the point *1* on the reaction coordinate ρ), which terminates at the point *a*. The second reaction begins at this point, and terminates at the point *b*. The point *c* denotes the initial point of the 'next' reaction, which terminates at the point *2*.

VIII. Conclusion

The stereochemical paths (mechanisms) of the elementary steps of the main types of chemical reaction, of which relatively few have so far been identified,[64, 185, 186, 232] have been studied in depth both experimentally and theoretically. Many workers[4, 13, 14, 22, 64, 185, 196, 202, 230] have successfully determined the stereochemical trajectories of their reaction paths, and the electronic nature of the driving force is now understood for most reactions. However, in practice chemical reactions are usually collective processes in a multicomponent system with a simultaneous or strictly correlated (relay mechanism) sequence of motions over the whole system. Biological reactions involving enzymes are a special case of these reactions. Therefore, in order to understand the nature of enzyme reactions we must progress from the study of the PES of simple systems to the study of the PES of chemical systems which model the course of several reactions at the same time. This calls, in turn, for the development of new methods of analysis of the topological structure of multidimensional PES, for the further development of nonempirical and semiempirical quantum-chemical methods of calculation, and lastly for an increase in the power and speed of response of the computers used in these studies.

Abstract. The mechanisms of the nonradiative transitions in lanthanide ions in solutions are discussed. The results of the use of this phenomenon in the study of the structures and stability constants of complexes of lanthanide ions in solutions are described. The possible uses of the nonradiative energy transfer between lanthanide ions in the determination of the stability constants of their complexes and for the detection of unstable dinuclear bridged complexes are considered. The luminescence-spectroscopic methods for the determination of the rates of rapid ligand exchange in lanthanide complexes in solutions are discussed. The bibliography includes 62 references.

I. Introduction

The luminescence-kinetic methods for the study of lanthanide complexes in solution have been increasingly widely used by investigators in recent years. This is due both to the ready accessibility of luminescence-kinetic apparatus to investigators (pulse type fluorimeters, pulse type tunable laser sources) and to the employment of Ln^{3+} as luminescence labels in biology and medicine.[1] The progress in the understanding of the mechanism of the quenching of the luminescence of Ln^{3+} ions has also played an important role.

This review deals with the following questions: the methods for the determination of the composition of the environment of the luminescent Ln^{3+} ion based on the measurement of its luminescence decay time; a version of the method involving the use of the phenomenon of the nonradiative energy transfer between ions; the study by the same method of unstable dinuclear bridged complexes; the luminescence-spectroscopic kinetic methods for the determination of the rates of rapid ligand exchange in lanthanide complexes.

The chemical properties of Ln^{3+} ions are known to be similar although not identical. On the other hand, their luminescence-spectroscopic properties differ greatly. This enables experimenters to select experimentally suitable ions and to carry out investigations involving them in a manner depending on the problem formulated. The greatest number of luminescence studies have been performed on Tb^{3+} and Eu^{3+} ions.[1,2] On the one hand, these ions have an appreciable luminescence quantum yield in most of the solvents used. On the other hand, the long-wavelength bands in the absorption spectra of these ions are located in the region where effective tunable dye-based lasers emit radiation, which is convenient for the experimenter. Yet another positive feature of the employment of these ions is the marked influence of the deuteriation of the surrounding molecules on the quantum yields and decay times of their luminescence, which makes it possible in many instances to obtain important information about the structure of the environment of the Ln^{3+} ion.

II. The rate constants for nonradiative transitions in lanthanide ions as an indicator of the structure of their environment

1. Modern ideas about the mechanism of nonradiative transitions in lanthanide ions in solutions

Ln^{3+} ions luminesce not only in crystals and glasses but also in aqueous solutions.[3] However, only Gd^{3+}, Tb^{3+}, and Eu^{3+} luminesce with an appreciable yield in water. The luminescence yields of the remaining lanthanide ions in water are low. The luminescence yields of Ln^{3+} ions in various media obey the general rule governing nonradiative transitions. The probability of the latter is lower the greater the electronic energy of the quantum converted into the energy of the vibrational or translational motion and the lower the maximum energy of the vibrational quanta in the molecular groups surrounding the ion.[4]

The most important step towards the understanding of the mechanism of the nonradiative transitions in Ln^{3+} ions was taken by Krop and Windsor.[5] They observed an appreciable increase (by a factor of several tens) in the decay time (τ) in the quantum yield (q) of the luminescence of Eu^{3+} ions from the $^5D_0$ level and of the Tb^{3+} ions from the $^5D_4$ level on passing from an aqueous to a deuteriated solution. This effect was explained by the smaller number of high-frequency quanta of the stretching vibrations of the H_2O molecules ($\nu_3^H \approx 3400$ cm^{-1}) compared with D_2O ($\nu_3^D \approx 2250$ cm^{-1}) required for the law of conservation of energy to hold in the nonradiative transitions. It was also established that the rate constant for the nonradiative transition (k_{nr}) in the Eu^{3+} and Tb^{3+} ions varies linearly with the mole fraction of H_2O in the H_2O-D_2O mixture as the solvent. The linear dependence of k_{nr} for the ions on the fraction of OH groups in the mixture was confirmed by Gallagher[6] and Heller[7] and by the latter also for Dy^{3+} and Sm^{3+}. These facts indicate that the

Table 1. The luminescence decay times for lanthanide ions in ordinary and deuteriated water and in hydrated crystals.

Ion (emitting level)	Base	T/K	τ/μs	Ref.
Tb^{3+}	H_2O	293	475	11
($^5D_4$)	D_2O	293	4000	11
	$TbCl_3 \cdot 6H_2O$	298	485	8
	$TbCl_3 \cdot 6D_2O$	298	2390	8
	$Y(C_2H_5SO_4)_3 \cdot 9H_2O$ (10% Tb^{3+})	300	429	9
	$YCl_3 \cdot 6H_2O$ (10% Tb^{3+})	300	482	9
Eu^{3+}	H_2O	293	125	11
($^5D_0$)	D_2O	293	4000	11
	$EuCl_3 \cdot 6H_2O$	298	130	8
	$EuCl_3 \cdot 6D_2O$	298	1650	8
	$Eu(C_2H_5SO_4) \cdot 9H_2O$	300	116	9
	$Eu(C_2H_5SO_4) \cdot 9D_2O$	300	750	9
Dy^{3+}	H_2O	293	3	10
($^4F_{9/2}$)	D_2O	293	60	10
	$GdCl_3 \cdot 6H_2O$ (1% Dy^{3+})	293	4	10
	$GdCl_3 \cdot 6D_2O$	293	67	10

quenching effects of each O–H oscillator around the Ln^{3+} ion are independent of one another. These results permit a choice to be made betwen two models of the exchange of the electronic excitation energy quantum; exchange with excitation of an individual high vibrational state of the molecular group surrounding the lanthanide ion; exchange for a set of vibrations of several molecular groups.

A similar effect of deuteriation in hydrated crystals of lanthanide ion salts has been observed by other workers.[8–10] Their data are presented in Table 1, which shows that τ for the Ln^{3+} ions in the hydrated crystals is close to τ for aqueous solutions and that the change in τ on passing from protonated to deuteriated crystals is similar to its change on deuteriation of aqueous solutions. These findings agree well with the fact that the inner (first) sphere surrounding the Ln^{3+} ion consists of water molecules both in water and in crystals.

2. The inductive-resonance theory of nonradiative transitions in lanthanide ions

Ideas concerning the nonradiative transitions in lanthanide ions have been developed[11] on the basis of inductive resonance energy transfer from the excited Ln^{3+} ion to the surrounding molecular groups, with their excitation to higher vibrational states. Questions concerning the energy transfer from the Ln^{3+} ion to water molecules have been discussed in the studies mentioned above,[5,9] but the mechanism of the interaction, initiating the energy transfer step and permitting semiempirical calculations of the constant k_{nr}, was not specified in them. In other investigations,[11–13] it was postulated that the nonradiative transitions are caused by electromagnetic interactions between the oscillator corresponding to the radiative downward electronic or vibronic transition from the deactivating level and the oscillator of the vibrational transition in the groups surrounding the ion and involved in energy resonance with the electronic (vibronic) oscillator.[11–13] The energy level scheme explaining this model is presented in Fig. 1.

Thus the model mentioned above is close to the energy transfer model in Förster's theory[14] with the difference that the energy acceptor is a purely vibrational oscillator. As in Förster's model, it is postulated that the energy transfer step is followed by the rapid (compared with the rate of transfer) deactivation of the vibrational oscillator excited in the transfer process. This hypothesis has been

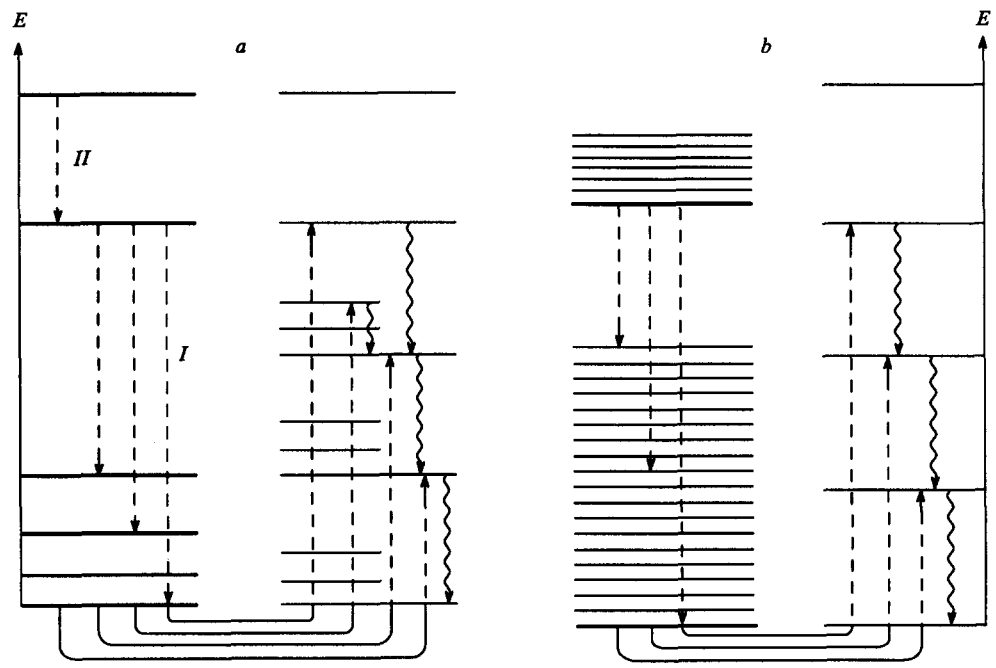

Figure 1. The energy level scheme explaining the inductive-resonance theory of nonradiative transitions: (*a*) weak vibronic linkage (Ln^{3+} ions) [(*I*) multiphonon nonradiative transition; (*II*) single-phonon nonradiative transition]; (*b*) strong (moderately strong) vibronic linkage (transition metal ions). The electronic (bold lines) and vibronic (thin lines) levels of the ions are shown on the left-hand sides of Figs *a* and *b*; the promoting-accepting vibrational levels of the molecules surrounding the ions are shown on the right; the vertical dashed lines designate the energy transfer inducing the nonradiative transition between the electronic levels of the ions and the excitation of the vibrational levels of the surrounding molecules.

confirmed experimentally in studies undertaken to estimate the rates of vibrational relaxation in solutions.[15] A further approximation, permitting specific calculations of the rate constants for nonradiative transitions, involves the selection of a multipolar interaction. In most cases, the treatment may be restricted to the approximation involving the interaction of electrical dipoles, as has been done in the derivation of Förster's familiar formula for the nonradiative electronic energy transfer between organic molecules.[14] Experimental confirmation of the possibility of using this approximation will be given below.

In the dipole–dipole approximation, the rate constant for the nonradiative transitions in the Ln^{3+} ions from the given excited level may be calculated provided the following features are known: the true luminescence spectrum (purely electronic or vibronic) associated with the transition from the given level to all the lower electronic levels of the given ion and the overall rate constant for emission from this level; the quantitative vibrational absorption spectra of the molecular groups, ligands, and solvent molecules surrounding the ion in the region of overlap with the luminescence spectrum of the ion; the distances from the ion to each molecular group responsible for the given vibrational absorption.

The expression for k_{nr} assumes the following form in this case:

$$k_{nr} = \sum \frac{8.8 \times 10^{-25} k_e \varkappa^2}{n^4 R_i^6} \int_0^\infty I^n(\nu)\, \varepsilon_i^{vibr}(\nu)\, \nu^{-4}\, d\nu , \qquad (1)$$

where k_e is the rate constant for the electrical dipole radiative transition from the given level to all the lower levels (s^{-1}), $\varkappa^2$ a coefficient which depends on the mutual orientation of the interacting dipoles (the average quantity $\overline{\varkappa^2} = 2/3$ is normally employed), n the refractive index of the medium, R_i the distance from the Ln^{3+} ion to the corresponding molecular groups (cm), $I^n(\nu)$ the luminescence spectrum, normalised for a unit area, emitted from the same level and expressed in terms of quantum intensities on the wave number ν scale (cm^{-1}), and $\varepsilon_i^{vibr}(\nu)$ the molar decadic vibrational absorption coefficient in the main and overtone regions for the molecular groups responsible for the absorption bands overlapping with the luminescence spectrum.

Naturally it is almost impossible to take into account all the molecular groups surrounding the Ln^{3+} ion in solution and even their position relative to the ion is usually not known exactly. However, one should bear in mind that the strongest interactions inducing the nonradiative transition involve groups adjoining directly the Ln^{3+} ions, i.e. located in the inner coordination sphere. Such molecular groups usually make the greatest contribution to k_{nr}. Only in the absence from the inner coordination layer of vibrating molecular groups capable of initiating the nonradiative transition, for example owing to the smallness of the vibrational quantum, is it necessary to take into account the influence of the second and more remote layers of molecular groups surrounding the ion as the main contribution to k_{nr}.

In many cases, it is useful to take into account only the first (inner) ordered sphere comprising molecules surrounding the ion [Eqn (1)], while the more remote molecules can be regarded as a continuous medium. The influence of remote molecules is taken into account by using the formula derived by Galanin and Frank[16] for the decay of a dipole in the absorping medium

$$k'_{nr} = \frac{k_e}{16\pi^4 n^4 a^3} \int_0^\infty I^n(\nu)\, \alpha(\nu)\, \nu^{-4}\, d\nu , \qquad (2)$$

where a is the radius of the sphere around the ion in which there are no oscillators absorbing the emission from the Ln^{3+} ion and $\alpha(\nu)$ is the linear absorption coefficient of the solvent (cm^{-1}). When account is taken of the effect of the molecules (groups) in the inner sphere of the ion in accordance with Eqn (1), a is the size of the inner sphere and the contribution of the remaining molecules outside the inner sphere is calculated by Eqn (2) in terms of the continuous medium approximation.

Calculations by Eqns (1) and (2) make it possible to take into account the influence on the nonradiative transitions by a factor such as the vibronic interaction in terms of the vibronic component of the luminescence spectrum. The vibronic spectra of Ln^{3+} ions usually have a low intensity and in most cases hardly affect k_{nr}. They can improve the resonance conditions if the narrow absorption bands of C–H group type do not overlap with the narrow band due to the electronic transition in the Ln^{3+} ion. However, in the calculation of k_{nr} for transition metal ions, characterised by extensive vibronic spectra, the overlap of the vibrational absorption spectra with the latter is in most cases decisive. As shown in a theoretical study,[17] it is then important to divide the vibrations into two types: vibrations contributing to the vibronic luminescence spectrum (accepting vibrations) and vibrations the absorption spectrum of which in the region of the main frequencies or overtones overlaps with the luminescence spectrum (promoting-accepting vibrations), since they initiate the nonradiative transition and accept part of the energy. Another component of the exchanging electronic energy quantum is accepted by the vibrations active in the vibronic spectrum. The vibronic levels illustrating this approach are presented schematically in Fig. 1.

Within the framework of this approach, the anharmonicity of the vibrations is taken into account: automatically, since for a multiphoton nonradiative transition the luminescence spectrum $I^n(\nu)$, included in Eqns (1) and (2), largely overlaps with the vibrational spectrum in the region of the overtones and compound frequencies, the latter spectrum being determined by the anharmonicity of the promoting-accepting vibrations of the molecular groups surrounding the ion.

We shall now consider how the inductive-resonance theory of nonradiative transitions agrees with the experimental decay times and luminescence quantum yields for Ln^{3+} ions in solutions and other media obtained by the present authors and available in the literature. The decay time of the luminescence of Ln^{3+} ions with an energy gap $20\,000 \geqslant \Delta E \geqslant 4000-5000$ cm^{-1} depends greatly on the replacement of protium atoms by deuterium atoms in the molecular groups located in the vicinity of the ion. The effect of deuteriation is undoubtedly associated with the change in the rate of the nonradiative transitions because the luminescence yield varies in parallel with τ and there are no physical grounds for such a sharp increase in the emission rate constant on deuteriation. From the standpoint of the inductive-resonance theory of nonradiative transitions, the influence of deuteriation is determined by the sharp change in the vibrational absorption owing to the decrease in the stretching vibration frequencies when H is replaced by D. Fig. 2 (see next page) presents the luminescence spectrum of Dy^{3+} in D_2O and the vibrational absorption spectra of H_2O and D_2O and of H_2O in a $GdCl_3.6H_2O$ crystal. Comparison of the luminescence (Fig. 2a) and absorption (Figs 2*b* and 2*c*) spectra of H_2O and D_2O shows that in the case of D_2O the overlap integral in Eqns (1) and (2) is many times smaller than in the case of H_2O.

Comparison of the overlap integrals of the spectra in Eqns (1) and (2) for the usual and deuteriated compounds makes it possible to calculate, provided that the luminescence and vibrational absorption spectra are known, the influence of deuteriation on the nonradiative transition rate constant for the given ion and its environment. Table 2 shows that, for the majority of Ln^{3+} ions, the effect of the deuteriation of the molecules surrounding the ion can be calculated by Eqns (1) and (2) with satisfactory accuracy. Table 2 also presents the experimental luminescence decay times

$$\tau = (k_e + k_{nr})^{-1} ,$$

where k_e is the rate constant for the emission from the given level of the ion and k_{nr} is the rate constant for the nonradiative transition from the same level. Since k_e does not change on deuteriation of the molecules surrounding the ion and only k_{nr} is altered, the dependence of τ on deuteriation for different energy gaps is as follows: for large gaps, $\Delta E \approx 30\,000$ cm^{-1} (for example, for

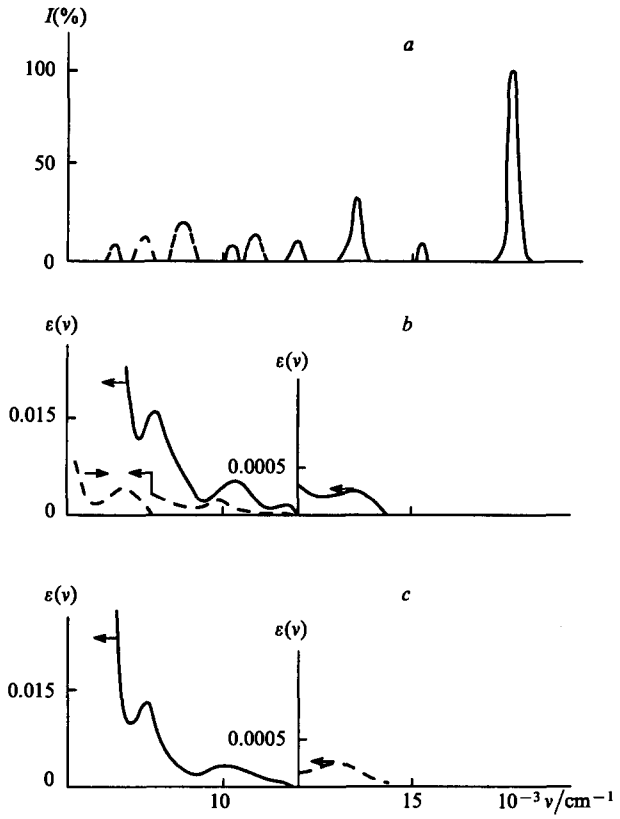

Figure 2. Luminescence spectra of the Dy^{3+} ion in D_2O (*a*) (the luminescence bands, the scale of which has been increased by a factor of 10, are shown by a dashed line), the absorption spectra of H_2O (continuous line) and D_2O (dashed line) in solution (*b*), and the spectra of H_2O in the $GdCl_3.6H_2O$ crystal (*c*) at 293 K.

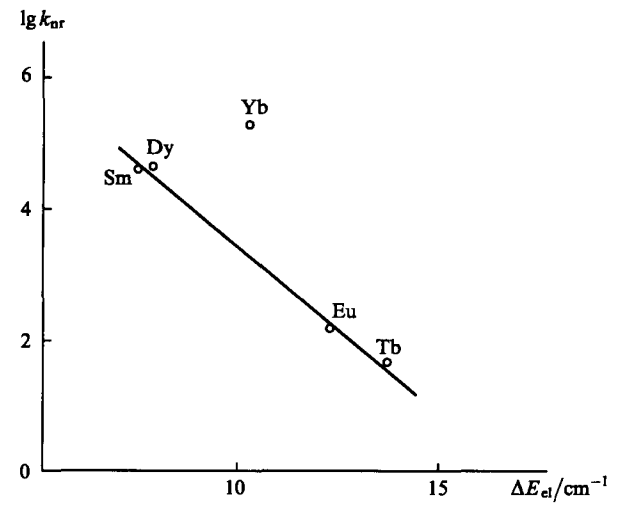

Figure 3. Dependence of the rate constant for the nonradiative transitions from the resonance levels of the Ln^{3+} ions in methanol-d_1 (293 K) on the difference between the energies of the emitting level and the lower level closest to it.

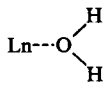
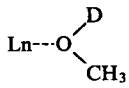
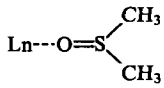
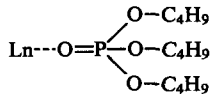
Gd^{3+}), the constant k_{nr} varies by many orders of magnitude, but τ is almost independent of deuteriation because in this region $k_e \geqslant k_{nr}$, so that $\tau \approx k_e^{-1}$. For gaps of medium size, $\Delta E = 20\,000-4000$ cm^{-1}, the constant k_{nr} depends less on deuteriation, but in this region $k_{nr} \geqslant k_e$ and τ increases markedly on deuteriation of the molecules surrounding the ion [$Eu^{3+}(^5D_0)$, $Yb^{3+}(^2F_{5/2})$, $Dy^{3+}(^4F_{9/2})$, $Nd^{3+}(^4F_{3/2})$]. In the region $\Delta E \leqslant 4000$ cm^{-1}, where $k_{nr} \gg k_e$ (for surrounding groups with H and D atoms), the dependence of k_{nr} and τ on such groups is determined by the overlap of the structural luminescence spectrum of the Ln^{3+} ion with the vibrational absorption spectrum, and may vary from a very large value for Er^{3+} ($^4I_{11/2}$) in water to low values for $Er^{3+}(^4I_{11/2})$ and $Pr^{3+}(^3P_0)$ in dimethyl sulfoxide, and even to an absence of the influence of deuteriation in $Eu^{3+}(^5D_1)$.

In this region, there is also the possibility of the opposite effect of deuteriation — a decrease in τ in deuterium-containing molecules.









For Ln^{3+} ions surrounded by particular groups in the case where the nonradiative transition is of the multiphonon type, i.e. $\Delta E_{el} \geqslant 2h\nu_{vibr}^{max}$, a nearly inverse exponential dependence of k_{nr} on the energy gap ΔE_{el} between the emitting level and the nearest lower level is observed. Such an exponential dependence of k_{nr} on ΔE_{el} can be explained by the fact that the intensity of the overtones of the vibrational transitions diminishes approximately in a geometrical progression with increase in the number of the overtone.[18]

From the standpoint of the inductive-resonance theory of nonradiative transitions, the inverse exponential dependence of k_{nr} on ΔE for multiphonon transitions is a special case of a more general relation — the proportionality of k_{nr} to the overlap integral between the luminescence spectrum of Ln^{3+} ions and the vibrational absorption spectrum of the molecules surrounding the ion for an approximately constant k_e and a constant distribution of the quantum intensity in the luminescence spectrum. Fig. 3 illustrates such a relation. The appreciable deviation of the k_{nr} for ytterbium is due to the fact that an intense luminescence is observed for this ion in the region of the long wavelength band, whereas for the remaining ions (Sm^{3+}, Dy^{3+}, Eu^{3+}, and Tb^{3+}) the long wavelength bands constitute a small proportion of the overall luminescence intensity (see, for example, Fig. 2).

Table 2. The experimental constants k_{nr} (I) and their values calculated by Eqns (1) and (2) (II) for lanthanide ions in ordinary and deuteriated solvents.

Ln^{3+}	Transition	ΔE^{min}/cm^{-1}	Solvent	k_{nr}^H/k_{nr}^D		τ^D/τ^H

 (5.0; 5.3)[a]	2.5	3.7	10.5	5.5	6.9	1.7
 (6.0; 6.3)[a]	1.5	3.8	15	4.5	9.7	3.5

[a] Here and henceforth the larger distance refers to Dy^{3+} and the smaller distance to Yb^{3+}.
[b] Aqueous solutions have not been included in the comparison column because the vibration frequency of the OH group differs appreciably from that of the CH group.
[c] Relative units.

According to the inductive-resonance theory of nonradiative transitions, for the interaction of the electrical dipoles in the Ln^{3+} ion and the ligands surrounding it [electrical dipoles comprising the Ln^{3+} ion and the ligand surrounding it?], the contribution to k_{nr} is inversely proportional to the sixth power of the distance between them. The electromagnetic interactions inducing the nonradiative transitions are universal and should be independent of the presence or absence of chemical bonds between them and the molecular group involved in the exchange.

Having postulated the occurrence of the dipole–dipole interaction, we compared the experimental and theoretical dependences of k_{nr} on the distances between the Ln^{3+} ion and the OH and CH groups most active in the exchange process. Eqn (2) was used for this purpose; the absorbing medium was assumed to be continuous and the dependence on the distance was expressed in terms of a sphere with a radius a. It was assumed that in the sphere there are no molecular groups with high frequency vibrations inducing the exchange of the electronic energy of the ion. Table 3 presents the values of k_{nr} for Dy^{3+} and Yb^{3+} in various solvents for increasing distances between the CH groups and the ion and the products $k_{nr}a^3$, which should remain constant if the electrical dipoles interact and hence Eqn (2) is valid. The products $k_{nr}a^5$, which would have remained constant if the interaction responsible for the nonradiative transition had been determined by the interaction between an electrical quadrupole and a dipole, i.e. if the formula for k_{nr} assumed the form

$$k_{nr}^q = \frac{9k_e}{32\pi^6 n^6 a^5} \int I^n(\nu)\,\alpha(\nu)\,\nu^{-6}\,d\nu,$$

are also presented.

The long-range and nonchemical nature of the interactions responsible for the nonradiative transitions in Ln^{3+} ions is confirmed by the influence on $\tau(k_{nr})$ by the solvent ion in the outer sphere of a bulky complex such as $Ln(NO_3)_3(TBP\text{-}d_{27})_3$ (here TBP-d_{27} is fully deuteriated tri-n-butyl phosphate).

Table 4 presents the values of τ and k_{nr} for lanthanide ion complexes with nitrate anions and the usual and fully deuteriated tri-n-butyl phosphate dissolved in CCl_4 and toluene-h_8. Toluene-h_8 is at a distance greater than 6 Å from the Nd^{3+} and Sm^{3+} ions and is not linked to them by any chemical bonds. However, it does affect appreciably τ and hence k_{nr} for the given ions.

The results of the study of the luminescence of the Dy^{3+} ion in the usual and fully deuteriated acetonitrile may be regarded as yet another confirmation of the inductive-resonance theory of nonradiative transitions. The point is that the frequency of the stretching vibration of the C≡N, group adjoining directly the Dy^{3+} ion (2254 cm^{-1}) is close to the stretching vibration frequency of the C–D bond (2257 cm^{-1}). It may be expected that τ for the Dy^{3+} ion in fully deuteriated acetonitrile is appreciably smaller than in the fully deuteriated dimethyl sulfoxide and acetone because the stretching vibration frequencies of the S=O and C=O groups are appreciably lower. However, measurements have shown that τ = 320 μs for Dy^{3+} in CD_3CN.[20] The value τ = 13.3 μs for Dy^{3+} in CD_3CN quoted by Haas et al.[19] is undoubtedly erroneous owing to the presence of the water impurity in this solution, the amount of which was not

determined. The value of τ which we measured is greater by a factor of ~ 1.5 than τ for the Dy^{3+} ion in dimethyl sulfoxide-d_6 (235 μs) and acetone-d_6 (235 μs) and is twice as great as τ in fully deuteriated methanol (150 μs). This finding has been explained in a study[20] where it was shown, by comparing the IR spectra of the usual and deuteriated acetonitrile, that the anharmonicity of the vibrations and the intensity of its overtones are small for the C≡N bond, which has an intense absorption band at 2254 cm^{-1}. On the other hand, the C–D vibrations, for which the intensity in the region of the main frequency is smaller compared with the C≡N vibration, become the principal vibrations, determining the absorption spectrum, in the region of overtones owing to the greater anharmonicity. Consequently, they make the greatest contribution to the overlap integral with the Dy^{3+} luminescence spectrum and hence they make the main contribution to k_{nr} for the Dy^{3+} ion despite the greater distance from the latter. This is fully consistent with experimental data.

In conclusion, it is essential to discuss the errors in the calculations of k_{nr} in accordance with the inductive-resonance theory. Firstly, owing to the rapid liquid exchange with the surrounding groups, an average pattern is observed in the liquid solutions and $\bar{\tau}$ may be made up of the times τ for the rapidly varying different conformations of the environment of the ion. So long as the exchange time is shorter than τ, the decay is exponential. If the ligand exchange time becomes greater than or equal to τ, the decay of the luminescence is nonexponential because each form of the complex decays with its own τ. The ligand exchange time for Ln^{3+} ions in water is of the order of 10^{-7} s.[21] Thus, if different complexes coexist in solution, a nonexponential decay of the luminescence will be observed for times shorter than 100 ns.

The next source of error in the calculations of k_{nr} is the inaccurate knowledge of the mutual disposition of the ligands and the ion, especially in liquid solutions. Yet another source of error consists in the fact that in most cases the spectrum of the pure solvent and not of the molecules directly coordinated to the Ln^{3+} ion is adopted as the vibrational absorption spectrum. The spectra of the directly coordinated molecules, especially of the OH groups of water or alcohols where the oxygen atom is linked directly to the Ln^{3+} ion, differ in the frequencies and anharmonicity of the vibrations, which undoubtedly introduces a definite error into the calculation of k_{nr}. In a number of instances no account is taken of the mutual orientation of the dipole moment of the electronic transition of the ion and of the vibrational absorption in the surrounding groups because the average value $\varkappa^2 = 2/3$ is used in Eqn (1). The quantity k_e in Eqns (1) and (2) introduces an appreciable error into the calculations of k_{nr} especially when its experimental determination is difficult and it is necessary to employ the value calculated by the Judd–Offelt method. Nevertheless, comparison of the experimental and theoretical values of k_{nr} in water and hydrated crystals shows that, even for water, the variations in frequencies and anharmonicity do not play a decisive role in the calculations of k_{nr}.

Yet another doubt is associated with the size of the interacting dipoles and with the possibility of using an expansion in powers of the distance between the ion and the promoting-accepting groups. However, one should note that the size of the emitting dipole is less than 0.6 Å, i.e. is smaller than the size of the 4*f* shell of the Ln^{3+} ions; the size of the dynamic oscillator in the high frequency vibration is close to the amplitude of the displacement of a light atom, i.e. $b = (2\hbar/m\omega)^{1/2} \approx 0.1$ Å, while the distance between the interacting centres is greater than 2.4 Å.[22] Thus the conditions used in the derivation of Eqn (1) are satisfied.

Table 5 presents the luminescence decay times for the most frequently used Ln^{3+} ions in various solvents. The results of the interpretation of these data are presented in Table 6. They represent estimates of the contributions to k_{nr} by various molecular groups at different distances from the Ln^{3+} ion for six such ions. The estimates are naturally fairly approximate because in most cases we are dealing with the overall influence on k_{nr} of the inner and more remote spheres surrounding the ion. By replacing the molecules in the inner sphere, we as a rule alter simultaneously the absorption by the entire remaining mass of the solution and hence its contribution to k_{nr}. Furthermore, in order to estimate the contribution of an individual molecular group, it is necessary to know as exactly as possible the number of molecular groups in the inner coordination sphere of the ion, which is not always available.

Table 6. Approximate estimates of the contributions of the molecular groups located at different distances from the Ln^{3+} ions to k_{nr}/s^{-1} according to different data.[1,2,11-13,21-29]

Ln^{3+}	Level	O–H 2.2–2.5 Å	N–H 2.2–2.5 Å	CH_3 3.6–3.9 Å	CH_3 5.0–5.3 Å	C_3H_7 6.0–6.3 Å	C–D 2.2–2.5 Å
Tb^{3+}	$^5D_4$	100–200	70	12	–	–	–
Eu^{3+}	$^5D_0$	400–500	800–1000	40	–	–	10
Dy^{3+}	$^4F_{9/2}$	20000	–	9000	1700	900	1000
Sm^{3+}	$^4G_{5/2}$	18000	–	9000	4300	750	700
Yb^{3+}	$^4F_{5/2}$	3.5×10^5	–	36000	6000	5000	1.3×10^4
Er^{3+}	$^4I_{11/2}$	$(3-5) \times 10^8$	–	–	3.3×10^6	–	5×10^6

This quantity is influenced also by the change in the emission rate constant when the groups surrounding the Ln^{3+} ions are altered. The estimates of the contributions to k_{nr} by the first and all the remaining spheres based on Eqn (2) in terms of the dipole–dipole approximation for water molecules yield ~7:1 if the distances to the first and second coordination spheres are assumed to be 2.36 and 4.50 Å respectively (according to X-ray diffraction data[22]).

3. Determination of the stability constants of lanthanide ion complexes in liquid solutions by the method of nonradiative transitions

In one of the first studies devoted to the influence of the deuteriation of the solvent on the intensity (I) and decay time of the luminescence of Ln^{3+} ions, Kropp and Windsor[5] turned their attention to the dependence of τ and I on the presence of the anions of various acids in water and on the pH of the medium. In another study,[27] they were the first to suggest that the number of molecular OH groups attached directly to the Ln^{3+} ions and exhibiting high frequency vibrations be estimated from the changes in τ and I on complex formation. Here use was made of the property involving the independent effect of each oscillator on the deactivation of the ion (linear dependence of k_{nr} on the concentration of OH groups in the solution).

Kropp and Windsor[27] measured the dependence of the decay times of the luminescence of the Eu^{3+} and Tb^{3+} ions dissolved in ordinary and deuteriated water on the $KOOCCH_3$ and $KOOCCD_3$ concentrations (0–5 M). For the same concentrations of acetate and lanthanide ions, it is possible to formulate the following expression for the difference between the reciprocals of the luminescence decay times in ordinary and deuteriated water:

$$(\tau^H)^{-1} - (\tau^D)^{-1} = m(k_{nr}^{H_2O} - k_{nr}^{D_2O}) + \{k_e^H([Ac^-]) - k_e^D([Ac^-])\},$$

where m is the number of water molecules in the inner sphere of the ion at the given acetate concentration and $k_{nr}^{H_2O}$ and $k_{nr}^{D_2O}$ are the rate constants for the nonradiative transitions in the Ln^{3+} ions induced by H_2O and D_2O molecules respectively. The second expression in brackets on the right-hand side of the equation is zero because the constants k_e for the Ln^{3+} ion are the same in H_2O and D_2O in the presence of identical acetate concentrations. The estimation of the contribution by one water molecule to the quenching constant yielded the following results (k_{nr}/s^{-1}):

$$k_{nr}^{H_2O} = 9400/m_s; \quad k_{nr}^{D_2O} = 370/m_s;$$

for Eu^{3+} and

$$k_{nr}^{H_2O} = 2200/m_s; \quad k_{nr}^{D_2O} = 275/m_s,$$

for Tb^{3+}, where m_s is the number of water molecules in the inner hydration shell of the ion when no other ligands are present in it. Kropp and Windsor suggested that $k_{nr}^{H_2O}$ and $k_{nr}^{D_2O}$ are independent of the acetate concentration. From our point of view, this is incorrect, since according to Eqn (1) $k_{nr}^{H_2O}$ and $k_{nr}^{D_2O}$ are proportional to k_e and the latter constants for Eu^{3+} and Tb^{3+} have been shown by Kropp and Windsor themselves to depend on the concentration of acetate ions.

Later Horrocks and coworkers[2,28,29] used this method to determine the number of water molecules involved in complexes of Ln^{3+} ions, in particular in complexes of interest to biologists. The number of coordinated water molecules was determined from the formula

$$m = \frac{(\tau^H)^{-1} - (\tau^D)^{-1}}{k_{nr}^{H_2O}(Ln)},$$

where $k_{nr}(Eu) = 952\ s^{-1}$ and $k_{nr}(Tb) = 238\ s^{-1}$. A linear dependence of $(\tau^H)^{-1} - (\tau^D)^{-1}$ on the number of water molecules in the first coordination spheres of various complexes, determined from X-ray diffraction data, was observed. However, in our view, in this case too it is necessary to introduce a correction for the change in k_e and for the intensity distribution in the Ln^{3+} luminescence spectra, especially for the longest-wavelength bands.

In view of the foregoing, we believe it is more correct to use the luminescence decay time as an indicator in the method of corresponding solutions (as has been done by Gruzdev and Ermolaev[30]) rather than employing it directly to estimate the number of water molecules or other ligands in the first coordination sphere (as suggested by Kropp and Windsor and also by Horrocks). It is known[21] that ligand exchange in solution is fairly rapid for the majority of Ln^{3+} ion complexes compared with the decay times of the luminescence of ions exhibiting appreciable yields. In this case, the decay of the luminescence is exponential and the rate constant for the decay of the excited state of the Ln^{3+} ion is defined by the following expression:

$$\bar{k} = \bar{\tau}^{-1} = \frac{\sum_{n=0}^{N} \tau_n^{-1} \beta_n^* [L]^n}{\sum_{n=0}^{N} \beta_n^* [L]^n}, \quad (3)$$

where τ_n is the decay time of the luminescence of the corresponding complex, β_n^* the overall stability constant of the complex with n ligands and with the ion in the excited state, and [L] the equilibrium concentration of the free ligand. The rate constant for the decay of the excited state of the ion is the sum of two components: the emission rate constant and the rate constant for the nonradiative transitions. Both constants depend on the composition of the complex, but in the majority of cases the change in k_{nrn} when the structure of the complex is altered is appreciably greater than the change in k_{en}. Taking into account the data in Tables 5 and 6 and knowing the structure of the substituting and substituted ligands, it is possible to estimate the change in k_{nrn} following substitution for different Ln^{3+} ions. If k_{nr} changes little after substitution of, for example, an acetone molecule by a dimethyl sulfoxide molecule at Ln^{3+}, the sensitivity of the method can be increased sharply by employing as one of the ligands the fully deuteriated molecule,

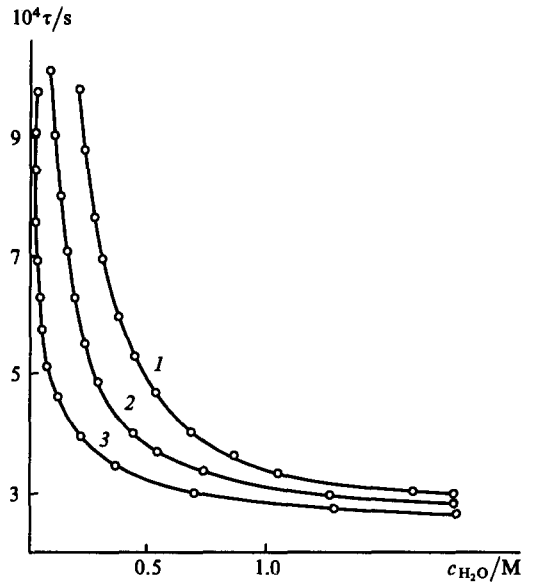

Figure 4. Dependence of the decay time of the luminescence of a europium nitrate solution in acetone on the overall concentration of water at 293 K; c_{Eu}/M: (*1*) 0.18; (*2*) 0.09; (*3*) 0.01.

i.e. $(CD_3)_2CO$ and $(CD_3)_2SO$ or conversely. One should then take into account the isotope exchange rate of hydrogen or deuterium.

As can be seen from Eqn. (3), the quantity $\bar{k}$ ($= \tau^{-1}$) is a function of the equilibrium free ligand concentration [L] only. Experiment showed that this function is unambiguous. In this case, it is possible to use the method of corresponding solutions for the determination of the stability constants.[31] The method has been used[30] to determine the stability constants of the Eu^{3+} complexes of water in acetone. Fig. 4 presents a series of curves reflecting the dependence of τ on the water concentration in dry acetone. Taking into account the material balance equation

$$c_L = \bar{n}c_{Eu} + \bar{n}^* c^*_{Eu^*} + [L], \qquad (4)$$

where c_L and [L] are the overall and equilibrium ligand concentrations respectively and $\bar{n}$ and $\bar{n}^*$ are the average numbers of ligands attached to the unexcited and excited ions, as well as the fact that in luminescence measurements the concentration of unexcited ions is always several orders of magnitude higher than that of excited ions, i.e. $c_{Eu} \gg c^*_{Eu^*}$, the second term on the right hand side of Eqn (4) may be neglected. The formation constant for the $Eu-H_2O$ system in acetone was determined with the aid of the curves presented in Fig. 4 and of Eqn (4). It is illustrated in Fig. 5. We emphasise that this expresses $\bar{n}$ as a function of [L] for unexcited Eu^{3+} ions, so that it may be compared with the results of traditional chemical methods.

Having a set of values $\bar{n}$ and [L], it is possible to calculate the stability constants of the complexes from the expression

$$\bar{n} = \frac{\sum n\beta_n[L]^n}{\sum \beta_n[L]^n}.$$

The calculation has been carried out by the least squares method (LSM) for three-ligand and four-ligand types of complexes. More accurate values were obtained for four-ligand types (i) of complexes.[30]

i	$\beta_i \times 10^{-(n+2)}/(\text{mol dm}^{-3})^i$	$K_i/(\text{mol dm}^{-3})^i$
1	1.27 ± 0.2	1.27 ± 0.2
2	5.6 ± 0.6	44.1 ± 8.6
3	4.4 ± 0.8	7.9 ± 1.6
4	5.9 ± 0.9	1.34 ± 0.4

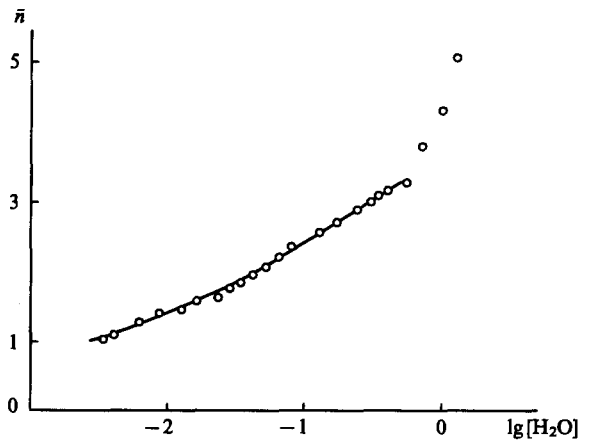

Figure 5. Dependence of the average number of water molecules in the first coordination sphere of the Eu^{3+} ion (europium nitrate solution in acetone) on the free ligand concentration [H_2O] at 293 K.

In the range $\bar{n} \geqslant 3$, the function $\bar{n} - \lg[H_2O]$ exhibits a sharp break (Fig. 5). It has been suggested that the displacement of the anion NO_3^- by water begins following an increase in the concentration of water in acetone and after the incorporation into the first coordination sphere of Eu^{3+} of more than three water molecules. The appearance in solution of free NO_3^- anions (a complex forming agent of the second type), which compete with Eu^{3+} for water molecules, is not taken into account in the method of corresponding solutions, so that the method yields unduly high values of $\bar{n}$ in this region.

This hypothesis that water displaces the NO_3^- anion for $\bar{n} \geqslant 2.5-3.0$ has been tested[30] by the energy transfer luminescence method. The dependence of the average rate of energy transfer from Eu^{3+} to Nd^{3+} in acetone on the average number of water molecules around Eu^{3+} is illustrated in Fig. 6. The concentration of Eu^{3+} (0.19 M) was 19 times greater than that of Nd^{3+} (0.01 M), which made it possible to use the values of $\bar{n}$ obtained above. For $\bar{n} = 2.5-3.0$, a sharp decrease in k'_t begins owing to the appearance of Coulombic repulsion between the complexes of the donor Eu^{3+} and the acceptor Nd^{3+} when their NO_3^- anions are substituted by water molecules. Therefore, only the values of $\bar{n} \leqslant 2.9$ were used in the calculation of the stability constants.

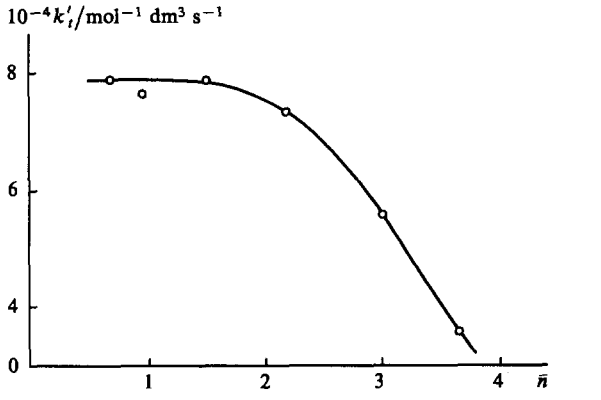

Figure 6. Dependence of the average rate constant for the energy transfer from europium to neodymium in acetone on the average number of water molecules in the first coordination sphere of Eu^{3+}. $c_{Eu} = 0.19$ M; $c_{Nd} = 0.01$ M.

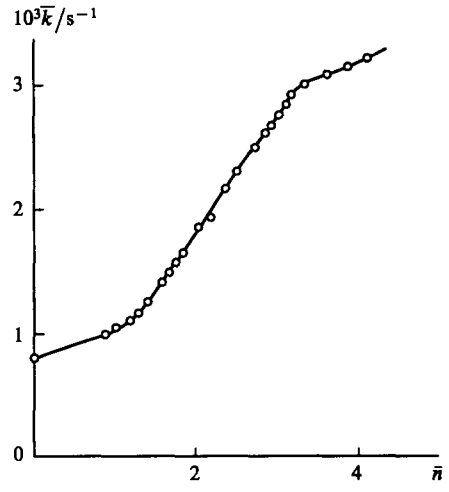

Figure 7. Dependence of the average rate constant for the deactivation of excited Eu^{3+} ions in acetone on the average number of water molecules in the first coordination sphere of the Eu^{3+} ion.

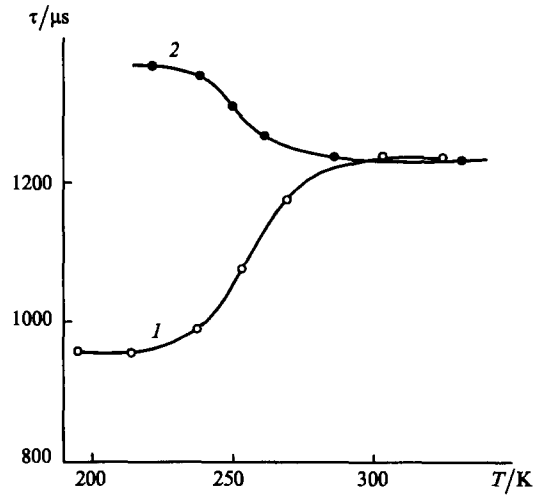

Figure 8. Temperature dependence of the decay time of the $Eu(NO_3)_3$ luminescence (c_{Eu} = 0.01 M) in partly dried acetone: (*1*) with added H_2O ($c_{H_2O} < c_{Eu}$); (*2*) with added D_2O ($c_{D_2O} < c_{Eu}$).

Fig. 7 presents the dependence of the average rate constant $\bar{k} = \bar{\tau}^{-1}$ for the deactivation of Eu^{3+} ions in acetone on the average number of water molecules $\bar{n}$ in the first coordination sphere of the ion. In the range of values of $\bar{n}$ from 1 to 3, the dependence of $\bar{k}$ on $\bar{n}$ is nearly linear. This shows that the emission constant k for complexes containing between one and three water molecules is invariant.

The luminescence-kinetic method also makes it possible to investigate the influence of the change in temperature on the structure of the environment of lanthanide ions in liquid solutions. It has been observed[32,33] that the decay times of the luminescence of Eu^{3+} and Tb^{3+} in weakly donating (according to Gutmann) solvents (acetonitrile, acetone, and ethyl acetate) increase with increase in temperature, in contrast to the usually observed temperature-induced quenching of the luminescence. On the other hand, in highly donating solvents (dimethyl sulfoxide, dimethylformamide, water), τ for the Eu^{3+} and Tb^{3+} ions is independent of temperature over a wide range of the latter.

It has been shown[32,33] that the increase in τ with temperature in weakly donating solvents is due to the removal of residual water molecules from the inner spheres of the ions and their replacement by solvent molecules which have lower deactivating capacities. Fig. 8 presents the curves describing the variation of τ for Eu^{3+} in partly dried acetone as a function of temperature. The activation energy for the splitting off of the last water molecule from the Eu^{3+} ion in acetone has been determined with the aid of these curves (36×10^3 J mol^{-1}).

Mention should be made of the method, proposed by Bünzli and Vuckovic, for the investigation of the inner coordination sphere of the Tb^{3+} ion in weakly donating solvents (acetonitrile) on the basis of the break in the Stern–Volmer linear plot for the quenching (or excitation) of the luminescence of the ion following the introduction of highly donating water molecules (quenching) or dimethyl sulfoxide molecules (excitation) into the solution.[34] The method is most effective when there is a large difference between the complex-forming capacities of the solvent and the added 'quenching agent' in relation to the Ln^{3+} ion. The complex nature of the quenching of the $Tb(NO_3)_3$ solution in acetonitrile by water[1,34] may be due to the fact that, after the displacement of three acetonitrile molecules from the outer sphere by water, the subsequent addition of water leads to the removal of NO_3^- anions.[30]

The possibility of using the inductive-resonance theory of nonradiative transitions for the study of complex formation involving the outer coordination sphere of lanthanide ions has been demonstrated.[35] Neutral neodymium complexes with three NO_3^- anions and three tributyl phosphate molecules were investigated. The quenching of the luminescence of the neodymium complex by water can be explained satisfactorily solely on the hypothesis that the water molecules hydrogen-bonded to a free tributyl phosphate molecule (asymmetric associated species) exert a quenching effect. On the other hand, the water molecules bound to two tributyl phosphate molecules (symmetrical associated species) have virtually no quenching effect on the luminescence of the neodymium complex. There are no free water molecules under these conditions. The high quenching constant can be explained by the protracted encounter between the neodymium complex and the asymmetric water associated species resulting from the formation of a hydrogen bond between the free hydroxy-group of water and a NO_3^- anion in the neodymium complex. The concentration of the asymmetric water associated species in solution was determined from the IR spectra.

III. The application of nonradiative energy transfer between lanthanide ions in the study of complex formation

The problem of the use of the phenomenon of nonradiative energy transfer between organic molecules and lanthanide ions for the investigation of the complex formation reaction between them in solutions has been examined in detail in a review.[36] Since the 17 years which have elapsed since then have not introduced appreciable corrections to the physical and chemical treatment of these phenomena, we shall not return to this problem and will concentrate attention on the application of the phenomenon of the nonradiative energy transfer between different lanthanide ions in liquid solutions to the study of complex formation.

In the first investigations of nonradiative energy transfer between different lanthanide ions in liquid solutions,[37–42] it was already noted that the bimolecular rate constants for the energy transfer (k_t'/dm^3 mol^{-1} s^{-1}) between Tb^{3+} and Eu^{3+} ions (energy donors), on the one hand, and Nd^{3+}, Ho^{3+}, Er^{3+}, etc. ions (energy acceptors), on the other, are five orders of magnitude lower than the rate constant for the process determined by diffusion in highly donating solvents, including water.[40,41] This is due to the low absorption coefficients of the energy acceptors and hence the low overlap integral (which enters into Förster's formula for the energy transfer rate constant) between the normalised luminescence spectra of the donors and the absorption spectra of the acceptors, the low emission rate constants for the energy donors, and the hindrance to the mutual approach of the energy donors and

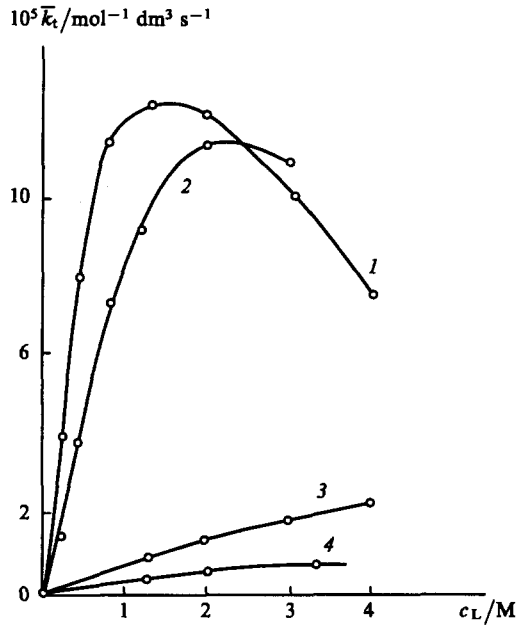

Figure 9. Dependence of the average rate constant for the nonradiative energy transfer from Tb^{3+} (0.03 M) to Nd^{3+} (0.015 M) in water at 293 K on the added carboxylic acid salts:[49] (*1*) CH_3COONa; (*2*) $CH_2ClCOOK$; (*3*) $CHCl_2COOK$; (*4*) CCl_3COOK.

acceptors owing to the Coulombic repulsion forces between the charged Ln^{3+} ion complexes surrounded by neutral solvent molecules.

It has been noted[41,42] that k'_t increases sharply after the addition to the aqueous solution of various alkali metal salts or acids whose anions form complexes with the lanthanide ions. Fig. 9 presents the dependence of the rate constant for energy transfer from Tb^{3+} ($^5D_4$) to Nd^{3+} in water on the concentration of various sodium and potassium salts and derivatives of acetic and other acids. The increase in the rate of transfer on formation of complexes between the lanthanides and the anions is caused both by the decrease in the Coulombic repulsion between the donor and acceptor owing to the neutralisation of the ionic charge on formation of complexes with the anions and by the formation of unstable bridged dinuclear donor Ln^{3+}–anion–acceptor Ln^{3+} complexes, which increase the duration of the encounter between the excited donor and acceptor.

The question of the influence of electrostatic repulsion and attraction of the charged donor and acceptor on the rate of energy transfer in solutions was first examined by Bodunov.[43,44] It was shown that this effect cannot explain quantitatively the experimental data.

The greatest increase in k'_t occurs in the inner-sphere complex formation reactions with anions which can give rise to bridged complexes. The outer-sphere complex formation also influences appreciably the energy transfer in certain cases.

The high sensitivity of k'_t to the inner-sphere complex formation made it possible to develop, using the phenomenon of energy transfer, a procedure for the determination of the stability constants of lanthanide ion complexes.[45] The method is a variant of Bjerrum's method of corresponding solutions,[31] extended to the case of the simultaneous presence in solution of two different central groups, and makes it possible to determine simultaneously the stability constants of complexes of two lanthanide ions—the energy donor and acceptor, where the indicator which depends unambiguously on the free ligand is k'_t. Using the experimental fact that the decay of the donor luminescence is exponential in the presence of the acceptor, it is possible to formulate the following expression for the rate of deactivation of the excited states of the donor in the presence of the acceptor:

$$-\frac{dc_{D^*}}{dt} = k_0^D c_{D^*} + k'_t c_{D^*} c_A ,$$

$$\bar{k}'_t = (k^D - k_0^D)c_A^{-1}; \quad k_0^D = \tau_{D0}^{-1}; \quad k^D = \tau_D^{-1} ,$$

$$\bar{k}'_t = \frac{\sum_{n=0}^{N}\sum_{m=0}^{M} k_t^{nm}\,\beta_n^{D^*}\,\beta_m^{A}\,[L]^{n+m}}{\left(\sum_{n=0}^{N}\beta_n^{D^*}\,[L]^n\right)\left(\sum_{m=0}^{M}\beta_m^{A}\,[L]^m\right)}, \qquad (5)$$

where c_{D^*} is the concentration of the excited energy donor (D^*), c_A the overall concentration of the unexcited energy acceptor (A), [L] the equilibrium concentration of the free ligand, and $\beta_n^{D^*}$ and β_m^A are respectively the overall stability constants of the complexes of the excited donor ions and unexcited acceptor ions

$$\beta_n^{D^*} = \frac{[D^*L_n]}{[D^*][L]^n}; \quad \beta_m^A = \frac{[AL_m]}{[A][L]^m}.$$

It follows from Eqn (5) that $\bar{k}'_t$ is an unambiguous function of the free ligand concentration [L] and can therefore be used as an indicator in the method of corresponding solutions. The quantity

$$\bar{\tau} = (\bar{k}_e^D + \bar{k}_{nr}^D)^{-1},$$

also depends on the free ligand concentration [L] and may be used to determine the stability constants. However, at the concentrations [L] employed it is small for aqueous solution (τ_0^D changes by not more than 2–3 units), while $\bar{k}'_t$ increases by 1–2 orders of magnitude following the addition of the ligand. Therefore $\bar{k}'_t$ was chosen as the parameter and the small changes in $\bar{\tau}_0^D$ were taken into account. For each acceptor concentration, $\bar{\tau}_0^D$ was measured at the donor concentration equal to the sum of the concentrations of the donor and acceptor at the point where the quenching was measured. This is legitimate bearing in mind the small variation of the stability constants in the series of lanthanides. When the donor gives rise to concentration-induced quenching, in the measurement of $\bar{\tau}_0^D$ it is necessary to add to the solution neutral [sic! (Ed. of Translation)] ions (La^{3+}, Gd^{3+}) at the concentration equal to that of the acceptor.

In order to determine the average numbers of ligands around the energy donor ($\bar{n}_D$) and acceptor ($\bar{m}_A$) and the equilibrium ligand concentration, two series of measurements are performed. In the first series, the dependence of $\bar{k}'_t$ on the energy donor concentrations c_D with c_A = const. is determined and plotted for several ligand concentrations c_L (Fig. 10*a*), while in the second series the dependences of $\bar{k}'_t$ on the acceptor concentration c_A with c_D = const. are plotted for the same ligand concentrations (Fig. 10*b*). The series of corresponding solutions for which $\bar{n}_D$, $\bar{m}_A$, and [L] are the same are found from the points of intersection of the experimental curves with the k'_t = const. straight lines. Under the conditions of the luminescence measurements, the concentrations of the excited donor and acceptor ions may be neglected compared with those of the unexcited ions, so that the material balance equation is written in the following form:

$$c_L = \bar{n}_D c_D + \bar{m}_A c_A + [L] .$$

The method described has been used[45] to investigate the formation of complexes between Tb^{3+} (energy donor) and Nd^{3+} (energy acceptor) ions and acetate ions CH_3COO^- in water at the ionic strength of the solution I = 2.0 and at a temperature of 293 K. A constant ionic strength was maintained by adding $NaClO_4$, so that the overall concentration of CH_3COONa and $NaClO_4$ was 2.0 M. The straight lines drawn through points corresponding to constant $\bar{k}'_t$ are presented in Fig. 11. The quantities $\bar{n}_D$ and $\bar{m}_A$ are determined from the slopes of the straight lines and [L] is determined from their intercepts on the ordinate axis, (c_L is the overall concentration of the ligand

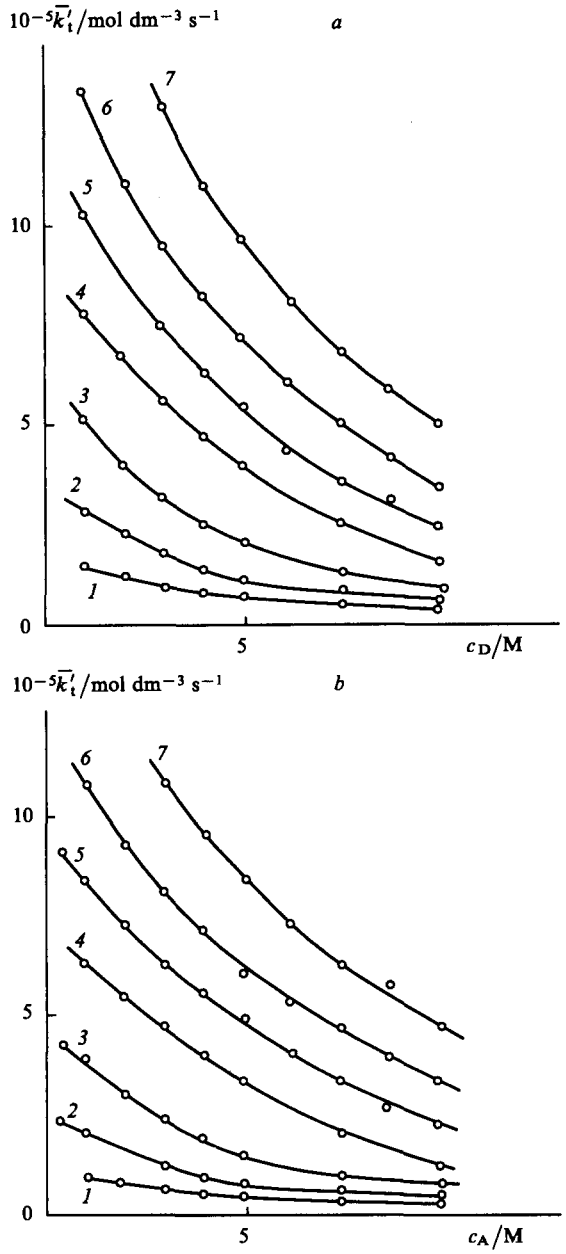

Figure 10. Dependence of the average rate constant for the energy transfer from $Tb^{3+}(^5D_4)$ to Nd^{3+} ions in water at 293 K and $I = 2.0$ on the concentration of the energy donor ions (*a*) at a constant concentration of the energy acceptor ions and on the concentration of the energy acceptor ions (*b*) at a constant concentration of the energy donor ions for different concentrations of sodium acetate (c_L/M): (*1*) 0.05; (*2*) 0.07; (*3*) 0.1; (*4*) 0.14; (*5*) 0.17; (*6*) 0.2; (*7*) 0.24.

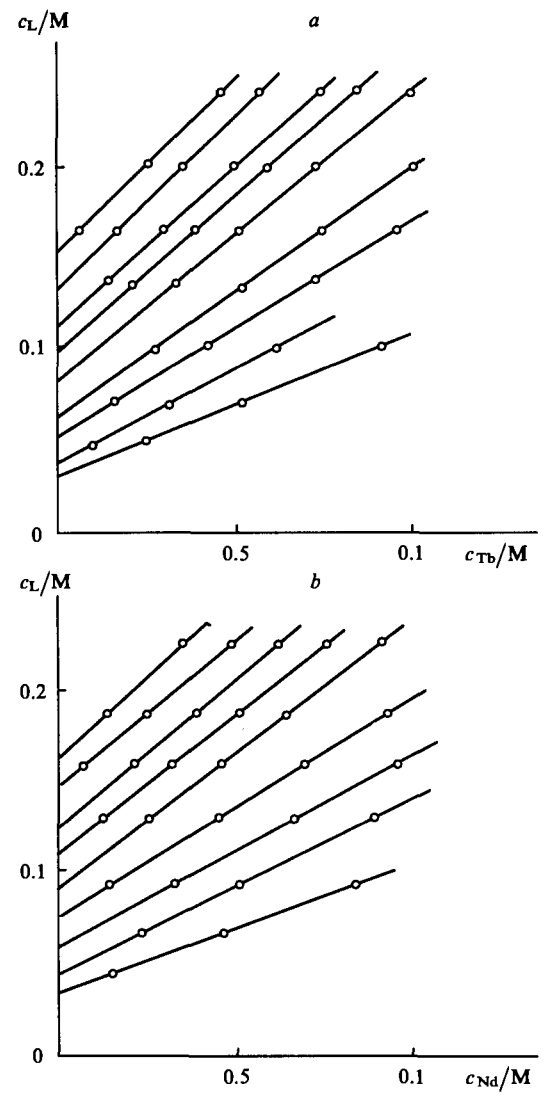

Figure 11. Dependence of the sodium acetate concentration on the concentrations of Tb^{3+} (*a*) and Nb^{3+} (*b*) for solutions with identical values of $\bar{k}'_t$ (corresponding solutions). The average numbers of the energy donors ($\bar{n}_{Tb}$) and the energy acceptors ($\bar{n}_{Nd}$) are determined from the slopes of the straight lines in Figs *a* and *b* respectively; the intercepts made by the straight lines on the ordinate axis yield the equilibrium ligand (acetate) concentrations.

CH_3COONa and c_D and c_A are respectively the overall concentrations of the Tb^{3+} donor and the Nd^{3+} acceptor). Fig. 12 presents the dependence of the average number of ligands around the donors (curve *1*) and acceptors (curve *2*) on the free ligand concentration [L]. The stability constants of the Tb^{3+} and Nd^{3+} complexes of CH_3COO^-, calculated from these data by the least squares method on the assumption that the first three complexes are formed, are presented in Table 7 (see following page). The stability constants obtained by the Fronaeus graphical method[31] were adopted as the zeroth approximation. For comparison, Table 7 presents the stability constants of neodymium acetate complexes obtained under similar conditions by the potentiometric method.[46] The stability constants of the neodymium complexes obtained by the luminescence energy transfer and potentiometric methods agree satisfactorily.

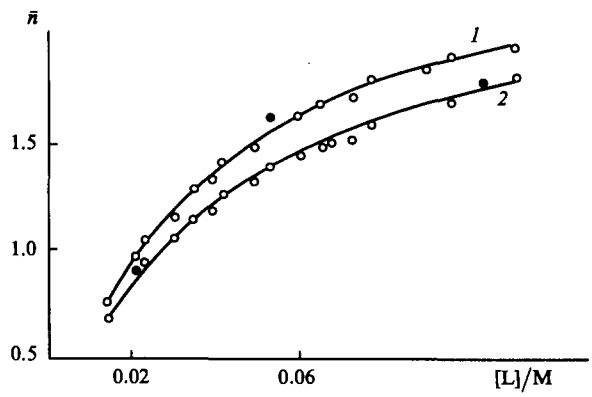

Figure 12. Dependence of the average number of acetate ions bound in the complexes with Tb^{3+} (curve *1*) and Nd^{3+} (curve *2*) on the equilibrium concentration of acetate ions [L]. The curves have been calculated from the stability constants obtained by the least squares method: (*1*) $\bar{n}_D = \bar{n}_{Tb}$; (*2*) $\bar{n}_A = \bar{n}_{Nd}$.

Nd^{3+}	73 ± 8	1180 ± 60	3300 ± 550	"
Potentiometric method [46]				
Nd^{3+}	80 ± 3	1020 ± 100	2900 ± 500	Fronaeus graphical method

We shall not dwell on the application of the nonradiative energy transfer between lanthanide ions in the study of the structures of biological objects because this problem is dealt with elsewhere.[1,2]

1. Detection of unstable bridged lanthanide ion complexes by the nonradiative energy transfer method

The marked increase in k_t' [for energy transfer] between lanthanide ions in solutions in the presence of a series of acid anions cannot be explained solely by the decrease in the electrostatic repulsion. It has been suggested[47,48] that unstable bridged dinuclear lanthanide complexes exist in which the anion (for example, CH_3COO^-) is linked via one atom (in the case of acetate, it is an oxygen atom) to the energy donor ion (for example, to Tb^{3+}), whilst via another atom it is linked to the energy acceptor ion (for example, Nd^{3+}). The formation of this type of bridged complex leads to the arrest of the encounter between the excited ion and the energy acceptor and hence increases their residence time in close proximity, which in fact leads to a significant increase in k_t'.

Table 8 presents the measured average rate constants for energy transfer from terbium and europium ions to neodymium ions in water and alcohol in the presence of acetate anions at the concentration for which k_t' is a maximum.

The decay of the luminescence of the energy donor is exponential in all cases, which indicates a rapid ligand exchange. It is seen from the data in Table 8 that the maximum values of k_t' in the presence of CH_3COO^- anions increase in the sequence water < methanol < ethanol < n-propanol, k_t increasing by a factor of 20 on passing from water to n-propanol. This difference cannot be accounted for by electrostatic repulsion because the complexes are uncharged under these conditions. The formation of unstable bridged dinuclear complexes may be regarded as the only explanation.

Since the quenching of the luminescence of the donor by the acceptor in the presence of acetate is dynamic in all cases, i.e. $q_0/q = \tau_0/\tau$, two variants may be considered.

1. The rate of energy transfer in the bridged complex is high and exceeds the rate of its dissociation, but the equilibrium concentration of the complex is low because of the low value of its stability constant and we therefore do not see any difference between τ_0/τ and q_0/q.

2. The rate of dissociation in the bridged complex exceeds the rate of energy transfer in the latter and the acceleration of the bimolecular energy transfer reaction is associated with the prolongation of the encounter, i.e. with the increase in the average residence time of the acceptor in the vicinity of the excited donor. The quenching (transfer) step does not accompany each step involving the formation of the excited donor–ligand–unexcited acceptor complex.

The appreciable increase [by a factor of ~ 200 (Table 8)] in the average rate constant for energy transfer between lanthanide ions in the presence of acetate ions suggests that energy transfer in the bridged complexes makes the main contribution to the quenching and the reaction can be formulated thus:

$$[D^*L_j] + [AL_i] \underset{k_{diss}^{ji}}{\overset{k_{ass}'^{(ji)}}{\rightleftharpoons}} [D^*L_jAL_i] \xrightarrow{k_t^{ji}} [DL_jA^*L_i] \xrightarrow{k_{diss}^{ji}} [DL_j] + [A^*L_i],$$

$$k_t'^{(ji)} = \frac{k_{ass}'^{(ji)} k_t^{(ji)}}{k_{diss}^{ji} + k_t^{ji}},$$

where D and A are the energy donor and acceptor ions respectively, the asterisk designates the excited states, k_t^{ji} is the first-order intracomplex energy transfer rate constant, and $k_t'^{(ji)}$ is the second-order rate constant for energy transfer between donor complexes with j ligands and acceptor complexes with i ligands. The average energy transfer rate constant is then given by

$$\bar{k}_t' = \sum_j \sum_i k_t'^{(ji)} \alpha_j^{D^*} \alpha_i^A,$$

where $\alpha_j^{D^*}$ and α_i^A are respectively the relative concentrations of the complexes of the excited donor and the unexcited acceptor of each type.

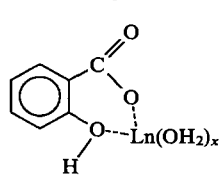
For $k_t^{(ji)} \gg k_{diss}^{(ji)}$, the average energy transfer rate constant corresponds to the average rate constant for the formation of the bridged complexes and is almost independent of the acceptor ion. For $k_{diss}^{ji} \gg k_t^{ji}$, the average rate of transfer should depend greatly on the properties of the acceptor, namely on the overlap integral between the luminescence spectrum of the energy donor and the absorption spectrum of the energy acceptor.

Table 8. Rate constants for the nonradiative energy transfer from terbium and europium ions to neodymium ions at 293 K (according to Gruzdev's data[49]).

Solvent	c/M				$\bar{k}_t'$/mol^{-1} dm^3 s^{-1}	
	CH_3COONa	Tb^{3+}	Eu^{3+}	Nd^{3+}	Tb^{3+} ($^5D_4$)	Eu^{3+} ($^5D_0$)
H_2O	0.0	0.03	0.03	0.1	7.5×10^3	3×10^3
	1.4	0.03	0.03	0.02	1.3×10^6	1.2×10^6
CH_3OH	0.0	0.02	0.02	0.03	2.4×10^4	1.0×10^4
	0.3	0.02	0.02	0.005	4.4×10^6	2.3×10^6
C_2H_5OH	0.0	0.02	0.02	0.03	3.8×10^4	2.2×10^4
	0.04	0.005	–	0.001	1.3×10^7	–
n-C_3H_7OH	0.0	0.02	0.02	0.03	5.5×10^4	4.0×10^4
	0.02	0.001	0.001	0.0001	2.8×10^7	1.8×10^7

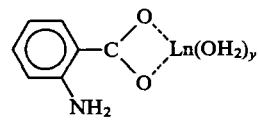
Note. All the ions were introduced into the solution in the form of the nitrates; the CH_3COONa concentrations at which the maximum value of $\bar{k}_t'$ is attained were employed.

Measurements have been made[49] of the maximum values of k_t' in the presence of CH_3COO^- ions at 293 K for three pairs of ions–energy donors and acceptors: $Dy^{3+}(^4F_{9/2})-Nd^{3+}$, $Tb^{3+}(^5D_4)-Nd^{3+}$, and $Tb^{3+}(^5D_4)-Eu^{3+}$. The following values have been obtained for these pairs (mol^{-1} dm^3 s^{-1}): 5×10^6; 1.3×10^6, and 9×10^4 respectively. They are correlated with the overlap integrals of the spectra for the above pairs, the ratios of which are $10:1.2:(\leqslant 0.1)$. This is unambiguous evidence in support of the second mechanism of the energy transfer in bridged complexes of the given type.



The important role of the bridged complexes in energy transfer between lanthanide ions has been confirmed.[49] A study was made of the energy transfer from salicylic (Sal^-), sulfosalicylic ($SSal^{2-}$), and anthranilic (Ant^-) acid complexes of samarium, terbium, and disprosium to the neodymium ion as the energy acceptor. At pH 5.9, the lifetimes of the Ln^{3+} complexes of Sal^- and $SSal^{2-}$ in water are more than 80 μs, which exceeds appreciably the lifetimes of the excited states of Dy^{3+} at the $^4F_{9/2}$ level and Sm^{3+} at the $^4G_{5/2}$ level [~3 μs (Table 5)]. The lifetime of the complex $[LnAnt]^{2+}$ in water exceeds 500 μs and is longer than the lifetime of Tb^{3+} at the $^5D_4$ level (475 μs). By creating in the solution a large excess of the Ln^{3+} ions (0.1 M) relative to the ligand concentration (10^{-4} M) and by exciting selectively only the Ln^{3+} ions bound in complexes via rapid ($\geqslant 10^8$ s^{-1}) intracomplex energy transfer from the ligands, this makes it possible to measure the rate constant for the reaction

$$[D^*L] + A \xrightarrow{k_t'} [DL] + A^*,$$



where $[D^*L]$ is the excited donor Ln^{3+} ion combined with the ligand and A the unexcited solvated energy acceptor Ln^{3+} ion. The following energy transfer reactions were investigated:

Reaction	$10^{-5}k_t'$/ mol^{-1} dm^3 s^{-1}
$(Dy^{3+})^* + Nd^{3+} \longrightarrow Dy^{3+} + (Nd^{3+})^*$	0.93
$[Dy^*Sal]^{2+} + Nd^{3+} \longrightarrow [DySal]^{2+} + (Nd^{3+})^*$	60
$[Dy^*SSal]^* + Nd^{3+} \longrightarrow [DySSal]^+ + (Nd^{3+})^*$	100
$[Dy^*Ant]^{2+} + Nd^{3+} \longrightarrow [DyAnt]^{2+} + (Nd^{3+})^*$	2.1
$(Tb^{3+})^* + Nd^{3+} \longrightarrow Tb^{3+} + (Nd^{3+})^*$	0.07
$[Tb^*Ant]^{2+} + Nd^{3+} \longrightarrow [TbAnt]^{2+} + (Nd^{3+})^*$	0.15
$(Sm^{3+})^* + Nd^{3+} \longrightarrow Sm^{3+} + (Nd^{3+})^*$	0.1
$[Sm^*Sal]^{2+} + Nd^{3+} \longrightarrow [SmSal]^{2+} + (Nd^{3+})^*$	3.4
$[Sm^*SSal]^+ + Nd^{3+} \longrightarrow [SmSSal]^+ + (Nd^{3+})^*$	4.6

Here the symbol for the lanthanide ion without brackets denotes a hydrate; the concentration of the Ln^{3+} ions was 0.1 M and that of the ligand 10^{-4} M. The rate constants for the nonradiative energy transfer between the lanthanide ion complexes in water at the ionic strength of the solution $I = 0.6$, 295 K, and pH 5.9 have been calculated[49] for the reactions listed above. The error in the determination of k_t' does not exceed 10%. The very marked acceleration of the energy transfer reaction for the complexes of lanthanide ions with salicylate and sulfosalicylate anions (by a factor of 35–100) and the very slight increase (by a factor of 2) in k_t' for the complex with the anthranilate anion are striking. The structure of the complex $[LnSal]^{2+}$ is

This complex is capable of giving rise to dinuclear bridged complexes via the free oxygen atom of the carboxy-group. On the other hand, the structure of the lanthanide complex with the anthranilate anion shows that it does not tend to form a dinuclear complex.

The slight increase in k_t' is in this case associated with the decrease in the electrostatic repulsion between the donor and the acceptor.

If it were possible to demonstrate unambiguously that the energy transfer in bridged complexes takes place via Förster's mechanism and to calculate the distance between the Ln^{3+} ions in the dinuclear complexes, one could estimate the rate constants for the intracomplex energy transfer in the bridged complex (k_t/s^{-1}). Then, having measured the rate constant for the energy transfer in solution k_t' (mol^{-1} dm^3 s^{-1}), it would be possible to calculate the equilibrium constant $K = k_t'/k_t$ for the bridged complex under the given conditions.

However, such calculations, which require reliable evidence for Förster's mechanism of energy transfer between lanthanide ions in solutions, the calculation of the overlap integral between the luminescence spectra of the energy donors and the absorption spectra of the acceptors, and a reasonable estimate of the relative disposition of the Ln^{3+} ions in the dinuclear bridged complex, have not so far been carried out.

IV. A luminescence-spectroscopic method for the determination of the rates of rapid ligand exchange in lanthanide ion complexes in liquid solutions

A new luminescence-spectroscopic method has been proposed[50] for the investigation of rapid ligand exchange reactions in lanthanide ion complexes. The main idea of the method is that one creates with the aid of a short light pulse a nonequilibrium distribution in the assembly of excited lanthanide ion complexes in solution. By following the kinetics of the variation of the luminescence spectra after the cessation of the exciting light pulse, it is possible to obtain information about the rate and, by altering the experimental conditions, also about the nature and mechanism of the relaxation processes. Such processes are the ligand exchange reactions (in particular, the dissociation and association reactions), electrophilic substitution reactions, conformational changes in the excited complexes, and the excitation energy migration process. Since the equilibrium constants for the excited and nonexcited lanthanide complexes differ only slightly, selective excitation of individual centres is essential in order to create a nonequilibrium distribution in the excited state.

The following conditions must be met for the successful application of the proposed method: 1. The rate of the transition of the complex from one form to another must exceed appreciably the rate of deactivation of the excited Ln^{3+} ions under the experimental conditions. 2. The two types of complexes, the kinetics of the transition reaction of which we have investigated, must have different spectral densities of the emission rate constant at the frequencies (wavelengths) at which the luminescence is recorded. 3. The duration of the selectively exciting light pulse must be appreciably shorter than the duration of the reaction investigated.

The simplest case of the coexistence in solution of only two types of complexes, $MLSolv_1$ and $MSolv_2$, has been examined.[50] Henceforth, for simplicity we shall omit the designations of the solvation shells of the complexes and the complexes will be designated by ML and M. The first type of complex (ML) can be converted into the second type (M) as a result of the ligand dissociation reaction and the second can be converted into the first as a result of the addition of the ligand during the lifetime of the

excited ions $\tau_1 = k_1^{-1}$ and $\tau_2 = k_1^{-1}$. It is then possible to formulate the following reaction scheme for the excited ions:

$$\begin{array}{ccc} M^*L & \underset{k_{as}[L]}{\overset{k_{diss}}{\rightleftharpoons}} & M^* + L \\ k_1 \downarrow & & \downarrow k_2 \\ ML & & M \end{array}$$

The system of differential equations describing the time variation of the concentrations of the excited complexes (c_1^*) and the solvates (c_2^*), taking into account the ligand exchange reactions, assumes the following form:

$$\frac{dc_1^*}{dt} = -(k_1 + k_{diss})\, c_1^* + k_{as}[L]\, c_2^*,$$

$$\frac{dc_2^*}{dt} = k_{diss}\, c_1^* - (k_2 + k_{as}[L])\, c_2^*, \qquad (6)$$

where [L] is the equilibrium ligand concentration. Eqns (6) are solved subject to the condition that k_{diss}, $k_{as}[L] \gg k_1$, k_2. The experimental luminescence intensity at a frequency ν is

$$I(t, \nu) = k_{e1}(\nu)\, c_1^* + k_{e2}(\nu)\, c_2^*,$$

where $k_{e1}(\nu)$ and $k_{e2}(\nu)$ are the spectral emission densities for the complex and the solvate at the frequency ν. After introducing the symbols N_1 and N_2 for the initial concentrations of the complex and the solvate at time $t = 0$, for which one can arbitrarily adopt the instant when the short exciting light pulse terminates, we obtain a solution in the following form:

$$I(t, \nu) \qquad (7)$$
$$= (N_1\alpha_2 - N_2\alpha_1)\{k_{e1}(\nu) - k_{e2}(\nu)\}\exp\{-(k_{diss}+k_{as}[L])t\}$$
$$+(N_1 + N_2)\{k_{e1}(\nu)\alpha_1 + k_{e2}(\nu)\alpha_2\}\exp\{-(k_1\alpha_1+k_2\alpha_2)t\},$$

where α_1 and α_2 are the fractions of the excited complex and solvate at equilibrium ($\alpha_1+\alpha_2 = 1$).

The first term in Eqn (7) describes the relaxation of the system to equilibrium via excited states and the second describes the kinetics of the decay of the luminescence of the system in the state of equilibrium. In order to be able to determine the sum of the rates of the forward and reverse complex formation reactions $\{k_{diss} + k_{as}[L]\}$ from the luminescence decay curve, the first term in Eqn (7) must be nonzero. An essential condition for this is that the excitation of one of the forms should be selective ($N_1\alpha_1^{-1} \neq N_2\alpha_2^{-1}$), and also that the spectral densities of the emission rate constant for the complex and solvate at the frequency corresponding to the observation of the luminescence should differ [$k_{e1}(\nu) \neq k_{e2}(\nu)$]. When the total luminescence light is recorded, Eqn (7) includes the integral of the product of the distribution of the spectral emission density for each complex and of the spectral sensitivity of the photoreceiver as well as the spectral transmission coefficient for the light filter employed. In order to be able to observe the effect, the above quantities must be nonzero.

The kinetics of the decay of the luminescence of labile complexes in solutions have been investigated.[51] Account was taken of the stepwise nature of the complex formation reaction and it was assumed that the rate of ligand exchange is appreciably higher than the rate of deactivation of the excited ions. When account is taken of these postulates, the solution of the equations for the luminescence intensity after pulse excitation consists of two parts, similar to the solution of the equations for two complexes. One part represents the sum of $n - 1$ 'fast' exponential functions corresponding to the establishment of equilibrium between different types of excited complexes and the second represents a significantly 'slower' exponential relation corresponding to the decay of the luminescence from the equilibrium state of the system of excited complexes. As in the simplest case, the observation of luminescence requires a nonequilibrium excitation of the system and a difference between the spectral densities of the emission rate constants for the test complexes at the observation frequency. It has also been concluded that, when three or more types of complexes with comparable rates of interconversion are present in solution, it is difficult to obtain quantitative data for the rates of ligand exchange. However, if the first stage of the complex formation is appreciably slower than the other stages, the measurement of the rate constants becomes possible.

The possibilities of the method proposed have been demonstrated.[50, 52, 53] In order to achieve the selectivity of the optical excitation, two procedures were used. In the first, the aromatic ligand in lanthanide ion complexes with such ligands (1,10-phenanthroline, 2,2′-bipyridyl, and naphthoic, salicylic, and sulfosalicylic acids) was excited by a nitrogen laser (λ_{exc} = 337 nm, $\Delta t \approx 20$ ns). This was followed by rapid ($t \leqslant 10^{-9}$ s) nonradiative energy transfer from the triplet state of the ligand to the lanthanide ion.[12, 36] In the second procedure, the excitation was achieved with the aid of a tunable laser based on the dye rhodamine 6G in the region of the $^5D_0 \leftarrow {}^7F_0$ transition of the europium ion. The selectivity was ensured by excitation in the spectral absorption band of the Eu^{3+} ion corresponding to the complex which it was necessary to excite.

Fig. 13 presents Eu^{3+} luminescence decay curves at the $^5D_0$ level (in D_2O at 295 K after pulse excitation by a nitrogen laser). Heavy water was used as the solvent because the lifetime of the excited state of the europium ion in it is many times greater than in H_2O (Table 5), so that the necessary condition is fulfilled — the rate of deactivation of the excited ion is many times lower than the rate of the ligand exchange.

The overall luminescence decay curve consists of two exponential components: the 'fast' component corresponding to the relaxation of the solution to the equilibrium state and the 'slower' exponential section corresponding to the decay of the equilibrium luminescence (Fig. 13). Since the concentration of 1,10-phenanthroline was 10^{-3} M and that of Eu^{3+} was 10^{-2} M and the absorption coefficient (λ = 334 nm) is 10^4 times greater

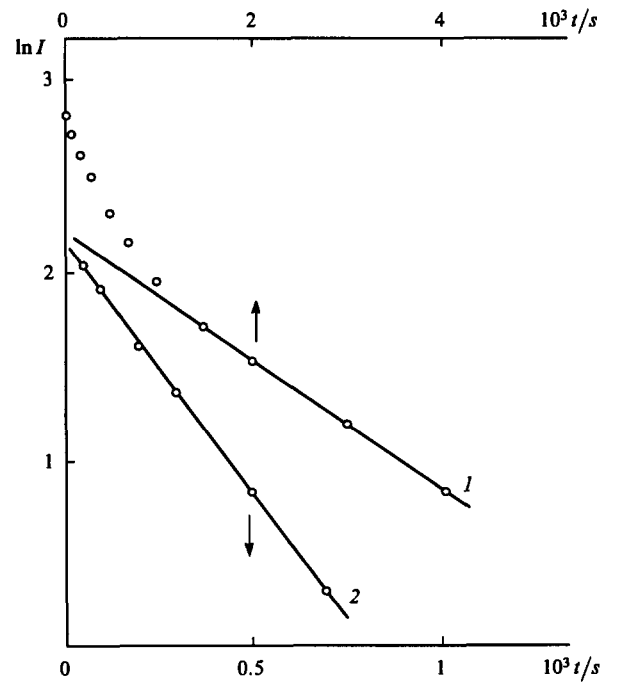


Figure 13. Time variation of the Eu^{3+} luminescence intensity corresponding to the λ = 613 nm emission band and sensitised by the intracomplex energy transfer from 1,10-phenanthroline (Phen). Solvent — D_2O, 295 K $c_{Eu(NO_3)_3 \cdot 6D_2O}$ = 0.01 M, c_{Phen} = 0.001 M, pulse excitation by a nitrogen laser (Δt = 20 ns, λ_{exc} = 337 nm); (*1*) equilibrium luminescence; (*2*) relaxation process.

Table 9. Rate constants for the dissociation of excited lanthanide ion complexes in solutions at 295 K.[49-53]

Ligand	Ion (level)	Solvent	k_{diss}/s^{-1} [a]	Reaction mechanism
Selective excitation by nonradiative energy transfer from the ligand to the lanthanide ion				
1,10-Phenanthroline	Eu^{3+} ($^5D_0$)	D_2O	2700 (44.4) [b]	dissociative opening of the chelate ring
2,2′-Bipyridyl	Eu^{3+} ($^5D_0$)	D_2O	22 000 (36) [b]	"
1-Naphthoate anion	Eu^{3+} ($^5D_0$)	CD_3OD	2.5×10^3	"
	Eu^{3+} ($^5D_0$)	$CD_3OD + D_2O$, 3:1	5.5×10^5	"
	Eu^{3+} ($^5D_0$)	$CH_3OH + H_2O$, 3:1	8.3×10^5	"
	Sm^{3+} ($^4G_{5/2}$)	$CD_3OD + D_2O$, 3:1	6.3×10^5	"
	Sm^{3+} ($^4G_{5/2}$)	$CD_3OD + D_2O$, 1:1	2.0×10^6	"
	Sm^{3+} ($^4G_{5/2}$)	D_2O	4.4×10^6	associative activation
	Sm^{3+} ($^4G_{5/2}$)	H_2O	5.5×10^6	associative activation
Salicylate anion	Tb^{3+} ($^5D_4$)	CH_3OH	4.0×10^3 [a]	"
	Tb^{3+} ($^5D_4$)	D_2O	7.6×10^9 [a]	acid catalysis
	Tb^{3+} ($^5D_4$)	H_2O	1.0×10^{10} [a]	acid catalysis addition of H^+
5-Sulfosalicylate dianion	Tb^{3+} ($^5D_4$)	CH_3OH	4.0×10^3	"
	Tb^{3+} ($^5D_4$)	D_2O	7.9×10^9 [a]	"
	Tb^{3+} ($^5D_4$)	H_2O	1.05×10^{10} [a]	"
Selective laser excitation at the wavelength corresponding to the $^5D_0 \leftarrow {}^7F_0$ transition of the Eu^{3+} ion				
1,10-Phenanthroline	Eu^{3+} ($^5D_0$)	D_2O	2.7×10^3	dissociative opening of the chelate ring
Acetate anion	Eu^{3+} ($^5D_0$)	H_2O	7.0×10^6 [d]	associative activation
	Gd^{3+} ($^8S_{7/2}$)	H_2O	7.0×10^6 [d]	associative activation
	Sm^{3+} ($^6H_{5/2}$)	H_2O	3.7×10^7 [e]	"
Iminodiacetate	[EuDCTA]$^-$ ($^5D_0$) [f]	H_2O	2.6×10^3	"

[a] The errors in k_{diss} do not exceed 20% – 30%.
[b] The numbers in brackets represent the activation energies for the reactions in kJ mol^{-1}.
[c] Second-order rate constant k' in mol^{-1} dm^3 s^{-1}.
[d] Value for the unexcited ion based on the data of Silber et al.[54] obtained by the temperature jump method.
[e] Value for the unexcited ion based on the data of Garza and Purdie[55] obtained by the acoustic absorption method.
[f] DCTA = 1,2-diaminocyclohexanetetraacetate.

for phenanthroline than for Eu^{3+}, there was a high excitation selectivity and the observed fast exponential function may be set equal to the dissociation rate constant (k_{diss}) for the complex. The value of this constant and also the value of the rate constant for the dissociation of the europium complex of 2,2′-bipyridyl in D_2O at 295 K are presented in Table 9.

The study of the dependence of k_{diss} for the above complexes on the temperature and the pH of the solution suggested a dissociative mechanism of the reaction in which the rate-limiting stage is the transfer of one of the donor nitrogen atoms to the second sphere of the Ln^{3+} ion (opening of the chelate ring), which is followed by rapid dissociation of the complex.

The study of the kinetics of the dissociation of europium and samarium complexes of the 1-naphthoate ion demonstrated that the rate of dissociation of the complex is greatly influenced by the solvent. On passing from pure methanol to a mixture of methanol and water and then to pure water, the rate of dissociation increases by three orders of magnitude (Table 9). One should bear in mind that, on excitation as a result of nonradiative energy transfer from the aromatic ligands, the $^5D_0$ level of the Eu^{3+} ion is populated via the $^5D_1$ level of europium. On the other hand, the rate of the nonradiative transition from the $^5D_1$ level to the $^5D_0$ level of europium is 10^6 s^{-1},[56] which limits the possibilities for the study of rapid dissociation reactions. Therefore the data for Sm^{3+}, where the rate of relaxation to the emitting $^4G_{5/2}$ level is appreciably higher, is quoted in Table 9 as the rate of dissociation of naphthoic acid [the naphthoic acid complex?] in water.

The dissociation reactions of the salicylic and sulfosalicylic acid complexes of the Tb^{3+} ion (the $^5D_4$ level) in methanol and water have been investigated. It has been shown that the rate of dissociation in water depends greatly on the pH of the solution, k_{diss} being directly proportional to the concentration of H^+ (H_3O^+) ions in water. Bimolecular constants, close in magnitude to the diffusion rate constant in water, are therefore quoted in Table 9 for these complexes. It is most likely that the first stage of the dissociation of these complexes involves the addition of a proton to the free oxygen of the COO^- group with subsequent departure of the ligand from the lanthanide ion. The constants k_{diss} have been measured by a similar method[57] for Tb^{3+} with the same ligands in water at $I = 0.06$ and pH 7.0. The constants k_{diss} exceeded by an order of magnitude those quoted by Gruzdev and Ermolaev[52,53] (Table 9). It may be that this is associated with the unduly high ligand concentration, comparable to the concentration of the Ln^{3+} ion. Complexes of lanthanide ions with different numbers of ligands coexist under these conditions and it is difficult to determine the values of k_{diss}. Furthermore, the authors[57] postulate that the rate of equilibration with respect to the excited ions is equal to the difference between the rates of dissociation and association, whereas it is in fact equal to their sum [see Eqn (7)]. These discrepancies are not discussed in the study quoted above.[57]

However, the selective excitation of the complexes via the excitation of the ligand and the nonradiative energy transfer to the Ln^{3+} ion is limited by the employment of mainly aromatic ligands. Therefore, in order to study the nonaromatic ligand exchange reactions, the second method for the creation of a high nonequilibrium distribution of the excited ion complexes — the method involving the selective excitation of specific complexes by illuminating the solution with the monochromatic light of a pulse-type tunable laser — was employed. The Eu^{3+} ion and its absorption band, corresponding to the $^5D_0 \leftarrow {}^7F_0$ transition, the position and strength of the oscillator of which are extremely sensitive to changes in the structure of the inner coordination sphere of the ion, are most suitable for these purposes.[1] The widely used rhodamine 6G-based tunable laser is also very suitable.

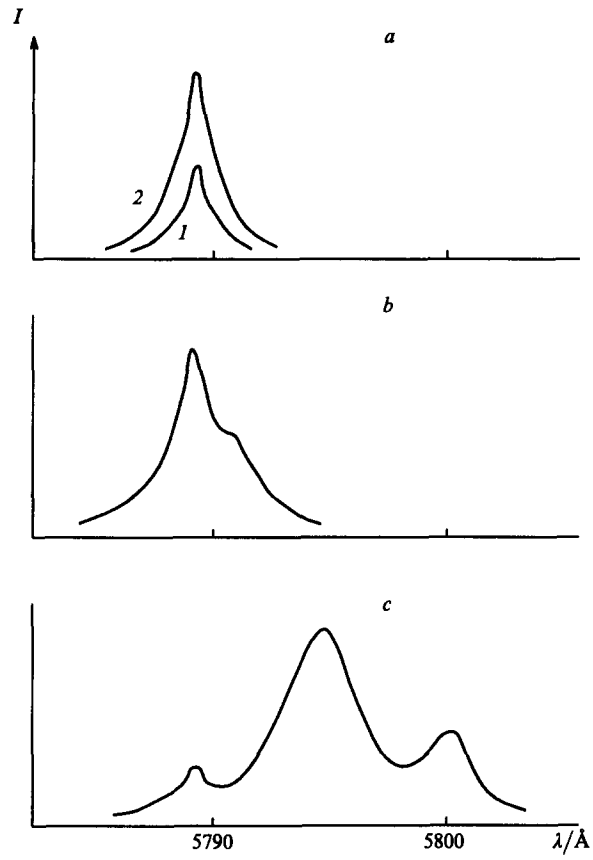

Figure 14. Luminescence excitation spectra in the $^5D_0 \leftarrow {}^7F_0$ transition in aqueous solutions containing Eu^{3+} ions (at the wavelength corresponding to the $^5D_0 \leftarrow {}^7F_0$ band) measured with the aid of a rhodamine 6G-based tunable laser: (*a*) $Eu(NO_3)_3$ (0.05 M) in H_2O (curve *1*) and $Eu(NO_3)_3$ (0.05 M)+NaAc (0.01 M) in H_2O (curve *2*); (*b*) $Eu(NO_3)_3$ (0.05 M)+Phen (0.01 M) in D_2O; (*c*) $Eu(NO_3)_3$ (0.05 M)+Na_2H_2EDTA (0.01 M) in D_2O, pD = 5.5; T = 295 K.

Fig. 14 presents the luminescence excitation spectra in the $^5D_0 \rightarrow {}^7F_1$ transition for various europium complexes in water by light corresponding to the $^5D_0 \leftarrow {}^7F_0$ band, measured with the aid of a rhodamine 6G-based tunable laser.[58] Such spectra correspond to the absorption spectra, the direct measurement of which is difficult owing to the extremely low oscillator strength of the transition. The rates of ligand exchange in the europium complexes of the acetate anion have been investigated by this method.[53,58] The selectivity of the excitation of the tunable laser was achieved because the molar absorption coefficient of the complex $(EuCH_3COO)^{2+}$ is approximately five times greater than that for the hydrate, although the positions of the $^5D_0 \leftarrow {}^7F_0$ absorption bands are identical. The luminescence decay curve for an aqueous solution of $Eu(NO_3)_3$ (5×10^{-2} M) + $NaCH_3COO$ (10^{-2} M) at 293 K, measured using the light corresponding to the hypersensitive $^5D_0 \rightarrow {}^7F_2$ band, is presented in Fig. 15. The relaxation time corresponding to the initial nonexponential section of the decay curve in Fig. 15 is 120 ns. Since the equilibrium is greatly displaced towards the solvates, the dissociation of the complex $(EuCH_3COO)^{2+}$ makes the main contribution to this quantity [see Eqn (7)]. Assuming that the stability constant of the complex (87 mol^{-1} dm^3) does not change appreciably on excitation, we obtain a dissociation rate constant of $(7 \pm 2) \times 10^6$ s^{-1}, which is close to the dissociation rate constant of the europium complex of the naphthoate anion and to the value found for the gadolinium acetate complex by the temperature jump method, but differs greatly from data obtained for samarium by the acoustic absorption method (Table 9).

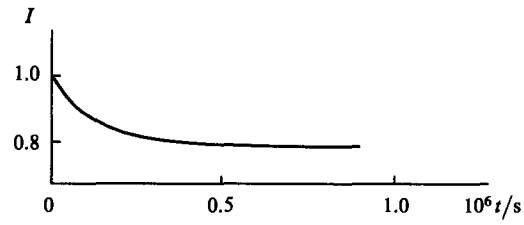

Figure 15. The luminescence decay curve for a solution of the europium complex of the acetate anion $(EuCH_3COO)^{2+}$ in water at the wavelength corresponding to the $^5D_0 \rightarrow {}^7F_2$ band (613 nm) on pulse excitation ($\Delta t \cong 20$ ns) by a rhodamine 6G-based tunable laser. The single-ligand complex $(EuCH_3COO)^{2+}$ is excited preferentially; $c_{Eu(NO_3)_3 \cdot 6H_2O}$ = 0.05 M; c_{CH_3COONa} = 0.01 M, T = 295 K.

Other processes may also lead to a nonexponential type of decay of the luminescence. Firstly, we have the reaction involving the substitution of the central atom in the excited state:
The contribution of this reaction may be determined from the

$$M^*L + M \longrightarrow M^* + ML\,.$$

dependence of the rate constant for the transition process on the concentration of the solvated ion.

Secondly, we have nonradiative electronic excitation energy transfer from the selectively excited complex to the unexcited solvate. As in the previous case, in order to distinguish the energy transfer from the dissociation of the complex, it is sufficient to investigate the dependence of the process on the concentration of solvated ions. It is more difficult to distinguish the energy transfer (migration) from the reaction involving the substitution of the central atom, since the rates of these processes increase with increasing concentration of the solvate. However, the energy transfer from the excited Ln^{3+} ions should not depend on the concentration of the lanthanum or lutetium added to the solution because the energy transfer to the latter is impossible for energetic reasons, whereas the central atom substitution reaction should accelerate in their presence.

It must be emphasised that the study of the transition process in connection with the kinetics of the decay of the luminescence after selective excitation makes it possible to obtain unique data concerning the migration (transfer) of energy between identical lanthanide ions in solutions. For example, the rate of migration of energy from the $^5D_0$ level of the Eu^{3+} ion in its complex with EDTA to the solvated Eu^{3+} ion in D_2O has been measured by this method.[59]

Thirdly, the nonexponential decay may be due to the presence of several types of complexes with different decay times which are not interconverted during the lifetime of the excited state of the ion. This process should be reflected in all the emission bands, whereas the dissociation reaction should be reflected only in the emission bands where the emission rate constant changes appreciably as a result of the dissociation. For example, under nonexponential conditions induced by several types of complexes, such conditions should be observed satisfactorily for europium on the basis of both the $^5D_0 \rightarrow {}^7F_1$ band and the $^5D_0 \rightarrow {}^7F_2$ band, whereas the dissociation of the complex can be observed only from the $^5D_0 \rightarrow {}^7F_2$ band.

The possibility of obtaining data on the kinetic parameters of the ligand exchange at excited lanthanide ions in solutions has also been considered.[1,2,60] Three variants were examined depending on the ratios of the rates of deactivation of the excited ions (complexes) and the rate of ligand exchange.

1. Slow exchange. The selective excitation of each complex in solution leads to luminescence involving exponential decay with τ characteristic of the given selectively excited complex, naturally provided that there is no energy transfer between the ions (complexes). In the case of incomplete (or in the total absence) of

selectivity of the excitation and also in the presence of energy transfer, a nonexponential decay of the luminescence is observed. Incidentally, this case can also be used to measure the rate of the slow ligand exchange, provided that the reaction leads to an appreciable shortening of τ. This method has been used[61] to investigate the rate constant for the incorporation of water in the inner sphere of chromium(III) hexathiocyanate. Later the same workers[62] used this method to determine the rates of the slow isotope exchange of hydrogen for deuterium in the complexes $Cr(en)_3^{3+}$ (where en = ethylenediamine) and $Cr(NH_3)_2(NCS)_4^-$ and their dependence on the pH(pD) of the solution.

2. Fast exchange. Having stated correctly that ligand exchange which is fast compared with the luminescence decay time leads to the exponential decay of the emission in later stages after the attainment of equilibrium with respect to the excited complexes. Horrocks and coworkers[2,60] for some reason neglected the transition process, which was later examined by Gruzdev and Ermolaev in 1977,[50] and did not point out the possibility of using it to measure the rates of rapid reactions.

3. The intermediate rate of exchange—corresponding to the case where the luminescence decay and exchange times are similar. In this case, differential equations have been formulated[60] for the concentrations of two types of complexes undergoing interconversion and deactivated at their own rates, similar to the equations quoted by Gruzdev and Ermolaev[50] [see Eqn (5)]. However, since the condition $\tau_1^{-1}, \tau_2^{-2} \ll k_{dis}, k_{as}[L]$ does not hold in this instance, a more complex solution is obtained than the solution based on the approximate formulae quoted by Gruzdev and Ermolaev[50] [Eqn (7)]. The intermediate case has been studied experimentally[60] in relation to the equilibrium between the europium complexes of 1,2-diaminocyclohexanetetraacetate ($DCTA^{4-}$) and iminodiacetate ($IMDA^{2-}$).

$$Eu(DCTA)^- + IMDA^{2-} \underset{k_{diss}}{\overset{k_{as}[IMDA^{2-}]}{\rightleftharpoons}} Eu(DCTA)(IMDA)^{3-}. \quad (8)$$

The experiment was performed at 293.5 K in aqueous solution at $EuCl_3$, H_4DCTA, and H_2IMDA concentrations of 0.4, 0.04, and 0.12 M respectively at pH 6–9 (NaOH) and $I = 1.0$ (KCl). Each complex was excited selectively by a dye-based laser at the wavelength corresponding to the $^5D_0 \leftarrow {}^7F_0$ band and each complex was detected selectively at the wavelengths of the $^5D_0 \rightarrow {}^7F_0$ bands of the Eu^{3+} ion. The decay of the luminescence was measured at three pH values for each pair of the combinations of the excitation wavelength (exciting mainly one of the complexes) and the observation wavelength characteristic of each complex—altogether four combinations. Using the solutions of the differential equations obtained and the expressions for the overall emission from the two complexes and including the fraction of the emission by each complex as a parameter, Horrocks et al.[60] found the constants k_{dis} and k'_{as}. The following values were obtained at pH 6.99:

$k_{diss}\{Eu(DCTA)(IMDA)^{3-}\} = 2.56 \times 10^3\ s^{-1}$;

$k_{as} = k'_{as}[IMDA^{2-}] = 13.4 \times 10^3\ s^{-1}$;

$\tau\{Eu(DCTA)^-\} = 0.32$ ms;

$\tau\{Eu(DCTA)(IMDA)^{3-}\} = 0.805$ ms.

It has been suggested that, instead of Eu^{3+}, the Sm^{3+} and Dy^{3+} ions be used in the study of faster ligand exchange reactions, as their luminescence in hydrogen-containing solvents decays faster by two orders of magnitude than that of Eu^{3+}.[2,60] However, in this case it is simpler and more accurate to employ Eu^{3+} complexes by carrying out measurements for the transition process on the basis of the decay of the Eu^{3+} luminescence using the method proposed by Gruzdev and Ermolaev.[50]

* * *

Luminescence research methods have been used recently in a wide variety of fields of science and engineering. This applies particularly to chemistry, photochemistry, and biology. Kinetic luminescence methods, in particular those involving laser excitation, have become more accessible to investigators. In the present review, we have attempted to draw the attention of chemists, with interests in the field of the chemistry of solutions of the lanthanide elements, to the possibilities of the study of these systems provided by the luminescence-kinetic methods.

