Abstract. The current state of the problem of the preparation from polymers of planar mono- and multi-layer organised structures on the surface of a liquid or a solid is analysed. The structure and physicochemical properties of the corresponding monolayers and Langmuir–Blodgett films are examined and the characteristic features of the packing of the macromolecules on the surface of the liquid, questions concerning the stability of their monomolecular films, the compatibility of high- and low-molecular-mass compounds in the monolayers, and the influence of the degree of polymerisation, size, and orientation of the side group on the phase state of the monolayers are discussed. Much attention is devoted to the methods of preparation of Langmuir–Blodgett polymer films with a specified architecture and to the study of the characteristics of these monolayer ensembles and the prospects for their practical employment in molecular devices. The bibliography includes 306 references.

I. Introduction

The perfection of the objects and processes in living nature has long attracted the attention of natural scientists, stimulating an endeavour to use the principles underlying the functioning of biological systems for the development of devices for different purposes operating at the molecular level. Evidently, this approach is applicable not only to the traditional objects in molecular engineering, namely functional (molecular) electronics, ionics, photonics, etc., but also to a wider range of systems. In particular, the idea of embodying in molecular constructions based on the biosimulation concept of a most important principle, namely the self-regulation of biological systems, appears extremely attractive. For example, in order to ensure the specified properties, it is at present necessary to introduce pigments, inhibitors, antioxidants, and plasticisers into polymer coatings and plastics at concentrations which are so high that they alter significantly (as a rule, impair) the entire set of the fundamental characteristics of the materials. The creation of systems capable of recognising external influences at the molecular level and of responding to them adequately is one of the urgent problems in modern science. The achievement of rapid, local, and selective recognition and response opens the way to a reduction of material and energy expenditure on the neutralisation of undesirable influences on the system.

In a broad sense, these problems constitute the subject of the rapidly developing supramolecular chemistry, i.e. the 'constructional chemistry of intermolecular linkages' according to the definition of Jean-Marie Lehn — the 1987 Nobel Laureate in chemistry.[1] The scheme presented in Fig. 1 (see over) demonstrates the transition from molecular chemistry to molecular and supramolecular devices.[1] Within the framework of the present review, the supra- and poly-molecular chemical characteristics of organised assemblies are examined in parallel (and not consecutively) because recognition, transformation, migration, etc. processes, assigned in Fig. 1 to the field of supramolecular chemistry, are discussed in relation to organised planar structures.

On the basis of the foregoing, the creation of molecular (supramolecular) devices must include at least three main stages.

1. The construction or synthesis of organic molecules carrying a specific function. This problem of molecular chemistry, in which questions concerning the organisation of individual atoms, their binding to one another, and their disposition in a specific manner relative to one another in order to impart to the molecule the required steric structure are considered.

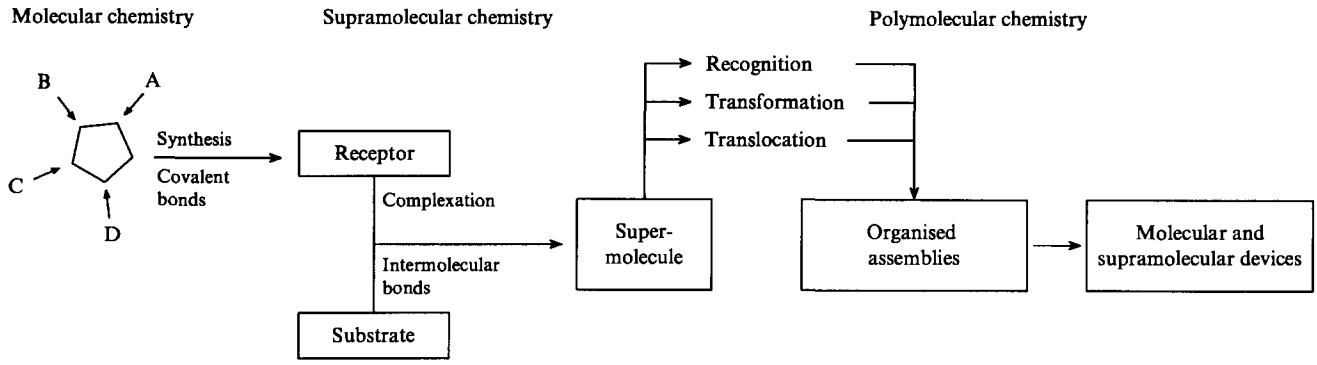

Figure 1. Transition from molecular to supramolecular chemistry.[1]

2. The creation of organised polymolecular assemblies. Evidently, the existing technological procedures for orienting materials, for example drawing, crystallisation, orientation in a flow, and epitaxial growth, are unsuitable for the preparation of assemblies of molecular dimensions. This problem is solved in two ways — primarily by self-assembly and forced organisation. The spontaneous formation of the nucleic acid double helix, which includes the recognition and selective pairing of bases, is a classical example of self-assembly. A second more recent example is the self-organisation of monolayers of alkylsiloxanes, aliphatic acids, dialkyl sulfides, dialkyl disulfides, and thiols on the surfaces of aluminium, silver, gold, silicon oxide, etc.[2-11] A higher level of this effect is illustrated in Fig. 2. A diphilic thiol and acid undergo selective adsorption and organisation on a mosaic surface consisting of sections of gold and aluminium oxide. Here too it is easy to identify two processes: the recognition of 'its own' support (Au for the thiol and Al_2O_3 for the acid) and self-organisation on the latter.

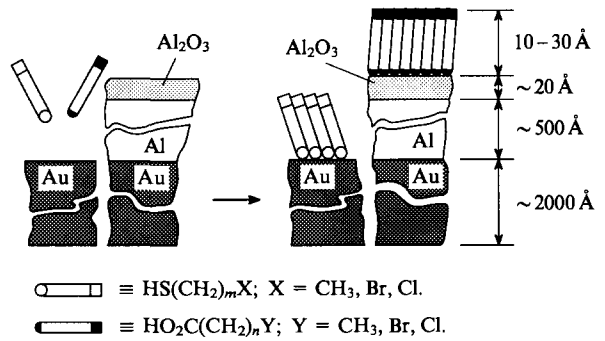

Figure 2. The formation of self-organised monolayers of diphilic molecules of an alkanethiol and a carboxylic acid on adsorption from solution on the surface of gold textured with aluminium oxide.[12]

The Langmuir–Blodgett method should be regarded as forced organisation, because the formation of a monolayer with a specified organisation on the surface of water and its transfer to a solid support require an energy expenditure.

Superlattices, i.e. nanometer layers of organic molecules with a specified alternation order with respect to their thickness, can be obtained only by the Langmuir–Blodgett method. It has been shown[13] that under these conditions the superlattices possess order also in the plane of the monolayers.

One may claim that the application of the Langmuir–Blodgett method always leads to the creation of molecular (supramolecular) constructions, the physical and chemical properties of which are largely determined by the cooperative nature of the behaviour of their constituent molecules.

3. The creation of molecular (supramolecular) devices. In order that a molecular construction should acquire the status of a device, it must be capable of performing a definite function. Solutions to this problem at a higher scale level are known — for example, in the existing devices for the storage and processing of information which employ only one physical effect and only one form of dynamic inhomogenity. The trend towards the miniaturisation of electronic instruments down to molecular devices entails the problem of the realisation and integration of various physical effects in one construction. However, being restricted solely by the 'safety tunnel', specifying the distances between molecular keys at 5–10 nm, such technology would make it possible to pack molecular electronic elements with a density of 10^{18} units per cm^3.[14]

Thus, in order to create molecular devices, it is necessary to seek molecular components capable of performing a specified function and suitable for incorporation into a system organised in a specific manner and formed by different types of polymolecular assemblies. The principal feature of these components and the devices formed from them consists in the fact that they perform their functions on the basis of the properties of molecules and supramolecules.[1] The nature of the components or functional groups introduced into the system determines the operations which can be performed by the molecular assemblies: energy, electron, and ion transfer, different types of chemical reactions, the recording, transmission, and storage of information, etc.

For low-molecular-mass diphilic compounds, studies involving all three stages indicated above are being actively prosecuted at the present time. One of the principal ways of carrying out the first of these (molecular chemistry) involves the grafting to the molecule carrying a definite physical functional group (tetracyanoquinodimethane, tetrathiafulvalene, thiophene, pyridine, dyes, etc.) of a hydrocarbon chain, which ensures the organisation of the monomolecular film on the surface of water.

In the case of polymer systems, this procedure is less appropriate in view of the limited set of macromolecules containing suitable functional groups. Therefore, in order to create monolayer-forming functional polymers, a different procedure is usually resorted to — side groups capable of responding to external influences are grafted onto the main hydrophobic chain. The polymerisation of functionalised monomers and their copolymerisation with inactive monomers, acting as spacer units in the polymer chain, are also employed.

The limited set of objects, the problem of the stability of the monolayers, and the complexity of the manipulations involved in the preparation of Langmuir–Blodgett films (LBF) are apparently the main causes of the appreciable lagging behind (especially in quantitative terms) of the research into high-molecular-mass mono- and multi-layer structures. On the other hand, the problem of the creation of molecular devices can hardly be solved without using high-molecular-mass compounds both in passive insulating layers and in active transforming and transmitting two-dimensional elements. However, the

studies on monolayers and LBF cannot be restricted to approaches traditional for low-molecular-mass compounds which have already been established as a result of attempts at the practical employment of the latter in molecular electronics, nonlinear optics, and other branches of engineering. The specific features of high-molecular-mass chemistry have given rise to a different range of fundamental questions and have influenced the applications of the corresponding monolayers and LBF.

A need has arisen for a more detailed consideration of the physical chemistry of the two-dimensional state of macromolecules and the establishment of a relation between the structure of polymers and their behaviour in a monolayer, the formation of multilayer, including alternating, high-molecular-mass assemblies, and for the study of the possibility of applying two-dimensional organised structures of high-molecular-mass compounds to traditional products of polymer chemistry—organic coatings, adhesives, and membranes (for example, for the preparation of materials with a specified gradient of a characteristic parameter). The theoretical interest in the phase behaviour of monolayers,[15] including high-molecular-mass monolayers, has arisen because certain approaches to the description of critical phenomena cannot be applied in the three-dimensional case but are fully applicable to a system with a smaller number of dimensions.[16]

In the first review, published in 1991,[17] two of the three known methods of preparation of polymeric LBF were examined: (1) the formation of monolayers from monomers on the surface of a liquid (water), their polymerisation in the monolayer, and their transfer to a solid support and (2) the formation of monolayers from monomers, their transfer to a solid support, and the polymerisation in the LBF of each layer or the multilayer film as a whole. A third method envisages the formation of monolayers on the surface of water from complete polymers with subsequent transfer to a solid support. The principal difference between these procedures (responsible for the differences between the approaches to the study of the corresponding systems) consists in the fact that in the first two cases the initial monolayers are formed from low-molecular-mass compounds (monomers), while in the last procedure they are formed from high-molecular-mass compounds. Although many of the problems associated with the transfer of polymer monolayers to solid supports are similar for the first and third procedures, this by no means applies to all of them. Thus the monomers forming the monolayer must be diphilic, insoluble in water, and involatile, but these requirements are not obligatory for monolayers of macromolecules. For example, poly(methyl methacrylate), which does not exhibit distinct diphilic properties, and cellulose derivatives or poly(vinyl alcohol), which are soluble in water, nevertheless form monolayers on the surface of water. These features of high-molecular-mass compounds, on the one hand, expand the number of objects of study and the possibility of using organised planar structures, and, on the other hand, create specific problems in the formation of LBF.

The study of the properties of macromolecules on the surface of water (a liquid) and their influence on the formation of multilayer structures on a solid support is essential for the preparation of high-quality LBF with a minimum number of defects and a homogeneous orientation, thickness, and surface density from polymer monolayers.

It is essential to note that the optimistic prediction in the first review[17] of an increase in the intensity of research into polymer monolayers and LBF expected in the immediate future has unfortunately not so far come true. Systematic studies on polymer monolayers, similar, for example, to the studies carried out on diacetylene monolayers and LBF, are not being prosecuted at the present time. Furthermore, the results of earlier investigations, many of which have not lost their current value, are inadequately taken into account in present day research.

The history of the research into macromolecules in monolayers began with the studies by Devaux in 1903.[18] Since then and up to the Second World War, mainly natural[19–21] and synthetic[22–24] polymers were investigated. However, most of these studies and systematic treatment of data on polymer monolayers date back to the 1940s–1950s.[25–27] In subsequent years, such investigations were performed quite vigorously and were marked by sudden surges due to the appearance of some new polymeric object or the discovery of interesting properties in an existing material. This refers, for example, to studies on polyorganosiloxanes (1960–1970) or to the current interest in conducting polymers (polythiophenes, polypyrroles), as well as fullerenes and their derivatives.[28,29]

Overall, two stages can be distinguished in the chronology of studies on thin polymer films. The early and longest stage involves mainly the investigation of monolayers of macromolecules on the surface of water. In the subsequent 15 years more attention was devoted to LBF in connection with the development of research into molecular architecture. Since LBF are formed by transferring monolayers from the surface of a liquid and reproduce to some extent the structure of these monolayers, the equivalence of both stages or aspects of the research into problems of molecular design becomes evident.

These considerations have determined the structure of the present review, in which the conditions governing the formation, equilibria, stability, and phase states of polymer monolayers and the influence on the latter by the molecular mass of the polymer, the length of the side chain, the composition and pH of the support, temperature, and other factors are analysed. Questions concerning the correspondence between the structural-morphological characteristics of monolayers of high-molecular-mass compounds on the surface of a liquid and in LBF also occupy an important place. The behaviour of monolayers in the collapse region as well as the specific features of the use of thin films of polymers for the formation of LBF are examined.

II. The genuine existence of polymer monolayers on the surface of a liquid

The short but rich in content review by Gaines in 1991[30] takes us back one hundred years to the period where the question of the genuine existence of monolayers of large molecules arose as a result of studies by Pokels.[31] Gaines believes that the 'either polymer or monolayer' dilemma still remains the order of the day, i.e. the question of the genuine existence of polymer monolayers remains of current interest. The genuineness of the monolayer or of the spreading process, i.e. of the existence of a state of the polymer layer in which each monomer unit is in contact with the surface of the subphase, has been tested in accordance with Crisp's recommendations.[26] According to the latter, genuine spreading occurs in the case where reproducible surface pressure (π)–area (A) relations are obtained when the concentration of the solution from which the monolayer is formed or the initial spreading area are altered, and also when the monolayer is deposited from different solvents. When the monolayer is formed by helical (polydimethylsiloxane on a low-energy liquid support[32]) or coiled (polystyrene[33]) macromolecules, it cannot formally be regarded as genuine. However, if its constituent molecules have several stable conformations and structural transformations (for example helix–coil) are possible on the surface of the liquid, then also the study of nongenuine monolayers of this kind may prove useful.

In the review mentioned above,[30] the author addresses the question whether it is possible that the macromolecular coils produced as a result of coiling up in the bulk of the solution could become uncoiled on reaching the surface of the liquid with formation of a true monolayer. There are apparently no fundamental objections to a positive answer to this question. Furthermore, an important argument in support of such an answer arises from the repeatedly established agreement

between the experimental limiting areas of the close-packed monolayer (A_0 at $\pi \to 0$) and the analogous parameters obtained from models.

Less unambiguous results were obtained in tests of the genuineness of the monolayers carried out in accordance with Crisp's criteria. In his studies on poly(vinyl acetate), poly(methyl methacrylate), and poly(methyl acrylate) monolayers, Crisp found that variation of the conditions in the preparation of the monolayers does not alter the compression isotherm. In these experiments, the concentration of the solutions was varied from 0.005% to 0.2% and the solvents were the 1 : 1 water–propyl alcohol mixture, acetone, and benzene for poly(vinyl acetate) and acetone, benzene, and toluene for the remaining two polymers.[25] However, in contrast to this, a dependence of the position of the compression isotherms on the concentration of the solution deposited on the surface of water has been observed in another study[27] for poly(methyl methacrylate) monolayers. Thus, when the concentration was varied from 0.018% to 0.2%, the limiting area per molecule (A_0) changed from 21 to 18 Å^2 (A_0 = 14.5 Å^2 according to Crisp). An even more marked influence of the concentration of the solution on A_0 has been observed[33] for polystyrene: an increase in the concentration of the solution from 0.033% to 0.2% lowered the area by a factor of 2.

The importance of these studies is evident, just as it is evident that they must be based on the ideas of the classical theory of polymer solutions and the modern views arising from the scaling method.

The deposition of monolayers from solutions in good, poor, and θ-solvents, where the macromolecular coils have different sizes and the nature of their interaction with the solvent and with one another is likewise different, can lead to the formation of various surface structures in the monolayers. The concentration of the polymer solution is also a fundamental parameter, which determines, for example, the degree of overlap of the coils. The transfer of the macromolecules from the bulk to the surface, occurring when the polymer solution spreads on the surface of a liquid, is accompanied by complex processes. The ratio of the rates of spreading and evaporation of the solvent, the replacement of the solvent by the liquid constituting the subphase (water), the influence of the field of surface forces, and the limitations as regards the possibility of a rearrangement in the conformation of the macromolecules imposed by the wall (surface) are factors which still have to be analysed.

The form of the macromolecules in the three- and two-dimensional states can be conveniently correlated by resorting to the scaling concept. We shall assume that the polymer is deposited from an effective solvent, the quality of which does not change on passing to the two-dimensional system, i.e. from the bulk-phase solution to the monolayer. In this case, the size of the macromolecules (R) is determined by a critical parameter in the form of a power exponent for different numbers of effective segments in the macromolecule (N) which are different for the three- and two-dimensional systems.[34,35]

Three-dimensional space: $R \sim N^{3/5}$
Two-dimensional space: $R \sim N^{3/4}$

This implies an increase in the size of the flattened macromolecular 'coils' when the molecules pass from the bulk of the solution to the surface and hence the existence of a threshold concentration

$$\frac{1}{A^*} = \frac{N}{S}$$

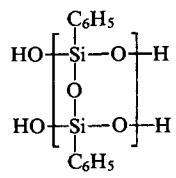
(where S is the area of the effective segment), for which there is a transition from a dilute two-dimensional solution to a semidilute solution where the flat coils begin to overlap on the surface of the solution. The possibility of a limited interpenetration of the planar coils in a two-dimensional system probably accounts for the stability of the polymer monolayers and the reversibility of the $\pi - A$ isotherms in compression–expansion cycles.

III. The stability of polymer monolayers

It is necessary to distinguish two approaches to the problem of the stability of monolayers. The first, commonest, reduces to the observation of the decrease in the area of the monolayer at a constant surface pressure and of the surface pressure when the mobile barrier is stopped (A = const) in the course of a definite arbitrarily selected time interval. As a rule, the purpose of such experiments is to establish the possibility of maintaining the necessary density of the monolayer in the course of the formation of the LBF.[36,37] Within the framework of this approach, the stability of the monolayers can be increased by altering the temperature and by introducing stabilising additives into the monolayer or the subphase and, in the case of ionogenic compounds, also by altering the pH of the support, by employing electrolyte solutions as the subphase, etc.

The second, more rigorous approach is associated with the establishment of thermodynamic equilibrium in the monolayers. It is based on a number of conditions, the main ones of which are the possibility of applying the techniques of thermodynamics and statistical physics to the calculation of the characteristics of the system, the determination of the phase state of the monolayers and of the transitions between them, and comparison of the results obtained by different workers. Within the framework of this approach, one has to solve the problem of the selection of a standard state of the system,[38] for which at least three versions have been proposed.