In conclusion we thank the Russian Fundamental Research Fund for financial support (Project No. 94-02-06192).

Selective hydrogenation of unsaturated ketones and acetylene alcohols

E M Sul'man

Contents

I. Introduction 923
II. Selective hydrogenation of unsaturated ketones 923
III. Selective hydrogenation of acetylene alcohols 929

Abstract. The data on selective hydrogenation of unsaturated ketones and acetylene alcohols are analysed. The requirements for choosing selective catalytic systems are surveyed. The routes for the reduction of oxygen-containing compounds and factors affecting them are considered. The bibliography includes 177 references.

I. Introduction

In recent years the problem of selectivity became one of the primary problems of catalysis. High selectivity is an essential characteristic of a catalyst, in addition to its activity and stability.[1,2] Selectivity is characterised by the ratio between the rate of accumulation of the target product and the overall rate of conversion of one of the starting compounds, by different routes, at a given temperature and a given composition of the reaction mixture.[3] A decrease in the selectivity of a catalyst results in the formation of side products that contaminate the target product. This leads to heavy expenses for its purification, to excessive consumption of raw materials and energy, and to deterioration of the environment owing to increase in the amounts of harmful aqueous and gaseous waste products.[4] The most significant and interesting in the theoretical and practical respects among the catalytic processes is catalytic hydrogenation, which is widely used for production of monomers, intermediate products, medical preparations, etc.

This review is devoted to the reduction of unsaturated ketones and acetylene alcohols of various structures and to choosing and developing selective catalytic systems.

II. Selective hydrogenation of unsaturated ketones

1. Hydrogenation of α, β-unsaturated ketones

The catalysts used for the reduction of double bonds in unsaturated ketones may be divided into two groups: the catalysts incorporating platinum metals as the main component or a modifier, and those containing Ni, Co, or Cu.

Hydrogenation of methyl vinyl ketone (MVK), benzylidenelacetone (BA), and benzylidenelacetophenone (BAP) selectively occurs in the presence of Rh/Al_2O_3, Pt and Pd oxides, colloidal Pt, Pd/C, Ru/C, Raney Ni, or Raney-type Co.[5–10] The ethylene bond, keto-group, and benzene ring are consecutively saturated in this process. It has been noted[7,11] that the order of the reaction of hydrogenation of C=C bonds in α, β-unsaturated ketones is close to zero. Enones having two or more substituents at the carbon atoms of the C=C bond have been shown to be reduced with low yields.[12]

As the temperature is increased, hydrogenation of BA slows down,[11] owing to pronounced adsorption of the substrate on the catalyst and displacement of hydrogen from the catalyst surface by benzylideneacetone. Introduction of halogen-containing additives to Ni-based catalysts also decelerates hydrogenation of BA, especially of its C=O group.

In order to ascertain the relationship between the reactivity of a series of unsaturated ketones (MVK, BA, and BAP taken as model compounds) and their chemical structure, the changes in thermodynamic functions: Gibbs free energy (ΔG°_{298}), enthalpy (ΔH°_{298}), and bond order ($p_{C=C}$) during hydrogenation have been calculated (without regard to effects of the solvent and the catalyst under standard conditions), and the results have been then compared with the rates of hydrogenation of these ketones on Raney nickel.[13,14]

The specific rates (W_{sp}) of hydrogenation of MVK, BA, and BAP in the presence of Raney nickel in ethanol and dioxane correlate with the values of ΔG°_{298} and $p_{C=C}$. This led the authors[13–15] to simple correlation equations:

$$W_{sp} = W_0' \exp(-K' \Delta G^\circ_{298}), \quad (1)$$
$$W_{sp} = W_0'' \exp(-K'' p_{C=C}).$$

Experimental data on hydrogenation of C=C bonds in unsaturated ketones are formally adequately described by the following equation:

$$W_i = \frac{k_i x_i}{1 + Q_i x_i}, \quad (2)$$

where W_i is the reaction rate when the initial concentrations of a substrate and a catalyst are equal to unity; k_i and Q_i are kinetic and adsorption parameters, $x_i = c_i/c_0$, where c_i is the concentration of the i-th component and c_0 is the initial concentration of the substrate. The need to take into account adsorption of MVK, BA, and BAP has been shown in specially carried out runs on hydrogenation of a mixture of ketones.[15]

The empirical equation (1) made it possible to predict the initial rates of the reduction of C_{13} and C_{18} ketones under standard conditions. Later, the results were confirmed experimentally. The deviation of the calculated values from the experimental results amounted to 15%.[16]

Hydrogenation of mesityl oxide on Pt-based catalysts involves the reduction of either the C=C bond (40 °C) or both this bond and the keto-group depending on the conditions under which the process is conducted. Under mild conditions (atmospheric pressure of H_2, 25 °C) on Pd/C, only the C=C bond is hydrogenated.[17,18] In the presence of platinum boride, hydrogenation of mesityl oxide is less selective.[19]

Palladium-based catalysts (Pd/SiO_2, Pd/C, Pd black) also ensure selective formation of methyl isobutyl ketone in the gaseous or liquid phase (methanol, ethanol).[20-23] Highly selective reduction of C=C bonds in α,β-unsaturated ketones has been observed on Pd/C at moderate temperatures and hydrogen pressures (75 °C, 0.5 MPa).[24] Hydrogenation of mesityl oxide on Pd/Al_2O_3 occurs selectively at 40 °C (the yield of the hydrogenation product is 99 %).[23] Increasing the temperature to 210 °C results in the formation of methylisobutylcarbinol, i.e. the C=O group is reduced, as well as the double bonds. In addition, the product of dehydration of methylisobutylcarbinol, viz. 2-methylpentane, has also been detected. Dzhaparidze et al.[25] have studied the kinetics and mechanism of selective hydrogenation of mesityl oxide yielding methyl isobutyl ketone in the presence of the industrial Pd catalyst in the vapour phase in a flow-circulation system. They showed that all the experimental data are adequately described by the following equation

$$W = \frac{k_1 P_1 P_{H_2}^{1/2}}{P_{H_2}^{1/2} + k_2 P_1 + k_3 P_2^2}, \quad (3)$$

where P_1 and P_2 are partial pressures of mesityl oxide and methyl isobutyl ketone, k_1, k_2, and k_3 are constants. Based on the analysis of the data on the H/D-isotope exchange in mesityl oxide and methyl isobutyl ketone, a multistage mechanism involving the formation of a semihydrogenated form has been proposed for this process.[25]

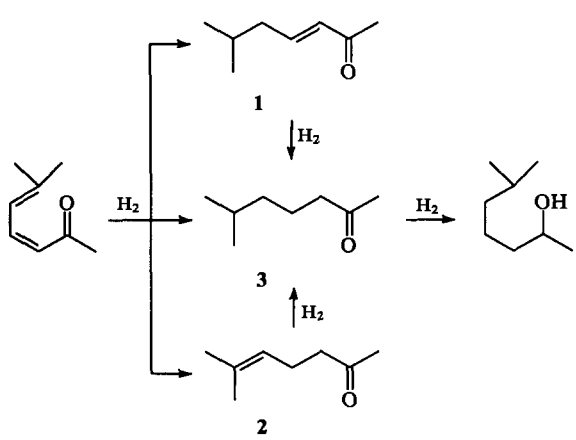
For selective reduction of mesityl oxide, as for the hydrogenation of methyl vinyl ketone, Rh-based catalysts are used.[8,9,26] To increase the rate of the reaction, Rh, Pt, and Pd are modified with rare earth metals (Y, Er, Yb).[27,28] Nitrogen-containing Rh complexes[29] and Ru, Rh, and Pd complexes with phosphines[30] are active and selective in the hydrogenation of mesityl oxide and methyl vinyl ketone. Borunova et al.[29] compared the catalytic activities of Rh/C and of Rh complexes with *N*-phenylanthranilic acid and tyrosine in the hydrogenation of α,β-unsaturated ketones and found that the activity of homogeneous catalysts is considerably higher than that of the heterogeneous Rh/C catalysts.

Reduction of α,β-unsaturated ketones in the presence of Rh, Ru, Pd, or Pt deposited on carbon has been shown to involve both direct hydrogenation of the C=C bond and 1,4-addition of hydrogen to the enone system.[10,31]

A large number of publications[32-37] are devoted to hydrogenation of mesityl oxide catalysed by Ni. In the presence of Raney nickel in various solvents, both the C=C bond and the carbonyl group are hydrogenated,[38,39] i.e. the reduction occurs nonselectively. It was assumed that the reaction, which occurs on the catalyst surface, between chemisorbed atomic hydrogen and adsorbed or nonadsorbed substrate is the rate-determining step of the process.[38] When supported Ni catalysts (30% Ni/Al_2O_3, 160–196 °C, without a solvent) are used, a yield of methyl isobutyl ketone of more than 96% can be achieved.[37]

Modification of Ni catalysts with halides of Group I, II, and III metals results in the increased selectivity of the process with respect to the saturation of C=C bonds.[35,36,40] According to the results obtained by Zhabrova,[41] modification is considered as a general phenomenon, which involves both promoting and poisoning of a catalyst. The use of NiI_2, ZnI_2, CdI_2, $FeBr_2$, $CdBr_2$, and $CoCl_2$ as modifying additives for Raney nickel has been patented.[33] The yield of methyl isobutyl ketone reached 94%. The authors of a paper,[40] who have compared the results of hydrogenation of mesityl oxide in the presence of unpoisoned Raney Ni and of Raney Ni poisoned with KI, concluded that adsorption of mesityl oxide on the catalyst is weaker than that of H_2.

Experiments have shown that the shielded double bond in mesityl oxide is hydrogenated at the same rate as the terminal C=C bond in methyl vinyl ketone.[42] Absorption of 1 mole of H_2 at 42 °C and an atmospheric pressure of hydrogen affords the saturated ketone with high selectivity. When the pressure is increased to 6 MPa, the C=O group is also reduced, but the second mole of H_2 is absorbed very slowly. It has been shown that the isolated double bond in 2-methylpent-1-en-4-one is hydrogenated four times more slowly than the C=C bond in mesityl oxide.



Hydrogenation of mesityl oxide in the presence of copper-based catalysts is not sufficiently selective.[43,44] The highest yield of methyl isobutyl ketone (86.5%) has been obtained at 180–220 °C, at a hydrogen : substrate molar ratio of approximately 1.2, in the presence of Cu_x-Cr_x-Mn oxides deposited directly on a carrier treated with a solution of H_2CrO_4. The process occurs more selectively in the presence of homogeneous catalysts: Cu compounds with additions of $LiAlH_4$.[45]

2. Hydrogenation of polyenones

When the conjugated system of unsaturated ketones is extended by one more double bond, hydrogenation products become more diverse. For example, reduction of 6-methylhepta-3,5-dien-2-one in hexane in the presence of $Pd/CaCO_3$ at atmospheric pressure of hydrogen and ambient temperature affords 67.6% of 6-methylhept-3-en-2-one and 30.2% of 6-methylheptan-2-one,[46] i.e. hydrogen adds initially at the C(5)=C(6) bond and then at the C(3)=C(4) bond. Hydrogenation of the diene alcohol on the same catalyst results in the initial saturation of the C(3)=C(4) bond. Apparently functional groups affect orientation of dienone molecules on the catalyst surface.

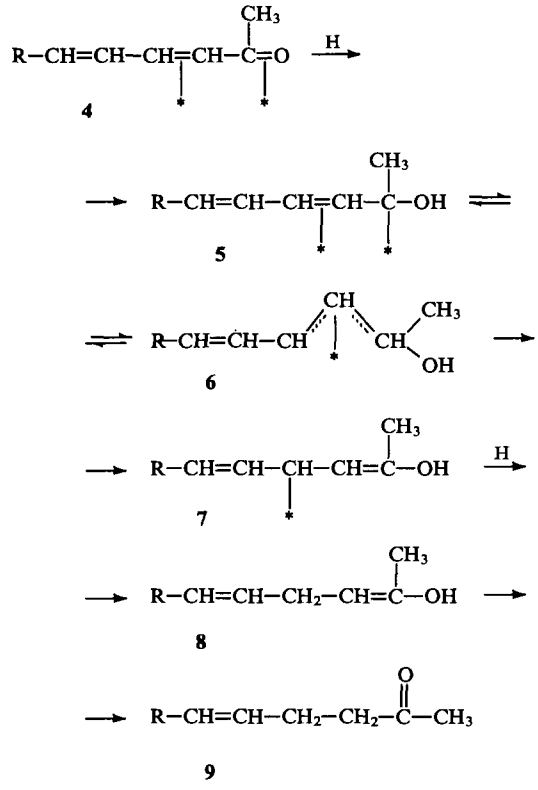
When dienones are hydrogenated in the presence of modified catalysts, hydrogen adds initially to the C(3)=C(4) bond and then to the C(5)=C(6) bond. A study[47] has been devoted to changes in the selectivity of the Pd-based catalyst occurring under the action of various modifying additives. Hydrogenation of 6-methylhepta-3,5-dien-2-one yields enones **1** and **2** and 6-methylheptan-2-one (**3**) (Scheme 1). To elucidate the route to the saturated ketone, hydrogenation was carried out in the presence of 5% $Pd/CaCO_3$, 1% Pd/Al_2O_3, or 1% Pd/TiO_2 at 1–5 MPa. In the case of unmodified Pd catalysts, the formation of ketone **3** is preceded by intermediate **1**. Modification of the catalysts with Cd promotes the preferential addition of H_2 to the C(3)=C(4) bond. Hydrogenation of 6-methylhepta-3,5-dien-2-one in the presence of Rh catalysts (Rh/Al_2O_3) with addition of 0.01%–1% Pb in methanol (70 °C, P_{H_2} = 5 MPa) or in the presence of Rh–Ru catalysts (2%–5% of the metal) deposited on carriers (Al, Ti, Zn, Zr, and Si oxides and aluminosilicate modified with 0.01%–1%

Scheme 1

Pb, Sn, Cd, or Bi[48]) affords enone **2** as the main product. In other words, as in the case of modified Pd catalysts, the C(3)=C(4) bond is the first to be saturated.

The route to the reduction of double bonds in a dienone system is determined not only by the nature of the catalyst and modifying agent and the number of these bonds, but also by the character of substituents in the dienone moiety. For example, in the case of cinnamylacetone in which the diene group is linked to an aryl group, the C(3)=C(4) bond is saturated first in the presence of Pd black, and then the saturation of the C(5)=C(6) bond takes place.[49]

Pseudoionone — 6,10-dimethylundeca-3,5,9-trien-2-one (A_1, a C_{13} unsaturated ketone), contains an isolated double bond in the 9,10 position, in addition to the dienone moiety. Several patents contain information on synthesis of hexahydropseudoionone — 6,10-dimethylundecan-2-one (A_4, a C_{13} saturated ketone) in the presence of 5% Pd/C, 5% $Pd/CaCO_3$, Pd/gauze, and Rh/gauze (50–70 °C, $P_{H_2} \leqslant 7$ MPa, yield 92.5%–96%).[50–53]



The liquid-phase hydrogenation of A_1 on 5% Pd/C has been found to yield products with various degrees of saturation: 3,4-dihydropseudoionone (*cis*- and *trans*-geranylacetone), 5,6-dihydropseudoionone (A_2), 3,4,5,6-tetrahydropseudoionone (A_3, citronellylacetone), and *cis*- and *trans*-isomers of 3,4,9,10-tetrahydropseudoionone.[54] Chromatographic analysis by the authors not only allowed them to detect these products in the reaction mixture but also confirmed that hydrogenation of ketone A_1 predominantly occurs via a multi-stage mechanism. Absorption of one mole of H_2 results in the formation of 70% of ketone A_2, and after absorption of two moles of H_2, 93% of ketone A_3 is produced.

In the hydrogenation of polyunsaturated and diene ketones in the presence of Ni[55] and Co catalysts,[56] as in the case of Pd catalysts,[46] H_2 adds mostly at the C(5)=C(6) double bond, and to a lesser degree it adds at the C(3)=C(4) bond. Modification of the Ni and Co catalysts with Pb, Cd, and Zn metals[48,49,55–59] or cations[60–62] changes the course of hydrogenation of this dienone: H_2 adds at the C(3)=C(4) bond conjugated with the keto-group. The catalysts used are Raney-type catalysts or blacks deposited on carriers (TiO_2, $Ca_3(PO_4)_2$, V_2O_5, ZnO, Al_2O_3, and MoO_3). Carriers affect the activity of catalysts without changing the reaction pathway.[57] Hydrogenation is carried out at temperatures of 20 to 125 °C and hydrogen pressures varying from atmospheric to 10.1 MPa; the amount of modifying additive is varied from 0.01% to 60% with respect to the weight of the catalyst. Modifiers not only affect the reaction pathway, but also lower activity of the catalyst and substantially decelerate hydrogenation of the carbonyl group.[49,59,62] The action of these additives cannot be reduced solely to poisoning the catalyst, they also promote it. Under severe conditions[59] the carbonyl group is reduced also on modified catalysts. Dienones (hepta-3,5-dien-2-one, 6-methylhepta-3,5-dien-2-one) and ketone A_1, the molecules of which contain diene groups, in the presence of both modified and unmodified catalysts behave in a similar way. This implies that the observed regularity is general: hydrogenation on catalysts modified with inorganic compounds begins with addition of hydrogen at the 3,4 positions. Introduction of pyridine leads to analogous results.[57]

It has been found that the structure of dienone influences the mode of addition of H_2.[59] For example, hydrogenation of hepta-3,5-dien-2-one and 6-methylhepta-3,5-dien-2-one in the presence of Ni catalyst modified with lead affords hept-3-en-2-one, hept-5-en-2-one, and 6-methylhept-5-en-2-one, respectively. Thus, in the latter case, hydrogen adds only at the C(3)=C(4) bond. This is probably due to the presence of a substituent at the C(6) atom and to a different orientation of the dienone molecule with respect to the surface of the catalyst.

Double bonds of a dienone are saturated either independently of each other or by 1,4-addition of hydrogen to the enone group. In fact, addition of hydrogen at the C(3)=C(4) bond, conjugated with the carbonyl group, may occur as the addition to the 1,4 positions of the enone system via intermediate formation of enol[60] (Scheme 2). In accordance with this Scheme, the final product, a ketone with a C(5)=C(6), is preceded by enol **8**, which is formed from the doubly-adsorbed substrate **4** via successive formation on the catalyst surface of semihydrogenated complex **5**, π-allylic complex **6**, σ-derivative **7**, and enol **8**. This Scheme has been confirmed by deuterium exchange. In the presence of the unmodified catalyst, enol is not produced.

Scheme 2

* is an active centre of the surface.

The results of these studies show that the change in the composition of the active catalyst surface caused by modification results in a change of its orienting properties and of the mechanism of the hydrogen addition to dienone.

A number of papers[16,63,64] present data on hydrogenation of pseudoionone under conditions excluding diffusion retardation. To increase selectivity of Ni catalysts the authors[63,64] used various modifying additives: K_2SO_4, KCl, KBr, and KI. It was found[63] that KI possesses the highest selectivity in the hydrogenation of the pseudoionone C=C bonds and all these modifiers, in terms of their selectivity, can be arranged in the sequence $K_2SO_4 < KCl < KBr \ll KI$.

When Zn and Cd halides were used, products of H_2 addition at the C(3)=C(4) bond of pseudoionone were detected in the catalysate. In the Fe^{2+}–Co^{2+}–Ni^{2+} series, the element with the greatest atomic number exhibits the highest catalytic activity.

The IR spectra of pseudoionone recorded after addition of $CoCl_2$ or $NiCl_2$ indicate that the additive interacts with the dienone system of the ketone: redistribution of the intensities of the absorption bands associated with the C=O group and the C=C–C=C bonds was observed.[16] Transition metal ions are likely to protect the ketone group against its reduction to an alcohol group.

To determine the optimum conditions for hydrogenation of the unsaturated ketone A_1 in the presence of the Ni–Co catalytic

system in isopropanol and to elucidate the reaction mechanism in detail, Sul'man[65,66] et al. investigated the kinetics of hydrogenation in a static system, varying the conditions of the process.

It was found that the reaction proceeds according to a parallel-sequential scheme [reactions (*1*)–(*4*), Scheme 3]. In addition to these reactions, transformation of the saturated ketone A_4 to the saturated alcohol A_5 ($A_4 \rightarrow A_5$) also occurs. The selectivity of hydrogenation of the C=C bonds in ketone A_1 diminished with increase in the temperature and hydrogen pressure. The highest selectivity with respect to ketone A_4 amounted to 95%–96%.

Hydrogenation of C_{13} and C_{18} polyene ketones in a dynamic regime in the presence of the Ni–Co catalytic system results in the accumulation of substantial amounts of saturated alcohols in the catalysate,[67] probably owing to retardation of internal diffusion.[68]

Hydrogenation of dienones is carried out not only on heterogeneous catalysts, but also in the presence of homogeneous catalysts, for example, Co complexes,[69,70] that are more selective in the formation of saturated ketones.

The saturation of polyenones in the presence of various catalysts may depend essentially on the initial concentration of the substrate and the nature of solvent. When the ketone concentration in the solution is increased from 10% to 50%, the reaction rate diminishes.[57] This can be attributed to adsorption of dienone from the catalyst surface with the displacement of hydrogen and to the complication of the process due to diffusion of hydrogen.

Experimental data on the kinetics of the hydrogenation of the ketone A_1 in Pr^iOH in the presence of 2% Pd/C are described by the linear relation[16,71–74]

$$\tau_{0.5} \sim q^n \quad (n = 1), \tag{4}$$

where $\tau_{0.5}$ is the time of half-conversion of ketone A_1 and $q = c_0/c_c$ (c_0 is the initial concentration of the substrate, c_c is the amount of the catalyst).

This relationship makes it possible to introduce the reduced time $\theta = t(c_c/c_0)$. Thus, the data obtained for different c_c values can be combined (Fig. 1).

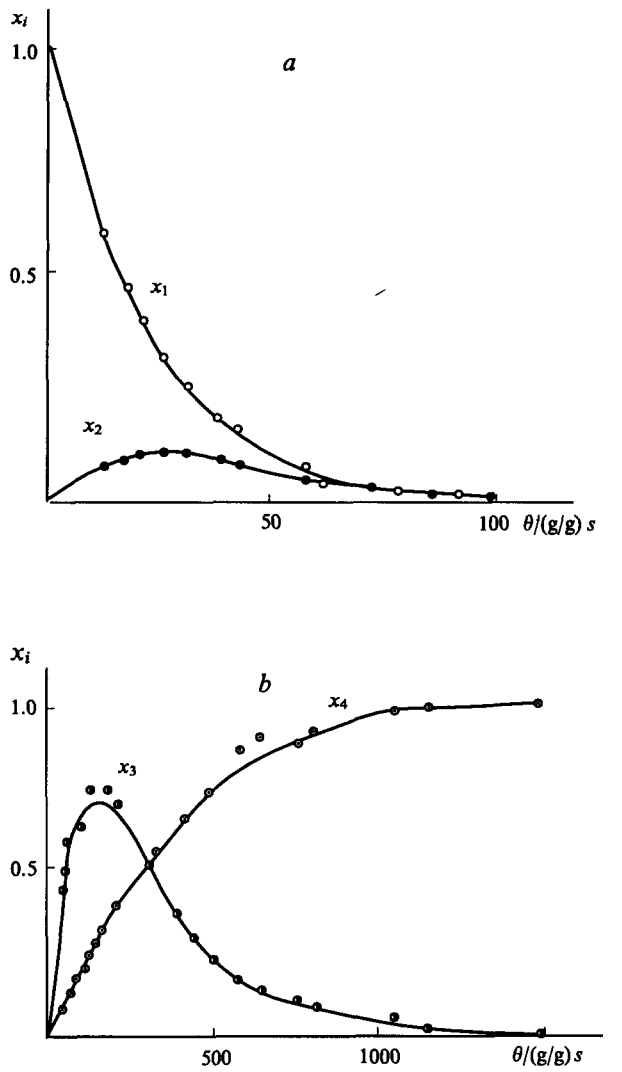
To explain the experimental data, various kinetic models have been used.[75] Application of the equation

$$W_i = k_i x_i \tag{5}$$

for describing the kinetics of the consecutive conversion of ketone A_1 to the saturated ketone A_4 led to systematic deviations of the calculated results from the experimental data. This fact, together with the possibility of direct addition of two or three moles of H_2 to ketone A_1, required consideration of a parallel-sequential Scheme 3. It has been noted that in the consecutive conversion of ketone A_1 to A_4, the first mole of H_2 (according to chromatographic analysis) adds predominantly at the C(5)=C(6) bond of A_1 and to a slight extent at the C(3)=C(4) and C(9)=C(10) bonds. In addition, it has been shown in special experiments that the kinetic model should be constructed with due regard for adsorption of ketone A_3. Statistical analysis showed that the best results have been obtained by using Eqn (2) and parallel-sequential Scheme 3 [(reactions (*1*)–(*3*)] with due regard for the adsorption of ketone A_3. The curves calculated from Eqn (2) are in good agreement with experimental curves (see Fig. 1).

Hydrogenation of ketone A_1 in the presence of 5% Pd/C under dynamic conditions proceeded nonselectively with formation of the saturated alcohol. This is accounted for by the influence of the internal-diffusion retardation on the reduction of this ketone on Pd/C and by lyophilisation of the system when charcoal is used as the carrier.[76]

For hydrogenation of pseudoionone, ethanol[54,76] and methanol[53,57,59] have been used as solvents. In a study[16,64] of hydrogenation of ketone A_1 in the presence of the Ni–Co catalytic system, it was found that the selectivity of the process is



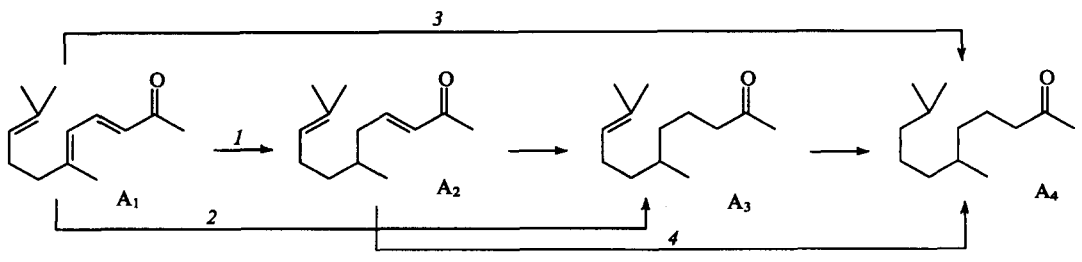


Figure 1. Composition of the catalysate in the hydrogenation of ketone A_1 in the presence of Pd/C ($T = 50\,^\circ C$, the hydrogen partial pressure is 2 MPa). Continuous lines show the results of the calculations; points correspond to experimental results.

Scheme 3

significantly affected by the nature of solvent (C_1-C_4 alcohols of normal and iso structures with addition of water were studied). In terms of the rate of the accumulation of ketone A_4, all these solvents can be arranged in the sequence: MeOH > EtOH > Pr^nOH + 15% H_2O > Pr^iOH + 5% H_2O > Pr^iOH > Pr^nOH > Bu^iOH > Bu^nOH. The optimum activity and selectivity (94%) of the Ni–Co catalytic system with respect to C=C bonds of pseudoionone were achieved in isopropanol. This is explained by the fact that isopropanol shows the least tendency to be adsorbed on Group VIII metals and, therefore, it weakens the interaction between the ketone and $CoCl_2$ in the solution bulk to a lesser degree.

The kinetics of hydrogenation of β-ionone in the presence of Pd and Ni catalysts have been studied both in open and in closed systems with varying conditions of the reaction and the nature of solvent.[77-80]

Of interest are papers dealing with hydrogenation of polyunsaturated ketones having more complex structures.[81-87] A method for preparing higher saturated ketones in the presence of the Pd/Al_2O_3 catalyst with a palladium content of 0.05 to 5 mass.% is described in a patent.[82] The yield of 6,10,14-trimethylpentadecan-2-one (A_8, a C_{18} saturated ketone) reached 95%. For selective reduction of unsaturated ketones to saturated ketones, an effective industrial Pd-based catalyst (ShPAK-0.5, 0.5% Pd/Al_2O_3) has been chosen.[16,84-87] The components used for its preparation, Pd/Al_2O_3 and Al_2O_3, were studied by various physicochemical methods [IR spectroscopy, X-ray photoelectron spectroscopy (XPS), extended X-ray absorption fine structure spectra (EXAFS), electron microscopy, and adsorption, analytical, and X-ray methods]. In conformity with EXAFS data,[88] it has been noted that the Pd–Pd distance increases upon deposition of palladium by 0.007 nm, which is due to the need for palladium to fit into the structure of the carrier. The free energy of the deposited palladium [$E_{fr}(Pd_{3d_{5/2}}) = 335.6$ eV] is close to that of massive palladium. The layers situated near the surface of palladium reduced in isopropanol contain carbon (Pd/C ~ 73). During thermal desorption (TDS), peaks due to hydrogen with T_{max} = 331 and 448 °C were detected, associated with destruction of hydrocarbons on the catalyst surface. Statistical analysis of the results of an electron-microscopic study of the catalyst active layer has shown that surface particles measure 2–5 nm; capillary impregnation of a sample with isopropanol made it possible to determine the average diameter of pores (9.5 nm) and porosity (0.57).[16]

In the presence of the ShPAK-0.5 catalyst, the kinetics of hydrogenation of pseudoionone have been studied, P_{H_2}, T_c, c_0, and c_c being varied over wide limits.[16,84] When the Pd/Al_2O_3 catalyst is used for the reduction of pseudoionone, the n value in Eqn (4) is 1, as in the case of Pd/C. The experimental results on the hydrogenation of pseudoionone under various reaction conditions are adequately described by Eqn (2), which suggests that hydrogenation of pseudoionone on Pd/Al_2O_3 and Pd/C proceeds via a common mechanism.

Hydrogenation of 6,10,14-trimethylpentadeca-3,5-dien-2-one (A_6, a C_{18} unsaturated ketone) in the presence of Pd/Al_2O_3 also occurs according to a parallel-sequential scheme (Scheme 4).

In this case, the n value in Eqn (4) is 1 or 2.[16,86] Experimental data were fitted using Eqn (4), and the optimum model for the process of hydrogenation of ketone A_6, which takes into account adsorption of the components of the reaction system, has been suggested.

$$W_1 = \frac{a_1 x_1}{(x_1 + Q_2 x_2 + Q_3 x_3)^n} \frac{P_{H_2}}{1 + b_1 P_{H_2}}, \quad (6)$$

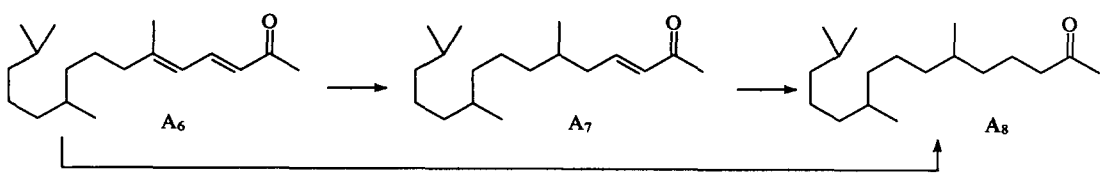
$$W_2 = \frac{a_2 x_1}{(x_1 + Q_2 x_2 + Q_3 x_3)^n} \frac{P_{H_2}}{1 + b_2 P_{H_2}}, \quad (7)$$

$$W_3 = \frac{a_3 x_2}{(x_1 + Q_2 x_2 + Q_3 x_3)^n} \frac{P_{H_2}}{1 + b_3 P_{H_2}}, \quad (8)$$

where $n = 1, 2$ and x_1, x_2, and x_3 are reduced concentrations of the unsaturated ketone A_6, 6,10,14-trimethylpentadeca-3-en-2-one (A_7), and the saturated ketone A_8, respectively. Parameters of Eqns (6)–(8) are listed in Table 1.

Table 1. The results of solving the inverse problem in terms of equations (6)–(8) for hydrogenation of ketone A_6 (50 °C).

$10^3 \times a_i$/mol² g⁻² s⁻¹ MPa⁻¹			b_i/MPa⁻¹			Q_2	Q_3
a_1	a_2	a_3	b_1	b_2	b_3		
3.51	1.43	0.77	0.93	1.00	1.35	2.11	0.62



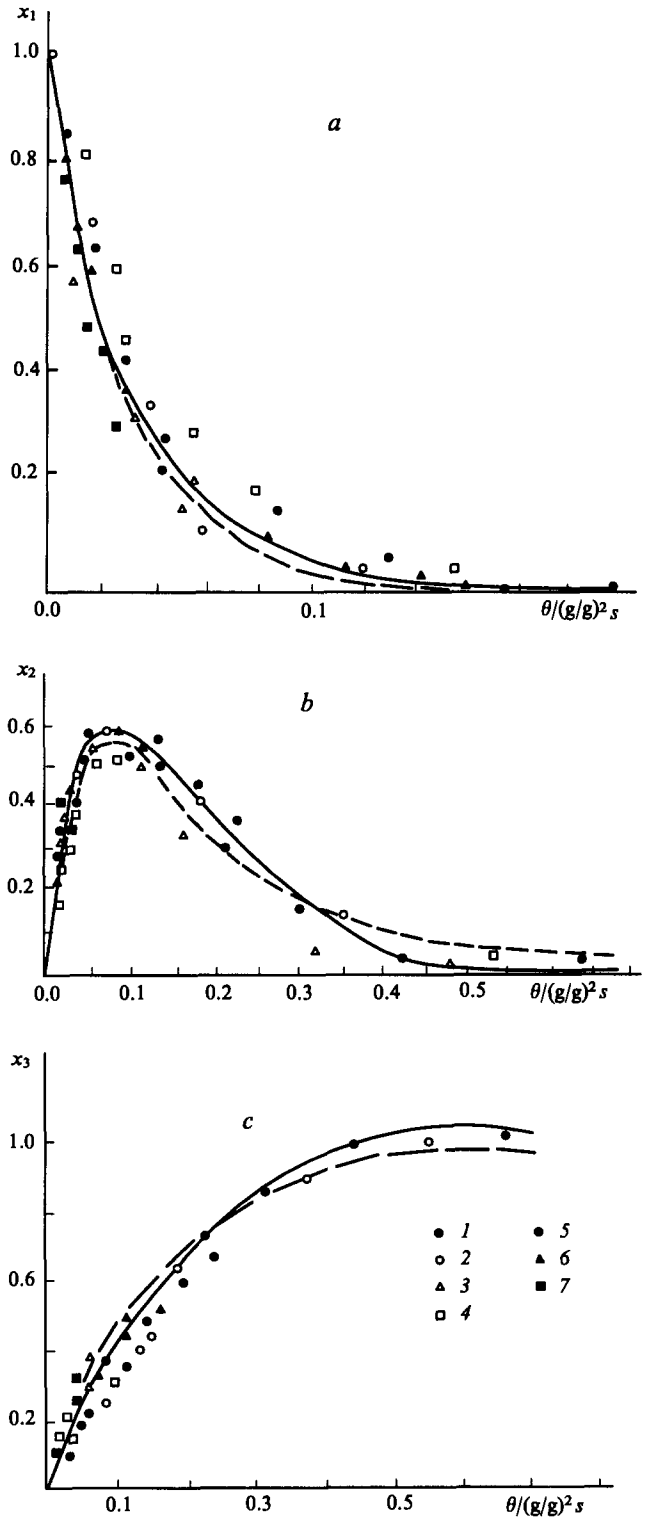
Comparison of the experimental and calculated curves (Fig. 2) showed that this model is in satisfactory agreement with the experimental observations: the error of the estimation of all the parameters of Eqns (6)–(8) lies within 10%. These equations attest to a complex mechanism of the hydrogenation reaction of ketone A_6.

In the physical justification of Eqns (6)–(8), we supposed[16] that the substrate is adsorbed on organometallic centres of the catalyst (Z')[89] that are formed as surface compounds, A_iZ' and $A_iZ'_2$, through the action of the substrate, solvent, and modifying additive. Hydrogen is activated on the metal atoms and diffuses to adsorbed substrate molecules.[90] Study of the influence of a competing inhibitor (pyridine) on the rate of hydrogenation of ketones A_1 and A_6, resorting to the XPS and TDS data, made it possible to conclude that the catalyst active centres have a complex structure; the IR spectra imply that the adsorption of ketones on the catalyst must be taken into account. The k_i, b_i, Q_i, and a_i parameters in Eqns (2) and (6)–(8) turned out to be complex combinations of constants.

It should be noted that in the presence of Pd/Al_2O_3, which is a selective catalyst of hydrogenation of polyunsaturated ketones, the saturated alcohol was formed neither under dynamic, nor under static conditions (the selectivity with respect to saturated ketones was 99.5%–99.7%).[91]

Metal-containing polymeric catalysts, for example those incorporating Rh, possess a number of advantages over traditional heterogeneous catalysts.[92,93] During the synthesis of a metallopolymer, formation of organometallic centres necessary for activation of the substrate is possible. To prepare rhodium-containing polymeric systems, the complex-formation reactions between rhodium chloride and rhodium carbonyl chloride and active olefin groups in a polymeric matrix have been

Scheme 4



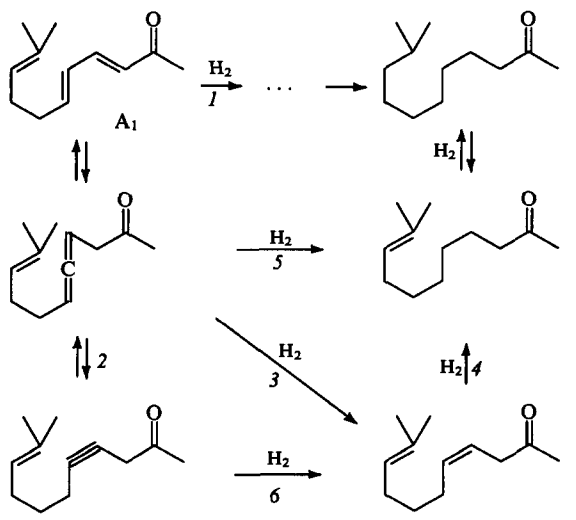


Figure 2. Generalised plots of the time variation of the composition of the reaction mixture during hydrogenation of ketones A_6 (*a*), A_7 (*b*), and A_8 (*c*) (Pd/Al_2O_3, $T = 25$ °C, $P_{H_2} = 2.5$ MPa). The continuous lines illustrate the results calculated according to model (6)–(8), the dashed lines correspond to the calculations according to the linear model, and the points are experimental results. q (g/g): (*1*) 37.5, (*2*) 71.4, (*3*) 75.0, (*4*) 107, (*5*) 143, (*6*) 250, (*7*) 750.

selected.[94] It was shown that the use of nonpolar solvents (benzene, toluene, hexane) results in deceleration of the hydrogenation. To the greatest degree this relates to hexane, possibly due to swelling of the polymeric catalysts in aromatic solvents, which results in increase in the number of available active centres. At the same time, polar aromatic compounds as well as THF, DMSO, and DMF are likely to be coordinated by the reactive centres of the catalyst, which leads to decrease in their activity. Good results were obtained when the hydrogenation of pseudoionone was carried out in alcohols. Isopropanol turned out to be the best, among the series of alcohols, as in the case of hydrogenation on the traditional heterogeneous catalyst, ShPAK-0.5 (Pd/Al_2O_3). Based on the study of the kinetics of hydrogenation of pseudoionone on a Rh-containing polymeric catalyst deposited on Al_2O_3 (Rh is twice deposited: on the polymer and on Al_2O_3), a kinetic model and a mechanism were proposed for the reaction. High stability of the Al_2O_3-deposited Rh-polymeric catalyst was noted.[95–97]

On an industrial scale, ketones A_1 and A_6 are produced by isomerisation of the corresponding allene ketones in ethanolic alkali. Hydrogenation of allene ketones in the presence of Ni and Pd catalysts was studied under static and dynamic conditions, the parameters of the process and the nature of solvent being varied over wide limits.[16] It was found that reduction of ketone A_1 occurs with a lower initial rate but much more selectively than that of ketone A_6. The selectivity of the hydrogenation of A_1 with respect to ketone A_4 in the presence of Raney Ni can be as high as 97.8%; that for the hydrogenation of A_6 with respect to A_8 is 53%.

The results of kinetic and spectroscopic studies suggest that in the presence of Pd/Al_2O_3 or the Ni–Co catalytic system, the reaction proceeds according to route (*1*) (Scheme 5) in all the solvents studied (C_1–C_4 alcohols of normal and iso structures, with or without addition of H_2O). In isopropanol in the presence of the Ni–Co catalytic system, route (*5*) is the predominant reaction path, and in the case of non-modified Raney Ni, routes (*2*) and (*6*) prevail.

Scheme 5

Analysis of the literature data on the selective hydrogenation of α, β-unsaturated and polyunsaturated ketones makes it possible to draw the following conclusions:

In the presence of platinum group catalysts, under mild conditions, the C = C bond in α, β-unsaturated ketones is reduced preferentially.

Pd- and Rh-containing polymeric and modified Ni catalysts (to a lesser degree) are the most selective catalysts of the hydrogenation of dienones and polyenones.

Highly selective addition of H_2 at the 1,2, 1,4, or 3,4 positions of the enone or dienone systems is possible, and C_{13} and C_{18} saturated ketones can be obtained from the corresponding allene ketones.

General features of the hydrogenation of unsaturated ketones have been identified:

Components of the reaction system affect significantly the selectivity and the activity of the catalyst with respect to double bonds of the ketone.

Interaction between the participants of the reaction, not only at the interface but also in the bulk of the solution, must be taken into account.

Heterogeneous catalysts can be modified not only by specially introduced additives but also by the solvent or substrate (this accounts for the observed nonlinear relations between kinetic parameters and the amount of catalyst).

Similar regularities are characteristic of the hydrogenation of acetylene alcohols.

III. Selective hydrogenation of acetylene alcohols

1. Catalysts for selective hydrogenation of C≡C bonds

A number of catalytic systems for selective hydrogenation of alkynes to alkenes have been described in the literature. Among these are homogeneous catalysts containing complexes of Group VIII metals (mostly Pd, Rh, Ni) with sulfur- and phosphorus-containing[98,99] ligands or nitrogen-containing organic chelating ligands (EDTA, ethylenamines, aminoacids, phenanthroline, morpholine, pyridine and its homologues, tertiary amines, etc).[100,101] Octylamine-based catalysts are most active in the hydrogenation of diphenylacetylene. Their selectivity with respect to the olefin amounts to 98%–100%. At the beginning of the reaction an induction period occurs, which disappears in the case where the complexes are first treated with hydrogen.[102]

However, homogeneous catalysts of the selective hydrogenation of acetylene compounds are not very effective from the technological standpoint. Therefore, in recent years studies on making them heterogeneous are being carried out.[103,104] In these studies, a modifying effect of oxygen and a substantial influence of a reduced hydrogen pressure ($\leqslant 0.01$ MPa) on the selective reduction of a C≡C bond to a C=C bond was found.[104] The selectivity with respect to olefin reaches 98%–99%. Unfortunately the above-mentioned papers contain no data on stability of the catalysts proposed.

Membrane catalysts based on Pd and its alloys have been considered as promising from the technological standpoint.[105–107] The high selectivity of conversion of acetylene alcohols in the presence of these catalysts is due to the fact that the concentration of hydrogen adsorbed on the catalyst surface and dissolved in its bulk can be controlled by varying the composition of the alloy and the hydrogen pressure at the operating side of the membrane. It was shown that these catalysts possess on average a 100-fold higher productivity per unit surface area than conventional catalysts,[108] the selectivity being 95%–99%.

However, supported catalysts are still the most technologically effective. One of the main lines of the search for selective catalysts of hydrogenation of acetylene compounds to ethylene compounds is modification of deposited Pd catalysts, which are most selective in the hydrogenation of a C≡C bond to a C=C bond. Heterogeneous catalytic systems for partial hydrogenation of a triple bond are listed in Table 2. Some authors (for example, Cerveny et al.[119]) attribute the enhanced activity and low selectivity of Pd/C with respect to formation of alkenes to the high degree of dispersion of the active metal on the carrier, however, they do not take into account the intensity of the interaction between the disperse phase and dispersion medium. On the contrary, Karturan et al.[128] have noted that Pd/SiO_2 possesses the maximum selectivity in the case where Pd is highly dispersed. Analysis of the data presented in Table 2 shows that the low-percentage Pd/Al_2O_3 catalyst modified with organic or inorganic substances is most widely used for the selective hydrogenation of C≡C bonds to C=C bonds.

Hydrogenation of dimethylethynylcarbinol. In a number of studies,[129–136] Pd catalysts modified with organic or inorganic additives were used for the selective hydrogenation of dimethylethynylcarbinol (DMEC, A_9, a C_5 acetylene alcohol) to the corresponding vinylic alcohol. For example, in a study of the reduction of carbinol A_9 yielding dimethylvinylcarbinol (DMVC, A_{10}, a C_5 ethylene alcohol) in the presence of 5%–20% $Pd/CaCO_3$ with addition of Zn, Cd, or Pb salts, it has been shown that the catalyst containing 20% Pd is the most selective. The dependence of the optimum modifier : catalyst ratio on the nature of the salt was noted; for Zn compounds this ratio is an order of magnitude higher, which is attributed to the lower adsorption ability of the Zn cation, as compared with Pb or Cd.[130]

It was found in a study of the hydrogenation of DMEC in the presence of 0.5% Pd/Al_2O_3 modified with the optimum amount of the specifically adsorbed Zn and Cd cations under static or dynamic conditions that the continuous process occurs with low selectivity, which, was suggested to be associated with transport phenomena.[129]

The selectivity of the reduction of DMEC to DMVC in the presence of the $Pd/CaCO_3$–$Zn(CH_3COO)_2$ catalytic system at a Zn : Pd atomic ratio of 0.75–5.87 was 92%–96% when 1 mole of H_2 had been absorbed; at this point the catalysate already contained 3.5%–5% of the saturated alcohol.[131] Introduction of nitrogen compounds (triethanolamine, triethylamine, NH_3) into this catalytic system suppresses hydrogenation of the C=C bond of the alcohol.

A catalyst for hydrogenation of DMEC to DMVC containing Pd and additives has been developed.[132] The laboratory and pilot

Table 2. Catalysts for the selective hydrogenation of C≡C bonds.

No. II/II	Catalyst, carrier, modifier, solvent, hydrogenation conditions	Ref.
1	Pd catalyst treated with alkali, 0–100 °C; 0.5–3.0 MPa	109
2	Pd/carrier (Al_2O_3, C, $CaCO_3$, $BaSO_4$, sepiolite), modified with heavy metal cations or organic amines	110, 111
3	the Lindlar catalyst, pyridine, in hexane	112
4	0.05% Pd/Al_2O_3	113, 114
5	0.05–5% Pd/Al_2O_3, $Pb(CH_3COO)_2$ or $Sn(CH_3COO)_2$ (modifier : catalyst = 2 : 5)	115
6	Pd/Al_2O_3 – Zn and/or, Cd, Bi and/or Tl	116
7	Pd/Al_2O_3 – Group VIB metals	117
8	Pd/Al_2O_3,$Pd/CaCO_3$, Pd/C	118
9	Pd/C, Pd/SiO_2 – Pb, Tl	119
10	0.1–60% of the hydrogenating Group VIII metal deposited on a carrier with 0.001%–10% of (Cd, Cu) oxides and 0.5–2% of K_2O added (relative to the overall weight of the catalyst)	120
11	Pd/carrier, Group IV elements (Sn or Pb)	121–123
12	Pd–Ag (Pd : Ag = 10 : 1)	124
13	Pd, modified with Ge, Sn, Pb or Sb	125
14	Pd/Al_2O_3 (0.3% Pd) with a Pd particle size of 8 nm	126
15	Zn – Cu, modified with alkali metals	127

tests on the hydrogenation of DMEC to DMVC showed that the Pd–Zn catalytic system is more active and selective than Pd–Pb.[133] The activity in the reduction of DMEC of low-percentage SiO_2-deposited Pd catalyst modified with chlorine-containing complexes of Ru(IV), Ir(IV), Rh(III) has also been studied.[134] In view of the fact that there is no additivity in the effect of the components of a catalyst on its activity and selectivity, it was suggested that heteronuclear metal complexes formed on the surface of the carrier are responsible for a definite reaction pathway. As has already been noted, the selectivity of the hydrogenation of DMEC to DMVC can be increased by using mixed catalysts. For this purpose, Pd–Cu/TiO_2 catalysts with various proportions of the active phase have been suggested.[135] The apparent activation energy for the hydrogenation of DMEC[136,137] varies from 16 to 50 kJ mol^{-1} and is determined by the nature of the components of catalytic system.

Hydrogenation of 3,7-dimethyloct-6-en-1-yn-3-ol. There are considerably fewer papers dealing with hydrogenation of 3,7-dimethyloct-6-en-1-yn-3-ol (DOL, A_{11}, a C_{10} acetylene alcohol). Interesting results have been obtained with Pd-based catalysts, which possess the highest selectivity.[138] When C_2–C_4 alcohols with the normal or branched structure are used as solvents, the proportion of linalool (LH, A_{12}, a C_{10} ethylene alcohol) in the catalysate is lower in the latter case. The selectivity of hydrogenation of DMEC to DMVC is higher than that of DOL to LH in all the alcohols. The apparent activation energy for the hydrogenation of DOL in the presence of Pd black amounts to 8.4–12.6 kJ mol^{-1}, i.e. it is lower than that for DMEC. At the same time, it has been shown[139] that lengthening of the hydrocarbon skeleton of acetylene alcohols from 5 to 8 atoms should be favourable for increase in the yield of the corresponding ethylene derivative in the hydrogenation process. Problems of selectivity of the catalytic hydrogenation of DOL have been considered in the literature.[118,140] Pd/$CaCO_3$ modified with Pb was used as the catalyst. However, the highest selectivity with respect to the conversion of DOL into LH is exhibited by γ-Al_2O_3-deposited Pd catalysts with a Pd content of 0.5%.[138] When the content of the active component is increased to 2%, the selectivity diminishes slightly, and when it is increased to 5%, the selectivity decreases substantially. Analysis of the degree of dispersion of Pd particles and their size distribution in the catalysts with different contents of the active component has shown that increase in the content of the active component results in increase in the proportion of particles of size 3.5–5 nm. The content of the dissolved hydrogen, promoting the saturation of a double bond,[128] in metal particles of diameter 5 nm corresponds to the ratio H : Pd = 1.[141,142] This is apparently the reason for the higher selectivity of 0.5% Pd/γ-Al_2O_3.

The influence of the hydrogen pressure in the range 1.01 to 5.05 MPa on the hydrogenation of DOL in the presence of Pd/Al_2O_3 has been studied.[138,143] A decrease in the selectivity at pressures above 3.03 MPa was observed. In the cases where the Pd/Al_2O_3 and Pd/$BaSO_4$ catalysts were used, the apparent activation energies were found to be approximately equal, while the reaction order with respect to the substrate is close to zero (in all the solvents) in the former case and is equal to unity (in EtOH) in the latter case. In addition, slight adsorption of the reaction products was observed.

The selectivity of hydrogenation of DOL, like that of DMEC, increases, when modifying additives are introduced into the reaction mixture.[144–146] A kinetic model for this reaction has been proposed.[147,148] Pd/C proved to be the least selective of the catalysts studied.[140,146]

Of interest are data on the hydrogenation of C≡C bonds of acetylene alcohols to C=C bonds in the presence of Pd immobilised in a polymeric matrix.[149]

This catalyst deposited on Al_2O_3[150] was used for preparing linalool. This system, like Rh-polymer/Al_2O_3 used for hydrogenation of unsaturated ketones,[95] possesses a series of advantages over the traditional heterogeneous catalysts, namely, high stability and mechanical strength, and requires no modifying additives (chemical poisons).

Hydrogenation of 3,7,11-trimethyldodec-1-yn-3-ol and 3,7,11,15-tetramethylhexadec-1-yn-3-ol. For hydrogenation of 3,7,11,15-tetramethylhexadec-1-yn-3-ol (dehydroisophytol, DHIP A_{13}, a C_{20} acetylene alcohol), the Lindlar catalyst prepared from commercial $Pb(CH_3COO)_2$ has been shown[151] to be more selective than this catalyst prepared from a preliminarily purified specimen. This fact led Rajaram and coworkers to the conclusion that microimpurities present in the commercial $Pb(CH_3COO)_2$ facilitate the selectivity of the process. In the list of these microimpurities they included Cu^{2+}, Cd^{2+}, Mn^{2+}, Fe^{3+}, and Co^{2+} ions and studied their effect on the selectivity of the Lindlar catalyst in the hydrogenation. The best results were obtained in the presence of $MnCl_2$, where the selectivity amounted to 97.2%.

A method has been patented for the selective reduction of acetylene alcohols in the presence of a Pd–M/carrier system (M is Zn, Bi, Cu, etc., the carrier is $CaCO_3$, $BaSO_4$, etc.) and a sulfur-containing or amino compound that are simply mixed with the Pd catalyst. The yield of isophytol was 98.3% and that of linalool was 98.6%.[152] Some authors recommend organophosphorus compounds as modifying additives for Pd catalysts of the hydrogenation of C_{20} acetylene alcohols and 3,7,11-trimethyldodec-1-yn-3-ol (dehydronerolidol, DHNL, A_{14}, a C_{15} acetylene alcohol).[153]

The hydrogenation reactions of C_5, C_{15}, and C_{20} acetylene alcohols to the corresponding ethylene analogues on Pd catalysts deposited on carriers of acidic or alkaline nature in the presence of iodides have been studied[154] under static and dynamic conditions in various solvents, varying the temperature, the hydrogen partial pressure, and the initial concentration of acetylene alcohol. An increase in the temperature and pressure was found to diminish the selectivity of the process. In the static system, the highest selectivity with respect to vinylcarbinol was achieved with Pd/$CaCO_3$ and Pd/ZnO–KI homogeneous-heterogeneous systems in MeOH. The author believe that the high selectivity observed with these carriers is due to their basic properties. They suggest that the reaction has the zeroth order with respect to substrate, though the relationships presented indicate that the reaction rate diminishes with decrease in the concentration of the substrate in the solution. The Pd/ZnO–KI system in EtOH was recommended for the reaction carried out under continuous conditions. However, the high starting selectivity of this catalyst (97.5%) quickly drops, due to gradual washing out of KI, which is readily soluble in EtOH.

A method of preparing ethylene alcohols from acetylene alcohols in the presence of the ShPAK-0.5 (0.5% Pd/Al_2O_3) catalyst modified with $Zn(CH_3COO)_2$, pyridine, and alkali has been developed.[16] The highest selectivity with respect to C_5, C_{10}, C_{15}, and C_{20} (99.2%–99.8%) ethylene alcohols in MeOH is achieved at a reduced hydrogen pressure. When catalysts with a controlled distribution of the active component[155] over a carrier grain have been used, high selectivity with respect to isophytol (98%) was achieved in the dynamic regime.[16] This is probably due to the absence of the internal-diffusion retardation.

Despite the fact that the use of modified Pd/Al_2O_3 for selective hydrogenation of the C_{15} and C_{20} acetylene alcohols is promising, studies aimed at the development of cheaper, more stable, more active, and no less selective catalysts are being carried out.[16] The research has several aims. The first of them is the development of novel Pd catalysts on polymeric carriers, the second is elaboration of methods for selective hydrogenation of acetylene alcohols in the presence of palladium-free catalysts, such as metal phthalocyanines (PcM) on oxides. PcM were chosen as the active component of the catalyst, in order to simulate the 'organometallic' active centre.

The selective hydrogenation of the A_{13} alcohol in the presence of Pd-containing polymeric catalysts with reaction parameters varying over wide ranges revealed the optimum substrate : catalyst

ratio, in terms of selectivity and duration of the reaction. This ratio confirmed that the formation of reactive complexes responsible for the reduction of the triple bond of the alcohol to the double bond is affected by the medium. Introduction of pyridine into the reaction system increases the selectivity of the conversion of the acetylene alcohol to the ethylene alcohol to 98%–99.3%.[149]

The selective hydrogenation of acetylene alcohols in the presence of PcM (M = Pd, Ni, Cu, Co) deposited on oxides (Al_2O_3, SiO_2) has been studied. The conditions in which the reaction was carried out, the nature of solvent, the method of the PcM deposition, and the content of the active component on the carrier have been varied. The experiments were carried out in the static and dynamic regimes.[16,156]

It was found[16] that transition from a polymolecular layer of PcM on the oxide carrier to a monomolecular layer results in an increase in the effectiveness of the catalytic action of immobilised PcM. The method of the PcM deposition on the oxide (from concentrated H_2SO_4 or from benzene) determines not only the activity of the catalyst but also the mechanism of its action. To elucidate the mechanism of the hydrogenation catalysis by PcM, kinetics of the hydrogenation of A_9 and A_{14} alcohols in the presence of $PcCo/SiO_2$ (0.2% Co, PcCo was deposited on the oxide from a solution in H_2SO_4) and $PcNi/Al_2O_3$ (0.2% Ni, PcNi was deposited on the oxide from a benzene solution) were studied. Under optimum conditions, the yield of the target product amounted to 99.2%–99.8%.

Analysis of the published papers allows the following conclusions to be drawn:

the most selective heterogeneous catalysts for hydrogenation of a triple bond to a double bond are Pd catalysts deposited on nonporous carriers ($BaSO_4$, $CaCO_3$) or on porous carriers (Al_2O_3, SiO_2) with small particles of the disperse phase (the latter has been satisfactorily confirmed by studies, which showed the dependence of the selectivity on the depth of the carrier porosity[128]);

modification of heterogeneous catalysts by inorganic additives of basic character, phosphorus- and sulfur-containing compounds, or salts of various metals favours an increase in the selectivity; the Pd–Zn system exhibits a fairly high activity with no loss in the selectivity;

catalytic systems based on PcM and Pd-containing polymers (on inorganic carriers) used for partial hydrogenation of C_5, C_{10}, C_{15}, and C_{20} acetylene alcohols possess high selectivities;

Pd/C has a low selectivity, which is attributed to the high degree of dispersion of this catalyst. The strength of the interaction between the disperse phase and the dispersion medium and thus the selectivity of the process can be controlled by varying the nature of the solvent and the concentration of the substrate.

2. The mechanism of the modification of catalysts for the selective hydrogenation of C≡C bonds

In a study of the selective hydrogenation of unsaturated ketones, interaction of the introduced additives with the solvent and the substrate within the bulk of the solution and an influence of the modifier on the heterogeneous catalyst have been observed.[16] The role of the modifier of catalysts of partial hydrogenation of C≡C bonds is that they poison the active centres at which further hydrogenation of the ethylene bond or hydrogenolysis of the substrate would have occurred[151,157,158] and promote the centres responsible for the saturation of the triple bond.[138] For example, it has been shown for Pd-containing catalytic systems that Pb, which blocks a part of the Pd surface, decreases the total adsorption of the hydrocarbon.[157] The centres with high bond energies are blocked first and, therefore, a sort of levelling of the substrate–metal bond energies occurs. The action of the modifying additives is explained as follows: the energies of metal–hydrogen and metal–substrate bonds and also the amount of hydrogen adsorbed change; the rate of release of the dissolved hydrogen decreases, since as a result of modification the activation energy of hydrogen desorption increases from 84 to 146.7 kJ mol^{-1}.[138,159] Thus, the addition of a modifying metal (for example, Pb or Zn) to the major component of the catalyst (for example, Pd) may change the electronic properties of the latter (the ligand effect) or the geometry of its surface.[160] The latter phenomenon is caused by a cluster effect or an ensemble effect.[161]

The cluster and ligand effects in bimetallic catalysts have been considered in detail in a review.[161] Clear-cut is the effect of modifying additives on the size of clusters of the active metal, which, in turn, determines the adsorption ability, activity, and selectivity of a catalytic system. The ligand effect, which is manifested as an electronic interaction between the modifier and the major component of the catalyst, causes the formation of strong bonds in the reactive complex. Charge transfer from the metal to the modifier or conversely is determined by the difference between the electronegativities of the components. In addition, the second component prevents carbonisation, poisoning, and agglomeration of a multicomponent catalyst. It also acts as a diluent of the surface, so that, of all the thermodynamically possible routes to the substrate transformation, only that reaction selectively occurs which requires a small ensemble. A definite concentration of the specifically adsorbed ions results, so that the dissolved hydrogen becomes the main hydrogenating agent.[159] However, this is inconsistent with the inferences of some researchers, who showed experimentally that the dissolved hydrogen exerts a negative effect on the selectivity of hydrogenation of acetylene compounds.[128]

Study of the thermal desorption of hydrogen and carbon monoxide from $Pd–Pb/Al_2O_3$ catalysts led Karski and Paryjczak[162] to the conclusion that the introduction of Pb into Pd/Al_2O_3 results only in a decrease in the amount of the gases sorbed, but causes no noticeable change in the activation energy of desorption.[162] In other words, these authors observed only the manifestation of the cluster effect.

Investigation of the mechanism of the action of poisons that enter in the composition of the Lindlar and Rosenmund catalysts is of some interest.[163] Analysis of the extensive literature data on the Lindlar catalyst and various methods for its modification, allowed the authors to conclude that the poisons are not involved in the catalytic process and do not occupy the active centres; they only change the structure of the catalyst surface. An electron-microscopic study showed that under the action of amines, species with low surface areas are formed.

Regarding the action of the Lindlar catalyst and the Lindlar catalyst–$MnCl_2$ catalytic system, two suggestions have been made:[151] 1) active ensembles for hydrogenation of a triple bond to a double bond and for hydrogenation of a double bond to a single bond are dissimilar; 2) there occurs a 'mobile' distribution of the cations of the modifying metal over the Pd surface. These suggestions have been confirmed by experimental results.

Effects of various substances, either present in the reaction mixture or added to it, on the selectivity of the catalytic hydrogenation of unsaturated compounds have been considered. It was noted that the mechanism of the action of additives is usually complex, nevertheless, in a number of cases it can be explained in terms of the ligand effect.[164] Introduction of electron-donor compounds, for example, piperidine, in a catalytic system results in an increase in its activity and selectivity with respect to the conversion of acetylenes to olefins.[165]

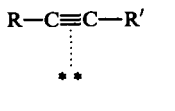
Comparing electronegativities,[166] electronic work functions, the first and second ionisation potentials, and standard electrode potentials[167] relative to Pd of the modifiers recommended in the literature, one may infer that the magnitudes of these parameters characterise to a certain extent the interaction between Pd and a modifier provided that there is information on the modification mechanism. For example, reasoning from electonegativities and assuming, as was done by Lindlar,[144] that a Pd–modifier catalytic system incorporates the modifier in the form of metal, one may conclude that modifiers act with respect to Pd as donor ligands.

A number of researchers, who have studied the action of a solution of $ZnCl_2$ (or $CdCl_2$) in a hydrogen atmosphere on the

reduced 1% Pd/Al_2O_3 catalyst, inferred that complex surface clusters, $Pd-Zn/Al_2O_3$ and $Pd-Cd/Al_2O_3$, are formed.[168]

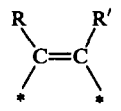
Of the possible modifiers for 0.5% Pd/Al_2O_3, $Zn(CH_3COO)_2$ was chosen.[16,169-171] The modified catalyst proved to be more selective in the hydrogenation of the A_{14} carbinol to isophytol (IP, A_{15}, a C_{20} ethylene alcohol) (93.2%) than the nonmodified catalyst (76%). Zn probably acts as a donor of electrons with respect to Pd and, therefore, it increases the possibility of the charge transfer to the acetylene alcohol. In addition, the metal–modifier bifunctional active centre levels the negative effect of the dissolved hydrogen. Finally, Zn prevents coke formation. All these effects ensure the higher selectivity of the modified catalyst. Modified Pd/Al_2O_3 was studied by various physicochemical methods. It was found that due to the modification of the catalyst, its porosity decreases from 0.57 to 0.04 and the effective pore radius decreases from 9.5 to 0.7 nm; this diminishes the influence of the internal diffusion in the hydrogenation of A_{14} in the kinetic regime. The increase in the degree of dispersion of surface Pd particles (2–3 nm) lowers the amount of the dissolved hydrogen and results in a higher selectivity of the conversion of the A_{14} alcohol to A_{15}. The decrease in $E_b(Pd_{3d_{5/2}})$ by 0.6 eV is attributed to the electron-donor properties of Zn. Based on the EXAFS spectra, the Pd–Zn distance was determined, and it was concluded that the interaction between Pd and Zn occurs via a ligand. Further modification of the catalyst with organic (pyridine) or inorganic (KOH) bases (base : catalyst = 1 : 10) made it possible to achieve the highest selectivity of the hydrogenation of the A_{14} acetylene alcohol to the A_{15} ethylene alcohol in the presence of this catalyst (99.2%).

3. Mechanism of the adsorption and catalysis of acetylene compounds

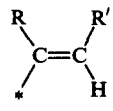


Acetylenic compounds, like ethylene compounds, can be adsorbed by both associative and dissociative mechanisms.[31,172] In the presence of hydrogen, acetylenes are adsorbed on the catalyst surface mostly by an associative mechanism.[173]

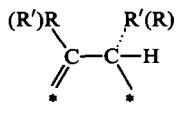
Considering adsorption of acetylene alcohols with various carbon chain lengths, one should take into account both inductive and mesomeric effects,[174] the latter withdrawing electron density from the triple bond to the oxygen atom.



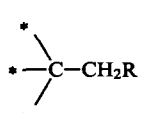
With increase in the carbon chain length, the inductive effect grows, which acts in the opposite direction, i.e. tends to increase the electron density at the C≡C bond. These effects, together with steric factors, govern the adsorption and catalysis in the case of acetylene alcohols.



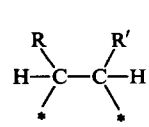
It has been suggested that selective catalytic hydrogenation of acetylene alcohols involves formation of the following surface structures:[151]



10



11



12

13

14

15

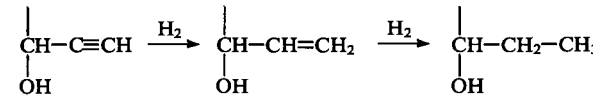
* is an active centre of the surface;

** is a diatomic active centre of the surface.

Intermediate compounds **10–12** may arise upon the reduction of an acetylene to an olefin, while structures **13–15** are intermediates on the way to the fully reduced products.

According to quantum-chemical calculations, the most probable mechanism of the hydrogenation of DMEC to DMVC involves formation of negatively charged forms of DMEC on the metal surface, though this does not rule out the possibility that the reaction occurs via an electronically excited form of DMEC, i.e. the participants of the catalytic system (modifiers, solvent) should be chosen in such a way as to provide the predominant electron transfer from the metal to the substrate.[175] Karavanov et al.[176] believe that the rate-determining factor in the hydrogenation of linalool is addition of the first mole of hydrogen.

All the foregoing attests to complexity of mechanisms of the catalysis and adsorption of acetylene compounds. This is probably due to the fact that active centres with different coordination numbers exist on the catalyst surfaces. The active centres with high coordination numbers, where a competing mechanism of adsorption is possible, are likely to prevail at faces of crystals. On the contrary, active centres with low coordination numbers, that favour formation of an involved multi-ligand complex on chemisorption, predominate at corners, edges, and defects. It should be noted that those alkynes[151] are involved in the complex formation, which change the surface structure of the catalyst in the course of the adsorption and catalysis.



In order to identify details of the mechanism of the selective hydrogenation of acetylene alcohols, kinetics of hydrogenation of C_5, C_{15}, and C_{20} alcohols under static conditions have been studied, such parameters as T_c, P_{H_2}, c_O, c_C, and the nature of solvent being varied.[16]

Using Eqn (4) and taking into account the formal expression

$$W_1' = \frac{a_i x_i}{xX_1 + Qx_2} \frac{P_{H_2}}{1 + b_1 P_{H_2}}, \qquad (9)$$

where x_i are the reduced concentrations of acetylene ($i = 1$), ethylene ($i = 2$), and saturated alcohols ($i = 3$), for the reaction sequence depicted in Scheme 6, we managed to fit the experimental data on the hydrogenation of acetylene alcohols in methanol (Fig. 3).

Scheme 6

Based IR spectroscopic data, acetylene and ethylene alcohols were arranged, in terms of their adsorption ability, in the sequence $C_{20} > C_{15} > C_5$; the selectivity of their hydrogenation changes in the reverse order.

It should be noted that the generalised curves (Fig. 3) have an induction period at $0 \leqslant \theta \leqslant \theta_i$, the duration of which depends on the nature of alcohol. The above-given equation (9) does not hold in this region. The experimental data in this region are adequately described by the following relation:

$$\frac{dx_1}{d\theta} = -\frac{B}{x_1^n}, \qquad (11)$$

where B is a parameter.

The results of the interpretation of the experimental data on C_5, C_{15}, and C_{20} alcohols are presented in Table 3. The induction period has been attributed to the formation of a hetero-ligand reactive complex, which is responsible for the selectivity of the process, on the catalyst surface. The higher the molecular mass (M) of the alcohol, the stronger is its coordination with the catalyst, the lower is θ_i and the selectivity of the process.

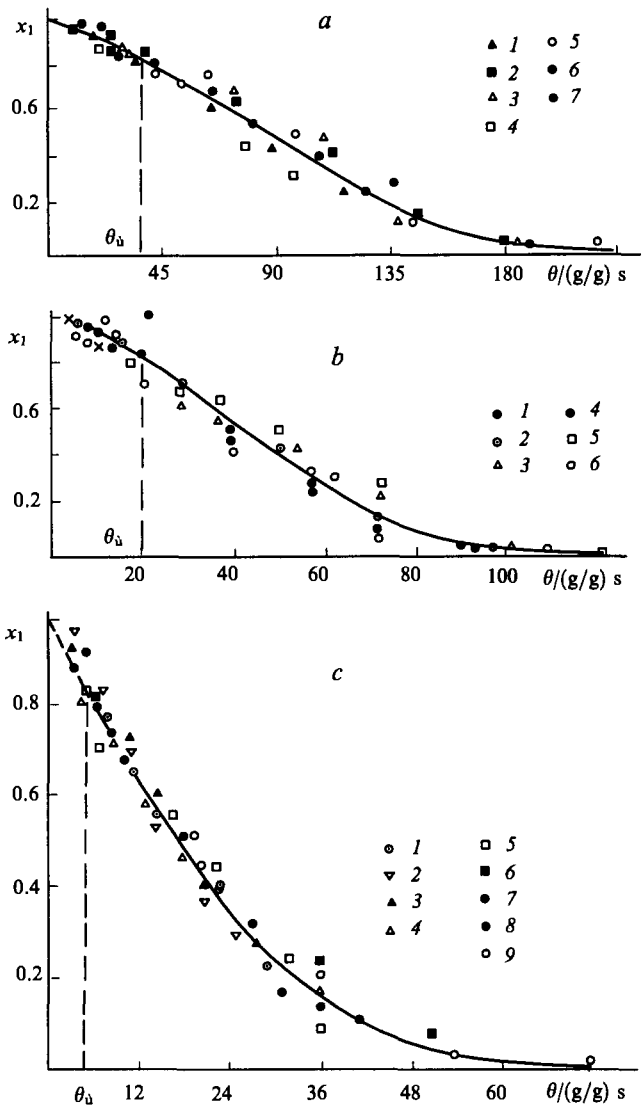


Figure 3. The dependence of x_1 on θ during hydrogenation of acetylenic alcohols A_9 (*a*), A_{13} (*b*), and A_{14} (*c*).
(*a*) T = 60 °C, P_{H_2} = 0.04 MPa, q(g/g): (*1*) 33, (*2*) 50, (*3*) 25, (*4*) 25, (*5*) 14, (*6*) 13, (*7*) 63;
(*b*) T = 40 °C, P_{H_2} = 0.07 MPa, q(g/g): (*1*) 55, (*2*) 50, (*3*) 30, (*4*) 15, (*5*) 15, (*6*) 100;
(*c*) T = 40 °C, P_{H_2} = 0.07 MPa, q(g/g): (*1*) 250, (*2*) 250, (*3*) 250, (*4*) 200, (*5*) 175, (*6*) 125, (*7*) 100, (*8*) 88.5, (*9*) 50.0

Table 3. The effect of the nature of alcohol on the characteristics of the induction period and the selectivity (S) of the process (T = 40 °C, P_{H_2} = 0.07 MPa).

Acetylenic alcohol	$n+1$	θ_i	S(%)
C_5	1.50	82.8	98.6
C_{15}	1.22	20.0	97.6
C_{20}	1.16	5.0	85.3

Analysis of the induction periods for acetylene alcohols affords the following relationship:

$$\theta_i = \frac{126\,764}{M^{1.65}} \quad (M^{n+1} = \text{const}). \tag{12}$$

On the basis of this equation, the θ_i and n values for dehydrolinalool were calculated: θ_i = 28 (g/g) s and $(n+1)$ = 1.32, which agrees with experimental results.[16]

Owing to the competing character of adsorption from solutions, the adsorption of substrates may be considerably affected by the ability of the solvent to solvate reactants and to be coordinated by the catalyst. When considering multi-component multiphase systems, one should take into account the strength of the interaction between the disperse phase and the dispersion medium and the phenomenon of drainage[177] of the dispersion medium from the gap (pore) formed by the lyophilic disperse phase. This accounts for the fact that the hydrogenation of A_{13} in isopropanol involves higher energetic barriers (45 kJ mol^{-1}) than that in methanol (25 kJ mol^{-1}) and that of all the solvents studied, methanol provides the optimum selectivity with respect to ethylene alcohols.

As a result of studies on adsorption and using IR spectroscopic data, we revised[16] the sites of the coordination of H_2 and acetylene alcohol to a PcM molecule. It turned out that the alcohol is coordinated by the nitrogen atoms of the azo bridges. At low P_{H_2} values, hydrogen is predominantly coordinated to the central metal atom, while at elevated P_{H_2} [10.1 MPa] it is coordinated to both the metal atom and the organic ligand.

Analysis of the literature data on the selective hydrogenation of acetylene alcohols in the presence of PcM attached to inorganic carriers, Pd-containing polymeric catalysts, and modified Pd catalysts made it possible to identify some general regularities: the reaction proceeds via a hetero-ligand reactive complex (solvent, substrate, hydrogen, catalyst, modifier, and carrier), which has a multilayer structure; all the participants of the complex (their nature and amount) exert a mutual influence on the catalytic activity and selectivity of the process; the reactants are activated on different active sites ('metallic' or 'organometallic'). The same regularities were found for the hydrogenation of unsaturated ketones. The catalytic system should be regarded as a homogeneous-heterogeneous system. The validity of this description is confirmed by the observed non-linear dependences of the reaction rates on the ratio between the concentrations of the participants of the reaction.

Metal-complex catalysts in the hydrogenation of unsaturated glycerides of natural oils

S R Savel'ev, N F Noskova

Contents

I. Introduction 937
II. Carbonyl, chelate, and other complexes of the Group VIII transition metals 937
III. Ziegler–Natta catalysts 938

Abstract. Information on the use of organometallic catalysts for the hydrogenation of natural oils published since 1979 is reviewed. Organometallic systems of the Ziegler–Natta type are shown to be the most promising. The nature of the catalytic activity of complex organometallic hydrogenation systems is discussed. The bibliography includes 84 references.

I. Introduction

Catalytic hydrogenation is the method mainly used in the treatment of natural oils and fats, and is widely used, for example, in the production of detergents and greases, in the oiling of leathers, and in the preparation of esters, especially in the food products industry.

The industrial production of hydrogenated fats for foodstuffs and for technical applications is carried out in the presence of heterogeneous, suspended catalysts, mainly based on nickel or on nickel–copper (with or without carriers), and also on stationary catalysts.[1] However, heterogeneous catalysts for the hydrogenation of fats have some serious shortcomings: their activity and selectivity are relatively low, and high temperatures and pressures are needed to obtain adequate performance.

In recent years studies of the hydrogenation of fats in the presence of metal-complex catalyts have attracted wide interest. Homogeneous organometallic catalysts offer a high selectivity in the hydrogenation of fats. The most promising metal-complex catalysts were found to be those of the Ziegler–Natta type, with an activity not only much greater than the activity of heterogeneaeous catalysts but also adequate for low-temperature operation. This feature not only safeguards the biological properties of the fats but also offers substantial savings in energy.

In the last 10–15 years there has been a marked jump in our understanding of the nature of the catalytic activity of organometallic catalytic complexes. The combined use of Mössbauer, EPR, and IR spectroscopy, of magnetic susceptibility methods, etc. have made it clear that associated polynuclear complexes are responsible for the catalytic effects.

The aim in this review is to assess the state and the prospects of this new field of study: the development and application of metal-complex catalysts for the hydrogenation of the unsaturated glycerides of oils and fats. Much of the work on the Ziegler–Natta catalysts discussed in the review was carried out at the laboratory for organometallic catalysts of the Institute for Organic Catalysis and Electrochemistry of the National Academy of Sciences of the Republic of Kazakhstan.

II. Carbonyl, chelate, and other complexes of the Group VIII transition metals

The main constituents of fats and oils are the triglycerides, containing radicals of saturated (palmitic, stearic, etc.) and of unsaturated fatty acids (oleic, linoleic, linolenic, etc.).

The first review of studies of homogeneous hydrogenation was published by James.[2] It dealt mainly with the work of Shashimoto, Frankel, and Cecchi.

James pointed out that a stage of positional isomerisation of the non-conjugated substrate (triene, diene) into the conjugated analogue precedes the hydrogenation of linolenate and of linoleate in the presence of metal carbonyls and of the phosphine complexes of Pt, Pd, and Ni. The substrate can be activated either directly or after the formation of the mono- or dihydride of the transition metal. Active catalytic systems can be formed after the dissociation of the ligand (as in the case of metal carbonyls), or alternatively they can be formed after solvation (acetylacetonates) or as a result of ligand substitution (platinum tin chloride systems).

Later studies were devoted to the kinetic properties, to establishing the nature of the catalytically active complexes, and to formulating practically convenient catalytic systems.

Ucciani et al.[3] showed that $HCo(CO)_3$ is the active component of catalytic sytems based on $Co_2(CO)_8$. He proposed a catalytic hydrogenation cycle in which the first activation stage includes the conjugation of the unsaturated compound. The description of a cobalt catalyst protected by an envelope of fully hydrogenated palm oil[4] is also of interest.

Of the known metal carbonyls the most promising catalysts for the hydrogenation of fats and oils are the arenechromium complexes, characterised by a high selectivity and a strong suppression of the *cis–trans* isomerisation processes.[5] Hydrogenation takes place slowly [approximately 0.1–0.6 mol H_2 (g-at Cr)$^{-1}$ min^{-1}] at temperatures above 423 K and hydrogen pressures of 2–10 MPa, and the composition of the liquid hydrogenated product is close to the fatty acid composition of oleic acid.

During hydrogenation in the presence of benzoato and polystyrene metal complexes[6] the conjugated esters of soya bean oil showed an enhanced selectivity towards the formation of dienes from trienes in comparison with the hydrogenation of nonconjugated esters, the content of *trans* isomers being only 1%–3%.

The activity of chromium carbonyls is increased by the action of ultraviolet radiation on the catalyst,[7] and also by supporting the catalyst on the surface of poly(phenylsilicon).[8] In the latter case the selectivity of the hydrogenation is also enhanced.

High selectivity is also found in other chromium carbonyl catalysts based on $Cr(CO)_3PPh_3$, which were studied[9] in connection with the hydrogenation of canola oil at 473 K and 1.7 MPa.

Among the chelates the acetylacetonates and bissalicylaldiminates are most often used for the hydrogenation of fatty acids and their methyl esters. The main advantage of these systems is the almost complete absence of conjugated dienes and *trans* isomers among the products (<0.1%). In the presence of palladium acetylacetonates hydrogenation is carried out at 323–353 K and 0.5–5.0 MPa (see Refs 10 and 11). Chelates of Pd(II), Pd(0), Ni(0), and Rh(I) were studied in the hydrogenation of the methyl esters of the acids in soya bean oil.[12] The reaction with $NaBH_4$ was used to activate the complexes. With high metal contents in the substrate (1–2 mass%) the hydrogenation proceeds at 323–373 K and 0.5–1.0 MPa with a selectivity close to that of heterogeneous catalysts.

By supporting the palladium complexes on phosphinated polystyrene[13] the reaction could be carried out under mild conditions (213–353 K and 0.1 MPa) with a low Pd content in the substrate (40 mg Pd per 1 kg of ester).

Workers at the Petrochemicals Synthesis Institute of the Russian Academy of Sciences have recently synthesised new highly active catalysts, based on complexes of palladium with ligands containing nitrogen and supported on Al_2O_3, for the hydrogenation of the triacetylglycerides of fats.[14–16] The catalysts performed successfully in tests on a large laboratory pilot plant model of an industrial hydrogenation reactor. IR spectroscopy results led to the conclusion[14–16] that in this case the catalytic activity is due to the hydride forms of palladium produced during the reaction.

The properties of cationic rhodium catalysts have been studied in depth during the hydrogenation of methyl linoleate and its isomers under mild conditions, using $[Rh(NBO)L_2]^+PF_6^-$ (L = $P(i\text{-}C_4H_9)_3$, $P(C_2H_5)_2(C_6H_5)$, and $P(CH_3)_3$; NBO is norbornadiene).[17] The course of the reaction depends on the nature of the ligand (catalyst). Thus, whereas in the presence of a catalyst with L = $P(C_2H_5)_2(C_6H_5)$ the hydrogenation of methyl linoleate proceeds through a conjugated intermediate state, when a catalyst with L = $P(CH_3)_3$ is used one of the C=C bonds is directly hydrogenated.

Systems of the type of $RhBr[P(C_6H_5)_3]_3$ and $[Rh(NBO)diphos]^+$ [where diphos is $(C_6H_5)_2P-CH_2-CH_2-P(C_6H_5)_2$] are active catalysts for the hydrogenation of fats, and they give products containing only low amounts of the *trans* isomers.[18–20]

The use of ruthenium complexes has been discussed,[21–26] and their high selectivity towards the formation of monoenes has been stressed. By depositing the complex $RuCl_3[As(C_6H_5)_3]_2.CH_3OH$ on montmorillonite and then reducing it to $RuCl_2(H_2)[As(C_6H_5)_3]_2$ (see Ref. 23) those workers were able to hydrogenate jujube oil, which contains the esters of the C_{40-44} acids and C_{20-22} alcohols, and also unsaturated acids in dioxan at atmospheric pressure and 293–318 K. When supported on clay the catalyst is stable and can undergo many cycles without significant changes in structure or in activity.

It has been concluded[26] that the active ruthenium catalyst prepared by dissolving $RuCl_3$ in ROH (R = $i\text{-}C_3H_7$, $n\text{-}C_4H_9$, $n\text{-}C_6H_{13}$, $n\text{-}C_8H_{17}$) is a hydride complex of ruthenium formed by the dissociation of the alkoxide of ruthenium in a hydrogen atmosphere.

III. Ziegler–Natta catalysts

1. Use of the catalysts in the hydrogenation of fats

Systematic studies of the hydrogenation of fats with catalysts of the Ziegler type have recently been reported from laboratories in Czechoslovakia,[27–34] France,[35–39] the USA,[40–42] and Kazakhstan.[43–58]

The first of these groups of workers used the pentadionates,[31] carboxylates,[32] acetylacetonates,[27,28] and n-butyl-salicylaldiminates[29] of nickel and other metals as catalysts, and triethylaluminium and sodium bis-(2-metoxyethoxy)dihydroaluminate, $NaAlH_2(OCH_2CH_2OCH_3)_2$ as the alkylating component. The hydrogenation takes place both with and without a solvent. As reported,[28] the methyl esters of soya bean oil were hydrogenated under mild conditions for a catalyst concentration of 0.05% Ni in the substrate and an Al:Ni component ratio in the catalyst varying from 0.2 to 3.0. The need to use a molar excess of the organoaluminium component has been explained[28] by postulating the hydrogenation mechanism proposed by Sloane:[59]

$$AlR_3 + NiX_2 \longrightarrow R_2AlX + RNiX,$$

$$RNiX + H_2 \longrightarrow RH + HNiX,$$

$$\backslash C{=}C / + HNiX \longrightarrow HC(\backslash)-C(/)-NiX,$$

$$HC(\backslash)-C(/)-NiX + H_2 \longrightarrow HC(\backslash)-CH(/) + HNiX.$$

It is suggested that under the chosen conditions the alkylation of NiX_2 is acceptably fast only at high enough concentrations of triethylaluminium in the reaction mixture. The authors[28] do not limit the role of the aluminium alkyl to the initial activation of the system: they assume the possibility of alkylation of the dimeric nickel compound $(NiX)_2$ formed by the reaction

$$HC(\backslash)-C(/)-NiX + HNiX \longrightarrow HC(\backslash)-CH(/) + (NiX)_2.$$

Systems based on $NaAlH_2(OCH_2CH_2OCH_3)_2$, unlike those based on triethylaluminium, are effective in the hydrogenation of fats even with no solvent (353–423 K, 0.1–2.0 MPa).[27,28]

Since one of the main obstacles to the practical use of Ziegler catalysts in the hydrogenation of fats is the difficulty of separating them from the final product and of using them repeatedly there has been great interest in a method of hydrogenating the esters of unsaturated fatty acids using nickel bis-(n-butylsalicylaldiminate supported on oxide carriers (aluminosilicate or aluminium oxide), or activated $Al(C_2H_5)_3$ or $AlCl(C_2H_5)_2$ (see Ref. 29). At 293–298 K and hydrogen pressures of 0.1–0.15 MPa rapeseed oil was satisfactorily hydrogenated re-using the catalyst three times without any loss of activity [the specific rate of the hydrogenation was W_{sp} = 1.2–20.5 mol H_2 (g-at Ni)$^{-1}$ min^{-1}]. The catalyst was separated from the product by simple filtration.

In the case of an unsaturated catalyst the separation required special procedures such as treating the solution with concentrated phosphoric acid or an aqueous solution of the same acid,[34] and saponification with an aqueous solution of metal hydroxide or carbonate at 313–353 K (see Ref. 33).

French workers have made valuable contributions to studies of the hydrogenation of fats by assigning the Ziegler catalysts to the 'superactive' class.[35] By hydrogenating five tonnes of castor oil in an industrial plant at a relatively low temperature (433 K) and hydrogen pressure (1.5 MPa) they established that the activity of the Ziegler nickel catalysts is 22 times greater than the activity of heterogeneous industrial nickel.[35] They suggested[35] that the low concentration of the nickel (between 10 and 200 ppm) and its high activity should more than outweigh the cost of the Ziegler catalyst.

The hydrogenation of castor oil on these catalysts is selective, and the unwanted 12-ketostearic acid is formed in negligibly small amounts, which is an additional advantage of these systems over the heterogeneous nickel catalysts. Futhermore an original and economical way of separating the catalyst from the product was found. Vigorous stirring of the hydrogenation product with 10% of water at 373 K produces a precipitate from which a final product containing only 0.0001% of Ni can be separated by filtration with 0.2% of coactivator.

The work of the French scientists stimulated world-wide interest, and was patented in 10 countries. These disclosures [36,37] described the hydrogenation of solvent-free soya bean oil with a catalyst prepared from a transition metal salt and a hot concentrated solution of aluminium alkyl, which is undoubtedly the main drawback of this method. A wide range of transition metals was specified as hydrogenation catalysts (Ni, Cr, Ag, Cu, Ni–Ag, Ni–Mn, Ni–Fe, Ni–Cu) in the form of palmitates, stearates, oleates, octoates, etc. Metal complexes supported on oxide carriers (Al_2O_3, SiO_2, Cr_2O_3) were used in some experiments. It was shown that the most active of these catalysts is nickel stearate ($NiSt_2$) [W_{sp} = 16.3 mol H_2 (g-at Ni)$^{-1}$min^{-1}], and that with this catalyst the selectivity of the conversion of dienes into monoenes can reach 76%. Highly selective catalysts based on $NiSt_2$–$CuSt_2$ and on $Ni(acac)_2Py_2$ have a low activity [W_{sp} = 0.63 and 0.9 mol H_2 (g-at Ni)$^{-1}$ min^{-1} respectively].

A modelling method based on the chemical introduction of labels into linolenic, linoleic, and oleic acid chains has been used to explain the mechanism of the selective hydrogenation of fats. [38] It was shown that linolenic acid hydrogenated on a nickel catalyst to the complete conversion of the triene contains not only 3.5%–5.0% of the diene but also 3%–4% of the monoene (the initial concentration of linolenic acid was 7%–10%). Therefore the saturation of the triene is accompanied by saturation of the resulting diene.

Simultaneous saturation of the diene and the monoene takes place during the hydrogenation of the methyl esters of soya bean oil. [39] A catalytic cycle including a complex of Ni(0) with a coordinated diene and monoene has been proposed [39] on the basis of the observation that the oxidative addition of hydrogen takes place after the coordination of the substrate (with the metal) to the so-called 'exposed nickel' by the scheme

$$Ni(OOCR)_2 + Al(C_2H_5)_3 \longrightarrow \longrightarrow Ni(C_2H_5)_2 + Al(C_2H_5)(OOCR)_2,$$

$$Ni(C_2H_5)_2 \longrightarrow Ni^0 + 2(C_2H_5)^{\cdot},$$

$$2(C_2H_5)^{\cdot} \longrightarrow C_2H_4 + C_2H_6.$$

The main conclusion reached [39] in respect of the selectivity of these systems is that the final product contains an enhanced amount of stearate: this is thought to be an unavoidable disadvantage of the nickel Ziegler catalysts.

However, as will be shown below, by using some strictly defined catalyst preparation conditions and an Al-organic component (of the alumoxane type) we can obtain nickel systems in which the hydrogenation of a diene to a monoene takes place with a selectivity of 93%–100%.

A selective catalyst for the hydrogenation of the linolenate to the linoleate in soya bean oil, based on copper stearate with triethylaluminium and diethylmagnesium, has been described. [40] At 443 K, with a hydrogen pressure up to 1.5 MPa and a copper concentration in the oil of 0.1%–0.025%, the concentration of linolenate in the product could be lowered to 0.75% while the concentration of stearate increased from 3.9% to 5.2%. An increase in the activity of these systems was achieved by using trialkylsilicon as the alkylating component, but in this case the selectivity was slightly suppressed. [41]

A detailed description of the properties of copper catalysts and of the methods of increasing their activity has been published. [40] The activity of the copper catalysts is strongly influenced by the nature of the alkylating component, whose favourable effect increases in the sequence

$$Al(C_2H_5)_3 < Al(C_2H_5)_2(OC_2H_5) < < Mg(C_2H_5)_2 < AlH(i\text{-}C_4H_9)_2 < Al(n\text{-}C_4H_9)_3.$$

The addition of aluminium oxide to the $CuSt_2$–$Al(C_2H_5)_3$ catalyst increased its activity five-fold. [42] This activating action of the Al_2O_3 was explained by the adsorption on the carrier of harmful impurities (phosphatides, free fatty acids, etc.) which poisoned the catalyst. An experiment on the hydrogenation of soya bean oil with the addition of various amounts of ethanol has been described. [42] The addition of 0.5% of ethanol lowers the iodine number by 20 units (i.e. it activates the catalyst) as compared with the catalyst without the addition. Additions of 1%–2% of ethanol have the opposite effect, and in the presence of 5% of ethanol the hydrogenation of the oil is almost totally suppressed. According to Koritala [42] this is because of the interaction between ethanol and $Al(C_2H_5)_3$. A concentration of ethanol of 0.5% is sufficient to replace one ethyl group in the $Al(C_2H_5)_3$ by an ethoxy group; the resulting $Al(OC_2H_5)(C_2H_5)_2$ produces a better catalyst with the copper stearate than $Al(C_2H_5)_3$. At higher ethanol concentrations the triethylaluminium begins to decompose.

A programme of studies [43–53] of the hydrogenation of sunflower oil in a solvent (heptane) at 293–353 K involved a wide range of catalysts based on nickel, cobalt, chromium, copper, and iron stearates, and their mixtures with an alkylating agent (triethylaluminium). The following sequence of activities was noted: $NiSt_2 > CoSt_2 \gg FeSt_3 > CrSt_3 > CuSt_2$. The Al:M ratio needed to prepare the catalysts with the greatest hydrogenation activity was strongly temperature-dependent. The kinetic order was zero with respect to the substrate and close to unity with respect to the catalyst and the hydrogen. In every case the selectivity of the hydrogenation of linoleate to oleate increased with temperature and with the concentration of the substrate.

Supporting the stearates of Ni, Co, and Fe on Al_2O_3 increased the activity of the organometallic catalysts in solution, but lowered their selectivity. [45–48] The $NiSt_2/Al_2O_3$–$Al(C_2H_5)_3$ catalyst was proposed for the preparation of tristearin under mild conditions. [49]

The greatest increase in the activity of the catalyst by depositing it on a carrier (almost 60-fold as compared with the unsupported catalyst) was achieved in the $FeSt_3/Ni(OH)_2$–$Al(C_2H_5)_3$ system (see Ref. 50). The maximum rate [225.1 mol H_2 (g-at Fe)$^{-1}$ min^{-1}] was observed for a 50% content of the iron stearate on $Ni(OH)_2$.

With the aim of intensifying the hydrogenation of vegetable oils in solvents, Marusich and Noskova [51] examined the use of donor additives to the $NiSt_2$–$Al(C_2H_5)_3$ catalyst (water, glycerol, the tributyl ester of phosphoric acid, and ethanol). The additives increased the rate of the reaction by a factor of 1.2–1.8. The highest rates were observed for the following ratios between the additive and the nickel: 5:1 (water and ethanol), 1:1 (tributyl phosphate), and 5:1 (glycerol). Unlike Koritala, [42] who attributed the activating effect of ethanol to the formation of ethoxy groups, Marusich and Noskova [51] postulated the formation (in the case of water and ethanol) of alkylalumoxanes, i.e. of compounds containing an Al–O–Al group [$R_2Al(OAlR)_nOAlR_2$]. In fact, special experiments with different alkylalumoxanes [54–81] produced very active, selective, and thermally stable catalysts for the hydrogenation of fats.

Table 1. Effect of the nature of the Al-organic component of an organonickel catalyst on the activity, selectivity, and thermodynamic characteristics of the hydrogenation of the glycerides of sunflower seed oil (for the optimum Al : Ni ratios).

[a] ΔE^* is the apparent activation energy. [b] ΔS^* is the entropy of activation.

Noskova and co-workers [69, 70] used a wide range of aluminium trialkyls (R = C_2H_5, i-C_4H_9, C_9H_{19}) and alumoxanes (R = C_2H_5 and i-C_4H_9 and n = 0, 2, 4, 8, 18, and 21) as alkylating components, and found that in the absence of a solvent the selectivity of the hydrogenation is almost unaffected by the nature of the alkyl radical (Table 1). Therefore the ratios of the stability constants of the complexes with linoleate and with oleate and those of the rate of transformation of linoleate and oleate are not very different for complexes with different R. On the other hand the suppression of the rate of hydrogenation at 313 K by increasing the molecular mass of the organoaluminium compound is explained by the decrease in reducing power in the series C_2H_5, i-C_4H_9, C_9H_{19} and by the increased steric hindrance to the activation of the substrate.

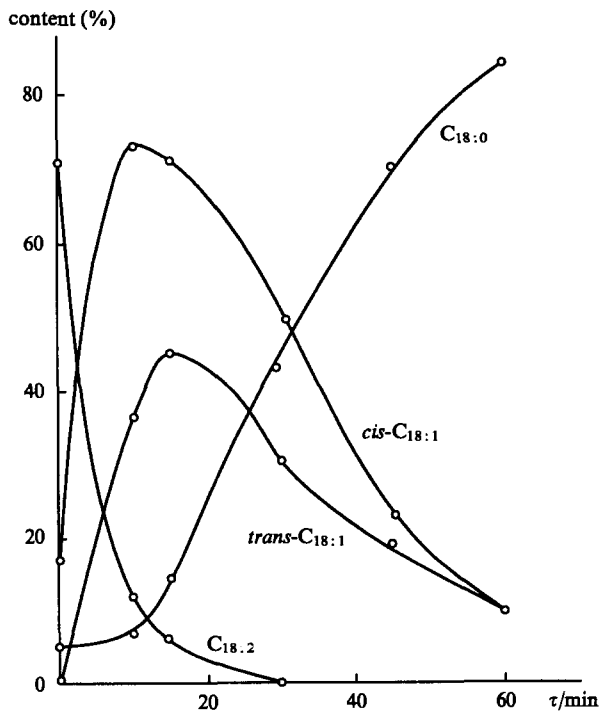

Figure 1. Kinetics of the hydrogenation of sunflower oil: changes in the fatty acid composition of the catalysate obtained on $NiSt_2-Al_2O(C_2H_5)_4$ (Al : Ni = 11, 423 K, 0.05% Ni in oil).

An oil without solvent is hydrogenated more slowly than in heptane (see Table 1). In the absence of a solvent the reaction takes place on all the catalysts with a selectivity of 92% – 100% towards the conversion of linoleate into oleate.

The kinetics of the hydrogenation of sunflower seed oil (1 kg) and the change in the fatty acid composition at 423 K and atmospheric pressure are shown in Fig. 1. The hydrogenation of the linoleate in the presence of 0.047% of Ni in the oil goes practically to completion in the first 15 minutes, during which the concentration of stearate increases from 4.5% to 16%. The rate of hydrogenation of the *trans* unsaturated isomers is lower than the rate of hydrogenation of the linoleate and of the *cis* isomers of oleic acid. After 60 min 11% of the *trans* isomer of oleic acid is the only unsaturated acid remaining in the oil.

Comparing the activities of the organometallic catalyst $NiSt_2-(i\text{-}C_4H_9)_2Al_2OAl(i\text{-}C_4H_9)_2$ with that of the industrial heterogeneous catalyst DM-3 (USA) showed that in the presence of the former a 60% – 63% conversion of the ester is achieved in 10 – 15 min of hydrogenation at 423 K, whereas in the presence of DM-3 the same extent of conversion requires 60 min at 473 K.

Using Ziegler catalysts based on $NiSt_2-Al(C_2H_5)_3$ at 423 K under a pressure of 1.0 – 9.0 MPa the hydrogenation of the ethyl esters of fatty acids can be controlled towards the formation of saturated fatty acids. [71]

A catalyst similar to the Ziegler systems was obtained [72] by activating $Ti(C_5H_5)Cl_2$ with magnesium. The authors stressed [72] that this catalyst is effective in the hydrogenation of methyl linoleate at room temperature, but only in the presence of triphenylphosphine.

2. Nature of the catalytically active complexes

A detailed study [69] of the catalysts based on $FeSt_3-Al(C_2H_5)_3$ by Mössbauer, IR and EPR spectroscopy, magnetic susceptibility, and other methods allowed their structure to be established. High-spin Fe(III) and Fe(II) complexes were detected, and also polynuclear (at the transition metal) associated formations containing bound iron ions. All the complexes are mutually in a dynamic equilibrium depending on the genesis of the catalyst (relative concentrations of aluminium and iron, temperature of the process, carrier, nature and concentration of the solvent and of the gases, atmosphere, time of formation of the complex, presence and nature of a substrate). Polynuclear associations are formed as a result of the interaction of complexes of different valencies between the transition metal and the trialkylaluminium. Calculations of the number of transition metal ions in the association showed that for an Al/Fe ratio of 7 – 9 up to several tens of iron ions may be present.

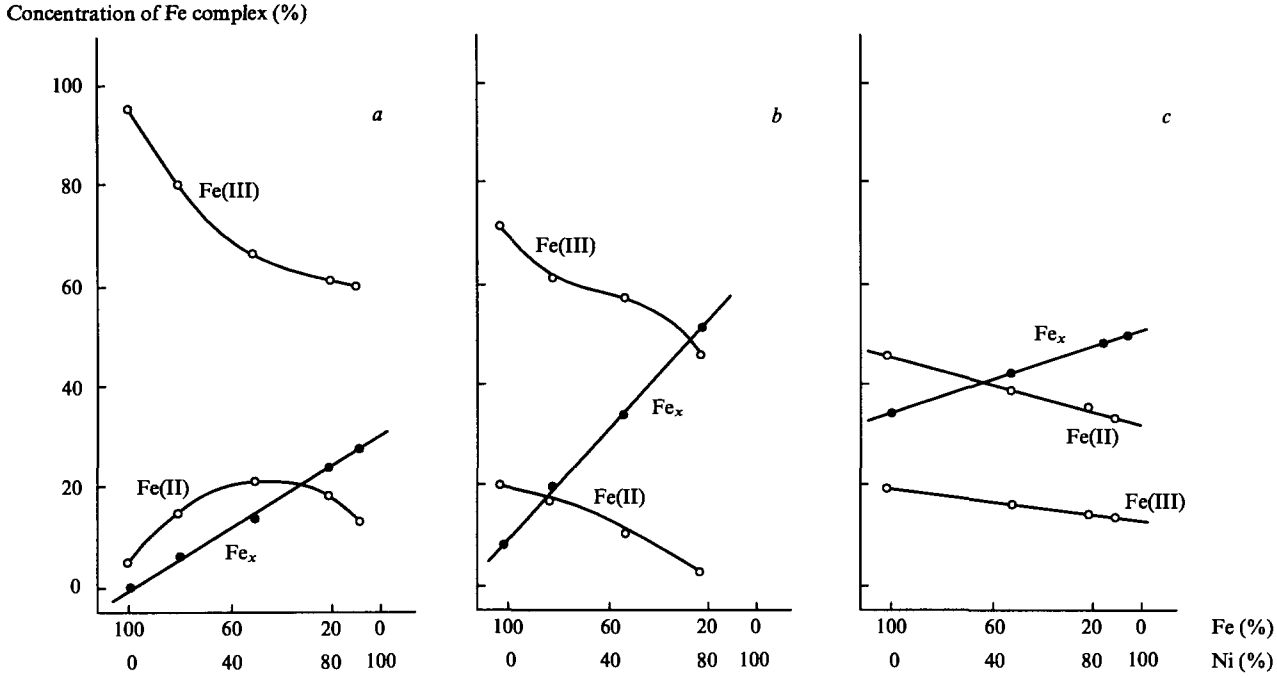

Figure 2. Changes in the concentration of the iron complexes as a function of the composition of the mixed $NiSt_2-FeSt_3-Al(C_2H_5)_3$ (293 K, $[\Sigma M] = 0.28 \times 10^{-3}$ mol); Al : ΣM: (*a*) 2; (*b*) 4; (*c*) 7.

An analysis of the dependence of the rates of hydrogenation of various unsaturated compounds on the concentration of the complex in the system showed unambiguously that the activity of organometallic catalysts is due to the presence of polynuclear complexes in the system.[60,61]

The polynuclear nature of the active complex was confirmed by a reverse synthesis which gave effective catalytic systems from undoubtedly polynuclear complexes of iron and of iron with chromium.[62-64] Active complexes of organometallic catalysts having a cluster nature have also been suggested.[65,66]

Ideas on the polynuclear nature of the active complexes of hydrogenation catalysts of the Ziegler–Natta type led to the belief that synergic systems could be obtained by mixing (in the synthesis) the salts of different transition metals or by supporting the salt of one transition metal on the hydroxide of another.[50,53,73] It was shown that mixed catalysts are not a simple mixture of the complexes of individual transition metals. The conclusion was that an ion of the second transition metal enters into the composition of the combined polynuclear complex, and forms a single system with the ion of the typical metal. As a result of partial reduction and electron transfer processes the transition metals in the conjugated system of the complex have a mixed valency, which enhances the reactivity of the complex.

The $^{57}FeSt_3-NiSt_2-Al(C_2H_5)_3$ catalysts have been studied by Mössbauer spectroscopy. Parallel tests of their catalytic activity towards the hydrogenation of sunflower oil were also carried out. By processing the spectra it was shown[67] that the system contains a set of iron complexes similar to that found in the system based on $^{57}FeSt_3-Al(C_2H_5)_3$ (see Ref. 60).

The Mössbauer parameters of the corresponding complexes in the two systems have similar values. The Fe : Ni ratio has little effect on the Mössbauer spectra of the complexes, but the relative concentration of the complexes is strongly dependent on this ratio. Fig. 2 shows the relative concentration of the various iron complexes [the high-spin Fe(III) and Fe(II), and the associated polynuclear Fe_x] in the $^{57}FeSt_3-NiSt_2-Al(C_2H_5)_3$ system with 10, 20, 50, and 80 mol% of Ni and a ratio of Al : ΣM = 2, 4, and 7. For each value of Al : ΣM the relative concentration of Fe(III) complexes decreases as the concentration of nickel stearate is increased, i.e. reduction processes are assisted by additions of $NiSt_2$. At the same time the relative concentration of associated polynuclear complexes increases almost linearly with the concentration of added stearate. The composition of the system is most strongly influenced by an increase in the content of $NiSt_2$ for a ratio of Al : ΣM < 4; for Al : ΣM = 7 these changes are much less marked, and for Al : ΣM > 7 they effectively vanish.

The increase in the content of polynuclear formations can be associated both with the fact that reduction processes are facilitated (as indicated by the most probable mechanism for the formation of polynuclear associations[60,61,68]) and with formation of stable polynuclear complexes when nickel is included in their composition. In the latter case the dynamic equilibrium between the associations and the other transition metal complexes is displaced towards the associations. This seems all the more likely in view of the tendency for mixed (heteroatomic) cluster complexes to be more stable than their analogues with atoms of one transition metal.[66]

The dependence of the composition of the $^{57}FeSt_3-NiSt_2-Al(C_2H_5)_3$ system and of its catalytic activity in the hydrogenation processes of fats on the amount of nickel stearate can be used to identify the complexes leading to hydrogenation. Property–composition correlation dependences show that [as in the systems[61] based on $^{57}FeSt_3-Al(C_2H_5)_3$] polar associated formations are responsible for the activity of the mixed systems, since a straight-line dependence is observed only between their concentration and the rate of hydrogenation (Fig. 3).