1. The state with an equilibrium spreading pressure,[39,40] i.e. with a surface pressure, established in the monolayer, which is in equilibrium with the volume of the substance.[41–44]



2. The state with a surface pressure corresponding to the phase transition between liquid-expanded and liquid-condensed states of the monolayer.[45,46]

3. The state with a surface pressure corresponding to the transition of the gaseous monolayer to a liquid one.[45,47]

Evidently the choice of the standard state is dictated by the behaviour of the monolayer. The rare data on the gaseous state of monolayers and the controversy concerning the phase transition between two liquid states do not engender optimism as regards the selection of the last two parameters as the standard ones even for the thoroughly investigated low-molecular-mass compounds. The only disadvantage of the equilibrium spreading pressure as a criterion of the thermodynamic stability of the monolayer is perhaps the fact that many compounds do not spread from the bulk phase under the usual experimental conditions (room temperature). The solution of this problem, i.e. the determination of the equilibrium spreading pressure (π_e) for such compounds, is seen by some workers[48] as a procedure involving the deposition on the surface of water of a concentrated solution of the test substance (for example, dipalmitoylphosphatidylcholine) until the maximum surface pressure is attained. This quantity is identified with π_e. It is believed[48] that this procedure is rapid, reliable, and reproducible and yields values of π_e which agree with the equilibrium spreading pressure determined by the traditional method involving spreading from the bulk phase. Another method for the determination of π_e has been proposed by Albrecht.[49] The pressure corresponding to the collapsed monolayer (palmitic acid), which is compressed under controlled conditions, is adopted as the equilibrium spreading pressure. Albrecht[49] notes the importance of this procedure for the determination of isotherms for polymers with long relaxation times. In principle, both procedures considered can be useful. However, one must understand that in either case the monolayer is in equilibrium not with its bulk phase (crystals) but with a hydrated form of the latter, which has an equilibrium spreading

pressure $\pi_e' > \pi_e$. For low-molecular-mass compounds, these questions have been examined in detail by Trapeznikov and coworkers.[50,51] For polymer monolayers, such studies have not yet been carried out.

Analysis of the temperature variations of the equilibrium spreading pressure has been carried out[52] in relation to ladder oligophenylsilsesquioxanes (M = 1 200) and polyphenylsilsesquioxanes (M = 60 000) on the surface of water.

1

As can be seen from Fig. 3, neither the oligomer nor the polymer spreads spontaneously from the bulk phase at 20 °C. The curve for the oligomer consists of the linear sections AB and BC with different slopes and of a high-temperature section parallel to the abscissa axis. The initial section (AB) has the highest slope; at T = 30 °C, the curve exhibits a break, the surface pressure at this point corresponding to the collapse pressure of the oligomer monolayer. This point may be associated with the onset of the formation of a new hydrated bulk phase of the oligomer, the properties of which differ from those of the bulk phase initially placed on the surface of water. The $\pi_e - T$ relation for the polymer is of a different type: as the temperature is raised from 20 to 35 °C, π_e changes insignificantly, after which its more rapid increase is observed. At T > 55 °C, the pressures π_e for the oligomer and polymer become similar and change only slightly on further increase in temperature. The appearance at the point C of yet another hydrated form of the oligomer is indicated by the following observations. At T = 60 °C, the white oligomer powder on the surface of water begins to undergo surface fusion and becomes transparent, assuming the form of lenses, which again become white at T = 70 °C. We may note that the melting points of the oligomer and the polymer are 150 and 400 °C respectively. Consequently, during spreading from the bulk phase on the surface of water, high-molecular-mass compounds can yield several hydrated forms, each of which has its own equilibrium spreading pressure π_e'. The existence of such forms with high values of $\pi_e' > \pi_e$ accounts for the possibility of obtaining reproducible and reversible monolayer compression isotherms for both low-molecular-mass compounds and for polymers. In this case, the metastable state of the monolayer of the initial (bulk phase) material proper becomes stable (corresponds to equilibrium) for hydrated derivatives of the latter. Therefore measurement of the temperature variations of the equilibrium spreading pressure or the determination of π_e' from data for the spreading of concentrated solutions may be recommended as procedures for the estimation of the degree of equilibrium in true monolayers.

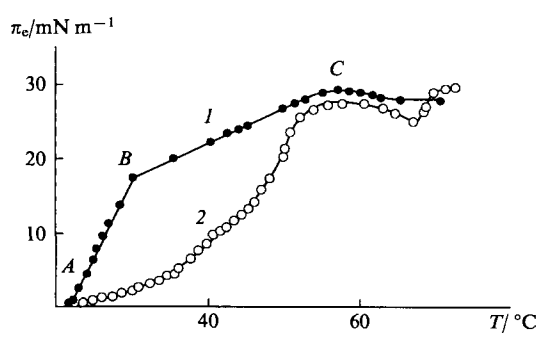


Figure 3. Temperature dependence of the equilibrium spreading pressure (π_e) for oligophenylsilsesquioxane (curve *1*) and polyphenylsilsesquioxane (curve *2*) on the surface of water.[52]

An important procedure for the determination of the stability of monolayers involves the analysis of their relaxation properties.[53–55] The critical parameters of the compression isotherms, obtained for surface pressures exceeding π_e or π_e', are determined by the relation between the relaxation times of the molecular processes occurring on compression of the monolayer and the time of the measurement, which is inversely proportional to the rate of deformation (but not compression) of the monolayer. It has been shown[56] for an arachidic acid monolayer that, with increase in the observation time from 600 to 3 × 10^5 s (the rate of deformation diminished correspondingly from 10% to 0.02% min^{-1}), the monolayer collapse pressure decreases from 60 to 20 mN m^{-1}. Unfortunately, such experiments are so far extremely rare for polymers having distinct viscoelastic properties and a large set of relaxation times.[57]

IV. The influence of the molecular mass of the polymer on the properties of the monolayers

The question of the influence of the molecular mass (or degree of polymerisation), a fundamental characteristic of macromolecules, on the behaviour of monolayers was actively discussed several decades ago. The outcome of these discussions is contained in the reviews already mentioned.[25,26,43,52] Here we present only a brief analysis of these problems, having supplemented it with the results of studies carried out in this field during the last twenty years. The commonest point of view is one according to which the $\pi - A$ isotherms are independent of the molecular mass in the range of surface pressures usually measured (π > 0.5 mN m^{-1}). This was first demonstrated[19] for cellulose derivatives. A similar result has been obtained[58] for hydroxypropyl- and hydroxyethyl-cellulose monolayers. A weak dependence of the compression isotherms on the degree of polymerisation has been established for poly(vinyl acetate),[25] poly(ethyl succinate),[23] and polyorganosiloxanes.[59–61] However, an increase in the limiting area per monomer residue from 18.7 to 26.8 Å^2 with increase in the molecular mass of the polymer from 2.5 × 10^4 to 10^6 has been observed[62] for poly(methyl methacrylate) monolayers. The ratio of the areas depends on the rate of compression of the monolayer, the monolayer of the high-molecular-mass specimen showing a more marked dependence. The dependence of A_0 on the molecular mass, found[63] for monolayers of oligoesters on the surface of water, vanishes when a 40% aluminium sulfate solution, which improves the spreading of the oligomers, is used as the subphase.

The differences in the behaviour of monolayers of polymers with low and high degrees of polymerisation are in many respects associated with the influence of the end groups of the molecules, which alter their polarity and the ability to spread or dissolve in the subphase. Naturally such influence is more significant in the case of short chains.

Whereas the question of the influence of molecular mass on surface pressure and surface potential remains controversial, the dependence of the mechanical properties of monolayers on the dimensions of macromolecules is not open to doubt. Despite this and also the large amount of information obtained from data on the viscoelastic properties of monolayers about the characteristics of the behaviour of macromolecules in a two-dimensional state (ranging from a dilute solution to the condensed phase), such studies are rarely carried out at the present time.

The final aim of the majority of studies designed to establish the dependence of the compression isotherms on the size of the macromolecules is the determination of the molecular masses of the polymers. Since this parameter is calculated on the basis of the two-dimensional analogue of the van't Hoff equation and its

modifications, the monolayer must be in the gaseous (vapour) state, although this state can be by no means always achieved for large molecules. Guastalla, who measured the surface pressure with a sensitivity to within 0.001 mN m^{-1}, may be regarded as the pioneer in this field of study.[64] Subsequently many attempts were undertaken to calculate the molecular masses of polymers in the region of isotherms with low surface pressures.[26,43,65] In particular, the molecular mass of a polymer obtained in the polymerisation of a double-stranded silane lipid in a monolayer has been determined recently.[66]

Numerous studies have been devoted to the determination of the molecular masses of polymers in the range of comparatively high surface pressures and hence high surface concentrations of the test substance. On the basis of such data, which have been reviewed,[52] one cannot reach a conclusion either about the possibility of using this region of compression isotherms to estimate the molecular mass of the polymer or whether the molecular mass found refers to the entire molecule or its segment.

V. The phase states of polymer monolayers

Much attention has been devoted in the past to the phase states of monolayers of low-molecular-mass compounds. There exist several classifications of these states,[67–69] which have been proposed by Adam,[42] Dervichian,[70] Harkins,[41] Stenhagen,[71] Lundquist,[72] and Lin.[73] Furthermore, the refinement of the structures of monolayers in different states is still being continued and communications are being published concerning the observation of new states of monolayers comprising small molecules.[67]

The phase states of monolayers of high-molecular-mass compounds have remained less investigated (and are being less investigated). Since Crisp's time, little attention has been paid to this question and the subdivision which he proposed for polymer monolayers into expanded and condensed can hardly be regarded as a classification of states. The causes of the situation which has arisen can be scarcely attributed to the poor 'distinctiveness', according to Gaines,[43] of the $\pi - A$ relations for polymer monolayers. It appears that, at the level attained in the study of polymer monolayers at the present time, it has not been possible to formulate an adequately rigorous classification of their phase states for a number of other reasons. Firstly, there have been virtually no systematic studies nowadays on the structure of polymer monolayers by modern methods, which are frequently employed for monolayers of low-molecular-mass compounds. The second reason is the complexity of polymeric objects and the consequent need to develop definite principles of study, which are applicable within the framework of a particular group of compounds. The latter consideration requires explanation. The classical objects for the study of the states of monolayers of low-molecular-mass substances are aliphatic acids and alcohols. By altering the length of the aliphatic chain in these compounds, it is possible to attain all the states of the monolayer ranging from gaseous to solid-condensed. From this it follows that the length of the hydrocarbon chain or its increment are fundamental characteristics, which determine the properties of the aliphatic alcohol and acid monolayers. In the previous section, it was shown that a fundamental characteristic of polymers—the molecular mass—hardly influences the state of the polymer monolayers and, if such influence does exist, it arises solely from the change in the fraction of the end groups on the surface. Therefore, comparison of the properties of monolayers of high-molecular-mass compounds is valid only within the framework of specially selected groups of polymers. Modern polymer chemistry provides interesting possibilities for the construction of homologous series of different types of large molecules. We shall attempt to designate such series.

1. Polymers without distinct diphilic properties, i.e. without side chains. Typical representatives are polyethers with different lengths of the polymethylene chain between the oxygen atoms. By increasing the complexity of the polar unit (ester, carbamate, and other groups) separating the polymethylene chains, it is possible to obtain other types of such systems. Copolymers and block copolymers of this series, with a variable ratio of the fragments in the main chain, are also interesting objects with controllable variation of the characteristics of the monolayers.

2. Polymers with weak diphilic properties, i.e. polymers having short side chains. In this case, the behaviour of the monolayer depends on the structure of not only the main chain but also of that of the side chain.

3. Polymers with long side chains. In the presence of long spacers in the main chain, the side chains behave to some extent independently of one another. The spacer can be inserted also between the main and side chains. The compatibility in the monolayer of incompatible monomers carrying specific functional groups can be achieved as a result of the spreading of the copolymer made up of the corresponding monomers.

4. Macrocyclic, ladder, and other polymers with a more complex chemical structure and behaviour.

The second possible method of combining different polymers may be based on a chemical principle where the variation of the properties of monolayers and LBF is considered within the framework of a single class of compounds, for example polyacrylates. This approach makes it possible to reduce to a minimum the differences in the chemical nature of the polymers and to trace in a fairly pure form the influence of the structure of the chains on the characteristics of the two-dimensional systems formed from them.

The latest reviews on polymer monolayers refer to the 1960s; during the period which has elapsed since then, many new studies, devoted to traditional and new polymers, including those specially synthesised for the formation of surface films, have been published. Bearing in mind the special interest in LBF, attention has been concentrated in these studies on functionalised monolayers.

It appears that analysis of the development of the field of surface chemistry should include a discussion of those properties of polymer monolayers which determine the possibility of the formation of high-quality LBF, functionalised films, and surfaces.

An essential condition for the preparation of LBF with a specified thickness and orientation is the formation of a genuine monolayer not containing nonspreading material. The question arises what should be the structure of the polymer chain and the ratio of the lengths and the compositions of the side chains and spacer groups. Should one in such cases graft the group with the required function to the polymer chain or should one produce a mixed monolayer with the matrix polymer? The use of binary mixtures (for the composition of side chains or copolymers) removes the problem of synthesis but the problem of compatibility then arises, especially if one is dealing with components having side chains of different lengths. Furthermore, it is essential to take into account the possibility of interlayer and intralayer diffusion in the LBF made up of mixed monolayers which disturbs the organisation of the monolayers established on the surface of the liquid. The immobilisation of the low-molecular-mass component can be achieved in at least four ways: (1) by the formation of a mixed monolayer from the chemically noninteracting polymer and an additive which are insoluble in the subphase; (2) by the introduction of a water-soluble polymer into the subphase under the monolayer of the second low-molecular-mass component; (3) by the introduction into the subphase of a functional additive under the polymer monolayer; (4) by the formation of a mixed monolayer of the polymer (oligomer, monomer) with an additive and subsequent immobilisation of the additive by cross-linking with a specified density.

The choice of the method for the formation of functionalised monolayers and LBF depends on the purpose of the two-dimensional system being formed. Modern macromolecular chemistry and molecular design have given rise to virtually unlimited possibilities for the construction of stable heteromolecular structures based on polymers.

Following the chosen chemical principle for the arrangement of polymers in groups, it is useful to begin the discussion with the traditional thoroughly investigated polymers of the acrylic and methacrylic series.

VI. Polyacrylates and polymethacrylates

1. Monolayers and Langmuir – Blodgett films based on homopolymers

The widely investigated acrylic and methacrylic polymers make it possible to follow the influence of the structure and composition of the main and side chains of the macromolecules on the properties of their monolayers. The base polymer is undoubtedly poly(methyl methacrylate) (PMMA). The increased interest in this polymer during recent years is due to its use as a positive electron-beam resist in the traditional technology for the deposition of a polymer solution onto a support.[74] The increase in the sensitivity and resolution of elements consisting of PMMA and its copolymers can be achieved by their deposition onto a solid support by the Langmuir – Blodgett method.[75]

The compression isotherms of monolayers of PMMA stereoisomers[76] are illustrated in Fig. 4, while Table 1 presents the molecular masses and limiting areas of the PMMA monolayers obtained by different workers. Evidently, in the formation of a true equilibrium monolayer, the differences between the polymer solution concentrations employed, the solvents, and the rates of compression should not have influenced quite so much the values of A_0. For monolayers of low-molecular-mass compounds (for example, aliphatic acids), it is difficult to imagine the existence of such discrepancies in the measurements of the limiting area. However, for small molecules the problems of stereoregularity, which are extremely important (as can be seen from Fig. 4) for the position of the compression isotherm, are manifested in a different way. Furthermore, the steric hindrance due to the chain structure of the polymers apparently precludes the complete assumption by the PMMA elementary units of the *cis*-conformation of the methoxycarbonyl groups most favourable for the formation of the monolayer (Fig. 5). It follows from the study of Labbauf and Zack[80] that the *cis*-form of the PMMA elementary unit gives rise to larger limiting areas than the *trans*-form. The experimental facts indicating the incomplete spreading of PMMA in a monolayer on the surface of water can apparently be explained[31]

by the high cohesion between the main chains of the polymer. Naturally in this case it is extremely difficult to seek a relation between the molecular mass of the polymer and the limiting area of the monolayer. Such behaviour of the PMMA monolayers is not general: for other polymers forming true monolayers, there is good agreement between the experimental compression isotherms obtained by different workers.

The replacement of the methyl group in the main chain by a hydrogen atom, i.e. the transition from methacrylic to acrylic polymers, increases sharply the ability of the polymer to form a true monolayer.

More extensive possibilities for controlling the structure of the monolayer and for introducing into the latter functionally significant fragments are associated with the alteration of the side groups of the polymers under consideration. The simplest example is provided by the increase in the length of the chain of the ester alkyl group in poly(alkyl methacrylates). As can be seen from Fig. 6, the replacement of the methyl group by the ethyl group in the side chain of the polymer greatly diminishes the cohesion between the main chains of macromolecules and leads to the expansion of the monolayer. Further increase in chain length and temperature[86] steadily increases the limiting areas and intensifies

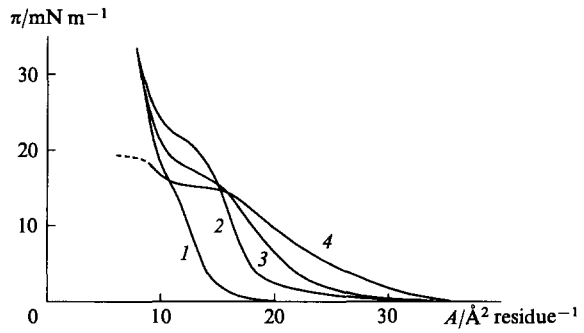

Figure 6. Surface pressure–area isotherms for monolayers of poly(alkyl methacrylates).[25] Alkyl: (*1*) methyl; (*2*) ethyl; (*3*) n-propyl; (*4*) n-butyl.

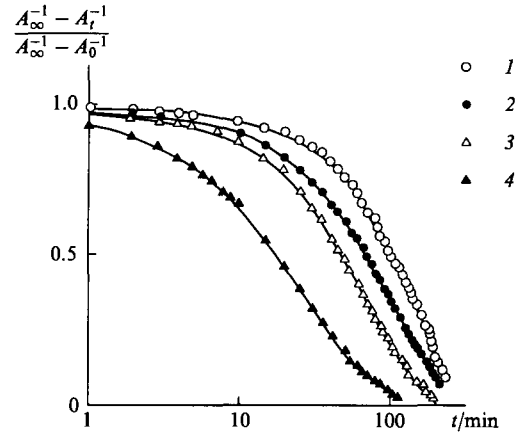
the tendency to form a plateau on the compression isotherms. Small side chains are incapable of interacting with adequate intensity and their role reduces to separating the main chains and lowering their cohesion. On the other hand, long hydrocarbon chains (C_{18}) impart a high rigidity to the condensed monolayer.[25]

The great interest in the study of poly(octadecyl acrylate) (PODA) and poly(octadecyl methacrylate) (PODMA) in monolayers[25,85–99] is caused, on the one hand, by the polymeric nature of these compounds and, on the other, by the presence of long hydrocarbon chains, which makes it possible to regard each elementary unit of the polymer as a classical diphilic surface-active low-molecular-mass substance. The discrepancies between the compression isotherms obtained by different workers for these polymers have been analysed.[90] It was postulated that these differences are caused by the type of solvent from which the monolayers were formed, the purity of the polymer, its molecular mass and/or its polydispersity, and the method used to obtain the compression isotherms. It has been shown that the discrepancies between the data of different workers are due mainly to methodological causes, i.e. the conditions under which the $\pi-A$ isotherms were obtained. It must be emphasised that the differences may be induced also by the crystallisation of the side chains of the polymer, which apparently begins from the hexadecyl members of this series.[86] An increase in temperature to 12 °C for poly(hexadecyl methacrylate) and to 29 °C for PODMA converts the solid polymer monolayers into liquid ones.[86]



The crystallisation of PODMA in the monolayer at different temperatures and surface pressures has been investigated.[98] It has been shown that the crystallisation kinetics may be described with the aid of the Avrami equation:[100]

$$-\ln\frac{A_\infty^{-1}-A_t^{-1}}{A_\infty^{-1}-A_0^{-1}}=kt^n,$$

where A_0, A_t and A_∞ are the areas per monomer unit at times 0, t, and ∞, n is a constant characterising the mechanism of the formation of the nuclei and the type of the growing structures, and k is the rate constant of the process.

Using these constants as adjustable parameters, a good agreement was obtained between theory and experiment. Fig. 7 shows that the crystallisation process proceeds at low surface pressures and is completed in the course of 2 h. Crystallisation disturbs the equilibrium nature of the monolayer, which is manifested by the hysteresis of the compression isotherms.

The possibility of crystallisation must be taken into account in the study of the kinetics of two-dimensional polymerisation accompanied by the shrinking of the monolayer. This question has been examined[92] in the analysis of the polymerisation of octadecyl methacrylate (ODMA). The same communication contains interesting data concerning the compatibility of ODMA and PODMA monolayers. Fig. 8 presents the dependence of the

average area of a mixed monomer and polymer monolayer on composition for different surface pressures. The shaded regions correspond to the crystallisation of the side chains, the upper contour of these regions corresponding to the area of the monolayer before crystallisation and the lower contour corresponding to the area after the completion of crystallisation. Crystallisation must be taken into account at low surface pressures and for degrees of conversion of the monomer exceeding 50%.