As can be seen from Table 1 the entropy of activation calculated for the formation of the intermediate active complex is negative for all the compositions of the catalyst and all the conditions of the process. Negative entropies are usually observed for the interaction of initial reactants including a bimolecular rate-limiting step, whose transition state is reached by the approach of the reactants (for example, the coordination of the substrate molecules with the metal ions),[74] i.e. for reactions passing through an associative transition state, probably by a concerted

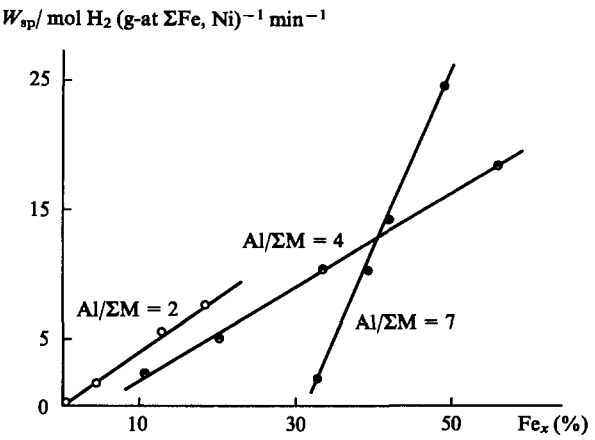

Figure 3. Dependence of the specific rate of hydrogenation of the linoleate from sunflower oil on the concentration of polynuclear Fe complexes in a mixed Ni–Fe catalyst.

(synchronous) mechanism. The latter is usually characterised by a zero or negative entropy of activation, and by a relatively low activation barrier, smaller than the dissociation energies of the weakest chemical bonds assumed in the adjusted process.[66] It can be seen from Table 1 that the apparent activation energy for the process is relatively low (17–34 kJ mol^{-1}). It seems probable that the coordination of hydrogen and of an unsaturated compound on a polynuclear complex involves their strict mutual orientation, with a decrease in the entropy of the active complex, and that a more or less synchronous exchange interaction of the coordinated substrate and hydrogen takes place during the rate-limiting step of the hydrogenation process.

Systematic studies of organometallic catalysts for the hydrogenation of fats, and the resulting evidence for the presence of catalytically active polynuclear and polyvalent complexes and of a dynamic equilibrium between the poly- and the mononuclear transition metal complexes, led to the suggestion[56,69,70,73] that

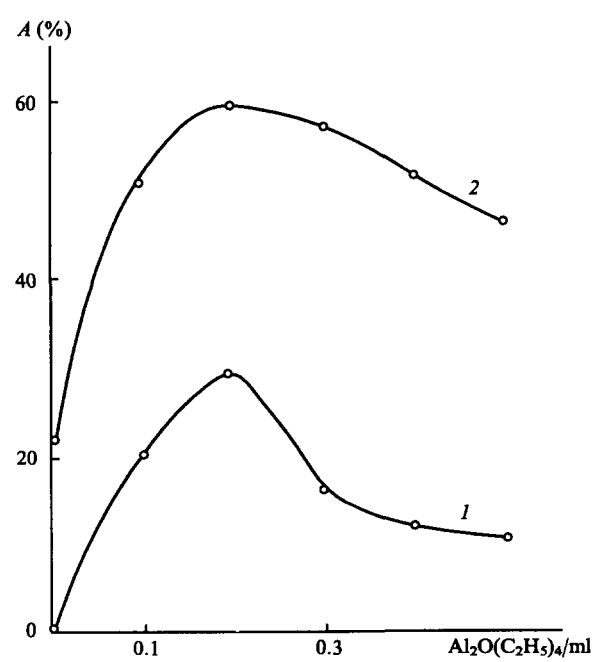

Figure 4. Effect of tetraethylalumoxane additions on the activity (*A*) of a Ni–Cu catalyst in the hydrogenation of sunflower oil at 473 K. Mass of Ni–Cu catalyst: (*1*) 0.03, (*2*) 0.1 g.

these catalysts (like organoaluminium compounds[56]) should be used as additives to heterogeneous catalysts in order to obtain heteropolynuclear and heterovalent complexes (clusters) on the surface of the latter. The following concepts were formulated: (1) the surface of heterogeneous metallic catalysts contains polynuclear (cluster) complexes; (2) there is a similarity between the coordinating powers of the metal atoms on the surface and in the metal complexes;[76–78] (3) like the compounds of the transition metals in solution the surface clusters can interact with Al-organic compounds and form active organometallic catalysts on the surface.

Thus, as shown in Fig. 4, the addition of tetraethylalumoxane to a low-activity nickel–copper heterogeneous catalyst of the VNIIZh-2 type (Ni:Cu = 1:2) increased its activity from 3%–20% to 30%–60%. The experimentally observed dependence of the activity of the catalyst on the amount of added alkyl-alumoxane can be explained by the similarly extremal relationships found in Ziegler catalysts.

Initially, at low concentrations of the Al-organic compound, the activity of the heterogeneous catalyst increased, both as a result of the faster reduction of the metals on the surface (according to ESCA data) and as a result of the formation of coordinated systems with the Al-organic compound on the surface. A further increase in the amount of Al-organic compound led to complex formation and blocking of the transition metal atoms on the surface by aluminium, which lowered the activity of the catalyst. This effect can be clearly seen at low concentrations of the heterogeneous catalyst (0.02%), when the Ni–Cu catalyst is almost completely inactive under the chosen conditions but the addition of tetraethylalumoxane can 'revive' it.

We shall complete our review of this series of papers[43–58,63,64,69,70,73] by summarising their most significant results.

The problem of synthesising a new generation of catalysts for the transformation of fats called for the development of concepts on the nature of the catalytically active complexes, for a detailed study of the changes in activity produced by changes in the genesis conditions (relative amount of the catalyst components, temperature, hydrogen pressure, concentration of catalyst, nature of the organic radical in the organoaluminium component of the catalyst, etc.), and for the determination of the kinetic and thermodynamic characteristics of the hydrogenation process and also of the selectivity and stability of the catalytic systems and of the composition of the final product.

Starting from a qualitative examination of the structure of the active polynuclear complex, and from Mössbauer spectroscopy data on the effect of the nature of the added compound on the irreversible or reversible (depending on the nature of the substrate) decomposition of this complex,[60] it was suggested that a substantial destabilisation of the polynuclear complex during the coordination of compounds such as fats in a solvent is caused by the localisation of charge on one bond of the resulting π complex induced by the strong π-acceptor properties of the substrate. In order to prevent the decomposition of the complex and to create an excess electron density on the conjugation chain in the polynuclear system it was suggested that donor additives should be used and that the nature of the aluminium component should be changed [replacing the traditional $Al(C_2H_5)_3$ by alkylalumoxanes]. These new concepts led to the development of a qualitatively new approach to the synthesis and production technology or organometallic Ziegler catalysts which overcame the serious shortcomings of AlR_3 catalysts (fire and explosion hazards) responsible for limitations and complications in the use of organometallic catalysts.

In the construction of catalytic systems it was possible to increase substantially the stability of the catalyst by creating conditions which suppressed the association of the polynuclear complexes (preparation of the catalyst in a vegetable oil, supporting the catalyst on a carrier). These changes allowed the catalysts to retain their initial activity for long periods.

Table 2. Hydrogenation of vegetable oils in n-heptane in the presence of metal-complex catalysts.

[a] Solvent: acetic acid. [b] MESO are the methyl esters of soya bean oil. [c] The reaction was carried out without a solvent.

Thus, Ni-organic catalysts with alumoxanes in oil showed no loss of activity after three years' storage in closed vessels.

The new ideas on the polynuclear character of the catalytically active complex led to the synthesis of mixed Ni–M catalysts (M = Fe, Co, Cr, Cu). Using the $NiSt_2-FeSt_3-Al(C_2H_5)_3$ system an increase in the number of heteropolynuclear complexes was achieved, and a straight-line dependence of the activity of the complexes on the concentration of $NiSt_2$ was established. The position of the maximum on the rate–composition curve for mixed catalysts under different conditions is determined by the Ni : M ratio (M is the transition metals), i. e. we have a cluster effect.

Allowance for the polynuclear and polyvalent nature of the active complexes in catalysts of the Ziegler–Natta type, and also in the surface layers of heterogeneous catalysts, led to a method of activation of industrial heterogeneous catalysts by small additions of an organometallic catalyst or of an organic aluminium compound.

The 'construction' of organometallic systems by varying the composition of the cocatalyst, by supporting the active complex on a carrier, or by synthesising it on the surface of a low-activity heterogeneous catalyst allowed organometallic catalysts to be used in some processes of practical importance, such as the selective hydrogenation of fats and the transesterification of glycerides (aimed at accelerating the production and improving the quality of a group of food products manufactured by the 'margarine industry')[79] or the positional isomerisation of non-conjugated linoleate (aimed at accelerating the production of drying oils and of conjugated dienes for organic synthesis).[80–83]

Table 2 summarises the information from various sources on the use of metal-complex catalysts in the hydrogenation of the unsaturated glycerides of natural oils. By outlining the main results obtained since 1979 the Table allows us to compare the effectiveness of metal-complex catalysts of various types.

Abstract. The principles of the structural and structural-functional organisation of the molecules of natural oligopeptides are discussed. The approach to the investigation of the biological activity of peptide hormones directed from structure to function is discussed in general terms and in relation to angiotensin II. It is shown that the polyfunctionality of peptides arises from their ability to exist in a series of conformational states under physiological conditions. A separate function of the peptide is achieved by means of a conformation characteristic of only this function among the conformations most preferred for the free molecule. The method of specific construction of artificial analogues, the steric structure of which corresponds to the set of low-energy physiologically active conformational states of the natural hormone, is examined. The bibliography includes 104 references.

I. Introduction

In the study of natural oligopeptides and proteins, investigators are faced with the need to solve four fundamental problems represented in the following scheme with an indication of the hierarchical relations between them:

E M Popov Department of Organic and Physical Chemistry, Moscow State Correspondence Institute of the Food Industry, Zemlyanoi val 73, 109803 Moscow, Russian Federation. Fax (7-095) 292 65 11. Tel. (7-095) 434 32 41

Received 25 August 1994

The first task involves the establishment of the chemical structure of the compound, namely the determination of the order in which the standard aminoacids are arranged in the peptide chain. The second task involves the identification of the steric form and conformational dynamics of the molecule on the basis of the known aminoacid sequence. The third task involves the study of the dependence of the biological and physiological properties of peptides and proteins on their molecular-structural organisation. Finally, the last task is associated with the consideration of these compounds from the evolutionary standpoint as historical objects. The entire preceding information is now being integrated and the concept of the triunity of the structure, function, and evolution of natural peptides and proteins is being established.

The scheme presented embraces all aspects of the studies on peptides and proteins and classifies them in terms of groups forming a closed cycle in a system of four general coordinates (substance, three-dimensional form, function, and time). The arrows indicate subordinate relations and hence establish a logically justified order in which the fundamental tasks should be considered in the direction from simple to complex or in the given instance from structure to function. This communication describes the fundamentals of this approach and discusses its possibilities in the study of the properties of natural oligopeptides both in general terms and as regards the specific example of angiotensin II.

The theme of the structural and structural-functional organisation of natural oligopeptides has attracted attention for two reasons. Firstly, these compounds are intrinsically extremely interesting in both cognitive and applied respects. They possess unique properties and participate actively in many vital processes. Secondly, the enhanced interest in natural oligopeptides is also due to their genetic relations with proteins. They are close to the latter as regards their evolutionary origin and because they are compounds of the same chemical type. Furthermore, valence and nonvalence interactions between peptides and proteins frequently occur in biological processes, so that the knowledge of the properties of low-molecular-mass peptides is of primary importance in the study of high-molecular-mass compounds of the same nature.

In comparing the properties of natural peptides and proteins, one must bear in mind some uncertainty in their subdivision. The aminoacid sequences encountered in nature form a virtually continuous series of compounds with a gradually increasing number of residues in the chain ranging from several units to many hundreds. It is natural to expect that, on passing from

low-molecular-mass peptides to high-molecular-mass proteins, the conformational properties of the molecules change monotonically and not abruptly. For example, it is evident that the nonvalence interactions between the residues, localised on comparatively small sections of the aminoacid sequence, play the same role in the formation of oligopeptides and polypeptides. The understanding of the steric structure and mechanism of the spontaneous, rapid, and error-free assembly of a protein sequence into the native conformation is therefore impossible without the establishment of the principles of the structural organisation of the low-molecular-mass peptides selected by evolution. Since there are no clearly defined boundaries between natural oligopeptides and polypeptides, the conformational theory of simpler molecules becomes a natural component of the conformational theory of the more complex molecules of the same nature. A definite continuity apparently exists also with respect to the structural-functional organisation of natural oligopeptides and proteins.

II. Structural organisation of peptides

The steric structures of many tens of natural oligopeptides and their synthetic analogues, containing from 5 to more than 30 aminoacid residues, were previously investigated with the aid of the semiempirical method of conformational analysis.[1-3] This resulted in the formulation of the following principles governing the structural organisation of the molecules of these compounds:[2]

1. Under physiological conditions, the steric structure of a natural oligopeptide is determined by a limited set of low-energy compact structures, the stability of which depends on all the nonvalence interactions between the atoms within and between the residues being concerted.

2. The preferred structures of the oligopeptide may differ in the shapes of the peptide skeleton, in the forms of the main chain within the limits of one shape (one structural type), and in the orientations of the side chains, within the limits of one form.

3. The displacement of the equilibrium position between a few conformations of the oligopeptides takes place in accordance with a fully defined low-energy mechanism involving a series of consecutive conformational transitions.

4. The high sensitivity (ready adaptability) of the position of the conformational equilibrium in a natural oligopeptide to the environment (solvent, receptor, enzyme) is due to the rigorous selectivity of the low-energy conformational states as regards specific changes in external conditions.

The question arises what are the common features and what are the differences between the structural organisations of the molecules of natural oligopeptides and proteins. One difference between them is evident—the steric construction of the low-molecular-mass peptides is characterised by a set of structures, i.e. by the position of the conformational equilibrium, while that of the proteins is characterised by a single three-dimensional structure under native conditions. More detailed information about the structural organisation of protein molecules is required for further discussion of this question. We shall use for this purpose the bifurcation thermodynamic model of the spontaneous coiling of the polypeptide chain developed by the author and the physical conformational theory of proteins which makes it possible to predict on the basis of the known aminoacid sequence the geometry of the three-dimensional structure and to estimate quantitatively the capacity of the latter for conformational rearrangements. These data were presented in detail with proof in a monograph.[2] Here we shall deal only briefly with the requirements for the establishment of a genetic relation between the structural organisations of natural oligopeptides and proteins.

The most important feature of the protein chain is the specific conformational nonuniformity of the natural aminoacid sequence, which is responsible for the occurrence of irreversible fluctuations and the appearance of bifurcations (irreversible deviations[4,5]) and hence for the very possibility of the spontaneous formation of a highly organised structure from chaos. One may claim that the essential feature of this phenomenon consists in the existence of a clear-cut interdependence of chemical structure, conformational properties, and irreversible fluctuations. The heterogeneity of the aminoacid sequence is responsible for the difference between the conformational possibilities in its individual sections, which engenders in its turn the thermodynamic nonuniformity of the fluctuations and their differentiation into equilibrium (reversible) and nonequilibrium (irreversible) fluctuation. The combination of the fluctuations and the order in which they follow one another determine the nature and direction of the mechanism of the rapid and error-free self-assembly of the protein chain. This relation is characteristic only of aminoacid sequences selected by evolution.[6] On the other hand, in the case of regular homogeneous or even heterogeneous synthetic polypeptides with a random aminoacid sequence, this random process cannot develop and does not lead to the evolution of the chain from the state of a statistical coil.

In order that the random search mechanism should really lead to the coiling of the chain, the selection of the bifurcation fluctuations need not represent the sorting of all the possible combinations of all the random changes in the entire polypeptide chain, the number of which and the time required for their occurrence being improbably large. Coiling will occur only when structure formation in the protein globule is initiated and developed for a definite time independently in different sections of the sequence. This will occur when fragments differing significantly in their conformational properties alternate in the protein chain. They can be divided approximately into two groups. The first group includes the conformationally rigid fragments the steric structure of which is fully determined by the interactions of their constituent aminoacid residues. The second group includes conformationally labile sections of the chain. They acquire their final steric form after the occurrence of not only short-range but also long-range interactions between the residues. Calculations for a large number of complex natural oligopeptides (25–35 residues in the chain) and for two low-molecular-mass proteins (neurotoxin II and trypsin inhibitor) revealed the following characteristic features in the organisation of their steric structures, which are evidently common to protein aminoacid sequences:

1. The possible conformations of all the fragments of the protein chain are determined to a large extent by the nature and sequence of their constituent aminoacid residues.

2. The conformationally rigid and labile fragments alternate along the polypeptide chain of the protein and in the initial stage of the coiling process are almost independent of one another.

3. The rigid and labile fragments are comparatively small and include not more than 12 residues (the longer rigid fragments have several formation centres).

Subject to the maintenance of the above conditions, the assembly of the proteins begins simultaneously and almost independently on conformationally rigid fragments separated by labile sections of the sequence, i.e. takes place in essence as the assembly of several oligopeptide molecules linked by fairly flexible chains. Random and nonordered selection of all possible fluctuations of virtually autonomous rigid fragments leads sooner or later but inevitably to the appearance in each of them of a bifurcational combination of irreversible conformational changes corresponding to a unique combination of fluctuations of the residues in the fragment. The time necessary for the structural self-organisation of the peptide section from n residues via a random search mechanism is 10^{n-14} s according to Wetlaufer.[7] Consequently, the duration of the assembly of the conformationally rigid fragment with $n < 12$ does not exceed 10^{-2} s, i.e. is entirely realistic.

In proteins, the conformationally labile sections alternating along a chain of approximately the same length also undergo significant changes during this period. The occurrence of internal interresidue interactions in these sections leads to the limitation of conformational freedom. Only a limited set of relatively stable

and, in the absence of long-range interactions, isoenergetic states arises from the enormous set of random states by the same random selection of reversible and irreversible fluctuations during the period $t = 10^{-2}$ s.

It follows from the picture of the coiling of the polypeptide chain described that natural oligopeptide molecules have a structural organisation similar to that of the conformationally rigid fragments of the protein chain. The native conformation of the protein can be represented as an association of oligopeptide molecules in conformations corresponding to their low-energy states and ensuring most effectively the close packing of the protein globule, i.e. forming the maximum number of stabilising contacts between one another and with the sequences connecting them. The isolated conformationally rigid protein fragments, lacking an additional external stabilisation, have a structural organisation which fully corresponds to that of the natural oligopeptide molecules.

The steric structure of the natural polypeptides considered as well as the structure of synthetic oligo- and polyaminoacids depends on the position of the conformational equilibrium rather than being unambiguously determined. A very significant difference consists in the fact that in natural oligopeptides the conformational equilibrium involves a small number of low-energy bifurcational states, which are readily interconverted, and not an enormous number of reversibly fluctuating forms of the statistical coil, as in the artificial peptides.

The knowledge of the principles of the molecular-structural organisation and the ability to predict quantitatively the possible conformations in natural oligopeptides on the basis of the aminoacid sequence constitute the first necessary step towards the understanding of the structural-functional organisation of protein molecules. However, before taking the next step in this direction, it is necessary to consider at least briefly two further questions. The first concerns the reliability of the results of the theoretical conformational analysis and hence of the reliability of the generalisations based on them, while the second concerns the possibilities inherent in the existing experimental methods for the investigation of conformations and the likely success of the empirical approach employed which involves the transition 'from function to structure'.

One's attitude to theoretical calculated data naturally depends on one's certainty that they reflect correctly at least in qualitative terms, if not always strictly quantitatively, the characteristic features of the experimental facts, phenomena, and relations which they describe. An objective idea about the accuracy of the geometrical parameters of the molecules calculated a priori has a special significance in our discussion because the theoretical approach should in fact become the basis for a rigorous solution of the problem of the structural-functional organisation of natural oligopeptides.

The reliability of the calculation of the steric structure of the peptides can be rarely tested by direct comparison of theoretical results with experimental data. Low-molecular-mass peptides exhibit an enhanced, conformational lability, compared with proteins, and their preparation in a crystalline form is therefore a complex and usually an insoluble problem. Consequently the applicability of X-ray diffraction to the study of the steric structures of oligopeptides is extremely limited. Even if it is possible to grow crystals suitable for this purpose and to obtain a diffraction pattern, serious difficulties arise in its interpretation. The method of isomorphous substitution cannot be used in this case to decode the X-ray diffraction pattern, since the incorporation of heavy atoms in the oligomeric molecules constituting the crystal lattice can greatly distort their conformational state; in contrast to proteins, in the study of oligopeptides this method is not really the method of isomorphous substitution. On the other hand, oligopeptides are too complex for their structure to solve with the aid of the direct X-ray diffraction method usually employed in the study of simple organic molecules. Even if it is possible to overcome all the difficulties noted above, nevertheless the problem will still remain unsolved. At best, out of the entire set of low-energy potentially physiologically active conformations of the peptides, only one will become known, namely that tending to form a crystal lattice. There is a possibility that it may have no bearing on the functioning of the compound.

There are at present virtually no crystallographic data on the steric structures of linear low-molecular-mass peptides (with the exception of synthetic dipeptides and tripeptides). X-Ray diffraction analysis has been performed only for relatively rigid macrocyclic natural and artificial oligopeptides and oligodepsipeptides such as gramicidin S, antamanide, enniatin B, valinomycin, and some of their complexes with metal ions.[8] Individual experimental data obtained for these compounds may be compared with the results of theoretical conformational analysis. Such a comparison is particularly instructive for the assessment of the objectivity of the calculated data because the theoretical study was carried out several years before the X-ray diffraction analysis of the same compounds.

The conformational analysis of the cyclic tetradepsipeptides (Gly–Glyco)$_2$, (MeAla–Lac)$_2$, and (MeVal–Hyiv)$_2$, consisting of regularly alternating α-aminoacid and α-hydroxyacid residues with different sets of configurations of the C^{α} atoms (DDDD, DDDL, DDLL, DLLD, LDLD, and LDDD),[9-13] shows that the *cis*, *trans*, *cis*, *trans*-configuration of the main chain is the most stable for these molecules, the peptide and ester groups having the *cis*- and *trans*-configurations respectively. Furthermore, calculation has shown that the introduction of the C^{α} substituents and *N*-methylation only narrow the range of allowed conformations. X-Ray diffraction fully confirmed these conclusions and the geometrical parameters found with its aid for the four diastereoisomers of cyclo-(MeVal-Hyiv)$_2$ with the LDLD, DLLD, DDDL, and LDDD configurations of the C^{α} atoms[8,15-20] agreed quantitatively with the theoretical parameters of the conformations of the corresponding molecules preferred on energy grounds.[10-12] Crystallographic data for enniatin B[21,22] and bovericin[23] also agree satisfactorily with calculated data for the lowest-energy conformation of enniatin B.[24,25] An idea about the similarity of the theoretical and experimental geometrical parameters of the molecules of cyclic tetra- and hexa-depsipeptides can be obtained from Table 1 (see over). Thus, in all cases where it is possible to make a direct comparison between theory and experiment a satisfactory quantitative agreement between the results is observed. However, as already noted, there are few such experimental data and they refer to fairly rigid cyclic oligomeric peptides and depsipeptides.

Physicochemical and primarily optical and resonance spectroscopic methods are used widely in the study of the steric structures of peptide derivatives in solution. However, in this case too the structural problem involving these compounds has remained unsolved for a whole series of reasons. The most serious of these is associated with the characteristic features of the formulation of the problem itself, which in the case of natural oligopeptides is more complex than for proteins and synthetic oligo- and poly-aminoacids. The knowledge of only one global conformation, as in the case of proteins, or ideas concerning the statistical mean conformational state, as in the case of synthetic peptides, are insufficient for a rational investigation of the structural-functional organisation of these compounds. A quantitative estimate of the geometrical parameters of a series of structures, the possible conformations of the latter, their interconversions, and the possibility of their occurrence under various conditions is needed here. The derivation of such information is outside the limits of the sensitivity of physicochemical methods and the possibilities for interpretation inherent in them. Furthermore, owing to the complexity of the compounds and the inadequate elucidation of the physical principles of the corresponding phenomena, none of the methods has as yet permitted an unambiguous and sufficiently complete description of even one conformational state of the peptide

predominating in solution on the basis of the results of experimental measurements.

This conclusion follows evidently from the analysis of the results of virtually all studies on the structure of oligopeptides by physicochemical methods. For example, for the elucidation of the steric structure of the octapeptide hormone angiotensin II, virtually the whole set of the existing methods have been resorted to: EPR and ^{1}H and ^{13}C NMR spectra, optical rotatory dispersion (ORD) and circular dichroism (CD) curves, IR and Raman spectra, fluorescence analysis, isotope exchange, etc. As a result, different investigators proposed seven completely different models of the steric structure of the octapeptide hormone corresponding to data obtained by one or several methods at once. However, none of these models, reflecting the state of only the main chain of the molecule, satisfies the entire set of experimental facts.[26] Such uncertainty is characteristic also of the treatment of numerous experimental data on the structure of the neurohypophyseal hormone oxytocin,[27] although in this case the study of the structure was facilitated by the presence of a disulfide linkage between the first and sixth aminoacid residues.

In relation to angiotensin and oxytocin, the peptide hormones which have been investigated most comprehensively and in greatest detail during the last two decades, it has been demonstrated convincingly that the existing physicochemical methods have only a limited applicability to the determination of the structural organisation of natural peptides. Without denying the value of experimental data, one can nevertheless state that a solution solely on their basis of the structural problem to the required extent — the determination of the geometry and conformational dynamics of the low-energy structures of the natural peptide — is at present impossible. The purely empirical approach predominating in conformational studies on peptides and incidentally also proteins uses data which are far from reflecting fully the nature of the phenomenon investigated. The existing gap between the required information and the experimental possibilities actually constitutes the reason for the lack of an appreciable progress in this field over a long period (since the 1960s).

At the present time, the possibilities of the existing physicochemical methods are limited to securing data in support of some kind of hypothetical or a priori calculated structure. Furthermore, the experimental test of the theoretical conformational analysis of peptides has its characteristic features. On the one hand, although a satisfactory agreement between the calculated results and experimental data is a positive finding, nevertheless it cannot serve as a reliable criterion of the validity of the theoretical prediction. In addition, strangely enough the lack of agreement does not imply incontrovertible proof that the calculated results do not correspond to reality. The difference between theoretical and experimental data can be induced by causes which do not play a decisive role in a rational study of the structural-functional organisation of the peptide. For example, a clear-cut discrepancy will occur when the entire set of the low-energy conformations is determined correctly and the geometry of each state is estimated satisfactorily but there is incomplete agreement between the dispositions of the conformations on the observed and real energy scales (a difference of 1.5–2.0 kcal mol^{-1} is sufficient).

Two methods have been proposed for the testing of the results of calculations.[2]

The first method for the assessment of calculated results does not require any experimental facts whatever on the steric structure of the peptides. Its essential feature consists in the selection for the theoretical study of objects such that the calculation for the latter entails an internal autonomous check of its results. For example, intramolecular disulfide bonds can serve as natural reference standards.

According to the theory[2,28,29] and Anfinsen's thermodynamic hypothesis,[30] the oxidation of the sulfur atoms of the cysteine molecules forming disulfide bridges in peptides is possible by virtue of the steric predisposition of the corresponding sections of the aminoacid sequence to conformational states in which the Cys residues are close to one another and the side chains have the mutual orientation necessary for the creation of a S–S bond. During the coiling of the polypeptide chain, the cysteine residues approach one another in the lowest-energy conformations of the linear sequence as a result of concerted stabilising nonvalence interactions between all the chain residues. In a multistage conformational analysis of fairly complex peptides, the attainment of the lowest-energy conformations in the concluding state of the calculation may be expected only when all the theoretical postulates underlying the calculations are adequate and the conformational state of the molecule has been described correctly in quantitative terms. The internal check method has been tested in the analysis of a large number of extremely complex cysteine-containing peptides: nonapeptide neurohypophyseal hormones,[27] apamin,[31], tertiapin,[32] and the MSD-peptide[33] containing respectively 18, 21, and 22 aminoacid residues, including cysteine, which forms two disulfide bonds, as well as insectotoxin[34] containing 36 residues, among which there are eight cysteine residues, etc.[1,2]

In the second assessment method, the correctness of the conformational analysis is tested by comparing the results of the calculation of the possible conformations in the oligopeptide fragments with experimental data on the geometry of the crystal structure of the protein. Such a comparison is at present realistic for two low-molecular-mass proteins — bovine pancreatic trypsin inhibitor (58 aminoacid residues in the chain) and neurotoxin II (61 aminoacid residues), for which the first a priori calculation of the three-dimensional structures has been carried out.[35,36] We shall quote data for the trypsin inhibitor, the steric structure of which is described by approximately 300 dihedral angles, which determine the geometry of all the main and side chains (φ, ψ, ω, and χ). It follows from the comparison of the calculated values of these angles and their experimental values obtained by X-ray diffraction with a resolution of 1.5 Å that the conformation of the inhibitor molecule found a priori is fully consistent with the crystallographic structure. The mean square discrepancies between the experimental and theoretical values of the dihedral angles are 13°, 13°, and 9° for the angles φ, ψ, and ω respectively. The discrepancy between the values of the dihedral angles for the side chain χ (18°) is also within the limits of the error of the high-resolution (1.5–2.0 Å) X-ray diffraction analysis of proteins.

Thus the reliability and the fairly high accuracy of the results of the theoretical conformational analysis of oligopeptides have been confirmed by the automatic formation of a regular system of disulfide bonds in the self-checking calculation and by the agreement between the geometries of the theoretical and crystallographic structures in the calculations for protein molecules.

III. Structural-functional organisation of peptides

As happened many years ago, the mechanisms of the physiological action of peptide hormones are studied nowadays both in the absence of the minimum necessary information about coupled receptors and without the knowledge of the structural organisation of the natural peptide cells. Studies are as a rule based on the results of kinetic measurements and biological tests of the hormone and its synthetic analogues, the latter being selected by the method of trial and error, i.e., strictly speaking, blindly. Thus, a purely empirical approach from function to structure predominates in the study of natural oligopeptides.

Neglect of the information about the geometry and possible conformations of molecules implies in essence the search for an a priori nonexistent direct relation between chemical structure and biological activity. Furthermore, in such an approach the existence of a direct and fairly simple relation between individual aminoacid residues and functions of the peptides is postulated. The idea of additivity inevitably implies that the structural organisation of the interacting molecules ceases to be cooperative, that such molecules are no longer complementary, and that biological processes are not induced and multistage. Nevertheless,

it has long been known that this cannot be done because detailed steric correspondences between the interacting molecules, determined mainly by the specific structural organisation of peptides and proteins, underlie biological processes, their interdependence, high sensitivity, rigorous selectivity, effectiveness, and automatic functioning.

When the 'from function to structure' approach is used, the lack of objective information about the steric organisation of peptides, constituting a natural intermediate link between the chemical structure and biological activity of compounds, is made good by phenomenological descriptions and frequently simply by the author's fantasies. A multiplicity of hypothetical ideas of all kinds, sometimes mutually exclusive, concerning the structural organisation of peptides are available in the literature. The proposed treatments of the mechanism of the action of natural peptides are excessively descriptive in character and lack predictive power.[37] This can be readily demonstrated in relation to studies devoted to angiotensin,[26] bradykinin potentiating peptides,[38,39] and neurohyposphyseal hormones.[27]

Thus it must be recognised that the purely empirical route to the establishment of a direct relation between biological activity and chemical structure is relatively ineffective and without prospects as regards the cognitive purely scientific aspect. It is essential to reverse the direction pursued in research, i.e. to employ the 'from structure to function' approach.

In the solution of the problem of the structural-functional organisation of natural oligopeptides, we shall assume that the aminoacid sequence of the hormone and its physiological activity spectrum together with quantitative estimates of each function are known. If the chemical structure of the peptide is known, it is possible to calculate the possible conformations of the molecule and to discover the set of the potentially active low-energy forms. It is required to establish on the basis of these data the relation between the electronic-conformational and physiological properties of the natural peptide. The physiological properties of peptides may be determined by the path of their interaction with the receptors, whereas information about the organisation of the coupled receptors is either completely lacking or is extremely scanty and, in discussing the properties of protein receptors, we shall be forced henceforth to resort to hypothetical ideas about their conformational and functional features.

In the first place, we suggest that the peptide–protein interactions occurring in living organisms have a unique physicochemical nature regardless of the structure of the specific object and the character of the biological function. Consequently, from a general scientific standpoint, all the numerous and extremely diverse functions of peptides and proteins can be subdivided into two groups of phenomena—physical and chemical. The former take place via the nonvalence interactions of peptides and proteins with one another and with molecules of a different kind. They can be static, as in the case of structural proteins, or dynamic, as in the active transport of metabolites. Together with nonvalence interactions, chemical functions include valence interactions which lead to reversible or irreversible changes in the chemical structure of the molecules. Enzymic reactions, in which the entire set of interactions, both nonvalence (physical) and valence (chemical), take place, may serve as an example. The above assumption presupposes that the interactions of a peptide hormone with a protein receptor are in essence analogous to the interactions of a peptide substrate with a proteolytic enzyme. If this is so, then the characteristic features of the structural and structural-functional organisation of the hormone and the substrate are the same, and this can also be said of the receptor and the enzyme. As regards the principles of the structural organisation of the molecules of peptide substrates and peptide hormones, their identity has been reliably established.

The characteristics of the structural-functional organisation of the molecules of enzyme proteins were discovered previously with the aid of a priori (i.e. in the direction 'from structure to function') calculations of the multistage mechanisms of the elementary steps in biocatalysis by α-chymotrypsin and β-trypsin.[40,43] The calculations were based on the general theory of biocatalysis developed by the author.[44] The characteristics of the structural-functional organisation of enzymes can be formulated in a fairly complete form in the following manner:

1. The active centre of a native enzyme is predisposed, firstly, to sorb a specific substrate in a conformation which in the free state of the molecule is one of the most preferred and, secondly, to undergo quite definite intrinsic conformational changes necessary for the subsequent chemical interactions.

2. The nonvalence enzyme–substrate interactions and the formation of the Michaelis complex do not lead to steric strain or enforced deformations in either the substrate or enzyme molecule. The conformational changes occurring in this stage of the catalytic reaction takes place exclusively by virtue of stabilising interactions and not as a result of unfavourable contacts between the enzyme and substrate atoms, which are simply absent.

3. In the Michaelis complex and in the subsequent complexes involved in the multistage catalytic step, polyfunctional closed systems are formed from the atomic groups of the enzyme and the sensitive site of the substrate. These systems are predisposed to undergo the corresponding specific reactions (for example, in the complexes of α-chymotrypsin and β-trypsin these are acylation and deacylation reactions). A chain of interdependent reactions catalysing one another, the initiation of which does not require an activation energy, occur in each of these systems. The role of the Michaelis complex is to create precisely this kind of autocatalytic closed system, and not to convert the substrate into a strained structure (the geometry of which is similar to that of the transition state) and catalytically active groups into unstrained conformations with an enhanced reactivity. The enzymic process is accelerated because termolecular, tetramolecular, and even higher-order reactions are reduced in such a system to a unimolecular interaction.

4. After the formation of the Michaelis complex as well as other intermediate nonvalence complexes, the additional mutual approach necessary for electronic and chemical interactions between the functional groups may be achieved as a result of Brownian collisions and in-phase normal vibrations of the macromolecular formation.

5. The lowest-energy conformational states of the complexes correspond in all the stages of the catalytic step to a productive mutual orientation of the reacting atomic groups of the enzyme and substrate, i.e. to a mutual disposition of the latter such that their maximum predisposition to undergo specific chemical interactions is achieved. The nonproductive conformations of the enzyme–substrate complexes are energetically much less preferred and their occurrence is unlikely. The transitions between all the chemically unstable intermediate states are accompanied by slight conformational changes, which do not give rise to steric strain.

Thus the enzyme performs its function without resorting to an enforced deformation of the sensitive site of the substrate and of the catalytic groups of the active centre. The catalytic step executed by the enzyme is a conformationally unstrained process. The exceptional efficiency and strict specificity of biological catalysts are not achieved as a result of special high-energy electronic-conformational states of the enzyme and substrates, as has been declared in all the existing concepts. On the contrary, the exceptional nature of this spontaneous natural phenomenon, which occurs without error and under very mild conditions, is the extreme simplicity and natural harmony in the interrelations between the enzyme and substrate developed by evolution at all stages. Biological catalysis has few analogies with the usual chemical catalysis and its mechanism cannot be reproduced by the so called congruent model system.

According to the hypothesis put forward above, the principles of the structural-functional organisation of enzymes listed may be applied to protein receptors. The author deliberately refrained from introducing terminological changes and from replacing the

concepts adopted in enzymology by others less specific. Enzyme catalysis, which consists of alternating physical and chemical phenomena, is one of the most complex processes in vital activity. Therefore, the principles described are of a general character and can be readily reduced to a particular special case. If the interactions of a natural oligopeptide with a protein receptor also include both these phenomena, i.e. nonvalence and valence interactions, then in its description it is necessary to replace only certain words. For example, instead of 'enzyme' one should put 'protein receptor' and the word 'substrate' should be replaced by 'peptide hormone', or both should be changed. On the other hand, if the peptide–receptor interactions are purely physical phenomena, then in the description one must omit everything concerning the chemical aspect of enzyme catalysis.

We now have all the necessary criteria which must be satisfied by the structural-functional organisation of natural oligopeptides. Firstly, it must correspond to the structural organisation of these molecules already known, i.e. must be a consequence of the latter. Secondly, it must complement the structural-functional organisation of protein receptors put forward above. Thirdly, it must not conflict with the known experimental facts concerning the physiological activity of many natural peptides and their synthetic analogues.

All the conditions mentioned above are satisfied for the following principles of the structural-functional organisation of natural oligopeptides.[1,27,39]

1. The spectrum of the functional activity of a low-molecular-mass peptide is determined by the existence under physiological conditions of equilibrium between several structures. In other words, the steric structure of a natural peptide molecule is predisposed to perform not one but several definite functions ('conformational equilibrium — polyfunctionality').

2. An individual function of the peptide is performed via a conformation, valid only for itself, of the most preferred structures forming part of the free molecule, i.e. the uniqueness of the geometry and of the dynamic properties of the corresponding conformational state of the given aminoacid sequence determine the selectivity and the specificity of each of its specific physiological activities ('one conformation — one function').

3. The effectiveness of the activity of the natural oligopeptide when all its functions operate can be accounted for by the alternation of the intramolecular interactions stabilising the preferred conformations and by the relative ease of the conformational transformations. In other words, the rapid response of the conformational equilibrium to a change in the medium ensures a sharp increase in the concentration of the required structure at the required place ('specific external conditions — actual conformation').

Having considered the principles of the structural and structural-functional organisation of natural oligopeptides and proteins, we shall now return to the consideration of the fundamental problem, posed above, concerning the search for a relation between structure and function and an attempt will be made to formulate this problem more rigorously and to outline a general approach to its solution. We recall that the aminoacid sequence of the peptide and its physiological functions, together with quantitative estimates of the activity of each, are known.

As already mentioned, the first step consists in the solution of the direct structural problem for the oligopeptide, i.e. in the determination for the latter of a set of the most probable low-energy conformational states. We begin with the hypothesis that only energy-preferred conformations or some of them can operate as physiologically active structures of the oligopeptides through which its functions are effected.

The next step in the determination of the relation between structure and biological activity is based, on the one hand, on the knowledge of the geometry and conformational properties of all the structures of the test peptides relevant to physiological activity and, on the other, on data concerning the entire spectrum of its activity. Thus the problem arises of the correlation between the set of known conformations and the set of known functions, i.e. of the elucidation of the relevant conformation for each physiological activity of the peptide. In the absence of concrete information about the geometry of the protein receptor, this problem does not have an unambiguous solution. The situation is appreciably simpler in the similarly formulated problem of enzyme–substrate interactions, where not only the organisational principles governing the molecules but also their possible conformations and three-dimensional structures are known.

Evidently the unique high-energy conformational state of the free substrate, which complements the geometry of the active centre of the enzyme, is in this case relevant to the performance of its function. In our case, the active centre of the receptor is unknown, so that its selection is impossible without additional information.

In the absence of data concerning the steric structures of the receptors interacting with various conformations of the peptide considered, the necessary information can be secured with the aid of a set of synthetic analogues of the natural sequence corresponding to special requirements. Each compound in this set must be monofunctional and hence should assume only one of the series of actual conformations of the natural peptide complementary to the active centre of the corresponding receptor. Thus synthetic analogues possessing prespecified electronic-conformational properties are essential for the solution of the problem of the structure and function of natural oligopeptides. Compared with the direct structural problem (a priori calculation of the conformations from the known aminoacid sequence), the problem arising here has the opposite formulation and we shall therefore call it the converse structural problem.[1]

The converse structural problem consists in the theoretical determination of the nature of the chemical modifications necessary for the differentiation of the conformation relevant to the corresponding function of the natural oligopeptide. A more general aim involves the specific formation of the chemical structure of the molecule known beforehand to assume the steric structure necessary for the performance of a fully defined function. The solution of this problem within the framework of the 'from structure to function' approach gives rise to extensive prospects not only for the quantitative study of the functioning of natural oligopeptides but also for the modelling of the active centres of enzymes and the search for medicinal preparations, substrates, inhibitors, antibodies, etc., such a search acquiring a specific aim. As already mentioned, hitherto artificial analogues have been synthesised purely intuitively by the method of trial and error.

The method which the present author has proposed for the solution of the converse structural problem is based on the quantitative conformational theory of natural peptides and proteins,[2,28,29] in particular on the estimation of the special role of the short-range interactions and of the spatial organisation of the aminoacid sequences selected by evolution and on the use of the natural classification of peptide structures.[29] This method has been described in detail elsewhere.[1] Before synthesis and biological tests, it permits the construction of specific artificial analogues the steric structure of which corresponds to the set of low-energy physiologically active conformational states of the natural oligopeptides.

The steps in studies on these lines may correspond to the following scheme:

1. Theoretical conformational analysis of the natural oligopeptide and the determination of all the most energy-preferred and hence potentially physiologically active conformational states (solution of the direct structural problem).

2. The creation of a series of artificial analogues, the set of steric structures of which corresponds to the set of low-energy physiologically active conformations (solution of the converse structural problem).

3. The synthesis and biochemical study of artificial model analogues, the determination of the spectrum of the physiological

activity of the natural oligopeptide, the quantitative estimation of its functional activity, the study of the specific interactions with receptors, etc.

4. Analysis of the results of the calculation and the experiment and the determination at the atomic-molecular level of the relation between chemical structure, the possible conformations, and the effectiveness of the physiological activity of the oligopeptide.

The essential feature of this scheme is that the experimental study of the structure, the biological activity, and the mechanism of the functioning is preceded by theoretical modelling resorting to conformational analysis and to quantum-chemical methods. In this respect, the order in which the studies are performed in the direction 'from structure to function' corresponds to an engineering approach.

In the treatment below, two interrelated problems, solved simultaneously, are considered. One of them is more specific and reduces to the establishment of the structural-functional organisation of the hormone angiotensin II with the aid of the approach described above. The second, more general problem involves the testing of the approach in a specific analysis and the estimation of its real possibilities. The choice of angiotensin II as the object of study was dictated by the fact that this natural oligopeptide has now been most thoroughly investigated and is therefore most suitable for testing the new approach.

IV. The structure and functions of angiotensin II

Angiotensin II, an octapeptide tissue hormone, forms part of the renin–angiotensin system in which its biogenesis and decomposition take place. Angiotensin II is the most powerful of the known pressor agents in the blood circulation system. It stimulates the contraction of the peripheral arterioles throughout the organism and hence increases the arterial pressure. In addition, angiotensin II activates the secretion of a series of hormones (mainly aldosterone), influences the operation of the heart, liver, and the central and peripheral components of the nervous system, and also induces a series of other responses in the mammalian organism. Table 2 lists the known functions of the hormone with an indication of the sites where they are manifested in organisms.

The decapeptide angiotensin I, which is a direct precursor of angiotensin II, is formed, according to the scheme presented below, from angiotensinogen, a globular blood protein, when the latter is acted upon by the proteolytic enzyme renin.

Table 2. The principal functions of angiotensin II and the sites where they are performed in the mammalian organism.

Function	Organs and tissues	Ref.
Stimulation of the contraction of smooth muscles	Smooth muscles of arterioles	45
Regulation of the secretion of aldosterone	Adrenal cortex	46
Regulation of the arterial pressure, secretion of vasopressin, intensification of thirst and appetite for salt	The brain (stem, hypothalamohypophyseal system, establishment of the neuronal thirst cycle, etc.)	47–49
Regulation of kidney haemodynamics, of the secretion of renin, and of the permeability of kidney channel walls	Kidneys (kidney arterioles, kidney channel walls, cells of the juxtaglomerular apparatus)	50–52
Increase in the strength of cardiac contractions	Heart muscle	53
Stimulation of the secretion of catecholamines	Adrenal medulla	54

Almost all tissues possess peptide activity which leads to the rapid decomposition of angiotensin II. Two varieties of angiotensin II have been isolated from mammalian blood. One of them is presented in the scheme, while the other differs from it by the Ile residue in the 5-position.

Angiotensin III

The chemical synthesis of angiotensin II in 1961 [55] initiated the study of its physiological functions. With the aid of numerous synthetic analogues of the hormone, it was possible to show that the natural peptide interacts with a series of receptors located in various tissues of the mammalian organism and possesses a fairly broad spectrum of biological activity.

Numerous studies on the steric structure of angiotensin II in solution have been published. Virtually the entire set of the existing physicochemical methods have been used in them: thin-film dialysis,[56] titration of ionogenic groups,[57] hydrogen exchange,[58] all types of optical and resonance molecular spectroscopy,[59–62] as well as a number of others. The results of the investigations and their interpretation are extremely contradictory. Different workers have proposed numerous significantly different structures for angiotensin II.[26] Each of them concerns exclusively the main chain of the molecule and satisfies only a limited range of experimental data (see, for example, Refs 26, 45, 58, 63, and 64). The positions of the side chains of the aminoacid residues, which constitute a large proportion of the molecule and determine its conformational state, were completely disregarded in the discussion of the structure of the hormone.

The first studies on angiotensin II by dialysis through thin films proved to be contradictory. In some investigations,[65, 66] it was concluded that the hormone molecule has a single compact form in solution, whilst in another investigation[56] the existence of conformational equilibrium between two forms was postulated.

The conclusions reached by different investigators from the analysis of kinetic data on the isotopic substitution of a proton in the hydrogen bonds of angiotensin II were no less contradictory. Scheraga and coworkers[67] noted that the rates of exchange of all the amide protons were the same. Lenkinski et al.[68] speak of an anomalously low rate of exchange of the His^6 amide proton, while Bleich et al.[69] differentiate the Val^3 and Val^5 residues for the same reason. Printz et al.[63] divided the amide protons into three groups in terms of the rate of exchange, the Asp^1 and Arg^2 protons being assigned to the group with the highest rates. In the classification proposed by Marshall,[70] all the exchanging protons were divided into four groups, the amide protons of all the angiotensin II residues, with the exception of Asp^1 and Phe^8, being assigned to a single group with the same rate of exchange.

Table 3. The number of low-energy conformations, having the same form of the main chain, calculated in the literature.[26,80-83]

80	10	1	1	2	0
26	1	6	4	0	2
81	1	4	5	0	2
82	2	0	0	5	0
83	0	2	0	0	6

The dissociation constants of the ionogenic groups of the hormone, obtained by potentiometric titration[57] and with the aid of NMR and CD spectra,[71] led to the conclusion that the N- and C-terminal groups of the peptide chain are close to one another, which permits their interaction. The distance between the groups is much smaller than the corresponding distance for angiotensin in the statistical coil conformation. In addition, it has been postulated[71] that all the ionogenic groups are accessible to the solvent and that the imidazole ring of the His^6 residue interacts with the benzene ring of the Tyr^4 residue and is remote from the Phe^8 residue.

According to Fermandjian and coworkers,[72,73] the ORD and CD spectra indicate the presence of an antiparallel structure in the angiotensin II molecule. The above workers interpreted similarly the vibrational spectra of the hormone.[60]

A series of studies have been devoted to the NMR spectra of angiotensin II, which yield most information about the steric structure of the molecule. However, here too there is no unanimity in the interpretation of the experimental data. Some workers believe that the spectra indicate the existence of angiotensin II in solution in a single conformation which has a predominantly extended form. Others[75] concluded that the molecule has a coiled form, in which the aromatic side chains of the Tyr^4 and His^6 residues are arranged parallel to one another and interact effectively, whilst the carbonyl group of the Asp^1 residue forms a hydrogen bond with the amino-group of the Tyr^4 residue. The study of the ^{13}C spin–lattice relaxation time led Sekatsis et al.[76] to the conclusion that the conformational mobility of the first two residues is high and that there is no bend in this part of the molecule. Using the same method, Deslauriers et al.,[77] reached a different conclusion. They believe that all the residues of angiotensin II, with the exception of Tyr^4, have approximately the same conformational freedom; the mobility of the side chain of the Tyr^4 residue, which interacts with many other residues of the molecule, is restricted to the greatest extent. The vicinal constants for all the aminoacid residues of angiotensin II[70,78,79] have values consistent with all those corresponding to each residue in the low-energy regions *R* and *B* and hence to 2^7 combinations of the conformational states of the residues in the peptide chain of the molecule.

The reasons for the low effectiveness of the physicochemical methods for the investigation of the steric structures of oligopeptides have already been described in detail. We shall only recall that, for the investigation of the structural-functional organisation of the molecules of these compounds, it is insufficient to know only the global conformation, i.e. the most preferred conformation as regards energy. Here a quantitative estimate of the geometrical parameters of a whole set of structures, their possible conformations, and the probability of their occurrence under various conditions is needed. Such information is so far beyond the limits of sensitivity of physicochemical methods and the possibilities for interpretation inherent in them, so that the semiempirical method of conformational analysis has been resorted to in order to solve the problems listed above. However, here too the results are fairly modest and contradictory. Table 3 presents the results of the calculations of the steric structure of angiotensin II carried out by different workers at different times.[29,80-83] Comparison shows that the sets of low-energy conformations found for the same hormone are not the same. Furthermore, none of them conflict with data obtained in a very wide range of studies carried out on this compound. The reasons for such significant discrepancies have been discussed in detail in a monograph.[2] Therefore we shall briefly note below only certain features of the approach of Galaktionov and coworkers[26,81] to the conformational analysis of natural oligopeptides. From our viewpoint, it is more logical for the solution of the direct structural problem than the approaches used by other investigators.[80,82]

In order to reduce the number of conformations considered with the simultaneous expansion of the critical range of energies, Galaktionov and coworkers[26,81] considered in a preliminary step models in which all the aminoacid residues, other than Arg and Pro, had been replaced by alanine residues. Next, all the possible optimum conformations were determined for the model peptide and the best of these then served as the initial structural variants of the main chain of the real peptide. This procedure is based on what is in our view a fundamentally incorrect hypothesis that the main chain plays a dominant role in determining the possible conformations of the peptides.

If this were the case and the one-third of all the atoms constituting the peptide skeleton did indeed determine the positions of the remaining two-thirds of atoms belonging to the side chains, then all the natural oligopeptides and proteins should have either identical forms of the main chain or a very limited number of such forms. As regards synthetic oligopeptides and polypeptides consisting of glycine and alanine residues and actually lacking side chains, their steric structures should have been described by single rigid structures and not by the state of a statistical coil, as happens in reality. Thus the hypothesis of Galaktionov and coworkers[26,81] is far from representing the true picture. The variations in the steric forms of proteins are almost as numerous as the variations in the order of disposition of the 20 standard aminoacid residues in this chain.

In both the first and second stages of the calculation, where the optimum mutual orientation of the side chains of the test peptides is sought for the selected steric forms of the main chain, mainly the electrostatic interactions of the ionogenic groups were emphasised (it was assumed that they are the main factor in the structural stabilisation). It is difficult to agree with this too because the arrangement of the peptide chain in the native conformation or (in the presence of a series of low-energy structures, as in the case of oligopeptides) the attainment of the conformational equilibrium takes place in aqueous solution under physiological conditions, which prevent an effective electrostatic interaction, abolishing it almost completely ($\varepsilon = 81$).

A characteristic feature of all the theoretical studies of the steric structure of angiotensin II[26,80-83] is the absence of any kind of classification of the conformational states of the molecule let alone one which would be justified from the physical standpoint and would embrace all possible structural variants arranged systematically in accordance with subordinate interrelations in terms of taxonomic categories. All the estimates of the optimum conformations in the studies under discussion were based on the relative values of the overall energy without a quantitative analysis of the contributions by individual intraresidue and interresidue

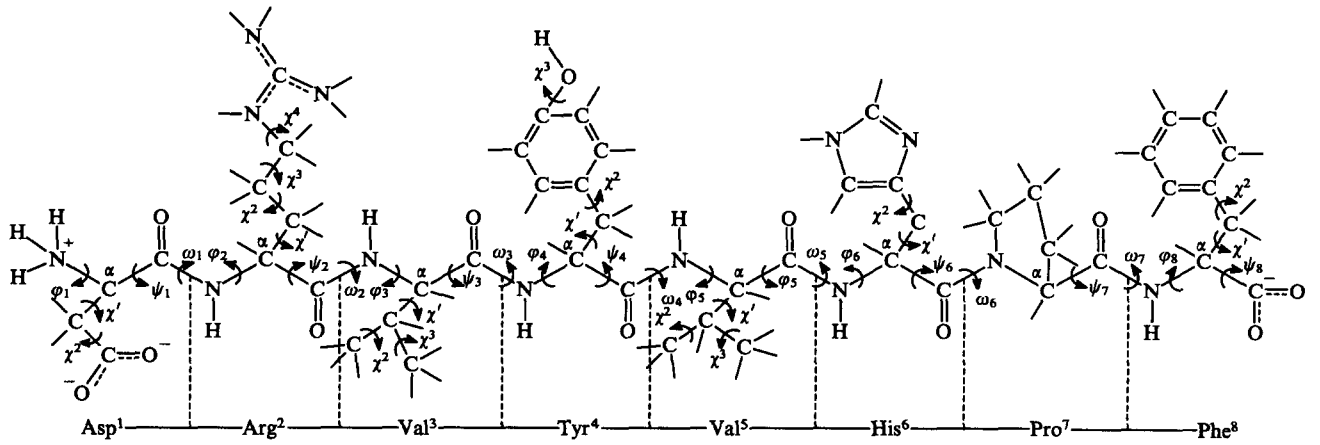

Figure 1. The calculated model of the angiotensin II molecule.

interactions in the structural variants of all the possible forms of different types of the main chain. There is therefore no guarantee that the results of the calculations[26,80–83] are free from either random omissions or incorrect assessments of the data obtained. Table 3 serves to confirm this conclusion.

Thus the available conformational data for angiotensin II could not be used to test the 'from structure to function' approach. This factor led the author of the review and Gogitidze to undertake their own analysis of the conformational states of this molecule.[84] The method of calculation, the notation, and the results are considered briefly below.

The structural organisation of the angiotensin II molecule was investigated on the basis of the conformational theory and the corresponding computational method developed in previous studies[2,85] on the assumption of the rigid valence scheme presented in Fig. 1. The possible conformations of the octapeptide hormone are determined by 41 values of the dihedral angles of rotation about the axes of the main chain (φ, ψ, ω) and the side chains (χ^1, χ^2, ...). The potential functions and the semiempirical parameters used in the calculation to estimate the nonvalence, electrostatic, torsional, and hydrogen bonding interactions were indicated previously.[86,87] The natural classification of the peptide structures in terms of three levels of steric organisation, namely the conformation, form, and shape of the main chain, was used in the calculation and in the description of the results. The classification was put forward in previous communications.[2,85,87]

A system of identifiers was used to designate the conformations. According to this system, the conformational state of each residue is defined by X^n_{ij}, where X characterises the form of the main chain of the residue (R, B, L, and P), n is the number of the residue in the sequence, and the symbols ij = 11, 12, 13, 21 etc. correspond to the position of the side chain (χ^1, χ^2, ...); the subscript 1 corresponds to values of the angles in the range from 0° to 120°, 2 corresponds to angles from 120° to −120°, and 3 corresponds to angles from −120° to 0°. Apart from its form, the main chain is characterised also by its shape or structural type described by the combination of the symbols *f* and *e*, which denote respectively the coiled and uncoiled configurations of the virtual $C^\alpha - C^\alpha_i - C^\alpha_{i+1} - C^\alpha_{i+2}$ bonds. The configuration is defined quantitatively by the virtual angle of rotation $\theta = \psi_i + \phi_{i+1}$ around the $C^\alpha_i - C^\alpha_{i+1}$ bond. The designations and the reference points for the angles of rotation correspond to the generally accepted nomenclature.[88]

The conformational analysis of the octapeptide hormone was carried out in three stages. The first included the independent calculation of five conformations overlapping as regards three aminoacid residues of the tetrapeptide fragments, the second stage involved the calculation for the hexapeptide fragment Asp¹ – His⁶, and the third involved the calculation for the entire angiotensin molecule.

The conformations of the hormone with relative energies from 0 to 8.0 kcal mol^{-1} are presented in Table 4. The first four

Table 4. The relative energies (ΔU/kcal mol^{-1}) and energy contributions (in kcal mol^{-1}) by the nonvalence (U_{nv}), electrostatic (U_{el}), and torsional (U_{tors}) interactions in the preferred optimum conformations of the angiotensin II molecule.

[a] The energy of hydrogen bonds has also been included in U_{nv}.

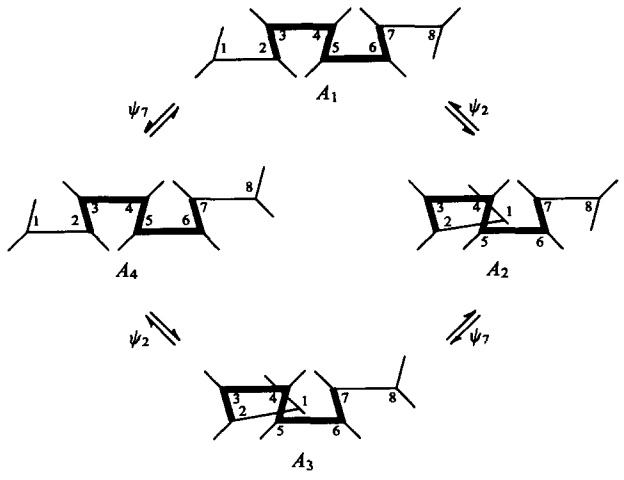

Figure 2. The shapes of the peptide skeleton and the pathways followed in the interconversions of the low-energy conformations of group *A* (Table 4).

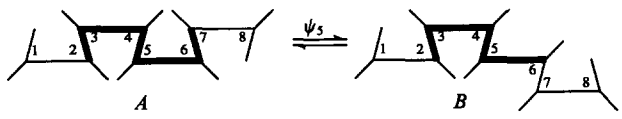

Figure 3. The interconversion of group *A* and *B* conformations (Table 4).

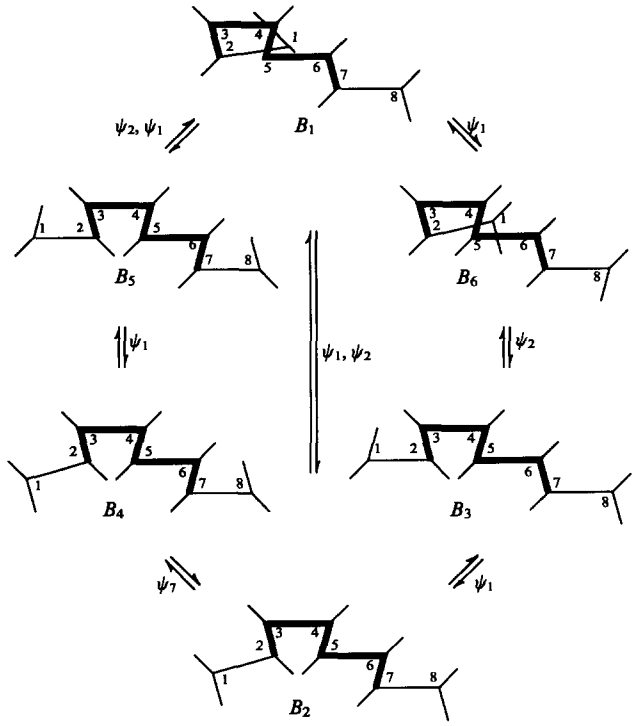

Figure 4. The shapes of the peptide skeleton and the pathways followed in the interconversions of the low-energy group *B* conformations (Table 4).

structures with $\Delta U = 0-4$ kcal mol^{-1} constitute group *A*. A rigid type *fef* nucleation of the central section of the molecule for relatively mobile N- and C-terminal dipeptide fragments is characteristic of these conformations. Fig. 2 illustrates the shapes of the peptide skeletons of these structures and the routes followed in their interconversions. All the changes in the conformational states of the main angiotensin chain within the limits of group *A*, corresponding to the low-energy $R \rightarrow B$ transitions, are affected through rotations about the $C^{\alpha}-C'$ bond of the Arg^2 or Pro^7 residue via a change in the corresponding angle ψ by 180°.

The next six conformations with a relatively low energy ($\Delta U = 3.5-7.0$ kcal mol^{-1}), combined in group *B*, also have the same structure of the central Val^3-Pro^7 section. It belongs to the *fee* shape and differs from the structure of this section in the preceding conformations by only one residue (Val^5). The transition between representatives of groups *A* and *B* is of the low-energy type and reduces to a change in the dihedral angle ψ_5 (Fig. 3). The side chain of the His residue is then moved away from the phenolic ring of the side chain of the Tyr residue, which leads to a slight (~1.0 kcal mol^{-1}) destabilisation of the conformations of group *B* relative to *A*. The shapes of the six low-energy conformations of group *B* and the routes followed in their interconversions are illustrated in Fig. 4.

The best conformations of groups *C*, *D*, *E*, and *F* (Table 4) are appreciably inferior to conformations of groups *A* and *B* as regards energy. They are less compact and are inferior primarily as regards the energy of the nonvalence interactions. The next representatives of these groups have energies exceeding 10 kcal mol^{-1}.

Table 5. The dihedral angles of rotation (in degrees) in the A_1 and B_1 (in brackets) conformations of the angiotensin II molecule.

Residue	Main chain			Side chain			
	ϕ	ψ	ω	χ^1	χ^2	χ^3	χ^4
Asp^1	−1	−60	−178	80	−92	–	–
	(−50)	(−60)	(180)	(178)	(−93)	(−)	(−)
Arg^2	−151	160	179	61	−179	64	−179
	(−86)	(−35)	(−176)	(−60)	(−178)	(180)	(180)
Val^3	−97	−60	179	178	−179	−179	–
	(−97)	(−61)	(−177)	(179)	(−180)	(−180)	(−)
Tyr^4	−90	146	−169	170	61	180	–
	(−91)	(44)	(−476)	(−175)	(90)	(180)	(−)
Val^5	61	−38	175	70	179	−175	–
	(−99)	(105)	(177)	(180)	(−179)	(180)	(−)
His^6	−85	126	174	−60	102	–	–
	(−122)	(153)	(174)	(59)	(92)	(−)	(−)
Pro^7	−60	−31	179	180	180	180	–
	(−60)	(124)	(−178)	(180)	(180)	(180)	(−)
Phe^8	−95	−38	–	60	86	–	–
	(−96)	(121)	(−)	(−60)	(92)	(−)	(−)

Thus the spectrum of the energy distribution of the optimum conformations of angiotensin II consists of several principal levels (A, B, C, ...), determined by the conformational states of the central fragment Val^3–His^6, and of a comparatively small number of sublevels differing in the conformational states of the labile N- and C-terminal dipeptides; the first can assume steric forms of all possible types (*ee*, *ef*, *fe*, *ff*) and the second can assume forms of only two types (*ee*, *ef*). The energy distribution of the conformations in each family depends to the greatest extent on the number and effectiveness of the stabilising contacts between the residues in the labile and rigid fragments.

It follows from the comparison of the energy contributions (presented in Table 4) by the nonvalence, electrostatic, and torsional interactions to the low-energy conformations of the angiotensin molecule that the nonvalence, mainly dispersion interactions (or, in other words, the packing density of the aminoacid sequence) are of decisive importance in the stabilisation of the steric structure. There is no clear-cut correlation between the quantities U and U_{nv}, although the trends in their variation are similar. The group A conformations are on average more compact than the group B conformations ($U_{nv}A = -38.6$ kcal mol^{-1} and $U_{nv}B = -36.4$ kcal mol^{-1}) let alone the group C and D conformations. The geometry and energy of the Val^3–His^6 fragment are virtually constant in the conformations of each group.

Thus the overall result of the solution of the direct structural problem for angiotensin II may be reduced to the claim that the structural organisation of the molecule is described by a comparatively small set of easily interconverted low-energy conformational states, which can be subdivided into several families. The states of the A and B families are most preferable in terms of energy and entropy. The geometrical parameters of their best representatives (A_1, B_1; Table 4) are presented in Table 5.

V. Synthetic analogues of angiotensin

The study of the possible conformations of angiotensin II [84] made it possible to discover the structural organisation of the hormone and to determine thereby the set of low-energy steric forms which are potentially biologically active. The solution of the next problem, concerning the structural-functional organisation of angiotensin II, consists in discovering within the discovered set of structures those relevant to the occurrence of physiological activities and in the establishment of specific relations between these structures and functions. The development of research on these lines requires the use of experimental data on the functional features of angiotensin II. The effect engendered by angiotensin II in the mammalian organism is the sum of diverse responses, the nature of which depends on the organs and tissues subjected to the action of the hormone (Table 2). The available experimental data show that, like the majority of other peptide hormones, angiotensin II is polyfunctional.

A large number of experimental data obtained in recent years constitute evidence in support of the heterogeneity of the angiotensin II receptor. This process will be examined in detail later and for the moment we shall only note that the polyfunctionality of angiotensin II and the heterogeneity of its receptors can be related naturally to the molecular structural organisation of the hormone, which has been investigated theoretically. Its predisposition to perform a series of functions is manifested by the existence under physiological conditions of several steric forms having similar energies and readily interconverted. The high effectiveness and rigorous selectivity of the interactions of angiotensin II with various receptors are associated with the fact that each of its functions is performed only via the conformation relevant to the given receptor, among the set of preferred structures of the free molecule.

Thus the search for the structural-functional organisation of angiotensin II reduces to the elucidation of the relevant conformation for each biological activity of the peptide. In the absence of necessary data on the potential surfaces for binding sites, the solution of this problem requires additional information. Data on the biological activity of synthetic analogues of natural peptides are normally employed as information of this kind. However, when one sets up a series of analogues in a random fashion without a preliminary study of the possible conformations of both the natural peptide and its artificial analogues, one seeks in essence a simple relation between individual residues of the aminoacid sequence of the hormone and its functions during the investigation. Since the hormone-stimulated allosteric effects arise as a result of multiple and not point contacts between the potential surfaces of the ligand and the receptor complementary to one another (otherwise there would have been no selectivity of the hormonal activity), the disturbance of the function on replacement of even one residue may be a consequence of a whole series of causes: the disappearance of the required functional group, the loss of the necessary dynamic properties of the relevant conformation, the prohibition of the latter as a consequence of the steric strain arising on replacement of the residue, the shift of the conformational equilibrium owing to changing conditions in the interaction with the environment, etc.

Consequently, the random replacement of individual residues does not permit a solution of the problem of the structural-functional organisation of hormones. This is indicated by the lack, during the course of several decades, of appreciable progress in studies on the relation between the structures and functions of angiotensin II, the encephalins and endorphins, neurohypophyseal hormones, bradykinin potentiating peptides, as well as a number of others, which have been prosecuted resorting to a multiplicity of artificial analogues. All this indicates the need to employ a special approach in the study of structural-functional relations for peptide hormones which would make it possible to abandon the method of trial and error and would permit a deliberate choice in the search for synthetic analogues before their synthesis and biological tests.

In this connection, we shall consider the study of Nikiforovich et al.[81] in which an attempt was made to identify the biologically active conformational states of angiotensin II using the results of theoretical analysis together with experimental data. It is assumed that the conformations of the molecules of the hormone and of two of its analogues (conformations A_1, A_2, ..., A_n), which exhibit a high affinity for a definite receptor, and the conformations B_1, B_2, ..., B_n, which are inactive, are known. The authors postulate that the conformations present in the sets of low-energy states of the hormones and the analogues A_1, A_2, ..., A_n and those absent from the sets B_1, B_2, ..., B_n are biologically active structures of angiotensin II.

In this approach, use was made of three synthetic analogues of angiotensin II with a high affinity for the receptor of the smooth muscle tissue of the rat and one without such affinity. However, calculation showed[81] that, among the conformations found for angiotensin II and three of its active analogues, there are none having identical fragments. The absence of such agreement is most probably evidence that the analysis of angiotensin II and of its analogues had been incorrect. However, the authors[81] took what is from our point of view a fundamentally incorrect step without questioning their results. They abandoned the principle that the potential surfaces of the hormone and the receptor are complementary and assumed that a point correspondence is sufficient for the formation of a productive complex. In order to select conformations, they took into account only two distances (and even then with variations within very wide limits) between the C^α atoms of the Val^3 residue and the C^α atoms of the His^6 (4.2–6.2 Å) and Pro^7 (6.7–8.2 Å) residues.

The chosen criterion is extremely ineffective, since generally speaking tens of completely different structures of angiotensin II, differing both in the form of the main chain and in the orientations of the side chains, may satisfy it. In particular, the above ranges of interatomic distances embrace one of the most favoured

conformations of [Pro^2]-angiotensin II for which we carried out calculations[89] and which is discussed below. It is an analogue the affinity of which for the receptors of the smooth muscle tissue is only 0.7% of the affinity of the natural peptide.

However, the choice of a more reliable criterion for the selection of conformations is not the only point at issue. The problem would have remained unsolved even if it had been found that angiotensin II and its active analogues have sets of low-energy conformations in common, which must have been observed for a correct solution of the direct structural problem. The employment of theoretical conformational analysis in the absence of information about the receptors and with a random choice of analogues does not solve the problem of the structural-functional organisation of the natural peptide.

Under the conditions of the polyfunctionality of angiotensin II and the heterogeneity of its receptors, the relations between the low-energy conformations and functions of the hormone may be established with the aid of an extremely small series of synthetic analogues, provided that each compound of the series assumes only one state out of the set of the preferred conformations of the natural peptide. Then all the analogues are able to perform only one hormonal function each or, more precisely, are able to reproduce the interaction of the hormone with only one receptor. When the analogues are monofunctional, their assembly can reproduce the entire spectrum of biological activity of the natural peptide. The problem arising in this case consists in the theoretical determination of the nature of the chemical modifications of the aminoacid sequence of the hormone which are necessary to differentiate a particular conformation relevant to the corresponding function of the natural peptide and the prohibition of all others (converse structural problem). In other words, one is dealing with the deliberate chemical construction of artificial analogues each of which is known beforehand to assume the steric structure necessary for the performance of a fully defined function.

Previously the author proposed a method for the solution of the converse structural problem.[1] It is based on the quantitative conformational theory of natural peptides and proteins,[2] in particular on the estimation of the special role of the nonvalence short-range interactions (intraresidue interactions) of the atoms in the spatial organisation of natural aminoacid sequences and on the use of the natural classification of peptide structures into shapes, forms, and conformations.[2] The short-range interactions have a property extremely important for the solution of the converse structural problem — they are able to determine fully the initial sets of allowed conformational states of the residues. When the peptide chain coils up, the conformational state of each residue is selected only from these sets. Therefore, by influencing in a controlled manner the changes in the short-range interactions, one can deliberately form sets of conformational states of the residues and hence act on the spatial organisation of the peptide effectively and purposefully. It has been shown[1] that this can be achieved by comparatively simple means which have been developed by nature itself in the course of the evolution of the organic world: it involves the replacement in the sequence of one standard residue by another differing significantly in its possible conformations (for example, the replacement of Gly by Ala or Pro), the chemical modification of the standard residue (*N*-methylation, replacement of a L-aminoacid by the D-isomer, etc.), and the replacement of an aminoacid by a hydroxyacid. It is also possible to exchange the Cys residues for Ala and exclude thereby the formation of disulfide bonds without introducing steric complications or, conversely, the residues which are spatially in close proximity may be replaced by Cys, promoting thereby the formation of macrocycles strengthened by S–S bridges. Thus there are many possibilities for the deliberate construction of a set of artificial analogues of the hormone.

We shall now consider the results of the solution of the converse structural problem for angiotensin II.[89] The relative energies of the interactions of atoms not linked by valence bonds in the preferred conformations of the hormone itself and in the related low-energy conformations of a series of its natural and synthetic analogues are compared in Table 6 (p. 948). We recall that the main aim of the investigation[89] was to test the concept of the heterogeneity of angiotensin receptors and to identify the conformations of the hormone responsible for definite functions on the basis of the approach proposed.[1] The starting points were, on the one hand, the aminoacid sequence of the hormone and hence its possible conformations and, on the other, the spectrum of the biological activity of the hormone and quantitative assessments of the activity of each function. After the determination of the minimum necessary set of synthetic analogues for each of them, equally exhaustive biological tests of the analogues are required. Therefore, it was necessary to base the treatment on the available experimental data. Although such data are most extensive for angiotensin II, nevertheless an acute deficiency of experimental facts concerning the biological tests of synthetic analogues is felt here also. The synthetic analogues were as a rule tested solely in terms of one function, so that the total spectra of their biological activities, which are very important in the given instance, remain unknown. The availability of such information would make it possible to extend greatly the results of our study.

The solution of the converse structural problem for angiotensin II was based on the known[84] set of the energy-preferred conformations of the natural molecule. Calculation showed that the structural organisation of the octapeptide hormone can be represented by a limited number of low-energy conformations which can be divided into two groups — *A* and *B* — depending on the geometry of the central tetrapeptide Val^3–His^6 fragment (Table 6). In each group, the conformations differ from one another by the states of the N- and C-terminal dipeptides and can be in their turn subdivided into structures with a free side chain of the Asp or Arg residue.

In mammalian organisms, angiotensin II is encountered in two varieties differing in the nature of the residue in the first position (Asp or Asn), which has only a weak effect on the functional spectra and physiological activities of both hormones. It is seen from Table 6 that the possible conformations of the natural [Asn^1]-AT II analogues are very similar to those of AT II with the Asp^1 residue in the first position. Only the change in the global conformation in group *A* merits attention. In the AT II molecule, the conformation A_1 has the lowest energy. The Arg^2 residue makes a significant contribution to it stabilisation. The hydrophobic part of the side chain of this residue enters into effective dispersion interactions with almost all the residues of the Val^3–Pro^7 fragment (-11.5 kcal mol^{-1}), while the guanidine group, carrying an integral positive charge, interacts also with the C-terminal Phe^8 residue, which is negatively charged (-2.9 kcal mol^{-1}). The aspartic acid residue hardly interacts with the remainder of the molecule and is oriented towards the surrounding medium. In the A_2 conformation, the energy of which (0.9 kcal mol^{-1}) exceeds only slightly the energy of A_1, the situation changes: the side chain of the Arg^2 residue is free, while that of Asp^1 is bound.

In contrast to AT II, in the [Asn^1]-AT II molecule there is no negative charge on the first residue and the stabilising energy of its electrostatic interaction with the Arg^2 residue is therefore sharply weakened. This is in fact the primary cause of the smaller preference for the A_1 conformation compared with A_2, which becomes the most favourable.

Calculation for angiotensin III, differing from angiotensin II by the absence of the first residue in the sequence, led to an interesting result, which was satisfactorily correlated (this will be demon-strated below) with the physiological activity. The removal of Asp^1 alters significantly the position of the $A \rightleftarrows B$ conformational equilibrium, displacing it to the right. The B_4 or B_5 conformation becomes the most favourable, which amounts to absolutely the same thing, and the A_1 conformation, which is best for angiotensin II, acquires a high relative energy 7.4 kcal mol^{-1} (Table 6, p. 948) and its occurrence becomes unlikely.

One of the causes of the increase in the energy of the A_1 conformation relative to B_4 is associated with the greater destabilising electrostatic energy of the interactions of the positive charges on the main and side chains of the Arg^2 residue; in the A_1 conformation, the energy of the nonvalence interactions of the arginine residue is $+14.0$ kcal mol^{-1}, while in B_4 it is $+9.0$ kcal mol^{-1}. The second cause of the shift of the conformational equilibrium in the absence of the N-terminal Asp^1 residue from angiotensin consists in more compact packing and hence a lower energy of the interresidue dispersion interactions of the valence nonbonded atoms of the Arg^2 side chain in the B_4 conformation (-22.1 kcal mol^{-1}) compared with the A_1 conformation (-17.6 kcal mol^{-1}).

Angiotensin I (Table 6) is a decapeptide containing the His and Leu residues in the C-terminal part of the sequence. The increase in chain length affects appreciably the energy distribution of the conformations. It leads to a stronger determination of the conformational states of the peptide, i.e. to a restriction of the conformational freedom. Of the structural set of angiotensin II, three group A conformations (A_1, A_2, and A_4) are actually allowed, A_1 and A_2 having the lowest energies, as before. The A_2 conformation is more favourable in terms of energy than A_1, since its potential surface is more complementary to the surface of the additional His^9-Leu^{10} dipeptide fragment. The appreciable increase in the energy of group B conformations in angiotensin I, which renders them virtually prohibited, can be explained, firstly, by the significantly weaker interactions of the His^9-Leu^{10} section with the remainder of the molecule (for example, their energy is -6.2 kcal mol^{-1} for B_1, whereas those for A_2 and A_1 are respectively -11.3 and -9.4 kcal mol^{-1}) and, secondly, by the loss, for steric reasons, of a series of stabilising interactions of the Phe^8 residue, which occupies terminal and intermediate positions in angiotensin II and angiotensin I respectively.

Whereas the lengthening of the peptide chain by two residues (AT I) lowers the relative energy of the group A conformations, its shortening by two residues compared with angiotensin II [At II$-$(1$-$6)-peptide] has the opposite effect: two of the four group B conformations acquire the lowest energy, which does not exceed 1.0 kcal mol^{-1}. However, the changes are not quite so marked as in the case of AT I and the possible conformations of the hexapeptide analogue of angiotensin, lacking a series of stabilising interactions following the loss of two residues, are naturally more numerous. Not only group A conformations but even group C_1-F_1 and especially D_1 conformations become realistic under certain external conditions.

The replacement of the valine residues in the third and fifth positions in the angiotensin II molecule by proline {[Pro^3]-AT II and [Pro^5]-AT II (Table 6)} and alanine {[Ala^3]-AT II and [Ala^5]-AT II} residues had as its aim the introduction of a definite and previously known steric hindrance to prevent the occurrence of a large number of conformations (the first two peptides). On the other hand, the aim was to render the aminoacid sequence of angiotensin II more labile and to estimate the restricting effect of fairly bulky valine residues branches at the C^α atom on the formation of the steric structure of the molecule (the second pair of peptides).

Being in the R form, the residue preceding proline has a higher energy owing to the overlap of the van der Waals radii of the hydrogen atoms of the methylene group of the proline ring. The B and then the L forms are most preferred for this residue. For this reason, the Arg^2-Pro^3 section of the [Pro^3]-angiotensin II analogue can only have the expanded e shape. Consequently, the occurrence of the six out of the fourteen possible low-energy conformations of angiotensin II with the R form of Arg^2 and the f shape of the dipeptide Arg^2-Pro^3 becomes unlikely for the synthetic analogue. Only the A_1 and A_4 structures with relative energies of 0 and 4.5 kcal mol^{-1} remain preferred. The energies of the remaining structures exceed 10.0 kcal mol^{-1}.

When Val^5 is replaced by Pro^5, neither group A nor group B conformations are prohibited, since the Tyr^4-Val^5 section has the uncoiled form in both cases. Nevertheless, calculation showed that here the situation is in principle similar to that just examined above, i.e. a decrease in the relative energy of the A conformations and an increase in that of the B conformations is observed.

Calculation showed that the replacement of Val^3 and Val^5 by alanine, which seemingly should have provided considerable conformational freedom to the main chain of the hormone within the limits of the same minima on the multidimensional potential surface, hardly affects the position of the conformational equilibrium. As before, the group A structures in a polar medium are preferable to the group B structures, while the C_1-F_1 structures have equally high energies. Therefore one may expect that the physiological activity spectra of the alanine analogues reproduce fairly completely the spectrum of the natural angiotensin II, in contrast to the proline analogues.

In [Pro^3]-AT II, the replacement involves the residue which not only dictates the purely steric conditions for the establishment of the conformational states of the molecule, as in the four synthetic analogues of the natural hormone examined above, but undoubtedly also plays an extremely important role in specific recognition or in the consequences of the hormone$-$receptor interactions. Such duality complicates somewhat the treatment of the results of the theoretical conformational analysis of the analogue (Table 6). It is remarkable that the B_6 and F_1 conformations, having a very high energy in angiotensin II, are the most preferred in [Pro^2]-AT II.

We shall consider a further five analogues of angiotensin II. The Phe residue of angiotensin II was replaced in succession by the Ala, Leu, Val, Ile, and finally Tyr residues, i.e. by hydrophobic residues with a gradually increasing bulk. The most significant changes in the set of energy-preferred conformations compared with the natural octapeptide were then observed. Group A structures predominate in all cases. The energy distribution of the [Tyr^8]-AT II conformations is virtually the same, as might have been expected, as that in angiotensin II.

The choice for calculation of all the angiotensin II analogues presented in Table 6, especially the last six, is dictated by the availability of the corresponding experimental data, which will be analysed in the next section in the light of the results of the conformational analysis described.

VI. Polyfunctionality of the hormone and heterogeneity of the receptors

The knowledge of the quantitative characteristics of the structural organisation of angiotensin II and it analogues is a necessary condition for the rational investigation of the structural-functional organisation of the hormone. However, this is still far from sufficient. The attempt to discover the physiological characteristics of angiotensin(II), like those of any other natural oligopeptides, encounters fundamental difficulties arising owing to the lack of knowledge of the causes of the polyfunctionality of peptide hormones. The lack of clarity in this problem is due to the extremely scanty information about the hormonal receptors. In other words, the problem of the structural-functional organisation of the hormone has to be solved in essence in the absence of information about the properties of its partners in the interactions.

There are two points of view on the cause of the polyfunctionality of angiotensin and other peptide hormones. According to one of them,[90] the ability of a particular hormone to stimulate completely different processes in different parts of the organism can be accounted for by the presence of several receptor proteins specific to the given hormone, i.e. by the heterogeneity of the receptors. This point of view does not conflict with the known structural organisation of the hormone molecules. Natural oligopeptides in the native state are not rigorously determined three-dimensional structures, as in the case of high-molecular-mass proteins, but consist of sets of comparatively few steric forms with a position of conformational equilibrium which is readily

altered by external forces.[2] The results of earlier investigations of the possible conformations of bradykinin-potentiating peptides[39] and neurohypophyseal hormones — oxytocin, vasopressin, vasotocin, and mesotocin — agree with this assumption.[27,91]

A different treatment of this phenomenon arises on the basis that each hormone is capable of forming a productive complex only with a single receptor and hence of inducing always the same allosteric change in its conformation. If the receptors are the same, then the polyfunctionality of the hormone is determined no longer by the specificity of the hormone–receptor interactions themselves but by the characteristic features of the systems receiving the signal which has been sent. In this case, the diversity of the physiological activities of the hormone is caused not by the unique structure of its molecule and the characteristic features of the interactions with the receptor protein but by the specificity of the structural organisation of the systems, which respond differently to the same signal arising from the same hormone–receptor complexes interacting with them.

The hypothesis of the heterogeneity of the hormonal receptors, in particular the angiotensin II receptors, has been confirmed by the results of studies carried out in recent years. Thus this is indicated also by the different nature of the interaction of angiotensin II analogues with the receptors in different tissues (for example, by the presence of several analogues with selective activity),[92–95] by the different effects of cations on the binding of the hormone itself to the receptors in the tissues of different organs,[95] and by the observation of hormone receptors, differing in molecular mass, in the tissues of rabbit liver,[96] the human placenta,[97] and the adrenal cortex of the rat and the dog.[98]

However, the most significant evidence in support of the heterogeneity of the receptors as a cause of the polyfunctionality of angiotensin II was obtained recently when nonpeptide antagonists of the hormone were employed.[90,99] The use of a new class of nonpeptide antagonists in the study of angiotensin II receptors made it possible to discover the presence of different types of specific angiotensin II receptors in the mammalian organism. Thus two complex organic compounds, which the authors designated as DUP-89 and WL-19, were employed in one of these studies[99] for the identification of the receptors in the tissue of the rat adrenal cortex. It was found that each of them may bind only to a receptor of a fully defined type, whereas angiotensin II exhibits a high affinity for both receptors. As a result, it was shown that even in a single tissue there are two receptors for the hormone, which assumes a different form in the cells of this tissue. Later the receptor having an enhanced affinity for the WL-19 antagonist was detected in the rat and human uterus and in the rat brain.[10] The use of other nonpeptide antagonists permitted also the differentiation of different types of angiotensin II receptors in tissues of the rat liver and rat brain vessels.[100,101]

Thus a whole series of experimental data indicate convincingly the existence of a set of angiotensin II receptors which impose different conformational requirements on the hormone. One of the tasks in the 'from structure to function' approach which we have been developing in relation to a specific object actually involves the establishment of a quantitative relation between the existing experimental data and the structural organisation of the angiotensin II molecule and thus achieves a more rigorous basis for the treatment of the polyfunctionality of peptide hormones in terms of the heterogeneity of the receptors.

If our hypothesis is valid and a fully defined conformation from the set of low-energy readily interconverted steric forms discovered for angiotensin[84] does indeed interact with only one receptor and hence is responsible for the performance of only one function, then the next task consists in the determination for each physiological activity of the hormone of a conformational state relevant to only this activity, i.e. complementary to the corresponding receptor. Thus the energy-preferred conformations known from theoretical analysis have to be correlated with the experimental functions. Since the structures of the receptors let alone of their active centres are unknown, this problem cannot be solved, as already mentioned, without resorting to additional information. Such information may be obtained by studying synthetic analogues of the hormone.

Synthetic analogues have already been used in endocrinology for many decades. However, despite the expenditure of enormous efforts and financial resources, the results obtained with their aid indicate a low effectiveness of this approach, particularly in the scientific, cognitive respect. We suggest that the problem is not with the approach itself (at the present time there is no alternative to it) but with the satisfactory employment of its potential.

Virtually all the studies on these lines suffer from three serious defects. The first, most significant, is due to the random selection of the artificial analogues. The second weak feature, which also precludes the rise of investigations of this kind above an empirical level, involves the neglect of the possibilities of the theoretical analysis of the conformational states of both the hormone itself and of the selected synthetic analogues. Finally the third deficiency, characteristic of studies in this field, consists in the absence of not only a theoretical basis but also of a single systematic approach to the experimental investigation of hormones. Despite the multiplicity of studies in this field, it is still not possible to compare even in only one case the activity of the hormone with the activities of synthetic analogues throughout the functional spectrum. As a rule, in the study of biological activities of a natural peptide, different sources, different tissues, and, what is most significant, different sets of analogues are employed in each case.

When the peptide hormones are polyfunctional and the receptors are heterogeneous but there is no information about the structure of the latter, the most important, key problem, the solution of which can only be attempted with the aid of the corresponding theoretical developments, consists in passing from the random, purely intuitive search for synthetic analogues by the method of trial and error to their purposeful selection corresponding to special requirements. In order to be useful in the study of the relation between the structure and functions of a hormone, each of its synthetic analogues must be as far as possible monofunctional, i.e. must perform one of the functions of the natural peptide and hence must be able to assume, out of the set of the relevant low-energy conformations, only one steric form complementary to the active centre of the corresponding receptor. A more general aim is the deliberate formation of the chemical structure of the molecule known beforehand to assume the steric structure needed for the performance of the planned fully defined function.

We shall now return to the object of our study — angiotensin II, for which the direct and converse structural problems have already been solved (Sections IV and V).[84,89] However, in a rational study of the hormone[102] it was necessary to deviate somewhat from the procedures dictated by strict logic. This enforced deviation, although not fundamental, nevertheless does not lead to the complete elucidation of the possibilities of the 'from structure to function' approach. This is due to the lack of the necessary experimental literature data, although angiotensin II is in fact one of the most fully investigated peptides. The known experimental facts are very numerous and concern both the hormone itself and many hundreds of its synthetic analogues. However, the weak features of the purely empirical approach, noted above, are characteristic of all these studies as well as the analogous studies on other hormones: the random selection of the analogues, the lack of knowledge of the principles governing the molecular structural organisation of the hormone and its derivatives, and also the lack of a systematic approach to the investigation of functions.

We have been unable to find experimental data on any of the enormous number of the synthetic analogues of angiotensin II investigated which would characterise its activity over the entire spectrum of the biological activity of the hormone. Only a few analogues have been discovered for which quantitative data concerning three functions of angiotensin II have been obtained: the stimulation of the contractions of the smooth muscles and the

Table 7. The pressor activities and quantitative characteristics of certain varieties of the biological activity of natural angiotensins and a number of their synthetic analogues.

Compound	Smooth muscle [45]								Adrenal medulla [47, 103]		Adrenal cortex [46, 103]			Pressor activity (%) [45]
	rabbit aorta				rat stomach

AT I	1.0	7.53	5.1		1.0	7.1	22		95		2	5		50

Note. α_E = internal activity (the ratio of the maximum response induced by the agonist to the maximum response induced by AT II); pD_2 = negative logarithm of the agonist concentration inducing an effect equal to half the maximum effect (affinity); pA = negative logarithm of the antagonist concentration reducing the effect of the agonist by a factor of two; RAf(%) = relative affinity (the affinity of the agonist relative to the affinity of angiotensin II); RA = relative activity (the ratio of the activity of the agonist to the activity of angiotensin II for doses with average effectiveness); RSIB = relative strength of the inhibition of binding (ratio of the concentrations of the analogue and angiotensin II inducing the displacement of 50% of labelled AT II in binding to a specific receptor); a gap in the Table denotes the absence of data on the given type of activity and a dash denotes the absence of the given type of activity.

[a] In relation to rat uterus receptors.

regulation of the secretion of aldosterene and catecholamines. The corresponding activities of these analogues and the natural peptides are compared in Table 7.

Among the quantitative estimates of the effectiveness of the interaction of the hormone and its analogues with receptors, the internal activities (α_E) and affinities for the receptor (pD_2) characterise most directly the characteristic features of the structural organisation of the molecules (see the footnotes to Table 7). For analogues with a full internal activity, the effective concentration of the antagonist required for the performance of the biological function and hence the probability of a steric structure of the given analogue complementary to the active centre of the receptor and corresponding to the given conformational state of the hormone can be inferred from the values of pD_2. Indeed, the greater the displacement of the position of the conformational equilibrium for the antagonist from that relevant to the given function of the steric structure, the higher should be its concentration for the attainment of a definite effect and hence the lower its affinity for the receptor.

On the other hand, the probability of the occurrence of the relevant conformations is determined by the relative internal energies, which we have found for the hormone and its analogues in the solution of the direct and converse problems. By comparing the data in Tables 6 and 7, we shall attempt to obtain an idea about the significance of a particular conformational state for the performance of the corresponding function, i.e. about the structural-functional organisation of angiotensin II. We may note that Table 6 might be supplemented by any number of examples however large. For example, it is not difficult to calculate the possible conformations of all these hundreds of synthetic analogues of angiotensin II which have been synthesised and subjected to biological tests but which, alas, have been non-systematic and incomplete. However, for the existing level of experimental studies, the expansion of Table 6 would contribute little to the solution of the problems postulated and presented in Table 7.

The solution of the direct problem[84] showed that the possible conformations of angiotensin II may be described by a set of a few low-energy forms subdivided into two representative groups *A* and *B* and the single forms $C_1 - F_1$ (Table 6). Within the limits of one group, the conformations have the same steric structure of the central $Val^3-Tyr^4-Val^5-His^6$ tetrapeptide section of the molecule and differ from one another only in the orientations of the N- and C-terminal dipeptide fragments.

The results obtained in the solution of the converse problem[89] show that replacements of aminoacids in the angiotensin II sequence can lead to significant changes in the possible conformations of the molecule. The replacements not involving the functional residues do not entail the appearance of new low-energy steric forms, giving rise to a displacement of the conformational equilibrium within the limits of the preferred forms of the natural peptide.

As can be seen from Table 7, the modifications of the chemical structure of the hormone are reflected selectively in the effectiveness of the activities characteristic of angiotensin II. Since the experimental data refer to the interactions of the hormone and its analogues with the acceptors of the smooth muscle and adrenal cortex tissues, we shall attempt initially to identify the optimum conformational states of angiotensin II complementary to precisely these receptors.

The proline-containing analogues may be of special interest, since the replacement of any residue in the aminoacid sequence by Pro has a significant effect on the possible conformations of the entire molecule. We shall compare two such analogues with each other and with angiotensin II as regards steric structure and biological activity — [Pro^2]-AT II and [Pro^3]-AT II.

The replacement of the second residue in the aminoacid sequence of the hormone by proline leads to the almost complete loss of the affinity for the smooth muscle receptors by the [Pro^2]-AT II analogue (the relative affinity does not exceed 0.7% in this case), while the replacement of the third residue leaves the affinity of [Pro^3]-AT II for the receptors of the same tissue fairly significant (40%) compared with the hormone itself. On the other hand, highly concentrated doses of the second compound have no effect whatsoever on the secretion of aldosterone.[92]

The conformational states of the two proline-containing analogues also differ sharply. Among all the low-energy conformations of the [Pro^3]-AT II molecule, the group *A* representatives are the most realistic (Table 6). On the other hand, these conformations hardly occur for [Pro^2]-AT II; the equilibrium is markedly displaced towards the B_6 and F_1 conformations, which have the highest energies in the set of angiotensin II.

Thus comparison of the conformational and biological properties of the hormone and of two of its proline-containing analogues lead to the hypothesis that the group *A* steric structures are relevant to the interactions with the receptors of the smooth muscle tissue. However, this assumption may not prove to be entirely rigorous owing to the nonequivalence of the replacements. Whereas the replacement in the case of [Pro^3]-AT II is homologous (Val^3 is replaced by Pro^3) and therefore has an exclusively steric effect on the possible conformations of the molecule, in the case of [Pro^2]-AT II it is nonhomologous (Arg^2 is substituted by Pro^2) and, apart from the changes in the system of intramolecular nonvalence interactions of the atoms, involves the loss of a guanidine group, which may play an important functional role in the mutual relations between the hormone and the receptors.

Furthermore, the hypothesis that type *A* conformations are relevant to the contractile function of angiotensin II in the smooth muscles of arterioles is seemingly inconsistent with the available data for another proline analogue — [Pro^5]-AT II. Although there is virtually no quantitative information about its functions in the literature, nevertheless it is known that the pressor activity of this analogue is an order of magnitude lower than that of the natural peptide (Table 7), which indicates its low affinity for the smooth muscle tissue receptors. However, the group *A* conformations responsible, according to our hypothesis, for the contractile function are most preferred in [Pro^5]-AT II. At first sight, the contradiction is extremely serious, since in this case the replacement of Val^5 by Pro^5 is homologous. Nevertheless the discrepancy may be only apparent, since the loss of the pressor activity by the given analogue is susceptible to a different interpretation.

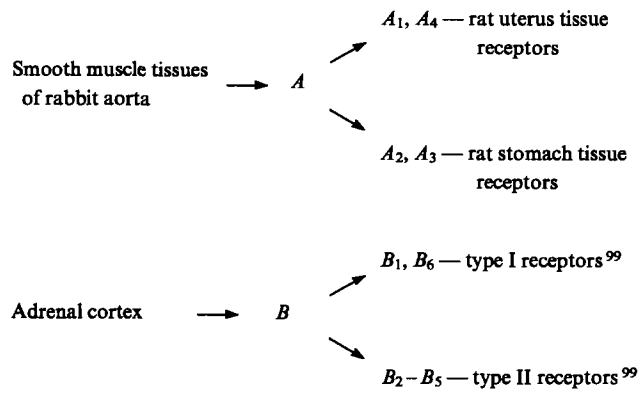
Calculation of the conformations of the [Pro^5]-AT II molecule showed that the inclusion of the Pro residue between Tyr^4 and His^6 leads to a significant limitation of the conformational freedom of the peptide chain and to the deformation of the group *A* steric structure of the molecule without causing, however, the displacement of the dihedral angles φ and ψ outside the limits of the *fef* shape of the central tetrapeptide section. Thus, whereas the distances between the C^α atoms of the tyrosine and histidine residues in this group of conformers are about 5.5 Å for angiotensin II, for the [Pro^5]-AT II analogue they are 7.4 Å. Furthermore, the activity of the compound may be influenced by the fact that the Pro^5 residue limits significantly the mobility of the side chains of adjacent residues, which undoubtedly interact effectively with the receptors.

Although our hypothesis that the group *A* conformations must participate in the operation of the contractile function of angiotensin II is fairly controversial nevertheless it will remain a working hypothesis.

Important evidence in support of this hypothesis follows from a comparison of the possible conformations and biological activities of angiotensin II and angiotensin III — a natural heptapeptide which differs from the octapeptide hormone considered by the absence of the N-terminal Asp^1 residue. Both compounds have the same spectrum of biological activities, but their effectiveness is significantly different except when they function in the tissues of the adrenal cortex. Numerous investigations have shown that, although the effectiveness of angiotensin III in its action on the remaining tissues is reduced compared with angiotensin II,

nevertheless the heptapeptide hormone induces in the adrenal cortex tissue the same aldosterone-stimulating effect as the octapeptide hormone[103] and, according to certain data,[46] is actually superior to the latter.

If our hypothesis concerning the cause of the polyfunctionality of the hormones is correct, then the angiotensin III molecule should have the corresponding possible conformations adequately reflecting the observed similarity and difference in its biological activity compared with angiotensin II. Indeed, the elimination of the N-terminal residue displaces sharply the conformational equilibrium towards group *B* structures: the $B_4(B_5)$ conformation becomes most preferred and is then followed in this respect by $B_2(B_3)$, B_1, and B_6, which are inferior to the most favourable conformation by 1.8 and 4.1 kcal mol^{-1} respectively (Table 6). In group *A*, there is only one low-energy conformation — A_2 (1.2 kcal mol^{-1}). Thus, among the steric structures related to the low-energy conformations of angiotensin II, in the case of angiotensin III the most probable conformations are $B_4(B_5)$, A_2, $B_2(B_3)$, as well as B_1 and B_6, i.e. there is a sharp displacement of the conformational equilibrium towards representatives of group *B*.



It has been reported[99] that, of the two types of receptors (I and II) isolated from the adrenal cortex tissue with the aid of the DUP-89 and WL-19 nonpeptide antagonists already mentioned, which bind the angiotensin II molecules equally effectively, only type II receptors[99] exhibit a high affinity for angiotensin III. On the other hand, the affinity of the heptapeptide hormone for type I receptors is reduced compared with the type II receptors by a factor of 12.

The effectiveness of the interaction of angiotensin III with the smooth muscle tissue receptors depends on the source and the organ. The affinity of the hormone for the receptors of the rat stomach tissue is lower by a factor of two than that of angiotensin II, while that for the receptors of the rabbit aorta tissue is reduced by a factor of almost 20.[45] The decrease in the affinity of angiotensin III for the receptors observed in these cases can be accounted for by the higher energy of the group *A* conformations responsible, according to our hypothesis, for the interaction of the hormone with the smooth muscle tissue receptors. The latter apparently have different requirements for the conformational state of the agonist. In this case, the A_1 and A_4 states can be assigned to the class of relevant states for the interaction of the hormone with the receptors of the rabbit aorta tissue, while the A_2 and A_3 states may be regarded as relevant to the interaction of the hormone with the rat stomach tissue receptors.

The high affinity of angiotensin III for the adrenal cortex receptors is consistent with the maximum probability of the occurrence of group *B* conformations, which permits the conclusion that these are relevant to the aldosterone-stimulating activity of the hormone. One can go further and postulate that the $B_4(B_5)$ and $B_2(B_3)$ conformations are complementary to the active centres of type II receptors,[99] while the B_1 and B_6 conformations are complementary to the active centres of type I receptors.[99]

[Asn^1]-AT II, another analogue of angiotensin II, is almost fully provided with all the functions of the [Asp^1]-AT II hormone under consideration. The interactions with rabbit aorta tissue receptors are an exception. The possible conformations of the [Asn^1]-AT II and [Asp^1]-AT II molecules are also very similar (Table 6), if one disregards the differences between the energies of the A_1 and A_4 conformations and hence between the probabilities of their occurrence, the probability being significantly smaller in the case of [Asn^1]-AT II. The affinity of this molecule for the rabbit aorta receptors is also appreciably reduced (Table 7). Thus the results of the conformational analysis and of the biological tests on this analogue agree with our conclusion that the A_1 and A_4 conformations are complementary to the rabbit aorta receptors.

Thus comparative analysis of the conformational properties and biological activities of the hormone and its analogues has shown that there is a relation between the biological activities and conformational states of angiotensin II, according to which the structural variants of group *A* interact with the receptors predominating in the smooth muscle tissues and those of group *B* interact with the receptors predominating in the adrenal cortex tissues, the representatives of each group being in their turn subdivided into subgroups according to the following scheme:

The classification of the conformations in terms of subgroups is consistent with a fully defined system of intramolecular contacts between atoms not linked by valence bonds.

In solving the direct problem for angiotensin II, it was established that the Arg^2 residue makes the greatest contribution to the stabilisation of the A_1, A_4, and B_2-B_5 conformations. The Asp^1 side chain is oriented towards the medium and interacts electrostatically only with the positively charged guanidine group of Arg^2; the energy of the interaction of Arg^2 with the rest of the molecule does not exceed 1 kcal mol^{-1} and is in addition destabilising in character.

Another system of intramolecular contacts obtains in the A_2, A_3, and B_1, B_6 conformations; the Arg^2 side chain is oriented in the direction away from the molecule and interacts only weakly with the other residues, while Asp^1 has numerous stabilising contacts.

The conformations of different subgroups differ also as regards the nature of the stabilising interactions. Whereas the A_2, A_3, and B_1, B_6 conformations are preferred as regards the energy of the nonvalence interactions between the atoms, the A_1, A_4 and B_2-B_5 conformations are preferred as regards electrostatic interactions and hydrogen bonds. The alternating responses of the conformations of both subgroups to the polarity of the medium combined with the ease of their interconversions makes the position of the conformational equilibrium in angiotensin II extremely sensitive to external conditions, primarily to specific interactions with receptors.

Some of the conformations of angiotensin II presented in Table 6 differ in the position of the C-terminal Phe^8 residue, which is of exceptional importance for the performance of the functions of the hormone. The elimination of this residue deprives angiotensin of virtually all its physiological activities. Thus [des-Phe^8]-AT II was found to be active only in relation to the rat brain tissues. The octapeptide analogues in which Phe^8 has been replaced by other aminoacid residues as a rule bind effectively to the hormone receptors but do not stimulate the corresponding signals.[45] The results of calculations for the [Ala^8]-, [Leu^8]-, and [Ile^8]-AT II analogues presented in Table 6 demonstrate relatively small changes in the possible conformations of these molecules compared with the natural peptide. On the other hand, it follows from Table 7 that none of them possesses the full spectrum of the biological activities of angiotensin II.

Hitherto we have considered the activities of the hormone and its analogues on the smooth muscle and adrenal cortex tissues. There is very little information about the interactions of angiotensin II with the receptors in other tissues. The known facts, concerning, for example, the receptors of the medulla of the

adrenal glands,[104] indicate that their structural requirements as regards the nature and steric structure of the C-terminal section of the aminoacid sequence are less rigorous. Thus [His^9-, Leu^{10}]-AT II, which is a precursor of the octapeptide hormone having a low affinity for the receptors in the smooth muscle and in the adrenal cortex, manifests the same activity as angiotensin II in the adrenal medulla. The synthetic analogue [Ala^8]-AT II, which behaves, as already mentioned, as an antagonist of angiotensin II in most tissues, nevertheless does not block the activity of the hormone in the medulla and actually exhibits some agonistic activity. Thus the lengthening of the peptide chain from the C- end and the replacement of Phe^8 by Ala^8 do not prevent in the given instance either the binding to the receptor or its stimulation.

VII. Conclusion

In conclusion we may note an important feature of the functioning of angiotensin II, which consists in the interdependence of all its numerous physiological activities in the mammalian organism. A number of factors, such as a decrease of the concentration of Na^+ ions in the blood, a decrease in the volume of circulating blood, and a fall in the arterial pressure lead to an increase in the secretion of renin by the kidneys and hence to an increase in the concentration of angiotensin II in mammalian blood.

The interaction of the hormone with the receptors located in different tissues induces responses designed to return the corresponding parameters to normal, the hormone acting at the tissue, systemic, and central levels. Thus the angiotensin II-induced increase in the tonus of the smooth musculature of the arterioles and the intensification of the secretion of catecholamines by the adrenal medulla increase the arterial pressure.

The retention of water and Na^+ ions in the organisms is effected by the hormone mainly via stimulating the secretion of aldosterone by the adrenal cortex, by the stimulation of the secretion of vasopressin by the hypothalamohypophyseal system, and also by the direct action of the hormone on the kidneys. The above activities of angiotensin II are supplemented by its effect on the central and peripheral divisions of the nervous system, which mediates the pressor effects and also intensifies thirst and the appetite for salt. This leads in its turn to an increase in the volume of the circulating blood and the normalisation of the pressure.

Thus the change in external conditions induces in the organism a complicated set of responses stimulated by a unique factor, namely angiotensin II, and directed towards a single aim — the maintenance of a constant internal medium within the organism.

The ability to effect productive interactions with a series of receptors at once and hence to perform simultaneously the corresponding number of coordinated functions is ensured by the structural-functional organisation of angiotensin II which the present author has investigated.