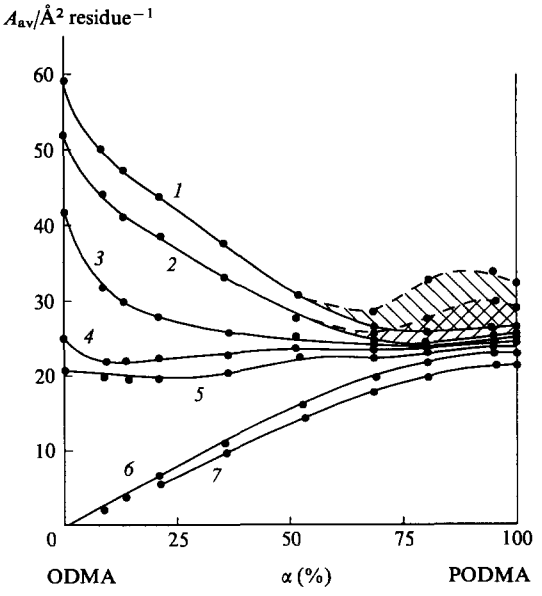

Figure 8. Dependence of the average area (A_{av}) per monomer residue on the polymer content (α = degree of conversion) in a mixed ODMA/PODMA monolayer at T = 27 °C and different surface pressures (mN m⁻¹): (*1*) 0.5; (*2*) 2.0; (*3*) 4.0; (*4*) 7.0; (*5*) 13.0; (*6*) 30.0; (*7*) 40.0. The cross-hatched regions correspond to the crystallisation of the side chains.[92]

Despite the major role of secondary cohesion, manifested for long-chain poly(alkyl methacrylate) in the crystallisation of side chains, the influence of the structure of the main chain of the polymer also persists. As can be seen from Fig. 9, the PODA monolayer is more condensed than the monolayer of its methacrylic analogue, i.e. the absence of methyl groups attached to the main chain in the first polymer diminishes the steric hindrance to its conformational rotation.[87]

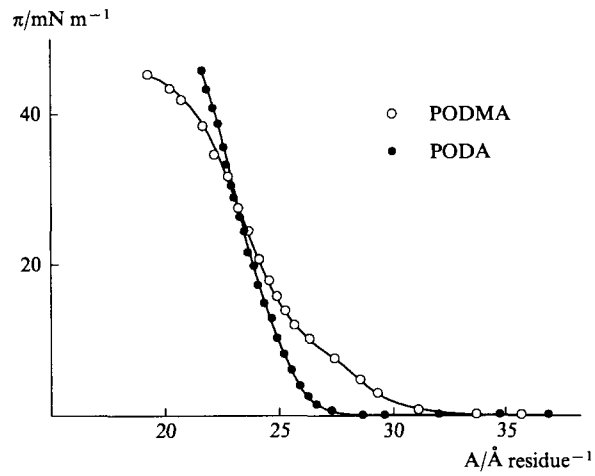

Figure 9. Surface pressure – area isotherms for PODA (M_w = 23 300, M_n = 13 000) and PODMA (M_w = 321 000, and M_n = 97 200) monolayers.[87]

These data agree with the results of the measurement of the resistance to the evaporation of water (r) through PODMA and PODA monolayers:[90] the values of r for the PODA monolayer are several times higher than for PODMA but are an order of magnitude lower than for octadecanol. Evidently, the high rigidity of the polymer chain prevents the close packing of the hydrocarbon chains in the monolayer. The introduction of a small amount of octadecanol into the polymer monolayer makes it possible to attain the level of r values characteristic of a pure octadecanol monolayer.[90]

The orientation of the side chains in LBF based on PODA and PODMA has been investigated[87,88] by polarisation IR spectroscopy in the transmission and glancing incidence versions. It has been shown[87] that an orientation of the hydro-carbon side chains almost perpendicular to the surface of the support occurs in mono- and multi-layer LBF of the Z type for both monomers. It has also been noted that their orientation depends on the type of the main polymer chain and the surface pressure at which the monolayers have been transferred. However, it has been found[88] that the orientation of the PODMA side chains in the monolayer LBF differs significantly from the perpendicular orientation of these groups in the multilayer LBF.

The introduction of aromatic substituents into the side chain of a methacrylic polymer [poly(phenyl methacrylate) and poly(benzyl methacrylate)],[101,102] leads to the formation of a condensed monolayer with small limiting areas. Although the authors themselves[101,102] have assigned the monolayers of these homopolymers to the expanded type, nevertheless the low values of A_0 and the temperature dependence of the surface pressure characteristic of a collapsed monolayer indicate the absence of true spreading.

Thus, among the investigated methacrylic homopolymers substituted most simply in the side chains, the most stable monolayers are formed by homopolymers which contain moderately and very long aliphatic side chains. We shall consider in greater detail the properties of one of them — poly(isobutyl methacrylate) (PIBMA), which forms true monolayers and high-quality LBF. It has been shown[103] that the compression isotherm for this polymer has a point of inflection at A = 19 Å^2 per monomer residue (the calculated A_0 is 20–21 Å^2 per residue), after which the monolayer collapses according to X-ray diffraction data. The linearity of the $\pi - A$ relation for $\pi < 0.5$ mN m^{-1} made it possible to determine the molecular mass of the polymer, which was found to be close to the value determined viscometrically for the PIBMA bulk-phase solution (1.7×10^5 and 2.3×10^5 respectively). There are interesting data, obtained by Naito,[103] concerning the influence of the hydrophobic properties of the surface of the solid support on the degree of transfer of the monolayer (ρ) onto the latter (the vertical method). Fig. 10 presents the dependence of ρ on the wetting angle (θ) for water on the surface of silicon. The degree of wetting was changed by varying the time of the preliminary treatment of the surface of silicon in hexamethyldisilazane. Fig. 10 shows that $\rho = 1$ for $0° < \theta < 90°$ as the support moves upwards from the aqueous subphase, while for the opposite direction of motion we have $\rho = 1$ for $\theta > 73°$. This angle corresponds to θ for water on both types of surfaces of the transferred polymer LBF. Fig. 11 illustrates the dependence of the degree of transfer on the number of LBF pairs for two silicon supports with $\theta = 65°$ and 100°. The first layer was deposited by immersing the support in the subphase. It is seen that ρ is close to 1 for a support with $\theta = 100°$. Supports with $\theta = 65°$ exhibit a considerable scatter in the values of ρ, i.e. the first monolayer exerts a significant influence on the formation of the subsequent layers. We may note two features of LBF made up PIBMA:[103] the absence of defects in the LBF (scanning electron microscopy, magnification 5×10^4) and the suppression of cadmium stearate recrystallisation processes in alternating LBF containing ten internal monolayers of the above low-molecular-mass surfactant and three outer PIBMA monolayers.

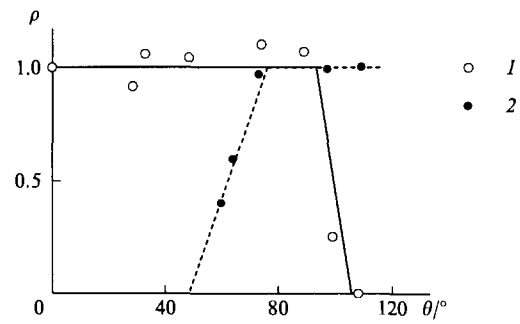

Figure 10. Dependence of the degree of transfer of the PIBMA monolayer on the wettability of the silicon surface which has been rendered hydrophobic.[103] Surface pressure in the transfer process 12.5 mN m^{-1}. Direction of motion of the support: (*1*) upwards; (*2*) downwards.

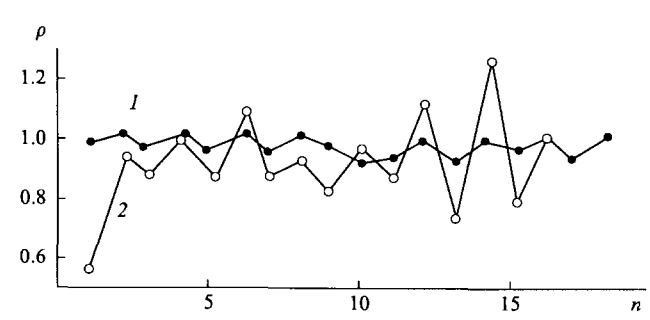

Figure 11. Dependence of the degree of transfer of the PIBMA monolayer onto silicon supports rendered hydrophobic to different extents on the number of layers.[103] Wetting angle for water: (*1*) 100°; (*2*) 65°.

Multilayer PIBMA LBF with a thickness up to 200 Å have also been investigated [104] and the extent of their defectiveness was analysed by the method involving electrolytic decoration with copper. In full agreement with Naito's data, [103] Matsuda et al. [104] showed that the LBF made up of four monolayers (42 Å) is homogeneous and has a lower density of defects (pin holes) than the analogous cadmium arachidate LBF.

More complex heterostructures containing PIBMA have been obtained: [105] (1) LBF made up of alternating PIBMA and heptacosa-10,12-diynoic or arachidic acid monolayers (altogether 20 heterolayers); (2) LBF made up of alternating units comprising one acid layer and three PIBMA layers (altogether 20 heterolayers); (3) LBF consisting of alternating PIBMA and acid bilayers (altogether 10 heterolayers). LBF of the Z type (relative to the acids) were formed in the first two cases, whilst in the third Y type LBF were produced. It was shown that, in the LBF of the first type, one polymer layer does not prevent its rearrangement and penetration by acid molecules. The diffusion of acid molecules is suppressed with increase in the number of PIBMA layers (the second type of the LBF structure). Nevertheless the authors [105] concluded that, in order to obtain more perfect heterostructures with a higher stability as a function of time, it is necessary to employ a polymer which is more rigid than PIBMA.

2. Monolayers and Langmuir – Blodgett films based on copolymers

The presence of substituents in each monomer unit of acrylic and methacrylic homopolymers creates definite difficulties in the formation of highly organised monolayers and LBF. [89] One of the ways of solving this problem involves the introduction of a hydrophilic spacer, which separates the side and main chains. It has been shown [106, 107] in relation to double-stranded methacrylic lipids that the introduction of a spacer leads to the formation of stable monolayers, the collapse pressure and the limiting area of which are close to the corresponding parameters for the monomeric lipid.

Another procedure, leading to an increase in the stability of polymer monolayers, involves the inclusion of a hydrophilic spacer in the main chain. A procedure such as hydrolysis of poly(n-butyl acrylate) to different extents has been used for this purpose. [108] Table 2 shows that, with increase in the degree of hydrolysis, the limiting area of the monolayer diminishes owing to the displacement of polar acid groups from the surface to the subphase. However, the presence of polar groups makes it possible to regulate the structure of the monolayer by varying the pH and by introducing an electrolyte into the subphase. According to the data in Table 2, an increase in the sodium chloride concentration in the aqueous subphase leads to the return of the acid groups to the surface and hence to an increase in the limiting areas, the theoretical and experimental values of A_0 being virtually identical for a 15% NaCl concentration.

Table 2. The limiting areas of poly(n-butyl acrylate) (PBA) monolayers for different degrees of hydrolysis of the polymer and different sodium chloride concentrations in the subphase. [108]

Degree of hydrolysis (%)	A_0/Å^2 residue^{-1}

36	17.5	22.5	25.7	26.8	26.7
45	16.5	20.8	24.2	25.7	25.9
53	16.0	20.4	23.9	25.3	25.4

Studies of copolymer monolayers have just as long a history as those of homopolymer monolayers. As in the case of traditional investigations of copolymers in bulk and in solution, the main problem remains the elucidation of the influence of the ratio of the monomer residues constituting the copolymer on the characteristics of the systems considered — in the given instance two-dimensional systems. The properties of monolayers comprising copolymers and mixtures of the corresponding homopolymers have been compared in a number of studies. Attention was concentrated in these investigations (most of which were carried out during the period preceding the active study of LBF) on the phase behaviour of the systems. Recently much attention began to be devoted to the possibility of obtaining LBF from monolayers of copolymers (including block copolymers) and mixed monolayers. Mixed polymer monolayers and especially copolymer monolayers with low-molecular-mass surfactants are of great practical importance, since, compared with monolayers and LBF made up of copolymers and mixed polymer monolayers, they facilitate the introduction of functional additives and the regulation of the properties of the two-dimensional systems.

Hitherto these problems have been most fully investigated for methacrylic and acrylic copolymer monolayers containing side chains with different numbers of carbon atoms. Copolymers of methyl and hexadecyl acrylates, [109] butyl and dodecyl methacrylates, [110] octadecyl and dodecyl methacrylates, [111, 112] butyl and octadecyl methacrylates, [91] and methacrylic acid and methyl acrylate, [113] as well as diblock copolymers of PMMA and polyvinyl(4-pyridinium) bromide [114] have been investigated. Vigorous studies on monolayers have been carried out for copolymers containing double-stranded elementary units or spacers of different composition in the main chain. [106, 107, 115–117]

The properties of monolayers comprising copolymers and mixtures of the homopolymers of octadecyl methacrylate (PODMA) and butyl methacrylate (PBMA) examined above have been investigated. [91] Figs 12 and 13 illustrate the dependence of the surface pressure, corresponding to three characteristic points on the compression isotherms for the copolymers and mixtures, and of the limiting area of the monolayer on its composition. The PBMA monolayer of the liquid-condensed type has two singular points corresponding to a phase transition (14.3 mN m^{-1}) and collapse (16.7 mN m^{-1}), while the PODMA monolayer of the solid-condensed type has a single singular point at 52.6 mN m^{-1} corresponding to collapse. All three singular points are present on the isotherms for the mixed monolayers containing between 30 and 70 mol.% of PODMA. On the basis of Crisp's phase rule for mixed mono-layers (the two components are compatible in the monolayer if π at the singular point varies with composition and conversely), it was concluded [91] that, for a 70% PODMA content, the homopolymers are incompatible. The compression isotherms for copolymer monolayers have a single singular point (collapse) and, for PODMA contents in the copolymer molecule up to 60%, the monolayer remains in the liquid-condensed state. The transition of the copolymer monolayer from the liquid to the solid state can be detected also on the dependence of the limiting area of the monolayer on composition (Fig. 13), which exhibits a sharp jump towards lower values of A_0 for a 70% content of PODMA. It follows from Fig. 13 that three compatibility regions are characteristic of the mixed monolayers: for low contents of PODMA (low surface pressure) and PBMA (high surface pressure), the components are compatible, whereas in the middle range of compositions the polymers are incompatible in the monolayer.

The properties of monolayers of dodecyl methacrylate–octadecyl methacrylate copolymers and the corresponding mixed homopolymer monolayers have been compared. [111–113] As for other combinations of the monomers, (C_4 and C_{18}) [91] and (C_{14} and C_{16}), [109] an increase in the content of the long-chain fragment (C_{18}) in the copolymer leads to the formation of a more condensed monolayer: the collapse pressure increases, the singular points vanish, and the compressibility diminishes.

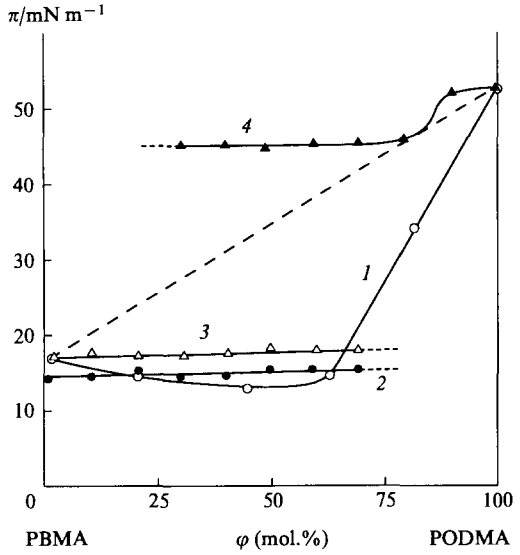

Figure 12. Dependence of the surface pressure at the characteristic points on the compression isotherms on the ratio of PODMA and PBMA in the copolymers (curve *1*) and the mixtures (curves *2*–*4*).[91]

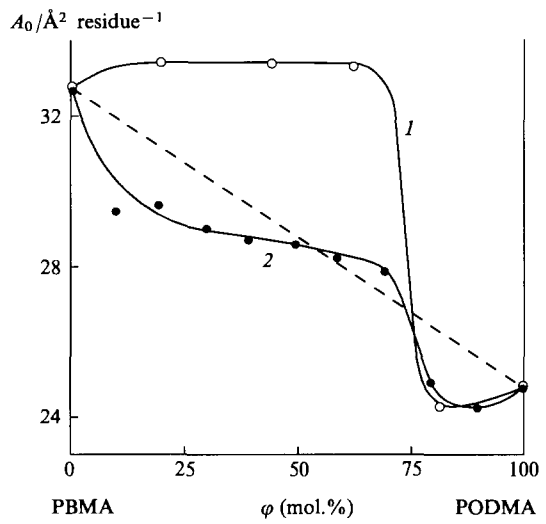

Figure 13. Dependence of the limiting areas (A_0) of the monolayers comprising the copolymers (curve *1*) and mixtures of the PODMA and PBMA homopolymers (curve *2*) on their ratio in the mixture.[91]

Consequently, by increasing the fraction of the long-chain fragment in the copolymer, it is possible to achieve a transition from the liquid to the solid state of the monolayer. The reverse transition, leading admittedly to disequilibrium in the monolayer, is achieved by increasing the temperature. For methacrylic copolymers containing C_{12} and C_{18} hydrocarbon groups in the side chain, such transitions occur in the temperature range 20–39 °C. Table 3 presents the conditions for the formation of liquid-condensed monolayers of poly(alkyl methacrylates) (homopolymers, copolymers, and mixtures). It is of interest to note that, on formation of the liquid state, the average length of the hydrocarbon side chain in the copolymer (copolymers *d*, C ⩽ 14.2) at 20 °C is the same as the number of carbon atoms in the side chain of the homopolymer (homopolymer *a*) at the same temperature. For a mixture of homopolymers, the transition to the liquid state occurs for a smaller average length of the side chain (mixture *f*, C ⩽ 12.6). Mixtures form more stable monolayers than the individual phases of the homopolymers, each of which may contain a small amount of another phase.[112]

Table 3. Conditions in the formation of liquid-condensed monolayers of poly(n-alkyl methacrylates).[112]

Monolayer	Average number of carbon atoms in alkyl group	Transition temperature/°C
Homopolymer		
a	⩽14	20
b	⩽16	35
c	⩽18	39
Copolymer (C_{12} + C_{18})		
d	⩽14.2 (⩽36% ODMA)	20
e	–[a]	35
Mixture of C_{12} and C_{18}		
f	⩽12.6 (⩽10% ODMA)	20
g	⩽13.2 (⩽20% ODMA)	35
h	–[a]	39

[a] Almost all the polymers form liquid-condensed monolayers.

The influence of the composition of the subphase on the properties of the monolayers and LBF of the 1 : 1 methacrylic acid – methyl acrylate copolymer has been investigated.[113] On the surface of pure water, this copolymer does not form a stable monolayer. The introduction of Cd^{2+} ions into the support improves its stability. The solid monolayer of the copolymer on the surface of an aqueous solution containing La^{3+} ions at pH 6.89 has the highest stability. When the copolymer monolayers are transferred to the hydrophilic surface of glass from the Langmuir trough by the usual vertical method, the dependence of the degree of transfer (ρ) on the number of cycles has the form illustrated in Fig. 14*a*. Evidently a Z type transfer takes place, the degree of transfer increasing with increase in the number of layers. In order to obtain higher-quality LBF from the copolymer, the authors[113] used a Langmuir trough with moving walls. This made

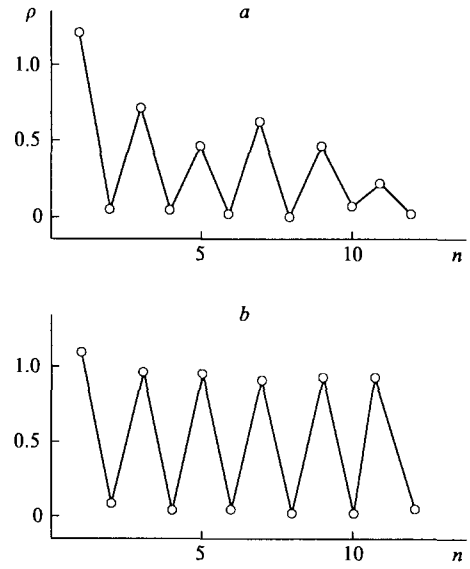

Figure 14. Dependence of the degree of transfer (ρ) on the number of cycles for the methacrylic acid – methyl acrylate copolymer LBF:[113] (*a*) usual Langmuir trough; (*b*) Langmuir trough with moving walls.