Problems in mechanochemistry and prospects for its development

P Yu Butyagin

Contents

I. Introduction 965
II. The present state of research 965
III. Prospects for further development and expected results 971

Abstract. The results of studies on nonthermal chemical reactions induced by the deformation of solids are summarised in the review. Attention is concentrated on the analysis of processes involving the dissipation of elastic energy, the description of the nature and properties of the intermediate nonequilibrium states, and also studies of processes involving the low-temperature molecular mixing of solid reagents. The possible trends in further research are discussed. The bibliography includes 89 references.

I. Introduction

Mechanochemistry is the study of the influence of elastic and plastic deformations on the reactivities of solids. This definition is not quite complete and rigorous, but it emphasises the relation between mechanochemistry and other branches of chemical science. Chemical reactions unaccompanied by a change in volume and the appearance (or relaxation) of internal stresses are indeed rare; mechanochemistry is therefore an indissoluble component of the physical chemistry and chemistry of solids.

The vigorous development of mechanochemistry during the last decade became possible as a result of advances in fundamental research and the improvement of many technological processes, including the synthesis of new materials. The intersections of mechanochemistry with adjacent branches of knowledge such as the physics and chemistry of the solid state, the theory of strength, physicochemical mechanics, catalysis, chemical engineering, materials science, geology, biochemistry, the chemistry of medicinal drugs, etc. have been no less important. The application of mechanochemical methods in engineering (in the manufacture of building materials and ceramics, including superconducting ones, in powder metallurgy, in the food and pharmaceutical industries, etc.) have also attracted the attention of investigators and technologists to mechanochemistry.

The extensive possibilities of mechanochemistry as the chemistry of nonthermal low-temperature reactions are illustrated by the fact that refractory substances and intermetallic compounds, inorganic and organic compounds, and molecular complexes have been synthesised, polymers and pharmaceutical preparations have been modified, and composite materials have been created in the solid phase without dissolution or fusion of the reactants. Mechanochemical syntheses are carried out at a comparatively low temperature, where the formation of an ideal crystal structure is difficult. This opens a route to the synthesis of substances and materials in the nanocrystalline and amorphous states.

The rate of development of mechanochemistry is reflected by the growth in the number of publications. The total number of journal articles on mechanochemistry published throughout the world increased over the last ten years almost by a factor of five and exceeded one thousand in 1992. The number of studies on the mechanochemistry of metals and alloys and also on the synthesis of various materials for engineering has greatly increased (see Refs 1–43).

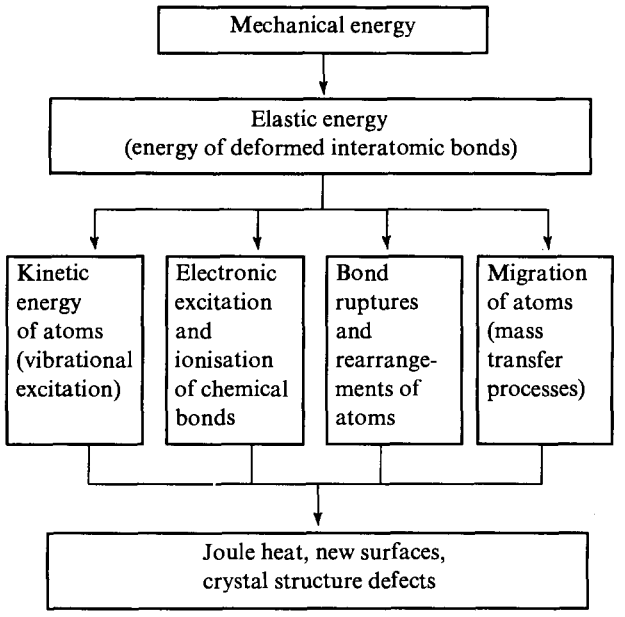
II. The present state of research

The period, lasting more than 100 years, in which mechanochemistry has been established as an independent field of knowledge has come to an end. During this time, mainly the results of qualitative observations of various effects have accumulated.

Nowadays no one believes that under the influence of mechanical action elastic energy is converted instantaneously, and without trace, into Joule heat.

It has been shown that, on deformation and disruption of solids, various energy-rich intermediate states arise in the first place, their subsequent decomposition resulting in the evolution of an appreciable proportion of the heat. In other words, there exists the so called 'black box' between work and heat; if energy is supplied to it faster than it can be converted into heat, it is possible to achieve various and unexpected chemical reactions.



Vibrationally an electronically excited bond, electrons and ions, metastable atomic structures, and other intermediate states may exist in the 'black box' and this list by no means exhausts its contents.

1. Transformations of elastic energy in solids

The scheme below illustrates the principal paths to the appearance and transformation of active nonequilibrium states arising when solids are subjected to mechanical influences.

Definite excess energy carriers with specific electronic and chemical structures, reactivities and relaxation mechanisms correspond to each of the pathways. Each state is characterised by a definite energy yield and lifetime. We shall consider the scheme below in greater detail.

2. Deformed interatomic bonds

Deformed covalent bonds are detected by IR spectroscopy (Fig. 1) and the extent of deformation is calculated from the shift of the absorption band maximum.[7,22,32,35,44] In metals and other crystals, the average degree of lattice deformation is calculated from the line shape in X-ray spectra. The deformed bond and its reactivity have long been considered by theoreticians and experimenters. In the construction of a kinetic theory of the strength of solids, attention has been concentrated on the reactions involving the rupture of elastically stressed bonds.[35] The effect of stresses on the rate constant k for this reaction was calculated from the Eyring–Kauzmann equation:

$$k = k_0 \exp\left(-\frac{E_a - \sigma V^{\neq}}{RT}\right),$$

where k_0 and E_a are the pre-exponential factor and the activation energy for the thermal decomposition and $\sigma V^{\neq}$ is the work performed by the elastic stresses in the reaction step (σ is the stress and $V^{\neq}$ the volume of activation).

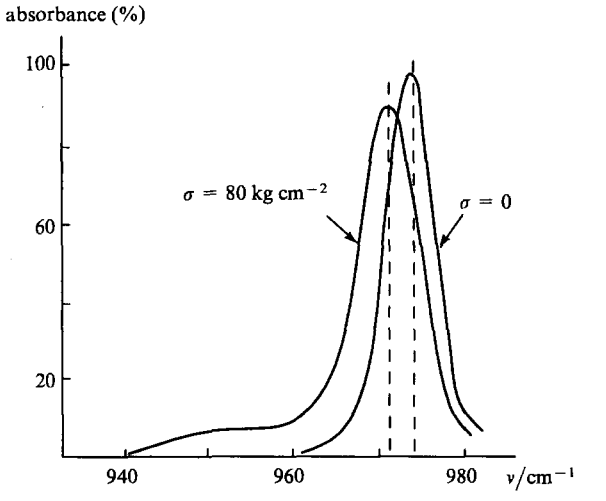


Figure 1. Skeletal vibrations of the main chain atoms in the IR spectrum of polypropylene in the initial state ($\sigma = 0$) and after extension by a load ($\sigma = 80\ \mathrm{kg\ cm^{-2}}$) (temperature 150 °C).[35]

In formulating this equation, it is implied that the active stresses facilitate the transitions through the energy barrier but do not affect its height. This approximation is apparently valid for the extension of bonds in the region of linear elasticity. For considerable deformations, one may expect a deviation from the linear energy relation. According to the results of quantum-chemical calculations,[45] a deformation of the C–C bond in the $\sim CH_2-CH_2-CH_2\sim$ chain close to the predissociation deformation lowers the ionisation potential of the hydrocarbon fragments almost by a factor of 2.

In substitution reactions, the reactivity of deformed fragments of organic molecules is characterised by the magnitude and sign of the coefficient of sensitivity to stresses.[14,32] Its value shows by what factor the rate constant changes following the extension or compression of a molecular fragment. For example, the rate constant for the hydrogen atom transfer reaction

$$R^{\cdot} + \sim CH_2-CH_2-CH_2\sim \rightarrow RH + \sim CH_2-CH^{\cdot}-CH_2\sim$$

is related to the deformation energy of the $-C-C-C-$bond skeleton by the expression[32]

$$\ln\frac{k(\varepsilon)}{k(\varepsilon=0)} = \alpha\frac{\Delta E^{0.5}}{RT},$$

where k are the rate constants for the reaction in the deformed [$k(\varepsilon)$] and nondeformed [$k(\varepsilon = 0)$] fragments, ΔE the deformation energy, and α an empirical constant the value of which depends on the nature of the hydrogen atom acceptor (in the abstraction of a H atom by an ozone molecule, $\alpha = 57\ \mathrm{J^{1/2}\ mol^{-1/2}}$).[32]

The above relation is valid for small deformations. It has been suggested that strongly deformed Si–O–Si linkages on the SiO_2 friction surface have reactivities similar to those of the $\equiv Si^{\cdot}\ldots{}^{\cdot}O-Si\equiv$ radical pairs. So far this is only a hypothesis put forward on the basis of the analysis of the kinetics of the reactions of SiO_2 with H_2, CO, and other molecules.[9] The first quantum-chemical calculations for substitution reactions involving deformed bonds were carried out several years ago.[44] It may be hoped that, as a result of the development of computer techniques and programs, it will become possible in the immediate future to investigate in greater depth the deformed fragments of molecules and their reactivities.

3. Vibrationally excited states

Several decades ago, there was a widely held view that impact or friction give rise to regions with an increased temperature — 'hot spots'. The initiation of chemical reactions was attributed to the existence of such spots.[21] The controversy concerning the possibility of an increase in temperature at the entrance to a crack or on the friction surface has still not ended. Mention of 'hot spots' may be found also in modern literature. Calculations of local temperature carried out by various investigators imply that the rate of evolution of Joule heat is much higher than the rate of removal of heat. However, the real situation is far from this highly simplified model. Several relaxation pathways usually operate. One of them involves the relaxation of the disturbed atomic structure, which is known to be a slow process, and energy transformations are therefore extended in time.

Judging from indirect features, centres with a high temperature exist only under extreme conditions. These include, for example, the instant when cavitation bubbles are flooded following the absorption of ultrasound in liquids.[19,27,41] Not only have the rates of absorption and transformation of the energy via different paths been calculated rigorously for this case[19] but measurements have also been made of the emission spectra,[41] confirming the existence of 'hot spots' with a temperature up to several thousands of degrees.

The first direct spectroscopic measurements revealing the state of the solid material at the instant of decomposition have been carried out for poly(methyl methacrylate). Their results are

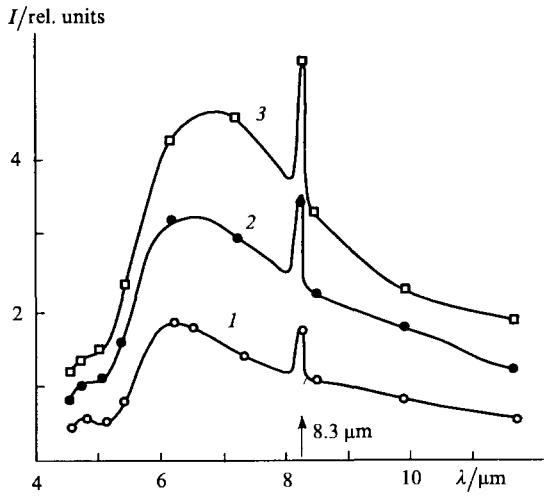

Figure 2. Thermal emission spectra obtained on disruption of a poly(methyl methacrylate) specimen.[37] Time elapsed from the start of disruption (μs): (*1*) 10; (*2*) 20, (*3*) 30.

illustrated in Fig. 2. The IR spectra measured at 10, 20, and 30 μs intervals after the initiation of the crack contain narrow lines, against the background of a broad thermal emission maximum, which correspond to vibrationally excited states. The lifetime of these states is short and the principal chemical mechanism of their destruction is the unimolecular isomerisation and decomposition of molecules accompanied by the ejection of fragments; bimolecular reactions with participation of 'hot' fragments of ruptured molecules have not been observed.

The first reports of the ejection of low-molecular-mass fragments on mechanical degradation of polymers appeared more than 25 years ago[46] and since then the decomposition of hot fragments has been frequently observed (see, for example, Zarkhin et al.[20] and Boldyrev[47]). The dynamics of the appearance, migration, and disappearance of excitations on dissociation of linear chains of atoms excited on rupture is investigated nowadays by molecular dynamics[43] or quantum-chemical methods.

For the occurrence of chemical reactions of highly excited states (decomposition, electron transfer, isomerisation, etc.), it is necessary that the energy level of the excited state should be close to the region where the potential curves corresponding to the initial and final states of the molecular or ionic fragment intersect. For example, when an ionic LiF crystal is cleaved, F atoms are ejected into the gas phase. The F^- anion must lose an electron in order to be able to leave the crystal: in contrast to F^-, the neutral F atom is not retained on the surface by electrostatic interaction forces. One of the hypotheses put forward to account for the emission of F atoms is as follows. Calculation[48] have shown that electron transfer in accordance with the scheme

$$F^-_{vib} \rightarrow F + e^-,$$

$$Li^+ + e^- \rightarrow Li,$$

is possible provided that the amplitude of the vibrations of the F^- ion, which are excited immediately after the dissociation of bonds at the entrance to the crack, exceeds 0.75 of the lattice parameter. Separation from the surface by this distance is equivalent to bond dissociation. In ionic crystals, decomposition into neutral atoms rather than ions is energetically more favourable.

It has been suggested that the ejection of hydrogen atoms on mechanical degradation of carbochain polymers[20] and of methane on degradation of polydimethylsiloxane[49] can be explained in this way. Apparently, after the dissociation of the chain, the amplitude of the vibrations of atoms in these polymers is such that, at the instant of their mutual approach, the distance between them diminishes so much that atomic rearrangements in accordance with the schemes

$$\sim CH(CH_3)\dot{C}H_2 \rightarrow \sim C(CH_3)=CH_2 + H^{\cdot}\text{(in polypropylene)},$$

and

$$=Si(CH_3)O^{\cdot} \rightarrow =Si=O + C^{\cdot}H_3\text{ (in polysiloxanes)},$$

became possible.

4. Electronic excitation and ionisation

All the consequences of electronic excitations and ionisation are usually combined in the group of mechanoemission phenomena. These include luminescence, static electrification, electron emission, and other effects associated both with the appearance of single electrically charged centres and with the effect of electric fields (static electrification). An extensive literature has been devoted to this problem.[9, 15, 30, 48]

Mechanical excitation of the electronic subsystem has been observed in crystals with different types of interatomic bonds. Examples of such processes in metallic copper[50] and magnesium oxide[9, 51] are presented below.

The 2.14 eV and 1.70–1.72 eV lines in the mechanoluminescence spectrum of copper (Fig. 3) correspond to electron transitions from surface electronic states to holes at the top of the *d* band of copper. The holes in the *d* bands are localised at dislocation nuclei, while electron–hole recombination, accompanied by the emission of light quanta, is induced by the emergence of dislocations onto the surface during the plastic deformation of the specimen.[30]

In magnesium oxide, electronic excitation with electron transition through the band gap may be represented as a chemical reaction involving electron transfer from the anion to the cation.[9]

$$\{Mg^{2+}O^{2-}\} \rightarrow \{Mg^+ \ldots O^-\}^*$$

Different distances between the ions correspond to the initial and excited states. When the excitation is induced by the absorption of UV light quanta, the lifetime of the $\{Mg^+ \ldots O^-\}^*$ excitons is short, since the necessary change in the interatomic distance is hindered by the rigid crystal matrix.

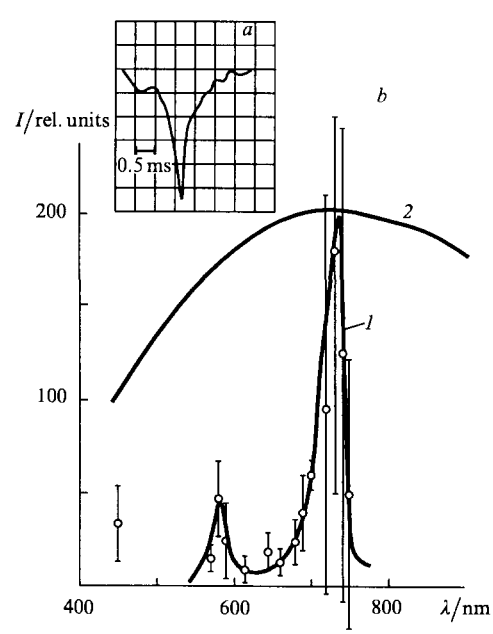

Figure 3. Oscillogram (*a*) and mechanoluminescence (*b*, curve *1*) and the thermal emission (*b*, curve *2*) spectra for copper at $T = 4000$ K.[50] The application of a load (impact) and the measurements (at the opposite end faces of a cylindrical specimen) were performed in vacuo at 10^{-5} GPa.

The same transition on friction is induced by the deformation of the surface, which increases the interionic distances to values corresponding to the $\{Mg^+ \ldots O^-\}$ structure, while electron transfer completes the stabilisation of this new state. At room temperature ($T \approx 0.1\ T_{pl}$), the thermal relaxation of the deformed surface is retarded and the long-lived quasi-exciton $\{Mg^+ \ldots O^-\}$ states may be preserved and investigated by spectroscopic, adsorption, and EPR methods.[51]

From the chemical point of view, the $\{Mg^+ \ldots O^-\}$ structures should be interpreted as radical pairs in which the oxygen radical-ion is one of the most active chemical species. In this case, the friction surface is distinguished by a high reactivity. The mechanical activation of the surfaces of many oxides is associated with the formation of quasi-exciton states.

Thus electronic excitation may be induced not only by the absorption of emission quanta but also by deformation, which creates configurations of atoms or ions favourable for electron transfer.

Other mechanisms also exist of the appearance of electrically charged centres and electric fields on disruption, deformation, and friction in crystals.[15,30,52] One of them is associated with the separation of the charges on the electrical double layer when contact between solid surfaces is broken.[15] On disruption and plastic deformation, the charges are separated between the dislocation nucleus and the compensating 'coat' (oppositely charged point defects). When a moving dislocation emerges onto the surface, the 'coat' remains in the bulk of the crystal. The growth of a crack as well as friction between surfaces are therefore a source of a wide variety of electrophysical effects.[30,52,53]

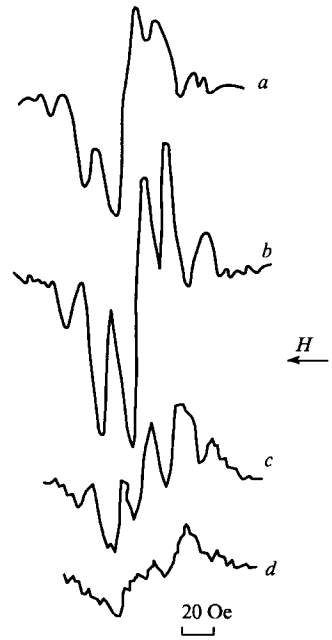

Figure 4. EPR spectra of the free radicals detected at the site of the mechanical rupture of DNA molecules isolated in a dilute frozen solution in D_2O: (*a*) and (*b*) different DNA specimens at 80 K; (*c*) and (*d*) the same specimens after raising the temperature to 195 and 217 K respectively (the rupture takes place in the deoxyribose unit).[54,55]

5. The dissociations and rearrangements of interatomic bonds

The mechanical properties of substances have been described fairly fully in the literature and constants such as the modulus of elasticity, the elastic limit, strength, hardness, etc. may be found in handbooks. On the other hand, quantitative data characterising the resistance of various substances to mechanical loads are not quite so extensive and studies on the kinetics and mechanisms of mechanical destruction have invariably attracted attention.

Indeed, failure is impossible without the dissociation of interatomic bonds and it therefore remains in essence a chemical step. The breakdown of polymers, molecular crystals, inorganic compounds, and metals is therefore regarded in mechanochemistry as a degradation process in the analysis of which it is necessary to take into account the nature of the bonds and the chemical structure of the corresponding substances.

Many examples of the chemical degradation of simple and complex substances on failure and deformation may be quoted (see, for example, Refs 1, 3, 5, 9, 14, 16, 20, 22, 35, 43, 46–49, 54–56, and 58).

The example of the mechanical destruction of polymers, in which not only the supermolecular structure is disrupted but macromolecules are cleaved, has become classical. The free radicals formed at the ends of the broken chain are detected and investigated by the EPR method. They have been observed on failure and deformation of polymers with different structures — ranging from polyethylene to DNA. In order to detect the primary radicals at the site of rupture, DNA molecules were isolated from one another in a dilute solution, the solution was frozen, and the destruction was observed at 80 K (Fig. 4).[54,55]

The radicals frequently initiate chain degradation and cross-linking. The chain degradation of three-dimensional polyacrylate esters,[16] cellulose,[55] and carbons[23] has been described. Polyethylene differs from these polymers by a tendency towards cross-linking.

On degradation of silicon dioxide, the dense network of siloxane bonds is ruptured and the radicals formed disproportionate. Two-coordinated silicon atoms and other irregular groups accumulate under these conditions.[9,56] The chemical properties of 'mechanical' radicals and their subsequent reactions in solids having directed bonds and on their surfaces are analysed within the framework of the theory of the reactivity of free radicals. The principal difference distinguishing radicals in solids is their high stability due to their fixation on the surface or in the bulk of crystals. Their destruction is usually induced by their involvement in chemical reactions and by the existence of various relay mechanisms of the migration of the free valence.

In metals, where there are no strictly directed bonds between atoms, the chemically reactive centres are atoms, with a low degree of coordination, within the dislocation nuclei and other structural defects. Prolonged mechanical treatment leads to extensive disordering with stabilisation of nanocrystalline or amorphous structures.[13,24,25,39,40,42,57,59–67] The degree of disordering is frequently characterised by the dimensions of microcrystalline blocks separated by intergrain boundaries. Their dimensions and residual deformation are calculated from the line shape in the X-ray spectra. The merging of the lines into a single broad band corresponds to the transition of the substance to the X-ray-amorphous state.

The degradation of ionic crystals[1,4,11,12,21,37,38] may be accompanied by the decomposition of complex anions and ionisation of the substance. Salts in which the cation is much smaller than the anion, for example, silver oxalate $Ag_2C_2O_4$, are distinguished by a high sensitivity to mechanical influences. The salt decomposes more than half during mechanical treatment at room temperature, this being detected by the liberation of the metal and carbon dioxide. Crystalline hydrates (for example, kaolin), which on mechanical treatment initially lose water of crystallisation, decompose even more readily. Finally, salts with unstable anions (azides, perchlorates, etc.) decompose explosively under impact.

Thus studies on the degradative phenomena in the course of disruption and deformation processes have shown that the macroscopic deformation pattern conceals profound changes in the chemical structure of the substance. Plastic deformation cannot therefore be regarded in isolation from chemical consequences.

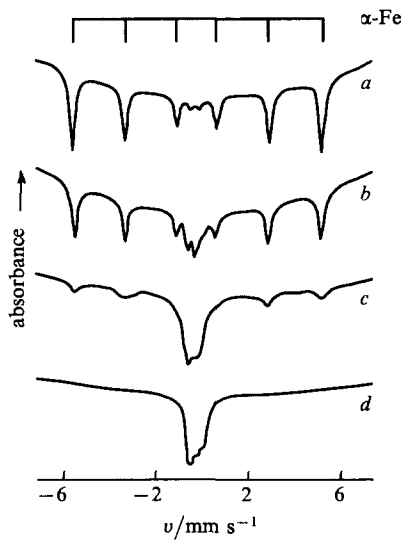
Since the reactivity of solids is their structure-sensitive property, the disordering and degradation (activation) processes are used in chemistry and chemical engineering to accelerate processes involving dissolution, sintering, synthesis, and decomposition of solid reagents.

6. Mass transfer processes

Irreversible changes in the form and size of a solid on plastic deformation are inevitably accompanied by the displacements of atoms in its bulk relative to one another. Relay mechanisms of the migration of structural defects frequently predominate under these conditions.

a. Deformation mobility

The deformation mobility of atoms (molecules, ions) and its scale are demonstrated by the phenomenon of the miscibility of various substances under the conditions of joint mechanical treatment. One of the striking examples is the dissolution of tungsten in iron[65] and nickel[66] at room temperature (Fig. 5).



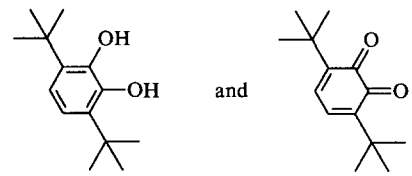


Figure 5. Mössbauer spectra of the 1 : 1 Fe/W mixture after mechanical treatment at room temperature in a vibromill.[29] Dose of supplied mechanical energy (kJ g^{-1}): (*a*) 5; (*b*) 10; (*c*) 60; (*d*) 100.

In terms of all their features, these are systems where miscibility is most difficult. Tungsten belongs to the strongest metals and the enthalpies of its mixing with iron and nickel are low: ~ -3 kJ mol^{-1} for mixing with nickel and ~ 0 kJ mol^{-1} for mixing with iron. The thermal mobility of atoms is almost frozen, since the temperature of the mechanical treatment does not exceed 0.2 T_m of the mixture components [T_m = melting point (Ed. of Translation)].

The initial stage of the dissolution of tungsten in nickel was detected from the increase in the nickel lattice parameter from 0.352 to 0.364 nm during the mechanical treatment of a mixture of the powders.[66] On more prolonged mechanical treatment, the nickel and iron crystal structures gradually break down; this can be seen from a series of Mössbauer spectra of the Fe/W mixture (Fig. 5). The growth of the amorphous halo in the spectra of the Fe/W mixtures is accompanied by the appearance of a single line in the spectrum, reflecting the formation of the paramagnetic iron compounds Fe_7W_6 or Fe_2W. Consequently tungsten atoms are inserted in the first coordination sphere of the iron atoms and the dissolution is not confined to the surface layer but involves the entire bulk of the substance.

The list of systems in which deformation mixing at the atomic or molecular level has been observed may be greatly expanded. It includes not only metals[17,24,25,37,39,40,42] and inorganic compounds,[1,5,8,12,21,26,28,53,59,67,68] but also plastic mixtures of organic substances.[39] The interest in molecular mixing has not disappeared to this day. Thus the appearance of an EPR signal has been observed recently when powders of a sterically hindered phenol and the quinone were mixed:[70]

The signal corresponds to the spectrum of radical pairs stable at room temperature (Fig. 6).

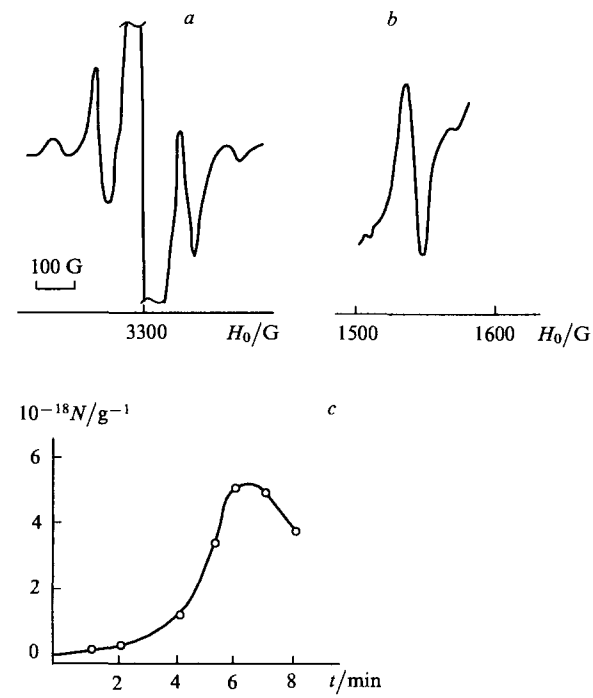

Figure 6. EPR spectra of the free radicals (central line) and radical pairs (outer lines) recorded on grinding a mixture of 3,6-di-*tert*-butyl-catechol and 3,6-di-*tert*-butyl-*o*-quinone powders in the region of 3000 G (*a*) and 1500 G (*b*). (*c*) Kinetics of the accumulation of radical pairs.[70]

On mixing, the molecules come into contact and the mobile hydrogen atom passes from the phenol to the quinone; this results in the formation of two adjacent radicals—a radical pair. The EPR spectrum of such a pair is illustrated in Fig. 6*a* and the kinetics of the accumulation of the radicals are illustrated in Fig. 6*c*. The number of pairs characterises the number of molecules in contact. During the mechanical treatment of a mixture of the phenol and quinone powders, the number of radical pairs increased to 5×10^{18} g^{-1} (in other similar systems, the increase was 1×10^{19} g^{-1}), which is a little less than 1% of the total number of molecules. When mixing is continued, the radical pairs begin to move apart, which is observed from the accumulation of the signals due to individual radicals (the average line in the spectrum of Fig. 6*a*).

Thus there is at present no doubt about the existence of the phenomenon of the low-temperature deformation mixing at the atomic (or molecular) level and its high effectiveness for both hard and soft substances.

b. Mechanochemical synthesis

Deformation mixing at the molecular level has led to the possibility of carrying out chemical reactions in mixtures of solids at room temperature whereupon diffusion is almost frozen. It is nowadays possible to find in the literature descriptions of several hundreds of such reactions, which have been achieved on Bridgeman's anvils,[8,18] in various mills,[1,21,24,25,38] attrition mills,[71,72] and disintegrators,[12] on rollers,[3,28] and in shock waves.[2]

It is important to emphasise that there are conditions under which the deformation mixing of solid reagents is completed by the formation of a new crystalline phase comprising the reaction products. Consequently the ordering of the product phase takes place under the same conditions as the disordering of the crystal structures of the starting materials.

Crystalline products may be formed in the reactions between simple and complex organic or inorganic compounds, between metals (mechanical fusion), and in mixtures of two or several solid components. As an example, Fig. 7*a* presents the kinetic curve for the synthesis of lead ferroniobate from a mixture of powders of three oxides:[36]

$$4\,PbO + Nb_2O_5 + Fe_2O_3 \rightarrow 4\,Pb(Fe_{0.5}Nb_{0.5})O_3\,.$$

The yield of the crystalline product phase was recorded by X-ray phase analysis (Fig. 7*b*). The figure shows clearly that the formation of the product is accompanied by its degradation. If the mechanical treatment is not stopped, then the content of the product synthesised in the mixture begins to fall.

During a prolonged mechanical treatment of a mixture of boron and carbon powders at room temperature, the accumulation of boron carbide was observed. There can be no doubt about the reality of the nonthermal mechanism of the synthesis of boron carbide, since the temperature in the apparatus was lower by 2000 K than the melting point of the components, while the heat of reaction is low. The formation of the nanocrystalline boron carbide was detected by X-ray diffraction despite the fact that the unit cell of B_4C contains more than 100 atoms. Thus plastic deformation induces not only the breakdown of the crystals of individual substances but also the formation of new crystal structures in mixtures of solid reagents.

The formation of the crystalline phase of the product in multicomponent reaction mixtures reveals yet another feature of the transformations of the elastic energy in solids, which is no less promising for chemistry. Under the same conditions, two at first sight incompatible processes are intertwined in the above process, namely, the decomposition and ordering of the crystal structures.

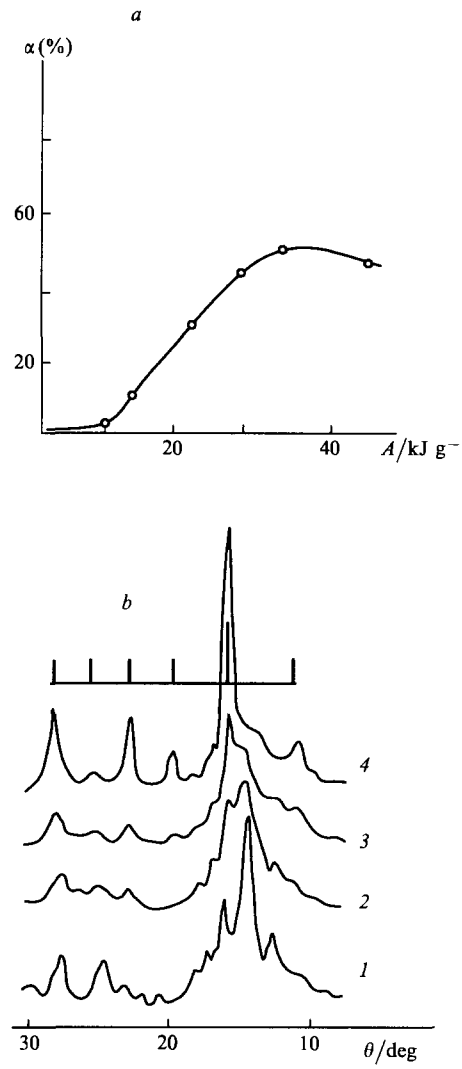

Figure 7. Kinetics of the mechanochemical synthesis of lead ferroniobate from a mixture of iron oxide, niobium oxide, and lead oxide powders at room temperature (*a*). Diffractometer traces for the mixture at different stages of the reaction (*b*) (the positions of the product lines are indicated in the top part of the figure).[36]

Table 1. Mechanochemical synthesis in metal–nonmetal mixtures (according to the data of Shelimov and Butyagin[81]).

Mixture	T_{ad}	T_m	Mixture	T_{ad}	T_m	Mixture	T_{ad}	T_m
Explosive reactions								
Zn + S	3380	693	Ti + C	3210	1941	Zr + 2S	5930	2128
Cd + S	2280	594	Ti + 2B	3190	1941	Hf + C	3900	2500
2In + 3S	2160	430	5Ti + 3Si	2390	1941	Hf + 2B	3520	2500
Sn + S	1640	505	Zr + C	3410	2128	5V + 3Si	2400	2190
Sn + 2S	1140	505	Zr + 2B	3310	2128	2Ni + Si	1590	1728
Pb + S	1620	600	Zr + 3Si	2480	2128			
Reactions without explosion								
2Cu + S	1267	1357	2As + 2S	580	1087	Ta + C	2730	3287
2Ag + S	695	1234	2Sb + 2S	880	904	Ti + B	2600	1941
Ge + S	1173	1210	Nb + 2B	2350	2740	2W + C	670	3700

Note. The data on the explosion in each reaction system have been taken from Refs 33, 75, 78–81, and 83; T_{ad} = adiabatic combustion temperature of the mixture; T_m = melting point of the metal.

The destabilising effect of elastic stresses on the crystals has proved favourable for the mixing of the components at the molecular (atomic) level. The formation of crystalline reaction products indicates a trend towards ordering. The greater the shift of the reaction equilibrium towards the products, the stronger is the manifestation of this trend.

In exothermic reaction mixtures, the formation of the product is accompanied by the evolution of heat. By varying the intensity of the mechanical treatment and the rate of removal of heat, it is possible to create in such systems conditions favourable for the mechanical initiation of thermal explosion. During the last decade, explosive mechanochemical synthesis has become the object of continuous attention by investigators.[29,33,73-81]

In the initial stage of the mechanical treatment, the size of the powder particles diminishes, the mixture is stirred, and the area of contact between the reactants increases. Under these conditions, the reaction begins to develop in the surface zone and heat is evolved. So long as the particles are large, the degree of their reaction is low and the temperature remains at a low level. After the increase in the area of the surface of contact to several square metres per gram, the rate of reaction increases so much that there is insufficient time for heat to be removed and the reaction passes into the self-acceleration regime.

In reaction mixtures for which the adiabatic reaction temperature is equal to or greater than the melting point of one of the components and the rate of application of the mechanical energy dose is above a critical level, the self-acceleration condition is replaced by thermal explosion (see Table 1 and Shelimov and Butyagin[81]).

* * *

Vibrational and electronic excitation as well as phenomena involving the degradation and disordering of crystals, deformation mixing, and synthesis represent the content of the large field of nonthermal physicochemical and chemical reactions. This field complements the classical thermal theory and significantly expands its possibilities. The phenomena considered are no less interesting for solid state physics, materials science, and other branches of natural sciences.

From the chemical point of view, reactions in mixtures of powders and processes involving the mechanical activation of solid reagents are the most promising. However, the experience accumulated in laboratories is being gradually assimilated in engineering. The list of mechanochemical reactions achieved on a small scale embraces various classes of solid-phase reactions.

Thus gas–solid reactions include the synthesis of nitrides, hydrides, and carbonyls on interaction of gases (nitrogen, hydrogen, carbon monoxide, etc.) with powdered metals and nonmetals.[61-64,82-85] The first experiments on pseudocatalytic reactions under the conditions of the mechanical treatment of a powdered catalyst have already been carried out.[83,85]

The list of solid–solid reactions is the longest. It includes the synthesis of carbides, borides, and silicides from the initial elements (TiC, TiB_2, B_4C, etc.[33,74-76,81]), the reduction of oxides by metals,[77] and the synthesis of ferrites, superconducting ceramics, and other oxide materials.[1,6,12,36] Mechanical fusion, i.e. the preparation of alloys, intermetallic compounds, and composite materials from them, also belongs to processes of this class[17,24,25,28,39,40,42,59,60,65,67,68,72,73]. Solid-phase organic synthesis[2,6,18] includes the preparation of phthalazole, amine acylation reactions, Diels–Alder condensation, the polymerisation of solid monomers, etc. Modification of medicinal drugs and the preparation of compositions with a controlled liberation of medicinal forms constitute a related field.

A by no means complete list of systems investigated has been presented here, but even these examples emphasise the breadth and scale of the accumulated knowledge. Nowadays there is a transition in mechanochemistry from laboratory research to technological developments. A diverse range of laboratory mechanochemical reactors has been created and exists. It is possible to activate and synthesise in them organic and inorganic substances.[1,8,71,72,86]

Unfortunately, the reactors have not always been successfully characterised (dose, rate of application of dose) to be able to compare the results obtained by different workers or to give recommendations concerning the scaling of experiments. Vigorous research is being prosecuted on these lines.[71,72,86]

However, the choice of manufacturing apparatus is as a rule restricted to equipment which has been created for other purposes—grinding, extrusion, etc. Theoretical studies on the conditions of the synthesis in large-scale mechanochemical reactors taking into account the dynamics and energy relations of specific processes can be counted on one's fingers, i.e. the laboratory experiment–technological tests link has not yet been established.

III. Prospects for further development and expected results

1. Reactivity of elastically deformed solids

Studies on the role of elastic stresses in solid-phase reactions were apparently developed in several directions. They can be given conventional names: (1) electronic structure and reactivity of elastically deformed interatomic bonds; (2) elastic model of solid-phase reactions; (3) reactions in structural relaxation processes. The first of these has already been examined in Section II. 2. The contents of the others will be briefly described below.

The second aspect of the above investigations deals with reactions in continuous media, where it is necessary to take into account the deformation of not only the reaction centre proper but also of its environment. Within the framework of the elastic approximation, the potential energy of the reaction centre is represented as the sum of the energy of the chemical interaction proper U_{chem} and the deformation energy U_{str}. The height of the energy barrier in the reaction involving such a reaction centre is equal to the difference between the energies of the system in the transition and initial states. The complex structure of the reaction barrier in the solid phase is illustrated by the scheme below:

$$E = (U^{\#}_{chem} + U^{\#}_{str}) - (U^{0}_{chem} + U^{0}_{str}).$$

The superscripts '#' and '0' denote the transition and initial states.

Computer calculations of the energy barrier in model reactions are not very complex (Fig. 8) when they are carried out by the method of molecular dynamics and do not involve changes in the electronic subsystem, but because of this the results of such calculations are approximate. Fig. 8*a* illustrates the model for the calculation of the barrier height when an extraneous atom is inserted in the crystal lattice. This atom, designated by a filled circle, is acted upon by a force F, which displaces it downwards at a constant rate. Here one calculates both the change in the energy of the atom (Fig. 8*b*, curve *1*), and the deformation of its environment (curve *2*), i.e. all the components of the barrier structure (the schemes in Figs 8*c* and 8*d* illustrate the macrokinetics of the deformation mixing). The first results of such calculations have shown that the deformation contribution may be dominant under certain conditions.[28,87] The calculations of the barrier structure are valid for both thermal and mechanochemical reactions.

The main difference between mechanical reactions and the usual thermofluctuation reactions is the use of different methods for overcoming the energy barrier separating the initial and final states in the elementary reaction step. It is as a rule understood that the form and height of the energy barrier are independent of the way in which it is overcome: under the influence of elastic stresses or by the thermofluctuation route.

However, systematic studies on the effect of elastic stresses and of the rate of deformation on the form of the potential surface and the route followed during the movement of the system of reacting species along the reaction coordinate have not been carried out.

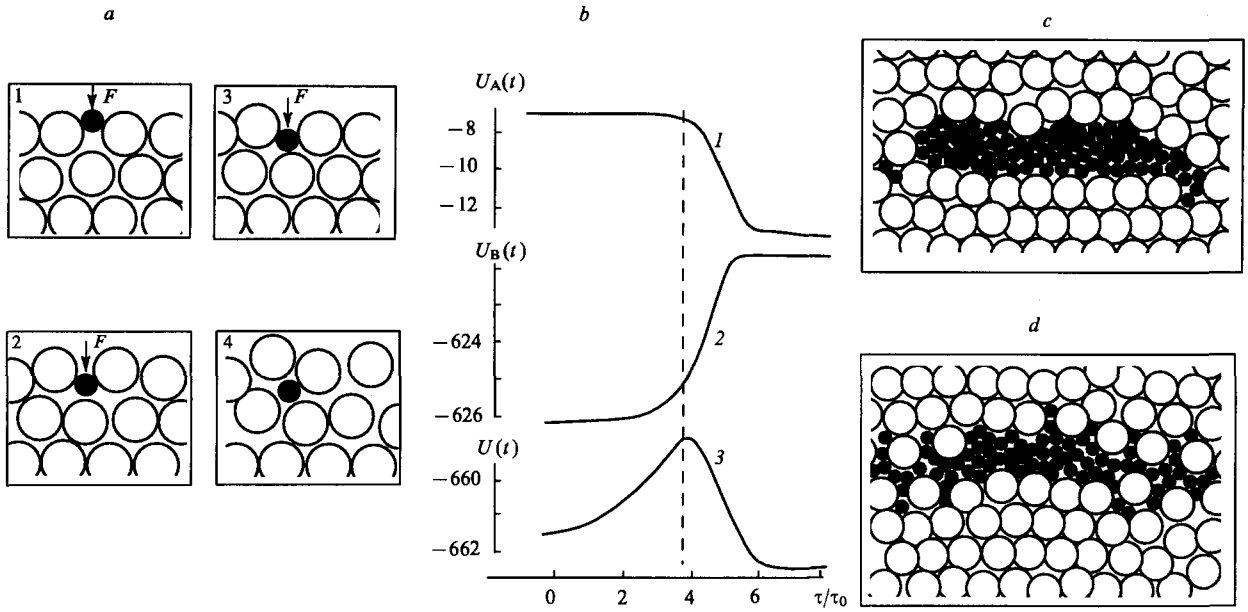

Figure 8. Modelling of deformation mixing by the method of molecular dynamics. Permeation of an atom through the surface: (*a*) scheme; (*b*) calculation of the changes in the energy of the atom itself [$U_A(t)$] (curve *1*) and of the crystal [$U_B(t)$] (curve *2*) and of the height of the energy barrier [$U(t)$] (curve 3) for a three-dimensional model; (*c*) and (*d*) stages in deformation mixing on uniaxial compression of a three-layer model.[9, 10, 28, 29]

The limits of the applicability of this approximation are therefore also unknown. It may be hoped that the search for answers to these questions will begin in the immediate future.

Mechanochemical reactions in solids are known to be induced not only by the direct action of elastic stresses but also by elastic energy relaxation processes. Studies on the kinetics and mechanisms of the reactions accompanying structural relaxation belong to the third aspect. Unjustifiably little attention has been devoted in the literature to the mechanisms of these reactions as well as relaxation itself, which can be accounted for by the difficulties in the experimental study of these processes.

One of the first studies[48] was devoted to calculations of the probability of the emission of atoms from the cleavage surfaces of alkali metal halide crystals. An experimental investigation of rapid structural relaxation has been recently carried out by synchrotron radiation diffraction methods.[5] It may be hoped that the results will stimulate the formulation of further studies.

Nowadays all the available theoretical models are restricted to the analysis of the relaxation of a one-dimensional chain of atoms and the secondary reactions occurring after its rupture.[20] However, it is no less important that, under certain conditions, the energy liberated in the elementary reaction steps assumes the form of a compression wave (soliton), which initiates the reactions in the neighbouring cells, etc. Such self-supporting relay reactions began to be observed recently in both computer and physical experiments.[20]

2. The mechanisms of mechanochemical reactions

a. Degradation

In the study of the disordering of crystals of simple and complex substances, much attention is devoted to the problem of the degradation or dispersion limit. The term 'limit' is given to the smallest dimension of the crystal block or another fragment of the initial structure remaining unchanged under the conditions of prolonged mechanical treatment.

The ideas about the degradation limit (dispersion limit), based on the results of calculations of the strength of microcrystals, which previously seemed unshakeable, restricted mechanical dispersion to crystal fragment dimensions of tens of nanometers. However, it has been observed recently that for many isotypical crystals (face-centred cubic metals,[57] alkali metal halides[53]) the degree of disordering is greater the stronger the substance. This finding gave rise to interest in problems of the concentration of elastic energy, the determination of the degradation limit, and the study of the mechanisms of dispersion.

Recently the views on the nature of mechanical dispersion have begun to change.[25, 89] Instead of the disruption of individual microcrystals, the deformation of complex polycrystalline structures, threaded by intergrain boundaries and interfaces, is now analysed. From this point of view, the decrease in the size of microcrystalline blocks on plastic deformation is equivalent to an increase in the density of the network of dislocation boundaries. Hence follow a series of consequences important for a deeper understanding of both the processes occurring in the material and of the mechanisms of the chemical reactions.

Thus, in the migration of dislocations, combined into boundaries and 'sweeping' through the bulk of the crystal during their motion, work is expended on the reorganisation of the crystal structure accompanied by rearrangements of atoms, the production of defects, and other processes favouring chemical reactions.

The denser the network of boundaries, the larger the 'swept' volume. If in the course of the operation of stresses, the boundaries 'sweep' the entire or almost the entire volume of the substance, one may speak of the possibility, in principle, of a global deformation disordering of the crystals. The transition to such a 'deformation-transparent' state requires that the average distance between the boundaries L, virtually equal to the size of the crystalline blocks, should decrease to a critical value L_{cr} satisfying the condition:

$$L = L_{cr} \quad \text{when} \quad \dot{\varepsilon}_{cr} = \frac{1}{L}\frac{dL}{dt} = \frac{1}{\tau},$$

where τ is the duration of the operational stresses, and $\dot{\varepsilon}_{cr}$ the critical rate of deformation, which depends on many factors. The quantity $\dot{\varepsilon}_{cr}$ may be estimated from the equations of the theory of plasticity. It may be hoped that a rigorous theory of 'deformation transparency' will appear in the immediate future. It will then become possible to relate the observed dispersion limit not to the indivisibility of the nanocrystals but to the establishment of a dynamic equilibrium between the processes involving global disordering and spontaneous relaxation,[25, 89] which is induced by

the tendency of the substance to return to its natural ordered state (plastic deformation creates the mobility necesary for this purpose).

This incipient concept is much more fruitful for chemistry, since it removes the limitations to the scale of the mobility of the structural elements of the solid and draws attention to the extent of the possible chemical consequences of deformation processes in the regions corresponding to the motion of the intergrain boundaries and interfaces.

The possibility, in principle, of profound changes in the chemical and physical properties of substances on deformation should not encounter serious objections. Thus many inorganic crystals consist of species (ions) which are stable only in a powerful crystal field generated by the electrostatic interaction forces. When the deformation weakens the crystal field, then the species constituting the crystal also lose their stability and their properties change.

Thus the weakening of the crystal field in the narrow-band oxides GeO_2 and SnO_2 as a result of the disordering of the crystal structure is accompanied by a decrease in the width of the band gap with a corresponding change in physical and chemical properties: colour, conductivity, and reactivity, including catalytic activity.[51]

The examples examined demonstrate the extensive possibilities of the phenomenon of mechanical activation, to which several monographs have been devoted.[1,6,21,38] This field of research has a solid experimental basis and in future years one may expect the discovery, if not of new phenomena, then of new relations between the sensitivity of substances to mechanical loads and the change in reactivity on activation, on the one hand, and the nature of the interatomic bonds and the chemical structure of specific compounds, on the other.

b. Solid–solid reactions

The reactions between solid substances at a low temperature, carried out without preliminary dissolution, fusion, or sintering of the reactants, constitute one of the most promising branches of mechanochemistry, which, as before, has attracted the attention of investigators.

The mechanisms and kinetics of the processes in mixtures of solid reactants, where elastic stresses and chemical forces act simultaneously while the deformation and the reaction are closely intertwined, are not considered in either mechanics or chemical kinetics. Here there are no ready solutions from other branches of solid state physics and chemistry.

The kinetic description of solid-phase reactions is complicated by the fact that the dispersity, phase composition, and the defect structure and mechanical properties of the reaction medium vary continuously during its mechanical treatment.

The development of a theory of solid-phase reactions is still not complete. It is necessary that it should allow a description of the mechanisms and kinetics of solid phase reactions in such a way that they would permit the use in mechanochemistry of the large body of knowledge in classical thermochemistry. The problem is not quite so simple as might appear at first sight. Analysis of the results of the studies in recent years suggests the following logic for the development of the theory.

The interpenetration of atoms begins on the surface of contact of the components, so that the work involved in the formation of the interface is one of the important factors in the initial stage of the reaction. Together with elastic stresses, chemical forces operate here also; they in fact determine to a large extent the intensity of the mixing.[1,28,87,88] The results of computer experiments have revealed the specific role of chemical affinity in deformation mixing.[28] Experiment shows that the greater the energy of the mixing in the system

$$A + B \rightarrow AB,$$

and the more extensive the contact zones, the more complete and thorough the mixing.

The insertion of an atom A in a crystal B is hindered by a definite energy barrier. At a low temperature, this barrier is overcome by the action of elastic stresses. The barrier is lower, the greater the energy gain on interaction of the atoms A and B. Therefore, for the same level of elastic stresses, the probability of overcoming the barrier increases with increasing energy of mixing.

An excess energy accumulates in the reaction mixture during mechanical treatment. There are several carriers of this energy; these are the residual elastic stresses, interfaces, intergrain boundaries, amorphous regions, regions of supersaturated solid solutions, and other metastable structures. The accumulation of energy cannot be infinite, the accumulated energy being discarded at some stage and the structure of the reaction mixture becoming ordered. In mixtures of solid reactants, the equilibrium state to which the system passes on relaxation may prove to be the crystalline phase of the reaction products.[87,88] The more thorough the mixing and the higher the level of the stored energy, the greater the probability of the formation of the product phase on relaxation.

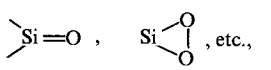
It may be expected that a two-stage mechanism of solid-phase reactions, namely deformation mixing–relaxation, will again attract the attention of investigators in the coming years. It is essential to select key parameters characterising the dynamics of the deformation mixing and the critical state of the reaction mixture, to examine the conditions under which mixing is replaced by relaxation, and to discover the specific mechanisms of the relaxation for substances with different types of interatomic bonds.[25,87,88]

Apart from deformation mixing, in real plastic materials it is necessary to take into account also diffusional processes, which may facilitate structural relaxation. Indeed, a dense network of interfaces and intergrain boundaries may play the role of accelerated-diffusion channels even in the absence of deformation. Furthermore, a decrease in the size of the microcrystalline blocks to 10^{-9}–10^{-8} m is equivalent to the shortening of the diffusion pathways (X) and of the duration of permeation (t) by many orders of magnitude ($t = X^2/D$). Therefore nanocrystalline particles become diffusionally transparent in reaction mixtures where the diffusion coefficient (D) is close to 10^{-20} m^2 s^{-1}.

Simultaneously with the theory of deformation mixing, the theory of quasi-explosive and explosive mechanochemical reactions in exothermic systems, where the energy liberated in relaxation processes is sufficient for the self-acceleration of the reaction, will develop. Furthermore, the range of reaction systems investigated will probably expand greatly.

The intense development of the mechanochemical synthesis of inorganic substances, intermetallic compounds, and alloys is associated with their successful employment in materials science (superconducting ceramics, heat resistant and ultrastrong materials, amorphous alloys, nanocrystalline materials, etc.). In creating such materials, it is important not only to synthesise a substance with a specified chemical constitution but also to achieve the specific formation of its structure. Mechanochemical methods make this possible.

The advantages of mechanochemical methods—ecological purity (the absence of solvents or annealing furnaces), simplicity, and the possibility of the chemical and structural modification of the product—are being comparatively slowly realised in organic chemistry. However, the first signs that such conservation attitudes will be soon overcome have already appeared: the mechanochemistry of medicinal drugs, the mechanochemistry of carbons, etc. has been developed. As time goes by, the efforts of investigators will be distributed uniformly between the mechanical syntheses of organic and inorganic substances. The search for methods of synthesis, optimal in mechanochemistry and unrelated to the mechanisms adopted in thermochemistry, will be continued.



c. Gas–solid reactions

A fresh surface which is exposed following the disruption of a solid or produced as a result of friction is, as it were, designed for participation in chemical reactions. The atoms of such a surface

are coordinatively unsaturated and the problem is merely to select their partners in the reaction. Otherwise, the active surface ceases to exist in rearrangements and oxidation or hydration processes.

In order to account for the mechanisms of the chemical reactions occurring with participation of a freshly formed surface, it is essential to know the valence state of the atoms on this surface, their reactivity, and the rates of structural rearrangement (relaxation). These studies have already been combined in an independent field (mechanical chemisorption or tribosorption[9,21,51,56,85]).

Hitherto the majority of studies have been carried out for the freshly formed silicon dioxide surface.[9,56] Silicon and oxygen atoms with ruptured bonds ($\equiv Si^{\cdot}$, $=Si:$, $\equiv SiO^{\cdot}$) in the ground and electronically excited states, new atomic groups

deformed siloxane linkages, and other centres have been detected on it. The electronic structure and constitution of these fragments have been described and measurements have been made of the rate constants for the reactions of the principal centres with gases and their course has been determined. The nature and properties of the active surfaces of ionic oxides, graphite, silicon, and individual metals have also been investigated.

It has recently become clear that the spectrum of nonequilibrium chemically reactive states is much wider than appeared previously. The energy liberated on reaction with gases is sufficient to excite the electronic subsystem of the crystals with ejection of fragments comprising complex anions, emission of electrons, including those with energies up to tens of kiloelectronvolts[15]), and also the emission of neutrons on disruption of deuterium-containing crystals.[53] The theory of mechanoemission phenomena continues to be developed (see, for example, Molotskii[30]) and the experimental and theoretical studies in this interesting field will continue for many decades.

The chemisorption of gases on a freshly formed surface is widely used as a kind of instrument for the determination of the degree of damage of the crystal structure. Chemisorption is the first stage in the interaction of solids with gases; however, solid–gas reactions are not always restricted to monomolecular surface coverage. Three examples of a more far-reaching development of these reactions are presented below.

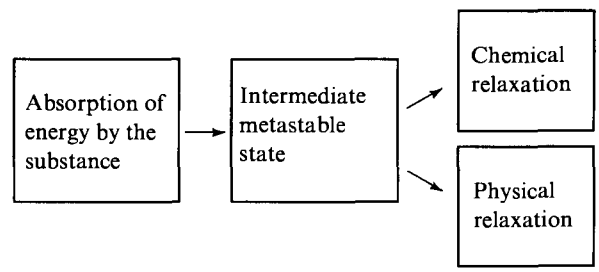
Thus volatile carbonyl complexes are formed on the active surface of nickel in the presence of CO, nickel pentacarbonyl being desorbed from the metal surface into the gas phase. The renewal of the surface continues until almost the entire metal has been converted into $Ni(CO)_5$.[21]

Molecules of gases such as N_2, NH_3, O_2, CO, and others dissociate into atoms on chemisorption, as a result of which surface compounds are stabilised on the active surface.[9] On plastic deformation and friction, increasing numbers of fresh atoms from the bulk of the solid particles are carried to the surface, where they interact with the gas. The repeated renewal of the surface in the gaseous atmosphere leads ultimately to the formation of the solid–gas reaction product phase (the corresponding nitride, oxide, or another compound).[82]

Reactions of yet another type have been discovered in the $Zr-(H_2+CO)$ and $Zr-(H_2+C)$ systems.[83,85] Thus mechanical treatment of zirconium powder promotes the acceleration of the dissolution of hydrogen in it. The hydrogen dissolved in the metal hydrogenates either the CO molecules which have been chemisorbed on the surface or the graphite added to the hydride powder. The reaction

$$CO + H_2 \rightarrow CH_4,$$

during the mechanical treatment of the metal powder under a $(CO+H_2)$ atmosphere can be regarded as the prototype of future mechanocatalytic processes.



There is no doubt that examples of solid–gas and solid–liquid reactions will multiply in the immediate future and that the first hypotheses concerning their mechanisms will be revised or rejected. Conditions ensuring a high effectiveness of low-temperature mechanical reactions between solids and the external medium will be found on the basis of the study of these reactions. The reactions can be used not only for the chemical syntheses but also in catalysis and in the modification of solid surfaces—their stabilisation, improvement of their corrosion resistance, etc.

It is noteworthy that phenomena involving mechanical chemisorption, catalysis, and synthesis are part of the more general problem of the interactions of the solid undergoing deformation and the external medium. Here mechanochemistry will become ever more closely intertwined with physicochemical mechanics and colloid chemistry.[34] These sciences are concerned with the study of the effect of the medium on processes involving the mechanical treatment of solids—their disruption (dispersion, friction, and plastic deformation (the Rebinder effect). Therefore all the manifestations of chemical reactivity, reflecting the development of deformation and revealing the dissipation of elastic energy, are equally interesting for both mechanochemistry and for different manifestations of the Rebinder effect (strengthening or facilitation of disruption, etc.).

3. Kinetic models of mechanochemical reactions

One of the principal problems in the theory of nonthermal chemical reactions is the elucidation of the relation between the expenditure of energy and the reactivity of the reactants. The current state of research does not permit the establishment of a complete balance for the energy transformations, while a quantitative description of all the relaxation pathways in mechanochemical reactions is hardly likely to be achieved soon.

The route involving the search for a kinetic description of nonthermal reactions appears more realistic. Among those possible, the following scheme remains more attractive:

It is similar to that presented at the very beginning of the review. The kinetic equation corresponding to this scheme has the following form:

$$\frac{\delta\Delta\varphi}{\delta t} = I - \frac{\Delta\varphi}{\tau_{chem}} - \frac{\Delta\varphi}{\tau_{phys}},$$

where $\Delta\varphi$ is the excess energy of the intermediate states (it can be represented as $\Delta\varphi = N\varphi g$, where N is the concentration of excess energy carriers, and φ and g are their energy and yield), I is the supplied energy flux, τ_{chem} is the characteristic chemical relaxation time, and τ_{phys} is the characteristic physical relaxation time. Chemical relaxation is understood as the employment of part of the excess energy in chemical or physicochemical reactions, while physical relaxation includes the remaining energy dissipation channels.

Under stationary conditions, the rate of a chemical reaction W_{chem} is

$$W_{chem} = Ig\frac{\tau_{phys}}{\tau_{phys} + \tau_{chem}},$$

and its energy yield G_{chem} is given by

$$G_{chem} = \frac{W_{chem}}{I} .$$

Evidently, the advantage of this scheme consists in the fact that it makes it possible to relate the conditions in the mechanical treatment, the rate of the chemical reaction, and its energy yield G (in mol MJ^{-1}). Naturally, in each specific case the scheme will be specified in greater detail and expanded. However, the above advantage will be preserved.

The energy yield G is one of the principal quantitative characteristics of mechanochemical reactions.[9] It can be calculated or predicted, provided that the mechanism or physical model of the process is known. For example, if the height of the energy barrier is E in the elementary step of a nonthermal reaction, then the maximum energy yield G_{max} is given by $G_{max} = 1/E_a$. For the experimental determination of the yield, it is sufficient to measure the amount of products and the work performed.

As a rule, in degradation reactions the energy yield is small and lies in the range from 10^{-4} to 10^{-1} mol MJ^{-1}. Its numerical value characterises the sensitivity of the given compound to mechanical influences. The generation of defects is (with rare exceptions) an energy-consuming process. Systems in which chain degradation develops or there is a possibility of other self-acceleration mechanisms are an exception.

Deformation mixing and synthesis are usually characterised by comparatively high yields — up to 1–10 mol MJ^{-1}. Even in the most difficult case involving the mixing of tungsten with iron (Fig. 5), the yield is 0.1 mol MJ^{-1}. Naturally, the yield depends on the conditions in the mechanical treatment — the rate of deformation and the frequency of the influences, temperature, the nature of the surrounding medium, and other factors.

The measurements and calculations of the energy yields lead to the possibility of using in mechanochemistry data banks comprising the kinetic and thermodynamic characteristics of thermochemical reactions. For example, the relation $G_{max} = 1/E_a$ includes the activation energy for the reaction. A correlation between G and thermodynamic parameters in a series of isotypical reactions has been observed more than once.[1] It may be hoped that systematic measurements and calculations and analysis of the energy yields will lead to the creation of a quantitative picture of mechanochemical reactions which will possess predictive power.

* * *

Summarising the results of numerous studies on mechanochemistry, one may differentiate several aspects of fundamental investigations with which the development and further progress in this interesting and promising field of knowledge are associated.

These include primarily the following:

the discovery of the molecular mechanisms of the deformation of simple and complex substances as well as their mixtures combined with the elucidation of the nature of the intermediate nonequilibrium states;

the kinetic description of the mechanical degradation, atomic migration, and molecular mixing processes as well as chemical reactions involving the formation of new crystalline or amorphous structures under deformation and energy dissipation conditions;

the study of the relation between thermal and nonthermal reactions in which the energy barrier is overcome either via a thermal fluctuation mechanism or under the influence of elastic stresses.

Altogether, these aspects are combined into the problem of the systematic description of the laws governing chemical reactions under the conditions of the joint action of mechanical and chemical forces.

Abstract. New theoretical and experimental data on the grain-boundary dissolution process in polycrystalline metals are reviewed. The original effects during transcrystallite dissolution are discussed, the basic models are analysed, and the localisation mechanism of the dissolution process on the phase bondaries of polycrystals is described. The bibliography includes 86 references.

I. Introduction

Internal boundaries in metallic crystals include low-angle boundaries formed by dislocations, grain boundaries (GB), and phase boundaries between inclusions and the matrix. In addition to the creation of strong fields due to the elastic distortion of the metal lattice (M), chemical heterogeneity is a characteristic property of these defects of the solid state. The electrochemical etching effect is observed during the dissolution of these structures.

Among nonequilibrium planar solid-state defects, the grain boundaries play a major role in the corrosion – mechanical erosion of metals. At present the metallographic evaluation of the grain composition of polycrystalline metals is based on the selective acceleration of the etching process by the grain boundaries. The role of GB is most marked during intercrystallite corrosion, and has been studied extensively.[1–4] All these workers tried to relate the differences in chemical composition of the grain-boundary region to its enhanced rate of dissolution.

From the practical point of view the effect of the grain-boundary segregation of hydrogen on the corrosion of metals is of the greatest interest, because hydrogen (the most mobile impurity in metals) can form new hydride phases on the GB and also influence their penetrability as barriers to the passage of dislocations through the boundary during plastic deformation. By using the grain boundary theory we can obtain a quantitative estimate of the contribution of GB to the corrosion, and present a physical picture of the dissolution of polycrystals. The formation of a stable fractal structure (a closed network of etched grain boundaries) strengthens the resistance of a solid to an aggressive medium. The dissolution of surface mechanical stress raisers improves the physical and mechanical properties of metallic items. The unique adsorption properties of GB allow the use of this effect in metallurgy, microelectronics, and other technological areas.

Paradoxically, the blocking of the dissolution of grain boundaries by an inhibitor (surface-active substance, impurity, etc.) has not yet attracted adequate theoretical studies, in spite of the striking advances which have been made in our understanding of the structure of the GB (see the work of Gleiter, Baluffi, Chadwick, Orlov, and others),[5–9] and also of the great practical importance of grain-boundary dissolution. In the representation of high-angle GB, regions of bad and good coincidence have been described [10] by various models: the coincident block lattice (CBL), the grain boundary displacement lattice (GDL), and the full overlap lattice (FOL). Grain boundaries are not a layer of amorphous material, and they can be modelled by the coincident block lattice structure with appropriate parameters.[11]

In the CBL model the grain boundaries are classified as general or special. A special GB in this model has a well defined period, characterised by the reciprocal bulk density of the coincident blocks (Σ). In body-centred (BCC) and in face-centred cubic crystals (f.c.c.) a distinction is made[10] between low-energy ($\Sigma = 3, 9, 11, 17, 27,$ and 33) and high-energy GB (Σ = 5, 7, 13, and 15). The structural model of the GB can be approximated by the model of close packed structural units (Voronyi polyhedra).

Body-centred polyhedra form vacancy-saturated loose regions in the crystal when linked. Boundaries of a general type are adequately described by the structural units model, and they include regions with a periodic structure separated by grain-boundary dislocations. In the presence of external stimuli point defects and line defects are always formed on polycrystals. Subgrain low-angle boundaries are assumed to consist of dislocation networks. There are substantial differences between the dissolution mechanisms of low-angle boundaries and of grain boundaries.

The object of the present review is to analyse the results of studies of the effect of internal boundaries in polycrystals on the phase interaction processes at metal–electrolyte contacts. The need to review these data arose because of the appearance of new models of the dissolution of GB, and of the availability of reliable experimental results on the chemistry of GB and of phase interfaces.

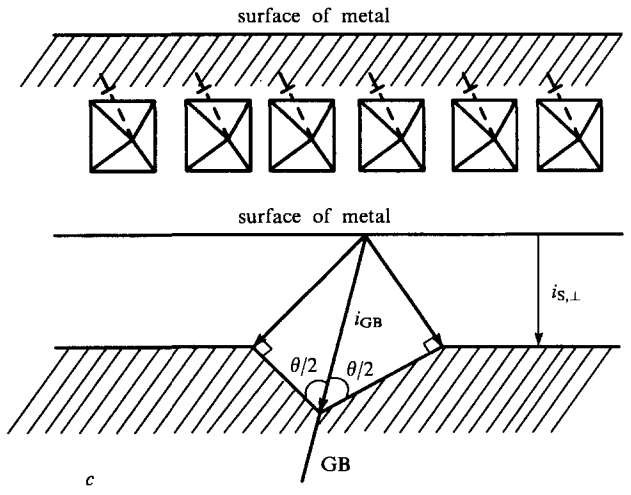
II. Dissolution and adsorption of surface-active impurities on low-angle boundaries and on grain boundaries



Subsurface dislocations induce the formation of three-dimensional clusters on the crystal surface, which inhibit the action of impurities. Dislocation planes arranged as elastic networks form low-angle boundaries with a misorientation angle $\theta = 2\arcsin(\boldsymbol{b}/2l_d)$, where $\boldsymbol{b}$ is the Burgers vector and l_d is the distance between dislocations. The internal fractal structure of these dislocation networks can be seen on the surface of the crystal as a group of dislocation etch pits (EP) (Fig. 1*a*), the distance between etch pits being an approximate measure of the parameter l_d, from which the misorientation angle θ can be determined. A new phase formed on low-angle boundaries is accommodated in the structure with a specific fractal dimensionality. The dissolution on grain-boundary dislocations for which $l_d > 2\boldsymbol{b}$ is described within the theory developed, for example, in Refs 4 and 12. If the grain-boundary dislocations merge together and lose their individuality, etch grooves are formed on the GB (Fig. 1*b*). The dissolution follows different paths on interblock low-angle ($\theta < 3°-5°$) and high-angle boundaries ($\theta > 15°$) (Fig. 1*c*).

a

b

c

Figure 1. Dissolution on a low-angle boundary (*a*) and the boundary of nickel grains (*b*) (× 12 000) together with a schematic illustration of the grain-boundary dissolution (*c*).

A model of the dissolution on high-angle GB in the simplest form (but corresponding to experimental observations) can be constructed as follows.[13,14] In a pure (>99.99%) bicrystal dissolution along a GB (see Fig. 1*b*) takes place as a result of the generation of dissolution steps whose density depends on the angle θ. The relationship between the dissolution rate (or current) along the plane of the grain boundary i_{GB} and the dissolution rate (or current) normal to the metal surface $i_{S,\perp}$ (see Fig. 1*c*) is the following:

$$\frac{i_{GB}}{i_{S,\perp}} = \frac{1}{\sin(\theta/2)} , \tag{1}$$

$$\Delta i = i_{GB} - i_{S,\perp} = a_S + b_S i_{S,\perp} , \tag{2}$$

for $\lim i_{GB} \to \infty$, $\dfrac{i_{GB}}{i_{S,\perp}} = \dfrac{1}{\sin(\theta_0/2)}$ and $b_S = \dfrac{1}{\sin(\theta_0/2)} - 1$,

for $\lim i_{S,\perp} \to 0$, $i_{GB} \to i_{GB,0}$ and $a_S = i_{GB} = i_{GB,0}$.

Here θ and i_{GB} are the limiting angle and the grain-boundary current, independent of the dissolution of the bulk of the grain, i.e. they are the characteristic parameters of the grain-boundary dissolution.

In the absence of passivation of the grain surface, the rate (or current) of the dissolution on a GB is described by the Marcus formula

$$i_{GB} = i_{GB,0} + \frac{1}{\sin(\theta_0/2)} i_{S,\perp} . \tag{3}$$

By use of the fundamental kinetic equation for the electrochemical dissolution current, Eqn (3) can be expressed in terms of experimentally determined electrochemical parameters. We shall write the Marcus formula[15] as

$$i = K\frac{k_B}{h_p}\frac{Tz^{\neq}}{z}a_0^0 \exp\frac{-\Delta\bar{G}^{\neq}}{RT}\exp\frac{\alpha F\Phi}{RT}\exp\frac{(a-n)F\Phi_1}{RT} , \tag{4}$$

where K is the rate constant for the reaction, $(k_BT/h_p)^{-1}$ is the lifetime of the activated complex (Ac) between the adparticle and a surface atom of the metal (and k_B is Boltzmann's constant), $z^{\neq}$ and z are the partition functions referred to unit volume of the AC and of the reactants in the electrolyte, a_0^0 is the activity of the AC, $\Delta G^{\neq}$ is the nonelectric part of the free energy of activation at low coverages of the metal surface by adparticles, F is the Faraday, Φ is the electron work function, n is the valency of the Ox species in solution, a is the transfer coefficient of the electrode reaction, and Φ_1 is the potential step in the diffuse part of the electrical double layer (EDL).

We simplify Eqn (4) to

$$i = Kc\exp\frac{-[\alpha F(\Phi - \Phi_1) + nF\Phi_1]}{RT} . \tag{5}$$

Here $c = (k_B T_{Z^*}/h_p x) a_0^0 \exp(-\Delta\bar{G}^{\neq}/RT)$ is a term corresponding to the formation of active centres (Ac) on the surface; $(\Phi - \Phi_1)$ is the potential of the electrode relative to the outer coating of the Helmholtz reaction layer. By using formulae (4) and (5), the expression (1) can be converted into

$$\frac{i_{GB}}{i_{S,\perp}} = \frac{K_{GB}}{K_{S,\perp}} \frac{c_{GB}}{c_{S,\perp}} \frac{\exp\{-[\alpha F(\Phi - \Phi_1) + nFF_1]/RT\}_{GB}}{\exp\{-[\alpha F(\Phi - \Phi_1) + nFF_1]/RT\}_{GB}}$$

$$= \frac{1}{\sin(\theta/2)} = \frac{c_{GB}}{c_{S,\perp}} . \quad (6)$$

At high current densities ($i_{S,\perp} \to \infty$):

$$\frac{c_{GB}}{c_{S,\perp}} \to \exp\frac{-\Delta_{GB}(\Delta\bar{G}_0^{\neq})}{RT} = \frac{1}{\sin(\theta/2)} , \quad (7)$$

where $\Delta_{GB}(\Delta\bar{G}_0^{\neq}) = \Delta\bar{G}_{0,GB}^{\neq} - \Delta G_{0,S,\perp}^{\neq}$ is the difference between the energies of formation of the Ac on the grain boundary and on the bulk of the grain. For example, this difference, determined for the Ni/1 M H_2SO_4 system at 298 K, was 32 mJ m^{-2} for a GB with $\theta = 104°$. The dissolution current on the GB, independent of the corrosion current in the bulk of the grain [the first term in formula (3)], is determined by the expression

$$i_{GB,0} = a_{GB}^* i_{0,S,\perp} \exp\frac{-\Delta_{GB}(\Delta\bar{G}^{\neq})}{RT} , \quad (8)$$

where a_{GB}^* is the activity of the surface-active centres distributed over the GB (from the physical point of view it is the surface activity of the grain-boundary dislocations). The trapped lattice dislocations increase the energy of the GB by an amount equal to the elastic field of the dislocations:[16]

$$\Delta E \cong \frac{G_c b^2}{4\pi(1-\nu)2l_d} \ln\frac{e\alpha l_d}{\pi b} , \quad (9)$$

where G_c is the shear modulus, ν is Poisson's ratio, e is the base of natural logarithms, α (= 1–2) is the energy parameter of the dislocation core, and l_d is the distance from the dislocation to the surface. For a given polycrystal, the parameter ΔE depends also on Σ and θ. The corrosion activity of the GB in very pure polycrystals varies periodically with the number of dislocations absorbed (ρ_d) and with the misorientation angle (θ), thus influencing the adsorption properties of both the GB themselves and the adjacent grain-boundary volumes.

The adsorption properties of the grain-boundary volumes affect the dissolution process. The adsorption on the GB is examined both 'from inside' (from the bulk of the grain) and 'from above' (from the interface). The adsorption 'from inside' is produced by the diffusional inflow of impurities on the GB and obeys the expression

$$\frac{c(t) - c_0}{c_\infty - c_0} = 1 - \exp\frac{-4Dt}{(\Delta\gamma^{\neq})^2 d^2} \operatorname{erfc}\frac{2(Dt)^{1/2}}{d\Delta\gamma^{\neq}} , \quad (10)$$

where $c(t)$ is the concentration of impurities on the GB at time t, c_0 and c_∞ are the initial and the equilibrium concentration of impurities on the GB, $\Delta\gamma^{\neq} \cong (\exp\Delta H)/k_B T$ is the supersaturation, ΔH is the enthalpy of the GB–impurity bond, D is the coefficient of diffusion of the impurity in the crystal, and d is the thickness of the GB. For hydrogen $D_H = 1 \times 10^{-8} - 1 \times 10^{-9}$ m^2 s^{-1} and $\Delta H = 10 - 60$ kJ mol^{-1}. Deformation of the polycrystal can induce the accumulation of impurities on the GB by dislocational transport.[17] Moving dislocations adsorb the impurities and transport them over the GB. The dislocational permeability of the GB is determined by the angle θ, and the chemical properties of the GB vary accordingly.

The equilibrium segregation of the impurities (added atoms or originally present impurities) on the GB can be described[17] by the Fermi–Dirac distribution

$$c = c_{0,L} \exp\frac{\Delta G_a}{RT}\left(1 + c_{0,L}\exp\frac{\Delta G_a}{RT}\right)^{-1} = c_0 \exp\frac{\Delta H}{RT} , \quad (11)$$

where $c_{0,L}$ is the equilibrium concentration in the solution and ΔG_a is the difference in free energy between the additives dissolved in the GB and in the crystal lattice. The enthalpy ΔH of the bond between the grain-boundary surface and the surface-active impurity species (similar in size to the atoms of the crystal) is in the range of 150–200 kJ mol^{-1} for the 3d metals. The adsorption on the GB can be calculated by using the Gibbs concepts of reversible adsorption and of the decrease in the surface tension of the grain boundaries produced by the creation of a surface excess. According to the Gibbs formula

$$d\gamma = Vdp - SdT - \sum_i \Gamma_i d\mu_i \quad (i = K^+, A^-, M^{n+}, e^-) , \quad (12)$$

where V and S are, respectively, the volume and the entropy of the adsorbed layer of the quasicrystalline phase of surface-active substance, Γ_i is the coverage of the metal surface by particles of the ith kind (Gibbs adsorption), $\mu_i = k_B T \ln c(x) + E(x) + \text{const}$ is the chemical potential of the ith species, $E(x)$ is the energy of the attractor, $\mu_0 \equiv E(x) + \text{const}$, K^+ and A^- are the cation and the anion of the supporting electrolyte, M^{n+} is the charged metal ion, and e^- is the electron. By using the Gibbs formula and the distribution (11) we can obtain an expression for the decrease in surface tension:

$$\Delta\gamma = \gamma_{GB} - \gamma_B = RT\,\theta_{GB} \ln\left(1 + c_0 \exp\frac{\Delta G_a}{RT}\right) . \quad (13)$$

Here γ_B is the absolute energy of formation of the GB, θ_{GB} is the coverage of the GB by impurity particles, and c_0 is the background concentration. The decrease in γ_{GB} is used to calculate $\Delta G_a = \Delta E_a - T\Delta S_a$, where ΔE_a and ΔS_a are the energy and the entropy change of the interaction of the surface-active impurity with the GB. Under equilibrium conditions the chemical potentials of the ith species (SAS particles) on the free metal surface (μ_S), on the grain boundary (μ_{GB}), and in the solution (μ_B) are identical.

In the interpretation formulated by McLean and Hondros[18] we require a knowledge of the dependence of the surface tension γ_{GB} of the grain boundary on the surface concentration of the adsorbate in order to determine the adsorption:

$$\gamma_{GB} - \gamma_B = -T\Delta S_a - \sum_i \Gamma_i \mu_i . \quad (14)$$

Here the coverage $\Gamma_i = -[\partial\gamma/\partial\mu_i]_{T,\mu_{j\neq i}}$ is a crystallographically determined quantity, because neighbouring grains are differently oriented and the adsorption of the SAS impurity on them is different. The Gibbs equation in the form (12) can be used to calculate Γ_i for the components from the known isotherms of the surface tension γ_{GB} and of the chemical potential μ_i of the components in the grain.[18] For a two-component system

$$d\gamma = -\Gamma_1 d\mu_1 - \Gamma_2 d\mu_2 = -\frac{\Gamma_2 d\mu_2}{1 - c} , \quad (15)$$

where c is the concentration of the SAS impurity.

In order to determine the adsorption accurately, we need to know the activity a of the components rather than their concentration c and to find the chemical potential of the adsorbed SAS.

In the theoretical description of the adsorption on polycrystals in terms of the lattice models we can use an approach developed for the analysis of stresses in Somigliana dislocations. In this case the adsorption properties on the grain boundaries and on their bulk should have their equilibrium values, and should be continuous at all points. The problem can be solved by the nonlinear theory of elasticity.[18]

The differences between adsorption–desorption processes on the surface of crystals and on the grain boundaries can be studied experimentally by comparing the electrochemical characteristics of monocrystals and polycrystals. A very instructive example of this approach is provided by the study of the anodic oxidation of CO on mono- and on polycrystalline Pt electrodes in 0.05 M $HClO_4$. At low overvoltages ($\eta < 0.1$ V), the adsorption is described by the Langmuir isotherm, is independent of the grain size and of the pH of the solution, and takes place according to the scheme

$$Pt(CO)_{ads} + H_2O \longleftrightarrow Pt(COOH)_{ads} + H^+ + e^-.$$

Increasing the overvoltage (to $\eta > 0.2$ V) and the concentration of active centres (by changing from single crystals to polycrystals) affects the final products. In the bulk of the grain boundaries, the electrochemical process follows a different path:

$$Pt(CO)_{ads} + OH^- \longleftrightarrow Pt(COOH)_{ads} + e^-,$$

$$Pt(CO)_{ads} + 3OH^- \longleftrightarrow Pt + CO_3^{2-} + 2H_2O + e^-.$$

On a platinum polycrystal with a small grain size (~ 1 μm) and a correspondingly large spread of GB, the formation of carbon dioxide becomes possible at high anodic potentials ($E > 1.4$ V):

$$Pt(CO)_{ads} + H_2O \longleftrightarrow Pt + CO_2 + 2H^+ + 2e^-.$$

Anodic polarisation in the high positive range of potentials ($E \gg 1.4$ V) activates the grain-boundary volumes in the metal. Even more complex reactions are possible (according to steric considerations) on extended defects of the GB surface: for example

$$CH_2\text{—}CH(CH_2)_8CO_2H + 4H_2O \longrightarrow$$

(Pt)

$$\longrightarrow Pt + H_3C(CH_2)_7CO_2H + 2CO_2 + 11H^+ + 11e^-.$$

The nature of this substantial change in the chemical path of the reactions reflects the difference in structure and in chemical composition between the grain-boundary volumes and the bulk of the grain. The polyhedral structure of the GB provides ready-made elements for the formation of surface clusters. The pores and the polyhedra of the GB in the 3*d* metals can be filled relatively easily with impurity elements (Ru, Os, Rh, Ir). Impurities which lower γ and favour the formation of GB with the most stable structure are usually concentrated on the GB: in most cases these are chalcophilic elements. Reactions taking place relatively easily on the GB include impurity precipitation and carbide formation, which lower the concentration of elements with a high oxygen affinity.

III. Distribution of dislocations in near-surface layers of crystals

Many physical, mechanical, and corrosion-electrochemical properties of polycrystalline metals depend on the distribution of dislocations (DD) near the internal boundaries. The DD process is statistically independent.[20] However, within the crystallites (and especially in the region of subgrain boundaries and of grain boundaries), DD in the form of planar aggregates are fairly often seen. An edge dislocation does not interact strongly with a low-angle dislocation boundary,[21] and when the slip plane of the edge dislocation is perpendicular to the wall the interaction is completely suppressed. On the other hand, high-angle GB act as dislocation stoppers, which cannot be surmounted by thermal activation. However, the long-range interaction of the dislocations with the GB is quite weak, as in the case of the low-angle boundaries.

The effect of the dislocation density ρ_d on the electrochemical behaviour of crystals in electrolytes has been studied intensively[22,23] in the context of confirming the Rebinder and Ioffe effects on the physicomechanical properties of crystals caused by exposure of the crystal surfaces to the components of liquid condensed media. The 'skin-deep' aggregation of dislocations in the near-surface layer is due essentially to the action of image forces, whose energy (in the framework of the linear theory of elasticity) is given by

$$E_u = \beta G_c b \ln \frac{2l_d}{b} . \tag{16}$$

In this case, $\beta = 1 - \nu$ for edge dislocations and $\beta = 1$ for screw dislocations; l_d is the distance from the dislocation to the surface. At a high level of relaxation of the near-surface layer of the crystal (i.e. for a change in the lattice constant of more than 10%) the inner electric double layer of the metal stops the 'floating' dislocation.[4] The dislocation distributions in the near-surface layer depend first of all on the type of crystal and on the nature of previous mechanical treatments. In an ultra-thin surface layer of the crystal, the parameter ρ_d can decrease (Fig. 2). In the case of rectilinear edge dislocations,[23] the distribution as a function of depth z can be calculated by using the formula

$$\rho_{d,z} \approx \frac{L}{z} \exp \frac{-E_{d,z}}{Lzk_BT} , \tag{17}$$

where L is the length of the dislocation (< 1 μm), and $E_{d,z}$ is the energy of the dislocation. For dislocation half-loops, the distribution takes the form

$$\rho_{d,z} \sim \frac{A}{z} \exp \frac{-B \ln z}{z} . \tag{18}$$

Here $A = G_c b^2/2\beta$ (G_c is the shear modulus) and B is the attenuation coefficient of sound in the crystal.

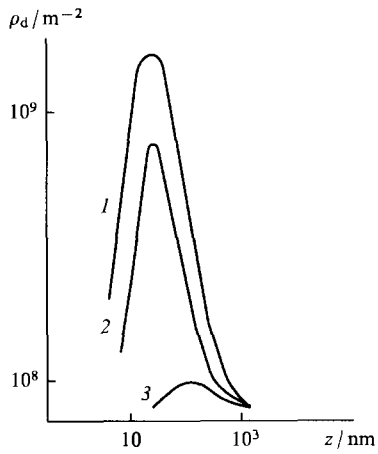


Figure 2. Distribution of rectilinear edge dislocation as a function of the depth of the near-surface layer (z) in copper (curve *1*), nickel (curve *2*), and silicon (curve *3*) crystals.

The distance from the crystal surface, where the density of dislocations $\rho_{d,z}$ is a maximum, can be determined from the condition $\partial\rho_{d,z}/\partial z = 0$:

$$z_{max} \equiv \frac{G_c b^3}{4\pi(1-\nu)} (k_BT)^{-1} , \tag{19}$$

where ν is Poisson's ratio.

The aggregation of edge dislocations in the near-surface layer of the metal is caused by thermoelastic stress effects. The analytic solution of the equilibrium distribution problem for rigid parallel rectilinear dislocations on the slip plane has been obtained [24,25] on the assumption of a continuous distribution for a periodic potential of the external forces $U(x)$. The x axis is perpendicular to the dislocation lines and corresponds to the slip direction. The equilibrium DD in the field of $U(x)$ (the potential energy for a unit length positive dislocation) is determined in this case by a function of their linear density $\rho_d(x)$ which can be expressed [16] as a Fourier series:

$$\rho_d(x) = \sum_{k=-\infty}^{+\infty} \rho_{d,k} \exp(ia_k x) \quad . \tag{20}$$

Here

$$\rho_{dd,k} = -\frac{2\pi|k|U_k}{|A|} \quad \text{for } k \neq 0 \quad (\rho_0 \text{ is arbitrary}),$$

$$U_k = \frac{1}{l}\int_{-l/2}^{+l/2} U(x)\exp(-ia_k x)\mathrm{d}x \quad , \tag{21}$$

$a_k = 2\pi k/l$ [l is the period of $U(x)$ and of $\rho(x)$].

Grain sub-boundaries and boundaries are characterised by local minima in the potential energy $U(x)$. Then, having calculated the DD for the self-repeating potential wells, we can describe the changes in ρ_d in the bicrystal. Fig. 3 shows the result of a computer calculation allowing for 40 harmonics ($-20 \leqslant k \leqslant 20$) in the representation of the $U(x)$ profile. In this case, the potential well has very steep walls, and therefore the emission of dislocations from this well and the surmounting of this obstacle are seriously hindered. However, outside the limits of the potential well $U(x)$ = const, and there is no elastic long-range interaction between the dislocations and this obstacle. The mid-point of one of the internal boundaries in the bicrystal was used as the origin for the measurements. The distribution of the dislocations is given within a single period of $\rho_d(x)$. As could have been expected, on the GB ρ_d is higher than the average level, but (conversely) the regions immediately adjacent to the boundary have a ρ_d value well below the average.

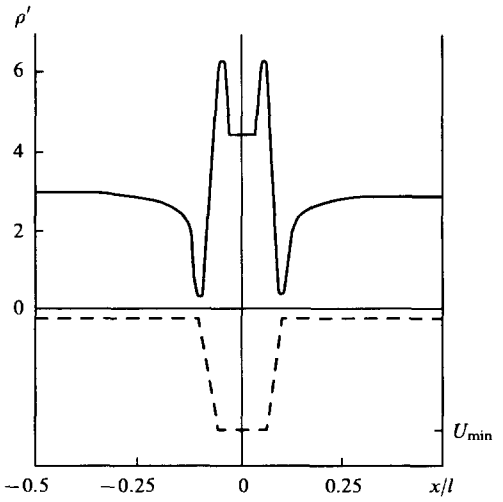

Figure 3. Distribution of dislocations in the field of repeated potential wells:

$$\rho' = \frac{Al}{2\pi|U_{min}|}\rho, \quad \rho = \frac{6\pi|U_{min}|}{Al} \quad .$$

An experimental determination of the DD near a grain boundary [misorientation angle of the grains θ = 13°–15°, for which expressions (17)–(20) are applicable] was carried out for pure iron (99.99%, $\rho_d = 2.0 \times 10^{11}$ m^{-2}). Selective electrochemical etching in the passive region of potential was applied in a 1 M solution of H_2SO_4 (290 K, E = 0.80 V, t = 300 s). Under these etching conditions, the nondislocated part of the crystal surface is passivated by oxides, and dissolution takes place only on the defects.

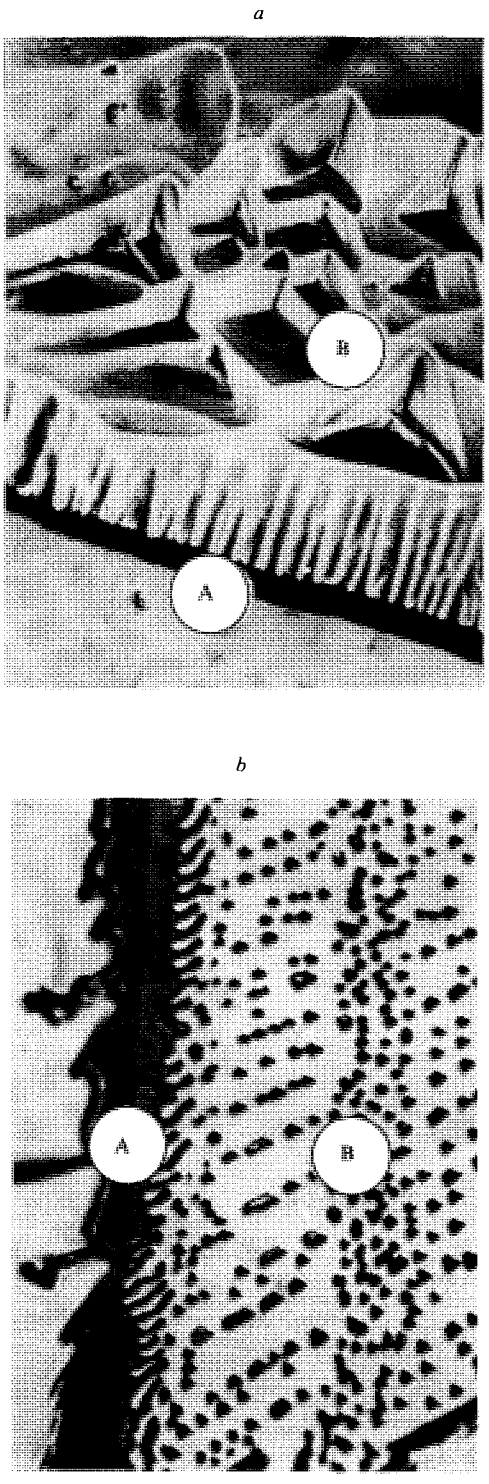

Figure 4. Electrochemical (*a*) and thermal (*b*) etching of zone-purified iron (× 960). A — grain-boundary; B — EP zone.

Etch pits (EP) are formed on the Fe(111) surface both in the region of the GB (Fig. 4*a*, region A) and at some distance from it (region B); there is a fairly wide 'dead' zone directly adjacent to the GB where no etch pits are found. The presence of a similar zone on the Fe(110) face is observed only after a hydrogen anneal of the iron ($p = 6 - 10^{-3}$ Pa, 1173 K, $t = 3.6 \times 10^3$ s) by the method of thermal EPs, which are formed because of the selective oxidation of the dislocation outcrops on the crystal surface (Fig. 4*b*). The size of the dislocation-free regions is 7–12 μm. We should note that thermal oxidation (unlike electrochemical etching) does not produce EP in the region of the boundaries.

The density of dislocations on the GB is higher than the average level, but in the region directly adjacent to the boundary it is anomalously low. This effect has stimulated the interest of experimental workers, and it has been carefully analysed [26] by high-resolution transmission electron microscopy methods. The width of the dislocation-free regions for GB with small Σ values was found to be ~15 μm. The localisation of the dissolution process on a defect has a protective action on the corrosion of the dislocation-free region. When polycrystals are exposed to corrosion-electrochemical interactions the selective dissolution of the dislocation outcrops results in the appearance of wide nonetched regions.

The distribution of ρ_d directly influences the rate of corrosion i_{cor}, which is low during the initial period of exposure but becomes stable after going through a maximum. [27]

The effect of corrosion-active media on the surface energy (which is stronger on the γ_{GB}) should be mentioned, in addition to the image forces and the thermoelastic stresses, as one of the physicochemical reasons for the accumulation of dislocations in the near-surface layer.

Extensive reports on the search for quantitative estimates of the effect of the dislocation density ρ_d on the dissolution of metals have been published. The change in the kinetic parameters of the anodic dissolution of iron in acid media produced by heat treatment is usually ascribed to a decrease in ρ_d. The intermediate $(FeOH)_{ads}$, chemisorbed on the iron atoms in a dislocation pipe $Fe(FeOH)_{ads}$ and which is able to catalyse the dissolution process, [28] is formed on the dislocations. These effects have been noted also on other transition metals (for example, nickel [29]). On deformed nickel ($\varepsilon > 10\%$) with a high density of dislocations, the adsorption of water dipoles in solutions of $Na_2SO_4 + (C_2H_5OH$, C_4H_9OH, $C_6H_{13}OH)$ blocks the AC (dislocation outcrops), and the dependence of the double-layer capacity c_{DL} on the electrode potential E (measured by a pulsed galvanostatic method) does not differ significantly from the background value. After annealing a nickel electrode (973 K, $t = 5.4 \times 10^3$ s), with a corresponding decrease in the spread of the GB and in ρ_d, we observe a decrease in c_{DL}. Adding to the solution substances with a high specific adsorption activity [$SC(NH_2)_2$, $(CH_3)_2CO$, C_3H_7COOH] produces changes in ρ_d which only marginally affect the $c_{DL}-E$ curves.

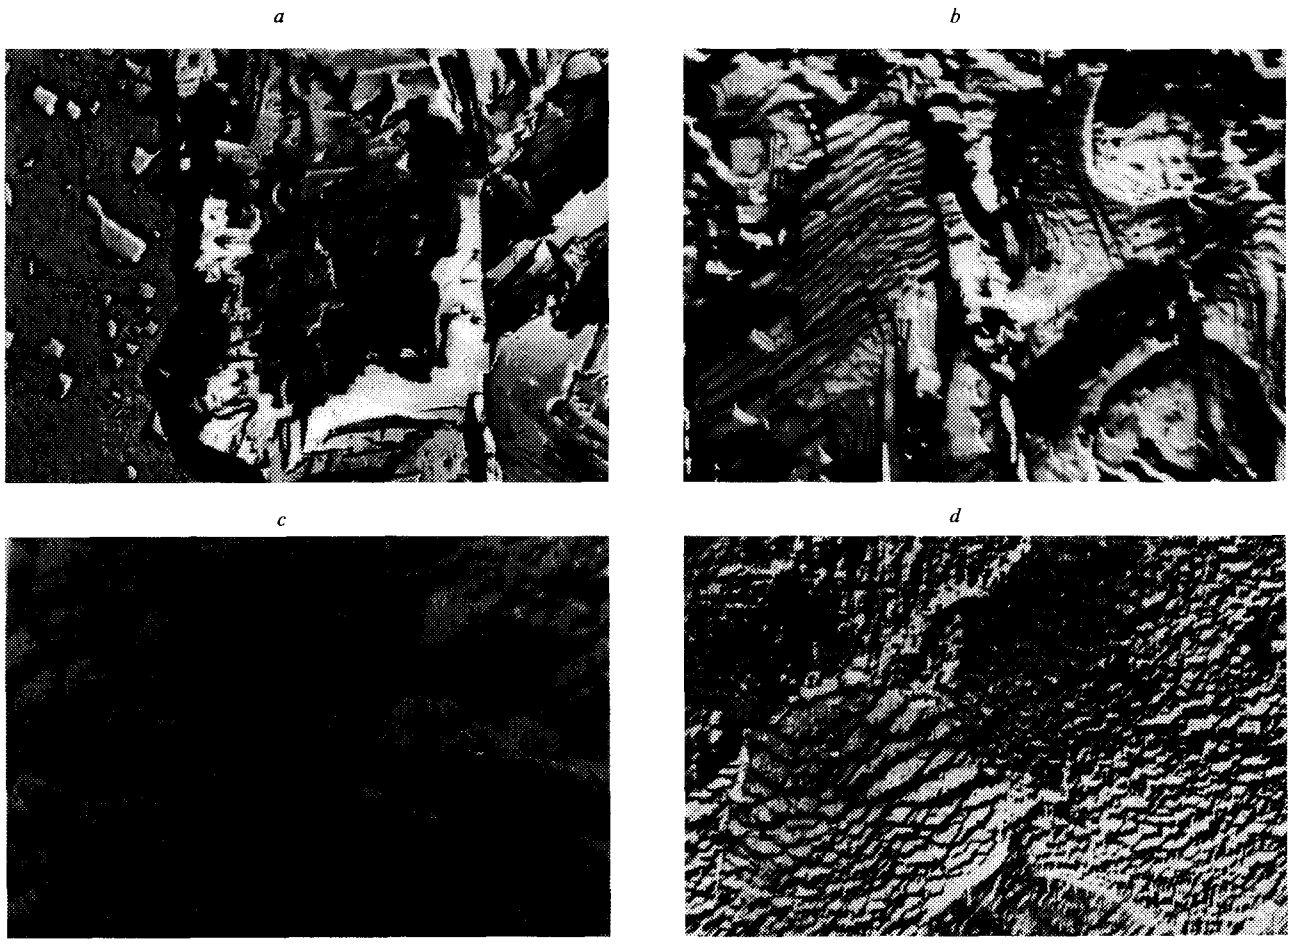

Figure 5. Morphology of the surfaces of dissolving iron (*a*), nickel (*b*), copper (*c*), and tungsten (*d*) polycrystals at the current oscillation potentials (× 12000).

IV. Current and potential oscillations during grain-boundary dissolution

On grain-boundary volumes the processes of dezincification (brass, bronze, Cu–Zn alloys) and of selective dissolution of stainless steels [30] and of other metals follow different paths. The oscillations of the anode current i_a at potentials more positive than the Flade potential E_{Fl} on the anodic polarisation curve are usually attributed [31,32] to an enhanced grain-boundary dissolution. A metallographic analysis of the surface of samples held for short times (t = 20–30 s) at different current oscillation potentials in the anodic region showed that grain-boundary volumes in polycrystals dissolve rapidly (Fig. 5). In many experimental studies it was assumed that the current oscillations were apparatus artefacts, and the oscillations were excluded from the $E-i_a$ curves. The enhanced adsorption activity of the GB allows us to control the current oscillations by introducing surfactants into the electrolyte. [4] Thus, the current oscillations on a nickel electrode can be suppressed by adding corrosion inhibitors to the solution [for example, n-octylphenylmethanesulfonate]. However, substances which act as corrosion inhibitors on annealed polycrystals may not have the same effect on elastically stressed metals (ε < 5%). The amplitude of the current oscillations on elastically stressed metals is higher, and the potential region which produces oscillations is wider, than in the case of annealed metals. Thus anthraquinone derivatives, which inhibit the acid corrosion of titanium and of stainless steels, accelerate the intercrystallite corrosion of stressed 12X18N9T stainless steel. [33]

The current (or potential) oscillations in potentiostatic (or galvanostatic) circuits are well known electrochemical effects, first reported by Fechner in 1928. Near the Flade potential E_{Fl} on the $E-i_a$ curve, we observe an electric instability whose amplitude decreases at more noble potentials (Fig. 6*a*). Early explanations of this effect relied on the assumption of a periodic transition of the metal from a passive into an active state. [32] On polycrystals of the transition metals, these activation regions should be found on grain boundaries. The diagnostic criterion of the instability (current oscillations) is provided by the appearance on the $E-i_a$ polarisation curves of regions with a negative slope $di(E)/dE(i) < 0$ (Fig. 6*b*). In accordance with the ideas of catastrophe theory, [35] this suggests the existence of three fluxes of particles with different i_a values for E = const.

Current oscillations associated with periodic passivation–repassivation reactions on the surfaces (mainly on the bulk of grain boundaries) of porous oxides have been explained as follows. The passivation–repassivation process alters the porosity of the passivating oxide films, $\varphi = f(\theta_{Ox})$, where θ_{Ox} is the coverage of the surface by the oxide phase (the accessibility of the metal surface to the electrolyte). The average rate of flow of the electrolyte $\bar{v}$ depends on the pressure p:

$$\bar{v} = -\Pi_i(\varphi)\,\nabla p\ ,$$

where Π_i is the permeability of the oxide layer. Ortoleva's model [36] assumes that an impenetrable oxide structure is more likely to be formed on a GB, and that the bulk of the grain has a porous oxide layer permeable to ions. Treating this layer as a structure consisting of n pores of volume L^3 and an insoluble oxide with a volume fraction $1-N_f$ gives the expression

$$\varphi + nL^3 = N_f\ . \tag{22}$$

The changes in porosity with time will be determined by the kinetics of the formation of pores in the oxide structure:

$$\frac{\partial\varphi}{\partial t} = -n\frac{\partial L^3}{\partial t}\ . \tag{23}$$

For the rate of growth of the oxide islets on the GB in two-dimensional coordinates, we can write

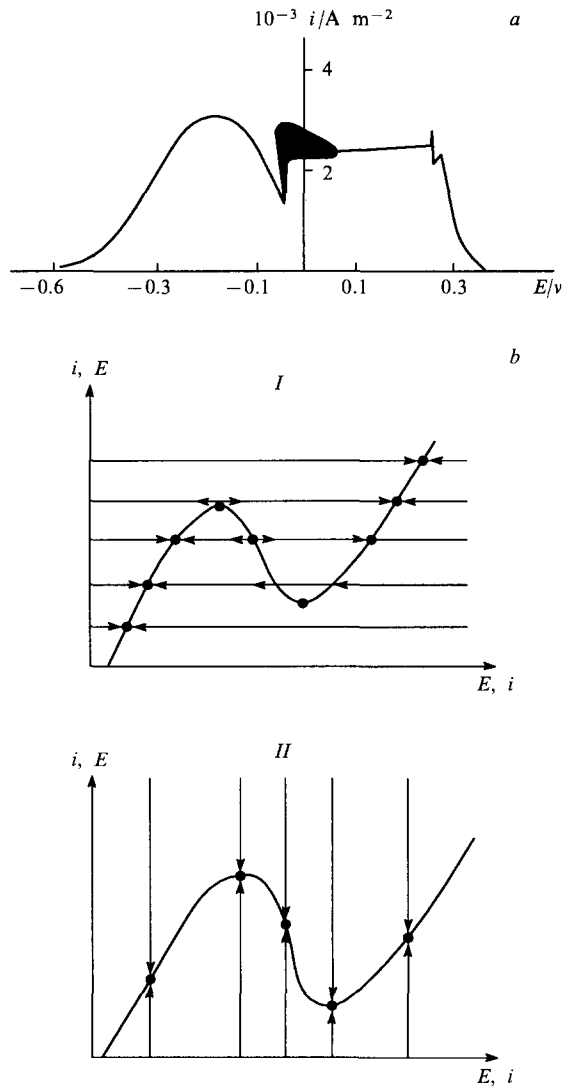

Figure 6. Polarisation curve (*a*) for the Fe–1 M H_2SO_4 system (V_E = 0.005 V s^{-1}) with a current oscillation section. The schematic illustration of the polarisation measurement (*b*) explains the appearance of sections with a negative slope on the $E-i$ curves.

$$\frac{\partial L^3}{\partial t} = KL^2[c(t) - c_0]\ , \tag{24}$$

where K is the rate constant for the growth of oxide, and c_0 and $c(t)$ are respectively, the equilibrium (in solution) and the time-dependent concentrations of the M^{n+} ions in the pore. From Eqns (22)–(24), we obtain

$$\frac{\partial\varphi}{\partial t} = -Kn^{-1/3}(N_f - \varphi)^{2/3}[c(t) - c_0]\ .$$

If the density of the electrolyte is independent of $c(t)$ and p, the law of energy conservation can be written in the form

$$\frac{\partial\varphi}{\partial t} = -\nabla\,[\varphi\chi(\varphi)\,\nabla p]\ ,$$

whereas for the dissolving metal we have

$$\frac{\partial\varphi}{\partial t} = \nabla[\varphi\Delta(\varphi)\,\nabla c(t) + \varphi c(t)\chi(\varphi)\,\nabla p] + \rho\frac{\partial\varphi}{\partial t}\ . \tag{25}$$

Here the diffusion coefficient $\Delta(\varphi)$ and the electric conductivity $\chi(\varphi)$ depend on the porosity (ρ is the density of the metal). An analysis of the solution of Eqn (25) shows that under the conditions of current and potential oscillations, the front of the moving phase boundary is unstable if it is planar.

The instability problem has a strong relevance to the processes responsible for the dissolution of polycrystalline metals. On the surface, we find regions (the GB and the bulk of the grain) comparable in area and in their relative contribution to the formation of a flux of dissolving matter. The specific flux of M^{n+} ions on the GB can be several orders of magnitude greater than the corresponding flux from the surface of the grain. At the same time the adsorption activity of the GB is also very much greater. If the electrolyte contains easily adsorbed components, these are redistributed on the surface during the dissolution of the crystal. This produces opposing transport effects through the fluxes of M^{n+} from the metal and to the metal on the phase boundary.

Current oscillations can be explained by a retardation (and acceleration) of the motion of the dissolution steps [37] as well as by the activation–passivation of the grain-boundary volumes. On an iron electrode in 0.5–1.0 M H_2SO_4, the salt $FeSO_4$ (in a colloidal state near the electrode surface) acts as a reversibly passivating reagent. The formation of oxides, hydroxides, and salts with a structure and properties varying as a function of the heterogeneity of the electrode surface is the basis of the most significant concepts regarding the current (or potential) oscillation phenomena. In the layer nearest to the electrode clusters of particles can be formed and have a stable existence. [38] Upon landing on the electrode surface, they settle on the steps and block their motion. The retardation mechanism is similar to that proposed by Khaldeev and Kamelin: [39,40] the aggregation of foreign particles into Toda chains, which block the motion of the surface dislocations.

In the oscillatory potential model, [41] it is assumed that the growth and dissolution of passive films are complicated by the transfer of H^+ ions between the electrode surface and the solution. This destabilises the passivation potential E_n and the Flade potential E_{Fl}. The oscillation process can be divided into the following stages:

(1) $E_n < E_{Fl}$; the electrode surface is activated, the metal dissolves, the current is limited by the transfer of the H^+ ions (whose concentration decreases in the neighbourhood of the surface);

(2) the parameter E_{Fl} is determined by the concentration of H^+ ions [$E_{Fl} \sim F(c_{H^+})$], which decreases during the first stage, so that the Flade potential also decreases: $E_{Fl} < E_n$;

(3) a passive film having a much lower rate of dissolution is formed;

(4) the E_{Fl} value increases as a result of the third stage, and $E_n < E_{Fl}$;

(5) the oxide film dissolves.

These cycles can be repeated indefinitely.

The kinetics of the process can be expressed as follows:

$$\frac{dE}{dt} = K_1 - K_2 - K_3\theta_{Ox} + K_4 E W(E, \theta_{Ox}) \ , \tag{26}$$

$$\frac{d\theta_{Ox}}{dt} = K_5 E W(E, \theta_{Ox}) \ , \tag{27}$$

where $E = E_n - E_{Fl}$ is the time-dependent potential; θ_{Ox} is the coverage (the passivated part of the surface). The rate constants for all the stages of the oscillatory process ($K_2 - K_5$) are positive. The function $W(E, \theta_{Ox})$, which normalises the coverage, is defined as follows:

$$W(E,\theta_{Ox}) = \theta_{Ox} + (1 - 2\theta_{Ox})U(E) \ , \tag{28}$$

where $U(E)$ is the Heaviside function. Therefore we can write

$$W(E,\theta_{Ox}) = \begin{cases} 1-\theta_{Ox} & \text{for } E > 0 \ , \\ \theta_{Ox} & \text{for } E < 0 \ . \end{cases}$$

Perlstein and Johnson [42] introduced the symbols $V = K_5E/K_2$ and $\tau = kt$ and put expressions (26) and (27) in the form

$$\frac{dV}{dt} = bh - V - b\theta_{Ox} + \frac{VG(V, \theta_{Ox})}{c} \ , \tag{29a}$$

$$\frac{d\theta_{Ox}}{dt} = VG(V, \theta_{Ox}) \ , \tag{29b}$$

and he replaced Eqn (28) by the normalised function

$$G(V,\theta_{Ox}) = \theta_{Ox} + (1 + 2\theta_{Ox})U(V) \ , \tag{30}$$

where $b = K_3K_5/K_2^2$, $c = K_2/K_4$, and $h = K_1/K_4$ (the quantities b and c are positive).

It follows from the equations given above that unique systems of states can exist:

$$(V,\theta_{Ox}) = \begin{cases} (bh,0) & h \leqslant 0 \\ (0,h) & 0 \leqslant h \leqslant 1 \\ (bh-b,1) & 1 \leqslant h \ . \end{cases}$$

Thus the stable state of the phase boundary is defined by the two parameters b and h.

In a subsequent modification [41] of Eqns (29) and (30), the function G was replaced by G^*, i.e.

$$\frac{dV}{dt} = bh - V - 6\theta_{Ox} + \frac{VG^*(V, \theta_{Ox})}{c} \ , \tag{31a}$$

$$\frac{d\theta_{Ox}}{dt} = VG^*(V, \theta_{Ox}) \ , \tag{31b}$$

$$G^*(V,\theta_{Ox}) = \theta_{Ox} + (1 - 2\theta_{Ox})\chi(V) \ ,$$

$$\chi(V) = 1 - \frac{1}{\exp(AV) + 1} \ ,$$

where A is a constant ($A \gg 0$). The function $\chi(V)$ is a degenerate Heaviside function. For large A, the χ value is close to zero (for negative V) and to 1 (for positive V). However, the function varies (between 0 and 1) near $V = 0$.

A very simple condition for the stable state follows from the modified relations (31);

$$V, \theta_{Ox} = 0, h \ ,$$

i.e. the stable potential V is zero, and a part of the metal surface ($\theta_{S,Ox}$) is passive; the latter is determined by the parameter h. The model is applicable for $0 \leqslant h \leqslant 1$.

An estimate of the potential oscillations can be used to determine the likelihood of depassivation of stainless steel. [43] In a system in which intermediate species are produced and disappear, the oscillations of the potential E are given by bifurcation theory [44] as

$$\frac{dx}{dt} = A - (B + 1)x + x^2 + D\frac{d^2x}{dr^2} \ , \tag{32a}$$

$$\frac{dy}{dt} = Bx - x^2y + QD\frac{d^2y}{dr^2} \ . \tag{32b}$$

Here x, y are real functions of the variables t and r (t is time, r is a spatial coordinate belonging to the segment [0, 1]; A, B, D, Q are positive numbers, where B is the bifurcation parameter. If the flux of particles towards the phase boundary is constant a new cycle begins for $B = 1 + A$. If the concentrations of the particles M_S^{n+} and M_L^{n+} on the two sides of the phase boundary remain constant, the new cycle begins at $B = A + D(1-Q)$. The solutions $X(0,t) = X(1,t)$, and $XY(0,t) = Y(1,t) = B/A$ are stationary.

V. Intercrystallite corrosion

Etch grooves are formed at the boundary between neighbouring grains of identical chemical composition in a bicrystal (Fig. 7). Mechanical equilibrium is achieved by superposing the interfacial tension forces γ_{SL} and the energy of the internal interfaces γ_{GB}. According to Mullins,[45] the condition for an equilibrium state is

$$\gamma_{GB} = 2\gamma_{SL}\cos\frac{\theta}{2} . \tag{33}$$

Near the etch groove, a ramp is formed (Fig. 7); its profile is given by the condition

$$m = \cot\frac{\theta}{2} . \tag{34}$$

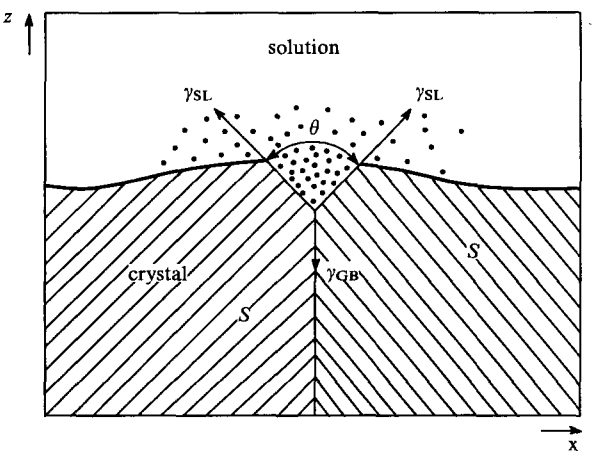

Figure 7. The formation of an etch groove on a metallic bicrystal.

We note that the existence of this profile follows both from the impurity distribution conditions near the GB and from the condition determining the change in the dislocation structure of the crystal near the GB (see Fig. 3). The distribution of impurities along the normal x to the plane of the GB is strongly nonlinear. On the plane of the GB, their concentration is much higher than the equilibrium value: this is followed by a 'dead' zone, after which the concentration suddenly increases.

Along the plane of the GB (i.e. along z), the impurities are distributed according to the relay (cooperative) grain-boundary diffusion mechanism.[46] This model assumes an alternation of grain-boundary barriers (body-centred polyhedra) and of free volumes. Grain-boundary segregations are formed during a preparative stage. In the second stage, the actual grain-boundary diffusion of impurities takes place as a result of a diffusion jump through the barrier and of a concerted displacement within the free (loose) volume. The Gibbs–Thomson relation describes the distribution of the impurity along x:

$$c_S(x,t) = c_\infty\left[1 + \frac{\gamma_{SL}\Omega}{RT}K_M(x,t)\right] . \tag{35}$$

Here c_∞ is the concentration of solution particles on the flat ($K_M = 0$) surface, Ω is the atomic volume of the metal crystal, and $K_M(x,t)$ is the curvature of the metal surface. Mullins[47] modified this model and adapted it to a pure diffusion treatment by introducing three parameters: the distance d between the top of the ramp and the bottom of the groove, the distance d' between the initial flat surface and the ramp, and the distance between the edges W:

$$d = 1.01\,m(A't)^{1/3} , \tag{36a}$$

$$d' = 0.86\,m(A't)^{1/3} , \tag{36b}$$

and

$$W = 5(A't)^{1/3} , \tag{36c}$$

where $A' = (D\gamma_{SL}\Omega^2c_\infty)/RT$, $t = A't$, and D is the diffusion coefficient of M^{n+} in the crystal. In the case of convective diffusion, the profile (see Fig. 7) may be asymmetric for the different crystals A and B of the bicrystal.[48] In x, y coordinates, the curvature of the metal surface is described by the expression

$$K_M(x,\tau,\alpha) = m(\pi\tau\alpha)^{-1/2}\exp\frac{-x^2}{4\tau\alpha} , \tag{37}$$

and the profile of the surface in the normalised $\eta = x/2\sqrt{\tau\alpha}$ coordinates is

$$\frac{W(\eta)}{2m\sqrt{\tau\alpha}} = -\eta\,\mathrm{erf}(\eta) - \frac{1}{\sqrt{\pi}}\exp(-\eta^2) + \eta = X(\eta) . \tag{38}$$

Here τ is the dimensionless time, $\alpha = Pe/2 = 0.5V/D_A$ (where Pe is the Péclet number, V is the average rate of penetration of A into the A–B bicrystal, and D_A is the diffusion coefficient of A in the A–B bicrystal).

If the diffusion process on the metal surface is markedly influenced by electromigration, the curvature of this surface in the two-dimensional variant (in x, y coordinates) corresponds to the expression[49]

$$K_M(x,\tau,\alpha) = \frac{2g}{1+\beta^{1/3}+\beta^{2/3}}(A_1,t)^{1/3}\sum_{n=0}^{\infty}b_{j,n}\left[\frac{x}{(A_jt)^{1/3}}\right]^n , \tag{39}$$

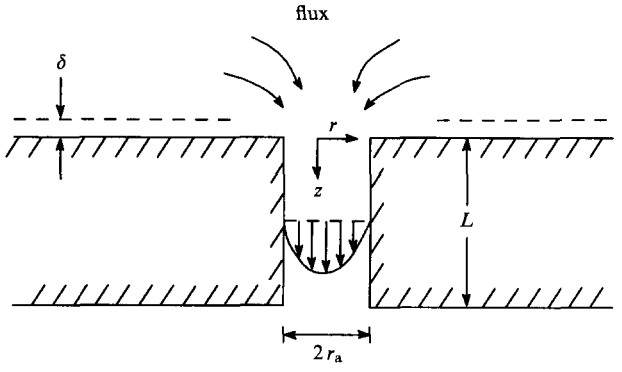
where $2g$ is the ratio of the free energies of the GB and of the surface per unit surface area, and $\beta = D_A/D_B$ (D_B is the diffusion coefficient of B in the A–B bicrystal), and

$$A_j = \frac{A'z|e^-|\rho i_m}{k_BT} ,$$

where $z|e^-|$ is the effective charge, ρ is the resistance, i_m is the electromigration current density, and $j = 1, 2$. The resulting profile is nonlinear, the maximum amplitude of y being found at $x = 1$.

When the difference in the rates of dissolution between the bulk of the grain and along the GB is large ($i_{GB} \gg i_{S,\perp}$), we can use a model proposed by Peschke et al.[37] and similar to the well known Fischer model, according to which an etch groove with perpendicular walls is formed (Fig. 8*a*). In practice, this state of affairs is typical of the dissolution of hydrogen-saturated polycrystals showing passivation (Figs 8*b* and 8*c*). The local loss of passivity on the GB produces a large increase in i_{GB} in the z direction. The convective diffusion equation

$$v(r)\frac{\partial c(x,t)}{\partial z} = D_A\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{\partial c(x,t)}{\partial r}\right]$$

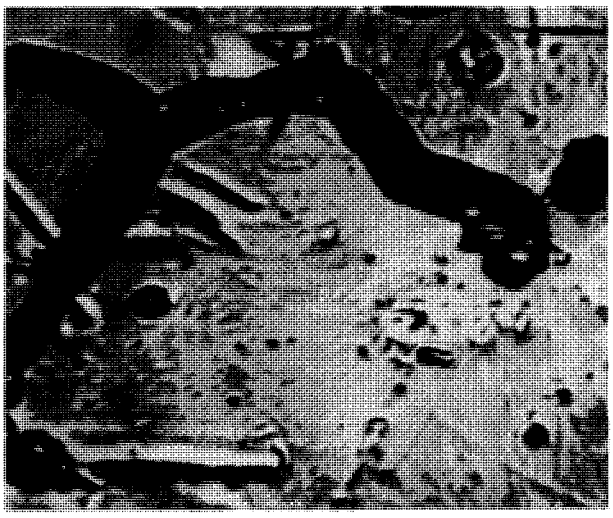


for this situation can be expressed as

$$F(\bar r)\frac{\partial\bar c}{\partial\bar z} = \frac{1}{Pe}\left[\frac{1}{\bar r}\frac{\partial}{\partial\bar r}\left(\bar r\frac{\partial\bar c}{\partial\bar r}\right)\right] , \tag{40}$$

where $F(\bar r)$ is the dimensionless velocity

$$F(\bar r) = \frac{1}{2}\frac{v(\bar r)}{V_0} = \frac{1}{2}\bar v(\bar r) ; \tag{41}$$



$\bar r = r/r_a$, $\bar z = z/z_a$, and $\bar c = c(x,t)/c_\infty$ are, respectively, the dimensionless values of the radius of the groove, of its depth, and of the concentration $c(x,t)$ of the substance near ($z = 0$) or far from the groove (c_∞).

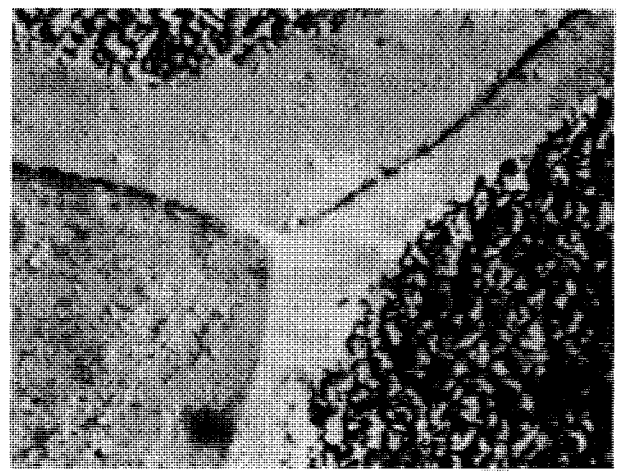
c

Figure 8. Model of an etch groove on the GB in thoroughly passivated metals (*a*) and the grain-boundary dissolution of hydrogen-saturated nickel (*b*) and 12X18N9T steel (*c*) polycrystals (× 960).

The boundary conditions are



$$\bar{c}\Big|_{\bar{z}=0} = 1, \quad \frac{\partial \bar{c}}{\partial \bar{r}}\Big|_{\bar{r}=0} = 0 \text{ , and } \frac{-\partial \bar{c}}{\partial \bar{r}}\Big|_{\bar{r}=1} = K_D \bar{c} \text{ ,}$$

where $K_D = kr_a/D_A$, and k is a constant.

The solution of the diffusion equation is

$$\bar{c} = \frac{1}{\Gamma(4/3)} \int_{\eta}^{\infty} \exp(-\eta^3) d\eta \text{ ,} \qquad (42)$$

a

b

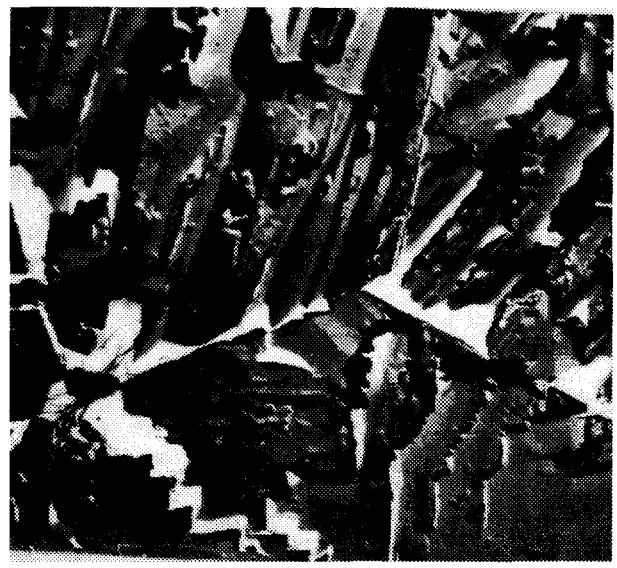


Figure 9. Dissolution of iron (*a*) and nickel (*b*) tricrystals (× 12000).

where $\eta = \bar{s}/(9/2\bar{z})^{1/3}$, $\Gamma(4/3) = 0.8934$ is the gamma-function, and $\bar{s} = Pe^{1/3}(1-\bar{r})$. The rate of dissolution in the groove is

$$i_{GB} = \frac{D_A c_B}{0.8934a} \left(\frac{9}{2}\bar{z}\right)^{-1/3} Pe^{1/3} \text{ ,}$$

where a is the lattice constant.

The model proposed by Peschke et al.[37] can be used to describe the dissolution of very pure metals in nonpassivating electrolytes, when $i_{GB} \approx i_{S,\perp}$. The bulk of the grains dissolves at different rates, depending on the crystal orientation of the adjacent single-crystal planes (*hkl*) in contact with the electrolyte (Fig. 9). As a result, some grains dissolve faster than others, and this is the main reason for the formation of a rough surface when a polycrystal is etched.

In a more realistic model the parameter r_a (the radius of the etch groove) varies nonlinearly along the normal z, and in the bulk of the metal $i_a \to 0$. In this case, $i_{GB} > i_{S,\perp}$. The analysis of this model is similar to the analysis of the diffusional permeability of the GB, in which surface diffusion does not play a dominant role.[10] In this model the layer concentration is

$$\bar{c} = \frac{8c_0 r_a}{\lambda} \int_0^{\infty} \operatorname{erfc}(\theta) \operatorname{erfc}\left(\frac{\omega}{2\sqrt{2\theta}}\right) d\theta \text{ ,} \qquad (43)$$

where $c_0 = c'(0,t)$ is the surface concentration, $\lambda = a/\sqrt{Dt}$ is a kinetic parameter, and $D = [(\sqrt{D_1} + \sqrt{D_2})/2]^{-2}$ is the effective bulk diffusion coefficient. As the corrosion process develops according to this model, a very harmful stress concentrator (with sharp notches) is formed on the metal surface and seriously degrades the strength of the metal under mechanical loads.

Experimental studies of the corrosion-induced breakdown of bicrystals began many years ago. The early work of Pfeil [50] showed that an iron bicrystal saturated with hydrogen splits into the two individual single crystals under the influence of applied mechanical stresses. Bicrystals of the *d* metals (V, Nb, Ta) offer convenient samples for the study of intercrystallite dissolution. These can be prepared by electron-beam zone melting with almost any misorientation angle θ. Estimates of the corrosion stability of symmetrical GB have shown [51] that the highest solubility is found in boundaries consisting of the least close-packed (100) and (110) planes of f.c.c. crystals.

The GB in a bicrystal effectively suppress the motion of dislocations, and therefore the dislocation density is higher in a bicrystal than in a single crystal grown under the same conditions. The effectiveness of this suppression depends on the angle θ. The GB with $\theta > 25°$ are less penetrable: on these boundaries, both the dislocation density and the rate of corrosion are enhanced.

When interpreting the changes in the rate of corrosion (K) along the boundary of a niobium crystal, we need to know both θ and the crystallographic orientation of the contacting single-crystal planes (hkl), and also the direction of the rotation angle of the grains ($\bar{n}$), since the parameter K for the given surfaces depends on their crystallographic direction [hkl]. It has been shown [41] that, at a [011]/[0$\bar{1}$1] boundary with $\theta = 16°$, the rate of corrosion and the depth of corrosional degradation (z_{cor}) are highest. The resulting concentration profile is asymmetric, because of the difference between the K values for the different faces. Linear relationships between θ and z_{cor} are observed only for $\theta \leqslant 20°$. Beyond this point, the linearity is perturbed, and at $\theta = 28°$ the plot of z_{cor} against θ develops a minimum apparently associated with a change in the structure of the GB with increase of θ. Whereas at low misorientation angles ($\theta < 20°$) the number of overlapping units decreases monotonically as θ is increased, when $\theta \geqslant 20°$ their number can increase at first and then fall sharply.

The dependence of the rate of corrosion on the reciprocal volume density of overlapping units Σ is nonmonotonic. Extrema in the dependence of K on Σ are found on GB, [13,14] in which the rotation axis is ⟨100⟩ for a GB with $\Sigma = 5$ {210} and $\Sigma = 5$ {310}, and also for a ⟨110⟩ axis for a GB with $\Sigma = 27$ {115} and $\Sigma = 11$ {113}. These data were confirmed experimentally by Miura and coworkers, [51-53] who showed that a copper bicrystal with $\Sigma = 3$ {111} dissolves much more slowly on the GB in 1 M $NaNO_2$ at 300 K than when $\Sigma = 9$ {221} and $\Sigma = 11$ {311}.

It follows from geometric considerations [54] of the structure of the GB that

$$\Sigma = m^2 + n^2(h^2 + k^2 + l^2) ,$$

$$\theta = 2\tan^{-1}\left(\frac{m}{n}\sqrt{h^2 + k^2 + l^2}\right) ,$$

where m and n are integers, and the Miller indices h, k, and l are determined by the vector of the rotation axis of the grains in the bicrystal. In cubic crystals, the following relationship is obeyed between the reciprocal density Σ and the angle θ:

$$\Sigma = \frac{n}{4}\left(1 + \cot\frac{\theta}{2}\right) , \qquad (44)$$

in which a well defined angle θ corresponds [54-56] to each value of Σ and n.

The intercrystallite dissolution (corrosion) (ICC) of various strongly passivating steels has attracted extensive studies. At the potentials of the active–passive transition some stainless steels have dis-solution currents on the grain-boundary bulk approximately 10^4 times greater than materials which are stable towards ICC. The two most commonly used tests for ICC are based on this effect: [57] Strauss's test [boiling the stainless steel samples in a solution of $H_2SO_4 + CuSO_4 + Cu$(powder), $t > 3.6 \times 10^4$ s], keeping the potential at $E = 0.35 \pm 0.03$ V, and Gouy's test (the sample is boiled, in cycles, in 65% HNO_3, $t > 8.6 \times 10^5$ s, and $E = 1.20 \pm 0.05$ V), i.e. the action of strongly oxidising media in the potential region of the transpassive state is simulated). For steels with a well-defined structure and known heat treatment regimes, we can use nondestructive electrochemical potentiostatic and galvanostatic control methods, based on etching in solutions containing chloride ions. One of the latest modifications of these methods [3] consists in analysing the anodic polarisation curves obtained by the potentiokinetic method ($V_E = 3.3 \times 10^{-3}$ V s^{-1}) in a solution of 10% H_2SO_4 + 0.0025 g l^{-1} KCNS. The curves are plotted from $E = 0.75$ V after a preliminary cathodic polarisation (−0.35 V, $t = 60$ s) and an anodic etch in the same solution (0 V, $t = 180$ s). If an anodic loop is not formed on the polarisation curve, the steel is not undergoing ICC. The liability to ICC is assessed [58] from the current in the active state, or from the ratio of the quantities of electricity passing through the electrode when the polarisation curve is plotted in the forward and in the reverse direction. If this ratio is >1, the steel is liable to ICC.

The dissolution currents on the grain-boundary volumes of austenitic stainless steels depend on the segregation of the impurities B, C, N, O, Si, P, and S. Allowance is needed not only for the chemical aspects of the interaction of these impurities with the atoms of the matrix but also for the elastic distortions produced on the GB by the segregation of the impurities. The harmful effect of these impurities on the ICC can be overcome by introducing antisegregants into the metal: additives which chemically bind the impurity by forming an inactive compound. This technical process arose from studies of the effect of hydride-forming impurities on the corrosion and on the physico-mechanical characteristics of hydrogenated polycrystals. When a metal is saturated with hydrogen, the impurities concentrated on

Table 1. The values of Σ and θ for the (100) and (111) planes of the grain boundaries (twisting of the cubic lattice and the misorientation angles for $\Sigma = 3$ and the possible values of n in the X-ray diffraction model).

the GB can form hydride phases, which grow from well defined generation centres. The growth kinetics of these phases are controlled by surface diffusion, by diffusion along the GB, or by the dislocation creep of the metal. In the first case, the rate of change of the radius r of a bubble of the hydride phase (for example, methane) is given by the equation[63]

$$\left(\frac{dr}{dt}\right)_{Sd} = \frac{27}{64}\left(\frac{B}{\Omega_b^3 \Delta^3}\right)[(1+Q\varepsilon\Delta)^{1/2} - 1]\left[\frac{1}{Q^3(1-d^2)^3}\right], \quad (45)$$

where $B = D_S\delta_S\Omega\gamma_S/k_BT$ [D_S and D_{GB} are the coefficients of surface and of grain-boundary hydrogen diffusion, $D_S = D_{0,S}\exp(-Q_S/RT)$, $\delta_S = \Omega^{1/3}$, Ω is the atomic volume, γ_S is the surface energy]; Ω_b is the half-volume of the bubble, $\Delta = D_S\delta_S/D_b\delta_{GB}$ [$D_b = D_{0,b}\exp(-Q_b/RT)$, δ_{GB} is the thickness of the GB],

$$Q = \frac{3d}{(1-d^2)^3}\left[\ln\frac{1}{d} - \frac{(3-d^2)(1-d^2)}{4}\right],$$

$$\varepsilon = \frac{2p_{CH_4}\Omega_b}{\gamma_S}, \qquad d = \frac{r}{\Omega_b}.$$

If grain-boundary diffusion is the rate-controlling step of the process, the growth rate of the gas bubble on the GB is

$$\left(\frac{dr}{dt}\right)_{GB} = \frac{3\Omega D_b\delta_{GB}}{d(1-d^2)^2 Q k_B T \Omega_b^2}\left[p_{CH_4} - \frac{\gamma_s(1-d^2)}{d\Omega_b}\right]. \quad (46)$$

Lastly, in the case of dislocation creep, when the growth of the bubble depends on the hydrogen–dislocation interaction and on the quantity of hydrogen transferred with the moving dislocations, the kinetics are described by the expression[64]

$$\left(\frac{dr}{dt}\right)_{dc} = \sqrt{3}\varepsilon_{cr}^0 G_c(d), \quad (47)$$

where

$$\varepsilon_{cr}^0 = \frac{AD_L b}{V_0 k_B T G_c^{N-1}}\left[p_{CH_4} - \left(\frac{2\gamma_S}{r}\right)^N\right],$$

$$G_c = \left(\frac{3}{2}N\right)^N \frac{\Omega_b d}{(1-d^{3/N})^N}.$$

Here A is a constant dependent on the material [see formula (18)], D_L is the coefficient of lattice (volume) diffusion of hydrogen, V_0 is the rate of dislocation creep, and N is the extent of creep.

Under the conditions $r^2 \ll n^{-1} \ll D_L t$, the radius of spherical formations deposited along the GB can be determined by the formula

$$r(z,t) = r(0,t)\left[1 + \left(\frac{2\pi n D_L}{15\delta_b D_{GB}}\right)^{1/2} z r^{1/2}(0,t)\right]^{-2}, \quad (48)$$

where n is the density of the generation centres of the new phase, and δ_b is the diameter of the bubble.

Point defects interact strongly with the GB, and therefore very pure bicrystals must be used in studies of the effect of small, mobile impurities (for example, the hydrogen isotopes). The segregation on the GB of impurities of the *s* and *sp* elements with atoms larger than those of the matrix strongly perturbs the GB structure and alters its hydrogen adsorption capacity.[66] The effective diffusion coefficient of hydrogen $D_{H,ef}$ in the grain-boundary volumes of the transition metals is almost two orders of magnitude greater than through the grain itself. The parameter $D_{H,ef}$ is strongly dependent on the angle θ. The most important experiments were carried out on Pd electrodes, but work on the 3*d* metals has also been reported. Thus, in a calculation of the diffusion coefficients in a bicrystal of very pure (99.999%) nickel with symmetrical boundaries having slopes of 39° (Σ = 9) and 129° (Σ = 11), it was found that $D_{D,ef}$ is 4.6×10^{-13} cm s^{-1} in the former case and 8–17 times greater in the latter.

The concentration of hydrogen in the grain boundary volumes induces a phase transformation and the formation of hydrides on the GB; the quantity $D_{D,ef}$ for the hydrogen-saturated nickel polycrystal is $\sim 3 \times 10^{-16}$ m^2 s^{-1}. The specific volume (density) of the hydride is usually different from that of the hydrogen-saturated matrix (the body of the grain). The dilatation effect arising under these conditions induces active processes involving the multiplication of dislocations in the crystallites. The hydrogen transferred together with the moving dislocations promotes further saturation of the GB by hydrogen.[68]

The cluster modelling of the GB on the basis of structural elements with octahedral and tetrahedral pores filled with the impurity atoms has shown[69] that the grain-boundary cohesion increases after the introduction of boron into nickel; it decreases if sulfur is concentrated on the GB. The first cluster calculations have been performed by Hashimoto's group for GB with Σ = 5 in iron containing phosphorus segregations.[70] Depending on the ratio of the dimensions of the pores and the impurity atoms, directed deformations on the GB can occur for steric reasons, inducing local phase transitions. The interatomic covalent bonds between the atoms of the matrix and the impurities are then strengthened, but the M–M bonds are weakened, the degree of weakening depending on θ and Σ. Subsequently, the influence of the impurities on the properties of many adsorbed surface phases was estimated and phase diagrams for the GB were constructed.[71]

Surface-active impurities, namely P, As, Sb, S, Se, Te, and Sn, greatly reduce the grain-boundary cohesion strength in iron and stainless steels, Si slightly reduces the cohesion, while Ni, C, and B increase it. The addition of N, C, and B slightly alters the segregation of the impurities of the first group on the GB. When the M–electrolyte interface is acted upon by electrolytes, there is a change in the pattern of the mutual influence of the impurities. The affinity of the impurity element for oxygen begins to play a dominant role. Technological additions of boron initiate ICC most vigorously in highly oxidising media — the effect of 0.001% B (X2ON20 steel) is analogous to the effect of ~0.1% P or ~1% Si.[72] The joint introduction of the C and P impurities, of C, and of doping amounts of Si results in the synergism of their activity associated with the localisation of chromium on the grain-boundary volumes in steel. The synergism can be accounted for by the grain-boundary segregation of C and P, inducing the depassivation of the GB as a result of the formation of less ordered oxide layers. An increase in the C content in steel ($0.1 < c_C < 0.3\%$) lowers the concentration of chromium on the grain boundaries as a result of the formation of the carbide $(Cr, Fe)_{22}C_6$ and hence impairs the passivation characteristics locally. However, the supersaturation of the near-surface layer of stainless steel (12X18N9T) with carbon ($c_C > 0.3\%$) increases its tendency towards ICC,[73] since the differences between structures of the oxide layers on the GB and on the body of the grain vanish.

Chromium actually diminishes the rate of dissolution of stainless steel in the passive range of potentials; the introduction of Ni, Mo, and N has a weak effect on the passivation of steel, but suppresses its dissolution in the active region. In the active dissolution of stainless steel, its near-surface layer is enriched in chromium and molybdenum, so that the formation of Cr–Mo–Ni intermetallic compounds as well as nitrides becomes possible. For equal amounts of carbon in austenitic stainless steels of different brands, the tendency towards intercrystallite corrosion is smaller for steels with a higher molybdenum concentration.[74] The joint action of chromium and other doping components (Ti, Ni, Mo, N) increases the zone corresponding to their influence on ICC. The width of the etch channels in ICC on GB is significantly greater (by a factor of 10–100) than the width of the boundary zones depleted in chromium. The width of the depleted zones in austenitic seals of the 304L and 316L types is not more than 1–2 μm. Consequently, in estimating the ICC, it is

necessary to take into account the influence and distribution of other impurities, in particular nitrogen.

Nitrogen, localised on structural defects, suppresses the selective dissolution of steel, which lowers the rate of corrosion. The sharp decrease in the solubility of transition metals after saturation with nitrogen is a well known phenomenon used in engineering. However, the concentration of nitrogen in steel must be maintained at a level $c_N \leqslant 0.13\%-0.15\%$ or $0.4\%-0.5\%$ (superaustenitic steels). Such a steel is resistant to the action of oxidation-reduction media and does not undergo ICC and slit corrosion in halide-containing solutions.[75] For $0.15\%-0.18\% < c_N < 0.4\%$, nitrides ($Cr_2N$) are formed vigorously and the rate of corrosion on the GB increases.[74]

The crystallographic stability is lost more readily on the GB, the overvoltage η being appreciably smaller than on the body of the grain. Correct crystallographic solutions of problems concerning the grain-boundary dissolution have been published by the groups of Froment and coworkers[13,14] and Gleiter.[76,77] Geometrical calculations are performed starting with the postulate that the rates of dissolution of neighbouring grains are different, so that the misorientation angles relative to the normal to the GB are also different. This makes it possible to calculate the changes in the surface tension $d\gamma$ by Eqn (15). The grain-boundary volume itself is not taken into account in such models; it is also disregarded in the CBL, GDL, and FOL models.

The grain-boundary dissolution process depends in many respects on the misorientation angle θ. By means of the texturing treatment of rolled sheet steel, it is possible to achieve changes in the rate of corrosion by several orders of magnitude and also to avoid the need for the use of corrosion inhibitors. There are definite critical angles θ_{cr} below which the GB have a low energy.[78] With increase in θ, the depth of the ICC increases and the stability of the GB falls. The decrease in the stability of the GB may be accompanied by the appearance on the bottom of the etch groove of a crack spreading into the bulk of the metal. The development of the crack depends subsequently on the topology and density of the dislocations in the local volumes of the metal. In the vicinity of a GB, there is an extensive dislocation structure with an increased content of mobile impurities. The dissolution process is undoubtedly associated with grain-boundary segregations, phase formation on the internal interfaces on heat treatment, ageing, and saturation with hydrogen.

In the estimation of the degree of corrosion on an interface by standard methods, the overall dissolution current i_Σ is regarded as the sum of the dissolution currents in the defects (i_D) (vacancies, dislocations, grain boundaries) and on the undamaged part of the surface (i_S). An exact quantitative separation of these currents is not always possible. For specimens, where either GB or only the material of the bulk of the grain appear on the working surface, it is possible to employ a novel method proposed by Khaldeev et al.[79] With the aid of this method, the influence of grain-boundary volumes on the electrochemical characteristics of the specimens was estimated experimentally and a study was made[79] of the influence of the vacuum heat treatment (673, 1073, and 1273 K, $t = 5 \times 10^5$ s) of M1 (99.90%) and M00 (99.95%) copper on the physical properties and corrosion in 0.5 M H_2SO_4.

The electrochemical characteristics of specimens annealed at a high temperature (973 and 1273 K for M00 and 1273 K for M1) change abruptly during anodic dissolution (Fig. 10). Thus, in the course of the continuous cyclic recording of polarisation curves for the same M1 specimen, one type *3'* curve is recorded after virtually only one type *3* curve, whilst for M00 copper annealed at 973 and 1273 K a type *6'* curve is recorded after 4–5 type *6* curves.

This can be accounted for as follows. High-temperature annealing leads to the growth of the grain (Fig. 10, curves *1* and *2*) and the formation of the so called bamboo structure, where GB cuts across the cross-section of the specimen in definite steps. The attainment of such boundaries in anodic dissolution leads to the appearance of anomalous $E-i$ curves (curves *3'*, *5'*, and *6'*), which has been confirmed by a parallel microscopic study. The

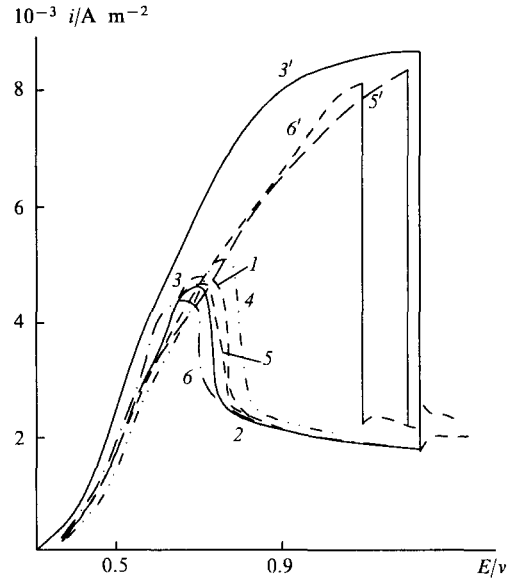

Figure 10. Anodic potentiodynamic ($V_E = 8 \times 10^{-4}$ V s^{-1}) curves for M1 (curves *1–3* and *3'*) and M00 (curves *4–6*, *5'* and *6'*) copper in 0.5 M H_2SO_4. Annealing temperature (K): (*1*) and (*4*) 673; (*2*), (*5*) and (*5'*) 973; (*3*), (*3'*), (*6*) and (*6'*) 1273.

formation of such a structure depends on the purity of the metal; in purer copper (M00), the grains are larger. At $T = 1273$ K, the grain diameter is $d_{M00} = 0.5-1.0$ mm, whereas $d_{M1} = 0.1$ mm, the value of d along the axis of the specimen being several times greater. Thus the highly pure M00 copper annealed at 1273 K contained a bicrystal in its cross-section as well as in the case where a layer with short GB was dissolved (a layer 0.03–0.05 mm thick dissolved during the recording of one curve); an almost twofold increase in i_{max} and E_{max} was observed [from $(4.5-4.6) \times 10^3$ to $(8.5-8.8) \times 10^3$ A m^{-2} and from 0.65–0.70 to 1.10–1.30 V respectively].

The purity of the metal influences significantly the mobility of the boundaries during annealing; as a rule, the impurities are concentrated in the vicinity of the GB. The accumulation of impurities on the GB may be regarded as a phase transition involving a change in the type of bond — from metallic in the bulk phase to predominantly covalent on the GB. This makes it possible to explain the differences in the behaviour of M1 and M00 copper. The anomalous dissolution is apparently not associated with changes in the nonequilibrium defects within the grain. With increase in the annealing temperature above 973 K, the relative resistance $K_\rho = \rho_{233}/(\rho_{293}-\rho_{77})$ (here ρ_{293} and ρ_{77} are the specific resistances at 293 and 77 K respectively), which makes it possible to estimate the degree of defectiveness of the GB of the grains, increases rapidly (Fig. 11, curves *3* and *4*). This indicates an increase in the degree of defectiveness in the region of the grain boundaries. Measurements of the internal friction Q^{-1} also indicate that a more ideal structure is created within the grain (Fig. 11, curves *5* and *6*). The nature of the variation of Q^{-1} shows that the movement of the dislocations within the grain is responsible for the increase in the internal friction: with increase in the size of the crystallites, there is an increase in the length of the dislocation segments between the points of strong attachment and the localisation of the impurities in the region of the GB promotes a smaller degree of blocking of the dislocations by the impurity atoms (Fe, Zn, Sb, Bi, P). The changes in i_{max} and E_{max} are not associated with the morphology of the intragrain volumes, since, according to the results of electron microscope analysis, there are no appreciable differences in surface rugosities for the specimens (Fig. 10, curves *1–6*). However, if the dissolution in the active range of potentials takes place on the GB for copper which has

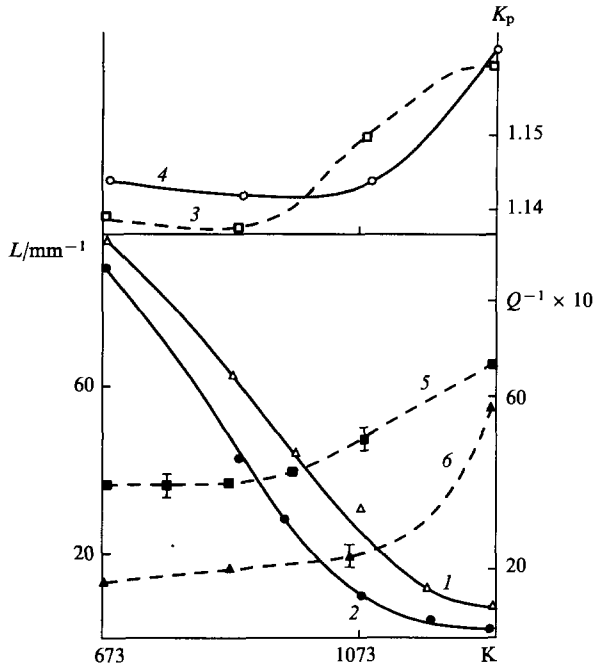

Figure 11. Dependence of the length of the grain boundaries (curves *1* and *2*), the relative electrical resistance (curves *3* and *4*), and the internal friction (Q) at a frequency of 1 Hz (curves *5* and *6*) on the annealing temperature for M1 (curves *1–3*) and M00 (curves *4–6*) copper.

been subjected to high-temperature annealing, the formation of etch channels is noted. Thus a decrease in the length of the GB and an increase in the concentration of defects and impurities in their vicinity may induce an appreciable anomalous change in the dissolution currents and passivation potentials.

Erb et al.[76] reached a similar conclusion. The method used in their experiment reduces to the following. In order to achieve the separate quantitative estimation of the rates of corrosion on the GB and on the bulk of the grain, two highly pure copper crystals (99.999%) and a Cu–Bi copper alloy (6×10^{-3}–7×10^{-2} at.% Bi) were sintered, after which only the GB (at $T = 263$ K, $t = 5.4 \times 10^5$ s) was subjected to corrosion in aqueous 12% HCl solution to which 1 g litre^{-1} of $FeCl_3.6H_2O$ had been added. The width of the etch groove formed is ~20–45 μm. The development of the ICC is associated with the increase in the local anode current i_a, caused by the accumulation of the bismuth impurities, and not with the increase in γ_{SL} (the free energy of the region of the metal lattice near the GB).

The analysis of the behaviour of triple grain contacts is important in the description of the stable networks of grain-boundaries on the surface of the crystal. On the basis of the modified Mullins model,[47] results have been obtained[70] according to which the region of the triple contact increases on dissolution and does not undergo a change in shape, the latter being determined solely by the free energy of the boundaries. The crater region of the contact is larger than the etch groove and its size increases with decrease in the angle between the boundaries converging at the point of contact. The corrosion-activated triple contact of the GB (and the GB themselves in textured materials) may become a dangerous concentrator of the disruption. Following the application of a load in excess of the ultimate strength and acidification of the medium in the corrosion pit, the crack increases catastrophically.[81] The rate of the abrupt growth of such a crack into the bulk of the material obeys a relation[81] analogous to the Kolmogorov–Johnson–Mell–Avraami equation:

$$V_c = \left[0.5m + \frac{\Delta a_p}{V_\delta}\left(1 - \exp\frac{-V_{\delta,S}}{t_p V_\delta}\right)\right] V_\delta \ , \qquad (49)$$

where m is the characteristic of the profile of the sloping side of the groove [Eqn (34)], Δa_p the sum of the changes in the internal conditions (constants of the material) and external conditions (the potential E, the rate of deformation V_d, and the composition and concentration c of the solution), and V_δ and $V_{\delta,S}$ are respectively the overall rate of expansion of the plastic failure zone (abrupt growth of the crack) and the corresponding rate in a single act. The abrupt growth is effected as a result of the formation of steps, which is accompanied by an increase in the rate of corrosion i_{cor}. The crack is initiated within narrower ranges of E and V_d than its propagation and depends greatly on the angle θ and the reciprocal of the density of the coincidence blocks Σ. The values of θ and Σ for which the M–M bonds are anomalously weakened are characteristic also of intense ICC.

VI. Dissolution of heterophase polycrystalline metals

The influence of bulky defects (microinclusions) on the dissolution of a metal must be considered in terms of a continuous approximation. The intragrain heterogeneity may be caused not only by mesolevel defects (single dislocations, low-angle boundaries of dislocation origin, and coherent binary layers), but also by rigid inclusions inducing both elastic and plastic deformation of the material of the grain. As a rule, the rates of dissolution of the inclusion and the matrix are different, while the stresses generated by the inclusions in the matrix are capable of altering significantly the rate of corrosion of the metal.

The role of nonmetallic inclusions in the corrosion process is complex: depending on their type and geometry, the rate of dissolution of the metal may both increase and diminish. Clearly i_{cor}, which depends on the sum of the internal factors (impurity composition, structure, and deformation state of the metal) and external factors (anionic composition and electrolyte parameters), may vary within wide limits, the greatest changes being observed in materials which dissolve under more nonequilibrium conditions (corrosion under stress, corrosion in slits and gaps, corrosion under the conditions of nonstationary movements of the electrolyte, corrosion in the anodic process, etc.).

It is of interest to examine the role of the rigid inclusions in the dissolution of a heterophase polycrystalline metal. This problem is of current interest for composite electrochemical coatings, carbon steels containing cementitic Fe_3C outcrops in ferrite, and also brass, titanium and its alloys (α-phase in a β-matrix), and certain other materials, since it is necessary to take into account the change in the deformation state of the matrix following the development of microinclusions. The rate of dissolution of an elastically deformed metal may increase significantly.

Plastic inclusions. We shall consider a periodic system of linear planar parallel inclusions. Their length is $2l$, their centres are located on the $0x$ axis, and the angles α of their inclination relative to the axis are equal (Fig. 12). In order to find the stresses arising under these conditions, it is necessary to solve the following integral equation:[82]

$$\int_{-l}^{l} [G(\rho, t)K(t - x, \rho^*) + G(\rho, t)L(t - x)]\mathrm{d}t = 0.5\pi i(\rho - \rho^*)F(\rho^*, x), \quad |x| < l \ , \qquad (50)$$

where

$$K(x, \rho^*) = 0.5\pi\rho^* l_d^{-1}\{\exp(i\alpha)\cot[\pi x \exp(i\alpha)]l_d^{-1}\} + \exp[(i\alpha)\cot(-i\alpha)]l_d^{-1} \ ,$$

$$L(x) = 0.5\pi l_d^{-1}\{\cot[\pi x \exp(-i\alpha)]l_d^{-1}\} - \pi x[\exp(-i\alpha)]\mathrm{cosec}^2[\pi x \exp(-i\alpha)]l_d^{-1}[\exp(-i\alpha) - \exp(-3i\alpha)]\cot[\pi x \exp(-i\alpha)]l_d^{-1} \ ,$$

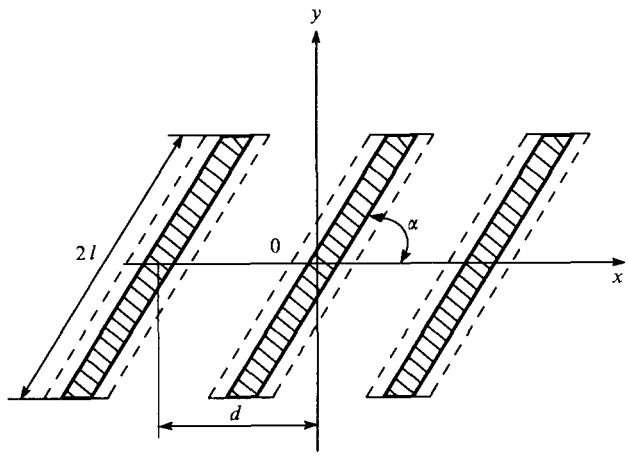

Figure 12. Schematic illustration of the matrix–rigid inclusion system.

$G(\rho,t)$ is a stresses function, $F(\rho^*,x)$ is a known displacement function, and ρ^* assumes the values L and $-l$ for rigid inclusions. The solution of this equation must satisfy the condition

$$\int_{-l}^{l} G(\rho,t)\mathrm{d}t = 0 \ .$$

Having expressed $G(\rho,t)$ in the form

$$G(\rho,t) = U(\rho,t) + \mathrm{i}V(\rho,t) \ ,$$

we obtain

$$\bar{G}(\rho,t) = U(\rho,t) - \mathrm{i}V(\rho,t) \ .$$

Having expanded the functions $\cot\varphi$ and $\mathrm{cosec}^2\varphi$ in a power series and having retained only the first two terms of the expansion (since they make the greatest contribution to the expansion for short distances between the defects), we obtain the following expressions for $K(x,\rho^*)$ and $L(x)$:

$$K(x,\rho^*) = \frac{\rho^*}{x} - \frac{\pi^2\rho^*\cos 2\alpha}{3l_\mathrm{d}^2}x \ ,$$

$$L(x) = \left(-\frac{2\pi^2}{3l_\mathrm{d}^2}\sin 3\alpha \sin\alpha\right)x + i\left(\frac{2\pi^2}{3l_\mathrm{d}^2}\cos 3\alpha \sin\alpha\right)x \ .$$

Having expressed $G(\rho,t)$ and $\bar{G}(\rho,t)$ in the form $G(\rho,t) = a_0 + a_1\rho + a_2 t + \mathrm{i}(b_0 + b_1\rho + b_2 t)$, i.e. containing only the linear terms in the expansions of $G(\rho,t)$ and $\bar{G}(\rho,t)$, we obtain a system of equations for the determination of the coefficients a_2 and b_2:

$$a_2\left[\rho^*\left(2l + x\ln\left|\frac{l-x}{l+x}\right|\right) - \frac{l^3}{3}\frac{\pi\rho^*\cos 2\alpha + 3\pi^2\sin 3\alpha\sin\alpha}{3l_\mathrm{d}^2}\right]$$

$$- b_2\frac{2\pi^2}{3l_\mathrm{d}^2}\cos 2\alpha\sin\alpha = 0.5\pi(\rho^* - \rho)B \ ,$$

$$- a_2\frac{2\pi^2}{3l_\mathrm{d}^2}\cos 3\alpha\sin\alpha \qquad (51)$$

$$+ b_2\left[\rho^*\left(2l + x\ln\left|\frac{l-x}{l+x}\right|\right) - \frac{l^3}{3}\frac{\pi\rho^*\cos 2\alpha}{3l_\mathrm{d}^2}\right.$$

$$\left. + \frac{l^3}{3}\frac{3\pi^2\sin 3\alpha\sin\alpha}{3l_\mathrm{d}^2}\right] = 0.5\pi(\rho - \rho^*)A \ .$$

Here $A(\rho^*,x)$ and $B(\rho^*,x)$ are the real and imaginary components of the function $F(\rho^*,x)$. The coefficients a_0, a_1, b_0, and b_1 do not enter into the expansion in view of the symmetry of the function $G(\rho^*,x)$, because in this case $a_0 + a_1\rho = 0$ and $b_0 + b_1\rho = 0$.

Having solved Eqn (51), we obtain expressions for the coefficients a_2 and b_2:

$$a_2 = \frac{-0.5\pi(\rho - \rho^*)B(\rho^*,x)}{\rho^*\left(2l + x\ln\left|\frac{l-x}{l+x}\right|\right) - \frac{l^3}{3}\frac{\pi\rho^*}{3l_\mathrm{d}^2}} \ ,$$

$$b_2 = \frac{0.5\pi(\rho - \rho^*)A(\rho^*,x)}{\rho^*\left(2l + x\ln\left|\frac{l-x}{l+x}\right|\right) - \frac{l^3}{3}\frac{\pi\rho^*}{3l_\mathrm{d}^2}} \qquad (52)$$

We shall consider the special case where the displacements are directed along the $0x$ axis. Analysis of the expressions for the coefficients a_2 and b_2 yields the following results: if $\alpha = 0$, then the stresses fall to zero for $l_\mathrm{d}\to 0$ and approach asymptotically a definite value for $l_\mathrm{d}\to\infty$. For a fixed distance l_d, the stresses vary as a function of x—the stresses diminish on moving away from the boundaries of the rigid inclusions. The curve relating the stresses to the distance to the GB has a minimum. We may note that the influence of the thickness of the inclusions on the distribution of the stresses is taken into account by the quantity l_d.

In the case of a uniform distribution of lamellar segregations in the matrix, a uniform stresses field arises within the crystals and the average density of the forces corresponds to the distribution of the surface forces. With increase in the number of inclusions of the second phase in a definite volume of the crystals, the overall surface energy on their interfaces also increases:[83]

$$\Delta\sigma = G_\mathrm{c}g^2\Delta c^2\mathrm{d}A_\mathrm{S}^2 + \frac{\gamma A_\mathrm{S}^3}{l_\mathrm{d}} \ ,$$

where $g = \mathrm{d}a/\mathrm{d}c$ is a derivative characterising the coherence of the transition on the interface, a the lattice parameter of the matrix, $\Delta c \approx \Delta\gamma^{\neq}$ the difference between the concentrations of the species in the phases proportional to the degree of supersaturation, A_S the area of the lamellar inclusions, and γ the surface tension. The minimum in $\Delta\sigma$ is observed for $\gamma = G_\mathrm{c}A_\mathrm{S}^{1/2}$. On formation of noncoincidence dislocations (ND) on the interfaces and also by virtue of the intensification of the diffusion of impurity atoms in the field of the elastic stresses of the species comprising the second phase, the stresses in the heterophase structure relax. The creation under these conditions of a sharp concentration profile of the impurities in the near-surface layer of the lamellar outcrops and the consequent dilatation effect induce an additional influx of impurities into this zone—an autocatalytic growth of inclusions takes place.

The physical picture of the distribution of stresses in the matrix and in the vicinity of the interfaces, obtained in terms of the continuous approximation within the framework of the linear theory of elasticity, is almost equivalent to the representation of the distribution of the dislocations at the interfaces. In the immediate vicinity of the interface, there are zones in which there is a sharp decrease in the level of the stresses and in the concentrations of the elementary deformation carriers. Subsequently they increase sharply. The background values of σ and ρ_d are attained for distances greater than the size of the dislocation (>1 μm). It is clear from the foregoing that the superfine-grained materials with a grain size $\leqslant 1$ μm have unique physicochemical characteristics and an increased corrosion resistance.

Spherical inclusions. Apart from lamellar inclusions, intragrain heterogeneity is induced by spherical inclusions.

We shall consider the appearance of stresses in the matrix in the vicinity of spherical dispersed particles (DP) without taking

into account the chemical nature of the latter. A continuous theory for the estimation of stresses in the vicinity of single particles of subatomic dimensions has been thoroughly developed and described.[84] The introduction of DP with a volume V and a surface area A_S into the crystals is accompanied by an increase in the volume of a finite crystal by ΔV and the appearance of a stress field. For a uniform distribution of N dispersed particles, the average stress

$$\langle\sigma\rangle = \frac{N}{V}P_d ,$$

and the average deformation

$$\langle\varepsilon\rangle = \frac{N}{V}A_S P_d .$$

(here P_d is the force dipoles tensor characterising the direction of the forces of the effect of DP on the matrix) are inversely proportional to the volume of the DP; for high ratios NA_S/V, the quantity $\langle\varepsilon\rangle$ should increase. The latter is characteristic of DP distributed uniformly in isotropic matrices. However, it can be readily seen that the average stress $\langle\sigma\rangle$ diminishes with decrease in the volume of the DP: the decrease in the level of the stressed state of a heterophase material as well as the creation of a uniform deformation should naturally promote an increase in its corrosion resistance, because the corrosion-induced destruction of metals is associated with the rupture of the M – M bonds. For ultradisperse particles, it is apparently also possible to confine the treatment to the continuous approximation, since the need for the employment of the microscopic lattice theory arises for mesolevel defects with dimensions less than 50 atomic radii (6–8 nm) — for coagulations of vacancies, clusters of extraneous atoms, dislocations, and disclinations.

We shall consider an assembly of DP in an isotropic matrix in which both the distance between the DP and the dimensions of the DP themselves vary. Such a situation is characteristic of real heterophase materials. The stresses near a single point source act radially and are proportional to x^{-1}, where x is the distance from the DP. If one considers the DP as a point source of stresses with the coordinates (0,0), then the stress at this point (Fig. 13) can be expressed by the relation

$$\sigma_{xy} = \frac{A}{\sqrt{(x-x_0)^2 + (y-y_0)^2}} ,$$

where A is a constant which depends on the material of the matrix. For several sources with coordinates (x_n, y_n), the superposition principle operates and the overall stress σ_Σ can be expressed in the form

$$\sigma_\Sigma = A\sum_{i=1}^{n} \frac{1}{\sqrt{(x-x_i)^2 + (y-y_y)^2}} . \qquad (53)$$

In calculating the sums in Eqn (53), we proceed as follows. Since the DP with the coordinates (0,0) is influenced most by the nearest particles, one can assume that the latter are distributed on a circumference with a radius R (Fig. 13) or on a circular sinusoid.

The stresses in the matrix $(\sigma_{x,y})$ are then formulated as follows:

$$\sigma_{x,y} = A\int_0^{2\pi} \frac{dA_S}{\sqrt{(x-\xi)^2 + (y-\eta)^2}} . \qquad (54)$$

In the parametric form, we have

$$\xi = R\cos t, \quad \eta = R\sin t.$$

Hence $dA_S = Rdt$. Having substituted the last expressions in Eqn (54), we obtain

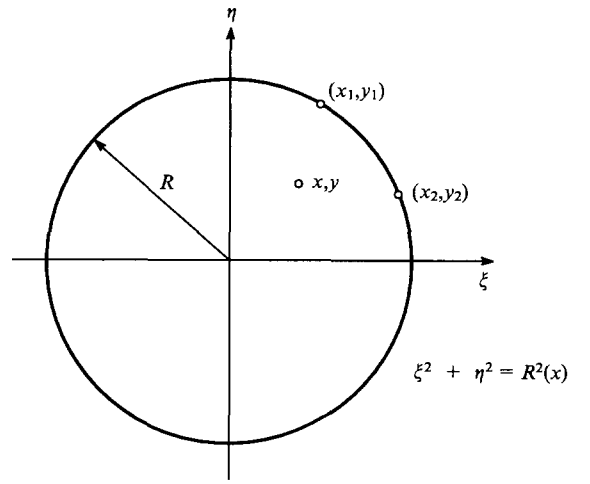

Figure 13. Model illustrating the disposition of disperse particles in a matrix.

$$\sigma_{x,y} = A\int_0^{2\pi} \frac{Rdt}{(x - R\cos t)^2 - (y - R\sin t)^2} . \qquad (55)$$

Since the disposition of the coordinate system (Fig. 13) makes it possible to regard the parameter of the point (x, y), at which the stresses are estimated, as fairly small, the integrand function in Eqn (55) can be expanded in series in x and y:

$$f(x,y) = f(0,0) + \frac{\partial f}{\partial x}(0,0)x + \frac{\partial f}{\partial y}(0,0)y + \frac{\partial^2 f}{\partial x^2}x^2 + 2\frac{\partial^2 f}{\partial x \partial y}xy + \frac{\partial^2 f}{\partial y^2}y^2 + O\left[\left(\sqrt{x^2+y^2}\right)^3\right] . \qquad (56)$$

Having formulated the derivatives for the terms of the integrand function $f(x, y)$, having substituted them in Eqn (56), and having integrated the latter for the stress $\sigma_{x,y}$, we obtain

$$\sigma_{x,y} = 2\pi A + \frac{4\pi A}{R^2}(x^2 + y^2) . \qquad (57)$$

We shall now analyse Eqn (57) taking into account the fact that R is a fixed quantity. For $0 < x < R$, $0 < y < R$, we have $\sigma_{x,y} \to 2\pi A$ if $x \to 0$ and $\sigma_{x,y} \to 10\pi A$ if $x \to R$.

Thus the stresses increase by a factor of 5 with increase in the distance from the DP and reach maximum values in the vicinity of $x = R$.

For spherical ultradisperse particles, the stresses can vary in accordance with a less steep law, in proportion to x^{-2} and not x^{-1}. In this case, the transformation of an equation of type (54) leads to the expression

$$\sigma_{x,y} = \frac{AR}{\sqrt{(x^2 - R^2) + 2y^2x^2}}\left(\frac{\pi}{2} + \arctan\frac{Ry}{(x^2 - R^2) + 2y^2x^2}\right), \qquad (58)$$

the analysis of which shows that the stress on a sphere is significantly smaller. We have

$$\sigma_{x,y} = \frac{\pi}{2}A$$

for $x = 0$ and $y = 0$, and

$$\sigma_{x,y} = \frac{3\pi A}{4R^3} .$$

for $x = R$ and $y = R$.

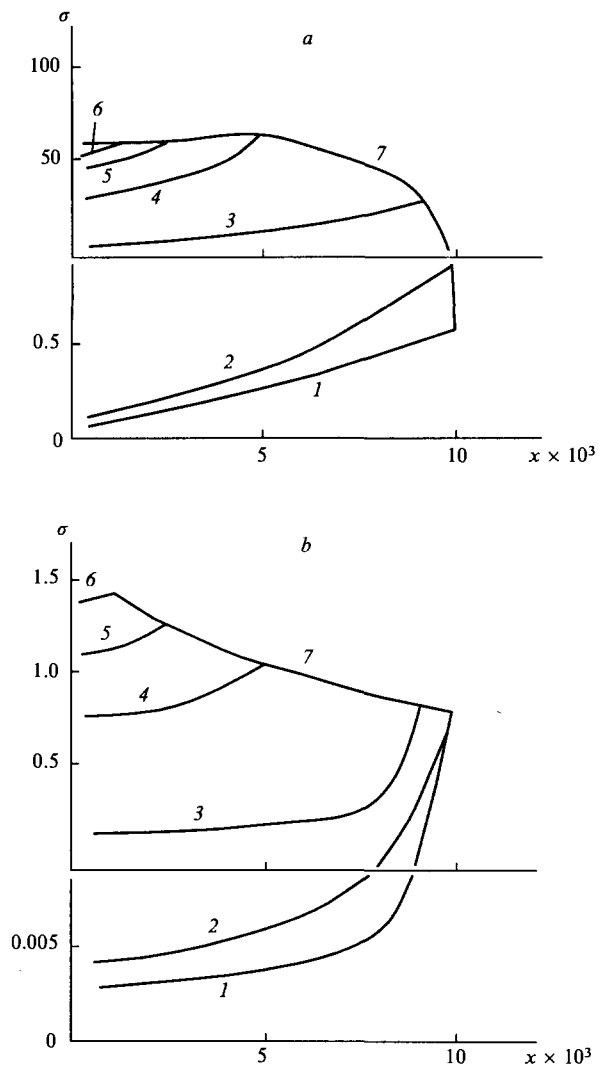

Figure 14. Dependence of the stresses in a matrix on the size of DP and the distance between them. Attenuation of the stresses in accordance with the x^{-1} (*a*) and x^{-2} (*b*) laws: r(nm): (*1*) 20; (*2*) 30; (*3*) 10^3; (*4*) 5×10^3; (*5*) 7.5×10^3; (*6*) 9×10^3; (*7*) stress level on a sphere with a radius $R = 10^4$ nm.

Numerical study of Eqns (56) and (57) for reasonable ratios of the DP radius and the quantity $R = 10^4$ nm (comparable to the grain size usually employed in metal technology) shows that, when the stresses are attenuated in accordance with the x^{-1} law (Fig. 14*a*), the quantity σ on the sphere where the surrounding DP are located is large. With decrease in the size of the DP, the stresses rapidly diminish—the greatest strengthening of the matrix is obtained for $x = 0.5R$ (Fig. 14*a*, curve *7*). When the stresses are attenuated in accordance with the x^{-2} law (Fig. 14*b*), the stresses level in the matrix is 2 orders of magnitude smaller than in the former case, but σ increases markedly in the vicinity of the DP. Under these conditions, the growth of stresses depends significantly on the size of the DP: the smaller the radius of the particles, the sharper the deformation profile (Fig. 14*b*, curves *1–3*). However, in a matrix uniformly saturated by particles the stresses change only slightly (Fig. 14*b*, curve *7*).

Thus the overall level of stresses in the matrix increases with decrease in the size of the DP and the stresses are localised in the vicinity of the DP.

The stresses near the DP relax, forming long noncoincident dislocations (ND) in the matrix. By virtue of this process, the density of dislocations ρ_d increases at the DP–matrix interface and microtwinned formations are produced [the process is usually observed experimentally in the study of thin foils by transmission electron microscopy (TEM)]. The continuous assessment of the stressed state in the vicinity of the DP–matrix interface does not conflict with the calculated model and the experiment on the distribution of dislocations in the vicinity of the grain boundary described above. The presence of an extremum in the stresses in an isotropic matrix promotes the appearance near the interface of zones with a reduced density of defects.

The equilibrium concentration of impurities in the matrix near a spherical particle with a radius r corresponds to the Gibbs–Thomson equation. We formulate this equation in the form

$$c_r(x,t) = c_\infty \exp\frac{2\gamma_{SL}\Omega}{rRT} ,$$

where c_∞ is the concentration of impurities on the inclusion–matrix interface in the case of a planar surface when $r \to \infty$ and $K_M = 0$. Analysis by Lifshits and Slezov[85] showed that, for a certain degree of supersaturation $\Delta\gamma^{\neq} = c - c_\infty = \text{const}$, the quantity

$$r_{cr} = -\frac{2\gamma_{SL}}{\Delta G_V} ,$$

corresponds to the equilibrium between a particle and the impurities near it. Here ΔG_V is the change in free energy in the crystal–liquid transition. The particle grows if $r > r_{cr}$ and is degraded if $r < r_{cr}$. The annihilation of small particles occurs as a result of consecutive pair interactions. Two particles with masses m and n form a new particle with a mass $m - n = k$: for long times t, the concentration of such particles is[86]

$$A_k(t) \sim \frac{A}{t(\ln t)^{k-1}} ,$$

where

$$A_k = \frac{(N-1)!}{(N-k)!} , \qquad k = 1, 2, \ldots, N-1;$$

N is the mass of a particle (cluster) having a finite volume.

The noncoincident dislocations, fixed on the DP, serve as pathways for the diffusional migration of impurities from particles having a low radius and undergoing degradation to larger particles. We shall analyse the growth of such DP in the matrix. For a uniform distribution of the particles (as above, the volume of a matrix having a radius R is considered), the particle is acted upon by a force $F = G_c/r$, the overall vector of which may be random.

If the distribution function for particles in the bulk of the matrix, the volume of which is limited by a radius R, is

$$f_0(R) = \frac{3}{r^3}R^2 ,$$

the overall distribution function can be formulated as follows:

$$g(x,y)\mathrm{d}x\,\mathrm{d}R = g_1(\varphi,R)\mathrm{d}\varphi\,\mathrm{d}R = \frac{3}{r^3}R^2\mathrm{d}R\frac{1}{2}\sin\varphi\,\mathrm{d}\varphi \qquad (59)$$

$$= \frac{3R^3}{2r^3G_c}\mathrm{d}R\,\mathrm{d}x ,$$

where φ is the angle between the specified direction and the direction of the force acting on the particle.

Having integrated Eqn (59) with respect to all R, we obtain the expression

$$f(x) = \frac{3}{2r^3G_c}\int_0^r R^3\mathrm{d}R = \frac{3}{8}\frac{r}{G} , \qquad (60)$$

which is valid for $|x| < G_c/r$. If $|x| > G_c/r$, then

$$f(x) = \frac{3}{2rG_c}\int_0^{G_c/|x|} R^3 dR = \frac{3}{8}\frac{G_c^3}{r^3|x|^4}. \quad (61)$$

It is possible to determine experimentally the distribution of stresses in the vicinity of a charged particle, i.e. the characteristics of such a stress can be estimated before the corrosion test. For example, the average expected stress MF is given by

$$MF = \int_0^\infty xf(x)dx$$

$$= \int_0^{G_c/r} x\frac{3}{8}\frac{r}{G_c}xdx + \int_{G/r}^\infty \frac{3}{8}\frac{G_c^3}{r^3}x^{-3}dx = \frac{3}{8}\frac{G_c}{r},$$

and the average scatter DF around this value is

$$DF = \int_0^\infty (x - MF)f(x)dx = \frac{7}{64}\frac{G_c}{r^2}, \quad (63)$$

i.e., for a particular metal, it is found that the smaller the size of the DP the higher the stresses level on the interface. In terms of mathematical statistics, the probability that the specified stress is exceeded is given by

$$P(\beta \leqslant x < +\infty) = \int_\beta^\infty f(x)dx;$$

β has two extreme values: if the concentration of particles is small so that $\beta < G_c/r$, we have $P = 3\beta/16$; if a volume with a radius R is overfilled with particles for $\beta \geqslant G_c/r$, we have $P = G_c^3/8r^3\beta^3$.

Thus, when the quantitative relation between the stresses level σ and the rate of corrosion i_{cor} is known, it is possible to determine the probability that the chemical resistance of the metal will change.

The quantity $\sigma_{x,y}$ was estimated above relative to a particle within the sphere on which the surrounding DP are located. The overall stresses arise as a result of the superposition of the $\sigma_{x,y}$ due to the assembly of DP, whereupon the extremum values of $\sigma_{x,y}$ within the sphere correspond to $x = 0.5R$ when the stresses are attenuated in accordance with both the x^{-1} and x^{-2} laws. It is noteworthy that the electrical characteristics of a surface with periodic inhomogeneities in the near-surface layer of the metal have an extremum at $x = 0.5r$.

Thus analysis shows that within the sphere there is a region with an extremum stresses level. Heterophase materials in which the ratio of the dimensions of the grain and the DP satisfies the condition $x = 0.5R$ exhibit the lowest corrosion resistance. Such situations may arise when two-phase alloys or ferrite-perlitic steels are employed in corrosive media and also for the local formation of hydrides in a matrix where particles of a second phase grow in the course of the hydrogen saturation process and there is a sudden increase in the rate of corrosion.

The relaxation of stresses in the vicinity of the DP takes place also as a result of the dislocation migration of impurities, i.e. as a result of local changes in chemical composition. The dislocation migration depends on the mobility of the dislocations V, which is related, in its turn, to their density by the simple expression

$$V = \frac{\dot{\varepsilon}}{\rho_d b}, \quad (64)$$

where $\dot{\varepsilon}$ is the rate of deformation of the crystal. It follows from Eqn (64) that an increase in ρ_d (for example, from 10^4 to 5×10^{18} m^{-2}) should lower significantly (by a factor of 10^5) the mobility for $\dot{\varepsilon} = \text{const}$. In the case of a hydrogen-saturated metal, $\dot{\varepsilon}$ should lie in the pre-Cottrell region, i.e. V should not exceed V_{cr} ($V_{cr} \leqslant 4D_D r_d^{-1}$, and r_d is the radius of the Cottrell atmosphere of the impurity atoms on a dislocation tube), whereupon dislocations are abstracted from the atmospheres of the impurity atoms. Favourable conditions for the relaxation of stresses and the redistribution of impurities arise at elevated temperatures and for low rates of deformation. For iron alloys, this corresponds to isothermal treatments at $T = 400$ K and $t > 6$ ks.

A nonuniform distribution of the DP in the matrix and hence the alternation of zones with different stressed states increases the risk of a sudden disintegration for high degrees of localisation of the corrosion process.

VII. Conclusion

In the physical chemistry of interfacial processes, a steady interest in the study of the influence of the structure of the interfaces on charge and material transfer processes has been manifested recently. The anomalies in the chemical reactivity of grain boundaries compared with the surfaces of crystals having structural defects with a definite structural hierarchy are due to their unusual structure. These anomalies can be used in electrocatalysis, in the electrosynthesis of organic compounds, and in the protection of metals against corrosion-induced disintegration.

The study of the metal–electrolyte corrosion system taking into account the influence of the metal defects at different structural levels (from point defects to bulk-phase defects) shows that a quantitative estimate of the effect of the dissolution proper should also be performed at different levels. If a point defect or a single dislocation induce a local distortion of the lattice which undergoes a rapid and sharp attenuation in the vicinity of the defect, then this promotes the intensification of a local form of corrosion — an etch pit is formed (in the case of a grain boundary an etch groove is produced, whilst slit corrosion may develop at the DP–matrix interface). Elastic deformations arising from the boundaries of grains and inclusions embrace the entire bulk of the grain and the groups nearest to it. In the latter case, the study of the influence of defects on corrosion becomes possible in terms of the continuous approximation using the theory of elasticity.

It is apparently to be expected that studies of controllable chemical reactions on the thoroughly tested surfaces of bi- and tricrystals will be undertaken. This will lead to new possibilities for the specific synthesis of new chemical products.

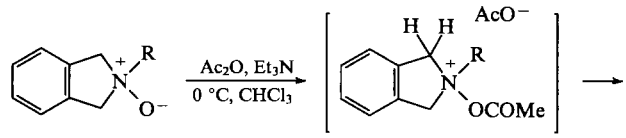
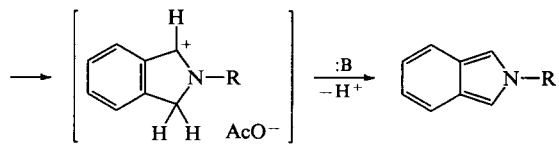
IV. Chemical properties	1009
V. Applications of isoindoles	1016

Abstract. Data on the synthesis and the physical and chemical properties of isoindoles published in 1981 – 1992 are considered. The problems of the aromaticity and the reactivity of the isoindole system are discussed. The bibliography includes 169 references.



I. Introduction

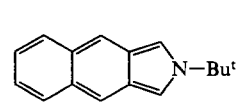
Several reviews[1,2] and monographs[3] on the chemistry of isoindole have been published in the last decade. However, the interest in this system is not flagging. New isoindoles have been obtained, some of which have been isolated in a pure form and some have been characterised as Diels–Alder adducts. New methods of synthesis of isoindole systems have been discovered. Calculations of the electronic structure have been carried out by methods which had not been applied previously, a new concept of the aromaticity of this system has been put forward, the X-ray diffraction analysis of isoindoles has been achieved, and new reactions have been investigated. Data have been published on the biological activity of isoindole systems.



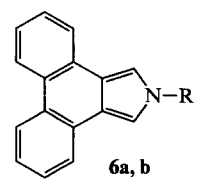
II. Methods of synthesis of isoindoles

1. Elimination reactions with participation of isoindoline *N*-oxides

The possibilities of this method, developed by German workers,[4] have been demonstrated in numerous examples and the method has attracted attention because of the high yields of 2-R-isoindoles. It consists in the treatment of the corresponding isoindoline *N*-oxide at a reduced temperature with acetic anhydride and triethylamine in chloroform and can be followed with the aid of ^{1}H NMR spectra. It has been suggested that the *O*-acetylation of the oxide **1** takes place initially and this is followed by the base-induced regiospecific 1,2-elimination of the elements of acetic acid from the intermediate **2**, and finally by the deprotonation of the intermediate 2-R-1*H*-isoindolium salts **3** with formation of 2-R-isoindoles **4**.



1 **2**



3 **4**

According to the authors,[4] the reaction resembles the Polonovski reaction. The available compounds indicate the possibility of extensive variation of the substituent in the 2-position in the system: the substituent can be an alkyl (10 compounds),[5] allyl,[4] and arylalkyl[6] group or the very frequently employed *tert*-butyl group.[5–12] In all the known examples of the isoindoles obtained by this procedure, the 1- and 3-positions in the system are free while the benzene component of the bicyclic system may contain methyl groups,[12] nitro-groups,[7] chlorine atoms,[12] or it can be condensed with other rings. The isoindoles **5**–**10** have been described in a number of communications.[6,8–10]

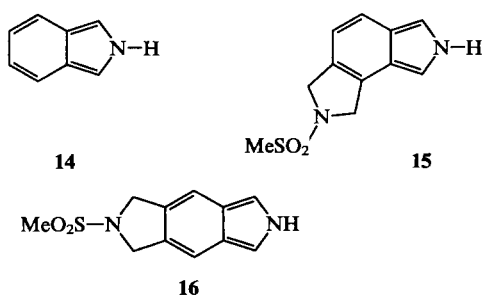
2. Elimination with participation of 2-R-isoindolines

The previously described method of synthesis of 2*H*-isoindoles via the 1,2-elimination of methanesulfinate from *N*-methanesulfinylisoindolines **11** on treatment with potassium *tert*-butoxide in dimethyl sulfoxide (DMSO) (60–65 °C) or ether has been developed further in a number of studies.[13–17] The required isoindolines **11** can be synthesised from the corresponding 1,2-bis(bromomethyl)benzenes and methanesulfonamide.[16] It has been suggested that the 1*H*-isoindole **12** is formed initially and then isomerises to the 2*H*-isoindole **13** as a result of a tautomeric transformation. The isoindoles **13a** (yield 94%) and **13b, c** have been described by Kreher and Kohl[14] and Kreher and Herd[17] respectively.

11 **12**

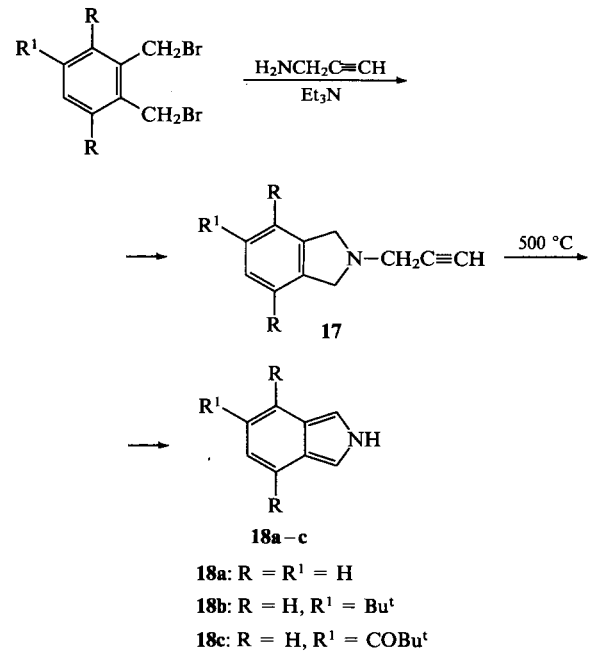


13a–c

13a: $R^1 = R^2 = R^3 = H$; $R^2 = COBu^t$

13b: $R^1 = R^2 = R^3 = R^4 = Cl$

13c: $R^1 = R^2 = R^3 = R^4 = Br$



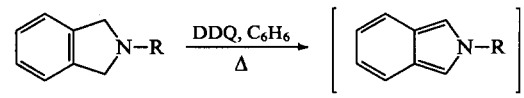
The isomeric compounds **15** and **16** as well as the parent isoindole **14** have been isolated by a similar method.[13] The last compound is obtained as a 0.05 M solution in ether.[15,16] The authors[15] believe that this method is in fact best for the preparation of solutions of the isoindole **14**.

14 **15**

16

The method involving the elimination of propyne from *N*-propargylisoindolines **17** at a high temperature can serve as a general approach to the synthesis of 2*H*-isoindoles **18**.[15,18] The yields of the products are fairly high. The isoindolines required are obtained from *o*-xylylene dibromides and propargylamine.

17



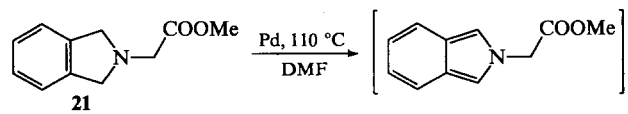
18a–c

18a: $R = R^1 = H$

18b: $R = H$, $R^1 = Bu^t$

18c: $R = H$, $R^1 = COBu^t$

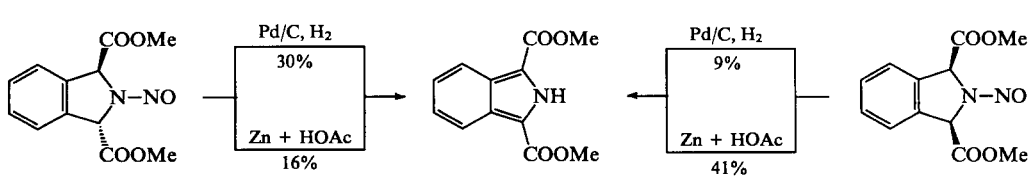
It has been shown[19] that 2-R-isoindoles can be obtained by dehydrogenating *N*-(ethoxycarbonyl)isoindolines **19** in benzene or diglyme with the aid of chloranil or 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). The isoindoles **20** were not isolated from the reaction mixture but were converted into Diels–Alder adducts with maleimide derivatives.



19 **20a, b**

20a: R = COOEt

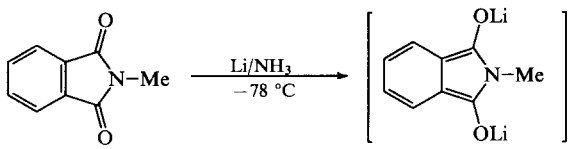
20b: R = Tos



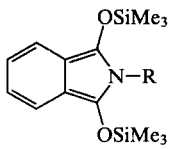
The dehydrogenation of the methyl ester of isoindoline-2-acetic acid **21** takes place in dimethylformamide (DMF) over palladium black at 110 °C and leads to the corresponding isoindole, which has also been characterised as the Diels–Alder adduct.[20]

21

The reduction of the stereoisomeric forms of *N*-nitrosoindoles (*E* and *Z*) leads to 1,3-dimethoxycarbonyl-2*H*-isoindole **22** in low yields (Scheme 1).[21]



Scheme 1

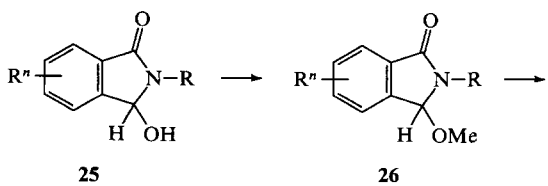


dl-*E* **22** meso-*Z*

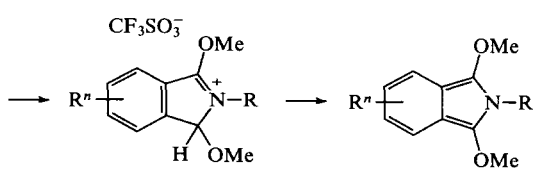
3. Synthesis of isoindoles from phthalimides

Flynn[22] was the first to demonstrate that the dianion of *N*-methylphthalimide has the *o*-quinonoid electronic structure **23**. The reduction of *N*-methylphthalimide dissolved in tetrahydrofuran (THF) by metallic lithium (2.1 equivalents) in liquid ammonia leads to a dark-red solution containing the dianion, the structure of which can be demonstrated by chemical reactions. The electrochemical reduction of *N*-methyl- and *N*-phenyl-phthalimides in anhydrous acetonitrile using a mercury cathode in the presence of tetraethylammonium chloride and an excess of trimethylsilyl chloride leads to the corresponding isoindoles **24a, b** via the dianion in **23**. When equivalent amounts of trimethylsilyl chloride are used, other products are formed.[23,24] The attempts to obtain the isoindoles **24c, d** from the corresponding phthalimides must be regarded as a development of this method. Under similar conditions, the electrochemical reductive silylation of *N*-alkoxyphthalimides leads to 2-alkoxy-1,3-bis(trimethylsiloxy)isoindoles.[25] All the isoindoles **24a–d** have been identified through the corresponding Diels–Alder adducts.

23



24a–d

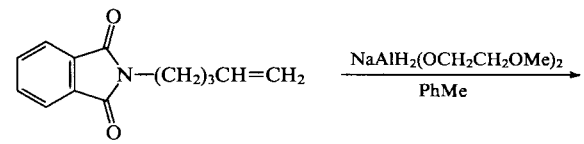


R = Me (**a**), Ph (**b**), OMe (**c**), OCH_2Ph (**d**)

The reduction of *N*-methyl- and *N*-phenyl-phthalimides at room temperature with zinc powder in 2,6-lutidine in the presence of THF and an excess of trimethylsilyl chloride has been investigated.[26] The reaction mixture was treated with ultrasound. The authors believe that the silylated isoindoles **24a, b** are also intermediates in this reaction.

A novel method of synthesis of 1,3-dimethoxy-2-R-isoindoles has been proposed.[27] It consists in the reduction of phthalimides by magnesium to 3-hydroxyphthalimidine **25**, which is converted into 3-methoxyphthalimidine **26**. The *O*-alkylation of the latter with CF_3SO_2OMe affords 1,3-dimethoxy-2-R-1*H*-isoindolium trifluoromethanesulfonate **27**, the deprotonation of which with the aid of lithium diisopropylamide leads to the relatively unstable 1,3-dimethoxy-2-R-isoindoles **28**, which have been identified via Diels–Alder adducts.

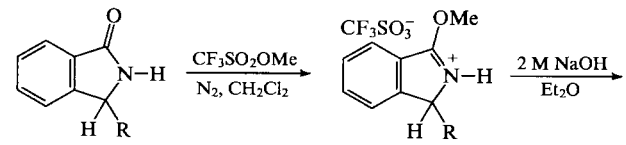
25 **26**



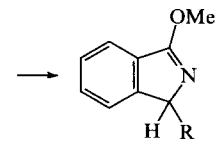
27 **28**

R = H, Me

R^n = H; 5,6-Me, 4,7-Me; 5,6-Cl



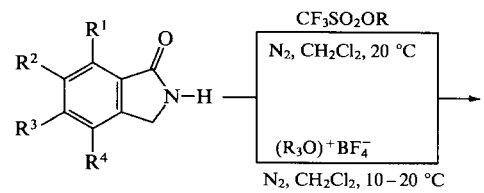
The method involving the chemical reduction of phthalimide has been used in the synthesis of the isoindole **29**. The target product was isolated in a moderate yield from a mixture with an isoindoline and phthalimidine.[28]

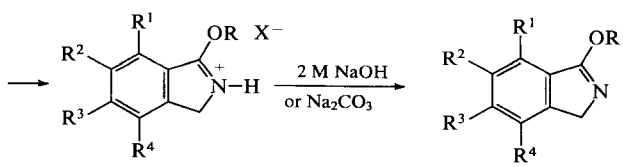


29

4. Synthesis of isoindoles from phthalimidines

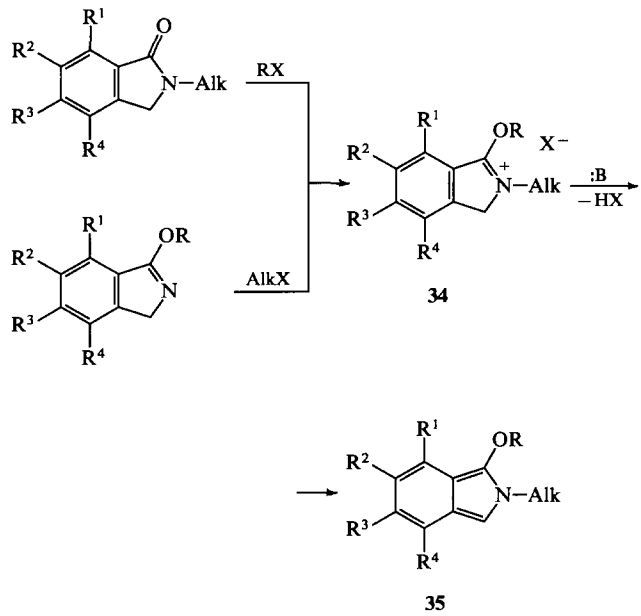
The study of the alkylation of various phthalimidines with the aid of the Meerwein reagent or methyl trifluoromethanesulfonate was continued during the period analysed.[29–32] Thus a series of 1-R-3-methoxy-1*H*-isoindoles **31** have been obtained by alkylating 1-R-3-oxo-1,2-dihydroisoindoles.[29,33] The regioselective *O*-alkylation in the first stage results in the formation of 1-R-3-methoxy-1*H*-isoindolium triflates **30** (the yields expressed in % are as follows for different R: 91 for Me, 72–89 for Ph, 4-MePh, and 4-ClPh, and 50 for 4-MeOPh), which are treated with a base in the presence of ether in the second stage. This method makes it possible to extract immediately the deprotonated products into the organic phase and to isolate 1-R-3-methoxy-1*H*-isoindoles **31** in 74%–93% yield.[29]





30

31



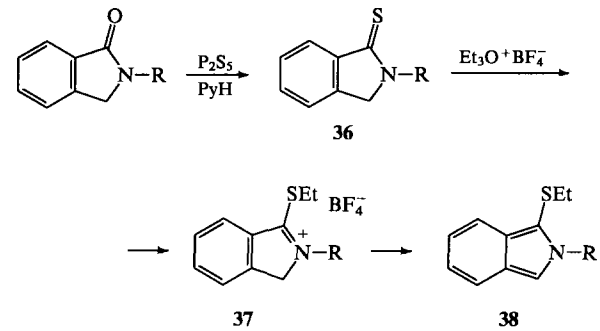
A series of 3-alkoxy-1*H*-isoindoles **33** (13 compounds), containing substituents of different electronic nature in the benzene part of the bicyclic compound, have been obtained by similar procedures.[30]

32 **33**

The preparation of the corresponding 3-ethoxy-1*H*-isoindole from 5,6-dimethoxyphthalimidine in 81% yield has been described.[34] The alkylation was carried out with triethyloxonium tetrafluoroborate. The study of the spectroscopic characteristics of compounds of type **31** and **33** showed that they exist exclusively in the isoindolenine form and do not exhibit a tendency towards conversion into the isoindole form.[29,30] If the isoindolenines **31** and **33** are alkylated with methyl trifluoromethanesulfonate, then the quaternary salts **34** are formed. These are the products of the regioselective *N*-alkylation which are readily deprotonated after treatment with bases (2 M NaOH or lithium diisopropylamide) and are converted into 1-alkoxy-2-methylisoindoles **35**.[31,32] The salts **34** can be obtained also by the direct *O*-alkylation of *N*-methylphthalimidines with the aid of the same alkylating agents, although such alkylation does not occur if the bicyclic system has been deactivated by substituents in the benzene component. This has been observed when attempts were made to alkylate 4,5,6,7-tetrachloro-*N*-methylphthalimidine with methyl trifluoromethanesulfonate.[31]

34

35



R = Me, Et

The alkoxyisoindoles **35** are unstable. They have been identified via Diels–Alder adducts, some of them being also investigated by the ^{1}H NMR method.

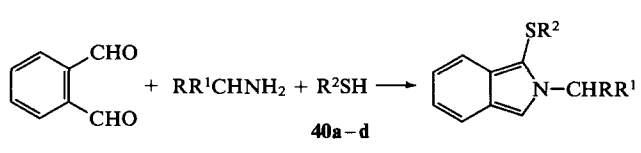
It was found that the stability of the compounds in solution depends on the type of the alkyl substituent at *N*(2). It it is a methyl group, then the ^{1}H NMR spectrum, recorded after brief drying of the organic layer, reveals the presence of a mixture consisting of the isoindole and the corresponding isoindolinone (for example, their ratios are 1 : 1.25 for R = Me and 1 : 1.5 for R = Et). The ratio for 2-*tert*-butyl-1-methoxy-2*H*-isoindole is more favourable (8 : 1).[32]

1-Ethylthio-2-R-isoindoles are obtained from the corresponding phthalimidines via their successive conversion initially into the thiophthalimidines **36** and then, by the regioselective *S*-alkylation of the latter, into 3-ethylthio-2-R-1*H*-isoindolium tetrafluoroborates **37**. The reaction chain is completed by the deprotonation of the above salts with formation of the isoindoles **38**.[35]

The isoindoles **38** are obtained as a result of the vacuum distillation of a thoroughly ground mixture of the salt **37** with an excess of solid alkali. The ^{1}H NMR spectra have been recorded for some of them. They can be identified as Diels–Alder adducts.[35]

36

37 38



R = Me, Ar

The reduction of phthalimidines with lithium tetrahydroaluminate was proposed a long time ago by Wittig and coworkers (quoted after Babichev and Kovtunenko[3]) as a method of synthesis of the isoindoles 4. However, according to the data of Kovtunenko et al.,[36] the main product of the reactions of a series of *N*-substituted phthalimidines is the corresponding isoindoline and the formation of traces of isoindoles can be detected only chromatographically. An effective method of synthesis of 2-R-isoindoles from phthalimidines involves the reduction of the latter with lithium bis(2-methoxyethoxy)dihydroaluminate in benzene or toluene. The corresponding isoindoline is as a rule formed as a side product (its yields vary from 5% to 10%). The pure isoindole can be obtained by employing the higher solubility of isoindolines in cold ether. The yields of the isoindoles **4** then amount to 70%–80%.[36]

5. *o*-Phthalic dialdehyde in the synthesis of isoindoles

The study of the fluorescence method for the determination of the terminal amino-groups in aminoacids, proteins, primary amines, etc. via their conversion into 1-alkylthio-2-R-isoindoles **41** continued in the 1980s.[37–44] The review by Garcia Alvarez-Coque et al.[45] covers more than 50 sources in which this reaction has been investigated. It has been shown that *o*-phthalic dialdehyde (OPD) **39** reacts with propylamine in the presence of ethanethiol or mercaptoethanol (ME) (compounds **40a, b**) to form the isoindoles **41a, b**, which have been investigated spectroscopically and identified via adducts with dimethyl ethynedicarboxylate.[39] The fluorescent products obtained by this reaction have been investigated[41] by the stopped flow method. It has been established that, in the presence of an excess of the OPD–ME adduct formed initially, the interaction of the latter with primary amines is pseudo-first order at rates consistent with overall second-order kinetics. It has been shown that the rate of the reaction of the OPD–ME adduct with various aminoacids follows second-order kinetics when OPD : ME : aminoacid ratios of 1 : 1.24 : 1 are maintained. It has been established that the rate of the reaction of the OPD–ME adduct with alanine is a maximum at pH 10.5–11.0, while a large excess of mercaptoethanol slows down the reaction. A decrease in the rate was also observed when mercaptoethanol was replaced by dithiothreitol or propanethiol.[37] An improved method for the preparation of the aminoacid mixture to be subsequently separated with the aid of high-performance liquid chromatography (HPLC) has been proposed.[38] It consists in the conversion of the aminoacid into type **41** isoindoles as a result of treatment with OPD and ME. The identification of the type **41** isoindoles obtained from the aminoacids, carried out after the HPLC with the aid of an electrochemical detector operating under oxidation conditions, has been described.[46] The products formed from a mixture of alkylamines with OPD during the post-column derivatisation (HPLC) have been investigated by chromatograph-linked mass-spectrometry. It has been shown[40] that, when the derivatisation is carried out in the presence of ethanethiol **40a**, the products determined are type **41** isoindoles.

Six β-aminothiols (of the L-cysteine type) have been investigated in the reaction with OPD. It was shown that fluorescent products are formed in such cases without introducing thiols from outside. On the basis of the study of these products and model type **41** isoindoles by combined HPLC (reversed phase) and chromatograph-linked mass spectrometry with subsequent fluorescence detection, it has been suggested that type **41** isoindoles are responsible for the fluorescence in this case also.[47] Comparison of three methods for the determination of traces of aliphatic amines with the aid of HPLC and by means of fluorescence detection showed that the derivatisation method via the corresponding isoindoles **41** has the lowest sensitivity.[43] In order to improve the fluorescence detection of primary amines after the HPLC, a study was made of the factors influencing the stability of the isoindoles **41**.[41,48–50] It was established that their stability increases both when 3-mercapto-1-propanol **40d** is used instead of mercaptoethanol **40c** [41] and following the replacement of R = H in the structure of compound **41** by R = Me.[41,48] It was found that the stability of the isoindoles **41** is also influenced by the structure of the amino-component. It was shown[51] that amino-compounds with a sterically shielded amino-group (L-tryptophan, L-DOPA, etc.) have an appreciable stabilising effect on the fluorescence parameters of the isoindole derivative. This is why it has been suggested that L-tryptophan be used as a standard in the fluorimetric determination of various thiols.[51] Experiments have shown that an excess of OPD in the reaction mixture catalyses the decomposition of the isoindole,[41,48] while an excess of ethanethiol has a stabilising effect.[48] According to Stobaugh et al.,[48] ethanethiol forms more stable isoindole derivatives under these conditions than β-mercaptoethanol: the stability, estimated in terms of the time taken for a 10% decrease in the fluorescence level, improves by a factor of at least 5. Jacobs et al.[49] believe that, among all the destabilising factors (the structure of the thiol, the nature of the solvent, the influence of the pH, etc.), the presence of an excess of OPD in the reaction mixture is the most dangerous. They have shown that, in the absence of an excess of OPD, type **41** isoindoles are entirely stable, while the results presented by Mading and Jacobs[50] clearly confirm that the destabilisation of the isoindoles **41** and the associated decrease in the fluorescence level are a direct consequence of the electrophilic attack by the excess OPD on the free C(3) position in the isoindole **41** system. Furthermore, in a number of instances the products in the interaction of isoindoles **41** with OPD have been isolated and identified.[50] A special study had been made[52] of the factors inducing the quenching of the fluorescence of type **41** isoindoles obtained from biogenic amines.

The individual disadvantages of the fluorescence analytical method examined above stimulated the search for new reagents among derivatives of *o*-acylbenzaldehydes.[44] The ketones **42a, b** have been examined and the stability and properties of the isoindoles **43** obtained from them and the corresponding isoindoles **41** have been compared.

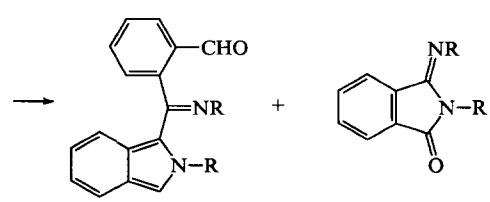
Under similar conditions of the synthesis, the yield of the isoindole **43a** (42%) is higher than that of the isoindole **43b** (32%). Under identical experimental conditions (pseudo-first order kinetics), it was found that the rate of formation of compound **43c** is significantly lower than the rates of formation of compounds **41d** and **43d**. The authors explained this finding by the steric hindrance generated by the phenyl group in the intermediate **A** when the carbonyl group is attacked intramolecularly by the nitrogen atom, on the one hand, and by the resonance stabilisation of the reactant **42b**, on the other.[44]



A

Having disproved the previous claim[1] that isoindoles are not formed from OPD and ammonia (or primary amines), Japanese workers[53] found the conditions for their isolation. They suggested that 99% alcohol be used as the solvent for the reaction and that the process itself should be carried out at 0 °C. The isoindoles **44** are isolated together with the imines **45** by column chromatography. It has been noted that, in the presence of tertiary butyl alcohol, the yield of the isoindoles **44** is somewhat better. *tert*-Butylamines does not react with OPD, which the authors explain by its being sterically hindered due to the presence of bulky *tert*-butyl groups. The use of aniline affords mainly 1-phenylimino-2-phenylisoindoline (79%) and only 2% of the corresponding imine **45** (R = Ph).[53]

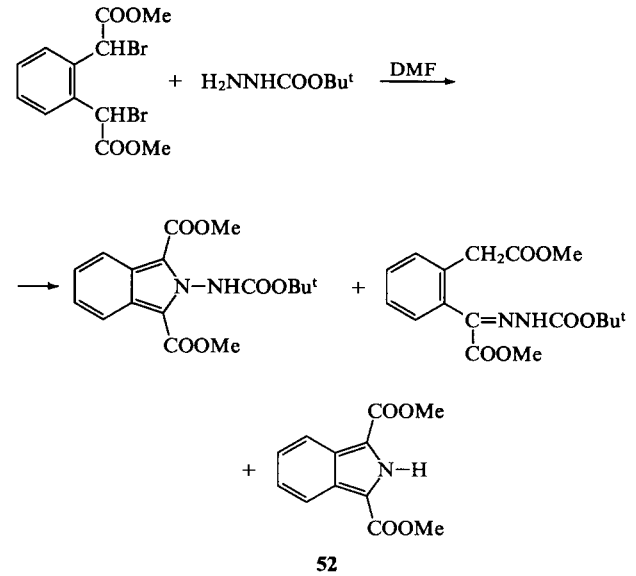
The chemists of the Monsanto Company discovered a convenient and effective method of synthesis of 1-cyano-2-methyl-2*H*-isoindole (the yield of compound **46a** was 92%), involving the interaction of OPD with methylamine hydrochloride and cyanide in methanol. The molar reactant ratios were OPD : ($MeNH_2$ + HCl) : KCN = 1 : 2.2 : 2.[54]

39 **46a–d**



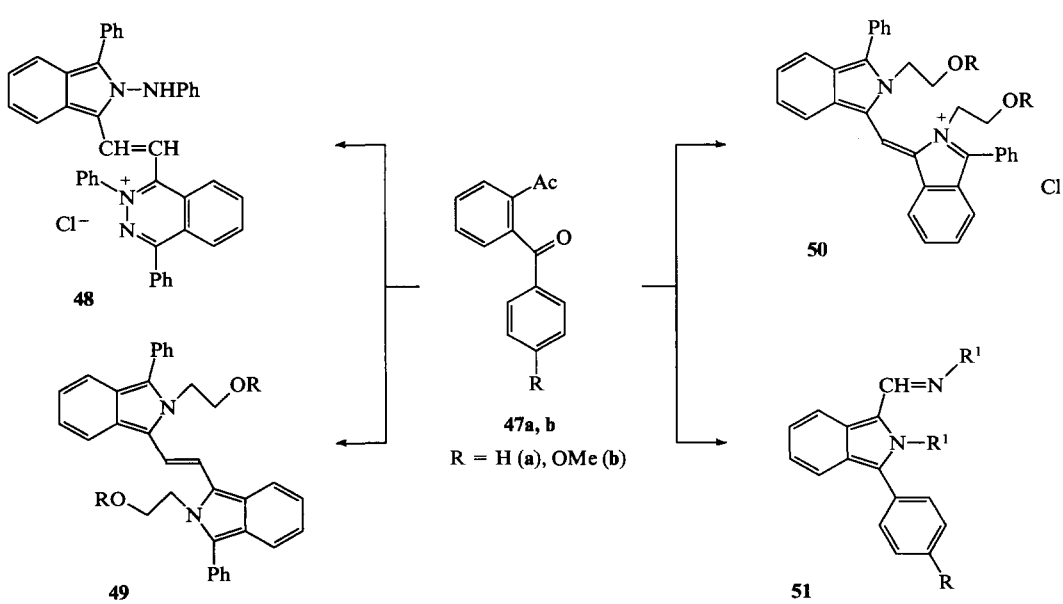
R = Me (**a**), Alk (**b**), 4-MeOPh (**c**), 3-HOOCPh (**d**)

It has been shown that, under the conditions of the Strecker reaction, OPD reacts with primary amines in the presence of sodium bisulfite to form 1-cyano-2-R-isoindoles **46** in very satisfactory yields in the case of alkylamines (59% to 86% for compound **46b**) and in poor yields of *p*-anisidine (33% for compound **46c**). The molar reactant ratios were OPD : RNH_2 : KCN : $NaHSO_3$ = 1 : 1.3 : 2.2 : 2.1.[55] *m*-(1-Cyano-2-indolyl)benzoic acid **46d** was obtained from *m*-aminobenzoic acid, OPD, and potassium cyanide in one stage.[56]

Japanese workers have been investigating the reactions of *o*-acylbenzophenone **47a** with ammonia derivatives for more than 25 years. The structures of the blue pigment **48**, formed from the diketone **47a** and phenylhydrazine in the presence of hydrochloric acid,[57] of the red pigments **49**, formed from compound **47a** and β-aminoethanol or its methyl ether in acetic acid,[58] and of the dark-blue pigments **50**, obtained from the same substances but in the presence of hydrochloric acid,[58] have been established during the last 10–15 years. It has been shown[57,59] that the diketones **47a,b** react with primary amines in the absence of acids to form 1,2-diaryl-3-(aryliminomethyl)isoindoles **51** (Scheme 2).