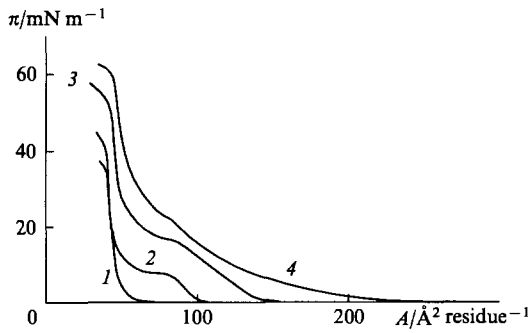

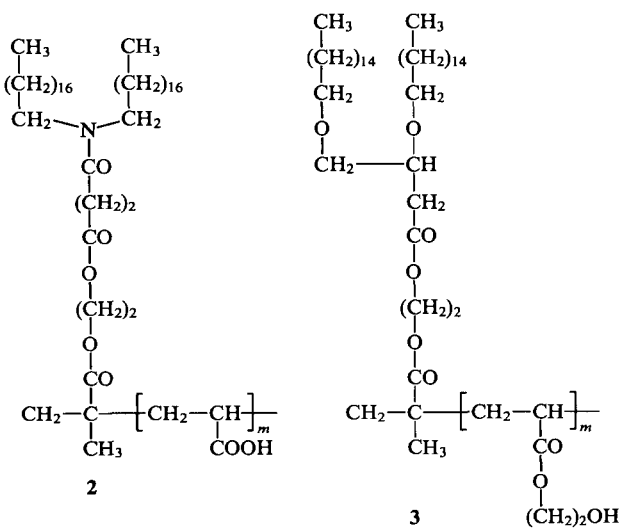

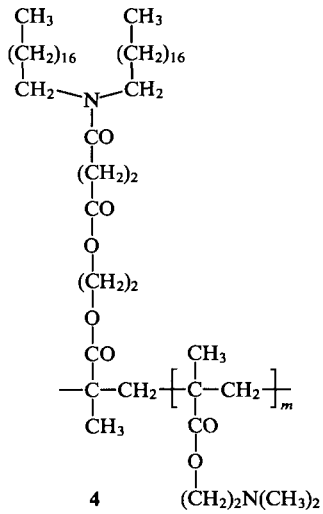

Figure 15. Surface pressure–area isotherms for the homopolymer (curve *1*, $m = 0$) and the copolymers **2** with different spacer: substituted residue ratios (m): (*2*) 1; (*3*) 5; (*4*) 10.[115]

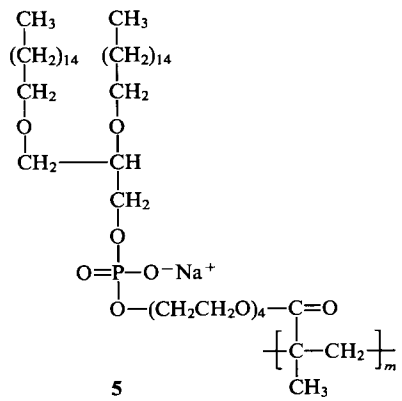
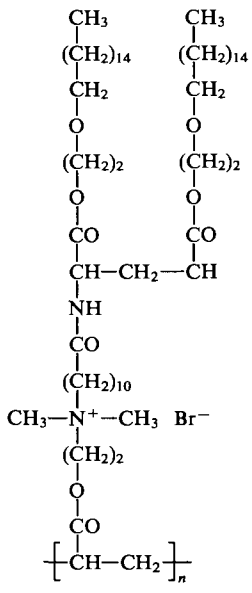
it possible to improve significantly the quality of the LBF whilst retaining the Z type of transfer (Fig. 14*b*). This conclusion is confirmed by the measurements of the wetting angles (θ) for water after each passage of the support through the monolayer: θ for water does not change for two opposed directions of motion of the support. The values of $\cos\theta$ for LBF were lower than for coatings obtained from a solution on a rotating support. This indicates a definite preferred orientation of the elementary units of the copolymer in the LBF. It was shown by IR Fourier spectroscopy and X-ray diffraction that the La^{3+} ion-stabilised LBF comprising the copolymer, which does not possess long-chain side chains, has a layered structure with a monolayer thickness of 8.4 Å. The formation of LBF from cross-linked two-dimensional networks gives rise to hope for an improvement of their thermal and mechanical stabilities.



The influence of the hydrophilic spacer on the behaviour of monolayers of copolymers of double-stranded lipids with acrylic acid (**2**) and with hydroxyethyl acrylate (**3**) has been investigated.[106,107,115–117] Fig. 15 presents the $\pi-A$ relations for the 2-(3-dioctadecylcarbamoylpropionyloxy)ethyl methacrylate–acrylic acid copolymer **2** with different contents of a hydrophilic spacer in the main chain (m is the number of elementary units of the spacer per substituted monomer residue). Evidently, with increase in m, the monolayers expand and the pressure corresponding to the phase transition from the liquid to the solid state of the monolayer increases. With increase in the content of unsubstituted acrylic acid residues in the copolymer, the phase transition temperature falls. X-Ray diffraction analysis of 30-layer LBF made up of copolymer **2** showed[115] that the intensity of the diffraction peaks increases with increase in m, whilst their width diminishes. The repeat period increases from 40.8 Å for the homopolymer to 59.5 Å for the copolymer with $m = 5$ and then decreases to 55.9 Å for the copolymer with $m = 10$. When the fraction of acrylic acid in the copolymer is too high, it becomes impossible to obtain LBF. The thermal stability of LBF rises with increase in m: the multilayer structure of copolymer **2** breaks down at 40 °C for $m = 1$, at 70 °C for $m = 5$, and at temperatures exceeding 120 °C for $m = 10$. The acrylic acid residues in the copolymer play a dual role. Functioning as hydrophilic spacers, they increase the mobility and the degree of order in the long-chain components of the copolymer. At the same time, the thermal stability increases by virtue of the formation of hydrogen bonds. Evidently these characteristics may be controlled by introducing electrolytes into the support or by changing its pH. Similar results have been obtained[107] for copolymer **3**.

The possibility of the practical employment of LBF based on copolymer **4**, containing a double-stranded spacer and a double-stranded monomer in proportions of 5 : 1, as a selective gas membrane has been examined.[118–120] The LBF of this copolymer with a thickness up to 60 monolayers were formed on a porous polymer support and its permeability to CH_4, N_2, CO_2, and H_2S was investigated at different temperatures. It was established that the membrane is selective with respect to H_2S and CO_2 relative to N_2 and CH_4, the selectivity increasing on heating above 35 °C. The rise in selectivity with temperature was explained by the disordering of the hydrocarbon side chains of the copolymer, which was detected by reflection-adsorption IR spectroscopy. The possibility of the chemical interaction of gaseous H_2S and CO_2 with the copolymer constituting the LBF plays an important role in the variation of the selectivity of such membranes.



Asymmetric membranes have been formed[121] on the surfaces of porous polytetrafluoroethylene supports in the form of LBF of copolymer **2** ($m = 5$) and homopolymer **5**. The influence of heat treatment on the structure and properties of the membranes was investigated by IR Fourier spectroscopy, both in transmission and in reflection at glancing incidence, and also by high-resolution scanning electron microscopy. It was established that heat treatment of the LBF (20 and 30 monolayers) below the melting points of the block copolymers leads merely to an insignificant disordering of the alkyl chains ($2C_{18}$ and $2C_{16}$) and to the disappearance of a large number of macroscopic defects. The dependence of the permeability of the heat-treated membranes on the size of the penetrant molecules led Stroeve et al.[122] to the conclusion that microdefects are retained in the LBF after heat treatment. Heating of the LBF above the melting point of the block copolymers disturbs the order in the layers and leads to the appearance of cavities and to the flow of the polymer within the pores.

5

LBF based on double-stranded ammonium derivatives of the polyacrylic acid **6** have found an interesting application [123] in studies on surface forces, which had been carried out earlier [124–126] mainly using LBF made up of low-molecular-mass surfactants.

6

The monolayer of compound **6** was transferred onto a solid hydrophilic support (mica) the latter moving from the air into the aqueous phase. The relations between the reduced attractive force (F/R; R is the radius of curvature of the surface of mica) and the distance (D) between the two surfaces of mica coated by a monolayer of compound **6** are presented in Fig. 16 for three liquid media. It is seen from the figure that the attractive force between the surfaces and pure water extends over a distance up to 3000 Å and that the surfaces merge for $D \simeq 760$ Å. Their separation requires an adhesive (breaking away) force of 280 mN m^{-1}, which is characteristic of hydrophobic surfaces. [127] It has been noted [123] that these forces differ from the long-range electrostatic repulsive forces and van der Waals attractive forces ($D \leqslant 30$ Å; force required to break adhesion 55 mN m^{-1}), which arise between unmodified negatively charged mica surfaces. [128] The formation of a stable monolayer on the surface of mica, achieved by an unusual transfer procedure (downwards onto a hydrophilic support), is due to the electrostatic interaction between the cationic polymer and the negatively charged mica surface. The upward movement of the support through the air/water interface leads to the formation of a less stable monolayer.

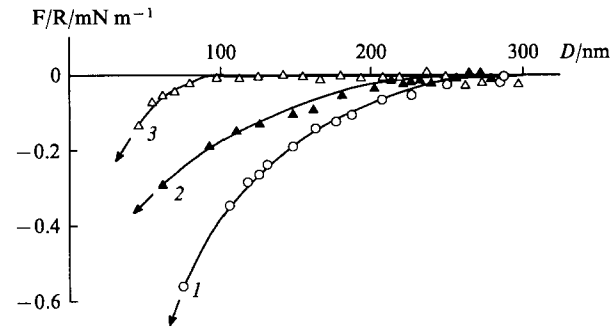


Figure 16. Dependence of the reduced attractive force on the distance between the surfaces of mica with monolayer LBF comprising polymer **6**. [123] Medium: (*1*) pure water; (*2*) 0.01 M NaBr solution; (*3*) 0.1 M NaBr solution.

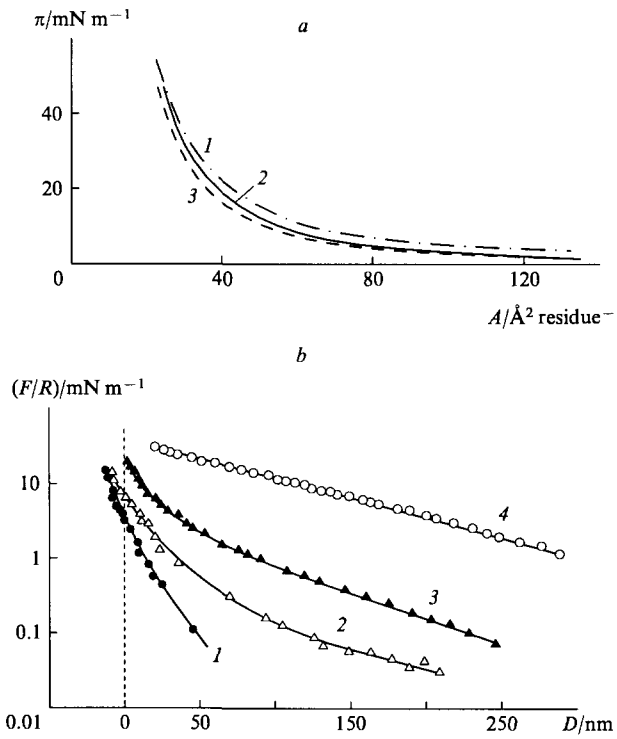
Fig. 17 illustrates the influence of pH on the compression isotherms and on the $F/R-D$ relations for a monolayer of a derivative of the methacrylic acid oligomer **7**. The monolayer was deposited onto a mica surface which had been rendered hydrophobic. In a neutral aqueous medium, long-range repulsive forces are manifested ($D \sim 3000$ Å), increasing markedly with increase in pH (Fig. 17*b*). At low pH, repulsion occurs only over short distances $D \simeq 600$ Å, which is due to the influence of the degree of ionisation of the acid groups on the conformation of the macromolecules (at a high degree of ionisation, the extended conformation of macromolecules obtains). It is of interest to note that, when the mica surfaces coated by a monolayer of compound **7** approach one another, the repulsion increases gradually and not sharply, in contrast to pure mica. This has been explained by a change in the conformation of the chains and the recombination of charges. [128]



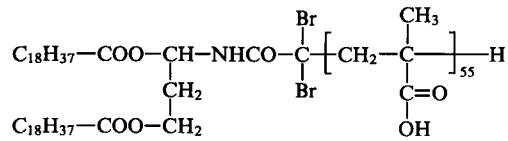


Figure 17. The influence of pH on the compression isotherms (*a*) and on the $F/R-D$ relations (*b*) for a monolayer comprising the oligomethacrylic acid derivative **7**: [123] (*a*) pH 3.1 (curve *1*), 5.6 (curve *2*), and 8.1 (curve *3*); (*b*) pH 3.5 (curve *1*), 4.6 (curve *2*), 5.6 (curve *3*), and 8.2 (curve *4*).

7

Thus the study of the surface forces acting between solid surfaces on which LBF have been deposited makes it possible to determine the quality of the LBF, the orientation of the molecule, and the interaction between them, i.e. to characterise quite fully the functionalised organic surfaces.

Gaines[30] formed homogeneous LBF from a homopolymer—syndiotactic PMMA—on the hydrophobic silicon surface. The dependence of the thickness of the LBF, measured ellipsometrically, on the number of transfer cycles is illustrated in Fig. 18. Evidently there is a linear relation between these parameters. The specific surface of a single monolayer, found ellipsometrically and on the basis of compression isotherms, was respectively 9.1 and 10.9 Å. Y type LBF have also been formed from PMMA on the surface of hydrophilic chromium films.[75] The thickness of 17-layer LBF, measured ellipsometrically, was 143 Å, i.e. 8.5 Å per monolayer. A test of this LBF as a positive electron-beam resist showed that the surface density of pin holes in the PMMA LBF was three orders of magnitude lower than in the film of the same thickness obtained from a solution of the polymer on a rotating support.

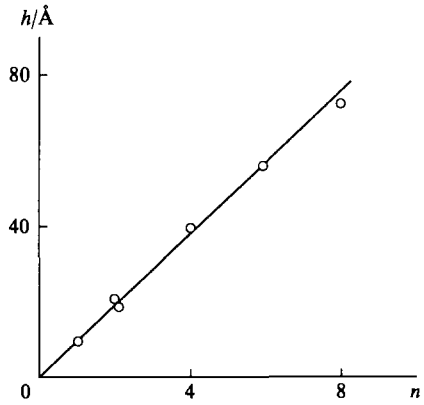

Figure 18. Dependence of the thickness of a syndiotactic PMMA film, deposited on a hydrophobic silicon surface at a surface pressure of 10 mN m^{-1}, on the number of transfer cycles.[30]

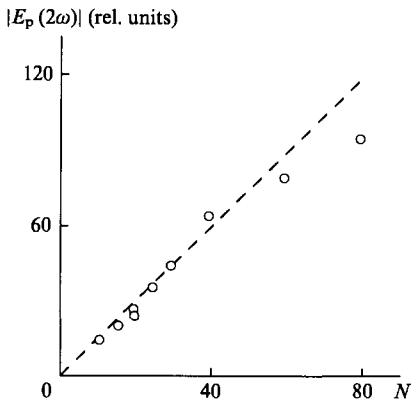
Acrylic and methacrylic polymers, into the side chains of which functional-group substituents have been introduced, have come to be widely used recently in the study of nonlinear optical (NLO) effects. A strategy for the creation of new NLO systems has been described.[129] It reduces, firstly, to the exclusive employment of monomeric objects and, secondly, to the introduction of perfluorocarbon groups, which ensure more marked hydrophobic properties for a shorter chain compared with hydrocarbon analogues. The influence of the number of bilayers formed by polymers **8** and **9** on the generation of the second optical harmonic was investigated.[129] Fig. 19 illustrates the dependence of the amplitude of the second harmonic (proportional to the square root of the intensity) on the number of bilayers (N) in the LBF comprising derivatives of acrylic (**8**) and oxazoline (**9**) polymers. Evidently the linearity of the relation is retained up to $N = 40$. The comparative decrease in the signal at $N > 40$ indicates the disturbance of the polar structure with increase in the number of layers. This effect may be associated with the fact that the LBF were obtained using two procedures: initially the first 40 layers and then, after several hours, the remaining layers.



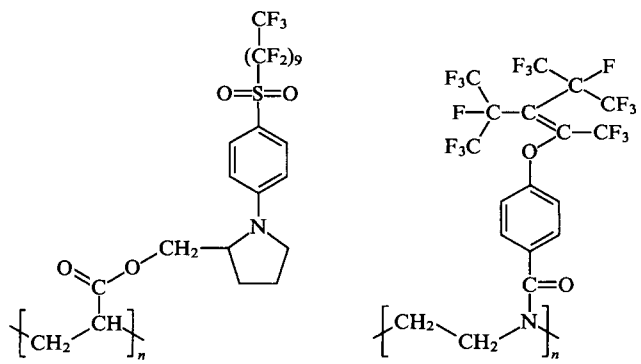


Figure 19. Dependence of the amplitude of the second harmonic on the number of LBF bilayers.[129] The dashed line represents the linear fit to the relaiton for $N \leqslant 40$.

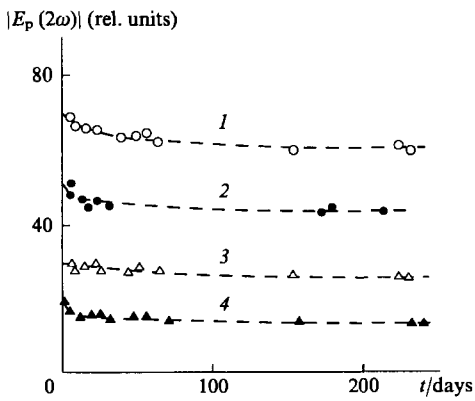
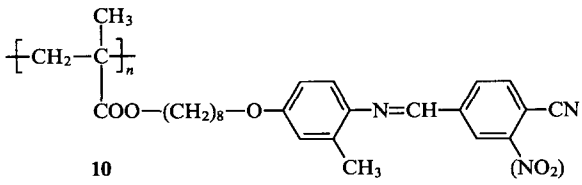
8 9

Fig. 20 illustrates the high stability of the polymer LBF, confirming the usefulness of the strategy selected by the authors.

The synthesis of polymethacrylates containing NLO-active fragments in the side chains has been described[130] and the results of studies on second harmonic generation with the LBF of a polymethacrylate derivative have been presented.[131] It has been shown that the formation of LBF from mixed monolayers of polymer **10** and stearic acid hardly alters the orientation of the side chains: according to polarisation UV spectroscopic data, the angle of inclination of the side chains relative to the support in the LBF of polymer **10** is 30° and in that made up of a mixture of polymer **10** and the aliphatic acid is 25°.





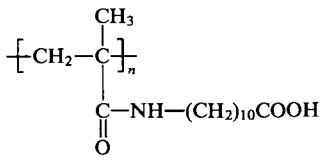


Figure 20. Dependence of the amplitude of the second harmonic on the LBF ageing time for specimens consisting of different numbers of bilayers:[129] (*1*) 40; (*2*) 30; (*3*) 20; (*4*) 10.

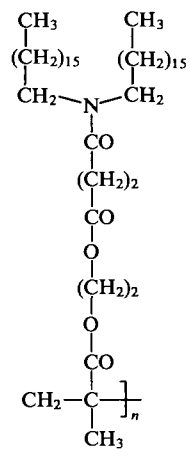
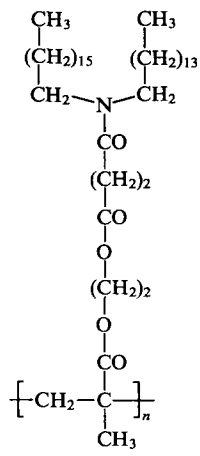
10

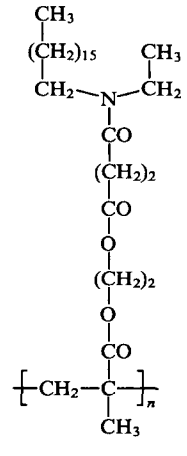


A similarity of the angles of chain inclination (36°) has been found [132] for the methacrylate derivatives **11** photopolymerised in the LBF. The authors note that this procedure is promising for the formation of LBF for NLO studies and applications.