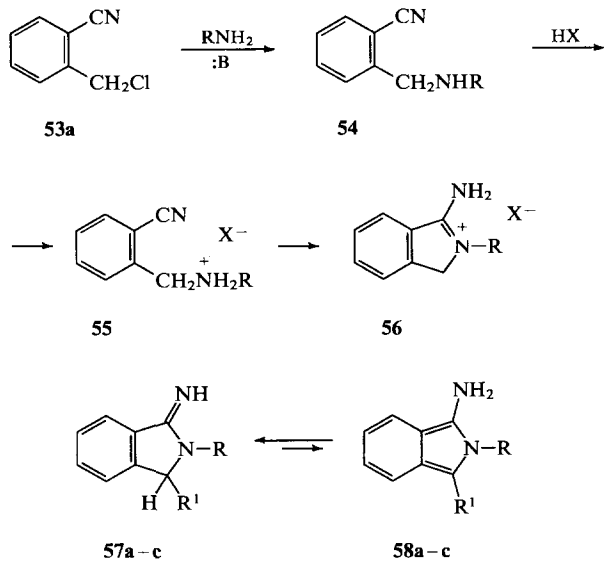
6. The synthesis of isoindoles from *ortho*-disubstituted benzenes

The interaction of dimethyl α,α′-dibromo-*o*-phenylenediacetate with *tert*-butyl carbazate has been investigated[21] and it has been shown that a mixture consisting of three compounds, including the known dimethyl 2*H*-isoindole-1,3-dicarboxylate **52**, is formed in DMF. The yield of the isoindole **52** is only 7% when the racemic dibromo-derivative is used and is lower still (5%) when it is obtained from the *meso*-form.[21]



52

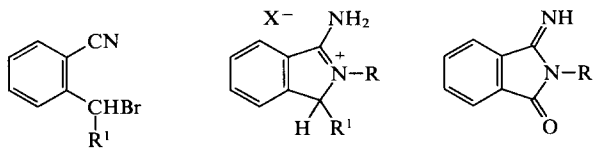
The interaction of *o*-chloro(bromo)methylbenzonitrile **53** with primary amines on heating in alcohol leads to 3-amino-2-R-1*H*-isoindolium salts **56** in one stage and in a high yield.[60,61] Derivatives of hydrazine, namely carboxylic acid hydrazides (R = $NHCOR^1$),[62,63] α-benzoyl-α-methylhydrazine [R = N(Me)COPh],[64] and *tert*-butyl carbazate [R = NHCOO.Bu^t],[65] also enter into this reaction on heating in DMF, forming the corresponding salts **56.**



If the interaction of compound **53a** with amines is carried out in the presence of bases, it is possible to isolate benzylamines **54**, which are entirely stable during storage and show no tendency to cyclise. On the other hand, the corresponding simple salts **55**, which are obtained on treatment with inorganic acids in the cold,

Scheme 2

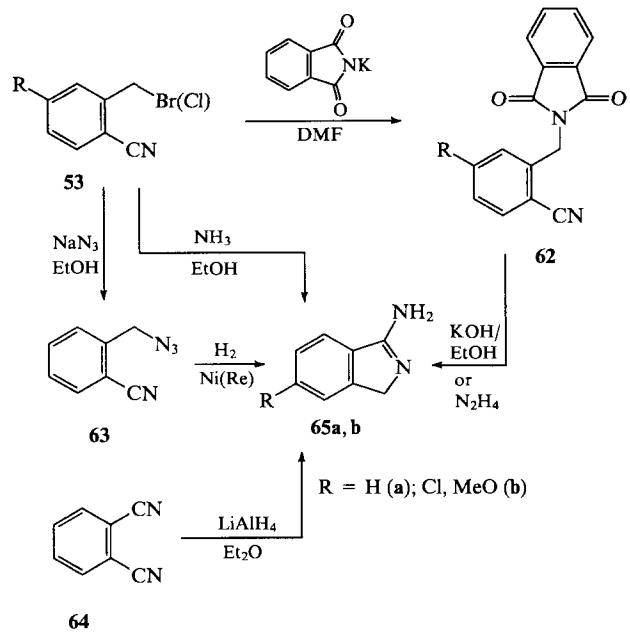
48 **49** **47a, b** R = H (**a**), OMe (**b**) **50** **51**



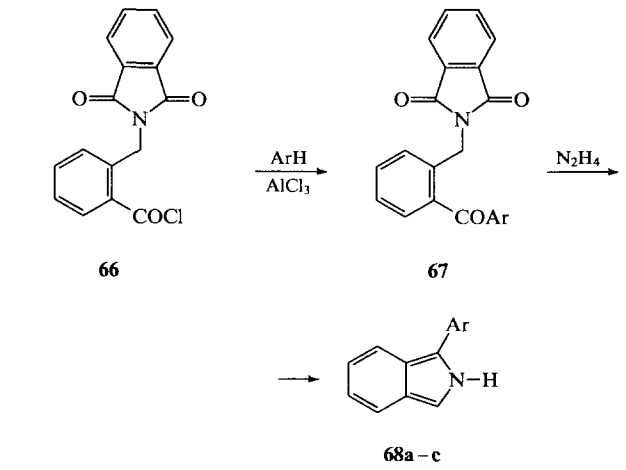
readily cyclise to aminoisoindolium salts **56** both in solution and in the solid phase. The study of the heterocyclisation of compound **55** to aminoisoindolium salts **56** by the ^{1}H NMR method in solution in DMSO-d_6 showed that this is a second-order reaction.[66] The salts **56** are deprotonated when they are treated with alkali or triethylamine and this leads to 1-imino-2-R-isoindolines **57a** and not be aminoisoindoles **58a** whatever the substituents.[67]

53a 54 55 56 57a–c 58a–c

α-Bromo-*o*-benzylbenzonitrile **59a** and α-bromo-*o*-cyanomethylbenzonitrile **59b** react with primary amines like the chloro-derivative **53a**.[60,68]



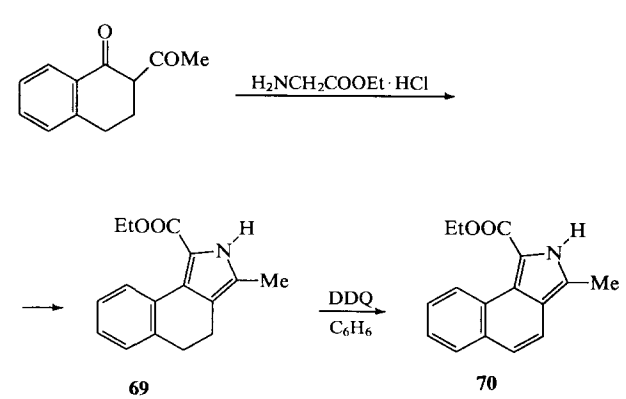
The salts **60a, b** are obtained in one stage and in a high yield and yet they are deprotonated in different ways. Whereas the salt **60a** gives rise to the corresponding stable imine of type **57b**,[67] the salts **60b** give rise to 1-amino-2-R-3-cyano-2*H*-isoindoles **58c**,[68] which are unstable in air, are readily oxidised, lose HCN, and are converted into the corresponding iminophthalimides **61**.



59a, b **60a, b** **61**

R^1 = Ph (**a**), CN (**b**) R^1 = Ph (**a**), CN (**b**)

o-Chloromethylbenzonitrile and its derivatives **53** can be transformed via different routes 3-amino-1*H*-isoindoles **65a, b**. The methods of synthesis of the latter compounds have been surveyed.[69] The reduction of the dinitrile **64** with lithium tetrahydroaluminate did not prove to be the best method of synthesis of compound **65a** and the authors, using the corresponding phthalimidomethyl derivatives **62**, obtained the aminoisoindoles **65a, b** in 38% and 51% yields respectively. The aminoisoindole **65a** has been synthesised in 23% yield by reducing *o*-azidomethylbenzonitrile **63**. The most convenient method of synthesis of the compound involves the direct amination of the nitrile **53** with an alcoholic solution of ammonia.[70]



The earlier method of Weber and L'vovska has been used to obtain three 1-aryl-2*H*-isoindoles **68a–c**.[71] Their yields are not quoted, although it has been shown that the acylation of toluene and *p*-xylene by the acid chloride **66** proceeds with low yields (31% and 33% respectively).

66 **67** **68a–c**

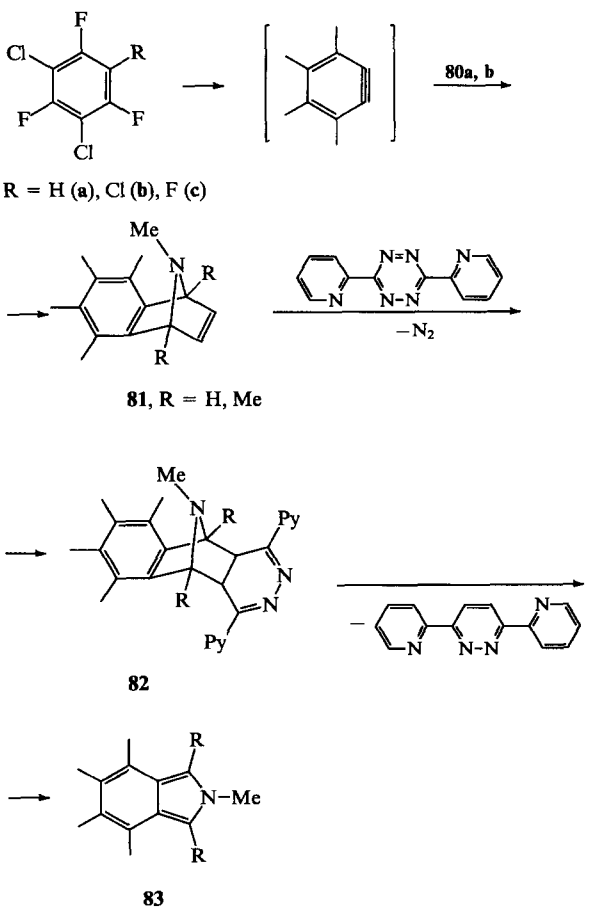
7. The synthesis of isoindoles from pyrroles

The conversion of 2,5-dimethylpyrroles into 1,3,4,7-tetramethylisoindoles has long been known,[1] but the fact that the latter can be formed in an aqueous medium at a high temperature has been demonstrated recently.[73] The studies on the reactions of 3,4-diformylpyrroles **71** initiated not so long ago have been continued and have yielded interesting results for the chemistry of isoindole (Scheme 3, see above).

Thus the condensation of compound **71** with γ-dicarbonyl compounds leads to high yields of 2*H*-isoindoles **72**–**74** and **77**,[74,75] whereas similar condensations with anhydrous hydrazine or glycine derivatives afford 5,6-diaza-2*H*-isoindoles **76** or 5-aza-2*H*-isoindoles **75**.[76]

It has been shown [76,77] that 3,4-diformyl-2,5-dimethylpyrroles **78a, b** as well as the 3,4-diacetyl derivatives **79a, b** enter successfully into similar reactions.

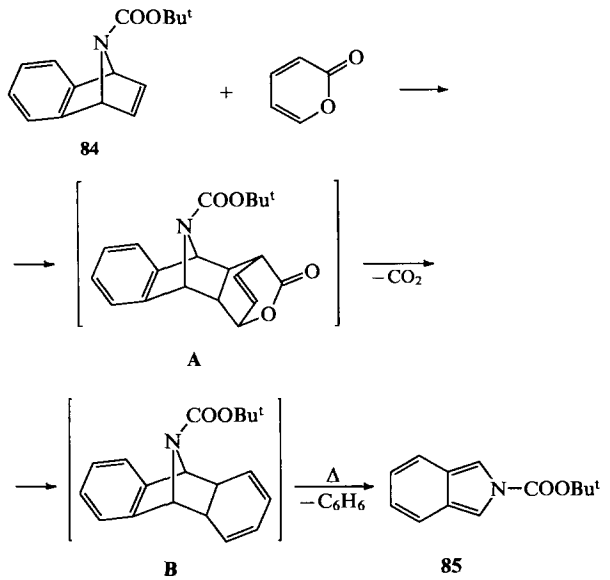


78a, b R = H (**a**), Me (**b**)

79a, b R = H (**a**), Me (**b**)

80a, b R = H (**a**), Me (**b**)

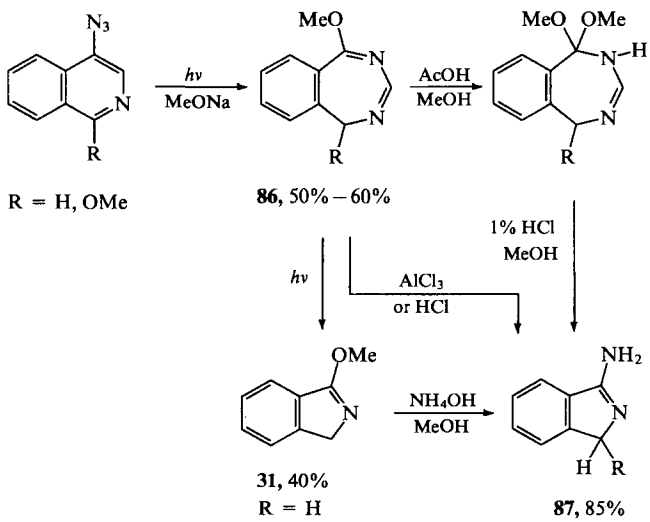
Pyrroles can be converted into the isoindole system also with the aid of the Diels–Alder retro-reaction.[78] The substituted dehydrobenzenes interact with the pyrroles **80a, b** and give rise to derivatives of 7-methyl- and 1,4,7-trimethyl-7-azabenzonorbornadienes **81**. As dienophiles, the latter undergo the [2 + 4]-addition reaction with 3,6-di-α-pyridyltetrazine, which leads to the dihydropyridazines **82** after the evolution of nitrogen and condensation with 7-azabenzonorbornane at the C(5)–C(6) bond. These complex polycyclic compounds readily decompose to 3,6-dipyridylpyridazine and 2-methyl- or 1,2,3-trimethyl-2*H*-isoindoles **83**, which contain in the benzene part of the molecule the substituents present in the initial dehydrobenzenes (yields 75%–89%). This process is used in the synthesis of various heterocycles and is called the Carboni–Lindsey reaction.



81, R = H, Me

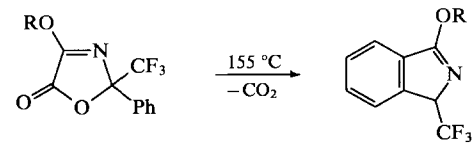
82

83



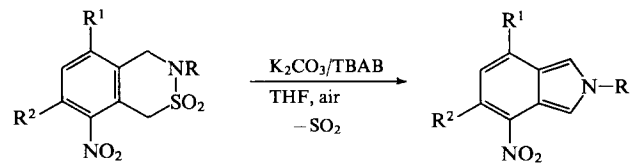
An improved procedure for the synthesis of isoindoles by refluxing a mixture of dipyridyltetrazine with derivatives of 7-azabenzonorbornadiene **81** in chloroform has also been described.[78] The end of the reaction is detected from the cessation of nitrogen evolution, which takes from 3–4 h (for R = H) to 24 h (for R = Me).

The 7-azabenzonorbornadiene **84**, obtained from the corresponding pyrrole and dehydrobenzene, gives rise to the adduct **A** on interaction with 2-pyrone. On heating, the adduct loses a carbon dioxide molecule and is converted into compound **B**. The isoindole **85** is formed subsequently as a result of the Diels – Alder retro-reaction with elimination of benzene.[79]

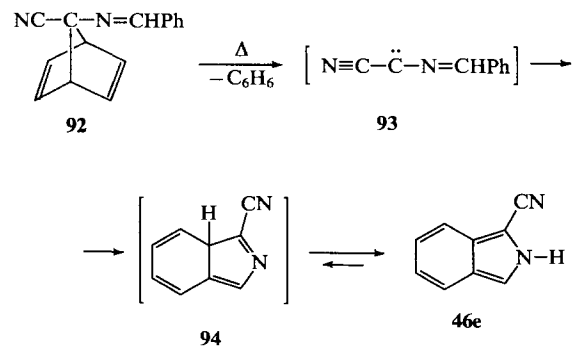


8. Other methods

The rearrangement of 2,4-benzodiazepines of type **86**, obtained by the photoisomerisation of 4-azidoisoquinolines, to isoindoles has been used to synthesise 3-amino-1-R-isoindoles **87** and 3-methoxy-1*H*-isoindole **31** (R = H).[80] Treatment of 1-R-5,5-dimethoxy-1*H*,4*H*-benzodiazepines with 1% hydrochloric acid solution in methanol leads to 3-R-1-aminoisoindolenines **87** in 85% yield. Irradiation for 6 h of a solution of 1-methoxy-5*H*-[2,4]-benzodiazepine **86** in methylene chloride affords 1-methoxyisoindolenine **31** (R = H), whilst treatment with HCl or $AlCl_3$ leads to the amino-derivative **87**.[80] Subsequently the authors extended the range of 4-azidoisoquinolines investigated and studied similar reactions for the benzodiazepines **86** with R = Me, Ph, or Cl.[81]

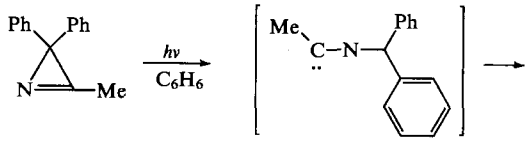


Racemic 1-ethoxy-3-(trifluoromethyl)-1*H*-isoindoles **89a, b** have been obtained by the thermal decarboxylation of oxazol-[2*H*]-one **88**.[82] It is emphasised that the reaction is possible only in the absence of dipolarophiles (for example, trifluoroacetophenone). Otherwise the latter (1,2-dipole) undergoes dipolar cycloaddition to the intermediate alkoxynitrile ylides (1,3-dipole) formed as a result of decarboxylation, which leads to dihydrooxazoles.[82]

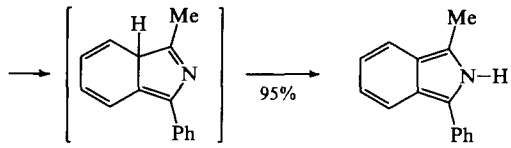


R = Et (**a**), Pr^i (**b**)

The oxidation of nitrobenzothiadiazine dioxides **90** with air in the presence of potassium carbonate and a phase-transfer catalyst (TBAB) leads to the corresponding isoindoles **91** after the elimination of sulfur dioxide. In the case of alkyl substituents at the nitrogen atom, the yields of compounds **91** are 53% – 74%, the yields falling sharply (39%) only for the *N*-phenyl derivative. If $R^1 = R^2 = H$ and R = Me, then 3-hydroxy-2,3-dimethyl-4-nitroisoindol-1-one is formed under the reaction conditions.[83]

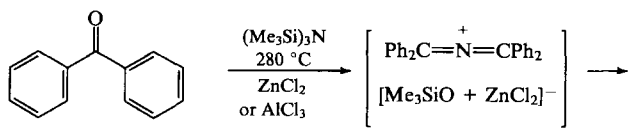


R = Me, Ph, $PhCH_2$
R^1 = H, F
R^2 = H, Cl

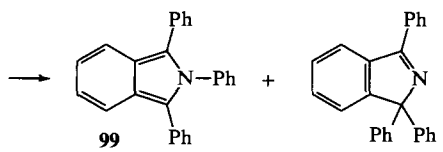


A novel approach to the synthesis of 1-cyano-2*H*-isoindole **46e** is based on the use of the norbornadiene **92** as the initial compound.[84] On heating in vacuo, the latter generates the carbene **93**, which undergoes intramolecular 1,5-electrocyclisation, forming the intermediate **94**. The subsequent 1,3-sigmatropic shift of the hydrogen atom from the carbon atom to the nitrogen atom in the intermediate **94** leads to the isoindole **46e**. The isoindole **46e** is isolated from the reaction mixture in 41% yield with the aid of preparative thin-layer chromatography and subsequent vacuum sublimation.[84]

The intramolecular heterocyclisation process, which is in many respects similar to that considered in the previous study, has been observed in the formation of the 2*H*-isoindole **98** from the azirine **95**. It has been reported[85] that the photochemical rearrangement of 3-methyl-2,2-diphenylazirine **95** to the nitrile ylide **96** and the cyclisation of the latter lead to the corresponding isoindole **98**. This reaction has been classified by the authors as a 1,5-electrocyclic process accompanied by the subsequent 1,3-sigmatropic shift of the proton in the intermediate **97**.

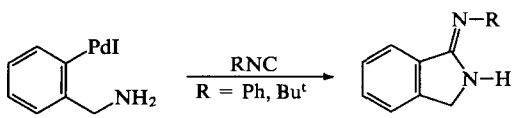


95 96

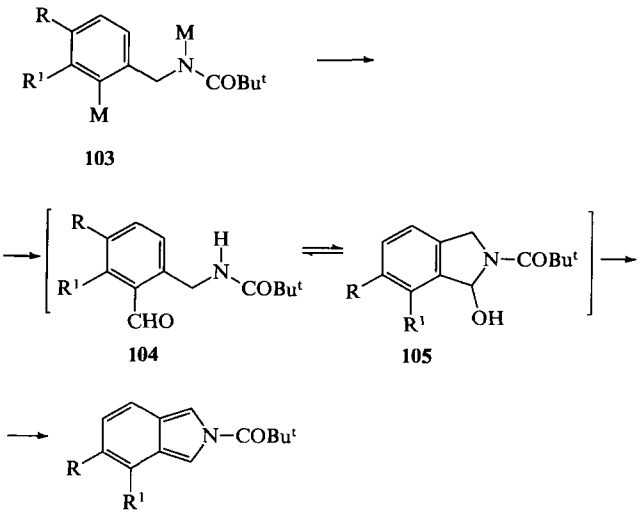


97 98

It has been shown that the cyclocondensation of benzophenone with tris(trimethylsilyl)amine at 280 °C in the presence of $ZnCl_2$ and $AlCl_3$ leads to a mixture of the isoindole **99** and 1,1,3-triphenyl-1*H*-isoindole. The yields of the isoindole **99** are 11% and 15% when zinc chloride and aluminium chloride are used respectively. The authors suggest that the intermediate in the formation of the above mixture of isoindoles is the azaallenium ion **100**.[86]



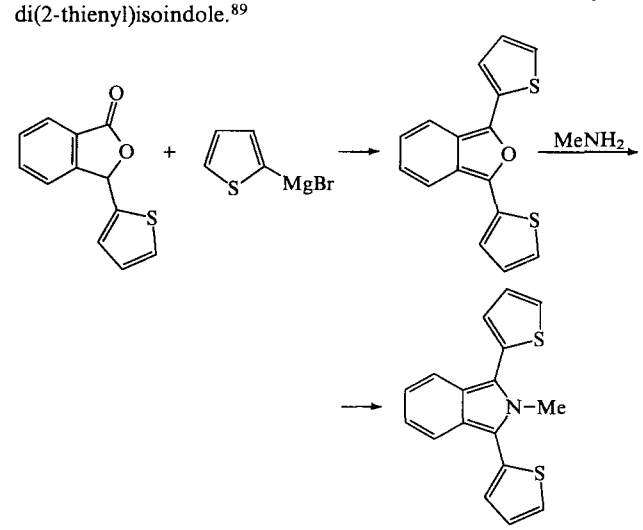
100



99

A method of synthesis of isoindoline imines **102** based on the insertion of isocyanides in a metal–carbon bond in the divalent palladium complex **101** has been described. The complex **101** is treated with the isocyanide in methylene chloride, after which the solvent is replaced by toluene and the reaction mixture is refluxed for 3 h. The imines **102** are isolated after making the mixture alkaline.[87]

101 102



Metallation of the amides **103** followed by treatment with DMF leads to the aldehydes **104**, which can be regarded as the open-chain form of the cyclic compound **105**. The existence of this kind of ring–chain tautomerism has been demonstrated by the NMR method. The conversion of the isoindolines **105** into the isoindoles **106** on refluxing in xylene has been described by isolating the adduct of the latter with *N*-phenylmaleimide.[88]

1,3-Di(2-thienyl)isobenzofuran can be obtained by the reaction of 3-(2-thienyl)phthalide with 2-thienylmagnesium bromide. After oxidative opening of the furan ring and treatment with methylamine, the isobenzofuran is transformed into 2-methyl-1,3-di(2-thienyl)isoindole.[89]

III. Theoretical and physical aspects

1. Theoretical aspects

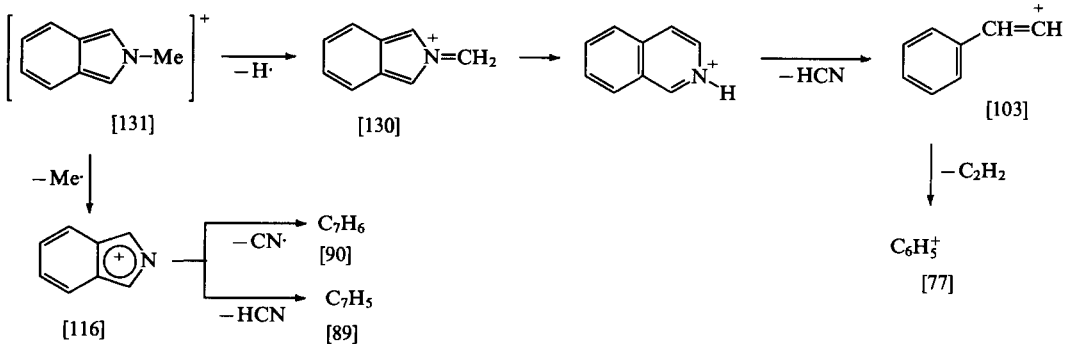
The phenomenon of isoindole has been discussed in a review [1] and in a monograph:[3] its aromaticity and high reactivity. Ideas concerning its electronic structure, with the aid of which attempts have been made to account for the above two properties which sometimes exclude one another, have been considered. In theoretical studies published recently, both semiempirical calculations (in terms of the Hückel,[90,91] PPP,[90,92] and CNDO[93], approximations) and nonempirical calculations[94] (the method of canonical molecular orbitals) have been employed; the resonance energies[90,92,95,96] various aromaticity indices,[92,95,97,98] enthalpies of formation,[91] and molecular geometry have been determined by the INDO[99] and MNDO[94] methods.

It is essential to note that a trend has arisen during the past period towards the introduction of new aromaticity indices and the derivation of correlations between the new and already existing indices. Fabian [90] proposed that the aromaticity of heterocycles, and especially isoindole, be estimated from the difference between the π-electronic energies of the heterocycle and the

corresponding iso-π-electron [9]annulenium ion. A new version of the iterative procedure of the Hückel molecular orbital method (the so-called χ-technique) has been used to calculate the HOMO energies and the enthalpies of formation of a series of heterocycles. According to this approach, the HOMO energies are 7.26 eV for isoindole, 7.71 eV for indole, and 8.08 eV for pyrrole. The result demonstrated a satisfactory agreement with the earlier calculations by Dewar and experimental data.[91] Kruszewski[92] formulated a rule on the basis of calculations for a large number of monocyclic and polycyclic heterocycles, including benzopyrroles (indole and isoindole) by the PPP method in terms of the variable β approximation. According to this rule, the condensation of an additional aromatic ring with the heterocycle gives rise to a more stable compound the greater the π-electron index of the bond involved in the process. One of the examples confirming this rule is the familiar difference between the properties of indole and isoindole. Analysis of the energy gaps by the HOMO–LUMO method for a large number of cyclic conjugated molecules (including benzopyrroles) suggested to the authors[98] the introduction of the concept of the absolute and relative 'hardness', which in their view reflects most effectively all three aspects of aromaticity: high stability, low reactivity, and the existence of ring currents. Although the 'hardness' of isoindole (0.482β) is significantly lower than that of indole (0.716β), it is nevertheless sufficient to conclude that isoindole is aromatic. Calculation of the topological resonance energies for benzopyrroles and their comparison with the analogous energy for benzene enabled the authors[95] to determine the degree of their aromaticity. It was found that the aromaticities, expressed as a percentage of that of benzene, are 83% for indole, 71% for isoindole, and only 63% for 2*H*-benzo[*f*]isoindole. Bird[97] introduced his aromaticity index from calculations based on experimental geometries of heterocyclic systems. According to this index, the aromaticity of, for example, 2-benzylisoindole **72** is slightly higher than that of benzimidazole **71** and indole **70**. New calculations of the Bird, Jalg,[100] and Pozharskii[100] structural aromaticity indices for isoindole have been published.[101] They were performed on the basis of the geometry obtained in accordance with the AM1 program; the following series of indices were obtained: 66.5 (Bird), 1.311 (Jalg), and 0.23 (Pozharskii) for indole and 68.9, 1.378, and 0.22 respectively for isoindole. It is important to note that the results of previous calculations, based on the analysis of canonical molecular orbitals, and the conclusions concerning the aromaticity of isoindoles have never been questioned, not even in recent years. However, the symmetry properties of the canonical molecular orbitals are known a priori to give rise to a significant delocalisation, which in fact hinders the comparison of the characteristics of individual chemical bonds and the structural fragments of different molecules (including isomers in terms of the position of the heteroatom of the indole–isoindole type), giving rise to various structural representations in order to reflect the specificity of their properties.[3] The above disadvantages are eliminated to an appreciable extent when localised molecular orbitals are considered. They make it possible to estimate a measure of the interaction of identical fragments with the rest of the complex molecule and hence serve as a test of the classical structural representation. This approach has in fact been applied to the indole–isoindole pair of isomers[93] and was then extended to the benzofuran–isobenzofuran and thionaphthene–benzo[*c*]thiophene.[102] Whilst confirming the conclusions concerning the aromaticity of isoindole, the authors believe that the π-electron system of isoindole is more integrated than that of indole. For the latter, they suggest that the electron system consisting of three fairly localised π-subsystems be considered: benzene rings, the C(2)–C(3) double bond, and the nitrogen atom with its electron pair.[93] Katritzky and coworkers[101] compiled and correlated the aromaticity characteristics based on geometrical, energy, and magnetic data for a series of benzo-condensed five-membered heterocycles, including condensed pyrroles.

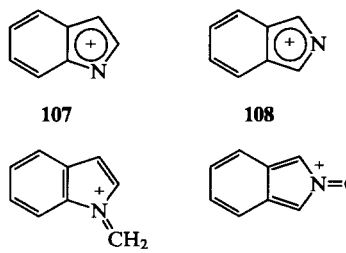
For the vast majority of structures investigated,[103–106] there is a satisfactory correlation between different characteristics used to estimate the aromaticity but here too the uniqueness of isoindole has been manifested [the data of Terent'ev et al.[107] (10 characteristics) virtually deviate from these correlations]. In a comparative quantum-chemical study of the polarisabilities (α) and hyperpolarisabilities (β) of a series of 'positional' isomers (including indolizine, indole, and isoindole), the authors[103] noted that the structural differences have a significantly smaller effect on α (109, 107, 109 a.u. respectively) than on β (2.93, −2.89, and −5.93 a.u. respectively). A theoretical study has been made[99] by the INDO method (with complete optimisation of the geometry) of the populations of the conformations of the still unknown 2-amino-2*H*-isoindole and it has been shown that the disposition of the free electron pair of the nitrogen atom of the amino-group at right angles to the plane of the bicyclic molecule is most favourable. In the course of the development of quantitative approaches to the resonance theory, Pipeng and Wengui[96] calculated the resonance energies of the various tautomeric forms in order to predict the preferred tautomer and the tendency towards a shift of the tautomeric equilibrium in a series of related structures. 1-Amino-2*H*-isoindole was included within the range of their interests. It exists in the form of the 3-amino-1*H*-tautomer,[1] which was confirmed on the basis of theoretical conclusions.

2. Spectroscopic data



Spectroscopic data (^{1}H NMR, ^{13}C NMR, IR, and UV) for various isoindoles have been described in detail in reviews[1,2] and in monographs.[3] The period which has elapsed has been characterised by the accumulation of quantitative information about the spectra of isoindoles. We therefore quote here only references to publications containing fairly extensive data on the spectroscopic characteristics of new isoindoles: ^{1}H NMR,[5,35,36,39,61,72,84,85] ^{15}N NMR,[99,104] ^{13}C NMR,[4,5] IR,[5,35,36,39,61,69,85,105] and UV.[35,36,39,61,85]

As regards the interpretation of studies on electronic spectra, the latter were surveyed in previous reviews.[1,2] The electronic structure of phthalocyanines without a central metal atom has been investigated[94] by means of nonempirical and semiempirical methods. The study was combined with the analysis of the constituents of this system: benzene, pyrrole, and isoindole. The electronic spectra of dimethinecyanines and merocyanines based on 1-dimethylamino-2-phenylisoindole have been discussed.[106] It has been noted that positive solvato-chromism is characteristic of merocyanines.

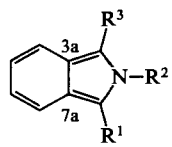


3. Mass-spectra of isoindoles

An attempt has been made in recent years to fill the gaps in the mass-spectrometric study of isoindoles. The decomposition of a series of isoindoles under electron impact, including those condensed along the *a* face, has been analysed.[107] It follows from these data that the molecular ion derived from 2-methylisoindole has the highest intensity in the spectrum and that the intensities of the peaks due to the other ions formed on fragmentation do not exceed 50% of that of M^+. The spectra have the usual overall form for aromatic compounds and confirm the electronic structure of isoindole put forward by Kovtunenko et al.[93] The appreciable π-bonding via the nitrogen atom in 2-methylisoindole has been demonstrated by the fact that the introduction of phenyl substituents in the 2-position (i.e. for 2-phenylisoindole) lowers the intensity of M^+ to 93% as a consequence of the competing conjugation of the free electron pair of the nitrogen atom with the benzene ring. In 2-(*p*-anisyl)isoindole, this type of competition has a smaller effect owing to the positive mesomeric effect of the methoxy-group. Comparison of the mass-spectrometric decomposition of 1-methylindole[107] with that of the isomeric 2-methylisoindole can also serve as confirmation of the postulated electronic structure of isoindole.[93] The stability of the ion **107** is lower than that of the ion **108**, which indicates a greater degree of

Scheme 4

inter-ring conjugation in the isoindole system — indicated by the values of $[M-CH_3]^+/M^+$. On the other hand, the intensity of the $[M-H]^+$ peak is much higher for *N*-methylindole than for *N*-methylisoindole, since here one is dealing with systems of a different kind: **109** and **110**, within the limits of which the π-bonding via the nitrogen atom is ruled out. In this case, the ion **110** loses the advantages of isoindole as an integrated 10π-electron system and is in fact an open-chain polyene, while the ion **109** remains aromatic in view of the aromaticity of the benzene ring, which to a large extent determines the stability of the indole system as a whole.[93] The routes leading to the fragmentation of different isoindoles have also been indicated,[107] for example, we have for *N*-methylisoindole.



The mass spectra of new 2-R-isoindoles (R = Bu^t, Bu^tCH_2, $PhCH_2$, adamantyl) have also been used for the purpose of their identification (Scheme 4).[5]

4. X-Ray diffraction data

Fairly numerous studies on the X-ray diffraction of isoindoles, which permit objective inferences about their geometry, have been published.[39,54,93,105,108–110] These data are presented in Table 1 and they all confirm the conclusion that isoindole is aromatic as a 10π-electron system. The molecules are planar. For example, the deviation of the atoms in 2-methylisoindole from the mean square plane passing through the atoms of the bicyclic system do not exceed 0.015(4) Å.[108] The tabulated data demonstrate the similarity of the bond lengths in the benzene fragment of isoindole structures and in naphthalene [in the latter, the bond lengths are 1.410 Å for C(3a)–C(7a); 1.425 Å for C(3a)–C(4); 1.361 Å for C(4)–C(5); and 1.421 Å for C(5)–C(6)], which in an argument in support of the delocalisation of the electron density.[108,109] The C(3a)–C(4) and C(7)–C(7a) bond lengths are close to those in classical aromatic compounds and differ significantly from the values characteristic of a single bond. This means that the electronic structure of isoindole cannot be represented by two independent components (a combination of butadiene and pyrrole). These two components are conjugated. The C–N bond lengths in the pyrrole fragment of the first four structures (see Table 1) are somewhat smaller than in pyrrole itself (1.383 Å). On the other hand, the C(3)–C(3a) bond lengths in isoindoles are somewhat greater than in pyrrole (1.371 Å). This probably indicates a greater delocalisation of the π-electron density in the pyrrole component of the bicyclic system compared with the parent heterocycle.

X-Ray diffraction of isoindole derivatives, including 2-methylisoindole, confirmed their electronic structure put forward on the basis of the analysis of localised molecular orbitals.[93]

Table 1. X-Ray diffraction data for isoindole derivatives.

2*H*-Isoindole			Bond length/Å										Ref.

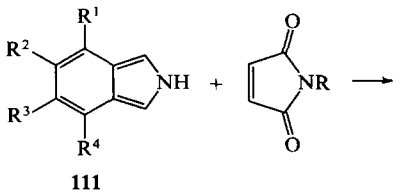
Note. The bond lengths are 1.468[93,108] and 1.460[54] for N–Me, 1.405[54] for C–CN, and 1.458[110] for N–CH_2.

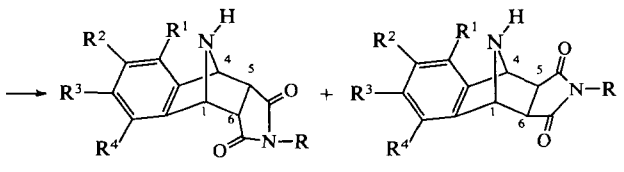
IV. Chemical properties

Isoindole and its derivatives are distinguished by a high reactivity. This is indicated by experimental data[111] on the rate constants for the acid-catalysed detritiation of a series of heterocycles (including *N*-methylisoindole). For example, in the indolizine (3-position), *N*-methylisoindole (1-position), and indole (3-position) series, the partial rate factors for the exchange reactions are in the proportions 1798.9 : 11 992.7 : 1. The authors calculated the values of σ^+ for the above heterocycles (−1.94, −2.04, and −1.57 respectively) and found that isoindole is one of the most reactive compounds among the known heterocyclic systems.[111] A mechanism has been proposed[112] for the tautomerism of 1,3,4,7-tetramethyl-2*H*-isoindole, taking into account the solvent effect on the basis of its spectrophotometric study.



1. The Diels–Alder reaction

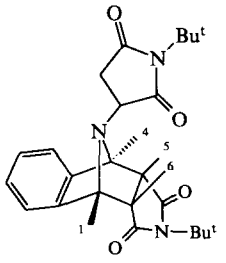
One of the most characteristic properties of isoindole and its derivatives is their ability to enter readily into the [2 + 4]-cycloaddition reaction. Furthermore, the usual method for the identification of unstable isoindoles involves their conversion into Diels–Alder adducts with maleimide derivatives.[1–3] We may mention in this connection a review[113] of the quantum-chemical methods used to predict the stereospecificity of the Diels–Alder reaction.



a. The interaction of isoindoles with maleimide derivatives

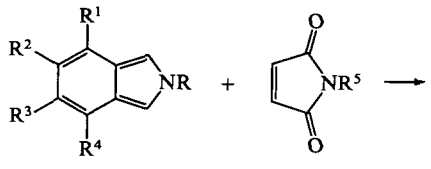
During the period considered, numerous communications were published in which mention is made of the adducts of isoindoles with maleimide derivatives. Certain generalisations facilitating the identification of the isomers formed are also known.[114,115]

NH-Isoindoles. The isoindoles **111** unsubstituted at the nitrogen atom give rise readily and in high yields (on average 80%) to a 1 : 1 mixture of the *endo*-adduct **112** and the *exo*-adduct **113** in which the endo-isomer predominates.[13,14,16,18] It is sometimes possible to separate these mixtures by chromatography,[16] but usually they are converted smoothly, after being kept for a short time in solvents (for example, in xylene), into the corresponding *exo*-isomers **113**.[14,16] The isomerisation **112** → **113** also occurs with participation of the solvent and under much milder conditions: at room temperature in DMSO over a period of 30 min (the ^{1}H NMR spectrum of the solution of the adduct **112** reveals its complete conversion into compound **113**).[16]

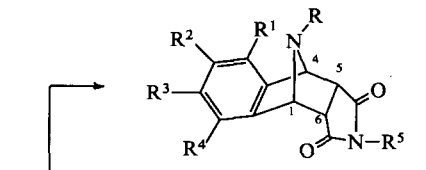


111

endo-**112** *exo*-**113**

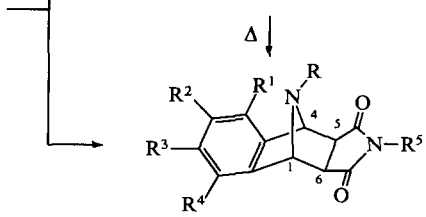


When the isoindole **14** is allowed to react with *N*-*tert*-butylmaleimide, the formation of a 1 : 2 adduct was observed. On the basis of spectroscopic characteristics, the structure **114** was attributed to it.[16]



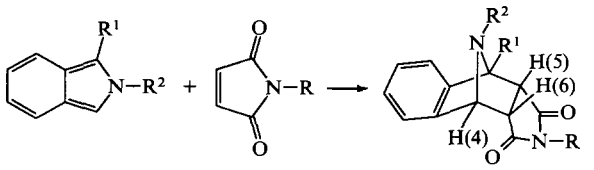
114

2-R-Isoindoles. The isoindoles **115** substituted at the nitrogen atom readily form 1 : 1 adducts.[6–8,19,20,79,116–118] Under kinetically controlled reaction conditions,[116] one then obtains exclusively the *endo*-isomers **116**,[7,8,19,79,88,116–118] while under thermodynamically controlled conditions the *exo*-isomers **117** are produced.[19,116–118] The diene reactivity of the isoindoles **115** is determined by the nature of the substituents in the benzene component of the bicyclic system; a decrease in the diene reactivity has been observed in 2-*tert*-butyl-5-nitroisoindole[7] and 2-R-4,5,6,7-tetrachloroisoindole,[118] while in 2-R-dibenzo[*e*,*g*]isoindole[6] it is not manifested at all on interaction with maleimide derivatives. It has been shown[118] that the Diels–Alder addition to 2-R-4,5,6,7-tetrachloroisoindole may be initiated by adding a catalyst—a Lewis acid ($AlCl_3$). The configurational stability of the *endo*-isomers depends to a large extent on the nature of the substituent at the nitrogen atom of the 7-azabenzonorbornene system **116**.



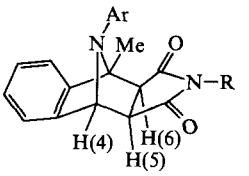
If this is an alkyl group, then the isomerisation **116** → **117** takes place relatively readily (for example, on refluxing in alcohol or xylene).[19,116–118] In the case of an aryl substituent, the attempts to isomerise the *endo*-isomer to the *exo*-isomer were unsuccessful.[119] The example of the *endo*-adduct of the isoindole **20b** is remarkable:[19] on refluxing in xylene or diglyme, isomerisation was not observed and only after heating for 19 h in Carbitol was it possible to achieve the isomerisation with 8% yield. The adducts **116** obtained from the isoindoles **106** cannot be isomerised to the corresponding *exo*-compound **117**. However, if the preliminary hydrolysis of the *N*-acyl group is carried out, then the isomerisation of the *exo*-adduct **113** proceeds extremely readily.[88] A series of unstable isoindoles **115** have been characterised in terms of the adduct **116**.[19,88,117] The unstable methyl ester of isoindole-2-acetic acid has been identified via the adduct with *N*-phenylmaleimide, to which the *exo*-structure was attributed without proof.[20] It has been shown[116] that the ^{1}H NMR spectra of the adducts **116** and **117** are more complex for R = Me than might have been foreseen: they demonstrate the occurrence of the *syn*- and *anti*-isomerism of the methyl group at N(7). The isomerism disappears when the lanthanide shift reagent Eu(fod)$_3$ is added to the test solution. Furthermore, the constant $J \approx 2$ Hz, for spin–spin coupling of the protons across four σ-bonds in the *W*-conformation, has been noted. All the features of the cycloaddition of maleimides to the isoindoles **115** are characteristic of their 5-aza-analogue 6-ethoxycarbonyl-2-methyl-2*H*-pyrrolo[3,4-*c*]pyridine[120] and of 2-methyl-6,7-diazabenzo[*f*]isoindole {7-methyl-1,4-diphenyl-7*H*-pyrrolo[3,4-*g*]-phthalazine}.[74]

115



endo-116

exo-117



1,2-Di- and 1,2,3-tri-substituted isoindoles. The identification of the isomeric Diels–Alder *exo*- and *endo*-adducts comprising isoindoles **118** asymmetrically substituted in the pyrrole component in terms of the spin–spin coupling pattern of the H(4), H(5), and H(6) protons in the ^{1}H NMR spectra becomes more complicated, which leads to possibile erroneous assignment of the configurations of the isomers.[35, 114, 121]

As a rule the 1 : 1 adducts **119** with the *endo*-configuration are formed from the type **118** isoindoles on interaction with maleimides under the conditions of kinetic control.[31, 32, 35, 114, 122] The majority of the isoindoles **118** investigated do not withstand the conditions of thermodynamically controlled cyclo-addition. Only one instance of the formation of the *exo*-adduct from such isoindoles is known — a series of compounds of structure **120** have been obtained from 2-methyl-1-phenylisoindole.[122] The corresponding *endo*-adducts are configurationally stable and do not isomerise to the *exo*-isomers **120**. The isoindoles **118c** unexpectedly react with maleimides, forming the dihydronaphthalene derivatives **121** under mild conditions.[114, 123] The isoindoles **118a, b** react with maleimides, affording the 1 : 2 adducts **122**, the formation of which is interpreted [31, 32, 124] as the initial Michael addition of one maleimide molecule with subsequent addition, this time of the Diels–Alder type, of a second dienophile molecule to the 1,2,3-trisubstituted isoindole formed. The establishment of the *endo*-configuration of the type **122** adducts is fairly difficult and has been carried out usually with the aid of X-ray diffraction [32] or from indirect ^{1}H NMR spectroscopic data.[31, 32, 124]

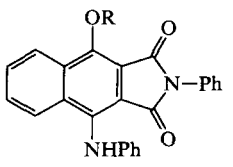
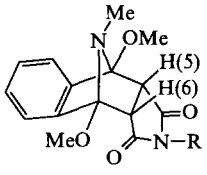
118c: R^1 = NMe_2

120

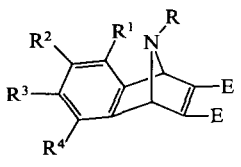


121

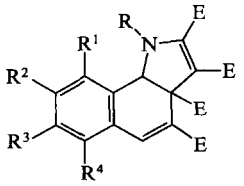


122

A similar problem was solved in the determination of the configuration of the adduct of the unstable 1,2,3-trisubstituted isoindoles **24** and **28** with maleimide. The interaction of a solution of compound **24b** with phenylmaleimide at room temperature afforded a mixture of two naphthalene derivatives: **123a** (10%) and **123b** (54%).[23] On the other hand, it has been shown [27] that type **28** isoindoles form with maleimides type **124** *endo*-adducts in a low yield (not more than 25%).

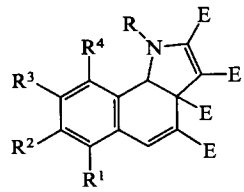


123a–b
R = H (**a**), $SiMe_3$ (**b**)



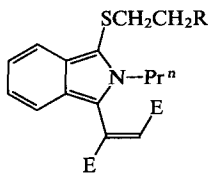
124

b. The interaction of isoindoles with ethynedicarboxylic acid esters



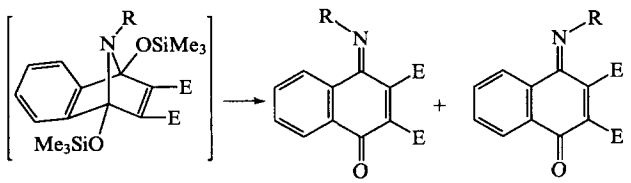
When the dimethyl ester of ethynedicarboxylic acid [acetylenedicarboxylic acid] (DMAC) is added to type **115** isoindoles, the latter give rise readily and in high yields to the 1 : 1 adducts **125** in the first stage. These can then be converted (in the presence of an excess of DMAC) into the 1 : 2 adducts **126** (**127**). The tendency to form compounds **127** is apparently determined by the bulk of the substituent R. For example, 2-*tert*-butyldibenzo-[*e*, *g*]isoindole **6a** does not form a type **126** adduct at all, whereas for its benzyl analogue **6b** under similar conditions the reaction path giving rise to such an adduct is the main one (the yield of compound **126** is 68%), the 7-azabenzonorbornadiene derivative **125** being formed only as a side product (yield 23%).[6]

125



126

127 E = COOMe



2-*tert*-Butyl-5-nitroisoindole,[7] 2-*tert*-butylbenzo[*f*]isoindole,[8] and the isoindoles **74**, **75**,[120] and **77**[35] afford type **125** products. A separable mixture of complex three-dimensional molecules with the *syn*- and *anti*-configurations is formed from the terminal pyrrole rings of the isoindole **74** when the latter reacts with DMAC.[35] The isomeric compounds **126** and **127** were isolated on treating with an excess of DMAC the corresponding type **125** adduct obtained from 2-methyl-5-azaisoindole.[120]

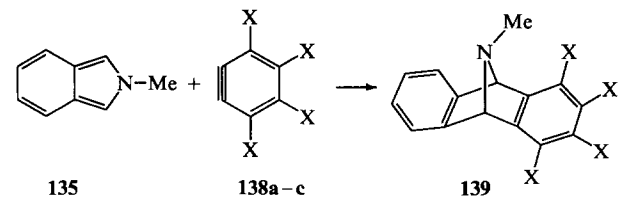
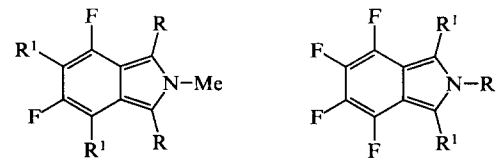
7-Methyl-1,4-diphenyl-7*H*-pyrrolo[3,4-*g*]phthalazine, a derivative of 2*H*-6,7-diazabenzo[*f*]isoindole, reacts similarly, forming initially a type **125** adduct and then a type **126** adduct.[74] Interaction of the isoindoles **40a, b** with DMAC is interesting. They give rise to the adducts **128a, b** with retention of the 10π-electron system.[39] On interaction with DMAC, the isoindoles **24b, c** afford the isomeric *syn*- and *anti*-imines **130** and **131** via intermediate type **129** adducts.[25,26] The isoindole **132** reacts with DMAC to form initially the 1:2 adduct **133**, while in the presence of an excess of DMAC the product is the 1:3 adduct **134**.[29] In contrast to compounds **24b, c**, the isoindole **24a** reacts with DMAC to form the dimethyl ester of (2-methyl-1-oxo-3-trimethylsiloxy-1,3-dihydroisoindol-3-yl) fumaric acid in 53% yield.[26]



132 **133** **134**

E = COOMe



c. The addition of dehydrobenzenes

The study of the addition of dehydrobenzenes and dehydronaphthalenes to isoindoles has recently acquired special significance in view of the discovery of effective reagents for the deamination of 7-azabenzonorbornadiene derivatives formed as a result of this reaction.[125] Such deamination constitutes a convenient method of synthesis of angularly and linearly condensed polycyclic hydrocarbons containing various substituents, which are difficult to obtain.[78,126-128] The isoindoles **6a, b** and **135** react readily with the arynes **138b, c** respectively, affording high yields of 1:1 adducts.[6,125-128] The isoindoles **7** and **8** likewise give rise to similar adducts but this time with the 1:2 composition, the imine bridges in these structures assuming the *anti*-configuration relative to one another.[10] The interaction of the isoindoles **137a, b** with the arynes **138** produces 1:1 adducts, but in all cases the 7-methyl-7-azadibenzonorbornadienes are obtained in significantly lower yields than the *N*-benzyl derivatives.[129] Complex polycyclic systems are formed on interaction with the naphthynes **140** and **141** and the 1,5- and 2,6-naphthadiynes **142** with the isoindoles **135**, **136a-c**, and **137a, b**. The last two naphthadiynes react with the isoindoles **135** and **137a** affording moderate yields of the 2:1 adducts **143a, b** and **144** with the *anti*-configuration of the imine bridges.[127,128]

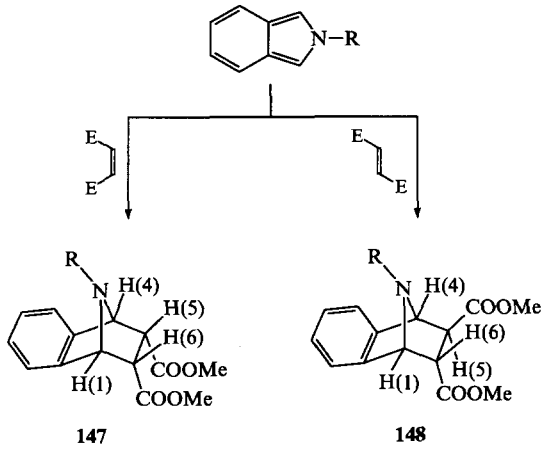
d. The addition of other unsaturated compounds

The intramolecular addition of a double bond to a diene isoindole system has been described:[28] on heating for 8 h (at 150 °C), *N*-(4-pentenyl)isoindole **29** partially forms the adduct **145**. Judging from ^{1}H NMR spectroscopic data, the ratio of the open-chain and cyclic forms which can be obtained at this temperature is 1 : 1, whereas after heating to 200 °C the equilibrium shifts towards the open-chain form **29**. On slow fractionation of the unpurified isoindole **29** at a reduced pressure, it is possible to obtain the pure adduct **145** in 80% yield.

29 **145**



It is of interest that a similar cyclisation is not observed for *N*-(5-hexenyl)isoindole.[28] The 1,3-di(trimethylsiloxy)isoindoles **24a, b** interact with methyl acrylate,[26] methyl vinyl ketone,[26] 1,2-dibenzoylethene,[23] and dimethyl maleate[26] to form exclu-sively the lactams **146a–e**. When dibenzoylethene is used, the isoindole **24a** affords a 27% yield of compound **146b** and traces of compound **146a**, while the isoindole **24b** shows the opposite behaviour, affording 51% of compound **146a** and traces of compound **146b**.[23]

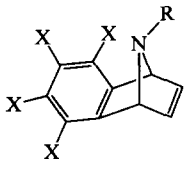
N-Methyl- and *N*-aryl-isoindoles readily combine with dimethyl esters of maleic and fumaric acids, affording the diastereoisomeric Diels–Alder adducts **147** and **148**. The high configurational stability of the *endo*-adduct **147** has been noted.[130]

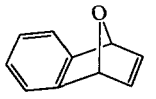
147 **148**

E = COOMe

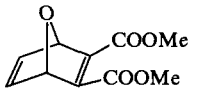
The synthesis of the structures obtained from 2-methyl-,[132] 1,2-dimethyl-,[131,132] and 1,2,3-trimethyl-2*H*-isoindoles[131–135] and the alkenes **149–153** has been described in a series of communications by German workers.[131–135] In the case of the alkenes **151–153**, one may expect theoretically the appearance of stereoisomers, although they have been actually identified only in the case of the adducts derived from compounds **151**[135] and **153**.[131,134]



149 **150**



151 **152** **153**



Prolonged refluxing of *N*-benzyl-4,5,6,7-tetrafluoroisoindole and the isoindoles **135** and **137a** with 7-R-7-azabenzonorbornadienes **154a–d** under a nitrogen atmosphere gives rise to between 6% and 61% yields of the 1 : 1 adducts **157** with the *exo, endo*-junction between the cyclic systems.[134] Equally elegant structures have been synthesised[79] by means of cycloaddition to the isoindole **85.**

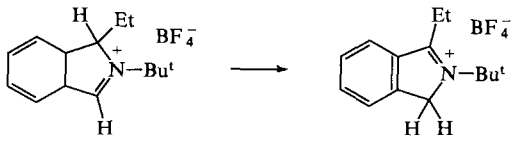
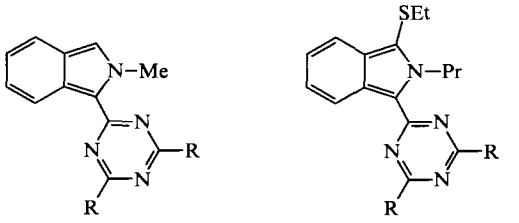
2. Electrophilic attack on isoindoles

a. Protonation



The available information about the basicity of isoindoles is extremely limited. The study of the basicity[36] of 2-R-isoindoles **4** by potentiometric titration in nitromethane showed the *N*-aryl-isoindoles are weaker bases by 5–6 orders of magnitude than *N*-methylisoindole (ΔpK_a† of the latter is 1.2). For comparison, we may note that in nitromethane ΔpK_a is +5.69 for pyridine and −0.6 for piperidine. For a series of *N*-(4-R-phenyl)isoindoles (R = H, Me, OMe, Br), the ΔpK_a depend linearly on the Hammett constant σ_p.[136] The loss of a proton by the isoindolium salts **33**, **36**, **56**, and **163** and its addition to isoindoles are reversible processes which can be readily detected from UV and ^{1}H NMR spectra. Thus the protonation of isoindoles entails the loss of the long-wavelength absorption [band C (Ref. 1)] in the electronic spectrum and an increase in the intensity of band B. In a number of instances, it is possible to obtain a high yield of isoindolium salts in a crystalline state from isoindoles: for example, from the isoindoles **5**[8] and **162**[11,137] 2-*tert*-butyl-5-nitroisoindole,[7] and 1-alkylthio-2-aryl-3-trifluoroacetylisoindole.[138]

b. Alkylation



The alkylation of 2-R-isoindoles, which are incapable of tautomeric transformations, takes place at the C(1) carbon atom with formation of type **166–168** indoles via compounds **163–165**. Thus treatment of 2-methylisoindole **135** with 2-chloro-4,6-difluoro-[139] or 2,4,6-trichloro-1,3,5-triazine[140] affords moderate yields of C(1)-alkylated isoindoles **166a, b**. The same compounds react with the isoindole **40a** to form the trisubstituted isoindoles **167**.[141]

The alkylation of the isoindole **162** with the Meerwein reagent leads initially to a high yield of the salt **164**, which isomerises to the more stable cation **165**.[11,137] It has been shown that alkylation of compound **162** with the aid of methyl iodide in methylene chloride gives rise to type **165** salts in 19% yield.[11]

The interaction of the isoindole **162** with 2,4-dibromo-3-pentanones **169a–c** in the MeCN–Cu–NaI system (method A) or the dioxane–Zn–CuCl–ultrasound system (method B) can probably be regarded as reductive alkylation.[142] The diastereoisomeric structures **170** and **171**, resembling tropanone, are then formed in 50%–60% yields (**170a** : **171a** = 2.4 : 1; **170b** : **171b** = 2.2 : 1). The use of the ketones **169a, b** entails the application of method A, while the use of compound **169c** entails the application of method B.[142] It has been shown[143,144] that the alkylation of the aminoisoindole **65a** by benzyl chlorides involves exclusively the endocyclic nitrogen atom with formation of aminoisoindolium salts of type **158a, b**. The alkylation of compound **65a** by α-haloketones proceeds similarly.[143]

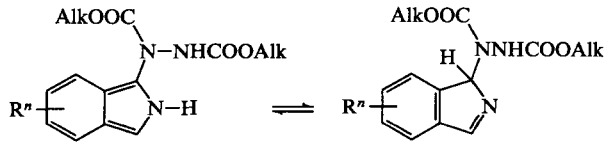
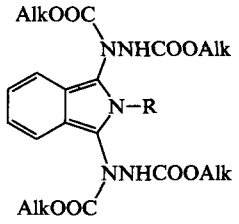
170a–c **171a–c**

c. Other electrophilic addition reactions

Maleic anhydride reacts in ether with the isoindoles **68a–c** unsubstituted at the nitrogen atom. The intermediate **172** formed initially via a Michael reaction recyclises with formation of derivatives of the pyrrolo[2,1-*a*]isoindoles **173**.[71] A process similar to that described above takes place in the interaction of the isoindoles **4** (R = Et), **5**, and **162** with azodicarboxylic acid esters.[7,8,145] The Diels–Alder reaction has not been observed in this instance, the Michael addition occurring with retention of the isoindole structure.



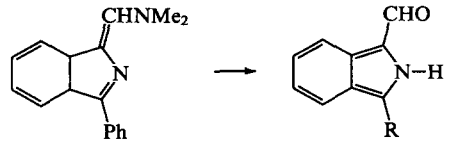
172



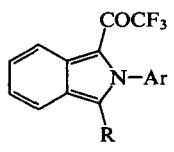
173

† ΔpK_a is the difference between the pK_a for a standard (diphenylguanidine) and the given substance.

The added hydrazine-1,2-dicarboxylate diester residue activates the isoindole structure **174**. As a rule, the reaction proceeds further, which leads exclusively to the 2 : 1 adduct **176**. The 1 : 1 adducts have been isolated only for 2-*tert*-butyl-5-nitroisoindole, the electronic system of which is somewhat deactivated by the presence of the nitro-group.[7] On the other hand, in the case of the isoindoles **4** (R = Et, Bu^t) and **5**, compounds of type **176** are formed exclusively.[8,145] Interesting results have been obtained in a study of the interaction of azodicarboxylic acid esters with NH-isoindoles **13** ($R^1 = R^3 = Me$, $R^2 = R^4 = H$, and $R^1 = R^2 = R^3 = R^4 = Me$),[145] **15** and **16**.[13] In the first three cases, the corresponding 1 : 1 adducts **174** are formed exclusively in 70%, 59%, and 45% yields, demonstrating the occurrence of prototropism (for example, in solvents of different polarity different contents of the isoindole structure **174** and the isoindolenine structure **175** are observed). On the other hand, the isoindole **16** affords under these conditions a 38% yield of the 2 : 1 adduct, which exists predominantly in the isoindolenine form.[13] The appearance of the isoindolenine tautomer has been explained by the formation of an intramolecular hydrogen bond between the ring nitrogen atom and the NH group of the hydrazine side group.

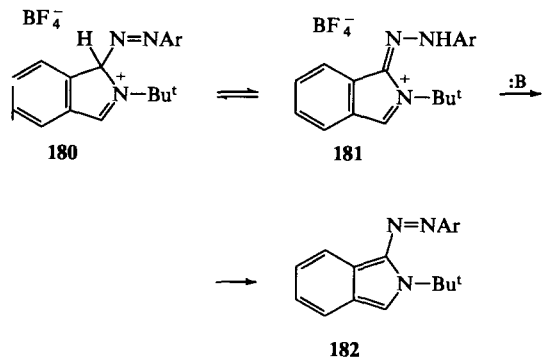


174 **175**



176

Electrophilic substitution in the isoindole series has been investigated in formylation[105] and trifluoroacetylation reactions.[138] The attempts to introduce the isoindole **68a** into Mannich, nitrosation, and nitration reactions were unsuccessful.[19] 1-Phenylisoindole **68a** reacts with the Vilsmeier reagent and gives rise to a 68% yield of 1-(*N*,*N*-dimethylaminomethylidene)-3-phenylisoindolenine **177**, which gives the 1-formyl-3-phenylisoindole **178** in 48% yield on alkaline hydrolysis.[105] *N*-Tolylisoindoles and 1-alkylthio-2-arylisoindoles **37** interact in pyridine with trifluoroacetic anhydride, forming the trifluoroacyl derivatives **179a, b**.[138]

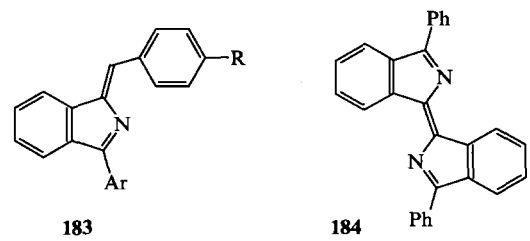


177 **178**

179a, b

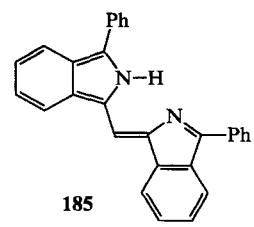
R = H (**a**), SAlk (**b**)

Isoindoles readily enter into the azo-coupling reaction in aqueous alcohol[19] or acetone[6,9,10,137] solutions exclusively via the pyrrole component of the bicyclic system. In the latter case, it is possible to observe the formation of the salt-like intermediate adducts of types **180** and **181**, which are converted into type **182** azo-dyes after treatment with bases.



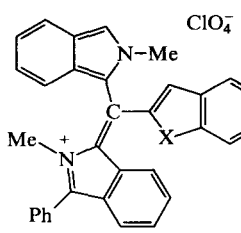
180 **181** **182**

This reaction has been investigated particularly widely in relation to the isoindole **162** with which six arenediazonium salts have been coupled.[11,137] Only *p*-nitrobenzenediazonium tetrafluoroborate has been coupled with the isoindoles **6a, b**,[6] **8**,[10] **9**, and **10**[9] and both type **182** azo-dyes and intermediate salts have been obtained. In the absence of steric hindrance in the initial isoindoles, the yields of the azo-dyes are as a rule nearly quantitative. An interesting reaction has been observed with the isoindole **182** (Ar = 4-ClC_6H_4) on treatment with *p*-nitrobenzenediazonium tetrafluoroborate: the salt **180** (Ar = 4-$O_2NC_6H_4$) was obtained in 39% yield, i.e. the phenylazo-group containing a chlorine atom was displaced and was replaced by the *p*-nitrophenylazo-group.[11] The coupling by the classical method of the isoindole **68a** unsubstituted at the nitrogen atom with toluene-*p*-diazonium chloride has been described:[19] the corresponding azo-dye was isolated in 63% yield and has λ_{max} = 467 nm.



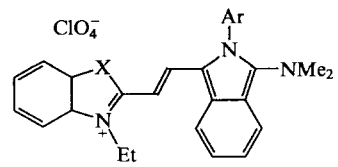
3. Condensation with aldehydes and their derivatives

In the interaction of the isoindoles **68b, c** with benzaldehyde and anisaldehyde in the presence of akali, type **183** isoindolenines were obtained in 13%–30% yields.[71] Under these conditions, the isoindole **68a** gives only small amounts of the yellow dimer **184**,[66] which can also be obtained in 53% yield by treating the isoindole **68a** with nitrous acid[19] or simply by refluxing in benzene.[71] The application of the latter operation to the isoindole **68b, c** makes it possible to isolate the corresponding dimers in yields not exceeding 15%. In the Mannich reaction with the isoindole **68a**, the dimer **184** is formed in 25% yield together with the blue pigment **185** (20%).[19]



183 **184**

The same blue pigment has been isolated as a result of the condensation of compound **68a** with paraformaldehyde in an alkaline medium (yield 15%) or in 63% and 44% yields on condensation of compound **68a** in an acid medium with the isoindole **178** or the isoindolenine **177** respectively.[19]



185

The condensation of benzaldehyde and a series of heterocyclic aldehydes with 2-methyl-1-phenylisoindole led to a series of coloured bis(2-methyl-1-phenylisoindol-3-yl)aryl(heteroaryl)-methanes **186**, which have been studied in detail both theoretically and spectroscopically.[146] The methods of synthesis of the dimethinecyanine and merocyanine dyes **187**, obtained from 2-aryl-1-dimethylaminoisoindoles, have been described.[106] Positive solvatochromism is characteristic of merocyanines of this type. The parent isoindole **14** and its 4,5,6,7-tetrafluoro-analogue condense with formaldehyde and benzaldehyde to form the tetrabenzoporphyrins **188**.[147] It was found that the most important factor governing the formation of such systems is the involvement of a metal ion, since in the absence of the latter the yields of compound **188** are significantly lower. The type of the complex-forming reagent also influences the yield considerably: the zinc ion is best. The replacement of the latter by nickel or copper ions gives rise to only traces of the corresponding porphyrin derivative. The attempts to introduce the sterically hindered 2,4,6-trimethylbenzaldehyde into this reaction have been described.[148] A later investigation[149] threw doubts on the purity of the zinc complex of *meso*-tetraphenyltetrabenzoporphyrin **188** isolated.

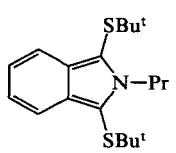
4. Other reactions of isoindoles

a. Oxidation



The autoxidation of the isoindole **40c** as a model compound for a whole series of fluorescent isoindoles has been investigated.[42] It was established that, when a solution of compound **40c** in aqueous acetonitrile is kept in air for 24 h, a mixture of four compounds **189–192** is produced.

The pure nitrosyl cyanide, generated from its adduct with anthracene, reacts with 1,3-dienes to form new cyclic adducts. However, the interaction with 2-methyl-1,3-diphenylisoindole entails the dissociation of the C–N bond in the latter and the formation of the imine **193** in 66% yield.[150] In order to investigate the possibility of the formation of isoindole radicals, a study has been made[151] of the electrochemical oxidation of the isoindoles **194a, b** in anhydrous acetonitrile. It was shown that the nature of the substituent at the N(2) nitrogen atom hardly affects the oxidation potential. The oxidation takes place in two stages, the first involving the formation of relatively stable radical-cations. In order to investigate the chemiluminescence reactions with fluorescent organic compounds, the isoindole **195** was oxidised by 4,5-dichlorophthaloyl peroxide in dimethyl phthalate.[152]

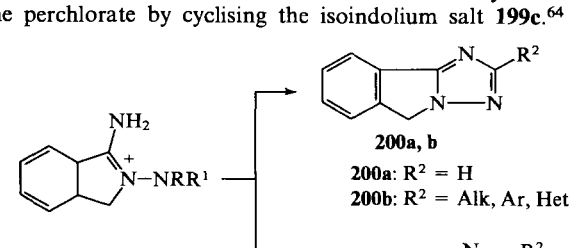
195

b. Heterocyclisation

Refluxing of the quaternary salt **196b** in aqueous solution of hydrobromic acid leads to a high yield of derivatives of 5*H*-imidazo[2,1-*a*]isoindole **197**.[153,154]

Even higher yields of compound **197** have been noted on refluxing aqueous solutions of type **196b** salts.[155] On the other hand, prolonged refluxing of the quaternary salt **196a** in the presence of sodium ethoxide leads to the condensation of the diazepine residue with the isoindole fragment and the formation of a 5-imino-5,13-dihydro-11*H*-isoindole[2,1-*a*][2,4]benzodiazepine **198** derivative.[144]



196a, b

196a: R = $CH_2C_6H_4CN$-*o*
196b: R = CH_2COR^1

197

198

Derivatives of 5*H*-1,2,4-triazolo[5,1-*a*]isoindole **200a** are formed in 32% yield on refluxing the salt **199a** with an excess of orthoformic ester.[65] Refluxing of the salts **199b** with phosphoryl chloride makes it possible to obtain the triazoloisoindoles **200b** [R = C_5H_{11} (17%) and R = Ph (97%)].[57,58,156] 3-Methyl-2-phenyl-3*H*-1,2,4-triazoloisoindole **201** has been synthesised as the perchlorate by cyclising the isoindolium salt **199c**.[64]

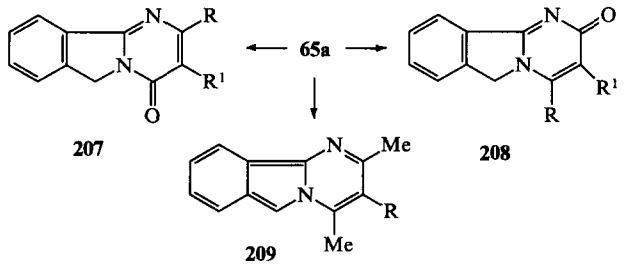
During the nucleophilic substitution of the ethoxy-group, 1-ethoxyisoindole **202** reacts relatively readily with primary amines to form derivatives of the aminoisoindole **203**,[69] while the reaction with carboxylic acid hydrazides affords compounds of type **204**.[156] The latter cyclise in polyphosphoric acid (PPC) to derivatives of 5*H*-1,2,4-triazolo[3,4-*a*]isoindole **205** in satisfactory yields.[156]

Homophthalic anhydrides give rise to isoindolo[2,1-*b*]isoquinolin-5(7*H*)-ones **206a–c** in satisfactory yields (75%) on heating with ethoxyisoindole **202** and its 5,6-dimethoxy-derivative in chlorobenzene.[34]



206a–c

206a: R = R¹ = H

206b: R = MeO, R¹ = H

206c: R = R¹ = MeO

It has been shown[157] that the condensation of the aminoisoindole **65a** with acetoacetic and benzoylacetic esters leads to derivatives of 6*H*-pyrimido[2,1-*a*]isoindol-4-one **207**. Further experiments also confirmed the possibility of the isolation from the reaction mixture of not only the 6*H*-pyrimido[2,1-*a*]isoindol-4-ones **207** but also their isomers **208**.[158,159] The criteria governing the differences between the isomeric systems **207** and **208** have been formulated and the conditions for the specific formation have been analysed in a number of investigations.[160–162] The condensation of the perchlorate **65a** with acetylacetone and methylacetylacetone, leading to a high yield of pyrimido[2,1-*a*]-isoindoles **209**, has also been described.[163]

V. Applications of isoindoles

One of the most important applications of isoindole derivatives involves their use as fluorescent labels. With the aid of isoindoles, it is possible to label the terminal amino-groups in various biological objects. The amino-groups are included in the 1-alkylthio-2*H*-isoindole system by treating them with *o*-phthalic dialdehyde and alkanethiols. An extensive literature, recently surveyed in a review,[45] has been devoted to this question. A comparatively new aspect of the employment of isoindole fluorescent labels is the detection with the aid of compounds such as **166** and **167** of the hydroxy-groups of steroids (17α- and 17β-estradiols, cortisone, estrone, etc.). The sensitivity of the method is of the order of 3 pmol in a 10 μl specimen.[139,140] It has been shown that the use of the isoindole **167** labels is an order of magnitude more effective than the use of compound **166** labels.[141] Other workers proposed the acyl azide obtained from the isoindole derivative **46d** for the detection of the same compounds.[56] Fluorescent isoindoles bound covalently to spectrin have been used to investigate the interaction of the latter with the phospholipids of pig erythrocytes.[164] 5-Fluoro-2-(1*H*-imidazol-2-yl)-2*H*-isoindole has been investigated together with other guanidine derivatives to achieve the treatment and prophylaxis of insulin-independent obesity.[165] Derivatives of compounds **200**[153,166] and **197**[154] exhibited a high contraceptive activity, while the preparation **203** with R = 3,4-$CH_2C_6H_3(OMe)_2$ exhibited the activity of a local anaesthetic which was twice as high as that of procaine.[69] It has been suggested that 1*H*-isoindoles be used as ligands in chromium pentacarbonyl complexes.[167] The electrical conductivities of polymer films obtained from isoindoles and their derivatives have been investigated.[168] Isoindoles have also been proposed as stabilisers and additives influencing the brightness of the electroplated tin layer on steel.[169]

Heterophosphacyclanes in organic synthesis

R A Cherkasov, M A Pudovik

Contents

I. Introduction 1019
II. σ^3-Heterophosphacyclanes 1020
III. σ^4-Diheterophosphacyclanes 1026
IV. σ^5-Mono- and di-heterophosphacyclanes 1031

Abstract. The review gives a systematic account of the use of mono- and di-heterophosphacyclanes, containing σ^3-, σ^4-, and σ^5- phosphorus atoms, for the synthesis of phosphorus-free organic substances. Data concerning the reaction mechanisms, the reactivities of cyclic organophosphorus compounds, and the factors determining the synthetic result of their chemical reactions are presented. In certain cases, the effectiveness of the employment of cyclic and acyclic phosphorus-containing reagents is compared. The bibliography includes 178 references.

I. Introduction

At the present stage, the synthetic organic chemistry of phosphorus is developing mainly in two directions. The first involves the functionalisation of organophosphorus substrates of increasing complexity, based on the chemical transformations of the organic functional groups already present in the molecule. One achieves in this way the introduction into the organophosphorus compounds of definite atomic groups which are potentially responsible for certain useful properties of the compound being synthesised, say pesticidal, or others. Phosphorus-containing functional groups may not actually participate in the chemical steps, exerting a different kind of effect on the fragment being transformed, which is susceptible to estimation including quantitative estimation.[1]

The second direction concerns the synthesis of organic compounds with participation of phosphorus-containing substances, which, after being involved in particular synthetic operations, 'remove' the phosphorus-containing functional group from the reaction sphere and the target product does not contain a phosphorus atom. This type of employment of organophosphorus reagents in organic synthesis has come to be widely used and has a long tradition. The phosphorus-containing compounds of this kind include, for example, the Wittig reagents — phosphorus ylides used to convert oxo-compounds into alkenes. The search for new highly effective functionalising phosphorus-containing reagents is being prosecuted at the present time.

Since the publication of the first and only monograph[2] devoted to the application of organophosphorus reagents in organic synthesis, many new communications have appeared in which this problem has been developed further. Thus in the 1980s, new multipurpose highly effective phosphorus-containing reagents were described. Among them mention should first be made of Lawesson's reagent (LR) (see Cherkasov et al.[3] and Kava and Levinson[4] and the literature quoted therein) — 2,4-bis-(*p*-methoxyphenyl)-1,2,3,4-dithiadiphosphetane 2,4-disulfide — and Mitsunobu's reagent[5] (MR)† — a betaine obtained by the interaction of triphenylphosphine and dialkyl azodicarboxylate. They have found extensive application not only in experimental practice but also in industrial organic synthesis. A recent review has been devoted to the employment of unsaturated compounds of tetracoordinate phosphorus for the synthesis of complex organic compounds.[7]

New aspects of the synthesis of organic compounds involving the employment of reagents containing a phosphorus atom involved in different types of coordination have begun to develop recently. Thus chiral phosphines[8] and phosphonates[9] are used in the catalysis of organic reactions and methods are being developed for the functionalisation of organic compounds with the aid of metastable derivatives of tricoordinate pentavalent phosphorus[10] and also of compounds of dicoordinate phosphorus.[11,12]

This review is devoted to a vigorously developing branch of phosphorus chemistry — the chemistry of heterophosphacyclanes — in its new aspect, namely their application in organic synthesis. If one disregards fairly old review publications describing the use of individual types of compounds of this class,[2] then this is the first attempt to treat systematically and survey the data which have accumulated in this field since 1980. Individual earlier literature sources are quoted here only to the extent that they are needed for a complete description of the problem under discussion. This communication completes a series of reviews devoted to the chemistry of heterophosphacyclanes containing a phosphorus atom with coordination numbers of three,[14] four,[15] five,[16] and six.[17] Considered jointly, these communications provide a complete picture of this currently important field of organoelement chemistry.

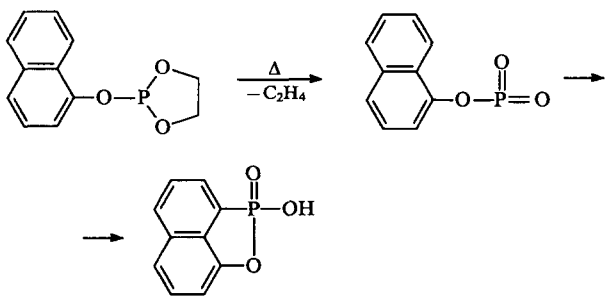
Uspekhi Khimii **63** (12) 1087 – 1113 (1994); translated by A K Grzybowski

† After the publication of Mitsunobu's review,[5] an extensive literature describing the application of MR in organic synthesis appeared (more than 400 publications). As an example, we may point to one of the later studies on the use of MR in the total synthesis of 20-membered macrocyclic antibiotics — venturicidins A and B[6] (see also Section IV).

II. σ^3-Heterophosphacyclanes

The use of σ^3-1,3,2-diheterophospholanes and σ^3-1,3,2-diheterophosphorinanes, substances which are thermodynamically less stable than the σ^4-phosphorus- and σ^5-phosphorus-containing derivatives with a similar structure,[14] is frequently associated with their conversion into the latter, which subsequently effect particular synthetic operations.

In the context of the chemical transformations described here, the σ^3-diheterophosphacyclanes themselves are not of special preparative interest and in most cases their behaviour resembles that of structurally similar acyclic phosphorus(III) derivatives. For example, organic phosphorus(III) derivatives are capable of deoxidising (desulfurising) suitable substrates, being themselves oxidised to phosphoryl (thiophosphoryl) compounds. The inclusion of a phosphorus(III) atom in a heterocycle entails a decrease (in nucleophilic reactions) or an increase (in electrophilic reactions) of the reactivity of the organophosphorus reagent.

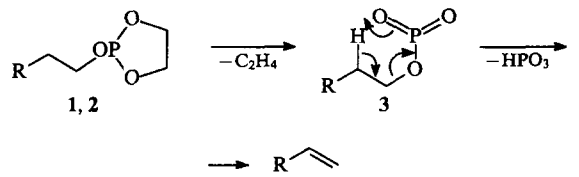


At the same time, thermal, photochemical, and chemical (for example as a result of substitution and disproportionation reactions) fragmentation processes involving or not involving the heterocyclic part of the molecule are extremely characteristic of σ^3-diheterophosphacyclanes, in contrast to the acyclic phosphorus(III) derivatives.

1. Thermal and photochemical fragmentation

The thermal reactions of cyclic esters of acids derived from phosphorus in the lowest oxidation state are usually associated with intramolecular rearrangements of the Arbuzov reaction type in those cases where the exocyclic fragment contains suitable functional groups, for example haloalkyl groups, and lead to organophosphorus products containing a phosphorus atom with a higher coordination number (CN).[14]

2-Aryloxy- and 2-alkoxy-1,3,2-dioxaphospholanes behave differently. On vacuum flash pyrolysis (700–800 °C, 0.001 Torr), they undergo fragmentation with liberation in the first stage of ethene and phosphorus-containing intermediates having the structure of metaphosphates‡ and undergoing further transformations.

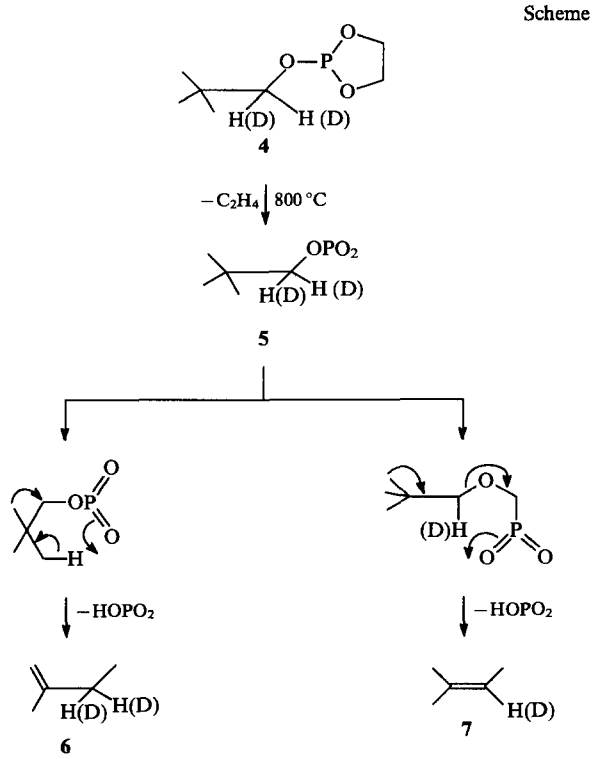


After liberating ethene, the aryl esters of ethylene phosphites are converted into the corresponding cyclic monoesters of arylphosphonic acids via the incorporation of the highly electrophilic pentavalent tricoordinate phosphorus atom in a sp^2-C–H bond of the aromatic fragment of the metaphosphates.[21–23]

According to Cadogan et al.,[21] the reaction described constitutes, in its intramolecular version, one of the most effective methods for the phosphorylation of aromatic nucleophilic substrates with the aid of highly electrophilic metastable phosphorus-containing reagents.

‡ We may note that in recent years there has been a marked growth of interest in these substances in connection with the appearance of the possibility of obtaining stable representatives of phosphorus compounds of this class and their use for the synthesis of natural organophosphorus products and in other phosphorylation reactions.[18–20]

However, if the exocyclic organyl fragment contains a β-hydrogen atom, alkenes are liberated — 2-vinylpyridine in the thermolysis of the phospholane **1** or phenyl vinyl ether in the case of compound **2**, as well as polymeric metaphosphoric acid. Intramolecular phosphorylation does not occur and a process analogous to the Chugaev reaction and the β-elimination via a six-centre transition state **3** similar to it take place.[21]



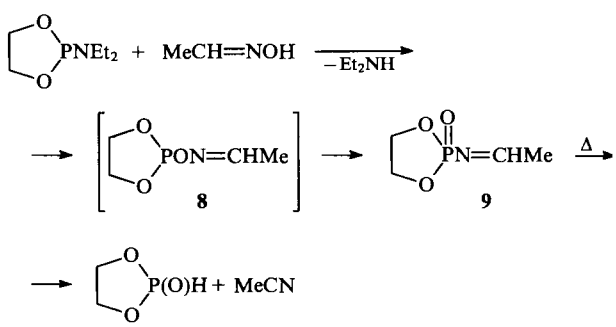
1, **2** **3**

1: R = Py
2: R = OPh

After the liberation of ethene, the pyrolysis of 2-neopentyloxy-1,3,2-dioxaphosphalane **4** under these conditions leads to the quantitative formation of a mixture of 2-methylbut-1-ene **6** and of its thermodynamically more stable isomer 2-methylbut-2-ene **7** in proportions of 2 : 1.[22,23] It is believed that the minor alkene **7** is formed as a result of the abstraction of an α-proton from the common intermediate **5**, whereas its isomer **6** arises through the elimination of a γ-proton and the unusual 1,2-methyl shift in the same intermediate metaphosphate (Scheme 1). The transformation of compound **5** into the alkenes **6** and **7** proceeds via a mechanism similar to the Wagner–Meerwein rearrangement but has the opposite polarity (there is a carbanionoid and not a carbonium ionoid transition state) and also in its concerted (and not sextet) variant.[24]

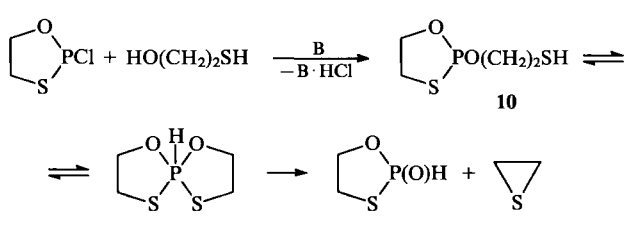
Scheme 1

This course of the reaction has been confirmed by the use of a deuteriated specimen of compound **4**, pyrolysis of which afforded the deuterium-containing alkenes **6**-d_2 and **7**-d_1 in proportions of 3.8 : 1. The observed deuterium isotope effect $k_H/k_D = 1.9$ agrees with the ratio of the deuteriated isomers obtained, indicating that the loss of hydrogen (deuterium) via the route leading to compound **7** is rate-determining.



2. Reactions involving substitution at the σ^3-P atom

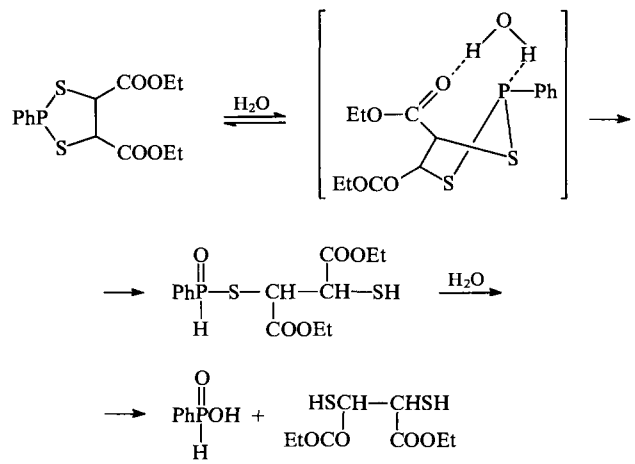
The thermally promoted fragmentation of diheterophosphacyclanes is frequently observed in the fractionation of the products of the interaction of cyclic phosphorous and phosphonous acid esters with electrophiles and nucleophiles. The elimination of phosphorus-free organic reaction products usually occurs in those cases where the exocyclic ester residue contains reactive functional groups. The cyclic skeleton of the phosphorus-containing substrate as a rule remains unchanged under these conditions. The above applies primarily to dioxaphospholanes.



In the vast majority of cases, such reactions take place with participation of intermediates in which the CN of the phosphorus atom is four or five. The inclusion of the phosphorus atom in a ring, especially a five-membered ring, stabilises such intermediates and in many cases this makes it possible to identify them and to infer the reaction pathway.

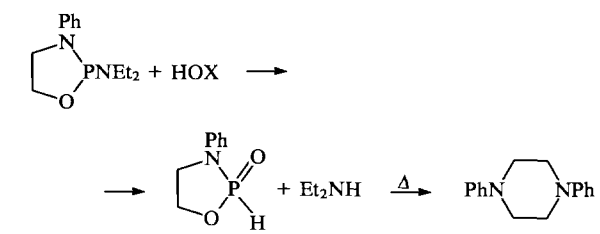
The substitution of readily eliminated groups by functionalised alcohols, accompanied by the isomerisation of the intermediate cyclic phosphites to tetracoordinate and pentacoordinate phosphorus compounds, leads, as a result of thermolysis, to the formation of small organic molecules; the phospholane ring remains unchanged under these conditions.

The interaction of the diethylamide of ethylenephosphorous acid with an oxime probably proceeds via a stage involving the formation of the unstable phosphite **8**, which isomerises to the N-phosphorylated anil **9**; in the course of fractionation, the latter decomposes into ethylenephosphorous acid and acetonitrile.[25]



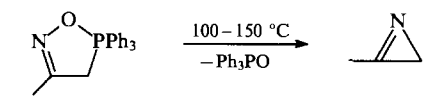
The esterification of 2-chloro-1,3,2-oxathiaphospholanes with mercaptoethanol in the presence of a base[26] does not stop at the 2-mercaptoethyl phosphite **10** stage, and is completed by the formation of a thiirane and a cyclic phosphorothious acid. It is difficult to say which of the intermediates—the phosphite intermediate **10** or the isomeric phosphorane intermediate **10a**—is responsible for the observed fragmentation.

We may note in this connection that a similar fragmentation of 1,2-dihydroxyalkylene derivatives of σ^5-P is an extremely characteristic property and is of preparative importance[16] (see also Subsection 3).



The endocyclic hydrolytic dissociation of the thioester linkages in 4,5-di(ethoxycarbonyl)-2-phenyl-1,3,2-dithiaphospholane takes place stepwise and leads to phenylphosphonous acid and diethyl dimercaptosuccinate.[27]

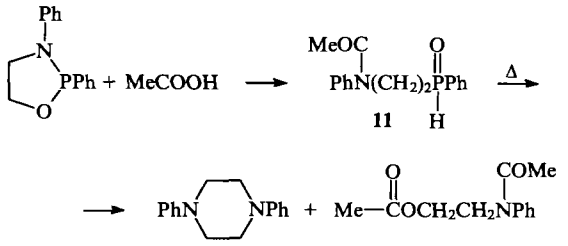
Kinetic study of the hydrolytic reaction led the authors to the conclusion that a hydrogen-bonded complex is formed prior to the establishment of equilibrium.



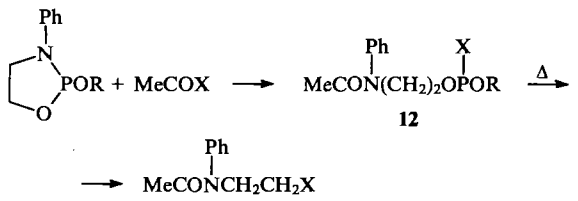
In contrast to the cyclic esters and thioesters of trivalent phosphorus acids, amidoesters containing an endocyclic tertiary nitrogen atom undergo a more profound transformation during the substitution reaction involving under these conditions a thermal fragmentation with cleavage of the oxazaphospholane ring.

On interaction with proton-containing nucleophiles (water,[30] acetic acid,[29,30] and ethanol[29]), 2-ethoxy-,[28] 2-phenyl-,[29] and 2-diethylamino-3-phenyl-1,3,2-oxazaphospholanes[29,30] afford *N,N*-diphenylpiperidine after fractionation. It has been suggested that, in the presence of a readily eliminated exocyclic group, the reaction takes place via a mechanism involving the nucleophilic substitution[30] of the exocyclic fragment.

X = H, COMe, Et.



The formation of the final product is probably due to the decomposition of the *N*-phenyloxazaphospholane fragment of the unstable hydrophosphoryl intermediate at elevated temperatures (100–120 °C) during the substitution reaction or during fractionation. One cannot rule out the possibility that the decomposition is accompanied by the initial formation of three-membered nitrogen-containing heterocycles, similarly to the formation of azirenes on pyrolysis of σ^5-1,5,2-oxazaphospholenes.[31]



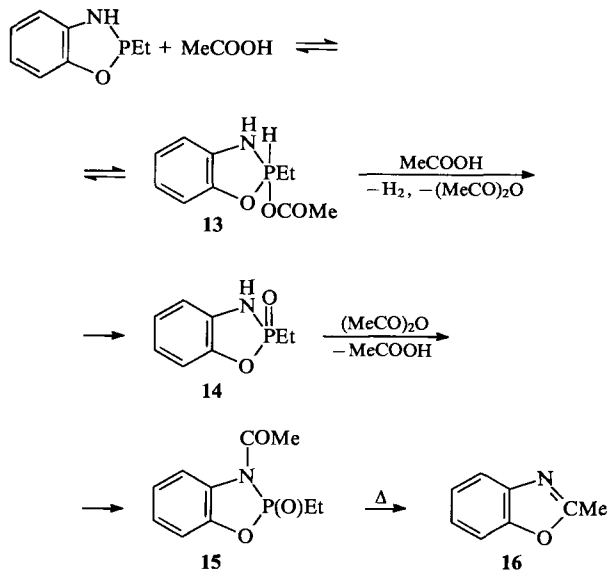
N-Phenylaziridine is evidently formed in the case under discussion, dimerising under the experimental conditions (see also Subsection 3). Naturally one cannot rule out also another mechanism of the formation of the piperidine ring from the phosphacyclane skeleton of the cyclic phosphoramidites.

The same synthetic result is attained also in the course of endocyclic substitution,[29] for example in the acetolysis of 2-diethylamino- or 2,3-diphenyl-1,3,2-oxazaphospholane.

The thermolysis of the phosphonite **11** makes it possible to obtain, together with *N*,*N*-diphenylpiperidine, also *N*-2-acetoxyethyl-*N*-phenylacetamide.

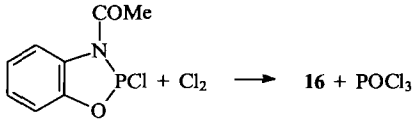
The oxazaphospholane ring may be cleaved not only by proton-containing nucleophiles but also by electrophiles — acetyl chloride[32] or acetic anhydride.[33]

X = Cl, OCOMe.



In both these cases, the interaction is evidently associated with the nucleophilic attack by the nitrogen atom on the carbonyl carbon atom of the acylating agent; the ring is then cleaved at the P–N bond. Further decomposition takes place with the elimination of the *O*-ester organyl fragment. It is difficult to reach definite conclusions about the mechanism of this unusual fragmentation of the functionalised phosphonites **11** or the phosphites **12**, again because the subsequent transformation of the 'phosphorus' part of the molecules remains unelucidated. One may only note that the elimination of the phosphorus-containing reaction products is associated with the dissociation of the sp^3-C–O bond in the *O*-ester group.

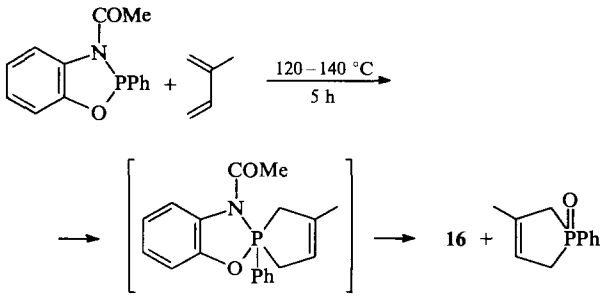
3. Reactions involving an increase in the coordination number of the σ^3-P atom



Decomposition accompanied by the opening of the ring at an endocyclic sp^2-C–O bond has been noted in the acylation of 2-ethyl-4,5-benzo-1,3,2-oxazaphospholane,[34] which is achieved under mild conditions (2 h, 20 °C) and represents a rare case of the oxidation of phosphorus(III) derivatives by carboxylic acids in the two-component version§.

The process probably begins[34] with the 1,1-addition of acetic acid to the phosphorus(III) atom of the benzophosphacyclane. The unstable hydrophosphorane **13** formed is deacylated by a second acetic acid molecule and is oxidised to the phosphonate **14** with liberation of hydrogen. The subsequent endocyclic *N*-acylation leads to the final *N*-acylphosphonate **15**. During fractionation, the latter affords 2-methylbenzoxazole **16** in 20% yield.

It has been demonstrated by means of a special experiment that, on heating to 150–200 °C in vacuo (20 Torr), the phosphonate **15** gives rise to the benzoxazole **16** in 68% yield.



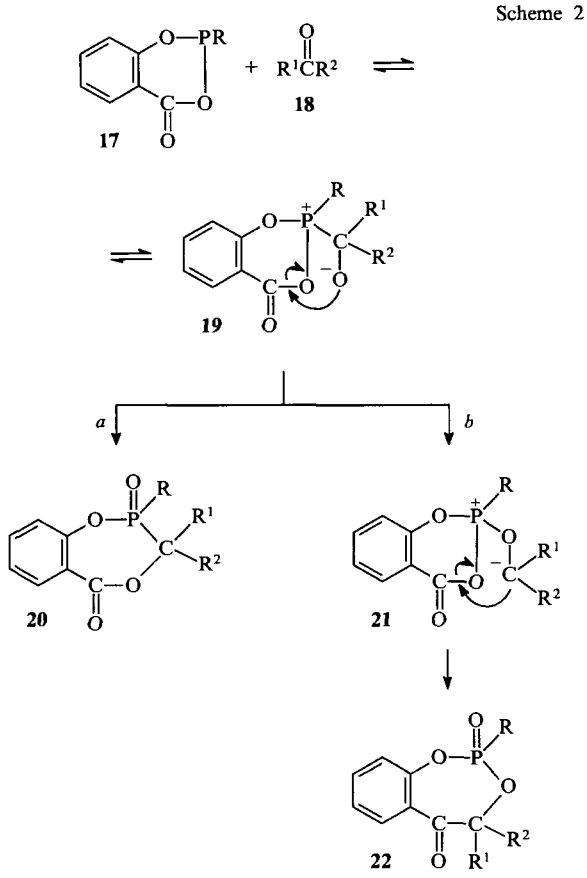
The formation of compound **16** as a result of the chlorination of 3-acetyl-2-chloro-4,5-benzo-1,3,2-oxazaphospholane has been established recently.[36]

Evidently in this case too the reaction leads to the formation of the addition product of chlorine to the σ^3-phosphacyclane — the corresponding trichlorophosphorane. The ultimate formation of phosphoryl chloride (and also apparently of ethyl metaphosphonate in the previous example) is clearly evidence in favour of the probable formation of a metastable aromatic intermediate of the acylamino-substituted dehydrobenzene type, or a similarly substituted phenyl radical, as a consequence of the heterolysis or homolysis of the sp^2-C–O bond.

Such fragmentation also takes place in the thermolysis of the unidentified product of the [1 + 4]-cycloaddition of 3-acetyl-2-phenyl-4,5-benzo-1,3,2-oxazaphospholane to 2-methylbutadiene.[37] Fractionation of the resulting mixture afforded the benzoxazole **16** and a cyclic phosphine oxide.

The fragmentation with cleavage of the diheterophospholane ring described above leads to a kind of transcyclisation of the phosphorus(III) substrate.

The endocyclic dissociation of the sp^2-C–O bond discussed here gives rise to interesting synthetic possibilities for the employment of the reactions of cyclic salicyl phosphites with carbonyl compounds activated by electron-accepting substituents.



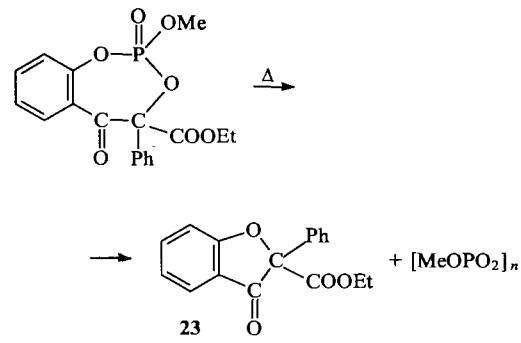
2-R-4-Oxo-5,6-benzo-1,3,2-dioxaphosphorinanes **17** — six-membered cyclic anhydrides containing the P(III)–O–C(O) fragment in the ring — readily interact with chloral,[38]

§ According to the data of Mukajama et al.,[35] trialkyl phosphites are oxidised by carboxylic acids in the presence of hydrogen acceptors — diphenylmercury and dibenzoylethene.

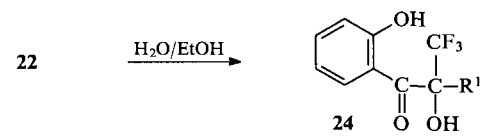
hexafluoroacetone,[39] mesoxalic acid esters,[40] ethyl benzoylformate,[41] methyl trifluoropyruvate,[42] and hexafluoroacetylacetone[43] with insertion of the carbonyl reagent in the six-membered ring and the formation of dioxaphosphepanes — a class of phosphorus-containing heterocycles which are relatively difficult to obtain.

It has been suggested[41] that the process begins with the attack by the nucleophilic P(III) atom on the carbonyl carbon atom of the other reactant (compound **18**) (Scheme 2).

Scheme 2



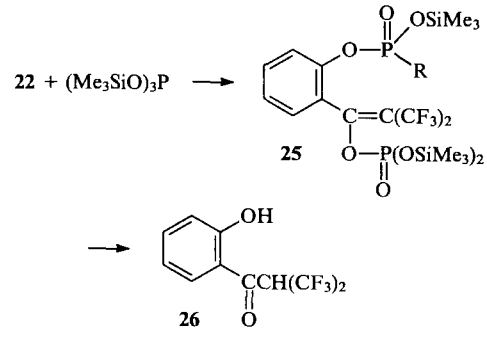
The dipolar ion **19** arising under these conditions may be stabilised via the intramolecular substitution at the carbonyl carbon atom by an oxy-anion (route *a*) with formation of the 1,4,2-dioxaphosphepane **20** (R^1 = H, R^2 = CCl_3); this reaction path occurs in the reactions of salicyl phosphites **17** with chloral.



The remaining carbonyl reagents employed gives rise to 1,3,2-dioxaphosphepanes **22**, the formation of which is preceded by the rearrangement of the ion **19** to the ion **21** (P–O–C→P–C–O) and intramolecular substitution, with participation of the carbanion, at the carbonyl carbon ion in the zwitterionic intermediate **21** (route *b*). This case is of greatest interest from the standpoint of the problems discussed in the review because it entails the formation of a new C–C bond.

It has been shown[41] that the vacuum fractionation of the phosphepane **22** (R = OMe, R^1 = Ph, R^2 = COOEt) is accompanied by its complete decomposition, which resulted in the formation of ethyl 2,3-dihydro-3-oxo-2-phenylbenzofuran-2-carboxylate **23** in 80% yield.

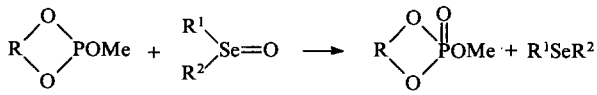
It has been noted[41] that derivatives of 2,3-dihydro-3-oxo-2-phenylbenzofuran-2-carboxylic acid had not been described before the study by the above workers[41] and only data concerning the isomeric acid with the carboxy-group in the 3-position in the benzofuran ring had been available.[44,45]



The protolytic reactions of the 1,3,2-dioxaphosphepanes **22**, obtained by the reaction of salicyl phosphites **17** (R = OMe) with hexafluoroacetone and hexafluoroacetylacetone provide the greatest possibilities for the synthesis of functionalised fluorine-containing ketones; the hydrolysis of the 1,3,2-dioxaphosphepanes in aqueous ethanol[43] leads to the hydroxyketones **24** (R^1 = CF_3 and CH_2COCF_3) respectively in a high yield.

R = OMe; R^1 = CF_3, CH_2COCF_3; R^2 = CF_3.

This method may be modified by phosphorylating the 1,3,2-dioxaphosphepanes **22** (R^1, R^2 = CF_3) with the aid of tris(trimethylsilyl) phosphite; hydrolysis of the diphosphate **25** makes it possible to obtain the ketone **26**, which does not contain α-hydroxy-substituents in the fluoroalkyl group.[46,47]

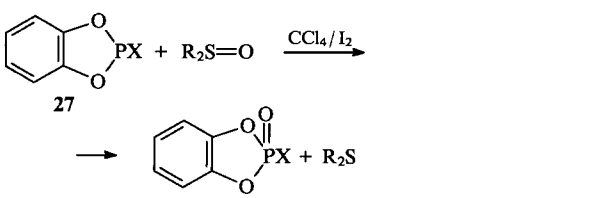


R^1 = R^2 = CF_3.

The driving force of the reactions described here is the well known tendency of phosphorus(III) derivatives to be converted into compounds with a thermodynamically stable phosphoryl group characterised by a high energy of the phosphorus–oxygen multiple bond.[14]

This property of the phosphorus(III) atom has been used in the reduction of oxides, sulfides,[48,49] and selenides[50,51] by σ^3-1,3,2-dioxaphospholanes and phosphorinanes.

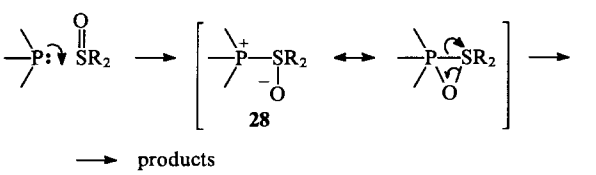
Under mild conditions, selenoxides are reduced almost wholly in solution in benzene or chloroform by 2-methoxy-4-methyl-1,3,2-dioxaphospholane or 2-methoxy-4-methyl-1,3,2-dioxaphosphorinane in 5 min with an appreciable exothermic effect.



R = CH_2CHMe, $(CH_2)_2CHMe$;

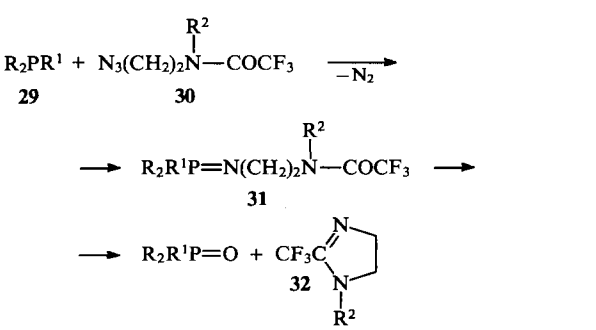
R^1 = Ph, Bz; R^2 = Et Ph, Bz.

The retention of the configuration of the phosphorus atom in the cyclic phosphates obtained as a result of the oxidation reactions has been noted.



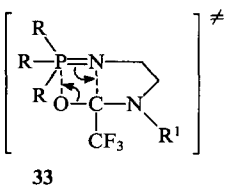
The deoxygenation of sulfoxides by 2-phenoxy-[50] and 2-chloro-1,3,2-benzodioxaphospholanes takes place readily in solution in CCl_4 at low temperatures, high temperature being required when acyclic phosphorus(III) derivatives are used.[51] Compounds **27** satisfy the principal requirements which must be met by reagents reducing sulfoxides to sulfides: they are readily available, are powerful electrophiles (electron-accepting agents), and can be easily removed after oxidation (by extraction with aqueous alkali).

X = Cl, OPh.



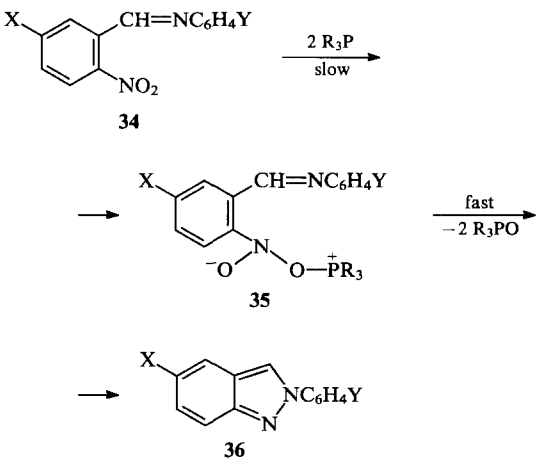
Traces of iodine catalyse the process, reducing the conversion time from 3 h to several minutes; the chloro-derivative **27** is very effective under these conditions. It deoxidises sulfoxides at room temperature over a short period.

It has been suggested [51] that the process involves the formation of the dipolar ion **28** as a result of the nucleophilic attack by phosphorus(III) on the sulfoxide sulfur atom.



However, the increase in the rate of deoxidation when the phospholanes **27** containing highly electron-accepting substituents at the phosphorus atom are employed is more likely to be evidence in support of the nucleophilic interaction of the sulfoxide oxygen with the electrophilic phosphorus(III) atom. The ability of the latter to both give up and receive electrons (biphilicity) is manifested particularly strikingly when it is incorporated in the diheterophosphacyclane ring.[14]

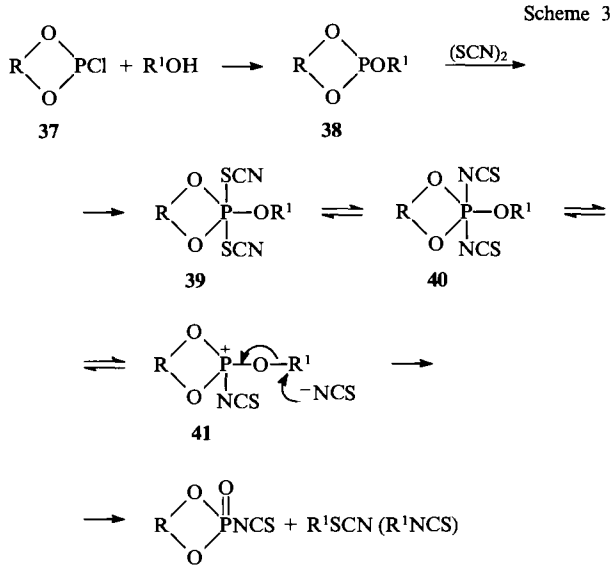
The electron-accepting effect of the alkylenedioxy-substituent at the phosphorus(III) atom is manifested in the reaction of the phosphorus(III) derivatives **29** with the azidoamides **30**.[52]



The incorporation of a phosphorus(III) atom in the five-membered ring of 2-diisopropylamino-1,3,2-benzodioxaphospholane **29** (R_2 = o-$C_6H_4O_2$, R^1 = Pr^i_2N) makes it possible to obtain 2-trifluoromethyl-2-imidazoline **32** (R^2 = H, Bu^t) in a high yield; triphenylphosphine affords only 20%–30% of the imidazoline **32** (R^2 = H) under these conditions; the yield increases to 80% (120 °C and 0.05 Torr). Tris-(dimethylamino)phosphine **29** (R = R^1 = Me_2N) does not yield even traces of the final product **32** over a period of 2 h at 120 °C. These experimental data can be best accounted for by the formation of a transition state **33** analogous to that in the Wittig reaction:

The nucleophilic attack by the carbonyl oxygen atom on the phosphimine phosphorus atom of the product **31** of the Staudinger reaction is facilitated in the presence of a powerful electron acceptor at this atom — the phenylenedioxy-substituent; by increasing the electron density at the imine phosphorus, the strongly electron-donating dialkylamino-group inhibits the Wittig reaction. Moderately strong electron acceptors (phenyl substituents) give rise to an intermediate result.

The opposite, deactivating effect of the incorporation of a phosphorus(III) atom in the five-membered dioxaphospholane ring has been established in a study of the kinetics of the reductive cyclisation of o-nitrobenzylideneanilines **34** to 2-substituted indazoles **36**.[53]



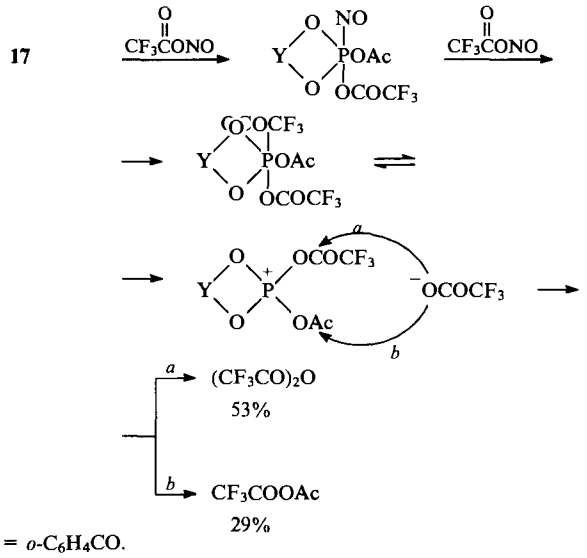
The introduction of electron-accepting substituents into aromatic rings and of electron-donating substituents at the phosphorus(III) atom promotes the occurrence of the process, the ratio of the rates of reaction of trialkyl phosphites and 2-alkoxy-1,3,2-dioxaphosphalanes being 7:1 under these conditions. Approximately the same ratio of the rates of quaternisation of cyclic and acyclic phosphites in the Arbuzov reaction led Armour et al.[53] to the conclusion that the rate-determining stage is nucleophilic attack by the phosphorus(III) atom of the deoxidising reagent on the oxygen of the nitro-group with formation of the intermediate **35**.

The very sharp increase (almost by two orders of magnitude) in the rate in the reaction of 2-ethoxy-1,3,2-diazaphospholane may be associated with the intermediate formation of a hydrogen-bonded complex favouring the reductive cyclisation. It is made up of the negatively charged oxygen atom in the zwitterion and the endocyclic NH fragment.

The ability to undergo readily a change in coordination number, observed in the reactions of phosphorus(III) derivatives and manifested particularly strikingly in σ^3-1,3,2-dioxaphospholanes, permits the use of these substances as condensing agents in the reactions of hydroxy-compounds with proton-containing nucleophiles.

It has been found [54-56] that alcohols are readily converted into thiocyanates and isothiocyanates in the reactions of 2-chloro-1,3,2-dioxaphospholanes **37** (Scheme 3).

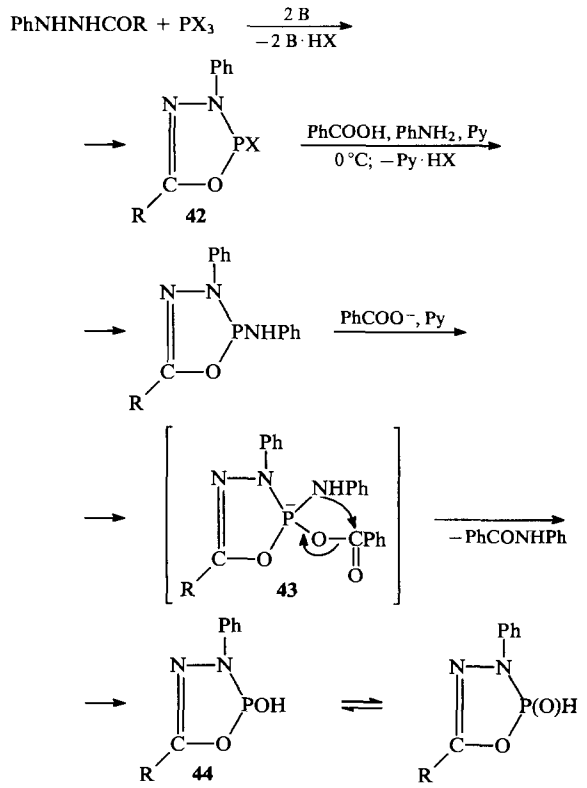
Scheme 3



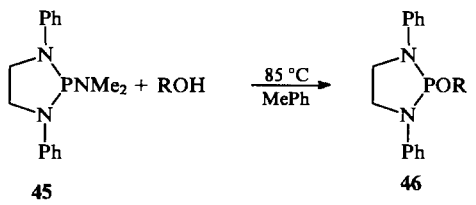
R = —CMe=CMe—; R^1 = Alkyl, R^2CO, $R^2_2P(O)$, $R^2_2P(S)$.

The products **38**, obtained by reacting phosphorochloridites with alcohols or carboxylic, dialkylphosphoric, and dialkylphosphorothioic acids, are made to react with thiocyanogen, which leads to alkyl and acyl isothiocyanates via a series of intermediates having the phosphorane (compounds **39** and **40**) and quasi-phosphonium (compound **41**) structures respectively. The use of secondary alcohols makes it possible to obtain isothiocyanates as well as thiocyanates. The dealkylation of the salt **41**, which proceeds via a mechanism involving nucleophilic substitution at the α-carbon atom of the alkoxy-group by the ambident anion SCN^-, is effected by the more bulky and nucleophilic sulfur atom for the n-alkyl group in primary alcohols. The increase in the degree of substitution at the α-sp^3-C atom (secondary alcohols) is accompanied by the competing S- and N-substitution.

We may note that a similar result is achieved in the conversion into the thiocyanate with the aid of a triphenylphosphine–thiocyanogen mixture (the so called Tamura's reagent [3]). The use of cyclic phosphorus(III) reagents makes it possible to carry out the process under very mild conditions. When the reaction was performed at the temperatures $-80 \rightarrow -30 \rightarrow +20$ °C, all the intermediates **39–41** generated in the reaction were detected by ^{31}P NMR spectroscopy. [53,54]



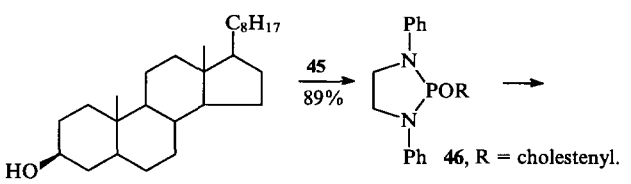
The condensing effect of cyclic phosphites is manifested in the reactions of the mixed anhydride **17** (R = OAc) with trifluoroacetyl nitrite.[57]

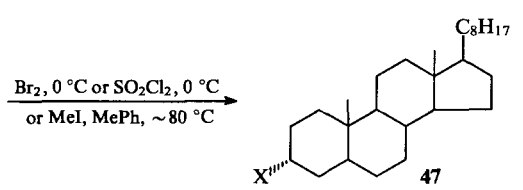


Y = *o*-C_6H_4CO.

It is assumed that in this case the process proceeds with participation of intermediates of the phosphorane and quasi-phosphonium types; the competing substitution by the trifluoroacetate anion of the trifluoromethylacetyl and acyl groups in the quasi-phosphonium salts affords the observed mixture of anhydrides as the products (routes *a* — main product, route *b* — a minor pathway).

This approach has been used recently to convert carboxylic acids into amides using the 2-X-5-R-3-phenyl-2,3-dihydro-1,3,4,2-oxadiazaphospholes **42**, obtained from phosphorus trihalides and 2-acylphenylhydrazine, as the condensing agents. [58] The process was carried out by adding compound **42** to a mixture of benzoic acid, aniline, and pyridine at 0 °C; the yield of the phenylamide of benzoic acid is nearly quantitative. It has been suggested that the key stage of the process is the formation of a type of pentacoordinate intermediate **43** and its subsequent decomposition into the final acylamide and the unstable cyclic acid **44**.

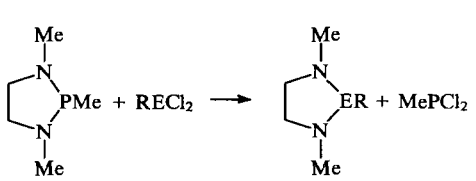




Finally, we may indicate also a method involving a kind of 'conservation' of alcohols, which is employed for their identification as part of the molecules of the readily crystallising 2-alkoxy-1,3,2-diazaphospholanes **46**, and their stereospecific conversion into organyl halides.[59] The cyclic phosphorous triamide **45** is converted on treatment with alcohols into alkoxy-derivatives, which are transformed into alkyl halides in accordance with the mechanism of the Arbuzov reaction.

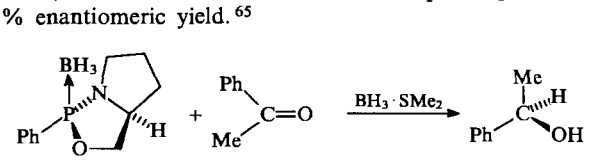
45 **46**

For example, β-cholestanol has been converted in this way by the phosphoramide **45** into the corresponding ester **46**, from which the halides **47** were obtained in high yields.



X = Cl (80%), Br (85%), I (75%).

As sometimes happens in the second stage of the Arbuzov reaction, the dealkylation of compound **46** is highly stereospecific with full inversion of configuration of the carbinol carbon atom.



4. Other reactions

We may note that the studies carried out a fairly long time ago on the exchange of the phosphorus(III) atom for other elements via the reaction described by Eisenhut and Schmutzler[60] and Das and Zuckerman[61] were not developed further.

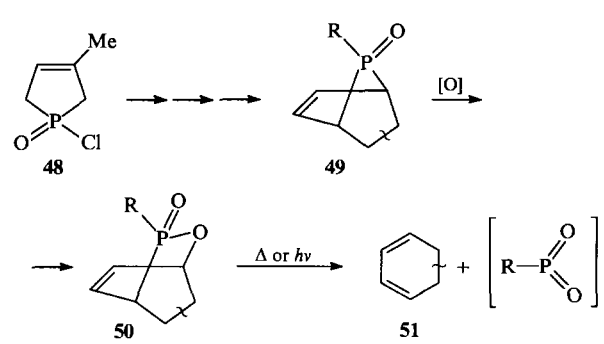
E = B, As; R = Ph, Cl.

Mention should be made of the cases where σ^3-oxazaphosphorinanes were used as chiral ligands in the metal [sic] complexes employed in asymmetric synthesis.[62-64] For example (2*R*, 4*S*)-2-phenyl-1,3,2-oxazaphosphorinane, coordinated to a boron hydride, reduces various ketones to the corresponding alcohols in 99% enantiomeric yield.[65]

However, a detailed consideration of this problem is outside the scope of this review.

III. σ^4-Diheterophosphacyclanes

Derivatives of tetracoordinate phosphorus have played an outstanding role in the development of methods for the conversion of carbonyl compounds into alkenes with the aid of phosphorus ylides (the Wittig reaction) and α-phosphorylated carbanions (the Horner–Wadsworth–Emmons reaction).[2,66-68] The introduction of a σ^4-P atom into the diheterophosphacyclane fragment is responsible for the specific behaviour of these phosphorus-containing reagents.

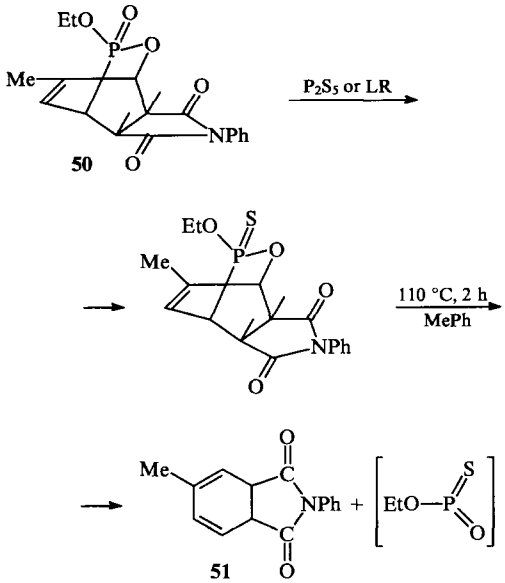


Other reactions of σ^4-diheterophosphacyclanes — thermal and photochemical fragmentation as well as solvolysis — have been less important in fine organic synthesis. We may note that the involvement of cyclic organophosphorus compounds in these processes has been exceptionally important for the development of methods of phosphorylation with the aid of metastable phosphorus-containing reagents[69] and nucleophilic substitution reactions at a tetrahedral phosphorus atom.[15]

1. Fragmentation of cyclic derivatives of tetracoordinate phosphorus

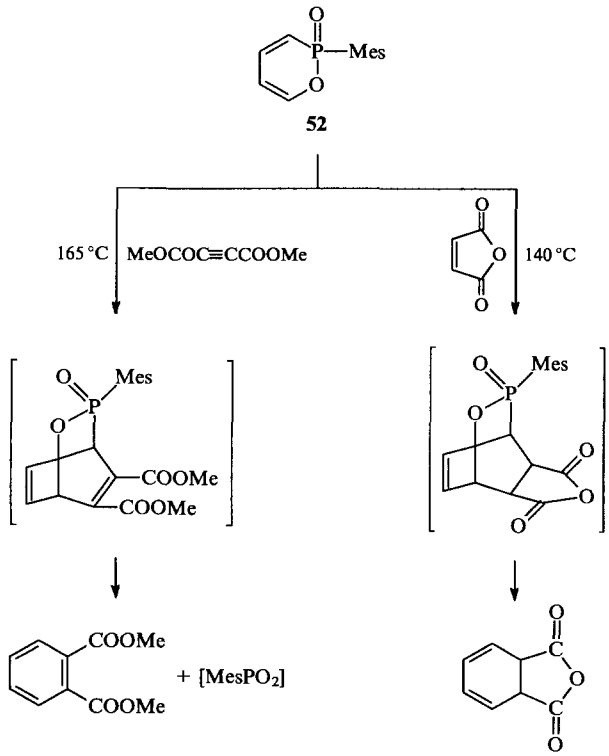
Like the analogous chemical processes with participation of cyclic phosphorus(III) derivatives, reactions of this type are used mainly for the generation of metastable derivatives of tricoordinate pentavalent phosphorus — metaphosphates and their amino- and thio-derivatives.

The formation of metaphosphates, which proceeds via the mechanism of the retrodiene synthesis, is accompanied by the liberation of phosphorus-free products obtained from the hydrocarbon skeleton of the initial, usually bicyclic, molecule.



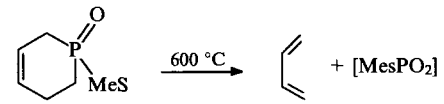
In a series of studies by Quin and coworkers,[69-74] it was found that derivatives of 2,3-oxaphosphabicyclo[2.2.2]octene **50**, obtained from compound **48**, constitute an excellent starting material for the generation of metaphosphates, which may be 'trapped' with the aid of suitable nucleophiles (alcohols, oxiranes, etc.).[69]

R = EtO, Me_2N, Bu^tO etc.



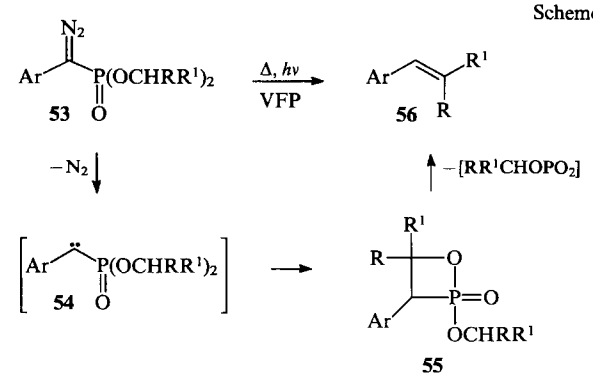
The initial cyclic phosphinochloridate **48** is converted into the strained 7-phosphanorbornene **49** via successive chemical transformations (for further details, see Quin et al.[69]). On treatment with peracids, compound **49** is converted into the phosphorylated derivative **50**.

The ease of the fragmentation of the phosphabicyclooctene depends on the conditions in this process: the thermal generation of the final products is achieved by heating in toluene at 100–110 °C; the photochemical fragmentation takes place very readily — at −75 °C under the influence of ultraviolet radiation. We may note that this constitutes a sharp difference between the bicyclic derivatives of σ^4-P and cyclic phosphites (see Subsection 1 of this Section), the decomposition of which requires heating to several hundreds of degrees. At a low temperature, it is possible to detect by ^{31}P NMR spectroscopy the metaphosphates obtained.[74] The high reactivity of the phosphacyclanes **50** is reflected in the ease of sulfurisation with the aid of P_2S_5 or Lawesson's reagent.[73]



The reactions described here make it possible to obtain also the dihydrophthalimide **51** and other cyclic dienes together with the derivatives of metaphosphates and metaphosphorothioates which are difficult to obtain.

In the reaction of the phosphorus analogue of α-pyrone, namely mesityl(butadienyl) phosphinate **52**, with dienophiles, the formation of Diels–Alder adducts is only postulated: at the elevated temperature required for the cycloaddition, they decompose via the pathway described above with formation of Diels–Alder aromatic adducts or aromatic dihydro-adducts. The initial phosphacyclane thus plays the role of the supplier of butadiene.[75]

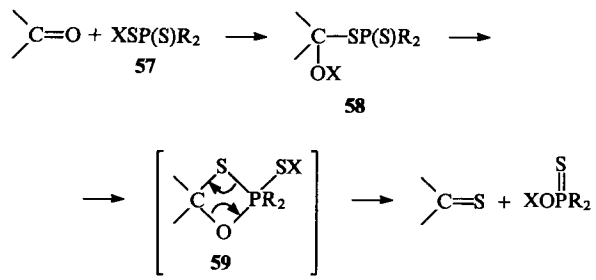


It is striking that the monocyclic alkene, which also serves as a source of the metaphosphonate and the diene, is pyrolysed under much more severe conditions.[75]

The intramolecular cyclisation of the carbenes **54**, obtained by vacuum flash photolysis (VFP) (350 °C, 10^{-5} Torr) of dialkyl α-diazobenzylphosphonates **53**, leads to the oxaphosphetanes **55**, which fragment under the reaction conditions to metaphosphates and substituted styrenes **56** (Scheme 4).[76]

Scheme 4

The cyclisation **54** → **55** takes place as a result of the intramolecular insertion of the carbene in a C–H bond of the ester alkyl group. The phosphacyclanes **55** can be isolated by vacuum flash photolysis at a lower temperature (275 °C) and this makes it possible to model the alkene elimination stage **55**→**56**. The high stability of the σ^4-oxaphosphetanes **55** (compared with the four-membered heterocyclic intermediates containing pentacoordinate phosphorus) in alkene formation reactions with the aid of phosphorus ylides and α-phosphorylated carbanions (see below) is striking.

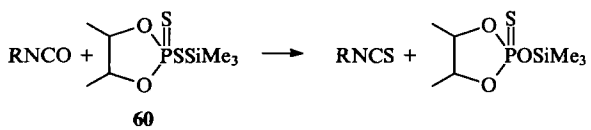


2. Nucleophilic substitution reactions

The highly electrophilic σ^4-P atom in σ^4-1,3,2-diheterophosphacyclanes is extremely sensitive to attack by charged or neutral nucleophiles: the rate of solvolysis of five-membered cyclic phosphates is several orders of magnitude higher than that of the tiralkyl phosphates with a similar composition.[15] The reason for this is believed to be the decrease in activation energy as a result of the involvement in the process of the thermodynamically stable pentacoordinate intermediate containing a diheterophospholane ring.[15] The equally high rates of cleavage of both endocyclic and exocyclic phosphorus–heteroatom bonds is striking. Acyclic and six-membered cyclic esters of σ^4-P acids react much more slowly. It is noteworthy that the diheterophosphorinane ring is relatively stable.

The endocyclic solvolytic reactions usually lead to phosphorus-containing acyclic products. This problem is outside the scope of this review, although it is important in the synthesis of biologically active phosphorus compounds. Among recent publications, we may mention a review[77] in which data are presented on the endocyclic hydrolysis of phosphazacyclanes used for the synthesis of phospholipids. The results of studies on the asymmetric synthesis of phosphorus-containing aminoacids using dioxa-, oxaza-, and diaza-phosphacyclanes have been surveyed in a review publication.[78] Finally, the photochemical decomposition of phosphate esters can also serve as a method of synthesis of unsaturated organics, which has been demonstrated in a recent review.[79].

There are few nucleophilic substitution reactions at the tetrahedral phosphorus atom forming part of the heterocycle which are used for the synthesis of phosphorus-free organic compounds. We may mention in the first place the so called

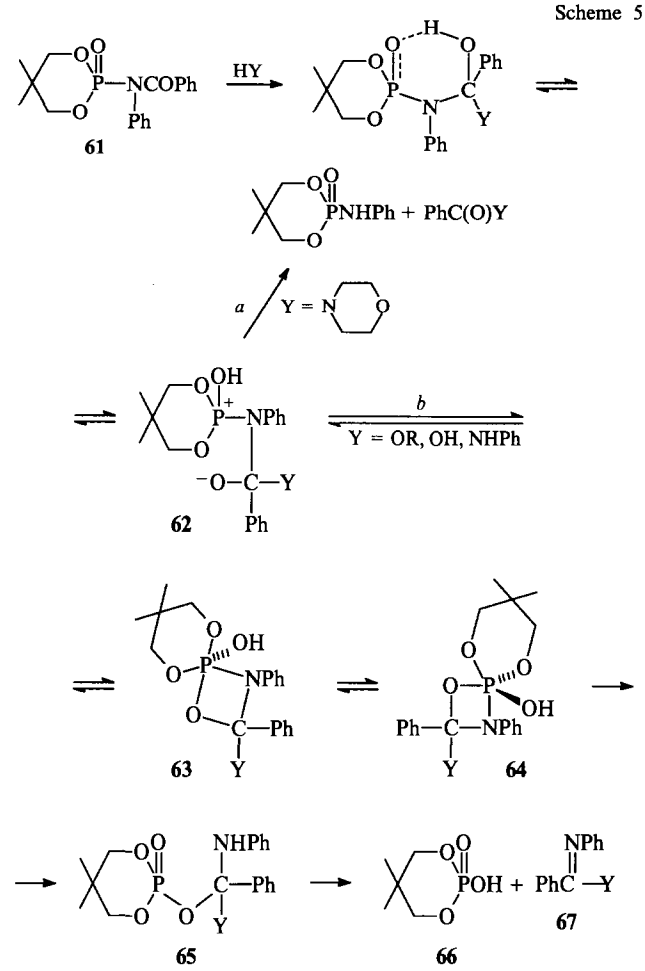


a sulfur atom on treatment with phosphorus dithio-acids or *S*-trimethylsilyl phosphorodithioates **57**.[3]

X = H, $SiMe_3$.

The reaction is completed by the addition of the dithio-derivatives **57** to the carbonyl group of the substrate; under mild conditions, the adducts **58** (X = $SiMe_3$) may be isolated. At an elevated temperature, the process develops further during fractionation and is completed by the formation of thiocarbonyl compounds and phosphorus-containing monothio-derivatives. The conversion of the hydroxy(siloxy)alkyl phosphorodithioates **58** into the final products takes place via a mechanism involving intramolecular nucleophilic substitution at the tetrahedral phosphorus atom.

The above method is especially effective for the conversion of aryl and acyl isocyanates into the corresponding isothiocyanates.[80-83] The silyl phosphorodithioate **60** is almost wholly converted into isocyanates and isothiocyanates at room temperature; the acyclic phosphorodithioates **57** (R = alkoxy-group) require heating in order to complete the reaction.



R = Ph, CCl_3CO, PhCO, $(EtO)_2PO$

The sharp increase in the sulfurising activity of phosphorodithioates following the introduction of a σ^4-P atom into a five-membered ring is most probably associated with the decrease in the energy of the type **59** intermediate.[82] The increase in the stability of phosphoranes as a result of spirocyclisation is well known.[16]

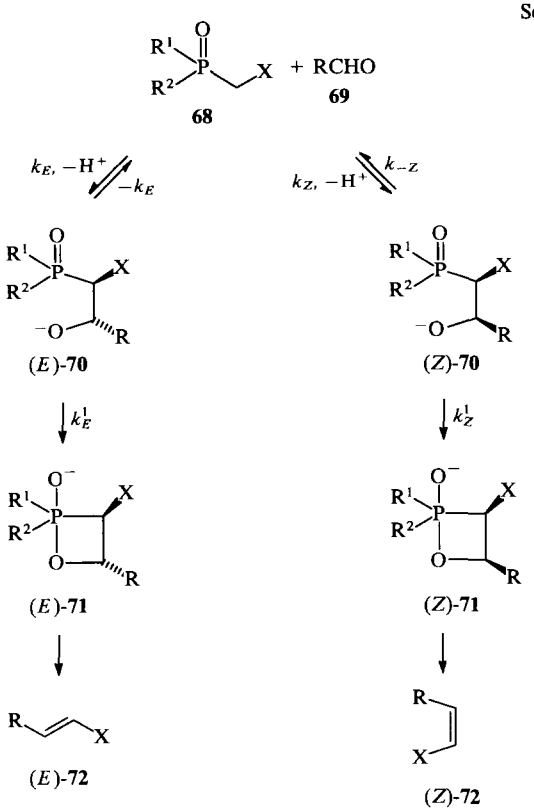
The comparatively low electrophilicity of the σ^4-P atom incorporated in a six-membered diheterophosphacyclane fragment may promote attack by an external nucleophile on an alternative electrophilic centre of the phosphorus-containing reagent if such is present. Thus the solvolysis of 2-(*N*-benzoyl-*N*-phenylamino)-5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinane **61**[84] takes place exclusively with attack by nucleophiles on the carbonyl centre and is accompanied by the O,N-migration of the phosphoryl group (Scheme 5).

Depending on the nature of the nucleophile (HY), the process proceeds with dissociation of the C–N bond (route *a*) in the key intermediate **62** or via its cyclisation to compound **63** and pseudorotation to give compound **64** (route *b*) and is continued by the dissociation of the C–O bond in the phosphate **65**. The reaction with morpholine proceeds via route *a* to give *N*-benzoylmorpholine and the anilide of a cyclic phosphoric acid, while the reactions with water, alcohol and aniline take place via route *b*, which is associated with the phosphorylotropic transformations noted above. The phenylimide **67** (Y = OMe), obtained in the reaction with methanol,[80] methylates the cyclic acid **66** (2 h, room temperature). The conversion of the *N*-acylphosphoramidate **61** into the acid **66** and the phenylimide **67** is completed after 7 h on treatment with phenol and after 10 h

Scheme 5

R = Me, Ph, CMe_3.

on treatment with *tert*-butyl alcohol. Aniline affords the anilinium salt of the cyclic phosphoric acid **66** and a high yield of *N*-phenyliminobenzanilide **67** (Y = NHPh) as the reaction products.



3. α-Phosphorylated carbanions

The reactions of α-phosphorylated stabilised carbanions with carbonyl compounds, for which the name 'Horner–Wadsworth–Emmons' (HWE) reaction has been established in recent years,[68] constitutes a classical method of synthesis of α,β-unsaturated carboxylic acid esters and other functionalised alkenes.

The HWE reaction as well as the Wittig reaction similar to it result in the preferential formation of the thermodynamically more stable (*E*)-alkenes. However, by varying the reaction conditions and the structure of the reactants, by introducing special additives, and by taking into account other factors, it is possible to vary the ratio of the (*E*)- and (*Z*)-products of the alkene formation process within wide limits.[66]

In the general case, the tendency towards formation of (*E*)- and (*Z*)-alkenes is considered from the standpoint of the reversibility of the formation of the intermediates, i.e. the ratios of the rates of the reaction stages k_{-E}/k_E^1 and k_Z/k_{-Z}^1 (Scheme 6).[67] Other conditions being equal, the increase in the stability of the (*E*)- and (*Z*)-alkoxides **70** and also of the pentacoordinate intermediates (*E*)- and (*Z*)-**71** determines the ease of their decomposition to alkenes. The process is kinetically controlled, (*Z*)-isomers are formed, whereas in the case where it is thermodynamically controlled there is a possibility of the reversibility of the process, leading to an increase in (*E*)-stereoselectivity.

Scheme 6

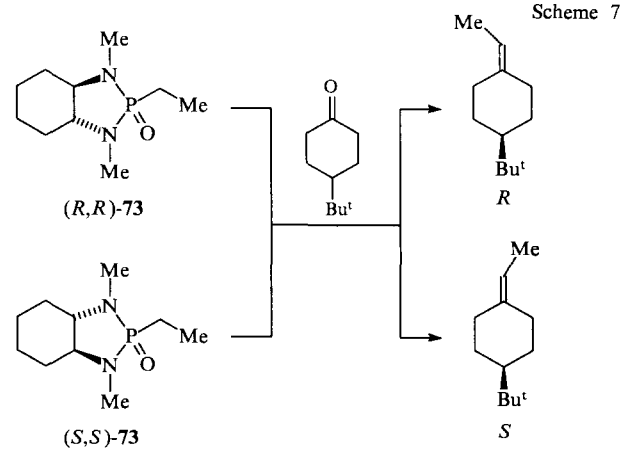
The tendency towards an increase in the 'reversibility factor' and hence in the ratio *E*/*Z* with increase in temperature and in the ease of the coordination of the metal-counterion in compound **70** (Li^+ is more effectively coordinated than Na^+ and K^+) has been established on numerous examples.[85,86] At the same time, an increase in the basicity of the medium and especially in the steric hindrance of the α-carbon atom in the carbonyl reactant **69** increases the content of the (*Z*)-isomer.[86] However, in the general case it is fairly difficult to predict the influence of the medium and structural factors on the stereochemical result of the HWE reaction because the conformational structure of the phosphonates **68**, the association of the carbanions obtained from them, and the relative contributions of all other factors may have a significant effect on the relative rates of the reactions leading to the (*E*)- and (*Z*)-isomers (see Scheme 6).

The influence of the environment of the σ^4-P atom and the synthetic consequences of its incorporation in the heterocycle are of special interest.

For the acyclic phosphonates **68**, it has been found that the replacement of the methoxy-groups in compound **68** ($R^1 = R^2 =$ MeO, X = COOEt) by the trifluoroethoxy-groups to give compound **68** ($R^1 = R^2 = CF_3CH_2O$, X = COOEt) in reactions with aldehydes leads to a sharp increase in the fraction of the (*Z*)-product up to the complete selectivity of the reaction with benzaldehyde. The methoxy-analogue of the phosphonate **68** gives rise exclusively to the *trans*-cinnamate **72** (R = Ph, X = COOEt) in this reaction, whereas the bis(fluoroethyl)phosphonate **68** wholly converts benzaldehyde into the *cis*-cinnamate ester **72** (R = Ph, X = COOEt). Evidently, this result is associated with the increase in the stability of the type **71** phosphoranes on enhancement of the electron-accepting properties of the substituents at σ^5-P, which is well known for phosphoranes.[16] This lowers the 'reversibility factor' and favours the (*Z*)-stereoselectivity.

This difference has been used recently for the (*Z*)- or (*E*)-selective conversion into alkenes in individual stages of the complex synthesis of a macrocyclic antibiotic—(+)-ikarugamicin.[87]

The phosphonates **68** of the σ^4-1,3,2-diheterophosphacyclane series have been recently investigated by various methods.[16,88–91] It was found that the stability and properties of the cyclophosphonate carbanions depend on the fine details of the steric structure, ring size, the structure of the acyclic functional groups, and the type of metal ion.



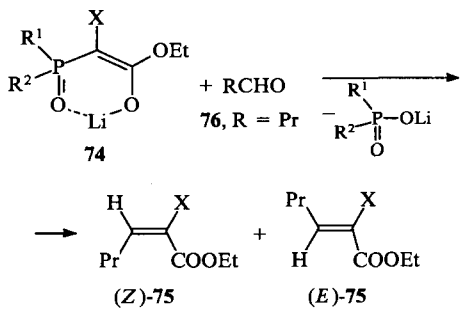
A distinctive feature of the conversion into an alkene with the aid of phosphacyclic carbanions is a high rate of reaction associated with the appreciable electrophilicity of the endocyclic σ^4-P atom (the tendency towards association and self-condensation is explained by the same feature[91]) and the distinct (*Z*)-specificity of the HWE reactions with participation of five- and six-membered cyclic phosphonates **68** ($R^1 + R^2$ = alkylene-1,2-dioxy- and -1,3-dioxy-, alkylene-1,2-diamino- and -1,3-diamino-, and alkylene-1-oxy-2-amino- and -1-oxy-3-amino).[16] The latter factor is associated with the stability of the pentacoordinate intermediates in which a σ^5-P atom is incorporated in the ring; it has been established that five-membered cyclic phosphonates exhibit an appreciably higher (*Z*)-selectivity [65% – 70% of the (*Z*)-isomer] than the six-membered and acyclic phosphonates.[15,68] This is a consequence of the well known stabilisation of phosphoranes by five-membered cyclic fragments (the five-membered ring effect).[16,17]

The rate of the HWE reaction increases markedly (almost by a factor of 20) when a phosphorus atom is incorporated in the dioxaphospholane ring in compound **68** [$R^1 + R^2$ = $OCH(CH_3)CH(CH_3)O$, X = COOEt] compared with the acyclic compounds **68** ($R^1 + R^2$ = OEt, X = COOEt). We may note, incidentally, that the latter is 35 times more reactive than the phosphine oxide **68** ($R^1 = R^2$ = Ph, X = COOEt).[68,92] These results are satisfactorily consistent with the hypothesis of the increased stability of the intermediate **70**: it increases for the following series of substituents at σ^5-P: phenyl < ethoxy- < alkylene-1,2-dioxy.

As already mentioned, the five-membered cyclic phosphonates **68** ($R^1 + R^2$ = alkylene-1,2-dioxy-, X = COOEt) were found to exhibit (*Z*)-selectivity, which increased sharply when the reaction was carried out with *tert*-butyl phosphonoacetate **68** [$R^1 + R^2$ = COH(Me)CH(Me)O, X = $COOBu^t$] at a low temperature (−20 °C) with lithium as the cation.[93] This feature has been used in the synthesis of pyrethroid insecticides (see Maryanoff and Reitz,[68] Tessier,[93] and the references quoted therein).

Unique diastereofacial selectivity has been demonstrated for the chiral diaminophosphonates (*R*,*R*)- and (*S*,*S*)-**73** synthesised from the two enantiomeric (*R*,*R*)- and (*S*,*S*)-1,2-diaminocyclohexanes.[94] An appreciable stereodifferentiating reactivity has been noted in the reactions of the potassium salts of the diazaphospholanes **73** with 4-*tert*-butylcyclohexanone: compound (*R*,*R*)-**73** forms a mixture of the isomeric (*R*)- and (*S*)-4-*tert*-butylcyclohexylideneethanes in proportions of 95 : 5; the use of the stereoisomer (*S*,*S*)-**73** inverts this ratio in favour of the (*S*)-alkene (Scheme 7).

Scheme 7



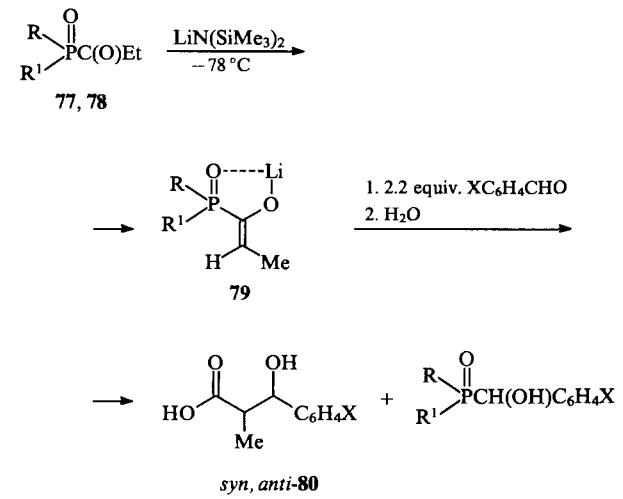
This stereochemical result of the HWE reaction with participation of compound **73** is difficult to explain from the standpoint of the 'reversibility factor'.[68,94] The cause of the above effect is more likely to be the initial topology of these cyclic phosphonates — their symmetry elements which predetermine in each case the nucleophilic attack on the carbonyl carbon atom in the sterically more accessible plane of the phosphorylated carbanion. It has been pointed out[94] that such asymmetric induction in the alkene formation reaction is useful for the synthesis of vitamins and pheromones or in the formation of chiral catalysts.

The stereospecific effect of the diazaphospholane fragment in the HWE reactions of lithium derivatives of the phosphonoacylates **74** with aliphatic aldehydes has been found in studies by Savignac and coworkers.[91,95–98] Table 1 presents the stereochemical results of the conversion of butyraldehyde into an alkene by treatment with α-n-propyl and α-chlorophosphonoacylates, which leads to the formation of a mixture of (*Z*)- and (*E*)-isomers. Oxygen-containing substituents, fluoroethyl substituents, as well as phosphorinane and dioxaphospholane reagents do not exhibit a stereospecific effect. We may only note that, in contrast to the α-alkylcyclophosphonates **74** (X = alkyl), their halo-substituted analogues **74** (X = Cl[96] and F[97]) were found to exhibit a considerable (*E*)-selectivity (cf. the data of Stiell and Gennari[85]).

The results of the formation of alkenes with the aid of derivatives of 1,3-dimethyl-2-oxo-1,3,2-diazaphospholanes constitute an isolated case. The reactions of compound **74** (X = Pr^n) lead to the preferential formation of the (*Z*)-isomers; the halo-substituted carbanions are distinguished by full (*E*)-stereoselectivity for chloro- and fluoro-substituents and for all the aldehydes **76** used in the alkene formation reaction.[96,97]

It is difficult to assign these results to only one cause. It has been shown,[97] for example, that the stereochemical effect depends on many external factors: the concentration of the phosphonate [the fraction of the (*Z*)-isomer falls with dilution], the temperature regime, the method of preparation of the lithium derivative **74**, and the nature of the alkene employed for this purpose as well as other additives (for example, lithium bromide and crown-ethers).

Table 1. The influence of substituents at the σ^4-P atom in the HWE reactions of the lithium salts of substituted α-phosphonoacetates with aldehydes.[91,96]

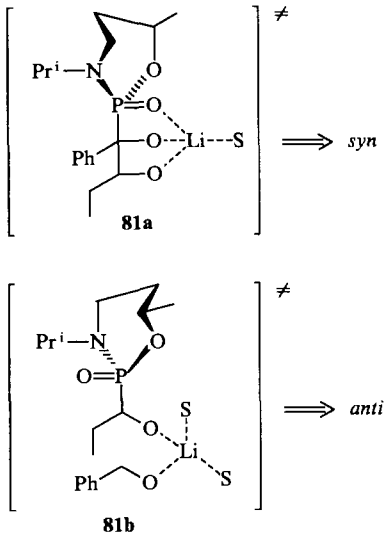


$R^1 + R^2$	Ratio of yields of (*Z*)- and (*E*)-isomers (%)	
	X = Pr^n (T = 20 °C)	X = Cl (T/°C)
$(EtO)_2$	37:63	55:45 (−20)
$(CF_3CH_2O)_2$	–	35:65 (−70)
$OCH_2C(Me_2)CH_2O$	61:39	25:75 (−40)
OCH(Me)CH(Me)O	62:38	–
$N(Et)(CH_2)_2N(Et)$	–	15:85 (−70)
$N(Me)CH_2)_2NMe$	76:24	2:98 (−70)
$N(Me)(CH_2)_3NMe$	Does not react	–
$(Me_2N)_2$	Does not react	–

The difficulty of assessing the factors which determine the stereochemical result of the reaction of compound **74** with the aldehyde **76** is caused, as noted above, by the tendency of the carbanions towards association and aggregation and by their equilibrium state associated with this behaviour, which is in its turn determined by the high electrophilicity of the endocyclic σ^4-P atom.

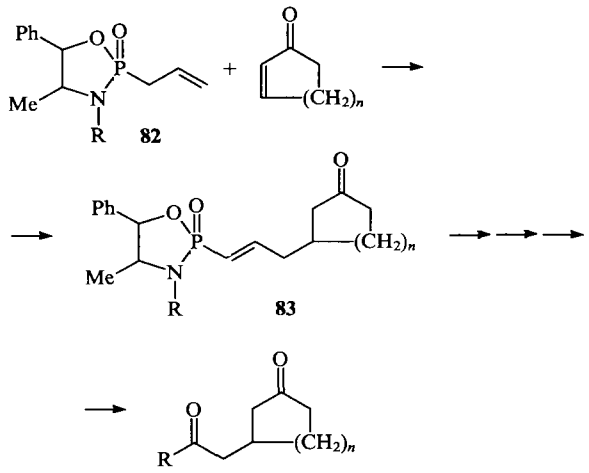
It is essential to emphasise that the use of cyclic α-phosphorylated carbanions in HWE reactions have a series of specific features associated with the greater reactivity of these substances due to their more pronounced sensitivity to the nucleophilic reactions of the endocyclic σ^4-P atom. Although the stereospecific effect of phosphacyclanes is not always easy to predict, it amounts as a rule to complete stereoselectivity. The latter is associated both with the characteristic features of the processes arising in the course of the HWE reactions of the cyclic intermediates and with the specific topology characteristic of cyclic reagents effecting the conversion into alkenes.

The base-promoted aldol condensation of diethyl propionylphosphonate **77**[99] and of its oxazaphosphorinane analogue **78**[100] with aromatic and aliphatic aldehydes is characterised by a high *syn*-diastereoselectivity (the ratio *syn* : *anti* = 98 : 2 and 94 : 6 for compound **80** obtained from compounds **77** and **78** respectively). The reaction makes it possible to produce the β-hydroxycarbonyl fragment of compound **80** under very mild conditions.



77: R = Pr^nCO, R^1 = OEt; **78**: R + R^1 = $OCH(CH_2)_2NPr^i$ (Me).

The authors[100] established that, when the N-substituent is fairly bulky, the chair conformation of the oxazaphosphorinane reagent **78** creates good possibilities for preferential enantiofacial selection (cf. the reagents **73**). The high degree of stereospecificity is in this case attributed to the formation of the highly organised transition state **81a** (Scheme 8).

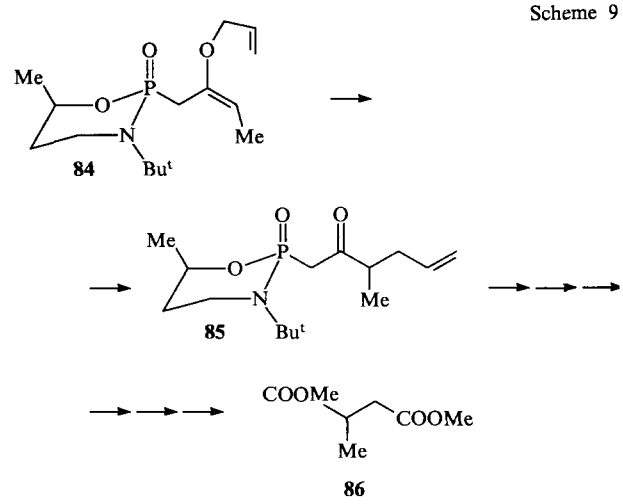


The tendency of lithium alkoxides of type **79** to associate, which was noted above, plays a significant role also in the reaction under discussion. The introduction of additives of the type of tetramethylethylenediamine (S), which coordinate the lithium ion, disturbs the stereocontrol: the increase in the fraction of the *anti*-conformer of **80** is attributed to the contribution by the activated complex **81b** formed with the phosphoryl group of the phosphacyclane liberated from the coordination sphere of lithium.

Scheme 8

S = solvent or additive.

Chiral allyl phosphonates having the oxazaphospholane structure, obtained from ephedrine **82** (R = Me) and its isopropyl analogue **82** (R = Pr^i), undergo 1,4-addition with cyclic enones, which leads to the formation of the 1,4-adducts **83** with a high enantioselectivity.[101] The latter have been converted into the corresponding aldehydes or acids with an oxocyclane structure.



n = 1 - 4; R = H, OH.

The optical yield of the products increases greatly on passing from the methyl homologue (70% - 74%) to the isopropyl homologue **82** (88% - 98%). The authors[101] emphasise the likely usefulness of this reaction for the synthesis of natural products.

The stereochemical control achieved by chiral carbanions containing the oxazaphosphorinane ring gives rise to asymmetric induction of the phosphonamidates **85** in the Claisen rearrangement (Scheme 9).[102-104]

It has been established that the oxidative decomposition of the product of the Claisen rearrangement **85**, obtained from *cis*-**84**, leads to the (*S*)-dimethyl methylsuccinate **86**, while the *trans*-isomer affords the (*R*)-enantiomer.[102] As in the previous cases, the result of the rearrangement is associated with the topological characteristics of the lithium carbanions derived from compound **84**, which determine the course of the isomerisation of the carbanion-stabilised allyl vinyl ether on one of the 'opposite' surfaces (made up of the multiple bonds, the carbanionic centre, and the P=O fragment) relative to the structural elements of the phosphoramide ring.[103]

Scheme 9

The arenesulfonyl group also exerts a similar accelerating and stereoregulating influence on the Claisen rearrangement, but a number of advantages of the phosphorylated allylvinyl substrates have been noted:[104] the great ease of synthesis, the possibility of an extensive structural variation of the phosphorus-containing fragments, and the thorough knowledge of the chemistry of the phosphorus-stabilised carbanions.

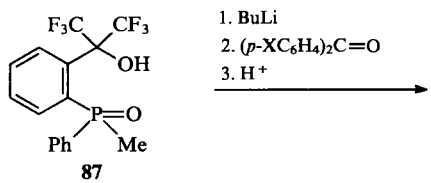
The data presented in this section reveal the exceptionally wide prospects for the employment of phosphacyclanes in stereospecific organic and organoelement synthesis. The relatively high availability of the cyclic organophosphorus compounds functionalised in the endocyclic fragment, the possibility of varying the composition and steric structure of the phosphorus-containing heterocycle, and the very high reactivity of the compounds discussed here — all these properties leave no doubt that this field of the chemistry of cyclic organophosphorus compounds has a great future.

IV. σ^5-Mono- and diheterophosphacyclanes

Derivatives of pentacoordinate phosphorus have played an important role in the development of the chemistry of organophosphorus compounds. The problem of the synthesis of substances of this type with a hypervalent central atom, questions concerning the electronic and steric structures, the chemical transformation of phosphoranes, and the role of pentacoordinated intermediates in the reactions of organophosphorus compounds — these and other questions of the theoretical and synthetic chemistry of phosphorus continue to remain in the centre of attention of investigators. Among the recent review publications devoted to problems of the synthesis and properties of σ^5-phosphacyclanes, mention may be made of those of Kumaras et al.[105] and Gloede.[106] Attention should also be drawn to the experimental studies which have revealed the role of σ^5-1,3,2-dioxaphospholane intermediates in biological processes associated with phosphate transport (see, for example, Kluger and Taylor[107] and Breslow et al.[108]).

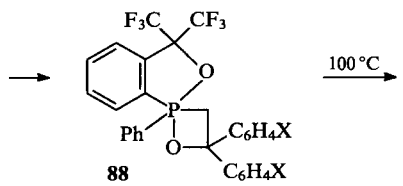
The introduction of a σ^5-phosphorus atom into a monocyclic and especially a spirocyclic system favours the stabilisation of phosphoranes. The recognition of this fact promoted the concentration of the efforts of chemists in the search for new reagents containing a pentacoordinate phosphorus atom as well as various complex functionalised compositions, which in the course of reactions give rise to σ^5-P compounds participating in a particular chemical operation.

The synthesis of σ^5-phosphacyclanes, modelling the intermediates in the most important reactions of organophosphorus compounds, for example hydroxyphosphoranes (intermediates in nucleophilic substitution at a tetrahedral phosphorus atom)[16] or 1,2-oxaphosphetanes (substances postulated as intermediates



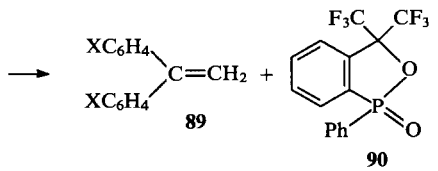
in the HWE and Wittig reactions)[109] assumed a particular importance. The synthesis and study of the transformations of the above substances have not only thrown light on their reaction mechanisms, but also made possible a specific approach to the selection of the optimum reagents and conditions for reactions with their participation in order to obtain complex organic substances, including natural products.

1. σ^5-1,2-Oxaphosphetanes and σ^5-1,2-oxaphospholanes



As already stated, the four-membered 1,2-oxaphosphacyclanes have been postulated as intermediates in reactions giving alkenes with the aid of Wittig reagents or α-phosphorylated carbanions. However, attempts to isolate and identify these substances, produced in the course of reactions involving conversion into alkenes, were unsuccessful for a long time: in the best case, it was possible to detect them by various spectroscopic methods.[110-113]

However, stable 1,2-oxaphosphetanes have been isolated recently and their thermal decomposition reactions, modelling the second stage of the HWE and Wittig reactions, have been investigated.[114,115,117-120]

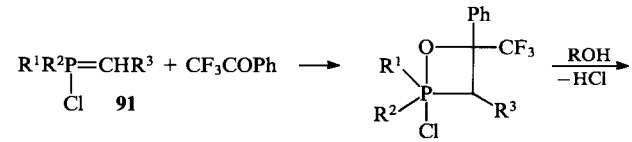


Successive treatment with butyllithium, diaryl ketones, and acids of the phosphine oxide **87**, containing the so called Martin's ligand[114,116] (acyclised aromatic ligand stabilised as a result of spirocyclisation as well as other unstable σ^5-P compounds, for example hydroxyphosphoranes[16]) together with the phenyl and methyl ligands makes it possible to obtain the stable spirocyclic 1,2-oxaphosphetanes **88**.

87

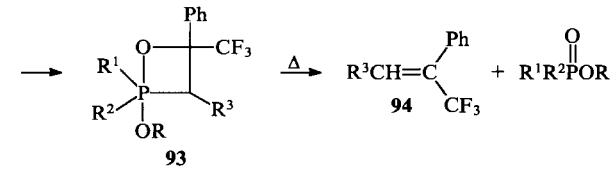
88

89 **90**



The phosphacyclanes **88**, which are entirely stable under the usual conditions (which has made it possible to establish their structure by X-ray diffraction[114]) are converted quantitatively on heating to 100 °C into 1,1-diarylethenes and the phosphinates **90** in accordance with the mechanism of the second stage of the Wittig and HWE reactions.

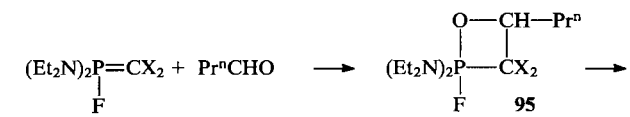
According to the Hammett equation, the rate of the decomposition reaction is

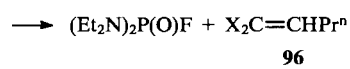


$$\lg(k/k_0) = -0.709(2\sigma_p^+) \qquad (r = 0.999),$$

with a negative reaction constant ($\rho = -0.709$), indicating the accelerating effect of the electron-donating substituent X. The relatively low sensitivity of the rate of decomposition to the polarity of the medium, the low negative activation entropy ($\Delta S^{\neq} = -5.7 \pm 0.75$ e.u.) and the small (in absolute magnitude) value of ρ indicate a concerted mechanism of the decomposition of compound **88** with a weakly polar transition state (slight asynchronicity in the dissociation of the P–C and C–O bonds in the oxaphosphetane fragment).

Stable 1,2-oxaphosphetanes **92** have been obtained by Kolodyazhnyi and coworkers[115,117] by the reaction of phenyl trifluoromethyl ketone with the halides **91** under very mild conditions (ether, 0 °C).

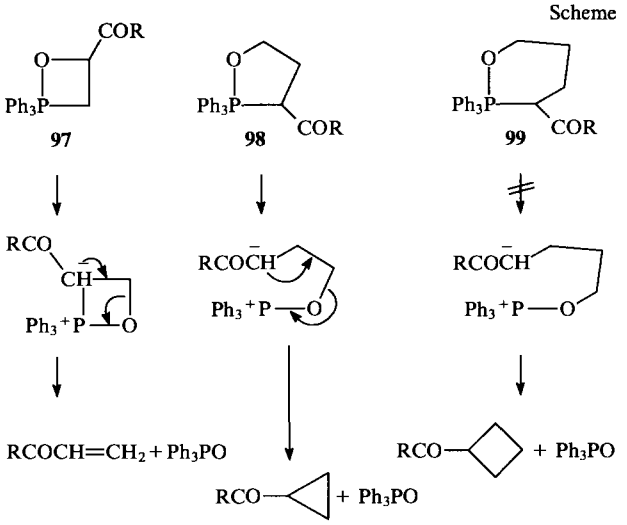




92

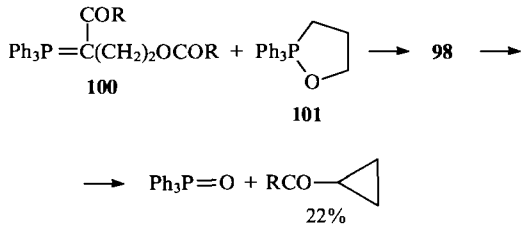
93 **94**

The chlorine atom in the chlorophosphinomethylene **91** is readily replaced by an ether group on treatment with methanol or phenol, while the 1,2-oxaphosphetanes **93** decompose on heating to the alkenes **94** and the corresponding phosphinates in accordance with the mechanism of the Wittig reaction. It is of interest that their precursors—2-halo-1,2-oxaphosphetanes **92**—do not exhibit a tendency to eliminate alkenes and on thermolysis as a rule undergo fragmentation with formation of the corresponding phosphorus-containing acyclic alkenes. The *P*-fluorophosphetanes **95**, decomposing to the *gem*-dihalide **96** and phosphorofluoridic diamides, constitute an exception.[118-120]



96

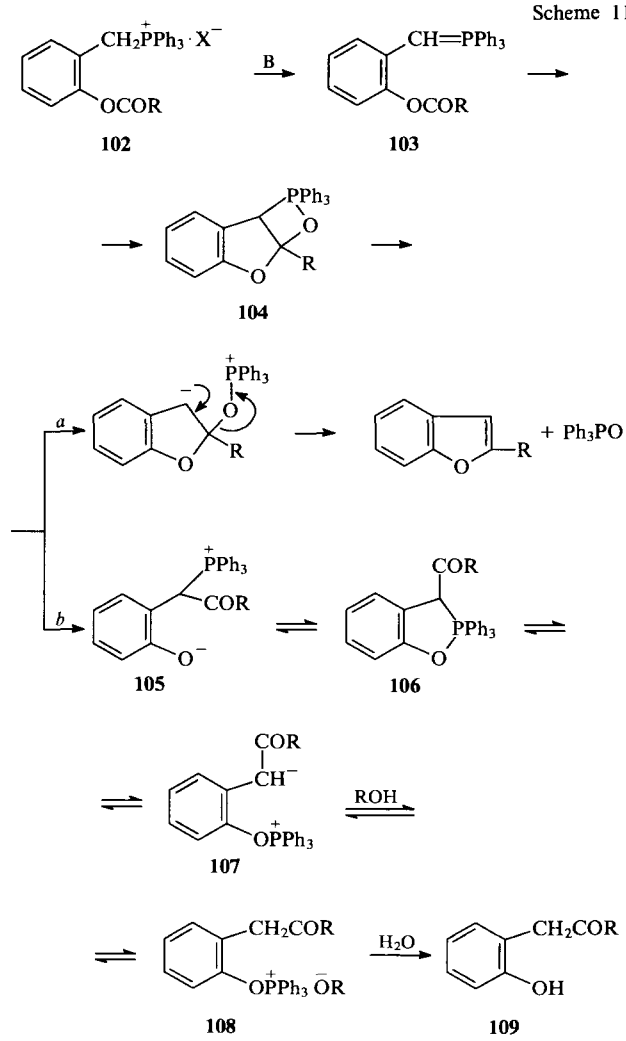
It has been postulated[119,120] that the electronegative atoms X favour the migration of the dihalomethylene group (and not of the oxygen atom) to the axial position in the phosphorane **95**, which results in the dissociation of the P–C (and not P–O) bond.



The conditions and nature of the decomposition of 1,2-oxaphosphacyclanes as well as the synthetic result of the fragmentation of the heterocycles depends significantly, other conditions being equal, on the size of the phosphorus–oxygen heterocycle.[121] The triphenyloxaphosphetanes **97** readily decompose in accordance with the general mechanism corresponding to the second stage of the Wittig reaction. The alkene is then produced more readily the more pronounced are the electron-accepting properties of the ring substituents (in this case, these are acyl or alkoxycarbonyl groups) (Scheme 10). It has been suggested[121,122] that the decomposition proceeds via a stage involving the open-chain phosphonium-carbanionic form of the intermediate, which results in the formation of a α,β-unsaturated ketones (for a phosphorane with an acyl substituent) and a phosphine oxide.

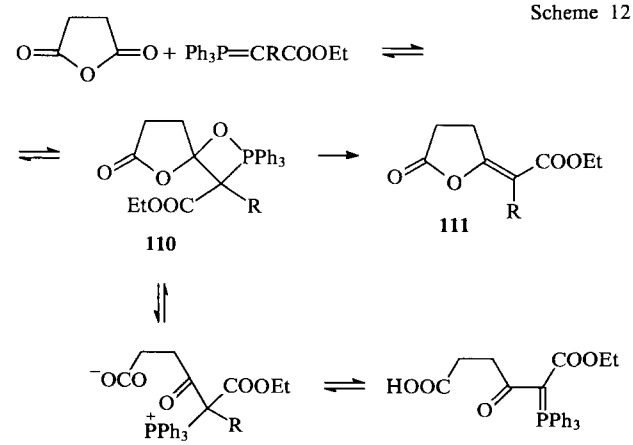
Scheme 10

The thermal decomposition of the 1,2-oxaphospholanes **98** to cyclopropyl ketones is achieved only in the presence of electron-accepting ring substituents, the unsubstituted ring being stable. The 1,2-oxaphosphorinanes **99**, even those containing electron-accepting substituents, are stable under the reaction conditions and do not decompose to cyclobutanes. It is believed [121] that these experimental results are influenced mainly by ring strain. These data are satisfactorily consistent with a repeatedly established fact — an increase in the chemical and thermal stability in the following series of phosphacyclanes: four-membered < five-membered < six-membered. [16]



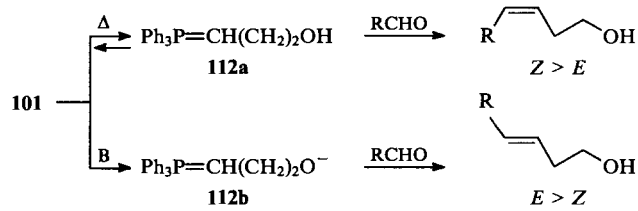
It is of interest that the cyclopropyl ketone can be obtained also as a result of the intermolecular transfer of the acyl group from the ylide **100** to the unsubstituted oxaphospholane **101**; the intermediate acyl-1,2-oxaphospholane **98** gives rise to the cyclopropyl ketone in 22% yield.

It has been established that the proton-donating properties of the medium can also determine the synthetic result of the decomposition of 1,2-oxaphosphetane. [123] Thus the intermediate four-membered tricyclic phosphorane **104**, obtained from 2-acyloxybenzylidenetriphenylphosphonium ylide **103** (which was in its turn obtained from the phosphonium salt **102**) decomposes in inert solvents to benzofurans via path *a* in accordance with an intramolecular acylation mechanism (**103** → **104**) (Scheme 11).



In proton-donating solvents (alcohols), the process proceeds with the successive cleavage and closure of rings via the phosphonium (compound **105**), benzophosphorane (compound **106**), and zwitterionic (compound **107**) intermediates. On treatment with alcohols, the last intermediate gives rise to the quasi-phosphonium salt **108**, the hydrolysis of which led to the isolation of the ketone **109** (Scheme 11, path *b*).

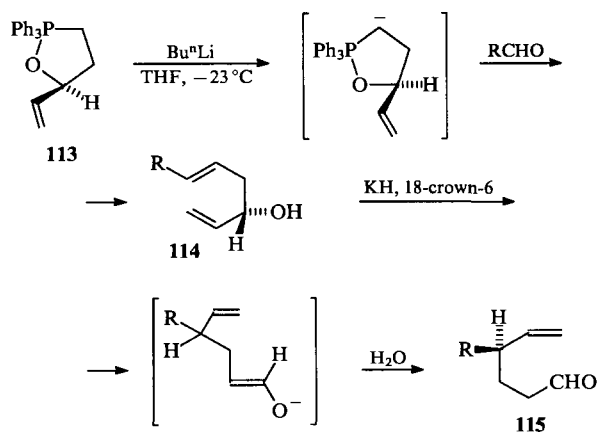
Scheme 11



Increase in ring strain in systems incorporating the 1,2-phosphetane fragment naturally facilitates the decomposition of the intermediates in the Wittig or HWE reactions to the corresponding alkenes. The very unstable phosphacyclane **110**, obtained in the course of the conversion of succinic anhydride into an alkene by treatment with an ylide, may be stabilised not only via elimination of the alkene **111** but also as a result of rearrangement to the open-chain phosphonium (for R = H, Me) or ylide (for R = H) organophosphorus intermediates in the alkene formation reaction (Scheme 12). [124]

Scheme 12

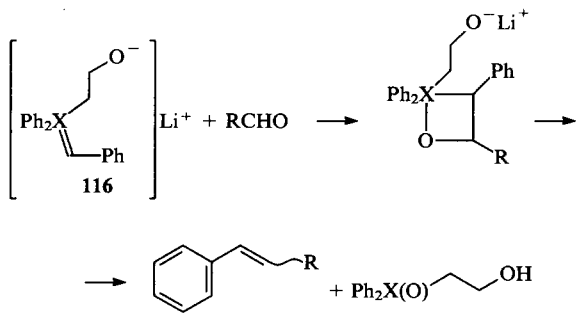
R = H, Me.



The data presented in this subsection and also in Subsection 2 indicate the relatively easy heterolysis of the phosphorus–oxygen and phosphorus–carbon bonds not only in the strained σ^5-1,2-oxaphosphetane ring but also in the σ^5-1,2-oxaphospholane ring. It has been established that the latter can be regarded as a latent ylide, which suggests that compounds of this series have the capacity to effect conversions into alkenes with the postulated involvement of the open-chain γ-oxido(hydroxy)ylide tautomeric form **112**. Furthermore, it has been shown in a series of studies [125–127] that the method of generation of the ylide **112** from the 1,2-oxaphospholane **101** determines to a significant extent the stereochemical result of the conversion of aldehydes into alkenes: the process whereby homoallyl alcohols are obtained as a result of the thermolysis of a phosphacyclane exhibits (*Z*)-selectivity and, in the presence of bases, (*E*)-selectivity.

The hydroxy-ylide **112a**, generated thermally from compound **101**, affords the (*Z*)- and (*E*)-alkenols (the ratio *Z* : *E* = 73 : 27 for R = Ph and 88 : 12 for R = C_6H_{11}) in the presence of benzaldehyde. The γ-oxidoylide **112b**, obtained by treating compound **101** with lithium bases, for example with $LiN(SiMe_3)_2$, gives rise to the (*E*)-stereoisomer in a mixture in which its content is high: *Z* : *E* = 4 : 96 (R = Ph) and 45 : 55 (R = C_6H_{11}).

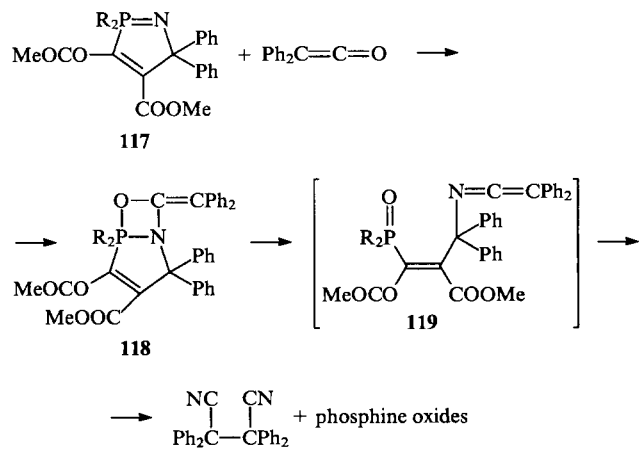
As in the HWE reactions, in the cases described the stereochemical result of the alkene formation process is determined by the combined influence of a large number of factors, which determine the conditions governing the formation and interconversion of the zwitterionic and 1,2-oxaphosphetane intermediates. The nonstabilised ylides in the Wittig reactions are usually characterised by a high (*Z*)-stereoselective activity; [2] the anomalous (*E*)-stereoselectivity, noted above, of the ylides generated from phosphacyclanes can be explained, apart from all other factors, by the effect of the ω-nucleophilic groups in the ylide **112**. [127]



The approach thus developed to the *trans*-selective synthesis of alkenes has been extended to 5-vinyl-1,2-oxaphospholanes **113**, which were found [128] to react with benzaldehyde to form the phenyldienol **114** (R = Ph) with the isomer ratio *trans* : *cis* = 9 : 1.

The ratio of the stereoisomeric *cis*- and *trans*-dienes **114**, obtained from aliphatic aldehydes (R = alkyl), is close to the equilibrium value. It has been noted [124] that 3-hydroxy-1,5-dienes of type **114** are extremely valuable synthons in the synthesis of natural products such as leukotriene B and prostaglandins.

In a highly basic medium (potassium hydride in the presence of a crown-ether), the hydroxydiene undergoes the Cope rearrangement to the unsaturated aldehyde **115**. Thus the above method makes it possible, as it were, to introduce a further two carbon atoms at the carbonyl carbon atom of the initial aldehyde and suggests an approach to the synthesis of the hexenal substrates **115** via the 3-hydroxy-1,5-diene stage.

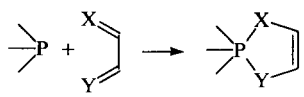


The ω-hydroxy-ylide *trans*-selectivity, described above, of the Wittig reaction proceeding via a stage involving the formation of a 1,2-phosphetane has found an interesting conformation when arsenic ylides were employed. [129] The β-oxidoylides **116** convert hexanal and piperonal into alkenes with different degrees of stereoselectivity depending on the nature of the central atom X: the ratio of the isomers of the substituted styrenes is *E* : *Z* = 70 : 30 for the phosphorus ylides **116** (X = P). The corresponding arsenic ylide **116** (X = As) ensures a highly selective synthesis of the (*E*)-alkene (100%).

X = P, As.

These results enabled Boudia et al. [129] to recommend arsenic ylides as alkene-forming reagents for the stereoselective synthesis of (*E*)-alkenes.

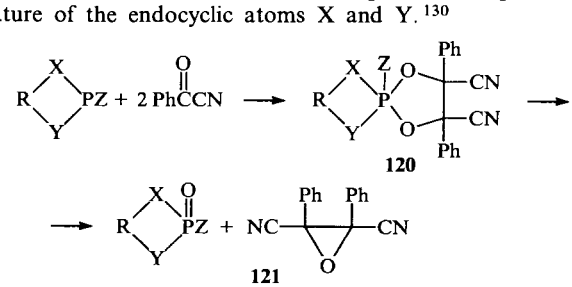
In conclusion of this Subsection, we shall draw attention to the unusual decomposition of the bicyclic adduct **118** obtained in a study of the 'phosphoroimine' version of the Wittig reaction between the azaphosphole **117** and diphenylketene. [130]



The spirocyclic 1,3,2-oxazaphosphetanes **118** (R = Me, Ph) isolated, which are stable in the crystalline state, decompose in chloroform at 48 °C in several minutes. However, contrary to expectations, the product of the intramolecular imination cannot be isolated. Instead of the latter, tetraphenylsuccinonitrile is obtained in 73% yield together with unidentified phosphorus-containing substances, tentatively assumed to be of the phosphine oxide type. It is believed that this reaction course is associated with the homolytic decomposition of compound **119**, characteristic also of other ketene imines, [130] and with the recombination of diphenylcyanomethyl radicals.

2. Thermolysis and solvolysis of 1,2-hetero- and 1,3,2-dihetero-phosphacyclanes and 1,2-hetero- and 1,3,2-dihetero-phosphacyclenes

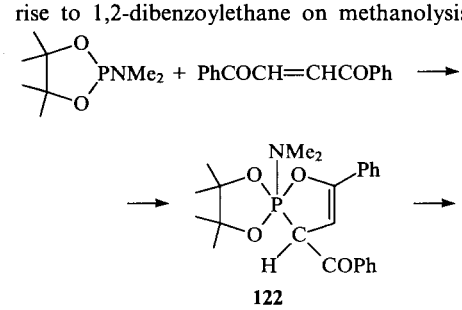
Reactions of the above type play an important role in the strategy for the employment of cyclic reagents containing σ^5-P in organic synthesis. The relative thermodynamic lability of σ^5-1,3,2-diheterophosphacyclanes, the pronounced Lewis acidity of the σ^5-P atom and the associated high reactivity of phosphoranes in nucleophilic substitution reactions are factors which have determined the choice of the substances described here for the synthesis of a wide variety of complex organic compounds. Without claiming to cover fully all the examples of the use of thermal and solvolytic processes with participation of 1,3,2-diheterophosphacyclanes for the synthesis of phosphorus-free substances, we shall draw attention to the thoroughly investigated processes involving the fragmentation of σ^5-dioxaphospholane functional groups in compounds of hypervalent phosphorus[2,16,17] and also to the 'enediol-phosphorane' strategy for the synthesis of hydroxycarbonyl substances developed by Ramirez and coworkers.[131,132] A detailed consideration of these interesting chemical reactions is outside the scope of the problems covered by the present review, but has been thoroughly described in the literature sources mentioned above.



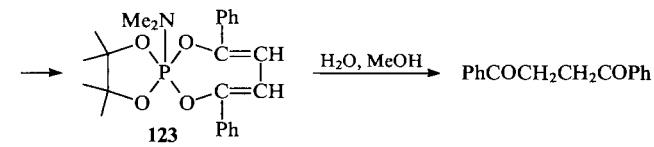
At the same time, new data have appeared during the last decade concerning the use of the thermal and solvolytic reactions of σ^5-1,3,2-diheterophosphacyclanes, mainly phospholanes and phospholenes, which are either specially synthesised for particular synthetic purposes or are formed as key intermediates in the multistage syntheses of polyfunctional organic compounds. Information about the role of pentacoordinated intermediates has been presented in a review;[16] only two examples of this kind, characterising the features of the application of the phosphorus-containing functionalising substances under discussion, are presented here.

One of the common synthetic procedures involving the use of the functionalising activity of phosphacyclanes is the thermal or solvolytic fragmentation of σ^5-1,3,2-dihetero- or σ^5-1,2-heterophoshacyclenes obtained from phosphorus(III) derivatives and α,β-unsaturated, α-dicarbonyl, diene, and similar synthons, which undergo [1 + 4]-cycloaddition with one another.

When subjected subsequently to thermal influences or entering into nucleophilic substitution reactions, as a rule with proton-containing nucleophiles, the σ^5-P adducts 'liberate' the carbon component of the ring and are converted into phosphoryl or similar reaction products.



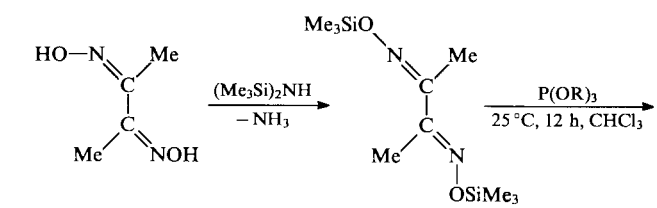
The phosphoranes **120**, which are obtained by the reaction of phosphorus(III) precursors with benzoyl cyanide, are fairly readily converted into the epoxides **121** on heating. The alkylenedioxy-analogue **120** (R = CH_2CH_2, X = Y = O) is fairly stable and decomposes on heating above 100 °C.[133,134] The diazaphospholane **120** (R = CH_2CH_2, X = Y = NMe) gives rise to an epoxide after being heated for 2 h at 80 °C and after being kept at room temperature for a long time. It has been noted that the *cis* : *trans* ratio of the isomers of compound **121** depends on the nature of the endocyclic atoms X and Y.[130]



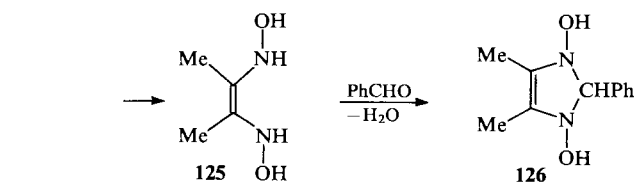
120

121

On treatment with proton nucleophiles, σ^5-1,3,2-diheterophosphacyclenes can decompose with formation of saturated organic products. Thus the spirocyclic aminophosphorane **122**, obtained from a phosphoramidite and 1,2-dibenzoylethene, gives rise to 1,2-dibenzoylethane on methanolysis.[135]



122

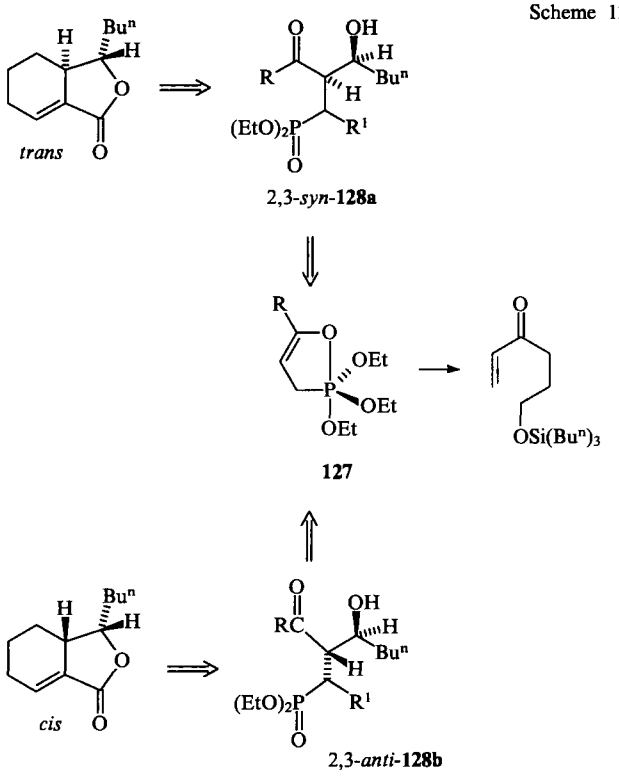


123

It has been established that under mild conditions the spirophosphorane **122** is converted into the σ^5-P-amide **123** containing a seven-membered ring. The amide actually fragments with cleavage of the phosphadiene ring. This unusual hydrogenation of an unsaturated diketone with the aid of water or methanol is based on the rarely encountered isomerisation of a five-membered ring to a seven-membered ring (**122** → **123**).

The hydrogenation on solvolysis of phosphacyclanes has been used to synthesise *cis*-2,3-bis(hydroxyamino)butene **125**.[136] Diacetyl dioxime is silylated, after which it is converted by reaction with phosphite into the phosphoranes **124** and these are hydrolysed, affording the butene **125**.

124

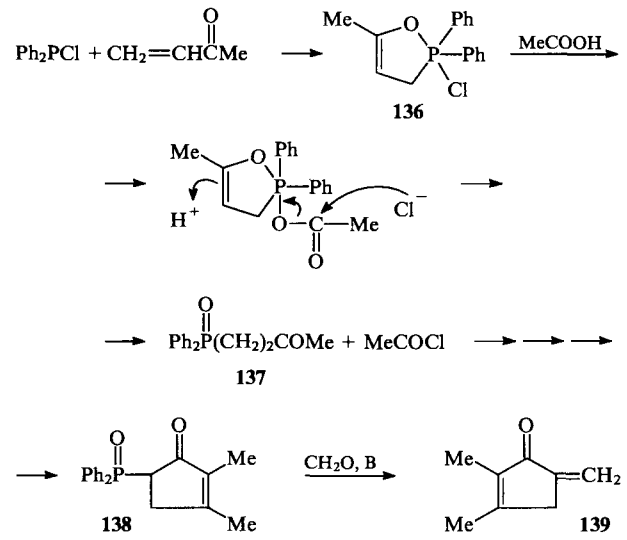


125 **126**

It has been shown that compound **125** can serve as a chelating ligand or as a precursor or nitrogen heterocycles; it readily gives rise to the imidazoline **126** on reaction with benzaldehyde.

The product of the [1 + 4]-cycloaddition of a α,β-unsaturated silylated ketone has been chosen as the key synthon in the synthesis of (+)-*trans*- and (+)-*cis*-neoknidylides.[133,134] Retrosynthetic analysis (Scheme 13) made it possible to develop a strategy for the synthesis of these natural products, including the formation of the highly substituted phosphonates **128a**, **b** and their conversion into the target products using the intramolecular HWE reaction.

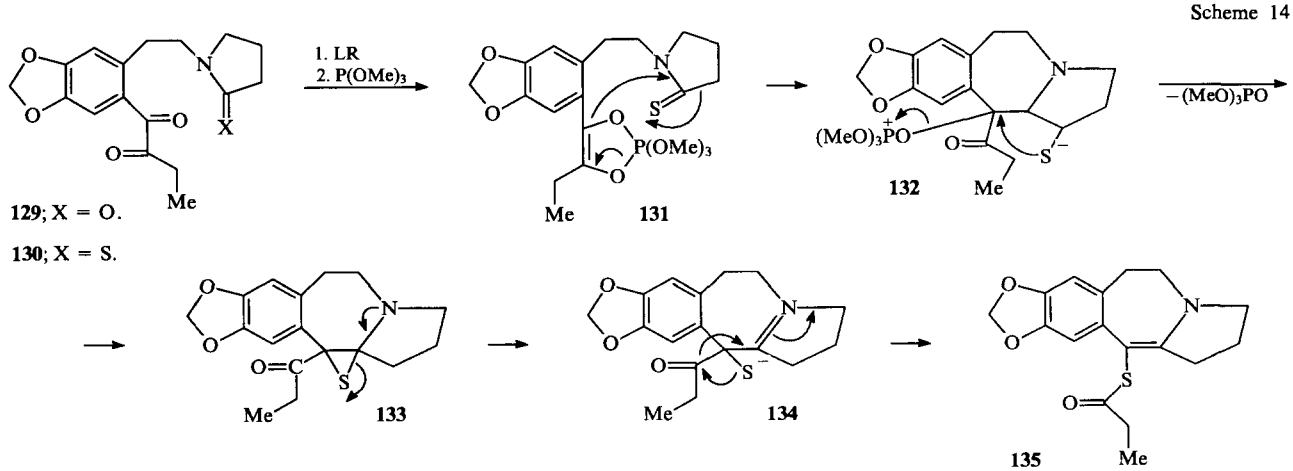
Scheme 13



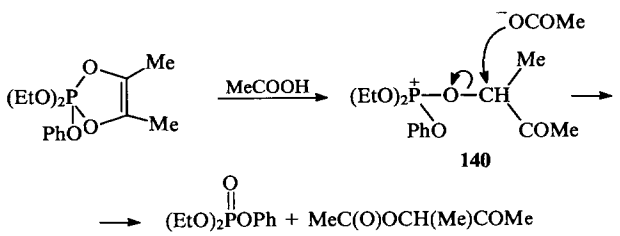
R = $(CH_2)_3OSi(Bu^n)_3$.

The above investigators used successfully the transformation of the 1,2-oxaphospholene **127** in order to synthesise biologically active natural products with the phosphonate structure.[138-140]

The ease of the closure and cleavage of the dioxaphospholane ring has been used for an unusual functionalisation in one of the stages of the total synthesis of natural benzoazepine derivatives of dihydroquinolines—chilenine and digallanezine (Scheme 14).[141] The closure of the benzoazepine ring **129**→**135** is attained by employing two organophosphorus reagents. The diketo-derivative of the γ-lactam **129** is converted into the γ-thiolactam **130** on treatment with Lavesson's reagent and the thiolactam is then converted into the 1,3,2-dioxaphospholene with the aid of trimethyl phosphite. The phosphorane **131**, identified on the basis of ^{31}P NMR spectroscopic data, undergoes a complex transformation under fairly severe conditions (refluxing of the phosphite) involving the closure to a seven-membered ring **131**→**132**, the substitution of trimethyl phosphate by a thiolate anion, the cleavage of the episulfide ring **132**→**133**, and finally the C→S propionyl shift with formation of the required polycyclic system **135**.

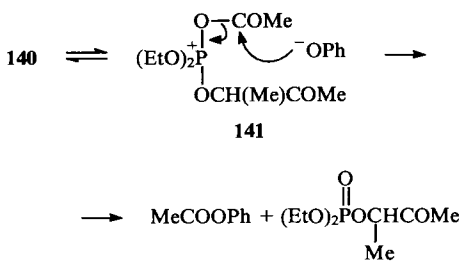


Cyclic phosphoranes—adducts formed in cycloaddition reactions—have been used also as precursors for the preparation of acyclic HWE reagents for subsequent use in the synthesis of natural products. Thus it has been shown[142] that the oxaphospholenes **136** can be conveniently employed for the synthesis of the β-ketophosphonates **137** by a reaction involving the cyclisation of compound **136** and subsequent deacylation.

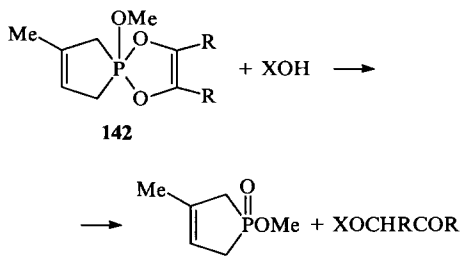


By means of a series of transformations in the aliphatic fragment, the phosphorylated ketone **137** has been converted into the phosphorylated cyclic enone **138**—the precursor of methylenomycin B **139**—a substance belonging to the family of the cyclopentanoid antibiotics. It is emphasised[138] that the 'phosphonate' strategy for the synthesis of compound **139** is convenient in view of the possibility of monitoring with the aid of ^{31}P NMR spectroscopy all the phosphorus-containing intermediates formed during the process.

The addition of α,β-unsaturated carbonyl and α-dicarbonyl compounds to phosphorus(III) substrates with the intermediate formation of 1,2-oxa- and 1,3,2-dioxa-phospholenes followed by the solvolytic cleavage of the five-membered phosphorus heterocycle constitutes in essence a synthetic route to products of the addition of proton nucleophiles to the unsaturated fragments of the initial 1,4-heterodiene. The functionalisation with the aid of acetic acid of the latent diacetyl to give α-acetoxyethyl methyl ketone (Scheme 15), which is similar to the 'hydrogenation' of unsaturated ketones or the dioxime examined above, has been described.[143]

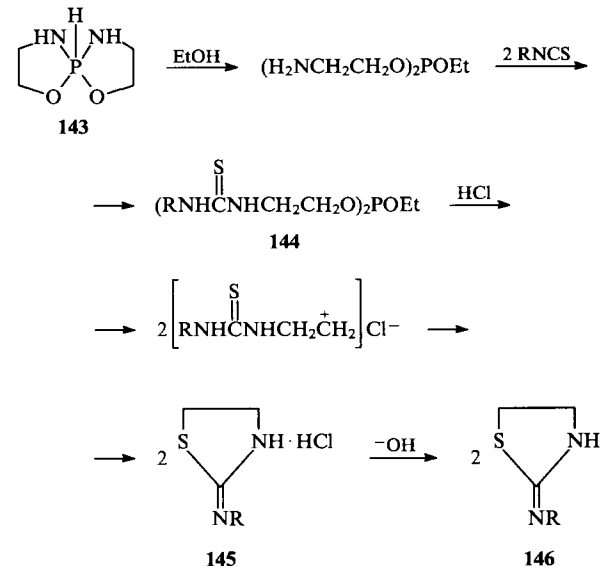


Scheme 14

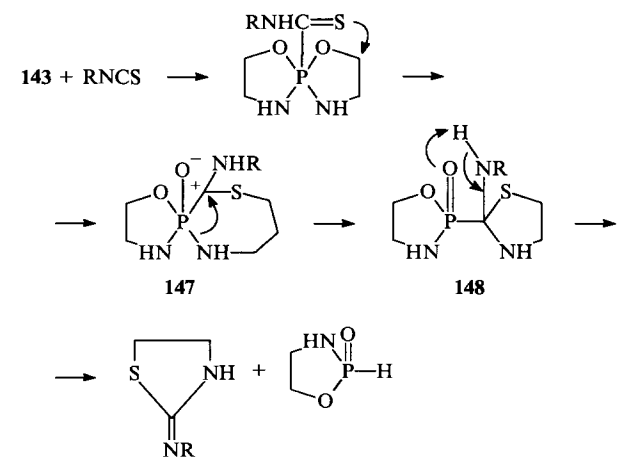


Scheme 15

The reaction is complicated by the dealkylation of the quasi-phosphonium salt **140** not only as a result of nucleophilic attack on the methylidyne carbon but also a result of the abstraction of the ethyl group. Furthermore, the ligand exchange **140**→**141** and deacylation by the phenoxide anion constitute an alternative route, which complicates the possible preparative use of the reaction described.

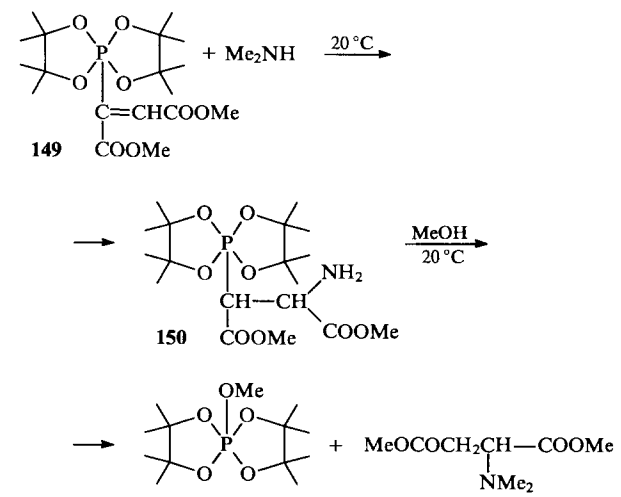


The enediol-phosphorane **142** (R = Me or Ph) is smoothly converted into the ketoalcohol (X = H) or α-acylated ether (X = Me) on decomposition of the dioxaphospholene ring as a result of hydrolysis or methanolysis.[144]



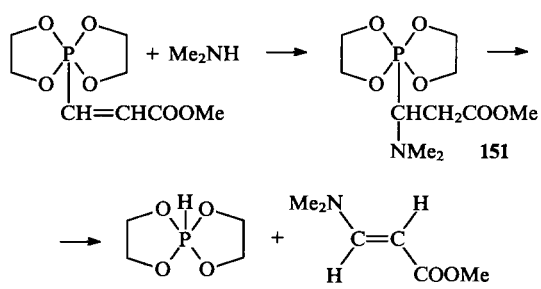
R = Me, Ph; X = H, Me.

As already stated, solvolysis accompanied by the dissociation of the phosphorus–heteroatom bond in saturated phosphacyclanes usually leads to phosphorus-containing acyclic substances. This renders even more unusual the reaction of spirocyclic oxazaphospholanes **143**, occurring when alkyl or aryl isothiocyanates are acted upon by σ^4-PH acids.[145,146] In alcohols, the process proceeds with dissociation of endocyclic phosphoramide bonds. The functionalisation of β-aminoethyl groups and acidolysis of the adduct **144** lead to phosphorus-free salts **145**, while 2-(phenylimino)thiazolidines **146** are formed when the system is rendered alkaline. The reaction proceeds under very mild conditions (25–30 °C) and involves the unusual dissociation of the C–O (and not P–O) bond in the intermediate phosphite **144**.[141]

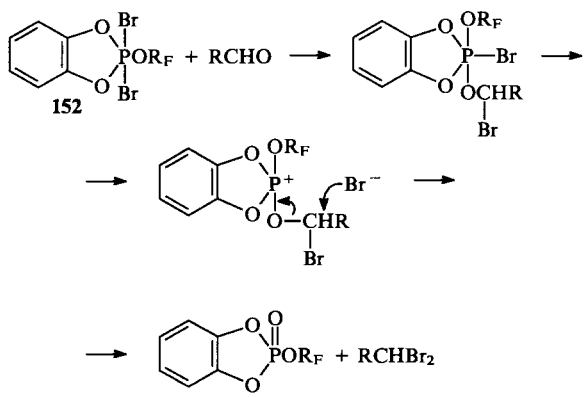


The same process, but this time requiring a higher temperature (80–100 °C), can be carried out also in aprotic solvents. The authors suggest[146] that in this case the process involves the addition of P–H to the isothiocyanate fragment and the rearrangement of the adduct with expansion of the ring to compound **147** caused by intramolecular *S*-alkylation. The endocyclic dissociation of the P–N bond and proton transfer in the intermediate **148** entail fragmentation to thiazolidines and unidentified cyclic hydrophosphoryl products. Two and one

alkylene-1-oxy-2-amino-fragments are involved in this reaction when the latter is carried out in alcohols and in an aprotic medium respectively.

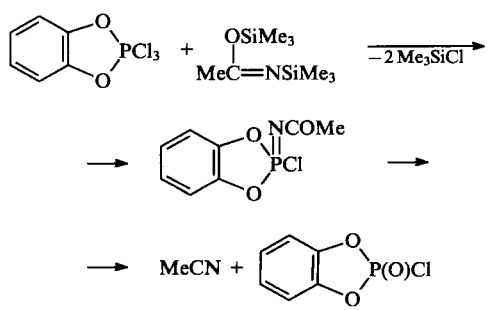


Only a few instances of the solvolysis of spirocyclic phosphoranes with retention of the cyclic skeleton of the phosphorus-containing reagent are known. Thus amination of the unsaturated spirophosphorane **149** and the subsequent methanolysis of the adduct **150** proceed with cleavage of the strong exocyclic P–C bond to give an aminosuccinic acid ester.[147]



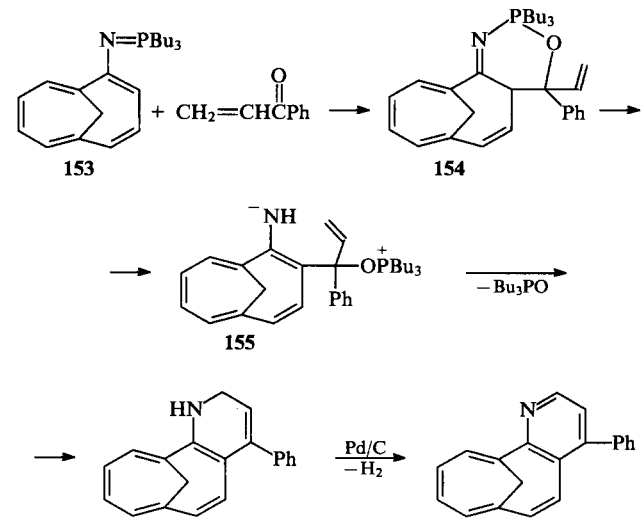
This rare example of the stability of the more labile ester linkages may be due to a tendency to retain the spirocyclic system, which, together with the tendency of oxyphosphoranes to be converted into a product with a phosphoryl group, can also become the driving force of chemical reactions with participation of phosphorus compounds.[15,16]

The exocyclic decomposition of substances of this kind is known also for thermal processes. Distillation of the adducts formed in the amination of compound **151** is accompanied by the formation of β-aminoacrylate. The synthetic result of such a process is a kind of substituton of the phosphaspirocyclane group at the vinyl β-carbon atom in the initial σ^4-P-acrylate.[148]



It is of interest to note that the reactions described in this subsection, involving the participation of unsaturated σ^5-phosphacyclane fragments, namely hydrogenation, the addition of proton nucleophiles, and substitution at unsaturated centres, resemble the unusual chemical behaviour of coordinated alkenes in transition metal π-complexes.[149]

We shall quote several new examples of the synthetic use of trihalo(phenylenedioxy)phosphoranes. The halogenating capacity of such phosphorus-containing reagents is well known.[106,150] However, it is characterised by a low selectivity in reactions with polyfunctional substrates. A new reaction of the phosphoranes **152** (R = $CH_2CF_2CHF_2$) with aliphatic and aromatic aldehydes, which proceeds via the insertion of the carbonyl group in the σ^5-P–Br bond and is completed by the *gem*-deoxyhalogenation of the initial substrate, has been described.[151]



Several advantages of the use of compound **152** over phosphorus pentachloride or phenylenedioxyphosphorus trichloride have been noted.[151]

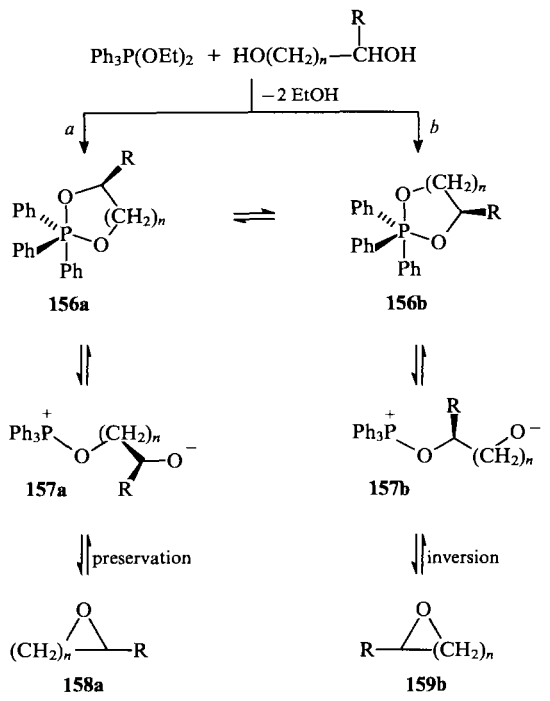
The oxidation-reduction reaction of a halophosphorane with disilylacetamide converts the latter into a nitrile.[152]

A rare case of the use of a latent ketone, bound in the six-membered phosphorus heterocycle, has been described.[153] The [4+2]-cycloaddition of the phosphimine **153** and phenyl vinyl ketone via a stage involving the formation of the adduct **154** and the betaine **155** in the presence of the Pd/C catalytic system leads to the formation of 4-phenyl-7,12-methanocyclodeca[*b*]pyridine.

The unusual regiochemistry of the phosphimine version of the Wittig reaction (cf. compound **118**) is striking in this example: the carbonyl carbon atom is oriented towards and adds to the ring C(2) atom and not to the imine nitrogen atom in compound **153**. The subsequent stepwise decomposition of the adduct **154** is responsible for the unusual design of the target tricyclopyridine.

3. The 'dioxaphospholane' methodology in organic synthesis

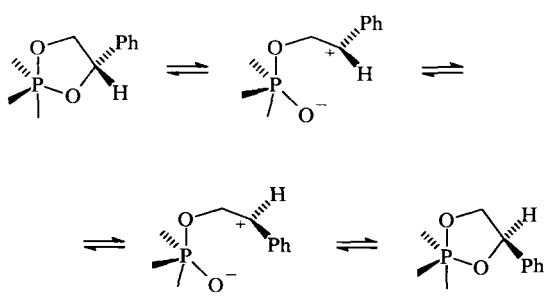
The type of reactions of σ^5-diheterophosphacyclanes described in this subsection is associated with the thermal decomposition of these compounds, which are specially synthesised for the functionalisation of organic substrates. The latter are, as it were, 'introduced' into the composition of the cyclic phosphorus-containing reagent, so that they can be made to undergo particular chemical transformations after phosphorylation. Evans called this approach the 'dioxaphospholane' methodology. It is characterised, as a rule, by high chemo-, regio-, and stereospecificities.



The thermal reactions of phosphoranes have been widely investigated, such studies including those undertaken in order to employ them in fine organic synthesis. Data on the thermal fragmentation of σ^5-phosphacyclanes, published mainly in the 1960s–1970s, are presented in two reviews.[16,154] During the last ten years, the dioxaphospholane methodology has expanded greatly, mainly in Evans' studies, and has served as an effective instrument for the functionalisation of organic compounds, mainly bifunctional substances with mobile hydrogen atoms.

Acyclic phosphoranes—pentaethoxyphosphorane,[155] bis-(neopentyloxy)triphenylphosphorane,[156] diethoxydiphenyl-polystyrylphosphorane,[157] and the especially widely used diethoxytriphenylphosphorane[158,159]—are extremely effective dehydrating agents which convert α,ω-diols and amino- and mercaptoalcohols into the corresponding oxacyclanes, azacyclanes, or thiacyclanes.

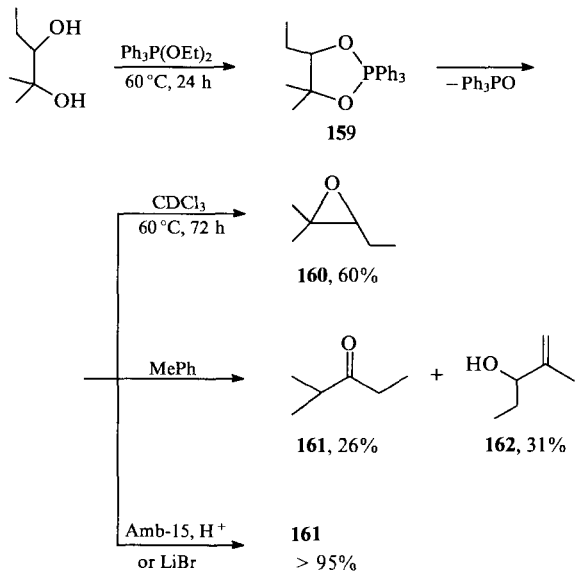
Optically active diols are cyclodehydrated to the corresponding cyclic ethers under relatively mild conditions—monosubstituted diols in 48 h at 40 °C and the sterically more hindered tri- and tetra-substituted diols over the same period but at 80–100 °C.[159,160] The phosphoranes obtained from *cis*-cyclohexane-diols are cyclodehydrated only at



280–300 °C.[159,161] The synthetic result of these reactions has been explained from the standpoint of the transformation of the intermediates having the structure of σ^5-1,3,2-heterophosphacyclanes and of the betaines formed from them (Scheme 16).

Scheme 16

The regioselective distribution of the stereoisomeric ethers formed as a result of the cyclodehydration is associated with the decomposition in the sequence: cyclophosphorane **156**, betaine **157**, and ether **158** and also with the direction of the intramolecular nucleophilic attack by the oxyanion on the α-carbon atom. The preservation of the stereochemistry of the initial diol in the final cyclic product reflects the preferred direction of attack on the unsubstituted carbon atom (path *a*); the reaction via path *b* is more difficult the more bulky the substituents in the initial diol. Under these conditions, the configuration is inverted — the stereochemistry of the initial diol is altered. Attack via path *a* on the unsubstituted carbon atom is effected more readily and this is the reason for the higher content of the stereoisomer **158a** in the products of the cyclodehydration of diols.

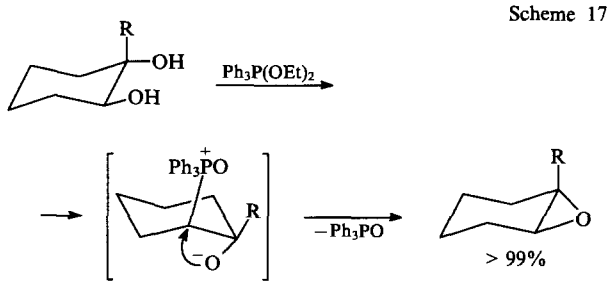


This postulate is in general valid: the regioselectivity of the cyclisation reaction increases with increasing bulk of the substituent R in the diol.[158] However, racemic styrene oxide was obtained in the reaction of (*S*)-(+)-phenylethane-1,2-diol. One of the possible causes of this is the irregular permutational isomerisation of the intermediate phosphacyclanes, which proceeds with dissociation of the C–O bond and not the P–O bond.

This type of isomerisation is due to the presence of favourable factors: the stabilising $(p-d)_\pi$ interaction of the equatorial phosphoryl oxygen atom with the phosphorus atom and of the carbonium ion centre with the phenyl substituent. Such racemisation of phosphoranes is a consequence also of the racemisation of the corresponding betaines and cyclic ethers. This example is quoted in order to demonstrate the stereochemical factors accompanying the synthetic use of the dioxaphospholane methodology.

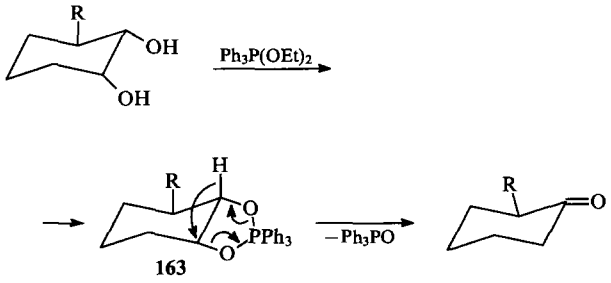
Another extremely important condition governing the usefulness of this methodology in the cyclodehydration reaction is the size of the future oxacyclane. 1,2-Diols give rise in this reaction to alkene oxides in 85%–99% yields, 1,4- and 1,5-diols afford the corresponding five- and six-membered rings in 70%–80% yields, while butane-1,3-diol produces an oxetane with only 3% conversion, i.e. the diol mainly undergoes monoethylation. Similarly, hexane-1,6-diol is converted into oxepane (6%) and ethyl hydroxyhexyl ether (50%).[160]

In certain cases,[160] the conditions governing the decomposition of the key σ^5-1,3,2-dioxaphosphacyclanes are decisive in the reactions of diols, particularly tri- and tetra-substituted diols.



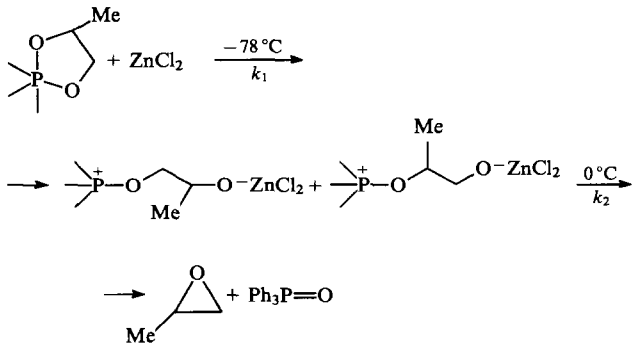
The dioxaphospholane **159**, obtained from 2-methylpentane-2,3-diol, reacts with LiBr (60 °C, 3 days, C_6D_6) to form only 2-methylpentan-3-one **161**; the same reaction in $CDCl_3$ gives 2,3-epoxy-2-methylpentane **160** (60%) as the only product; in toluene (100 °C), the ketone **161** is formed together with 3-hydroxy-2-methylpent-1-ene **162** (31%). The granulated polystyrenesulfonic acid (Amb-15) promotes the formation of the ketone **161**, possibly via the isomerisation of the epoxide **160**. The allyl alcohol **162** is obtained as a result of the intramolecular abstraction of a proton, which leads to the corresponding betaine.

The most unexpected result is the formation of a ketone (in this and other cases), which is associated with the migration of a hydride ion in a type **159** phosphorane or the corresponding betaine.