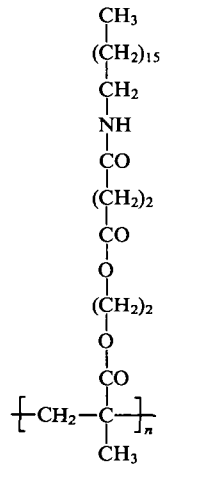


11

The employment of methacrylic polymers **12**–**15** with different configurations and compositions of the side chains for optical waveguides has been described. [133]

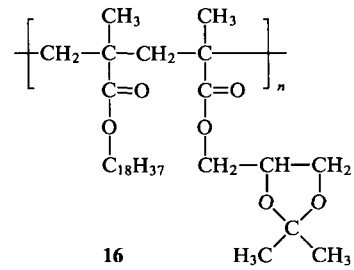


In the series of polymers presented above, the capacity for the formation of liquid monolayers increases from compound **12** to compound **15**. 500-Layer LBF (thickness 0.8 μm) have been obtained from polymer **14**. It was observed that the waveguides based on them suffer very low losses (2 dB cm^{-1} for wavelengths of 633 and 785 nm) by virtue of the low degree of order in the side chains, preventing the formation of light scattering domains.



12

13



14

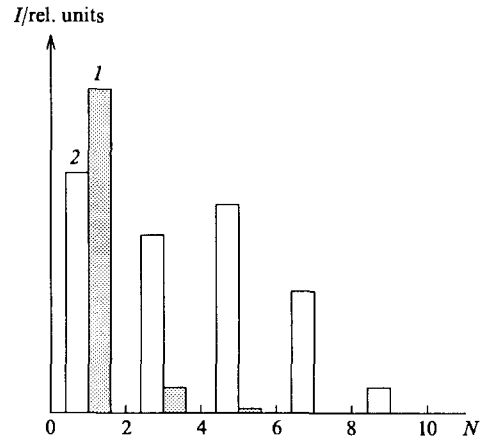
15

The low stability of LBF of low-molecular-mass compounds at elevated temperatures and *in vacuo*, the mutual diffusion of molecules belonging to different layers of the LBF, [134–137] and finally the possibility of the loss of the low-molecular-mass component from the monolayers (constituting the LBF) mixed with the polymer are all factors which have stimulated studies on high-molecular-mass multilayer, including alternating, structures.

The insulating properties and stability of LBF of stearic acid and the methacrylic copolymer **16**, deposited on the surface of silver, have been investigated [138] by the time-of-flight mass spectrometry of secondary ions.

16

Fig. 21 shows that the LBF of copolymer **16**, with a thickness equivalent to five monolayers, fully prevents the emission of secondary Ag^+ ions through the film. On the other hand, nine layers of stearic acid by no means fully suppress the diffusion of these ions.



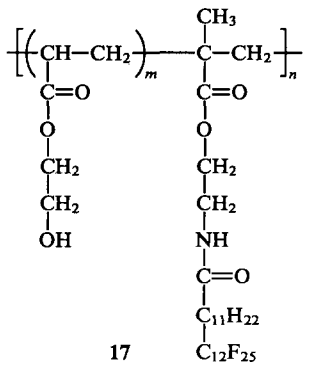


Figure 21. Dependence of the intensity of the signal due to secondary silver ions (normalised with respect to the $C_3H_5^+$ peak) on the number of layers: (*1*) for the methacrylic copolymer **16** LBF; (*2*) for the stearic acid LBF. [138]

In order to investigate the diffusion of the low-molecular-mass product from mixed monolayers involving the methacrylic polymer **16**, mixed 1 : 1 LBF with a fluorescent probe (a diphilic cyanine dye) were formed. Two mixed monolayers were deposited on the surface of silver on which a monolayer of copolymer **16** had already been deposited. Up to eight further monolayers of methacrylic copolymers were formed on the surface of the LBF obtained in this way. Fig. 22 illustrates the influence of the number of layers of copolymer **16** on the intensity of the mass spectrometric signal of the dye cation. Evidently two monolayers of the copolymer are sufficient to decrease significantly the signal intensity, but even eight layers do not fully suppress the diffusion of the dye ions through the copolymer LBF. The high stability of the LBF investigated is expressed by the retention of its properties on exposure to air at 10 °C for nine months and after boiling in water for 15 min. [138] Similar studies have been carried out [139] for copolymer **17**.

17

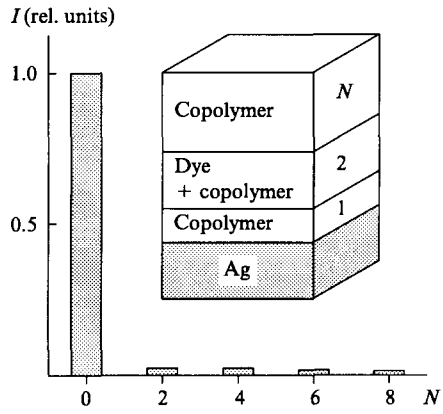

Figure 22. Dependence of the intensity of the signal due to secondary dye ions (normalised with respect to the $C_3H_5^+$ peak) on the number of outer layers of the methacrylic copolymer **16** for a mixed LBF.[138]

3. Mixed monolayers

In the analysis of the behaviour of monolayers of certain copolymers, the two-dimensional compatibility of mixtures of the corresponding homopolymers was examined. In this section we shall discuss in greater detail the behaviour of binary mixtures of polymers on the surface of a liquid. The principal questions which will be considered concern the compatibility of homopolymers in the two-dimensional state, the influence of the main and side chains on the compatibility of the polymers, including the case of markedly different lengths of the side chains in the components of the monolayer, and the determination of the thermodynamic parameters of the mixed monolayers.

The compatibility of the first and second members of the series of poly(alkyl acrylates)—PMMA and poly(ethyl methacrylate) (PEMA)—has been analysed.[81,140,141] On the basis of the compression isotherms for individual and mixed monolayers, calculations were made of the parameters characterising the excess free energy of mixing (ΔG_m) as described by Goodrich,[142] the coordination number of the two-dimensional quasi-lattice (Z') as described by Singer,[143] the partial immersion factor (f_m) as described by Frisch and Simha,[144] and the interaction energy (η^2/Z) between rigid segments lying on the surface†.[145] The dependence of ΔG_m on the mole fraction (φ) of PEMA in the PEMA–PMMA mixture is presented in Fig. 23. It is seen that the minimum negative value of ΔG_m corresponds to φ = 50%. The closeness of Z' to 2 for both the homopolymers themselves and for their mixtures (according to Davies and Rideal,[146] the flexibility is ~1%) indicates the rigidity of the acrylic macromolecules in the monolayers on the surface of water. The parameter f_m also does not change markedly for different component ratios, which indicates a similar degree of immersion of parts of the macromolecules in the aqueous subphase. The minima in the parameters η^2/Z and ΔG_m and also in the area of the monolayer at φ = 50% indicate the maximum cohesion between the segments of the macromolecules in this range of component ratios. As noted previously for other objects,[43,79,147] the maximum cohesion for the equimolar component content in the monolayer can be explained by the fact that the most rigorous alternation of the units of both polymers on the subphase can be attained for this component ratio. It has also been noted[81,140] that at 20–30 °C both components are compatible in the monolayer whatever the ratio.

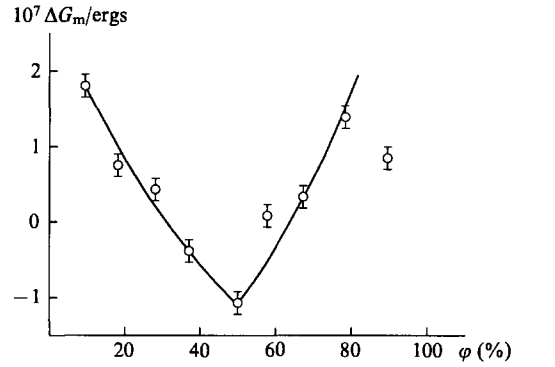

Figure 23. Dependence of the free energy of mixing on the composition of a monolayer comprising a PEMA–PMMA mixture.[140]

The compatibility with PMMA of the next member of the series—poly(propyl methacrylate) (PPMA)—has been investigated[148] for monolayers at the air/water and hexane/water interfaces. Using the parameters of the two-dimensional Huggins equation of state[149] and the ellipsometric method for the determination of the thickness of the monolayers, it has been shown that two-dimensional PMMA–PPMA mixtures are compatible on the surface of water and are thermodynamically more stable than monolayers of the pure polymers. The compatibility is due to the identical horizontal orientation of the side chains of both polymers on the surface of water, which is also promoted by the identical thickness (14 Å) of the PMMA and PPMA monolayers.[148,150]

The next member of the series—poly(n-butyl methacrylate) (PBMA)—is also compatible with PMMA in a monolayer on the surface of water.[79] The negative deviations of the surface area of the mixed monolayer from additivity and the minimum in the excess free energy for the equimolar component ratio (as for the mixed monolayers of PMMA and the lower homologues) indicate an increased stability of such a binary monolayer and the predominance of attractive forces between the molecules. The horizontal orientation of the side chains of the PBMA molecules for a low content of PMMA in the mixed monolayer changes to the vertical orientation and a strong interaction between the main chains of the polymers in the equimolar mixture.

Similar results, obtained for these binary mixtures, have been reported in another study.[140] The author analysed mixed monolayers of PEMA with PBMA. It is of interest that the behaviour of this system differs significantly from that of the mixed monolayers of PMMA with PEMA and PPMA: the monolayers of the individual components are thermodynamically more stable than the mixed PEMA–PBMA monolayers. It was shown that the maximum energy of mixing ΔG_m and the maximum parameter η^2/Z correspond to the 1:2 component ratio in the mixed monolayer. In this region, the positive deviations of the area of

† It is noteworthy that the thermodynamics, statistical physics, and molecular dynamics of monolayers of low-molecular-mass compounds and polymers are developing quite vigorously. However, analysis of the existing theories is outside the scope of the present review.

the monolayer from additivity reach maximum values. The results can be explained by the higher degree of hydration of the segments of the macromolecules in the mixture and the higher energies of repulsion between them for the component ratio indicated.

The vertical orientation of the long side chains of PODMA and the horizontal orientation of the short side chains of PMMA in their mixed monolayers on the surface of water prevent the formation of compatible monolayers.[148] This conclusion is based on data obtained with the aid of compression isotherms, according to which the area of the monolayer changes additively as its composition varies and the collapse pressure is independent of composition.

As mentioned above, mixed monolayers of PODMA and PBMA are compatible only in the range of compositions corresponding to a low content of the second component.[91] In mixed monolayers of poly(dodecyl methacrylate) and poly(octadecyl methacrylate), the inclined orientation of the dodecyl side chains and the vertical orientation of the octadecyl ones preclude the formation of a two-dimensional system with fully compatible components over the entire range of compositions,[112] although the mixtures can produce more stable films than the separate phases of the individual polymers.

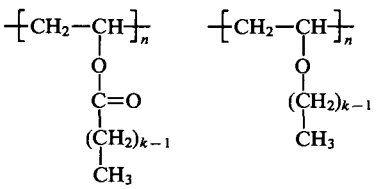
A similar approach, based on the analysis of the dependence of the limiting areas and collapse pressures, for poly(phenyl methacrylate) – poly(hexyl methacrylate) systems permitted the conclusion[102] that the mixed binary monolayers are incompatible on the surface of water in all the two-dimensional phase states of the monolayer. These data can also be accounted for by the different orientations of the side groups. In the mixed monolayers of poly(phenyl methacrylate) and poly(benzyl methacrylate), the identical orientation of the aromatic groups leads to the formation of fully compatible two-dimensional systems whatever the component ratio.[102]

The study of the compatibility of high-molecular-mass and low-molecular-mass compounds in monolayers is important for the preparation of functionalised LBF. An increase in the compatibility of molecules belonging to different classes of compounds can be achieved by employing molecules with ionisable groups. This problem has been investigated in relation to binary mixtures of PMMA with stearic, arachidic, myristic, and oleic acids and with stearylamine, the degree of ionisation of which can be regulated by varying the pH of the aqueous subphase.[151–153] The compatibility of such components is determined by two factors: the orientation of the side groups and the intensity of the intermolecular interactions, which become more intense on ionisation of polar groups. Nonionisable saturated acids and PMMA are incompatible in the monolayer. The unsaturated oleic acid, the orientation of the chains of which is close to that of the ester groups of PMMA, is compatible with this polymer whatever the component ratio. The negative influence of the differences in the orientation of the side groups of the polymer and the chains of low-molecular-mass surfactants on the compatibility in the monolayers can be neutralised by intensifying the interactions between polar groups of the polymer and the ionised groups of the acid or the amine. Thermodynamic analysis of the PMMA – stearic acid and PMMA – stearylamine binary systems[151] demonstrated that the mixed layers are more stable than the monolayers of the individual compounds. With increase in temperature, the stability of the monolayers falls. The compatibility of the components in such monolayers is determined by the enthalpy term in the free energy and depends on the degree of ionisation of the molecules. Evidently, an improvement in compatibility can be achieved also for ionisable macromolecular systems.

* * *

The properties of the monolayers and LBF of acrylic and methacrylic homopolymers, their mixtures, and copolymers embrace virtually all the principal approaches to the analysis of the behaviour of macromolecules in monolayers and a considerable proportion of the existing ideas concerning the preparation and properties of polymeric LBF.

The properties of monolayers of nonionisable homopolymers can be regulated by altering the length of the ester side chains, by introducing a hydrophilic spacer uncoupling the main and side chains, or by the partial hydrolysis of the side chains, which leads to the formation of a copolymer incorporating ionisable groups. An increase in the length of the ester groups leads initially to the expansion of the monolayer and then to its condensation as a result of the secondary cohesion between the long side chains. Crystallisation of these chains explains, on the one hand, the discrepancies between the data of different workers who investigated poly(octadecyl methacrylate) monolayers under different experimental conditions and, on the other, can lead to the formation of poor quality LBF owing to the oscillations of the meniscus along the three-phase contact line. Crystallisation processes in the LBF itself can be suppressed by forming on the latter several monolayers of an amorphous polymer with a specified rigidity. The introduction of a hydrophilic spacer, separating the main and side chains of a double-stranded lipid, leads to the formation of stable monolayers, the collapse pressure and limiting area of which are close to the corresponding parameters of the low-molecular-mass lipid. The generation of ionisable acid groups on hydrolysis of an acrylic homopolymer extends the possibilities for the variation of the conformation and packing density of the units of the macromolecules on the surface of water by varying the concentration of the electrolyte in the aqueous support or its pH.



By varying the composition of the copolymer or the mixed monolayer, it is possible to achieve its transition from one state to another and to alter the phase composition and the structural organisation of the phases. These transformations are carried out by varying the length of the side chains of the comonomers, by the specific alteration of the length of the hydrophilic spacer in the main chain, and also by the copolymerisation of nonionogenic and ionogenic monomers.

Mixed monolayers of polymers and especially polymers and low-molecular-mass surfactants are of practical value, since, compared with monolayers and LBF based on copolymers, they facilitate the introduction of functional additives and the regulation of the properties of two-dimensional systems. Regulation of the states of these monolayers and phase separation processes makes it possible to create monolayers with definite molecular and phase compositions. This opens, in its turn, a path to the formation of, for example, skeletised LBF with a controllable size and disposition of cavities and to the formation of functionalised LBF with a specified structure and surface density of integrated special groups. The structures and properties of mixed monolayers have been scarcely analysed from these standpoints and the possibilities for the construction of a particular phase structure of the monolayers have still not been utilised.

Despite the rigidity of the PMMA monolayer, in many instances it is possible to create from this polymer fairly uniform LBF characterised by a low density of defects and to use them as a positive electron-beam resist. The formation of more ordered LBF is to be expected when acrylic and methacrylic polymers with moderate and considerable lengths of the hydrocarbon chains and their copolymers or mixed monolayers are employed. These polymers and their derivatives are already being used to create non-linear optical systems, thick (500 layers) wave guides with low losses, selective membranes, and insulating layers.

VII. Poly(vinyl ethers) and poly(vinyl esters)

Among the representatives of polymers of this type, the parent polymer of which is poly(vinyl alcohol), the poly(vinyl esters) **18** have been most thoroughly investigated in monolayers. The poly(vinyl ethers) **19** have not been attracting the attention of investigators recently.

18 **19**

The interest in poly(vinyl alcohol) (PVA) is associated with the possibility of obtaining monolayers of this water-soluble polymer on the surface of water. The stability of PVA monolayers on the surface of water is determined to a large extent by the acetate groups remaining after the hydrolysis of poly(vinyl acetate),[25] which is used to obtain PVA. PVA monolayers belong to the liquid-expanded type; their compressibility is high and they are disrupted at low surface pressures. The absence of appreciable dissolution of PVA in the support is indicated by the rapid restoration of the film following the expansion of a compressed monolayer, which could not have occurred for a simple equilibrium between the solution and the surface layer.

The characteristics of the variation of the compression isotherms for monolayers with increase in the length of the side (ester or ether) chain in poly(vinyl ethers)[154] and poly(vinyl esters)[155] are similar to those which were noted for acrylic and methacrylic polymers.

Poly(vinyl ester), especially poly(vinyl acetate) (PVAC) and poly(vinyl stearate) (PVST), monolayers have been investigated to a much lesser extent than poly(vinyl ether) monolayers.

The active study of PVAC monolayers on the surface of a liquid[25,26,77,79,85,155–172] has been undertaken in view of their highly equilibrium nature: there is no hysteresis on the compression–expansion isotherms obtained at high speed. The thermodynamic properties of PVAC monolayers have been investigated[156,158] and it has been shown that the macromolecules are arranged on the surface of water in the form of two-dimensional deformed coils. They are moderately flexible and the interaction (attractive) forces between them are weak. These properties of PVAC have led to prospects for the preparation of monolayers using nonspreading polymers, such as the ethylene–propene copolymer, by grafting vinyl acetate groups onto them.[145]

Interesting data concerning the inversion of the quality of solvents for PVAC on passing from three-dimensional to two-dimensional solutions have been published.[170] The surface θ temperatures have been calculated from the dependences of the second virial coefficient on the reciprocal of temperature, obtained from the compression isotherms, and it was shown that methanol (a poor solvent for the bulk phase solution) becomes a good solvent for PVAC in the monolayer. This result, confirmed by Huggins's theory and experimental data for supports containing NaCl or methanol, is associated with the competition of two processes in the formation of the monolayer: the spreading of the polymer and the solubilisation of the solvent by the subphase.

Poly(vinyl stearate) monolayers have been investigated in connection with the problem of their nonuniformity with respect to the area of the Langmuir trough.[173] A linear decrease in the surface pressure with increase in the distance from the mobile barrier has been established. Fig. 24 shows that the pressure gradient depends on the area of the monolayer and that the change in π may reach a considerable magnitude (> 10 mN m^{-1}). In the case of the monomer (vinyl stearate), a homogenous monolayer is formed. The effects due to the inhomogeneity of polymer monolayers must be taken into account in the study of LBF.[173,174] The inhomogeneity of polymer monolayers, associated with the low rate of relaxation, can be eliminated by introducing into the latter diphilic low-molecular-mass plasticisers. Problems concerning the compatibility of high- and low-molecular-mass components in monolayers become important under these conditions.

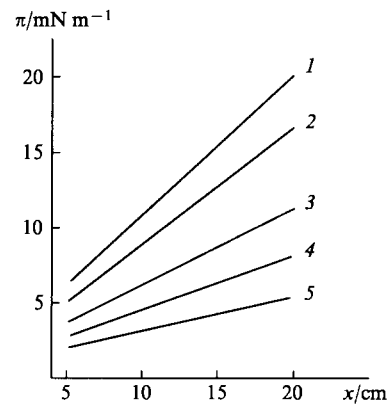


Figure 24. Dependence of the surface pressure in the poly(vinyl stearate) monolayer on the distance between the Wilhelmy plate and the fixed edge of the trough for different average areas (Å^2 per residue):[173] (*1*) 21.2; (*2*) 21.5; (*3*) 22.0; (*4*) 22.5; (*5*) 23.0.