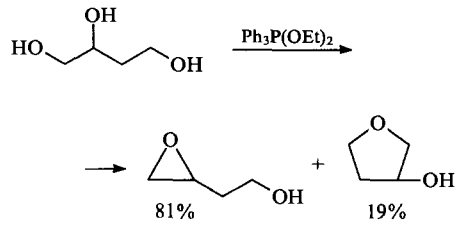
This phenomenon has been studied in detail in relation to cyclohexane- and methylcyclohexane-1,2-diols (Scheme 17).[159,160] The *trans*-diols are converted quantitatively into the corresponding epoxides via the general intramolecular nucleophilic substitution mechanism (the 3-*exo*-*tet*-mechanism[160]).

Scheme 17



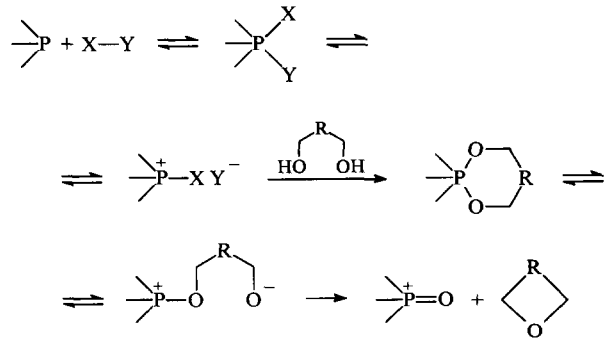
R = H, Me.

The reaction of *cis*-hexane-1,2-diol (boiling dichloromethane, 48 h) with an acyclic phosphorane affords the readily vacuum-distilled 1,3,2-dioxaphospholane **163**.



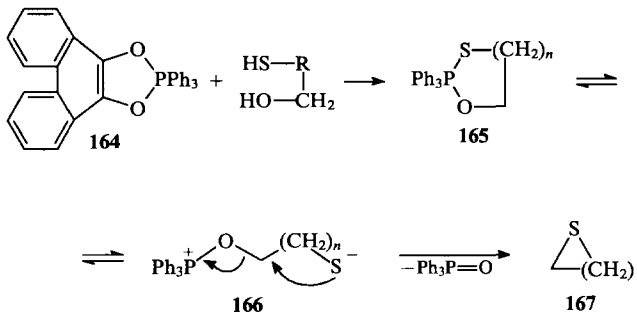
The vacuum thermolysis of compound **163** (220 °C, 15–23 Torr) gives rise to a quantitative yield of a cyclohexanone. The synchronous 1,2-hydride shift in the phosphorane **163** or in the corresponding betaine has been suggested [159,160] to account for the formation of the cyclic ketone.

An increase in the number of substituents in the initial diol promotes the stabilisation of the resulting cyclophosphoranes and a higher temperature is required for their decomposition (> 200 °C), the yield of the target oxacyclanes diminishing. In order to suppress this unfavourable factor, it has been suggested that Lewis acids be employed. [162,163] Thus the cyclodehydration of 1,2-diols in the presence of lithium bromide takes place at room temperature without side reactions, affording oxiranes in a high yield. The stronger Lewis acid $ZnCl_2$ induces the decomposition of the phosphorane to the betaine at −78 °C and cyclisation to the epoxide at 0 °C. This acceleration is caused by the facilitation of the dissociation of the ether bond in the phospholane as a result of coordination of the endocyclic oxygen atom to the Lewis acid; the stabilisation of the oxide (alkoxide?) anion by the acid also favours the overall course of the process.



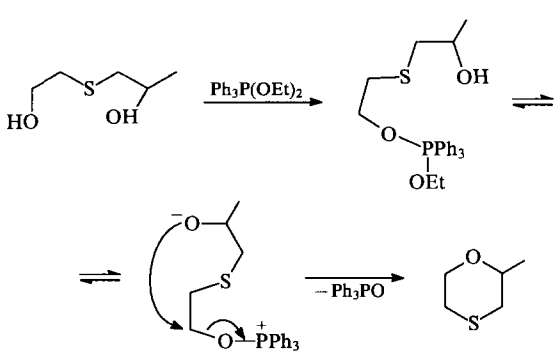
A kinetic study [162] of this process established the irreversibility of the formation of the betaine in the reaction promoted by $ZnCl_2$ ($k_2 \gg k_1$); apart from anything else, [162,163] this determines the stereospecificity of the cyclodehydration in the zinc chloride-induced reaction. The lithium ion, which exhibits a much lower tendency towards coordination, permits the existence of equilibrium between the betaines and the stereochemical result of the reaction is regulated by the relative rates of the intramolecular S_N2 attack by the oxyanion on the α-carbon atom.

The cyclodehydration of triols by means of the 'dioxaphospholane' methodology is a much more complex process because the phosphorylation is then coupled with the chemoselectivity of the hydroxyl involvement of the substrates. [164] In the general case, the formation of five-membered dioxaphosphacyclanes is preferred to the formation of rings of any other size. Thus butane-1,2,4-triol reacts with an equivalent of $Ph_3P(OEt)_2$ to form 3,4-epoxy-1-butanol (81%) and tetrahydro-3-furanol (19%).



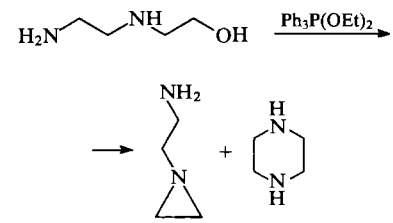
We may note that, as in the case where cyclodehydration is carried out by means of 'combined' phosphorus-containing reagents (PPh_3 + CCl_4; Mitsunobu's reagent), when this methodology is used there is a decrease in the tendency towards the formation of oxacyclanes on passing from three- and five-membered rings to six-membered rings and further to four- and seven-membered rings, which reflects the change in ring strain and cyclisation entropy on intramolecular nucleophilic substitution. [161]

The course of the cyclodehydration of bifunctional organic substrates discussed here may be induced, as already mentioned, not only by oxyphosphoranes but also by two-component condensed systems including phosphorus(III) compounds and organic molecules capable of biphilic interaction with the phosphorus(III) atom — dialkyl peroxides, carbon tetrachloride, and azodicarboxylate. [161,165,166] In all cases, the key intermediates in the cyclodehydration process are cyclophosphoranes obtained by the esterification of the acyclic phosphoranes (phosphonium salts) arising in the two-component system. In this case, the overall mechanism is described by the following sequence of reactions:

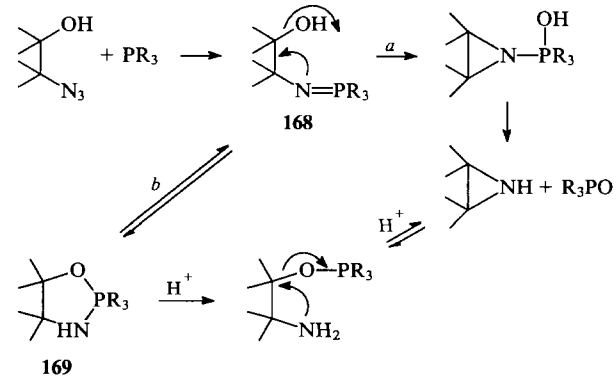


X = Y = OEt; X = Cl, Y = CCl_3; X–Y = ROCON=NCOOR.

Among the effective cyclodehydrating agents, 2,2,2-triphenyl-4,5-(2′,2″-biphenylene)-1,3,2-dioxaphospholane (**164**), which is more stable and convenient to handle than acyclic phosphoranes, merits special attention. The adduct **164** obtained from triphenylphosphine and phenanthrenequinone is stable in inert solvents and is especially effective for the cyclodehydration of mercaptoalcohols to cyclic sulfides.

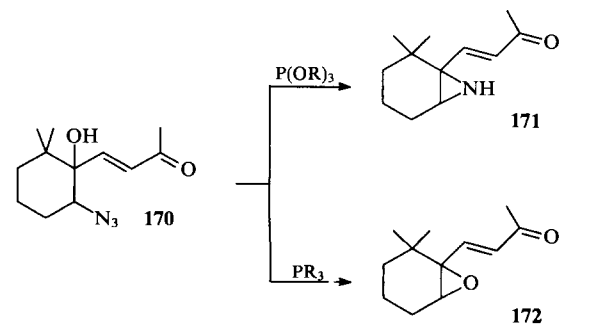


The reaction proceeds in accordance with the general mechanism: the transesterification to σ^5-oxathiaphosphacyclane **165** is followed by intramolecular substitution by the thiolate anion in the betaine **166**, which leads to the thiacyclanes **167** with three-membered (n = 1), five-membered (n = 3), and six-membered (n = 4) rings (yield > 80%). Special mention must be made of the high yield of thietanes (n = 3, 80%) compared with the yield of oxetane (3%), which enabled the authors[166] to emphasise the universality of the dioxaphosphorane methodology involving the use of compound **164**. The compound is also convenient because of the absence of reactions involving the alkylation of diols (mercapto- and aminoalcohols) of the kind occurring in the reactions with $Ph_3P(OEt)_2$. We may also mention the successful employment of this process for the synthesis of 1,4-oxathianes.[167]



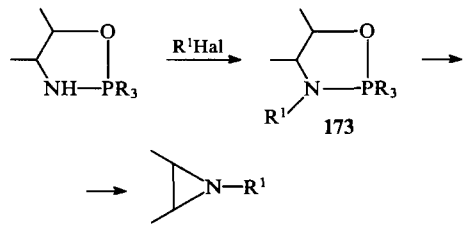
The effectiveness of the 'dioxaphospholane' methodology in cyclodehydration has also been demonstrated by the synthesis from 2-amino-2-benzylethanol and *trans*-2-aminocyclohexanol, with the aid of the phosphacyclene **164**, of the corresponding aziridines in 60% and 71% yields respectively. In this case too, the phosphacyclene was found to have an advantage over $Ph_3P(OEt)_2$, which exhibited only an *N*-ethylating capacity when an attempt was made to cyclodehydrate *trans*-2-aminocyclohexanol — *trans*-2-(*N*-ethylamino)cyclohexanol was obtained instead of the aziridine.[168]

Nevertheless, the use of this methodology in general makes it possible to convert *N*-alkyl- and *N*-aryl-β-aminoalcohols into the corresponding *N*-organylaziridines under relatively mild conditions (60 °C, 24–48 h).[168] This reaction has been noted for its high stereoselectivity — the retention of the configuration of the 'amino'-carbon atom. For example, the enantiomerically homogeneous (*S*)-(+)-2-amino-1-propanol and (*S*)-(−)-2-amino-3-phenyl-1-ethanol are cyclodehydrated with the aid of $Ph_3P(OEt)_2$ to the enantiomerically pure (*S*)-(+)-2-methylaziridine and (*S*)-(−)-2-benzylaziridine respectively (yield 85%).[168] At the same time, the chemoselectivity of the reaction is low: 2-[(2-aminoethyl)amino] ethanol affords a 1 : 1 mixture of aziridine and piperazine as a result of cyclodehydration.



An unexpected feature has been noted for this reaction[168] — the identity of the free energy of cyclodehydration in the formation of three-membered and six-membered nitrogen heterocycles.

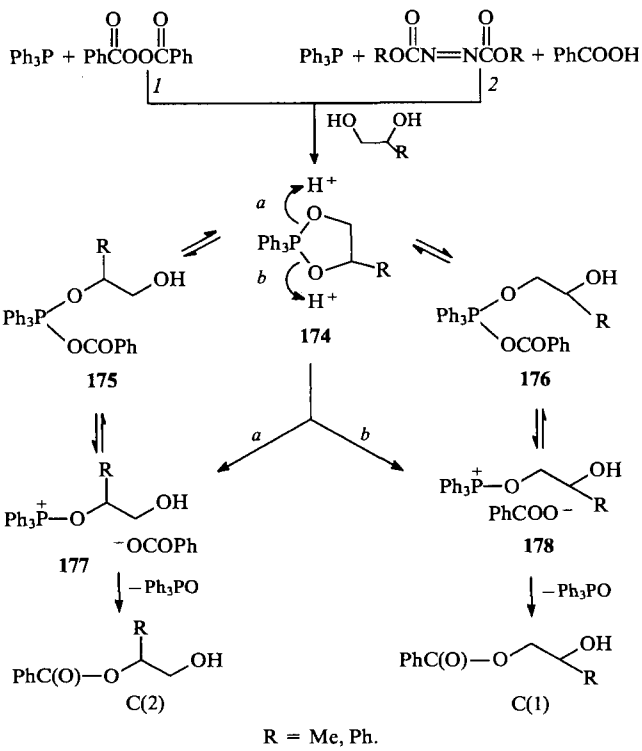
The concept of the appearance–decomposition of σ^5-1,3,2-oxazaphospholanes, which is close to the 'dioxaphospholane' methodology, proved fruitful also in explaining the routes leading to the conversion of azidoalcohols into aziridines on treatment with phosphorus(III) derivatives — triethyl and trimethyl phosphites or triphenylphosphine.[169,170] The process takes place in the presence of water or methanol and leads to aziridines under relatively mild conditions.



According to NMR spectroscopic data, path *b* is preferred because the decomposition of the product of the Staudinger reaction (the imine **168**), bypassing the phosphorane **169**, presupposes the unlikely intramolecular substitution of the hydroxy-group in the phosphimine **168**.[170] When the substituents are chosen appropriately in the initial azidoethanol, it is possible to isolate and identify both the phosphimines **168** and the oxazaphospholanes **169**. Furthermore, the interconversion **168**⇄**169** can be readily detected from ^{31}P NMR spectra.

We may draw attention to a very interesting fact which has not received a sufficiently convincing explanation: the synthesis of the bicyclic aziridine **171** from the corresponding azidohydrin is readily achieved on treatment with trimethyl or triethyl phosphite, whereas tertiary phosphines afford a complex mixture of substances, from which the epoxide **172** has been isolated.[171]

It was shown subsequently[172] that the range of aziridines obtained on fragmentation of σ^5-oxazaphospholanes can be extended by alkylating the endocyclic nitrogen atom with alkyl halides in the presence of strong bases (BuLi, NaH, or KH).

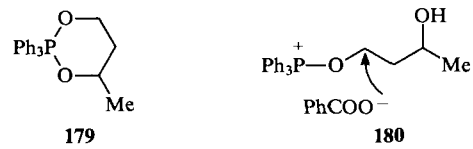


The conversion of compound **173** into *N*-substituted aziridines is facilitated by the addition of acid catalysts.

The key stage in cyclodehydration processes when the methodology under discussion is employed is undoubtedly the intramolecular S_N2 substitution at the α-carbon atom in the quasi-phosphonium intermediate by a thio-, amino-, or oxy-anion. It determines the synthetic (stereochemical result). The synthetic diversity of the reactions carried out using the 'dioxaphospholane' methodology has been achieved by involving 'external' nucleophiles in the reaction. In this case, the substitution of the nucleophilic phosphoryl fragment constitutes in essence the second stage (dealkylation) of the Arbuzov reaction, which, like all S_N2 reactions, takes place with inversion of configuration of the carbon atom. This determines the stereospecificity of the reactions under discussion, but in a number of instances an unusual chemoselectivity of the functionalisation of the organic substrates is observed.

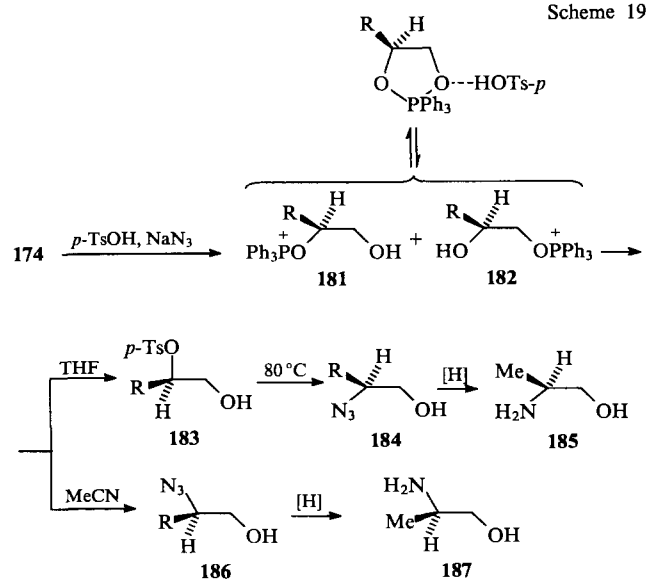
The monobenzoylation of asymmetric 1,2-diols (propane-1,2-diol and 1-phenylethane-1,2-diol) in which two dehydrating systems are employed — triphenylphosphine–benzoyl peroxide (1 : 1) and triphenylphosphine–dialkyl azodicarboxylate (Mitsunobu's reagent) — leads to kinetically and thermodynamically less stable isomers: C(2)-benzoates [C(2) : C(1) = 8 : 1 for methyl-substituted diols and 96 : 1 for phenyl-substituted diols] (Scheme 18).[173–175]

Scheme 18



R = Me, Ph.

The chemoselectivity of the benzoylation of diols can be best explained on the hypothesis of the formation and acid-catalysed decomposition of the same key σ^5-1,3,2-dioxaphospholane intermediate **174** [obtained when acyclic intermediates (not shown in Scheme 18) are esterified by diols] in the oxidative addition of benzoyl peroxide (reaction *1*) or the Mitsunobu reaction (reaction *2*) (Scheme 18).



If it is postulated that the rate-determining stage is nucleophilic substitution by the benzoate ion, a reaction typical of the second stage of the Arbuzov reaction, then preference should be given to path *b* via which the less substituted C(1) centre in compound **178** is attacked. However, the overwhelming advantage of pathway *a* [attack by the benzoate on the C(2) atom] led the authors to the conclusion[173] that the rate-determining reaction path involves the formation of a hydrogen bond between compound **174** and HOC(O)Ph, which takes place more readily for the oxygen atom attached to the unsubstituted C(1) atom. The process therefore takes place via path *a* with S_N2 substitution at the C(2) atom in the ion **177**. The inclusion of the acyloxyphosphoranes **175** and **176** in the scheme has been confirmed experimentally[173] and reflects the sequence of the diol phosphorylation steps with the preferential P-attack on the primary hydroxyl in compound **176**.

A detailed study of the mechanism of the Mitsunobu reaction[174] (reaction *2* in Scheme 18) also made it possible to determine the key role of the cyclic intermediate **174**. An indirect confirmation has been obtained in the benzoylation of butane-1,3-diol. In this case, the attack by the benzoyl group is to a large extent directed to the primary and not the secondary carbon atom, which may indicate that the cyclic six-membered intermediate **179** is not involved in the process. The latter takes place via the acyclic quasi-phosphonium salt **180** in accordance with the mechanism of the Arbuzov reaction.[173]

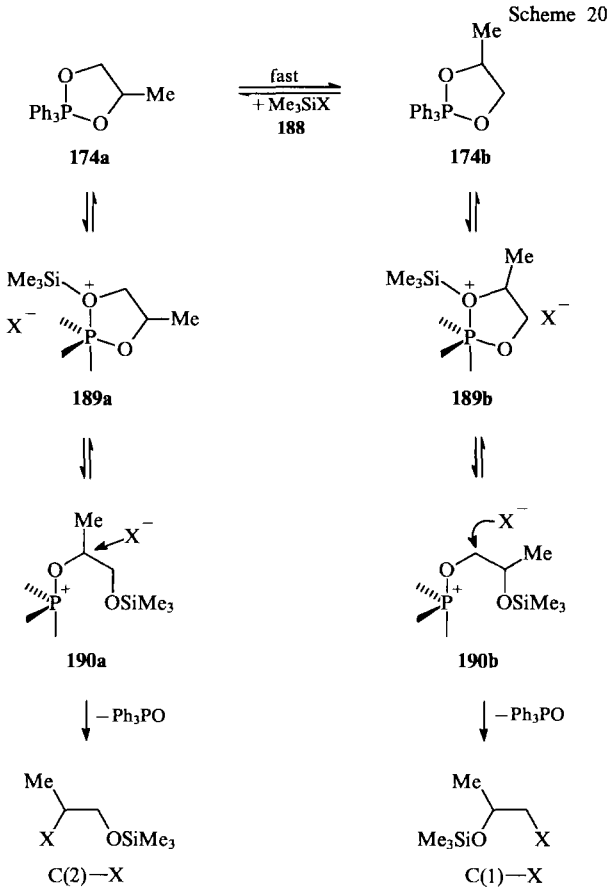
The hypothesis of the selective decomposition of σ^5-1,3,2-dioxaphospholanes by nucleophiles has become the basis of the stereospecific functionalisation, developed by Evans and coworkers,[176–178] of diols, in which the strategy of the regioselective dioxaphospholane methodology is employed. the reaction of σ^5-1,3,2-dioxaphospholane **174** (R = Me)

Scheme 19

with toluene-*p*-sulfonic acid in the presence of sodium azide affords initially the regioisomeric oxyphosphonium ions **181** and **182** in almost equal amounts, the ions being in dynamic equilibrium with the initial phosphorane, detected by ^{31}P NMR spectroscopy at low temperatures (−78 °C) (Scheme 19).[172]

At the usual temperature (25 °C), the sulfonate anion rapidly substitutes the phosphine oxide, affording (*R*)-2-(4-methylbenzoylsulfonyloxy)1-propanol **183** in >95% yield with a high degree of stereospecificity at the C(2) centre. The regioisomer with the tosylate group attached to the C(1) atom was not detected. Heating of the reaction mixture containing NaN_3 (80 °C, 8 h, THF) converts the tosylate **183** into (*S*)-2-azidopropanol **184** with an almost complete inversion of the configuration.

The same reaction in acetonitrile does not produce the sulfonate ester. The azide (*R*)-**186** was obtained instead in 93% yield. In highly polar media, the strongly nucleophilic N_3^- ion wins the competition with the tosylate ion; the substitution **181**→**186** takes place with complete inversion of the configuration at the C(2) centre. The configurational identity of the latter has been confirmed by the hydrogenation of the azides **184** and **186** to the known aminoalcohols (*S*)-**185** and (*R*)-**187** respectively (Scheme 19).



In this case, the experimental results can also be explained satisfactorily on the hypothesis of the initial coordination of compound **174** to toluene-*p*-sulfonic acid with participation of the sterically more accessible oxygen atom at the C(1) centre. This more apicophilic 'complex' oxygen atom is preferentially abstracted from the σ^5-P atom. The oxyphosphonium ion **181** activates the C(2) centre for nucleophilic attack. Thus the stereochemical outcome of reactions involving nucleophilic substitution in chiral 1,2-diols, 'protected' in the form of σ^5-1,3,2-dioxaphospholanes, consists in the inversion of the configuration at the C(2) centre in polar media and double inversion (overall retention of configuration) at this centre in nonpolar media.[172]

The idea of regulated protonation in the reactions of latent diols has been developed in relation to silicon-containing nucleophiles.[177,178] The interaction of the cyclane **174**, obtained from propane-1,2-diol, with the silylated nucleophiles **188** under very mild conditions leads to the regioisomeric siloxanes C(2)−X and C(1)−X with the former predominating, up to the almost complete regioselectivity for X = SPh or N_3 (Scheme 20).

By analogy with the selective protonation mechanism in reactions with benzoic or toluene-*p*-sulfonic acids, the nucleophilic selection in favour of C(2) is explained by the difficulty of the oxygenophilic attack by silicon on the apical oxygen atom in the rotational isomer **174b**, since in the structure of compound **189b** the silicon atom is subjected to a strong 'sandwich' type steric influence by the equatorial phenyl group and the close 2-methyl group. The preferential silylation of the oxygen atom at the C(1) centre in the structure **189a** is responsible for the ease of the nucleophilic attack on the C(2) centre in the quasi-phosphonium salt **190a**. The possibility of detecting the ions **190** by ^{31}P NMR spectroscopy makes it possible to determine the ratio of the regioisomeric ionic intermediates, which corresponds to the regioisomeric composition of the products obtained [C(2)−X: C(1)−X], the first regioisomer being favoured in all cases.

We believe that the experimental data presented in this review constitute convincing evidence for the importance and likely usefulness of heterophosphacyclanes in fine organic synthesis. The availability of phosphorus compounds of the type described, the wide variety of the valence and coordination states, the ease of the transition from one coordination state to another and hence the diversity of the structural and electronic types of organophosphorus compounds, the relative lability which at the same time permits the identification of different metastable states, the strength of the phosphorus−heteroatom bond, and the, as a rule, satisfactory solubility in media of different polarity are factors, which, together with other features, frequently lead investigators to make a choice in favour of phosphorus-containing reagents

Scheme 20

in the development of a strategy for the synthesis of polyfunctional organic substances. A characteristic of diheterophosphacyclanes, such as the stabilisation of cyclic hypervalent structures, is frequently also an attractive feature of these reagents: they permit well-founded inferences concerning the reaction paths of the substances.

An important positive property of cyclic organophosphorus reagents is the possibility of an extensive variation of the structures of both the cyclic and acyclic fragments of the molecule; this makes it possible, for example, to protect bifunctional and polyfunctional organic substances by organophosphorus functional groups (especially those containing a σ^5-phosphorus atom).

Finally one should include among the fairly important advantages of the use of cyclic organophosphorus reagents in multistage chemical processes the possibility of monitoring them by spectroscopic methods, especially ^{31}P NMR spectroscopy, because the characteristic regions in which the NMR signals of the phosphorus atom are manifested are sharply differentiated as a function of its valence and coordination states and its immediate environment.

Thus it is easy to foresee the growth of interest in these chemical compounds, which provide investigators concerned with synthesis a unique instrument for the functionalisation of organic substrates.

VIII. Conclusion	1060

Abstract. Studies in the field of membrane distillation are analysed. A critical analysis of the theoretical and experimental investigations of membrane distillation is presented. Attention is concentrated on the mechanism of mass transfer and the influence of various external factors on the process characteristics. Questions concerning the creation of modules and apparatus for membrane distillation and aspects of the practical employment of such distillation in order to obtain pure water, for the purification of waste water, and for the concentration of technological solutions in various branches of industry are considered quite fully. The advantages and disadvantages of membrane distillation compared with other membrane methods are analysed. The bibliography includes 97 references.

I. Introduction

The first mentions of membrane distillation (MD) as a separate membrane process date back to the beginning of the 1980s,[1–4] although at the end of the 1960s studies[5–8] were published of the membrane desalination of water, which is in essence membrane distillation. Since 1985, papers and conference proceedings devoted to the experimental and theoretical study of this process have been published systematically.[9–15] A special issue of the *Journal of Membrane Science* has been devoted to membrane distillation.[12] Each year the number of publications on membrane distillation increases and at the present time approximately 100 are already known.

Membrane distillation has aroused interest primarily as a method for the purification and desalination of water and also for the concentration of technological solutions. Compared with baromembrane methods (reverse osmosis, ultrafiltration, and microfiltration), membrane distillation has advantages which reside in the possibility of concentrating solutions of many involatile organic and inorganic substances up to conditions close to their solubility limit. The productivity in terms of the permeated material remains satisfactory under these conditions [5–10 litre(m^2 h)$^{-1}$]. The driving force of the membrane distillation process is the difference between the vapour pressures of the solvent on either side of the membrane, which is established as a result of the difference between the temperatures of the initial solution [the output side of the membrane] and of the permeated materials (or cooling agent) on its input (receiving) side. The temperature of the solution being concentrated is usually 50–80 °C, and that of the distillate is 20–25 °C. Consequently, high-energy heat can be used for membrane distillation. Furthermore, membrane distillation, not being a baromembrane process, does not require an excess pressure as in the case of microfiltration, ultrafiltration, and especially reverse osmosis.

Membrane distillation is a process in which the membrane itself does not affect the vapour–liquid equilibrium in the separation of solutions and liquids.[16] The term 'membrane distillation' is applied to processes which have the following characteristics: (1) the membrane must be porous; (2) it must not be wetted during the separation of the liquids; (3) there must be no capillary condensation within the membrane pores; (4) only vapour should be transferred through the membrane pores; (5) the membrane must not alter the vapour–liquid equilibrium during the separation of the components; (6) at least one side of the membrane must be in direct contact with the liquid; (7) for each component, the driving force of the mass transfer is the partial pressure gradient in the vapour phase.

Such an expanded definition of membrane distillation is necessary in connection with the fact that different investigators frequently name this process in different ways or employ for it the names of similar processes (transmembrane distillation, transvaporisation and thermotransvaporisation, membrane evaporation), which leads to confusion and errors. It must be emphasised that there is a fundamental difference between membrane distillation and transvaporisation, because the latter process is effected through nonporous membranes as a result of the dissolution and molecular diffusion of the solution components being separated.

Analysis of the existing publications indicates that membrane distillation is a promising membrane separation method as regards its applied aspect, which can be used with great effectiveness in processes such as the preparation of pure and highly pure water from waters with different salinities (including sea water),

M T Bryk, R R Nigmatullin Department of the Physical Chemistry of Membranes, Institute of Colloid Chemistry and the Chemistry of Water, National Academy of Sciences of Ukraine, prosp. Vernadskogo 42, 252680 Kiev, Ukraine. Fax (7-044) 452 02 76

the purification of waste water containing inorganic electrolytes and involatile organic compounds (with the exception of surfactants), the concentration of salts from the wash waters in electroplating and dyeing industries, the concentration of thermolabile biologically active substances (vitamins, enzymes, etc.), the concentration of sugar and glucose-fructose syrups, and the concentration of solutions of dilute involatile inorganic acids, alkalis, and other substances.

At the same time, the membrane process has still not been investigated sufficiently fully experimentally and theoretically. There is as yet no complete analysis of the available studies on membrane distillation, although the need for this has become evident. A paper[18] in which this problem has been examined partially can be regarded as an exception. The aim of the present review is an attempt to fill this gap, which in our view will promote a clearer understanding of the subject of further research in the field of membrane distillation.

II. Types of membrane distillation

Membrane distillation can be carried out in different technological versions, and it is therefore important to distinguish several of its modifications.[17,18]

Contact membrane distillation (CMD) is a process in which a liquid is in direct contact with both sides of the membrane. The liquid in contact with the receiving side of the membrane is a medium for the condensation of the vapour being transported (Fig. 1*a*).

Membrane distillation through a gas (vapour) layer—a process in which the vapour beyond the receiving side of the membrane is condensed on a cooled surface at a specified distance from the membrane and the condensed liquid is not in contact with the membrane (Fig. 1*b*).

Membrane distillation at a reduced pressure (vacuum membrane distillation)—a process in which the rarefaction (vacuum) is created in the space between the receiving side of the membrane and the shell of the membrane element. The permeated material is condensed beyond the limits of the membrane module.[15,17]

Membrane distillation in a gas stream (membrane distillation with passage of a gas)—a process in which a gas stream (as a rule nitrogen) is supplied at a specified rate along the receiving side of the membrane. The vapour of the permeated material carried away by the gas stream is condensed beyond the limits of the membrane module.[17,19,20]

Osmotic membrane distillation is carried out with solutions having a high salt content in the receiving component. The permeated material in the form of vapour passes through a microporous hydrophobic membrane from solutions with a low osmotic pressure into a stream of solution with a high osmotic pressure of the solvent (Fig. 1*c*).[21,22]

III. Membranes for membrane distillation

There have been only a few publications devoted to questions of the preparation of membranes specially designed for membrane distillation (see, for example, Refs 23–26). As a rule, the existing hydrophobic microfiltration membranes are used for these purposes in the form of films, tubes, or fibres.[10,16,19,20]

In the case of contact membrane distillation, the transfer of permeated material through the membrane pores is effected in the form of vapour from the surface of the liquid meniscus at the inlets to the pores on the output side of the membrane to the surface of the liquid meniscus at the entrance to the pores on the input (receiving) size of the membrane (Fig. 2). The membrane pores contain a vapour–air mixture, i.e. the membrane should not be wetted by the solution being separated, so that the main requirement which must be met by membranes for membrane distillation is their hydrophobicity. The hydrophobicity makes it possible to maintain a liquid–vapour interface at one or both membrane surfaces and ensures the separation of the evaporation and condensation surfaces. Furthermore, the polymeric materials

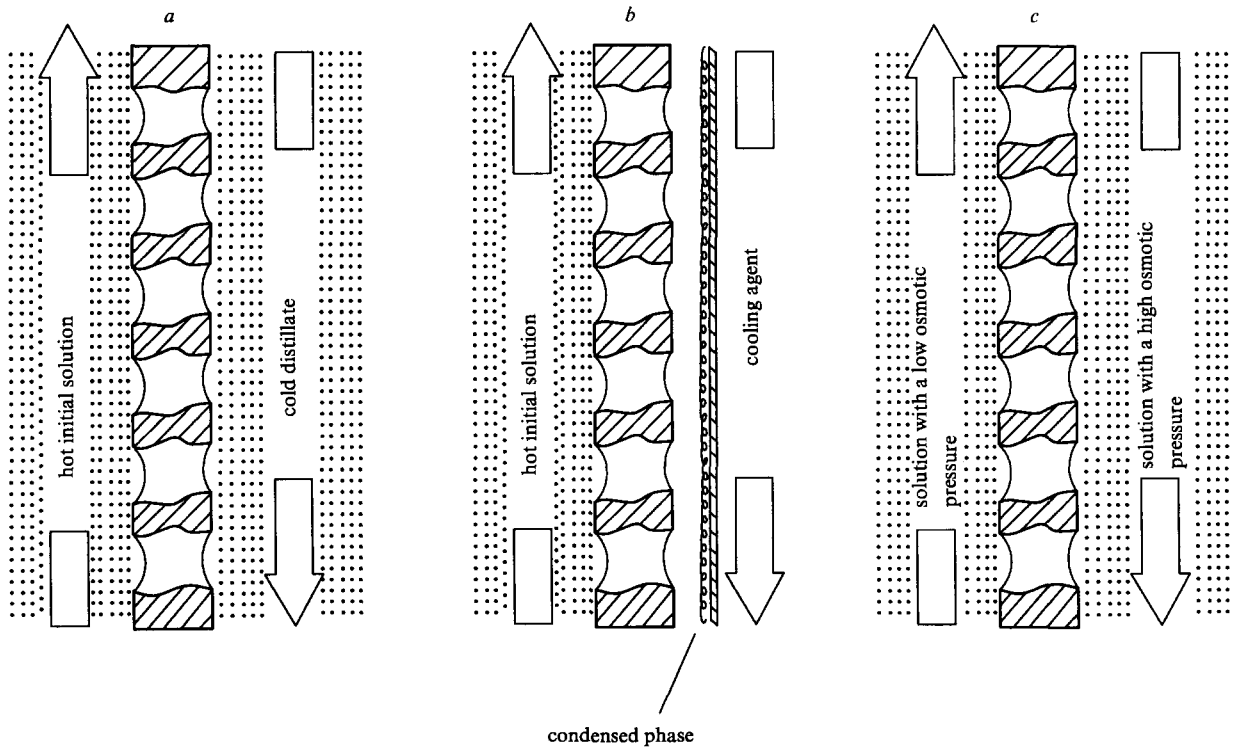

Figure 1. Different versions of the membrane distillation process; (*a*) contact membrane distillation;[17–19] (*b*) membrane distillation through a gas layer;[12,15,19] (*c*) osmotic distillation.[21,22]

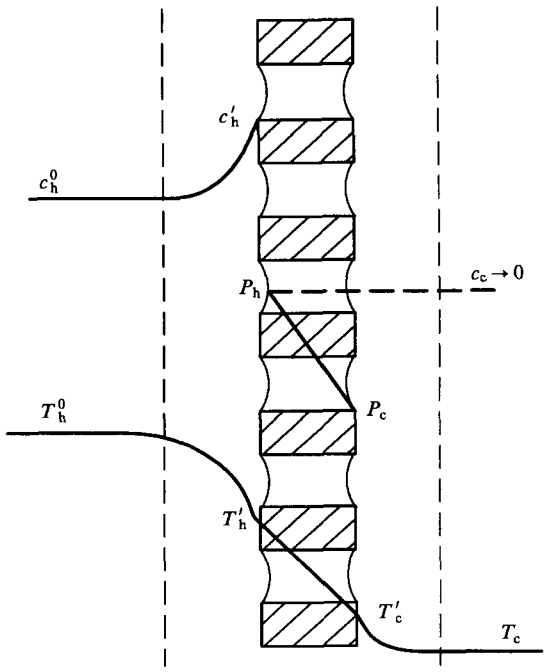

Figure 2. Schematic illustration of the membrane distillation process and the concentration and temperature profiles in membrane distillation.

used to prepare the membranes must possess a sufficiently high thermal stability and heat resistance in corrosive aqueous media.

Polypropylene,[10,20,21] polytetrafluoroethylene and other fluorine-containing polymers,[2,10,19-21] polyorganosiloxanes, poly(vinyl chloride),[27] etc. are mainly used as the polymeric materials satisfying the above conditions and possess in addition fibre- and film-forming capacities.

It is known[2,10,17,19] that, apart from the requirements stated above, the membranes used in membrane distillation must have a low thermal conductivity, a narrow size distribution of their pores, and an overall porosity of 30%–80%. A fairly important parameter for the productivity of the membrane in terms of the permeated material is the average pore diameter, which is believed to be optimum in the range 0.2–0.6 μm.[10,17,19] The membrane thickness must be as small as possible to ensure a high productivity of the membrane distillation process, but heat transfer must be minimised at the same time. The thickness of the membranes for membrane distillation is usually 100–300 μm.[17,19,24]

As already mentioned above, an important characteristic of the membrane is its hydrophobic properties. Therefore it is virtually impossible to employ membrane distillation for the separation of solutions and mixtures containing surfactants, which lower the surface tension and improve the wettability of the hydrophobic surface of the microporous membrane by water. Studies on the relation between the transport of water through polytetrafluoroethylene membranes and their wetting angle ($\alpha \approx 106°$) established[28] that there is a critical water pressure above which it permeates through the membrane as a convective stream. The absolute values of this pressure vary in the range 0.4–1.2 MPa and depend also on other parameters of the membrane (the pore size and the pore distribution) and on the surface tension of the medium being separated, which should not be less than 72×10^{-3} N m^{-1} for inorganic aqueous solutions.[28,29]

The critical concentrations of organic substances (alcohols, ethers, amines, ketones, and acids) in the solutions being separated are determined by the wettability of the membrane under the conditions of the separation process. The following condition for the wettability of the membrane has been proposed:[28]

$$\gamma_L = \gamma_L^p + \frac{\Delta p r_{max}}{2B}, \quad (1)$$

where γ_L is the surface tension of the liquid (solution, mixture) (N m^{-1}), γ_L^p the surface tension of the liquid (solution, mixture) at the boundary where it penetrates the pores of the microporous membrane (N m^{-1}), Δp the pressure difference (N m^{-2}), r_{max} the maximum pore radius (μm), and B the coefficient of the pore geometry.

It has been suggested that the critical concentrations of organic substances for a microporous membrane be calculated by a semiempirical method via the determination of the wetting angle of the material of the membrane.[28]

Unfortunately, the problem of the relation between the hydrophobicity of the surface of the membrane and the structure of water in the surface layers and also the structure of water within the membrane pores is not discussed in the literature.[30,31] The structure of the surface layers of water differs as a function of the nature and energy of the interaction of water molecules with membranes characterised by different surface hydrophobicities and pore dimensions, so that the physical characteristics of water (density, viscosity, phase transition temperatures, vapour pressure, etc.) also differ.[30,31] This undoubtedly must be taken into account in the study of the mechanism of the mass transfer in membrane distillation and in the optimisation of the transport characteristics of membranes.

There are few publications in the literature devoted to the preparation of special membranes for membrane distillation and to the study of their surface on structural characteristics. Among these, mention may be made of investigations[24-26] in which an attempt was made to obtain a hydrophobic layer on the surfaces of microporous cellulose acetate and nitrate membranes with the aid of methods for the radiation graft copolymerisation of styrene with pyridine and copolymerisation in plasma of octafluorocyclobutane (OFCB), CF_4, and trimethylvinylsilane $(CH_3)_3SiCH=CH_2$ (TMVS). This layer would determine the functional characteristics of the composite membrane prepared for membrane distillation. The plasma polymerisation of monomers was carried out under different conditions with the power of the discharge varying from 60 to 200 W for process durations between 5 and 90 min.[24]

In the radiation graft (co)polymerisation of the styrene–pyridine and styrene–carbon tetrachloride systems, the maximum wetting angle on the surface of a modified cellulose acetate membrane is attained for the ratios styrene : pyridine = 90 : 10 (69.5°) and styrene : pyridine : carbon tetrachloride = 85 : 10 : 5 (88.6°) (the wetting angle for the wetting of polystyrene by water is 91°). The introduction of CCl_4 into the system lowers the retention of NaCl (0.3 M) significantly to 66.7%–89.6%, whereas in the copolymerisation of styrene with pyridine the retention is 99.1%. The low retention is attributed to the formation of short grafted chains during comparatively short irradiation periods (~8 h).

The plasma polymerisation of OFCB and the copolymerisation of TMVS with tetrafluoroethylene (TFE) on the surfaces of cellulose nitrate membranes showed that the F : C ratio in the surface layer of the modified membrane and hence the wetting angle are determined by the power of the discharge. There is an extremum in the relations between the F : C ratio and the wetting angle, on the one hand, and the power of the discharge, on the other (Fig. 3, see next page). The lowest values of these quantities have been found for moderate discharge powers in the range 80–160 W. The maximum wetting angles of 113° and 120° are attained in the polymerisation of OFCB for discharge powers of 60 and 175–200 W respectively. For these parameters, a maximum retention of NaCl (0.5 M) of 92.0% is attained.

With increase in the plasma polymerisation time, an increase in the retaining capacity of the modified membranes and a decrease in their productivity are characteristic of all the systems investigated.[24-26] Electron microscope studies have shown that

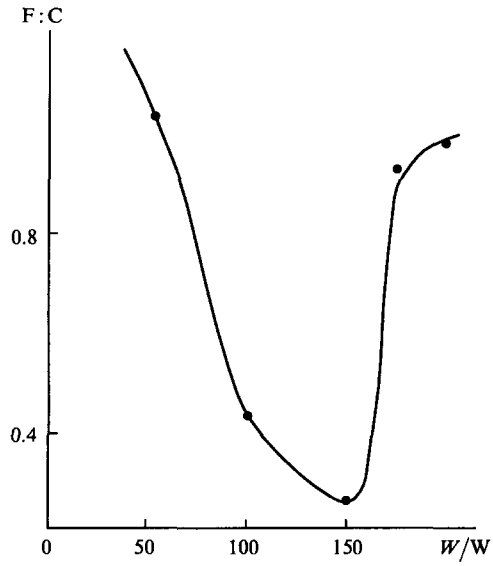

Figure 3. Dependence on the discharge power of the ratio of the contents of fluorine and carbon in the molecular structure of a cellulose nitrate membrane when the latter is modified by OFCB in a plasma.[24]

Table 1. The properties of the membranes used in membrane distillation.[24]

Membrane	Material	Permeability coefficient $10^3 K/\mathrm{kg\,(m^2\,h\,Pa)^{-1}}$	Retention (%)
Asymmetric poly(vinylidene fluoride)	poly-(vinylidene fluoride)	0.68	99.9
Modified by radiation-grafted polystyrene	cellulose acetate	0.14 0.96	99.1 66.7
Modified by OFCB in plasma	cellulose nitrate	0.82 1.32	99.5 99.1
Modified by TMVS–CF_4 in plasma	cellulose nitrate	1.81 2.22	99.9 99.4

this is associated with a decrease in the inlet diameters of the membrane pores and with an increase in the thickness of the modifying layer. Certain characteristics of the modified membranes are compared in Table 1 with those of an asymmetric porous membrane based on poly(vinylidene fluoride).

A novel membrane designed for the desalination of sea water or brines by membrane distillation has been described.[23] It has a multilayer construction based on an electrically conducting layer comprising polypropylene (25%–75%), poly(ethylene glycol) (10%–30%), graphite and ground charcoal (5%–75%), dibutyl phthalate (5%–20%), and sodium dodecyl sulfate (5%–25%). A hydrophobic polysiloxane film is deposited on this porous electrically conducting substrate from a solution or an emulsion. Such a membrane and the solution on the output side are heated by passing an electric current through the membrane.

IV. Mass and heat transfer in membrane distillation

Theoretical analysis of membrane distillation is based as a rule on the consideration of an ideal membrane, i.e. a membrane in which there are no wettable pores. In this case, the viscous flow of the liquid and thermodiffusion within the membrane pores are excluded and the diffusion of the permeated material is determined by the transport of solvent vapour by the vapour pressure gradient across the membrane. Consequently membrane distillation is a diffusion-controlled process and its phenomenological description is based on Fick's laws.

The diffusional mechanism of membrane distillation on real membranes has been confirmed in a study[32] the authors of which obtained linear relations between the flux of the permeated material and the reciprocal of the membrane thickness (Fick diffusion). Furthermore, the high retention of the involatile components of the solution (in excess of 99%) indicates the absence of convective flow in membrane distillation on real membranes. The phenomenological description of the membrane distillation process by means of Fick's laws is therefore entirely legitimate.[32–34] If the membrane pores are filled with air, the molar flux of water vapour is described by the equation[12]

$$N = -\frac{cD}{1-x}\frac{\mathrm{d}x}{\mathrm{d}z}, \tag{2}$$

where c is the molar concentration of the solution, D the diffusion coefficient of water vapour in the water–air mixture within the membrane pores, x the mole fraction of water vapour, and z a constant [sic. presumably a coordinate is intended (Ed. of Translation)].

The main problem arising in the solution of Eqn (2) is the difference between the diffusion coefficient within the membrane pores and the diffusion coefficient in a free medium and also the dependence of the coefficient on temperature and the vapour concentration. To simplify the problem, use has been made of the following empirical relation obtained from experimental data on diffusion in a water vapour–air mixture at ~40 °C:[12]

$$cD = 6.3 \times 10^{-5}\sqrt{T}. \tag{3}$$

Taking into account Eqn (3) and the morphology of the membrane, the following expression has been obtained for the molar flux of water (in the case of membrane distillation through a layer of gas):

$$N = 6.3 \times 10^{-5}\frac{1}{\delta/\varepsilon\sqrt{T_h} + L/\sqrt{T_c}}\ln\frac{1-x_c}{1-x_h}, \tag{4}$$

where δ and ε are the thickness and porosity of the membrane respectively, L is the thickness of the gas layer, and T_h and T_c are the temperatures on the hot and cold sides of the membrane respectively. This approach made it possible to determine the principal parameters influencing the flux and the nature of its dependence on the temperature regime and the morphology of the membrane.

Relations for the transport of gases (vapours) in porous-capillary media, based on the molecular-kinetic theory of gases, are usually employed in the description of diffusional transport of vapour in the membrane distillation process.[32,35] The general expression for the flux of permeated material, unrelated to the transport mechanism, assumes the form

$$J = \frac{K}{\sigma}(p_h - p_c) = \frac{K}{\sigma}\Delta p, \tag{5}$$

where p_h and p_c are the vapour pressures of the solvent on the hot and cold sides of the membrane respectively, and K is the permeability coefficient of the membrane. In contrast to the diffusion equation, the permeability coefficient K characterises both the properties of the gas and the morphological features of the membrane.

The diffusional transport of gases (vapours) in capillary-porous media is characterised by three flow regimes:[36-40] free-molecular (Knudsen diffusion), molecular, and transitional. The decisive parameter of the flow regime is the ratio of the mean free path of the molecules to the pore diameter.

If the mean free path greatly exceeds the pore size, Knudsen diffusion obtains. It is characterised by a greater number of collisions of the molecules with the pore wall than with one another. The molecular diffusion of vapours occurs if the free path of the molecules is smaller than the pore size, i.e. the number of collisions of the molecules with one another (or with the molecules of another kind) exceeds the number of collisions with the pore walls (viscous flow). Equations for mass transfer in capillary-porous media have been used for the transport of gases through porous membranes occurring under free-molecular and molecular diffusion conditions. For isotropic membranes, the flux of the permeated material is defined by the following equations:[35-37]

(a) for Knudsen diffusion,

$$J = \frac{2}{3}\frac{r\varepsilon}{\chi}\left(\frac{8M}{\pi RT}\right)^{1/2}\frac{\Delta p}{\delta} = \frac{K_K \Delta p}{\delta}, \quad (6)$$

where r is the membrane pore diameter, χ the tortuosity coefficient of the pores, and K_K the mass transfer coefficient under the conditions of Knudsen diffusion;

(b) for viscous flow,

$$J = \frac{1}{8}\frac{r^2\varepsilon}{\chi}\frac{1}{\eta}\frac{Mp}{RT}\frac{\Delta p}{\delta} = \frac{K_m \Delta p}{\delta}, \quad (7)$$

where η is the viscosity and K_m the mass transfer coefficient under the conditions of molecular diffusion.

There are a series of fundamental differences between a Knudsen flow and molecular diffusion, the main ones of which are the dependence of molecular diffusion on the average pressure.

If the free path of water molecules does not exceed 0.2 μm (in the temperature range 20–100 °C), i.e. is comparable to the size of the pores in the membranes employed for membrane distillation then the process occurs in the transitional regime. However, in certain studies the description of processes of this kind has been based on the molecular diffusion regime.[41]

The transitional regime is as a rule related not to the mixed nature of the transport but to the effects determined by the surface flow.[42] At the present time there is no single theoretical concept on the basis of which one could obtain a rigorous quantitative description of the process.

In the literature on the transport of gases in capillary-porous bodies, frequent attempts have been made to describe the mass transfer in the transitional regime by combining the equations describing the Knudsen and molecular diffusion or on the basis of empirical equations.[43]

In the study of the membrane distillation process, attempts have also been made to describe the mass transfer through porous membranes in the transitional regime. Thus it has been proposed[20] that the permeability constant be calculated from the Knudsen (D_K) and molecular (D_m) diffusion coefficients:

$$\frac{1}{K} = \frac{\chi\delta}{\varepsilon}\left(\frac{1}{D_m} + \frac{1}{D_K}\right). \quad (8)$$

An interesting approach to the description of diffusion in porous membranes in the transitional regime has been put forward.[36] On the grounds that in the Knudsen regime the flux is proportional to the pressure difference ($J \propto \Delta p$) while in the molecular regime it is proportional to the pressure difference and the pressure ($J \propto p\Delta p$), the authors suggested that in the transitional regime the permeability constant depends on different powers of the pressure:

$$\frac{K}{\delta} = a\psi^b, \quad (9)$$

whence

$$J = a\psi^b \Delta p, \quad (10)$$

where ψ is the dimensionless pressure, a the permeability constant of the membrane, and $b = 0$ for Knudsen diffusion and 1 for molecular diffusion; the constant a, characterising the properties of the membrane, is the coefficient of the proportionality between the flux and the pressure gradient. Thus, for the description of the flux of gas to the membrane, the two empirical coefficients a and b are determined from experimental data. Both parameters depend on the type of membrane and the gas transported. The permeability constant of the membrane is calculated from the relation $a = K/\delta$.

We may note that Zolotarev and Timashev[44] suggested that the permeability constant be determined from data for membrane distillation in a special cell, the receiving component of which consists of a small cylinder immersed in a vessel with a heated solution. The permeability constant is determined from the maximum height of the distillate column (h_∞) at the given temperature in the receiving component by means of the relation

$$J = K\Delta p = K\rho_d g h, \quad (11)$$

where g is the acceleration due to gravity, and h the height of the column of liquid.

An inversely proportional relation has been obtained[36] between the quantity $K/M\bar{u}$ (where $\bar{u}$ is the average velocity of the molecules) and the mean free path of the molecules. With the aid of this relation, it is possible to determine K for different gases, including water vapour, from transport data for other gases. This is important, since the determination of the transport characteristics of the membrane for the transport of water vapour in direct experiments is impossible because of the difficulties in the correct determination of the water vapour pressure in the membrane pores and of the degree of deaeration of the membrane. The latter factor is particularly important, since the presence of different molecules in the gas phase not only diminishes the partial pressure but also alters the nature of the process.

The description of the mass transfer has been based in a series of studies[37-39,45] on the equations for the transport of water vapour through a layer of air in accordance with molecular diffusion model, whereupon the molar flux is described by the equation[37,39]

$$N = \frac{1}{p_a}\frac{\varepsilon}{\chi\delta}\frac{MDp}{RT}\Delta p, \quad (12)$$

where p is the average gas pressure in the membrane and p_a the logarithmic mean pressure of air (Schofield et al.[37] suggested that the geometrical mean pressure be employed).

Ugrozov et al.[45] introduced the parameter $Kn = D_{as}/D_{Ks}$, where D_{as} is the effective coefficient of the mutual diffusion of the vapour in air and D_{Ks} the coefficient of the Knudsen diffusion of the vapour. The parameter Kn is regarded as the effective Knudsen number in the case of a porous medium and characterises the mechanism of the mass transfer. For $Kn < 0.1$, transport is effected by molecular diffusion, for $Kn > 10$ Knudsen diffusion obtains, and for $0.1 < Kn < 10$ the mass transfer takes place in the transitional regime. The flux of the permeated material is given by the equation

$$J = \frac{D_{as}pM}{RT\delta p_a(1 + Kn_0)}(p_h - p_c), \quad (13)$$

where p_a is the atmospheric pressure and $Kn_0 = D^0_{as}/D_{Ks}$ (D^0_{as} is the effective coefficient of the mutual diffusion of the vapour in air at atmospheric pressure, which depends explicitly on Kn_0; the equation can therefore also be employed for the calculation of the flux in any mass transfer regime).

The overall resistance of the membrane in the membrane distillation process is equal to the sum of the resistance of the membrane determined by its morphology and the molecular diffusion resistance.[37] In this case, the equation for the overall mass transfer is

$$J = \left(\frac{1}{a\psi^b} + \frac{p_a}{d}\right)^{-1} \Delta p , \tag{14}$$

where

$$d = \frac{\varepsilon}{\chi\delta}\frac{MD_p}{RT} .$$

This takes into account the diffusion coefficient of the gas and the morphology of the membrane. The satisfactory correlation between the experimental results and the theoretical results, predicted on the basis of the molecular diffusion of water vapour through a layer of air,[38] indicates that the latter form of diffusion predominates in the contact molecular distillation process. The analysis carried out by Schofield et al.[37] confirmed these conclusions. Only at low air pressures (under deaeration conditions) does the transport of water vapour in the membrane pores in the transition regime, described by the first term of Eqn (14), make a significant contribution.

In contact membrane distillation, the permeability to the permeated material is proportional to the difference between the vapour pressures and the porosity of the membrane and is inversely proportional to the thickness of the membrane and the air pressure in it. For the description of the process in terms of experimentally measurable parameters, the pressure distance is replaced by the temperature difference[38-40,44] (taking into account the temperature dependence of the vapour pressure and the diffusion coefficient). This approach demonstrates the dependence of the flux on the temperature regime. The vapour pressure also depends on the solution concentration, as a result of which the membrane permeability constant depends on the latter as well[38,39]

$$K = \frac{\varepsilon M}{\chi\delta R^2}\frac{pD}{T^b}\frac{\Delta H_V T^{b-3} p_m^*}{p_a}(1 - x_m) , \tag{15}$$

where $b = 1.75$ and 2.33 (Sarti et al.[38]), p_m^* is the average water vapour pressure over the pure solvent, ΔH_V the heat of vaporisation, and x_m the molar concentration of the solution.

As a consequence of the reduced vapour pressure over the solution, the transport of water through the membrane can take place only for a temperature gradient such that the vapour pressure over the hot solution exceeds that at the condensation surface. The minimum temperature difference is calculated by means of the equation[38]

$$\Delta T_0 = \frac{hT_m^2}{\lambda_m}\frac{x_h - x_c}{1 - x_m} , \tag{16}$$

where x is the mole fraction of all the dissolved substances.

The quantity ΔT_0 is used to estimate the direction of transport of water vapour in contact membrane distillation. In order to concentrate the solutions by contact membrane distillation, it is necessary that the working temperature difference should be greater than ΔT_0. When a solution with a high osmotic pressure is present on the receiving side of the membrane (osmotic distillation), the flow of water through the membrane is possible even in the absence of a temperature gradient, i.e. $\Delta T_0 < 0$.

The transfer of water from the solution in contact membrane distillation is always smaller than the transfer from the pure solvent. It has been suggested[46] that the dependence of the flux of the permeated material on the concentration be described as a function of the decrease in the flux of the permeated material from the pure solvent:

(a) at low solution concentrations (in the range where Raoult's law is valid):

$$J = J_0 - K\alpha p_h(0, T_h)c ; \tag{17a}$$

(b) at high concentrations:

$$J = J_0 K\alpha p_h(0, T_h)c + K\beta p_h(0, T_h)c^2 . \tag{17b}$$

The interpretation of experimental data in terms of the theoretical ideas described above requires the knowledge of the concentration and temperature of the solution in the near-membrane layers in order to determine correctly the driving force of the process. It is essential to note that the parameters in the near-membrane layers differ from the bulk-phase characteristics of the solution (see the temperature and concentration profiles in Fig. 2). The increase in the concentration of the involatile solutes in the near-membrane layer on the output side of the membrane is due to the phenomenon of concentration polarisation, common to all membrane processes, which exerts a negative influence on the productivity of the membrane distillation as a consequence of the decrease in the driving force of the process, as for other membrane processes. However, the relatively weak dependence of the vapour pressure on the concentration gives rise to only a slight decrease in productivity.[44]

As can be seen from Fig. 2, the temperature of the solution in the near-membrane layers also differs from the bulk-phase value owing to heat transfer through the membrane. This phenomenon has been called temperature polarisation. Like concentration polarisation, temperature polarisation has a negative influence on the productivity of the membrane distillation process as a consequence of the decrease in the temperature of the solution (the vapour pressure) on the evaporation surface and its increase on the condensation surface.

The description of the heat transfer in membrane distillation is based on the well known thermodynamic relations. The overall thermal resistance of the membrane system is then defined by analogy with the electrical resistance.[35,37,39,40] The heat transfer in the membrane distillation process takes place in three stages: heat transfer to the evaporation surface, heat transfer through the membrane, heat transfer from the condensation surface to the bulk of the distillate.

Heat transfer to and from the membrane surface is characterised by the heat transfer coefficients

$$Q = \alpha_h \Delta T_h = \alpha_c \Delta T_c , \tag{18}$$

where Q is the heat flux per unit area of the membrane and α_h and α_c are the heat transfer coefficients in the output and receiving sections respectively.

Heat transfer through the membrane takes place with the stream of vapour and as a result of transfer through a porous membrane the pores of which are filled with a gas phase. Heat transfer through the membrane represents heat losses in the membrane distillation process and is determined by the thermal conductivity of the porous polymer–gas composite structure:[35,37-40]

$$\lambda_m = \varepsilon\lambda_a + (1-\varepsilon)\lambda_p , \tag{19}$$

where λ_a and λ_p are the thermal conductivities of the vapour–air mixture and of the polymer membrane respectively.

For heat transfer as a result of thermal conductivity, we have

$$Q_1 = \left(\frac{\lambda_m}{\delta}\right)\Delta T_m = \lambda_1 \Delta T_m , \tag{20}$$

where λ_1 is the thermal conductivity of the membrane.

The heat transfer associated with the flow of vapour through the membrane is determined by the magnitude of the flux and the heat of vaporisation:

$$Q_2 = J\Delta H_V = \lambda_2 \Delta T_m , \tag{21}$$

where λ_2 is the heat transfer coefficient related to the vapour flux.

The heat balance equation is

$$Q = Q_1 + Q_2 . \tag{22}$$

Having solved Eqn (21) for J using Eqns (18)-(20) and (22), we obtain

$$J = \frac{\lambda_2}{\Delta H_v} \frac{\lambda}{\lambda_1 + \lambda_2 + \lambda} (T_h - T_c) , \tag{23}$$

where

$$\lambda = \left(\frac{1}{\alpha_h} + \frac{1}{\alpha_c} \right)^{-1} , \tag{24}$$

$$\lambda_1 = \frac{\varepsilon k_B + (1 - \varepsilon) k_m}{\delta} . \tag{25}$$

Eqn (23) reflects the influence of the heat transfer conditions on the productivity of the membrane. When account is taken of Eqn (20), Eqn (23) can be reduced to the form

$$\frac{\Delta T_m}{T_h - T_c} = \frac{\lambda}{\lambda_1 + \lambda_2 + \lambda} . \tag{26}$$

The ratio $\Delta T_m/(T_h - T_c)$ has been called the coefficient of temperature polarisation (CTP) and reflects the fraction of the overall driving force $T_h - T_c$ which ensures the operation of the true driving force ΔT_m. In the ideal case, the CTP should be unity, which corresponds to the equality of the temperatures in the surface layers and in the bulk phase.

The level of temperature polarisation depends both on the properties of the polymer membrane (λ_1) and on the heat transfer regime in the liquid flow (α_h, α_c). From the standpoint of the heat transfer through the membrane, an increase in the thickness of the latter tends to decrease the level of temperature polarisation. However, this entails an increase in the diffusion path for the water vapour. Hence, in order to attain the maximum productivity of the membrane distillation process, optimisation with respect to the thickness of the membrane is needed, as already stated.

The estimates carried out in a number of studies[35, 37, 47, 48] indicate that temperature polarisation is influenced mainly by the heat transfer conditions in the liquid streams, which are determined by the hydrodynamic conditions governing the flow of liquids within the channels of the membrane module. The level of temperature polarisation decreases with increase in the degree of turbulence of the streams within the channels.

The heat transfer in liquid streams depends on the orientation of the membrane and the Earth's gravitational field. The best conditions for heat transfer are achieved when the direction of natural convection coincides with the direction of heat transfer. Natural convection then influences the stability (thickness) of the near-membrane layer, which increases if the direction of natural convection coincides with the concentration profile and the temperature polarisation.[49] It has been confirmed experimentally[27, 38] that, for a horizontal disposition of the membrane and of the hot chamber (the hot chamber is located below), the maximum productivity of membrane distillation is attained.

The extremely high retention coefficients of involatile substances in the membrane distillation process were noted above. However, in practice the retention of involatile substances nevertheless does not attain 100%, which makes it necessary to take into account this fact in theoretical analysis. Thus the level of concentration polarisation in membrane distillation is estimated taking into account the incomplete retention of the solute.[34] The following expression has been obtained[34]:

$$\frac{c^0}{c} = (1 - \varphi) + \varphi \exp\left(\frac{Jl}{D} \right) , \tag{27}$$

where c and c^0 are the concentrations of the solution being separated on the surface of the membrane and in its bulk respectively. φ is the retention coefficient, l is the thickness of the near-membrane layer, and D is the diffusion coefficient.

According to Eqn (27), in order to minimise concentration polarisation it is desirable to maintain the flux at the level of l/D.

It has been suggested that the diffusion model of the selectivity of the established membrane distillation process be used for the description of the retention in the membrane distillation process on the basis of the hypothesis that a hydrophobic microporous membrane contains both hydrophobic and hydrophilic pores.[50, 51] The 'breakthrough' of the volatile solutes in membrane distillation is possible owing to their diffusion via the solution-filled hydrophilic pores. It is assumed that the hydrophilic pores have a smaller diameter than the hydrophobic ones. In our view the possibility of a decrease in selectivity as a consequence of the wetting of the largest pores owing to the pressure drop is less probable. Since the pores in membranes have submicron dimensions, even slight pressure drops lead to a significant convective flow of the solution. As a result, the retention coefficients should be lower than the experimental values and should depend on the concentration of the initial solution, which is not observed in practice.

Thus the relative hydrophilic porosity is the parameter of the nonideality of the membrane:[50]

$$\varepsilon_f = \frac{m_f}{m_0} = 1 - \frac{m}{m_0} , \tag{28}$$

where m_0 is the fraction of the membrane surface corresponding to all the pores, both hydrophobic (m) and hydrophilic (m_f) ($m_0 = m + m_f$).

According to the analysis carried out by Starikov,[50] the retention coefficient is a function of the nonideality of the membrane and of the hydrodynamic parameters of the system:

$$\varphi = \left[1 + \frac{m_1 D}{J\delta} \exp\left(\frac{Jl}{D} \right) \right]^{-1} . \tag{29}$$

In the presence of hydrophilic pores and a nonstirred near-membrane layer, the selectivity of the flux of permeated material passes through a maximum at $J = D/l$. We then have

$$\varphi_{max} = \frac{\delta}{\delta + l m_f e} . \tag{30}$$

Calculations have shown that the retention coefficient increases with increase in the flux and with decrease in the thickness of the unstirred layer.[50] Similar dependences of the selectivity are characteristic also of a multilayer membrane consisting of a hydrophobic microporous membrane with a thin hydrophilic surface layer.[51, 52]

The selectivity coefficient in membrane distillation for systems containing more than one volatile component is determined by the vapour–liquid equilibrium, which the membrane hardly affects. The description of the mass transfer, including the selectivity parameters, is hardly discussed in the relevant communication, as is the description of transvaporisation processes.[53]

V. Experimental studies on membrane distillation

The results of theoretical studies on heat and mass transfer in the membrane distillation process can serve as a basis for the treatment of experimental data and a satisfactory prediction of the possibilities of membrane distillation.

In the initial stage of the development of studies on membrane distillation, attempts were made to reconcile the experimental data obtained with the mathematical description of heat and mass transfer.[10, 12, 19, 54-64] The attempt to elucidate the influence of all factors on the principal process characteristics

was self-evident and entirely comprehensible.[10,12,15,54-61] Thus membrane distillation on microporous hydrophobic [polypropylene, poly(vinylidene fluoride), polytetrafluoroethylene], planar, and hollow-fibre membranes was investigated with the aid of model aqueous solutions of sodium chloride, glucose, or sucrose. Such studies[10,12,54-58,62-64] showed that the most important factors influencing the productivity with respect to the permeated material are the temperature, the temperature drop (vapour pressure drop) on either side of the membrane, the pore size, the overall porosity and thickness of the membrane, and the concentration of the initial solution. It was established that, for a constant temperature drop, the productivity of the membrane distillation process increases with increasing concentration of the initial solution and, when the latter is constant, the productivity increases with increase in the temperature drop (Fig. 4).

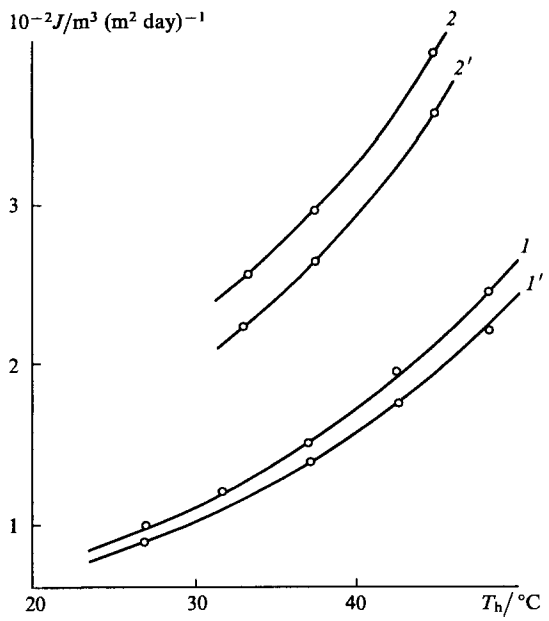

Figure 4. Dependence of the flux of the permeated material on the temperature of the hot sodium chloride solution.[64] ΔT/°C: (*1*) and (*1'*) 5.0; (*2*) and (*2'*) 9.5; c_{NaCl}/mol litre^{-1}: (*1*) and (*2*) 0.05; (*1'*) and (*2'*) 0.50.

Later investigations confirmed the general characteristics of the membrane distillation process and its dependence on the principal factors indicated above. At the same time, in these studies more continuous attention was devoted to individual factors influencing the process. Furthermore, whereas a distinct applied trend could be traced in the early studies (they dealt as a rule with simplified models of the process), in later investigations attempts were made to develop the theoretical foundations of membrane distillation with the aid of new revised experimental data (in particular, account was taken of heat exchange and of the nature and velocities of the fluxes in membrane cells, the temperature and concentration polarisations, etc.).[46,65-72]

The membrane distillation of solutions of sodium chloride and glucose at very high concentrations of the latter (up to 5 and 50 g litre^{-1} respectively) has been investigated in detail.[46] Analysis of the dependence of the productivity on concentration was based on the approximate Raoult's law, according to which the vapour pressure of the solvent was defined by the expression

$$p(c, T) \approx p(0, T)(1-\alpha c), \quad (31)$$

where $p(0, T)$ is the vapour pressure of the solvent at $c = 0$ for dilute solutions and c is the concentration of the solute. The coefficient α is then always positive.

On the other hand, at fairly high concentrations of the solution, a nonlinear dependence of the partial pressure of the solvent on concentration is observed:

$$p(c, T) \approx p(0, T)(1-\alpha c+\beta c^2). \quad (32)$$

The coefficient β can be both positive and negative. This corresponds to a positive or negative deviation from Raoult's law, which occurs at high solution concentrations.

It has been established[46] for a wide range of solution concentrations that there is a linear dependence of the flux of permeated material on the concentration [see Eqn (17b)]. It is important to note that the concentration of the substance not in the bulk phase but at the interface of the membrane, which is higher than the bulk phase concentration, should be employed in Eqns (17a), (17b), and (32).[41] The decrease in productivity with respect to permeated material with increasing solute concentration should be less appreciable, according to Eqn (32), if $\beta > 0$ and should be more applicable if $\beta < 0$.

Experimental studies on the membrane distillation of concentrated sodium chloride and glucose solutions confirmed satisfactorily the theoretical considerations described above (Figs 5*a* and 5*b*): at low solute concentrations, the relation $J = f(c)$ is linear, while at higher concentrations it is nonlinear. These effects are associated not only with deviations from Raoult's law but to a considerable extent also with the manifestation of concentration and temperature polarisations, which has been confirmed by experiments designed to investigate the $J = f(c)$ relation with and without stirring of the solution being separated (see curves *1* and *2* in Figs 5*a* and 5*b*).

A more rigorous study of the dependence of the productivity of the membrane distillation process on temperature and on the temperature difference on either side of the membrane confirmed[38,45,73,74] that the specific productivity of the contact membrane distillation process increases with increasing temperature difference for a fixed temperature T_x and also with increase in the average bulk-phase temperature. It has been shown that intensification of the stirring of the solution makes it possible to increase significantly (by a factor greater than 2) the productivity of the contact membrane distillation process, which is associated with the partial elimination of temperature and concentration polarisations.[34,38,45,46,69-75]

The influence of temperature and concentration polarisations on the functional characteristics of the membranes and on the membrane distillation process is always negative. A partial elimination of such polarisations can be achieved by altering the velocity and nature of the solution and permeated material fluxes at the output and receiving surfaces of the membrane.[72] The procedure in which the flow of the solution to be separated was rendered turbulent proved to be extremely effective, lowering the negative influence of concentration and temperature polarisations and intensifying the membrane distillation process, especially in flat chamber apparatus. The flow of the solution was rendered turbulent by stirring, and with the aid of pressure channels in apparatus and turbulators of different design. The movement of the membrane element relative to the solution being separated (when the membranes are arranged on rotating discs), as well as vibration and ultrasound, can be used.[72]

Analysis of experimental data on the effect of turbulent flow on the specific productivity of membranes showed[72] that, for $Re > 1500-2000$, an increase in the flux through the membrane is not observed. Here one should note that the procedure in which the flow solution is rendered turbulent is more effective than the one in which the flow of the permeated material is made turbulent.

The dependence of the separating characteristics of microfiltration membranes in the membrane distillation process on the average pore diameter has been noted.[75] This has been explained by the influence on the mass transfer by the predominant Knudsen or molecular mechanism of the diffusion of vapour through pores having different diameters and lengths. In real membranes with a

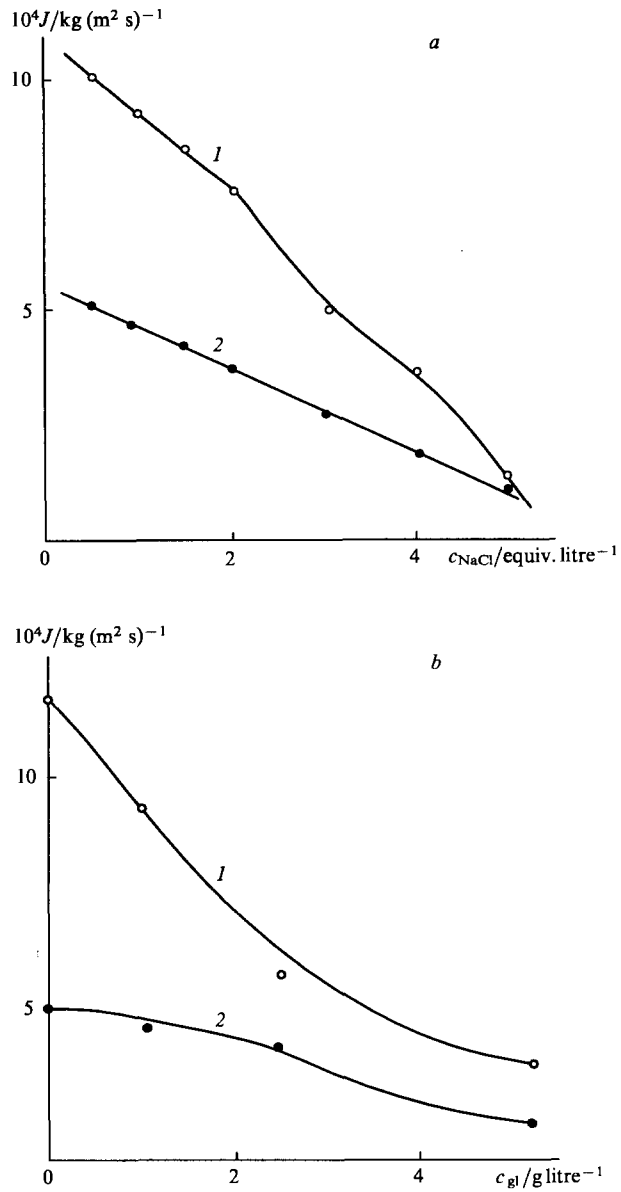

Figure 5. Dependence of the productivity of the contact membrane distillation process on the concentrations of NaCl (*a*) and glucose (*b*) in the solution:[73] (*1*) with stirring (600 rev min^{-1}); (*2*) without stirring (temperature of the hot solution 70 °C, temperature of the distillate 30 °C).

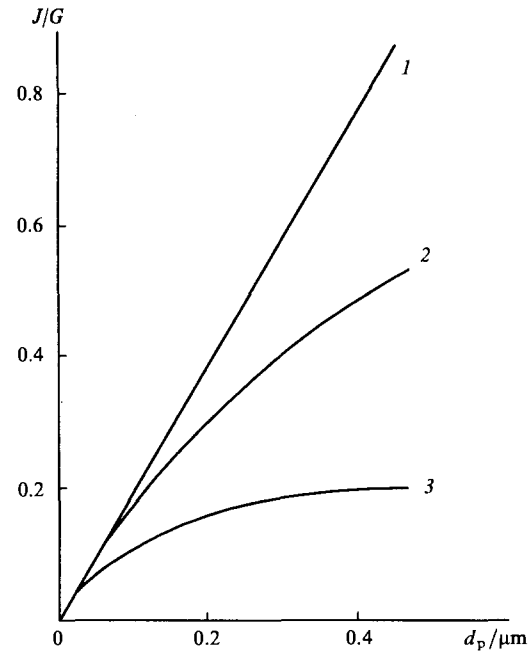

Figure 6. Dependence of the flux in the membrane distillation process on the pore size at different partial pressures of air (kPa): (*1*) 0; (*2*) 20; (*3*) 80.[72]

complex porous structure, a combined mass transfer takes place, i.e. with different contributions by both mechanisms, which has in fact been demonstrated experimentally and theoretically in a number of investigations.[37,45,72] Here one should take into account the fact that the presence or absence of an air layer in the membrane pores affects the mass transfer. The air in the membrane pores prevents the diffusion of water vapour and diminishes its flux through the membrane. Indeed, Fig. 6 shows that the dependences of the specific productivity of the membrane on the pore size are different for different partial pressures of air in the pores. For small pores, where the transfer is effected predominantly via Knudsen diffusion, the removal of air promotes only slightly an increase in the flux, whereas for membranes with a large pore diameter the flux to the membrane can be increased by 50% by deaeration.[72]

It has been noted that deaeration diminishes the heat transfer through the membrane by 10%–25%.[37,72] However, the hydrodynamic conditions, the pore structure, and the thickness of the thermophysical properties of the membranes are most important for the reduction of the influence of temperature polarisation on the intensity of the membrane distillation process.

The characteristics of the heat and mass transfer through PTFE membranes in the membrane distillation process have been determined experimentally with the aid of the $H_2SO_4-H_2O$, $HCl-H_2O$, NH_3-H_2O,[75] $NaCl-H_2O$,[55,56,75] and $C_2H_5OH-H_2O$ [53,69] systems at different temperatures and for different flow rates of the solution and the permeated material. It was established that the extents of heat and mass transfer are proportional to the temperature difference on either side of the membrane and depend on the porosity and thickness of the latter.[53,75,76] Expressions based on the material and heat balance equations for determining the flux of transferred substance have been obtained with the aid of mathematical modelling of the membrane distillation process. It is believed[75,76] that the calculated data agree well with the experimental results and that the membrane distillation process can be used to concentrate solutions such as juices, milk, sugar syrup, [aqueous] alcohol, etc.

Among the factors influencing the intensity of the membrane distillation, the hydrophobicity (wettability) of the membrane surfaces by the substances being separated has been considered in some investigations (see, for example, Yoshishige and co-workers[77,78]). The special importance of this factor is manifested for systems the concentraion of which leads to an appreciable decrease in surface tension (surfactants, alcohols, and certain water-soluble organic compounds).[28,29,77,78] Special procedures (modification of the membrane surfaces by more hydrophobic polymers or substances, a change in the size of the pores in the selective hydrophobic layer, etc.) make it possible to employ membrane distillation for the concentration of, for example, dilute solutions of alcohol. In such cases, it is possible to employ only membrane distillation through a gas (vapour) layer or vacuum membrane distillation.[15,17,19,53] The deposition of a layer of silicone rubber or poly-(1-trimethylsilyl-1-propylene) on the surface of microporous poly(vinylidene fluoride) membrane lowers the permeability to water and increases the selectivity of the membrane with respect to ethanol, acetone, acrylonitrile, and 1-butanol dissolved in water.[77,78] Not only the hydrophobicity of the membrane but also is asymmetry, the mechanism of the

sorption-desorption of the substances being separated, and also the changes in temperature gradient associated with the asymmetry and chemical composition of the membrane layers play a significant role in this process.

Studies of the membrane distillation process on different aqueous systems demonstrated the practical importance of this separation method and its advantages compared with other procedures, primarily the baromembrane methods. These advantages are associated with the possibility of separating concentrated and highly concentrated solutions, which as a rule do not require a complex preliminary purification.

VI. Modules and apparatus for membrane distillation

Membrane modules with all the existing configurations of membranes — flat, hollow fibre, and tubular — are employed for the membrane distillation process.

In contrast to baromembrane elements, two enforced flows are established within the channels of the membrane distillation modules (MDM) — the flow of the concentrate and the flow of the distillate (in the case of contact membrane distillation) or a gas (in the case of membrane distillation with a flow of gas). Furthermore, a cooling agent channel, separated from the gas space by the impermeable condensation surface, is essential for membrane distillation with a gas space.

The effectiveness of membrane distillation and other membrane processes is determined by the properties of the membranes and the design of the module. The principal parameter in the optimisation of the design of the MDM is the level of temperature polarisation. It was noted above that heat transfers in liquid streams exert an appreciable influence on such polarisation. The heat transfers are determined by the hydrodynamics of the flow of liquids within the channels of the membrane module, which depends on the design characteristics of the latter. The level of temperature polarisation can be estimated on the basis of the Nusselt number.[35,75]

From the standpoint of heat transfer, the most successful configuration is that of hollow-fibre membranes for which, at an internal diameter of 0.3 mm, a coefficient of temperature polarisation of 0.8 is already attained for $Re = 300$ (Table 2). However, with increase in the internal diameter to 1 mm, the attainment of CTP = 0.85 requires $Re = 3000$. For flat channels, the CTP increases with decrease in the thickness of the channel. Modules which are effective from the standpoint of the decrease in the level of temperature polarisation can be created on the basis of both hollow fibres and flat membranes (Table 2). This is indicated by the present state of development of the equipment for membrane distillation processes.

Spiral membrane distillation modules were proposed as early as 1982,[79] but we have been unable to find experimental data on the membrane distillation process carried out on MDM of this type. In our view, the lack of such data cannot be regarded as evidence that modules of the spiral type are unlikely to be useful. In such modules, it is entirely possible to create sufficiently narrow channels and to ensure enforced flows in the latter. Furthermore, the presence of spiral heat exchangers ensures effective heat exchange in MDM of this kind.

The Swedish cassette elements should probably be regarded as the first flat-frame MDM.[3,80,81] They consist of plastic plates with an internal channel for the stream of heated initial water in contact with two membranes. The working area of the membrane surface is 0.3 m^2. The membrane in the cassette is fitted on a porous base, which protects it from damage during the assembly of the module. The module is assembled from cassettes of the filter-press type. This entails the formation of a condensation channel (a gas space with a condensation surface) and a cooling water channel as a result of the employment of additional plates. This apparatus was created for membrane distillations through a gas layer or at a reduced pressure.

Unfortunately, apart from the above studies,[3,80,81] there have been no publications describing adequately the design of a flat-frame MDM. There is in fact no information whatever about the working parameters of the module, the hydrodynamic regime, the principles governing the organisation of the streams, etc.

Somewhat later, the membrane distillation process began to be carried out on hollow-fibre elements.[82–85] A hydrodynamic regime within the capillaries favourable for heat transfer is characteristic of MDM of this type.[37] However, it is fairly difficult to ensure effective heat and mass exchange on the outer side of the capillaries when a large number of bunches of capillaries are present.[75] It is important that stagnant zones should not form on the outer surface of the fibres.

Studies have been made on the hollow-fibre MDM with three types of packing of the capillaries:[75] parallel fibres, bunches of twisted fibres, and bunches of intertwined fibres. The packing comprising parallel fibres is made from a fabric material in which transverse filaments serve for the fixation of the hollow-fibres in the parallel direction. Such fabrics are rolled up and the rolls are packed in a jacket. The highest productivity has been observed for bunches of twisted and intertwined fibres. The highest packing density of the fibres, reaching 40% – 50%, occurs in the latter type of MDM. Bunches of intertwined and twisted fibres act as devices causing a turbulent flow within the shell of the hollow fibre MDM. Overall, the hydrodynamic regime established in the hollow-fibre MDM ensures the maximum productivity even for the laminar flow of liquids ($Re \approx 450$).[84]

Table 2. *Temperature polarisation for different membrane distillation systems.*[35]

70.7	38.7	32.4	66.3	2.83	1.73	4.6	2870	3.51

Note. The module consists of 2000 polypropylene fibres with internal and external diameters of 300 and 600 μm respectively and with a length of 400 mm. The area of the membranes is 1 m^2.

The flow of liquid media in hollow-fibre MDM is organised on the basis of the countercurrent principle. The temperatures at the inlet to and outlet from the module are then different. As can be seen from Table 3, the temperature differences are significant even for relatively short fibres (with a length of 400 mm). This leads to differences between the average temperatures in different sections of the fibre, i.e. the mass transfer conditions vary as a function of the length of the fibre. The differences between the inlet and outlet temperatures increase with the increasing length of the fibres and with decrease in the flow rate. Tests have been made hitherto on hollow-fibre MDM with fibre lengths up to 2 m and an internal diameter of the jacket of 250 mm. The area of the membrane for such MDM varies from 50 to 100 m^2.[84]

It is noteworthy that the differences between the mass transfer conditions for different sections of the membranes are equally characteristic of MDM of any configuration, but in the literature this problem has been discussed explicitly only in relation to the hollow-fibre MDM. It must be emphasised that the length of the membrane channel in the MDM is an important design feature, which requires optimisation both in the construction of modules and in the development of apparatus and technology.

In our view, the use for membrane distillation of the tubular modules with a low packing density of the membranes, which are as a rule very thick, is justified only in individual instances. Tubular MDM can probably be used to concentrate viscous solutions, characterised by impairment of heat transfer. Tubular MDM can ensure a satisfactory hydrodynamic regime in the flow of viscous liquids, particularly within the tubes.

Hitherto the available information about tubular MDM is limited. They are used predominantly for the desalination of water or for the concentration of aqueous solutions of low-molecular-mass substances.

A Japanese patent application[86] describes an unusual design of a tubular MDM. In this device, the evaporation system is separated from the condensation system, i.e. this is an apparatus for membrane distillation processes with a gas space. The evaporation and condensation systems consist of parallel tubes for the supply and removal of liquid media connected by a multiplicity of tubes in the condensation system or via tubular membranes in the evaporation system. A heated concentrated solution is supplied to the evaporation system, while a cooling liquid is supplied to the condensation system. The vapour which has passed through the tubular membranes condenses on the surfaces of metallic tubes of the condensation system and the distillate flows spontaneously into the collector.

Cartridge filters with a folded configuration of flat membranes have come to be fairly widely used to microfiltration processes. Cartridge elements based on polytetrafluoroethylene membranes with areas of 0.3 and 0.15 m^2 have been tested for membrane distillation.[87,88]

Apparatus for membrane distillation is, as a rule, of the circulation type, which ensures an increase in the degree of concentration and a more rational use of heat as a result of the decreased heat consumption in raising to its working temperature the solution being concentrated.

Depending on the heat transfer conditions and the length of the membrane channel of the MDM, the temperatures of the streams at the inlets and outlets differ to such an extent that the outlet temperature of the distillate may be higher than the inlet temperature of the solution being concentrated. In this case, it is possible to use part of the heat of the distillate to heat the solution undergoing concentration (Fig. 7*a*). However, in apparatus with heat recovery, the temperature difference between the two sides of the membranes, i.e. the specific productivity of the process, is small and this is why membranes with a high surface area are used in them.

In a number of cases, the problem of heat recovery is not formulated, for example if the membrane distillation is used to obtain water for boilers. In apparatus of this type (Fig. 7*b*), it is endeavoured to attain large temperature differences. Therefore the attainable specific selectivity of apparatus without recovery is higher, which lowers the capital expenditure and the expenditure on membranes.

From the standpoint of energy expenditure, the membrane distillation process is characterised by the energy efficiency parameter E, which is defined as the ratio of the part of the heat consumed on vaporisation to the overall heat introduced into the apparatus:[17,41]

$$E = \frac{JS\Delta H_V}{Fc_p(T_{in} - T_{out})}, \tag{33}$$

where S is the area of the membrane and F the flow rate of the initial solution with a heat capacity c_p and the temperatures T_{in} and T_{out} at the inlet to and outlet from the MDM.

As a consequence of the heat losses, E is always less than unity. The cost of the water purified by the membrane distillation method diminishes with increase in the temperature of the initial solution.[82]

The component which is always present in apparatus for membrane distillation processes is heat exchange equipment needed to heat the initial water to the working temperature and then maintain this during the membrane distillation process, and additionally for the utilisation of the heat from the distillate. Problems of heat exchange (outside the MDM) and of energy supply (source of energy) have scarcely been considered in studies on membrane distillation. In practice, these problems are solved by traditional engineering procedures.[85]

In discussing the economics of membrane distillation, Hanbury and Hodgkiess[89] noted that the process does not withstand competition when it is carried out on expensive tetrafluoroethylene membranes. This problem may be solved by employing polyalkene membranes or membranes made from chlorinated polyalkenes. The conclusion that Teflon membranes

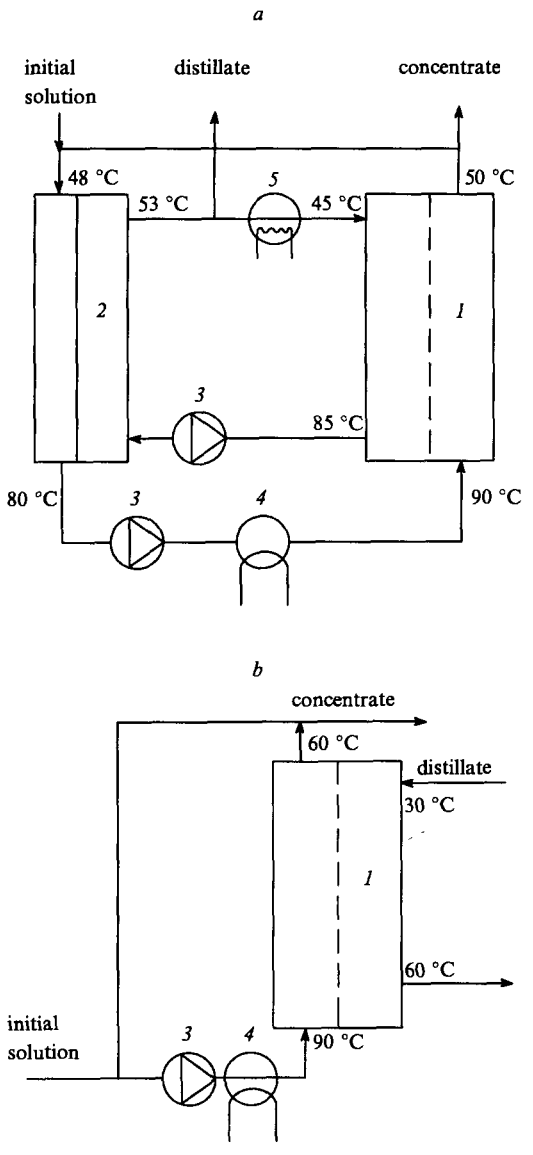

Figure 7. Schematic illustration of apparatus for membrane distillation with (*a*) and without (*b*) recovery of heat:[84] (*1*) membrane distillation module (MDM); (*2*) heat exchanger; (*3*) pump; (*4*) heater; (*5*) cooling unit.

are not competitive is not incontrovertible, bearing in mind the possible extended use of such membranes in membrane distillation.

According to the estimate of Fane et al.,[82] the expenditure on the operation of membrane distillation apparatus with a moderate power (5000 kg h^{-1}) is comparable to the expenditure on the operation of similar apparatus based on reverse osmosis. For less powerful apparatus, the expenditure is higher compared with the reverse osmotic apparatus. However, an advantage of membrane distillation is that it requires a less thorough preliminary purification of water.

VII. Applications of membrane distillation

The experimental data described above (see Section V) outline the range of technological processes in which membrane distillation may be employed. However, at the present time one is dealing only with the potential possibilities of the process. Despite the almost ten year history of the development of the equipment for membrane distillation, there are in fact no literature data on its long-term tests. The longest tests concern the treatment of artesian well water over a period of 18 weeks,[84] which indicate the stable operation of the apparatus.

It is possible to differentiate the following principal applications of membrane distillation: the preparation of pure water; the concentration of solutions of involatile substances; the purification of waste water; the isolation of volatile components from solutions containing also involatile substances; the separation of dilute water–organic liquid mixtures. Such subdivision is to some extent arbitrary. For example, the concentration of solutions of involatile substances leads to the simultaneous formation of pure water, whereas purification of waste water may involve the concentration of contaminating involatile substances, etc.

Preparation of pure water. When any aqueous solutions containing involatile substances are treated, highly pure water is obtained as the permeated material. Thus it has been shown[75] that the electrical conductivity of the distillate obtained on treating aqueous solutions of NaCl, H_2SO_4, and NaOH does not exceed 5 μS cm^{-1}. In the first place, membrane distillation is used[38,62,63,81] to obtain pure water from sea water and artesian well water.[84] The high quality of the water, which is almost independent of the concentration of the feed solution, has been noted. For example, when the electrical conductivity of artesian well water varied from 350 to 35000 μS cm^{-1}, the quality of the filtrate remained stable.[84] In carrying out the process, provision was made for only preliminary elimination of mechanical impurities. The long term operation is generally accompanied by a decrease in productivity as a function of time as a consequence of the contamination of the membranes. The recovery of the productivity in the treatment of artesian well water is achieved by washing the membranes with hydrochloric acid solution.[84] It is essential to note that, owing to the lack of results of long-term tests, the problems of the contamination and purification of membranes have been hardly described in the literature.

The use of membrane distillation for the final treatment of water in order to obtain sterile apyrogenic water is of interest.[87,88] It has been established that the content of endotoxins in the distillate obtained by membrane distillation is less than 1.0 ng $litre^{-1}$ when their content in the initial water is 11.3 ng $litre^{-1}$. Water of this quality is characterised as apyrogenic. Bacteria were not detected in the distillate. Membrane distillation ensures better elimination of particles than the usual distillation particularly the elimination of particles the size of which is less than 1 μm. The content of low-molecular-mass organic impurities, for example carbon, in water falls from 417 μg (on treatment of deionised water) to 280–290 μg per litre. The proposed apparatus with polytetrafluoroethylene membranes having a folded configuration (with areas of 0.30 and 0.15 m^2) makes it possible to obtain 20 kg of apyrogenic water per hour. Tests carried out over a period of 1000 h demonstrated the stability of the apparatus both as regards productivity and the quality of water.

Concentration of solutions of involatile substances. Membrane distillation is a promising method for the concentration of aqueous solutions of involatile substances. The possible concentration limits of the membrane distillation process greatly exceed those when reverse osmosis is used.

The membrane distillation method can be employed to concentrate aqueous solutions of sugars.[64,75] When a solution of glucose is concentrated, a sharp decrease in productivity is observed at a concentration in excess of 25 g $litre^{-1}$,[75] which is probably due to an increase in the viscosity of the solution, impairing the heat exchange conditions, and not to a decrease in the vapour pressure over the solution. In the treatment of viscous solutions, it is necessary to intensify the turbulence of the stream or to carry out the process at higher temperatures. Thus concentration of a sugar syrup at 86 °C is characterised by a productivity with respect to the distillate of 20–28 kg $(m^2\ h)^{-1}$ in the syrup concentration range from 10% to 40%.

The problem of the impairment of heat transfer as a consequence of the increase in concentration arises also when solutions of high-molecular-mass oligomeric substances are concentrated. For example, a fairly sharp decrease in productivity has been observed when a solution of gelatine was concentrated.[75] At the same time, one should note that the vapour pressures over solutions of high-molecular-mass compounds depend only slightly on the mass concentration of the polymer (owing to the low molar concentration of the solutions). As a result of this, water-soluble polymers may be concentrated in the presence of effective heat and mass exchange in the MDM channels, for example in a tubular MDM. We may note the high stability of the productivity in the concentration of oligomeric substances (Fig. 8), characterised by a low viscosity.

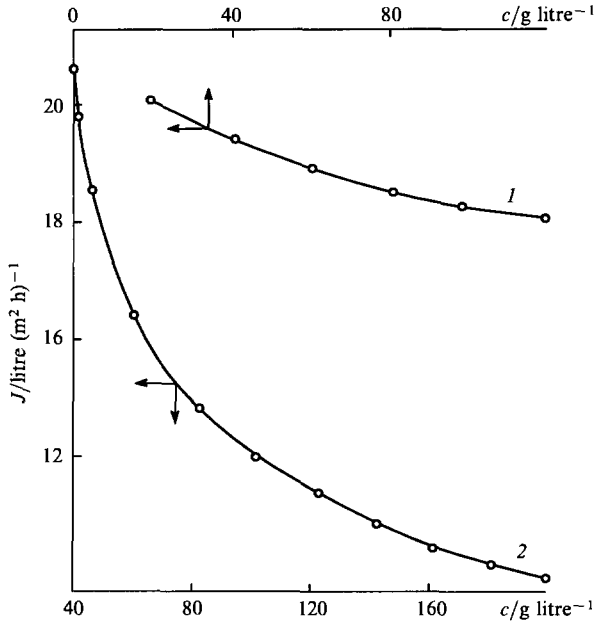

Figure 8. Dependence of the productivity of the membrane distillation process with respect to the permeated material on the solute concentration during the concentration of a solution of poly(ethylene glycol) with a molecular mass of 6000 (curve *1*) and waste water from a coke-chemical factory (curve *2*).

The problem of concentrating liquid products containing high-molecular-mass components frequently arises in the food industry. Thus it has been shown that membrane distillation is more effective in the concentration of mandarin juice as compared with reverse osmosis.[75] Membrane distillation makes it possible to attain threefold concentration with a gradual decrease in productivity as the degree of concentration rises from 10 to 7 kg $(m^2\ h)^{-1}$. On the other hand, reverse osmosis is characterised by a sharp decrease in productivity: after concentration by a factor of only 1.5, the productivity is 5 kg $(m^2\ h)^{-1}$. We may note that the treatment of mandarin juice by membrane distillation was carried out at 48 °C, i.e. under fairly mild conditions, which makes it possible to preserve the properties of the thermolabile components of the juice.

Even milder treatment conditions are attained is osmotic distillation, where the vapour pressure in the receiving part of the MDM is reduced as a result of the employment of solutions with a high osmotic pressure. Thus the concentration of orange, apple, and grapefruit juices at a temperature of 29 °C (40 °C in individual experiments) with the aid of a flat-frame module having a membrane area of 0.7 m^2 (a 28% solution of an inorganic electrolyte was passed through the receiving channels) has been described.[22] As in the case of contact membrane distillation, the productivity of osmotic membrane distillation depends on the hydrodynamic conditions in the flow within the capillaries of the apparatus; the absolute productivity did not exceed 2.5 litre $(m^2\ h)^{-1}$ as a consequence of the small temperature difference. The juices were concentrated until the attainment of a 50% content of the solutes.

Overall, the likely usefulness of membrane distillation for the concentration of solutions of thermolabile substances must be specially emphasised.[61] Studies on mass transfer in the concentration of solutions of vitamins C and B_1 by the contact membrane distillation method in the temperature range 50–60 °C showed that it is possible to obtain supersaturated (at room temperature) solutions of the vitamins: 50%–55% for vitamin C (the concentration of the saturated solution at 20 °C is 25.3 mass%) and 60%–65% for vitamin B_1 (the concentration of the saturated solution at 20 °C is 50 mass%). After cooling, the concentrated solutions of the vitamins and their crystallisation, the deposited vitamin may be separated and the solution can be again concentrated with the aid of membrane distillation. After the attainment of the concentrations indicated, the productivity of the contact membrane distillation is 6–8 litre $(m^2\ h)^{-1}$. It has decreased compared with the initial value by a factor of not more than 2–3.

The formation of supersaturated solutions in the membrane distillation process is not exceptional.[90,91] Thus membrane distillation has been suggested for the isolation of lanthanum compounds from a sulfuric acid extract of phosphogypsum.[91] The extract obtained on treatment of phosphogypsum contains 16% of sulfuric acid, 1.6% of Ln_2O_3, and 3.5% of CaO as the main components. The concentration of such an extract by membrane distillation was from 16% to 44% in terms of sulfuric acid, with a productivity of 215 and 80 litre $(m^2\ day)^{-1}$ at an extract temperature of 60 °C. After cooling the concentrate, a deposit containing up to 25% of lanthanum compounds was isolated. The formation of $CaSO_4$ crystals on the membrane surface has been observed when the process is carried out by a periodic procedure, this being a consequence of crystallisation from supersaturated solutions remaining on the membrane surface.

Purification of waste water. Water of very high quality is obtained in the purification of waste water by membrane distillation, whereas the concentrate may contain valuable components or even the target product of the manufacturing process at a high concentration up to supersaturated solutions. Thus the concentration of water from the manufacture of taurine (2-aminoethanesulfonic acid), containing taurine and sodium chloride, is accompanied by the crystallisation of taurine.[91] The deposit segregated contains up to 60% of taurine and impurities (sodium chloride). The product may be purified by recrystallisation.

Membrane distillation may become the principal procedure for the creation of closed water supply systems. Laboratory studies on systems for the recovery of water under conditions of space stations have been reported.[92]

Membrane distillation is perhaps the only alternative to vaporisation processes in the treatment of highly concentrated waste waters, including those from undertakings in different branches of industry. Experiments have been carried out on the purification of waste waters from the textile industries containing dyes.[41] It has been noted that membrane distillation can be best employed to concentrate further already concentrated waste water and it is therefore recommended that, in the purification of waste waters from textile undertakings, preliminary concentration by reverse osmosis be carried out with subsequent treatment of the concentrate by membrane distillation.[41]

The possibility of a high degree of concentration of aqueous salt solutions, in particular solutions of heavy metal salts, has been investigated.[93] The authors employed membrane distillation through a gas layer. In the concentration of nickel salts, a weak variation of the productivity with respect to permeated material

was noted. The productivity reached 25–30 litre $(m^2\ h)^{-1}$. The high quality of the permeated material was noted, which makes it possible to employ membrane distillation in combined schemes for the purification of wash waters and for the processing of spent solutions from the electroplating industry.

In the purification of waste waters from processing plants in the food industry, it is possible to obtain concentrated solutions of valuable food components. Thus treatment of whey by membrane distillation made it possible to obtain a concentrate containing 300 g $litre^{-1}$ of lactose for a process productivity with respect to the distillate of 0.43 m^3 $(m^2\ day)^{-1}$.[94]

As a rule, waste waters are complex multicomponent mixtures. Thus the waste water from the coke-chemical industry (water from the gas collector) contains up to 40 g $litre^{-1}$ of ammonium chloride, inorganic electrolytes, and various organic substances (phenols, pyridines, etc.). Such water is highly corrosive, especially at high temperatures, which makes problematical the employment of evaporation processes to be carried out at the critical temperatures.

Waste waters may be concentrated by membrane distillation up to a content of inorganic electrolytes of 200–250 g $litre^{-1}$ (Fig. 8). It is noteworthy that the waste waters from the coke-chemical industry contain volatile organic impurities, which also permeate through the membrane. After the treatment of such waste waters by membrane distillation, the permeate therefore contains volatile organic impurities (phenols, pyridine). These impurities can be made harmless by biological methods. The vital activity of the corresponding microorganisms is suppressed in the biological treatment of highly mineralised waste waters.

Isolation of volatile components from solutions of involatile substances. The example involving the concentration of waste waters partly demonstrates the possibility of using membrane distillation for the isolation of volatile components from solutions of involatile substances. For example, phenols can be removed from a concentrate of inorganic salts. However, so far there are no literature data on the deliberate technological employment of this approach. A system which makes it possible to isolate volatile substances from aqueous solutions by membrane distillation, before their analysis, has been described.[95] In this scheme, specimens with a volume not exceeding 6 ml are introduced into plastic tubes, their contents are boiled, and the vapour passes through a hydrophobic membrane and is then condensed. The method allows 100% isolation of substances in less than 60 min. It has been tested in experiments with cyanides, cyanide complexes, sulfides, phenol, and ammonia.[96]

Separation of water–organic solvent mixtures. The use of membrane distillation for the separation of water–organic solvent mixtures is an alternative to the transvaporisation and fractional distillation methods in the treatment of mixtures with a low content of the organic substances. Membrane distillation has been tested primarily in the separation of water–ethanol mixtures.[15,53,69,77,78,97] In the stationary regime, the concentration of ethanol in the permeated material increases by a factor of 2–3.[69,97] The productivity with respect to the permeated material then reaches 10 kg $(m^2\ h)^{-1}$ and more,[96] which greatly exceeds the productivity in transvaporisation. However, it has been shown[69] that the permeability of the membrane and its selective properties vary with time owing to the wetting of the pores.

VIII. Conclusion

Analysis of the available publications on membrane distillation supports the view that the method is promising for the solution of a series of technological problems. The advantages of membrane distillation compared with other membrane methods are associated with the low requirements which must be met in the preliminary purification of waste and other saline waters, the absence of excess working pressures, a satisfactory productivity even at high and very high concentrations of the solutes close to the solubility limit, the possibility of using low-energy heat in combination with the possibility of its recovery, the relative simplicity of the design of the modules and apparatus, the high quality of the permeated material (water), including the possibility of obtaining in one stage a pyrogenic sterile water, and the extensive possibilities for the technological employment of membrane distillation in many branches of industry.

The following disadvantages of membrane distillation may be noted: the impossibility of using it for the purification of water and the concentration of solutions containing surfactants and other water-soluble organic compounds with a low surface tension and a low boiling point (for example alcohols), the limited selection of hydrophobic materials suitable for the formation of membranes, and the high cost of such materials and of the membranes based on them. The last factor may not be quite so significant if the operating life of the membrane is sufficiently long (3–5 years).

Analysis of the advantages and disadvantages of membrane distillation compared with other membrane as well as physico-chemical purification and concentration methods leads to the conclusion that membrane distillation has on the whole significant advantages over the baro- and electro-membrane methods employed for such purposes both independently and in hybrid technological schemes involving other methods.

Bearing in mind that hitherto membrane distillation is still a little investigated process, the growth of interest in the method and in its extensive practical use is to be expected in the future. At the same time, problems which require consideration in the immediate future have already become apparent. In our view, they include the theoretical and experimental solution of problems of mass and heat transfer in relation to the real macrostructure of the membranes and the physical properties of the materials from which they are made. Hence follows the need to optimise the pore and geometrical characteristics of the membranes and modules and also for a rational search for materials with the required physical, physicochemical, and mechanical properties. A more thorough and purposeful study of problems of the hydrophobic-hydrophilic properties of the membrane surfaces and of their influence on the structure of water in thin surface layers and also on the nature of the interaction of the components of the solution with the membrane surface is required. Hitherto, this problem has not been solved for membrane distillation, although it may be important for the treatment of experimental data on the retention of components of the solutions and on the productivity of membranes with respect to the permeated material. Yet another special problem, associated with the possibility of the contamination of the membrane surfaces by sorbed solution components and with the formation of deposits on the hydrophobic surface and in the pores of the membrane, is related to the above problem. It has not been discussed in the literature, although its practical importance is evident especially for the estimation of the potential possibility of the use of membranes and of the time intervals at which they are to be regenerated and the development of procedures for such regeneration.

Experimental studies on the characteristics of the membrane distillation of solutions mixtures containing readily volatile and volatile components (wetting and not wetting the surfaces of hydrophobic membranes) and the determination of the critical concentrations and other physicochemical parameters of such systems are needed. In our view, kinetic studies on the membrane distillation process under the conditions of variable characteristics of the mixtures being separated are also important.

The above list of problems associated with the development of membrane distillation is incomplete, but we hope that the analysis of the available literature data will serve the purpose of a deeper study of membrane distillation and of its extensive practical employment.