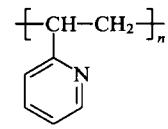
The study of mixed monolayers of vinyl stearate and PVST showed[174] that the surface pressure, measured on collapse, depends in a complex manner on the composition of the surface film. These data permit the conclusion that the components are incompatible at least in this region of the compression isotherms. The surface potential of the monolayer and the absorption at 950 cm^{-1} (out-of-plane scissors vibrations of the hydrogen atoms of the vinyl group) of an 80-layer LBF comprising mixed monolayers deposited on a germanium plate varies linearly with composition under these conditions. These integral characteristics, which are insensitive (in the given version) to the phase composition, have been used[174] to analyse the kinetics of the two-dimensional polymerisation of vinyl stearate. The PVST monolayer, obtained by the polymerisation of the monomer on the surface of water, was transferred much less effectively onto the surface of the germanium film ($\rho = 0.1$) than the monolayer prepared from PVST polymerised in the bulk phase.

In the study of the properties of mixed PVAC monolayers with low-molecular-mass compounds, two interesting facts were noted:[157] the reversibility of the compression isotherms with a rigorous additivity of the areas for mixtures of equal weight and high collapse pressures of the mixed monolayers, exceeding in most cases the π_c for the individual compounds (Table 4).

Table 4. The monolayer collapse pressures (mN m^{-1}) for individual compounds and their equilibrium binary mixtures with PVAC.[157]

Component	Individual monolayer	Mixed monolayer
Poly(vinyl acetate)	23	23
Stearic acid	42	55
n-Hexacosanoic acid	58	68
n-Hexatriacontanoic acid	58	70
2-Hydroxyethylstearic acid	57	69
Methyl stearate	36	41
1-Octadecanol	42	39
Cholesterol	42	38



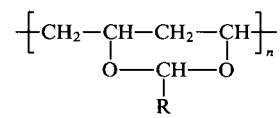
These results can be explained by the more intense interaction of the acetate groups with the carboxy-groups than their interaction with the hydroxy-groups or ester groups. Nevertheless, in view of the similarity of the collapse pressures for the monolayers of the pure polymer and its mixture, one can conclude, in conformity with Crisp's rule, that the compounds investigated are incompatible.

The identical orientation of the long hydrocarbon chains of PVST and stearic acid promotes their compatibility in mixed monolayers.[175] On the other hand, oleic acid, the hydrocarbon chain of which has the same length but is oriented horizontally along the surface of water owing to the presence of the double bond,[176] is incompatible with PVST in the monolayer but is compatible with PVAC.[177]

The decisive role of the orientation of the side chain is manifested also in the compatibility of polymer–polymer systems. Thus the similarity of the chemical structures of the PVAC and PMMA molecules promotes the complete compatibility of these polymers on the surface of water and the formation of ideal mixtures.[79,171] It must be emphasised that the dependences of the surface pressure on composition are monotonic for the uncollapsed and collapsed phases of this system and indicate the formation of true surface and bulk-phase solutions of the above polymer. A complete compatibility is also attained in mixed monolayers of PVAC and poly(ethyl acrylate) by virtue of the similar orientation of the units on the surface of water.[172] On the other hand, mixtures of PVAC with poly(vinyl butyrate) are compatible only in the region of equimolar ratios of the components. Such behaviour, similar to that examined above for PMMA–PBMA mixtures, can be explained in this instance not by the differences between the chain orientations but by the differences between the interactions of the units of these polymers with the molecules of the subphase.[171] All three isomeric poly(butyl methacrylates) (n-, *iso*-, and *tert*-butyl) are incompatible with PVAC in the monolayer.[79]

The PVST and PODMA polymers are compatible in mixed monolayers, which are more stable than the monolayers of the individual components. The incompatibility of PVAC and PVST in the monolayer is due to the different orientations of the ester side groups of these macromolecules on the surface of water.[148] Apparently a more homogeneous distribution of the monomer residues on the surface of water can be attained by forming the monolayers from copolymers of vinyl acetate and vinyl stearate.[155,178]

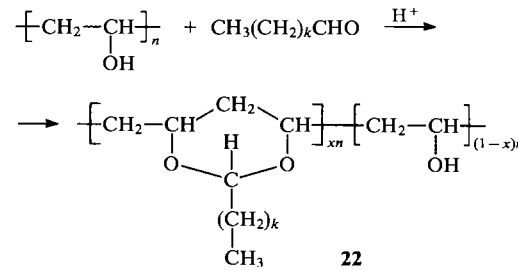
One of the few examples of compatibility in the monolayer of a polymer not containing a long hydrocarbon chain and classical surfactants is provided by binary mixtures of poly-2-vinylpyridine **20** with stearic acid, methyl stearate, or stearylamine.[179] In contrast to monolayers of the corresponding low-molecular-mass compound, neither temperature (15–35 °C) nor pH (6.2, 9.4) influence the compression isotherm. Thermodynamic analysis of the properties of monolayers of binary systems permitted the conclusion that the components are compatible in all three cases. For monolayers of compound **20** in a mixture with methyl stearate or stearylamine, the compatibility is determined by the enthalpy factor and is achieved through interactions between the polar groups of the components of the monolayer. The compatibility in the polymer **20**–stearic acid system is determined by the entropy factor and is apparently achieved by the immersion of the pyridylethylene units in the subphase. Owing to the high solubility of poly-2-vinylpyridine in the subphase, it has not been possible to obtain[30] a stable monolayer of poly-4-vinylpyridine with a reproducible surface pressure. Even the statistical copolymer of 4-vinylpyridine with 48 mol.% of acrylonitrile gives rise to monolayers which are stable only at a surface pressure $\leqslant 5$ mN m^{-1}.[30]



20

Thus the properties of the monolayers of poly(vinyl esters) have been investigated in fair detail. A distinctive feature of the first representative of this series—poly(vinyl acetate)—is the high stability of the monomers formed and high collapse pressures for mixed monolayers with low-molecular-mass compounds. These properties give rise to the hope for a wider employment of this polymer (and of its long-chain analogues) for the formation of stable monolayers and LBF. The ionisable polyvinyl derivatives of the type of polyvinylpyridine, which can be compatible with long-chain low-molecular-mass surfactants, merit a more vigorous investigation in monolayers. In the immediate future, one may expect an increase in the interest of investigators in the study of the structures and properties of LBF of these polymers and their mixtures with functionalised molecules.

VIII. Poly(vinyl acetals)



The polyalkylals **21** belong to the class of traditional polymers which have been used for a long time in practice. They are interesting objects for study in monolayers and LBF in view of the simplicity of their synthesis, which makes it possible to obtain macromolecules with different lengths of the side chains and with different degrees of acetal formation and also in view of the possibility of the cross-linking of the macromolecules.

21

Polymers containing electron-donating and electron-accepting groups have also been obtained recently, which has made it possible to investigate energy transfer processes in alternating LBF.

Polyacetals are obtained by the acetal formation reaction of poly(vinyl alcohol) in an acid medium. The degree of acetal formation x can vary within wide limits and can reach 80%.

22

Fig. 25 presents $\pi - A$ relations for five poly(vinyl acetals) with different lengths of the side chain ($k = 0-12$).[180] It can be seen that the collapse pressure of the monolayer increases and the compressibility diminishes with increase in k. The discrepancies between the limiting areas of the monolayers of poly(vinyl acetals) obtained by different workers[25,180,181] can be seen in Fig. 26. Evidently, the weak dependence of A_0 on n for long-chain homologues is due to the presence of the six-membered ring, which eliminates the influence of the hydrocarbon chain. The degree of polymerisation, which varies, for example for polyvinyloctal, from 300 to 2 600 ($x = 0.75-0.79$), also does not affect the limiting areas.[181] With decrease in x, the limiting areas diminish, which is associated with the hydrophilic nature of the

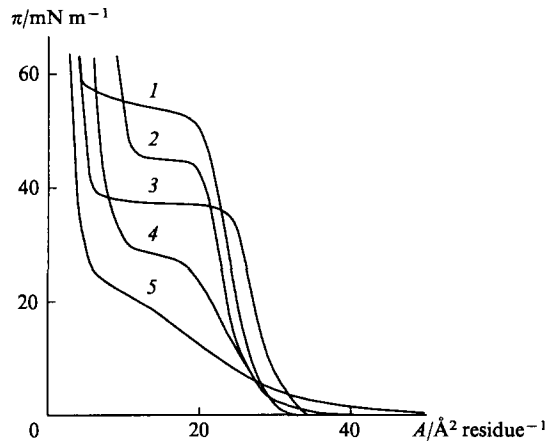


Figure 25. Compression isotherms for poly(vinyl acetals) **22** with different values of k: [180] (*1*) 12; (*2*) 10; (*3*) 6; (*4*) 2; (*5*) 0.

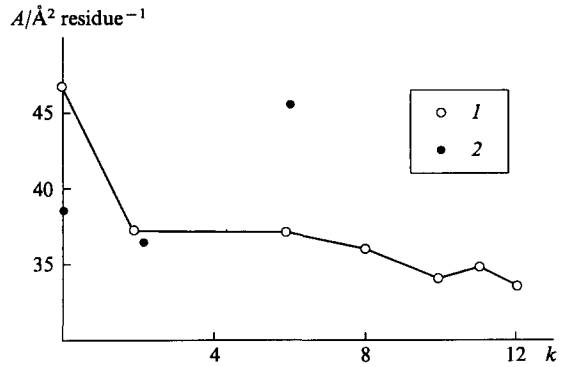

Figure 26. The influence of the length of the side chain (k) of poly(vinyl acetals) on the limiting areas of the monolayers according to the data of Oguchi et al. [180] (*1*) and Crisp [25] (*2*).

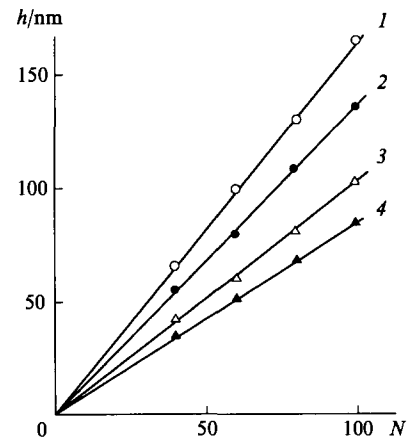

Figure 27. Dependence of the LBF thickness on the number of layers for four homologues of compound **22** with different values of k: [181] (*1*) 12; (*2*) 10; (*3*) 6; (*4*) 2.

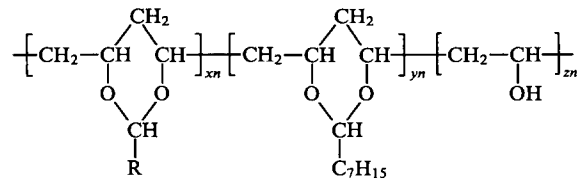
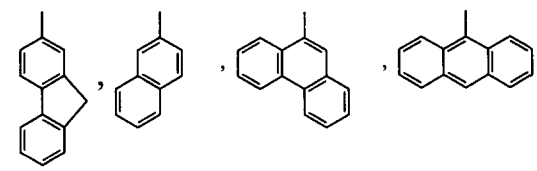


alcohol groups immersed in the subphase even at low surface pressures. The hysteresis of the isotherms for the polyvinyloctal monolayers compressed to $\pi \simeq 50$ mN m^{-1} [180,182] can be ruled out when the monolayers are obtained from mixed solutions of the polymer and iodine in chloroform. [182] The iodine atoms plasticise the monolayer and diminish its rigidity and the packing density of the side chains compared with the pure polyvinyloctal.

The fairly high homogeneity and stability of the poly(vinyl acetal) monolayers make it possible to obtain thick (up to 100 layers) Y type LBF. [180] Fig. 27 presents the dependence of the ellipsometrically determined thickness of the LBF on the number of layers for four homologues of compound **22** with k = 2, 6, 10, and 12. The linearity of the relations and their monotonic course in conformity with the size of the hydrocarbon chain as well as their slope, which yields the length of the hydrocarbon chain (~14 Å for k = 10 and 12), indicate the high quality of the LBF. [180,181]



These LBF can be used as negative electron-beam resists. The sensitivity of such a resist depends on the chain length of the acetal groups through which cross-linking takes place. [183] Although the sensitivity of the resists was lower on deposition by the LBF method than in the case where they were prepared by the traditional centrifugal procedure, the resolution for the former is appreciably higher and is determined by the diameter of the electron beam.

It is of interest to carry out similar studies with Z type LBF, which can be obtained from monolayers of iodine-containing polyvinyloctal. The introduction of chromophoric electron-donating and electron-accepting groups into the molecules of poly(vinyl acetals) makes it possible to investigate the photophysical properties of polymeric LBF.

Chromophoric fluorene, naphthalene, phenanthrene, and anthracene groups have been introduced into polyvinyloctal **23** as a result of the reaction of PVA with the corresponding aldehydes. [184,185] The fraction of chromophoric groups in the chain (x) did not exceed 0.12.

23

R = 

Analysis of the fluorescence spectra of two-layer LBF of chromophoric polyvinyloctals showed that aggregation (formation of excimers) does not occur and that the chromophores are distributed in the amorphous film as isolated species.

The influence of the thickness of the inert spacer layer in polyvinyloctal on the effectiveness of the energy transfer from the donor (fluorenyl) to the acceptor (anthryl) is illustrated in Fig. 28. The alternating LBF consisted of two layers of fluorene and anthracene derivatives of polyvinyloctals, between which N layers of chromophore-free polyvinyloctal were distributed. It is seen from the fluorescence spectra that the effectiveness of the energy transfer is controlled by the number of layers N: for a system without a spacer layer (N = 0), the emission of fluorenyl (300–330 nm) is quenched by the acceptor and amounts to only 25% of the intensity for systems with N = 8 or 10. Under these conditions, the sensitised emission of anthryl is observed in the range 390–460 nm in the spectrum of the system with N = 0. [184]

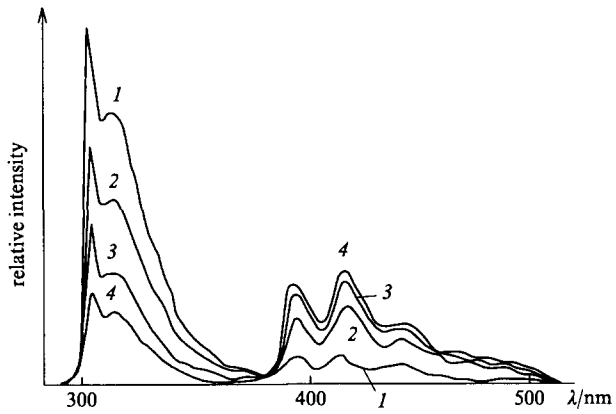


Figure 28. Fluorescence spectra of LBF containing layers of fluorenyl and anthryl derivatives of compound **23** separated by different numbers (N) of polyvinyloctal layers.[184] N = 10 (curve *1*), 8 (curve *1*), 4 (curve *2*), 2 (curve *3*), and 0 (curve *4*).

The effectiveness of the energy transfer can serve as a criterion for the determination of the thermal stability of LBF containing layers of chromophoric polyvinyloctals alternating with inert layers.[185] Fig. 29 presents the temperature variation of the ratio of the emission intensities of the acceptor at 438 nm (I_A) and the donor at 350 nm (I_P) for the 'phenanthryl/6/anthryl' system. Heating of this system (curve *1*) increases appreciably the ratio I_A/I_P starting from 40 °C. This is associated with the mutual approach of the chromophoric groups on heating. A further increase in temperature leads to the irreversible disordering of the system, which persists on its subsequent cooling (curve *1'*).

The thermal stability of poly(vinyl acetals) can be appreciably increased by cross-linking of the macromolecules with formaldehyde via the free alcohol groups.[185] The effectiveness of the cross-linking was determined from the change in the intensity of the fluorescence of the chromophoric poly(vinyl acetal) after it had been maintained in dichloromethane. As can be seen from Fig. 29, heating (curve *2*) and cooling (curve *2'*) of the cross-linked LBF have only a weak influence on the intensity ratio I_A/I_P, which indicates the constancy of the structure of the corresponding LBF.

Thus poly(vinyl acetals) provide a series of possibilities for the introduction of various functional groups into them. Based on them, it is possible to obtain cross-linked LBF with a high thermal stability. Evidently, these polymers will be investigated more vigorously in the immediate future.

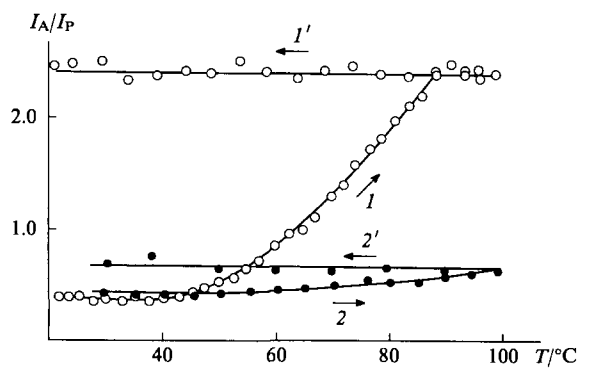

Figure 29. The influence of heating on the effectiveness of energy transfer (I_A/I_P) for noncross-linked (curves *1* and *1'*) and cross-linked (curves *2* and *2'*) 'phenanthryl/6/anthryl' systems.[185]

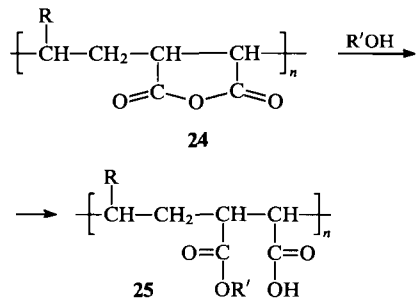
IX. Polymers based on maleic and fumaric acid derivatives



Two types of monomers and polymers derived from the isomeric maleic and fumaric acids and investigated in monolayers and LBF are known.

The first type includes the octadecyl monoesters of fumaric (ODF) and maleic (ODM) acids and the polymers based on them. The monolayer expands on photopolymerisation of ODF on the surface of water and contracts on photopolymerisation of ODM.[186,187] A 1:3 mixture of monomers polymerises without change in the area of the monolayer and can be used to form LBF with a low content of defects (cracks), the appearance of which is usually caused by the contraction of the monolayer on polymerisation.

The elastic properties of LBF of saturated ODF as well as the monomeric and polymerised ODF, 1:3 ODF–ODM mixtures, and ω-octadecenyl fumarate have been investigated by Brillouin spectroscopy.[188] The elastic constants of 30-layer LBF have been determined and it has been shown that they are low, decreasing still further on polymerisation for the majority of systems investigated owing to the formation of microcracks in the ODF on photopolymerisation. The polymerisation of mixed LBF comprising ODF and ODM leads to a slight increase in the elastic constants, which agrees with data obtained, showing the absence of contraction in this system on polymerisation.

Evidently the possibilities of these monomers for the creation of functionalised organic surfaces and organised films are far from having been exhausted.

Copolymers of vinylmaleic anhydride **24** belong to the second more widely investigated type. The reaction of compound **24** with water leads to the formation of poly(dicarboxylic acids) and that with alcohols affords the polyesters **25**.

24

25

Fig. 30 (see over) illustrates the influence of the ester side chain on the compression isotherms of the copolymers obtained by the esterification of poly(octadec-1-enyl-maleic anhydride). As can be seen from the figure, in contrast to the polymers examined previously in this instance the limiting areas of the monolayers increase linearly with increase in the length of the ester group, while the shape of the curves is retained. Hence it follows that the ester chains do not assume a vertical position on compression of the monolayer.[190]

Since the copolymers **25** contain unsubstituted carboxy-groups, the structure of their monolayer may be regulated by varying the pH of the subphase. For the copolymer with R' = CH_3, an increase in the pH of the subphase from 4.0 to 10.0 leads to an increase in the limiting area of the monolayer from 53 to 68 Å^2 per residue and to an increase in the collapse pressure from 22 to 40 mN m^{-1}.[189] Such behaviour can be explained by the ionisation of the carboxy-groups, which intensifies the repulsion between the molecules and the monolayer.

Recently these results were revised.[191] It was shown that at π = 30 mN m^{-1} the pH does not affect the area of the monolayer and that the collapse pressure does not increase with pH but either diminishes or passes through a minimum. The authors[191] note that the expansion of the monolayer as a result of the ionisation

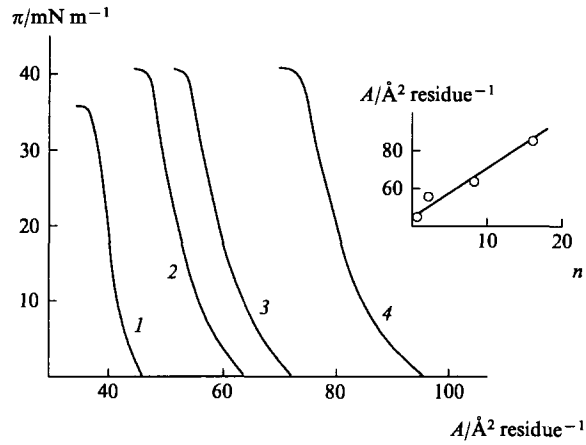


Figure 30. Compression isotherms for monolayers of copolymers of type **25** with R = $(CH_2)_{15}CH_3$ and different R′:[189] (*1*) H; (*2*) CH_3; (*3*) $(CH_2)_7CH_3$; (*4*) $(CH_2)_{15}CH_3$. The inset illustrates the dependence of the limiting area on the length of the group R′.

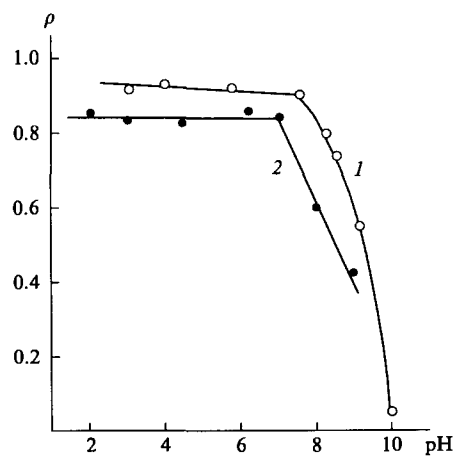
of the carboxy-groups can be compensated by the attraction due to the ion–dipole interactions or hydrogen bonding between the ionised carboxylate groups and the neutral acid residues.

High-quality Y type LBF have been obtained from compound **25** at pH 4.0–7.0 and 30 °C.[190,192,193] The introduction of Na^+ ions into the subphase significantly impairs the quality of the LBF, while in the presence of Cd^{2+} ions the LBF obtained are almost insoluble 'in all the solvents'.[189]

The influence of pH on the degree of transfer of copolymer monomers is illustrated in Fig. 31. The sharp decrease in ρ at pH > 8 can be explained by the development of repulsive forces between the surface of silicon and the ionised monolayer. The sharp increase in the viscosity of the monolayer at pH > 8.5 can also affect the quality of the LBF formed.[194] The degree of ionisation of the monolayers transferred onto a silicon prism has been determined[191] by distorted total internal reflection IR spectroscopy. The pK_a corresponding to the pH at which 50% ionisation takes place was found by monitoring the absorption bands of the unionised carboxy-groups. For the non-esterified and monoester derivatives of compound **25**, the pK_a were found to be in the range 8.0–8.5. This confirms the observed relation between the degree of transfer of the monolayer and the degree of ionisation of its constituent polymer.



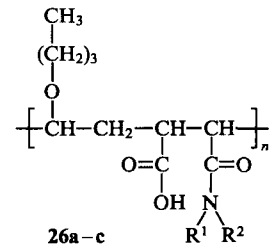


Figure 31. Dependence of the degree of transfer for the first ten LBF layers on pH for copolymer **25** with R = $(CH_2)_{15}CH_3$ and R′ = CH_3 (curve *1*) and H (curve *2*).[191]

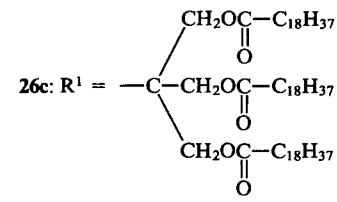
The influence of pH, ionic strength, and the concentration of Ca^{2+} ions in the subphase on the properties of monolayers of the hexadecyl vinyl ether–maleic acid copolymer, which constitute models of biological membranes, has been investigated[195] in a study of processes involving the binding of Ca^{2+} ions by membranes during muscle and nerve activity, in membrane transport, in enzymic reactions, etc.

The height of the Schottky barrier in metal–dielectric–semiconductor heterostructures may be regulated with the aid of LBF of poly(octadec-1-enylmaleic anhydride).[193] A change in the degree of hydrolysis of the anhydride groups in the Au–LBF–GaP system alters the height of the Schottky barrier as a result of the accumulation of electrons (increase in the charge) on the oxygen atom of the anhydride group.

The copolymers obtained as a result of the modification by the corresponding amine of the butyl vinyl ether–maleic anhydride copolymer **25** have interesting properties.[196]



Y type LBF of compounds containing single-stranded (**26a**), double-stranded (**26b**), and triple-stranded (**26c**) side chains were formed in the above study on the surface of porous (0.2 μm) polycarbonate films (Nuclepore) and the influence of the structure of the monolayer and of the number of layers in the LBF on the permeability of such a membrane to the electrolyte (KCl) was analysed.

26a–c

26a: $R^1 = C_{18}H_{37}$, R^2 = H.

26b: $R^1 = R^2 = C_{18}H_{37}$.

R^2 = H.

In order to determine the KCl flux (0.5 M solution), the conductivity of the aqueous phase was measured, assuming that there is a linear relation between the conductivity and the KCl concentration. Fig. 32 presents the dependence of the KCl flux on the number of layers of compound **26b** in the LBF at 22 °C. It is seen from the figure that the electrolyte flux diminishes sharply on deposition of 6–8 monolayers and subsequently remains unchanged. The influence of the number of side chains in the elementary unit of the copolymer molecule on the electrolyte flux is illustrated in Fig. 33. The electrolyte flux is not arrested by the LBF of the single-stranded derivative **26a** and is weakly inhibited by the LBF of the triple-stranded derivative **26c**. The double-stranded copolymer **26b**, which gives rise to the closest packing in

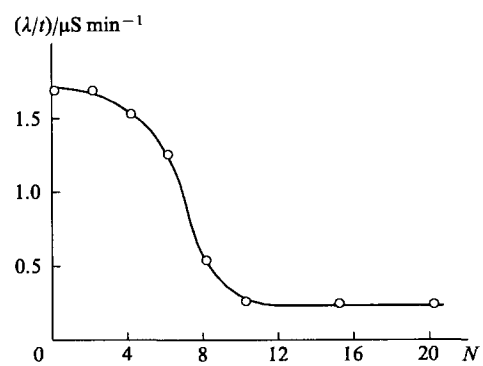


Figure 32. The influence of the number of layers of polymer **26b** (*N*) on the flux of KCl (λ/T) through a membrane at 22 °C.[196]

the monolayer (the limiting area of the **26b** monolayer is smaller than for the other two analogues), offers the greatest resistance to the electrolyte flux in the LBF. For membranes cast on a nuclear ultrafilter from solutions of compounds **26a–c**, the dependence of the flux on the number of side chains was not observed.[196] The stability of the LBF in aqueous solutions and the reproducibility of the results of the measurements of their permeability suggest the possibility of the practical employment of these selective membranes.

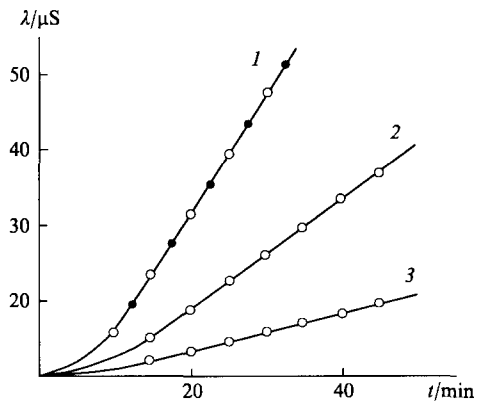

Figure 33. The permeability to KCl of LBF (20 layers) comprising polymers **26a** (curve *1*), **26c** (curve *2*), and **26b** (curve *3*) at 22 °C. Filled circles — data for the initial porous membrane (without LBF).[196]

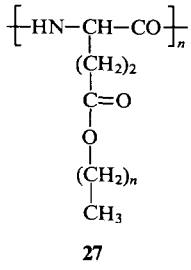
X. Synthetic polypeptides and polyorganosiloxanes. Monolayers consisting of helical molecules and thin films

It was noted above that an essential condition for the preparation of LBF with a calibrated thickness and a definite orientation of molecules is the formation of a true equilibrium monolayer in which each monomer residue is in contact with the surface of the aqueous subphase. In contrast to monolayers of low-molecular-mass compounds, for which collapse with formation of the bulk phase almost always occurs for $A < A_0$, for polymeric objects with extensive conformational possibilities a decrease in the area can lead to the formation of monolayers made up of more complex molecular structures: helices and coils. We shall examine the properties of such monolayers in relation to synthetic polypeptides and polyorganosiloxanes. For the latter, we shall also analyse the possibility of the formation of stable thin polymer films on the surface of a liquid. Both these aspects are associated with the behaviour of the monolayers in the collapse region.

1. The behaviour of polymer monolayers on collapse

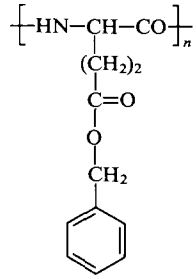
Many investigators[25,41–43,197–201] have been interested in the problem of the collapse of monolayers of low-molecular-mass compounds; polymer monolayers have been investigated to a much lesser extent in this respect. A brief analysis of this question can be usefully begun with the methods for the determination of the area of a close-packed polymer monolayer. Whereas the determination of the limiting areas of monolayers of low-molecular-mass substances by extrapolation to zero surface pressure is not open to disagreement, for polymer monolayers this parameter is determined in different ways. Two methods are normally employed for the determination of A_0: by extrapolation or from the beginning of the plateau on the compression isotherm. In this connection, it is essential to note that it is frequently difficult to determine the linear section for monolayers of the expanded type while for monolayers of the condensed type A_0 is frequently smaller than the area calculated on the basis of the model owing to the high interchain cohesion. Evidently, the uncertainty in the determination of the limiting area hinders the comparison and interpretation not only of experimental but also of theoretical results, since all the equations of state of monolayers include A_0 as a parameter.

There are differences in the behaviour of films of the liquid-expanded and condensed types compressed to small areas ($A < A_0$). The presence of a plateau over a wide range of areas is characteristic of the former, whereas for the latter the plateau is either absent or is weakly expressed. The first explanations, relating the existence of a plateau to the reorientation of the side chains, were criticised.[25] The concept of the 'upper film', based on the fact that the surface pressure increases on compression of the monolayer to a thickness equal approximately to $A_0/2$,[25] is poorly justified since the second rise in surface pressure (as will be seen from the data presented in the present section) depends on many factors. Nevertheless, data concerning the formation of two-layer or three-layer organic acid films have been presented for low-molecular-mass compounds.[202,203] However, there is no reliable evidence for the existence of such films.



One of the ways of retaining the two-dimensional organisation after the collapse of the true monolayer involves the formation of single-layer films of helical molecules.

2. Polypeptides



The properties of monolayers of natural proteins have been investigated very intensely and have been described in a series of monographs and review articles.[204–208]

Monolayers of synthetic polypeptides have been investigated in fair detail as models of biological membranes.[203,209–211] Since the biological aspects of the behaviour of monolayers of protein molecules are not the subject of the present review, we shall analyse the properties of synthetic polypeptide monolayers within the framework of the traditional approaches to polymeric objects. On this basis, we shall turn attention to the conformational transformations in the monolayers, the formation of multilayers on the surface of a liquid, the change in the structural homogeneity and rheological properties of monolayers on compression, and certain other questions.

Among synthetic polypeptides, poly-γ-alkyl-L-glutamates **27** and poly-γ-benzyl-L-glutamate **28** have been most thoroughly investigated. By altering the composition of the aqueous subphase and the type of solvent from which the monolayer is formed, it is possible to regulate the structure of the macromolecule on the surface of the liquid. The limiting area of the poly-γ-methyl-L-glutamate monolayer on the surface of a dilute solution of formic acid is greater by a factor of 1.5 than A_0 for the same monolayer on a pure aqueous subphase.[209] The authors' view[209] that a helical conformation of the macromolecules corresponds to the smaller areas has been frequently justly criticised.[212,213]

27

28

Fig. 34 presents the isotherms for poly-γ-methyl-L-glutamate monolayers deposited on the surface of water from a mixture of solvents.[212] It can be seen that the isotherms for the monolayers obtained from solution in pyridine with an admixture of chloroform have low values of A_0 and a high compressibility. On the other hand, the monolayer formed from solution in

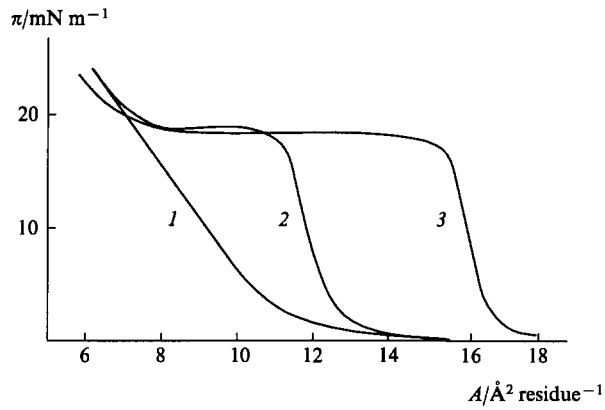


Figure 34. Compression isotherms for poly-γ-methyl-L-glutamate monolayers obtained on the surface of water from a mixed chloroform–pyridine solvent:[212] (*1*) 93% pyridine; (*2*) 77% pyridine; (*3*) 100% chloroform.

chloroform has a low compressibility, high limiting areas, and an extended plateau. Analysis of the IR spectra of monolayers of the polypeptides deposited at different surface pressures showed that the monolayers obtained from chloroform (higher A_0) consist of macromolecules in the form of α-helices, while in the monolayers formed from pyridine the macromolecules are in the extended β-conformations. It is of interest to note that, on compression of both types of monolayers, there is no transition from one type to another.[212]

Although doubts have been cast[211] on the possibility of the formation of β-structures in the monolayer, rheological studies[214] indicate significant differences in the behaviour of poly-γ-methyl-L-glutamate monolayers obtained from solutions in pyridine (β-structures) and in chloroform (α-helix). In contrast to the monolayer containing β-conformers, the surface viscosity (η_s) of which diminishes with increase in temperature, the η_s of the monolayer made up of α-helices increases. The $\eta_s - T$ relation for the poly-γ-methyl-L-glutamate monolayer, the molecules of which are in the form of α-helices, is illustrated in Fig. 35, which shows that an increase in temperature leads to irreversible changes in the monolayer: on subsequent decrease in temperature to 17 °C, the surface viscosity does not diminish. Such behaviour has been explained by the partial denaturation of the α-helices and the formation of hydrogen bonds between the molecules. The irreversibility of the temperature variation of the surface potential of the monolayer confirms this conclusion.[214]

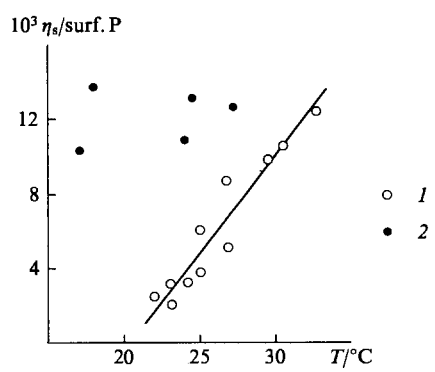

Figure 35. Temperature dependence of the surface viscosity (η_s) for a poly-γ-methyl-L-glutamate monolayer (initial structure—α-helices):[214] (*1*) data obtained with increase in temperature; (*2*) data obtained on subsequent reduction of temperature; A = 28.1 Å² per residue.

The novel results of Malcolm's studies[215,216] make it possible to examine the behaviour of polypeptide monolayers in the light of the important problem of the inhomogeneity of monolayers of viscoelastic systems, of which these polymers are typical representatives.

The form of the compression isotherms for poly-γ-ethyl-L-glutamate monolayers is influenced by the method of measurement of the surface pressure (Fig. 36).[216] For A > 12.5 Å² per residue, the isotherms obtained by the Wilhelmy and Langmuir (surface balance) methods are identical. However, the length of the plateau depends on the method of measurement, the position of the sensor (plate or strip) relative to the mobile barrier or the edge of the trough, and the orientation of the plate.

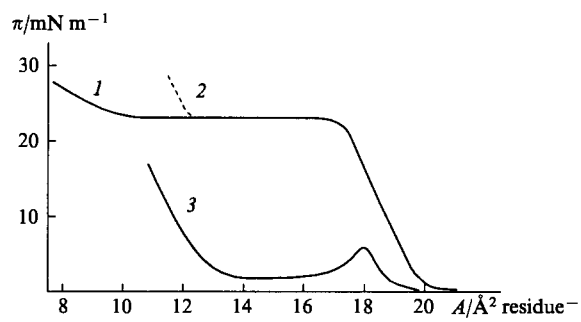

Figure 36. Compression isotherms for poly-γ-ethyl-L-glutamate monolayers:[216] (*1*) Langmuir balance with the sensor on the edge of the trough; (*2*) Wilhelmy method with the plate located 10 cm from the edge of the trough parallel to the barrier; (*3*) horizontal pressure applied to a glass plate 3 cm wide located in the same position as the Wilhelmy plate.

Thus in the measurement of the surface pressure by the Wilhelmy method, where the sensor is placed at a distance of 10 cm from the edge of the trough parallel to the mobile barrier, another increase in π (end of the plateau) is observed at A = 12.5 Å² per residue, while in the measurement by the Langmuir method, which is based on the measurement of the surface pressure at the edge of the trough, a new increase was observed at A = 9.5 Å² per residue. By placing the plate at different distances from the edge of the trough, Malcolm[216] showed that the length of the plateau decreases linearly with increase in this distance (Fig. 37).

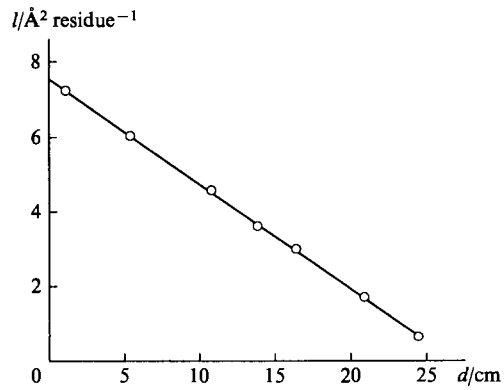

Figure 37. Dependence of the length of the plateau (*l*) on the compression isotherms for poly-γ-ethyl-L-glutamate monolayers on the distance (*d*) of the Wilhelmy plate from the edge of the trough.[216]

The deviation of the Wilhelmy plate from the vertical is characteristic of the measurement of π for viscoelastic polymer monolayers. Fig. 36 presents the dependence (curve *3*) of the horizontal force acting on the plate on the area of the monolayer.

Evidently the force increases in parallel with increase in the surface pressure before the beginning and at the end of the plateau. Together with this force, which is apparently thermodynamic in nature (the Marangoni effect), mechanical forces make a significant contribution to the displacement of the plate.

The effects described above are associated with the inhomogeneity of the poly-γ-ethyl-L-glutamate monolayers arising on compression. With the aid of thin strips of sulfur powder deposited through a template on the surface of the monolayer parallel to the barrier, the distribution of the inhomogeneities in the monolayer was visualised.[216] The displacement of the sulfur powder strips in the central part of the trough on compression of the monolayer is illustrated in Fig. 38.

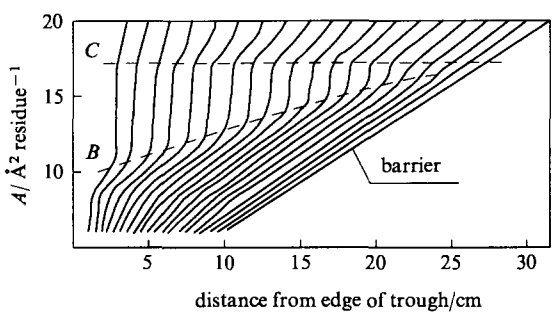

Figure 38. Displacement of sulfur powder strips along the central line of the trough from its edge on compression of a poly-γ-ethyl-L-glutamate monolayer.[216] Line *C* corresponds to the area for which the plateau begins; line *B* corresponds to transition to the bilayer film.

Up to the line *C*, corresponding to the onset of the increase in surface pressure and the formation of a bilayer film, the compression of the monolayer proceeds fairly uniformly. The region between the straight lines *C* and *B*, corresponding to the conversion of the monolayer film into a bilayer film, contains lines with slight displacements, and its size agrees well with the length of the plateau and the compression isotherms obtained by the Wilhelmy method. Finally, for $A < 9.5$ Å^2 per residue, the bilayer film collapses. The structure of the film is distorted most in the vicinity of the Wilhelmy plate and at the edges of the trough. The complex flow line distribution patterns arising on compression of the monolayers must be taken into account in the treatment of the results. In particular, viscometric data for polypeptide monolayers, which are interpreted in terms of denaturation processes,[214] can also be accounted for by experimental causes.[216] Similar problems arise in the analysis of the compatibility of the monolayers[217,218] and the kinetics of their collapse.[219]

In order to diminish or exclude the effects associated with the poor homogeneity of highly viscous monolayers, it is recommended[216] that symmetrical compression (the Wilhelmy method) or the surface balance method be employed. Naturally, these recommendations refer both to measurements of the surface potential and to viscometric studies on monolayers as well as the formation of homogeneous LBF. Different procedures for the compression of monolayers have been discussed[220,221] and the important role of rheological characteristics in the formation of homogeneous monolayers has been demonstrated[222] in relation to stearic acid and cadmium and aluminium stearates. By measuring the distribution of the surface pressure on the surface of the monolayer, it was shown[222] that the surface pressure is uniformly distributed over the entire surface for the acid and cadmium salt monolayers, the viscosity of which is low. In the case of the highly viscous aluminium stearate monolayer, the differences in π ($\Delta\pi$) can exceed 20 mN m^{-1}. Such behaviour has been explained from the standpoint of the dynamics of a liquid, which establishes direct proportionality between $\Delta\pi$ and η_s.

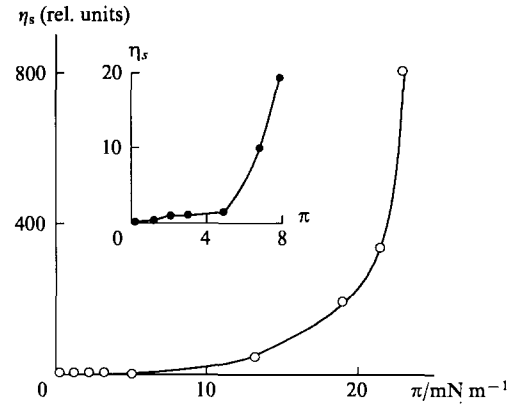

Figure 39. Dependence of the surface viscosity (η_s) on the surface pressure (π) for a poly-γ-methyl-L-glutamate monolayer at 17 °C.[218]

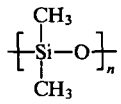
Fig. 39 presents the $\eta_s - \pi$ relation for a monolayer of poly-γ-methyl-L-glutamate α-helices.[218] Evidently the differences in the values of π on nonuniform compression of the monolayer can lead to abrupt changes in surface viscosity by factors of tens and hundreds.

In connection with the problem of the relationship between structure and the physicochemical properties of cell membranes, much attention has been devoted in the study of polypeptide films to their compatibility with lipids.[218,223–228] The compatibility was analysed for two conformations of the polymer molecules and also for monolayer and multilayer films.

The enantiomeric forms of poly-γ-methyl-L-glutamate are fully compatible in monolayers, like binary mixtures of other polypeptides.[211] The compatibility between polypeptides and lipids depends on the state of the monolayer of the latter (expanded or condensed).[223] The polypeptide in the β-form is incompatible with arachidic acid on the surface of 0.01 M HCl solution.[224] In the form of α-helices, poly-γ-benzyl-L-glutamate is compatible with palmitic and stearic acids in the monolayer for a polymer mole fraction in excess of 0.9.[227] In a multilayer film, these components are incompatible. On the other hand, poly-γ-methyl-L-glutamate is compatible with these acids both in the monolayer and in a multilayer film. The differences in the behaviour of the binary systems considered are determined by the different levels of aggregation of the polypeptide molecules in the films, by the different modes of interaction between the acids and polypeptides, and by the phase state of the acid monolayers. The properties of mixed monolayers of polypeptides and phospholipids can also be explained in the light of these ideas.[226] Analysis of the rheological properties of mixed monolayers of polypeptides with phospholipids and with cholesterol made it possible to establish a correlation between the surface viscosity of the monolayers and the stability of bilayer lipid membranes.[218]

Together with the use of polypeptide monolayers for the modelling of biological systems, multilayer (more than 500 monolayers) LBF of methyl glutamate–alkyl glutamate copolymers have attracted the attention of investigators recently as promising materials for optical wave guides with low losses[229,230] and also as photoresists and electron-beam resists.[231]



Thus the unusual feature of polypeptides consists in the fact that they form quasi-true monolayers of α-helices, the compression of which results in the formation of two- and three-layer films.[232–234] The breakdown of this conformation can be achieved by altering the temperature of the system and the composition of the support and of the solvent from which the monolayer is formed. The length of the plateau on the compression isotherms is determined by the method of measurement of the surface pressure and by the position of the sensor relative to the barrier and the walls of the trough. The inhomogeneity arising on compression of highly viscous monolayers, with long relaxation

times, leads to appreciable differences between the surface pressures for different sections of the trough. These effects can be reduced or eliminated in symmetrical compression or with the aid of special designs of the Langmuir trough. An increase in the homogeneity of polypeptide monolayers is essential for the construction of adequate models of biological membranes and also for the formation of high-quality LBF, which may find application in fibre optics.

3. Polyorganosiloxanes

a. Polydimethylsiloxane monolayers

Polyorganosiloxanes belong to the class of polymers which have been investigated in detail in monolayers. Most of the studies have been carried out on polydimethylsiloxane **29**.[235–245] The interest in this polymer is caused not only by its practical use as a surfactant in aqueous and nonaqueous media[246,247] but also by the possibility of forming stable monolayers from helical molecules.

29

Combined studies which have been carried out on polydimethylsiloxane (PDMS) monolayers and thin films made it possible to supplement the existing ideas concerning the structural transformations of this polymer on the surface of a liquid and also to consider the possibility of converting the monolayers into thin stable films.[52,239,240,245]

Fig. 40 presents the dependence of the surface pressure (determined by the Wilhelmy and Langmuir methods), the surface viscosity (determined using a rotating viscometer), and the surface potential (ΔV, determined by use of an ionising ^{210}Po electrode) on the area of the PDMS monolayer (M_η = 1.25 × 10^6). The sensitivity of the sensors (~0.01 mN m^{-1}) did not permit the measurement of surface pressures for areas in excess of 37 Å^2 per monomer residue. For A = 35–60 Å^2 per residue, the surface potential oscillates during scanning parallel to the surface, which indicates the inhomogeneity of the monolayer. In this range of areas, the macromolecules and their associated species lie on the surface of water in the form of discs—two-dimensional analogues of statistical coils; the siloxane dipoles adjoin the water molecules, while the methyl groups are directed towards the air phase. As a result, the *trans*-configuration of the PDMS molecules, which obtains in the bulk phase, is converted into the *cis*-configuration in the surface layer. In the range of areas from 37 to 20 Å^2 per residue, the isolated regions comprising the polymer approach one another and water is displaced from the gaps between them.[52,242] This process does not require much energy expenditure and π therefore increases only slightly. Starting from A = 20 Å^2 per residue, π increases sharply up to 7.6 mN m^{-1}; for A = 14 Å^2 per residue and in the range from 14 to 7.5 Å^2 per residue, π remains unchanged. The change in the hydration state of the monolayer when it is compressed has been examined in detail in a number of studies.[242–244] The constancy of the surface pressure for A < 14 Å^2 per residue indicates the formation of a helical conformation of the macromolecules: the energy expenditure in the displacement of the Si–O dipoles from the surface of the subphase is made good by the energy gain due to the internal compensation of the siloxane dipoles.

The exact determination of the region where macromolecules are converted into the helical form is of fundamental importance from the understanding of the processes involving the collapse of the true monolayer and the formation of transient films. Taking into account the ΔV–A relation as well as the temperature dependence of π (Fig. 40), one may conclude that the formation of helices in the monolayer begins for areas in the

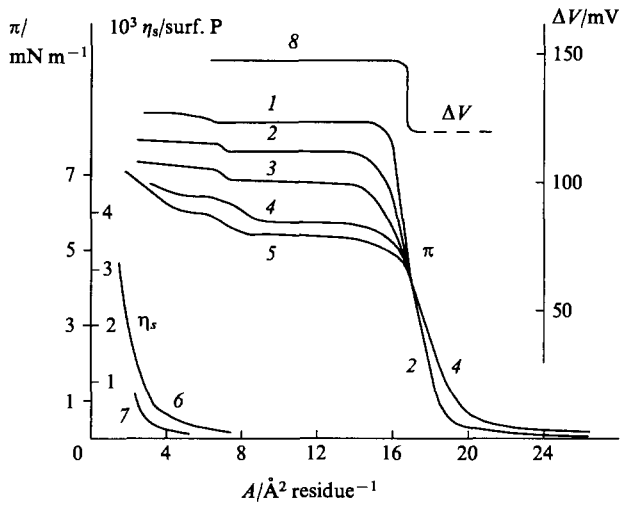


Figure 40. Dependence of the surface pressure (π), surface viscosity (η_s), and surface potential (ΔV) on the area of a PDMS monolayer on the surface of water at different temperatures (°C):[239] (*1*) 10; (*2*) 20; (*3*) 30; (*4*) 40; (*5*) 50; (*6*) 20; (*7*) 40; (*8*) 20.

range 16–17 Å^2 per residue, i.e. in the region of constant π. If a model comprising horizontally coaxial rings lying one on top of the other is used as an approximation to the helix, then in the case of PDMS containing 3, 6, and 8 monomer units corresponding to one turn of the helix, the following occupied areas are obtained: 10, 7.8, and 6.2 Å^2 per residue.[248] Thus the jump in surface pressure at A = 7.6 Å^2 per residue most probably corresponds to the formation of a close-packed monolayer of PDMS helices each containing six siloxane bonds per turn. The axes of the helices are arranged parallel to the surface of water.

In order to refine the mechanism of the conformational transformations in the PDMS monolayer, the temperature dependences of π and η_s were determined. Comparison of the dependences of the surface pressure on the area at different temperatures show that, for large values of A, the temperature coefficient of π is positive and small. With decrease in the area, the temperature coefficient changes sign and increases in absolute magnitude. The characteristic points for curves corresponding to different temperatures correspond to different areas. This permits the conclusion that the processes occurring in the monolayer at different temperatures during the compression process are identical.

In the region of the true monolayer, the surface viscosity is low (< 10^{-5} surf. P) (Fig. 40). An appreciable rise in η_s begins on formation of a close-packed monolayer made up of helices, the viscosity of the monolayer diminishing with increase in temperature.

The entropy (s_s) and enthalpy (h_s) of spreading were calculated with the aid of the temperature variations of the surface pressure.[41]

$$s_s = \left(\frac{\partial \pi}{\partial T}\right)_{A,a},$$

$$h_s = -\left[\frac{\partial(\pi/T)}{\partial(1/T)}\right]_{A,a} = T\left(\frac{\partial \pi}{\partial T}\right)_{A,a} - \pi,$$

where a is the overall area of the monolayer and of the free surface of water and T is the absolute temperature.

The calculation of the thermodynamic functions of spreading was preceded by the determination of the degree of equilibrium of the monolayer. By varying the concentration of the solutions, the number of drops, and the area provided for spreading and also by measuring the reversibility of the isotherms, it has been

shown that they are reproducible and hence the monolayer is in equilibrium.

The $s_s - A$ and $h_s - A$ relations for two temperatures are presented in Fig. 41. The thermodynamic functions and their relation with the structural transformations in the monolayer have been subjected to a detailed analysis.[52,239] Here we shall note that the change in the sign of the thermodynamic functions on compression of the monolayer in the region of $A \simeq 17$ Å^2 per residue indicates a transition of the system to a more ordered state. This transition may be associated with the formation of a monolayer of helical PDMS molecules, which is accompanied by the self-compensation of the Si–O dipoles.[236] The signs of s_s and h_s change for the same value of A as the one at which a jump ΔV was observed.

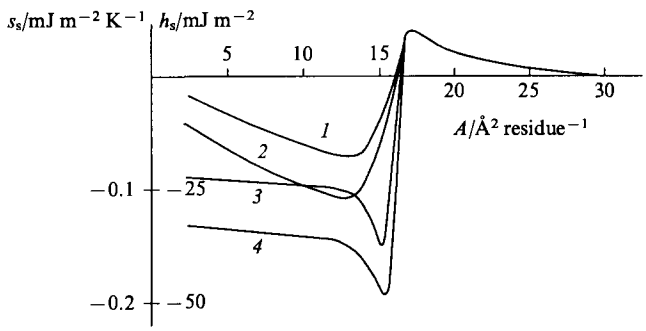

Figure 41. Dependence of the entropy (curves *1* and *3*) and enthalpy (curves *2* and *4*) of spreading on the area of a PDMS monolayer on the surface of water at 45 °C (curves *1* and *2*) and 15 °C (curves *3* and *4*).[239]

The experimental results obtained in the study of PDMS monolayers on the surface of water were subjected to a theoretical treatment using the familiar Singer,[143] Davies,[146] Motomura and Matuura,[249] and Frisch and Simha[144] equations of state for polymer monolayers. These equations and the parameters of the monolayers of high-molecular-mass compounds calculated with their aid have been subjected to a detailed analysis.[52] The calculations showed that the flexibility of the PDMS chains on the surface of water is extremely low despite the fact that in the bulk phase the polymer is extremely flexible. Evidently, the loss of one degree of freedom and also the retardation or complete absence of rotation, which are a consequence of the spreading of the polymer, render the chain conformationally rigid.

In order to refine the conclusions reached in the study of PDMS monolayers on the surface of water and also in order to elucidate the influence of the surface energy of the subphase on the properties of monolayers of this monomer, a study has been made of the behaviour of PDMS monolayers on the surface of aqueous 1,4-dioxane solutions at different concentrations.[52,250]

Dioxane concentration in solution (vol. %)	0	1	5	15	50	100
Surface tension of the solutions/nM m^{-1}	72.5	68.7	58.8	54.2	37.4	32.5

Fig. 42 presents the surface pressure (surface viscosity)–area isotherms at 20 °C for some of these subphases. The figure shows that, as the subphase becomes more hydrophobic, the shape of the $\pi - A$ isotherm changes: the surface pressure diminishes, the horizontal section vanishes, and the slope of the initial section decreases.

Evidently, replacement of the polar water molecules in the surface layer by the nonpolar dioxane molecules weakens the interaction of the subphase with the polar siloxane groups of the polymer. The change in the thermodynamic functions of spreading for polydimethylsiloxane monolayers on the surface

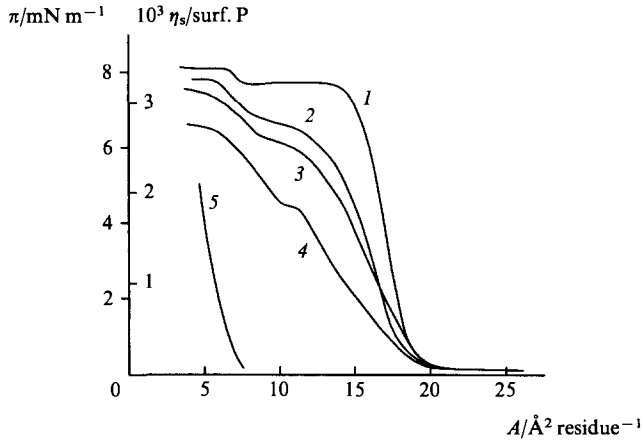

Figure 42. Dependence of the surface pressure (curves *1*–*4*) and surface viscosity (curve *5*) on the area of a PDMS monolayer on the surface of water (curve *1*) and solutions of dioxane in water (curves 2–5) at 20 °C.[250] Dioxane concentration (vol.%): (*2*) 5; (*3*) 15; (*4*) and (*5*) 50.

of a 50% aqueous solution of dioxane is illustrated in Fig. 43. Evidently, the entropy and enthalpy of spreading vary in the negative region for all the areas of the monolayer. The change in the sign of the thermodynamic functions on compression of the polymer monolayer on the surface of water (Fig. 41) was associated with the formation of the helical conformation of the macromolecules. On the other hand, in the case of the low-energy organic support, only the helical conformation is produced. The viscosity of this monolayer, like that of the monolayer on the surface of water, becomes appreciable only on formation of a close-packed film of helical molecules and when they are subsequently squeezed out from the surface of the support (Fig. 42).

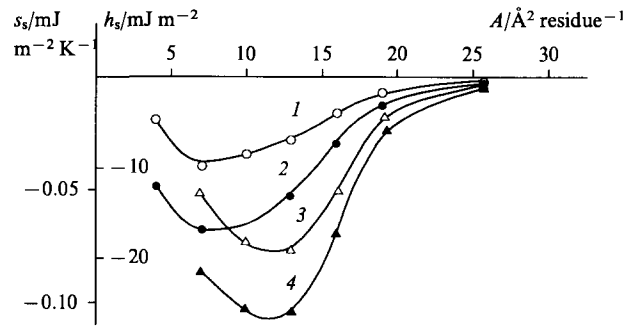

Figure 43. Dependence of the entropy (curves *1* and *3*) and enthalpy (curves *2* and *4*) of spreading on the area of a PDMS monolayer on the surface of a 50% solution of dioxane in water at 45 °C (curves *1* and *2*) and 15 °C (curves *3* and *4*).

In contrast to the PDMS monolayer on the surface of water, the compression of which up to the formation of a dense helical monolayer entails a change in ΔV by 150 mV which then remains constant, for the monolayer on the surface of 50% aqueous solution of dioxane $\Delta V = 0$ for all areas.

Important information about the influence of the surface energy of the subphase on the conformational transformations in the PDMS monolayer was obtained in a study of the spontaneous spreading of the polymer from the bulk phase on the surface of water, dioxane, and 5% and 50% solutions of dioxane in water. Fig. 44 presents the dependence of π and ΔV on the spreading time (t) of PDMS. Evidently the films are formed spontaneously on these supports. However, ΔV is nonzero only on

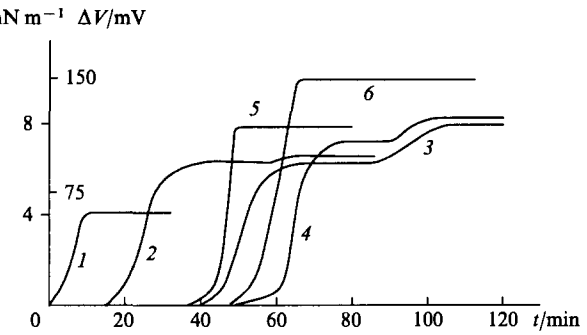

Figure 44. Kinetics of the spreading of PDMS on the surface of dioxane (curve *1*), solutions of dioxane in water [50% (curve *2*) and 5% (curves *3* and *5*)], and water (curves *4* and *6*): [250] (*2*)–(*4*) π; (*5*) and (*6*) ΔV.

dioxane solutions at concentrations ⩽5%. This result shows that the dipoles of the elementary units of PDMS are self-compensated in the helical macromolecule, while the zero dipole moment of the dioxane molecules ensures the constancy of ΔV whatever their orientation.

With increase in the concentration of dioxane in water, the rate of formation of the film from the bulk phase also increases and reaches a maximum on pure dioxane, despite the fact that PDMS hardly dissolves in dioxane and the surface tension of the latter is lower by a factor of 2 than that of water (Fig. 44). The macromolecules probably pass from the bulk phase to the film in the same helical conformation as that obtaining in the statistical coils of the bulk phase. The additional energy expenditure on the compression of two-dimensional discs and the new formation of helices on spontaneous compression of the monolayer, of the kind occurring at the air–water interface, is then ruled out.

Thus PDMS on a liquid hydrophobic surface forms a monolayer of helical molecules regardless of whether the polymer is deposited from solution or from the bulk phase.

b. Thin polydimethylsiloxane films on the surface of a liquid

The two-dimensional coil–helix conformational transition in the PDMS monolayer during its compression or spreading from the bulk phase must be regarded as a transition between a true monolayer and a thin polymer film. This film corresponds to equilibrium on the surface of the liquid. In this connection, a series of questions arise. What is the thickness which the films thus formed can have? Will they be stable? How will the stability be related to the surface energy of the subphase?

Hitherto the possibility of the formation of stable films thicker than single-layer films of both low-molecular-mass and high-molecular-mass substances on the surface of a liquid has been questioned. Whereas for low-molecular-mass compounds these ideas were based on numerous experimental studies,[41] such studies had not been made for high-molecular-mass compounds and in particular polymers.

In the studies of synthetic polypeptide monolayers on the surface of water examined above and in a recently published investigation [251] of monolayers of alkyl-trimethylammonium salts on the surface of mercury, the conclusion that multilayer films are formed was based on the presence of bends in the compression isotherms and on the analysis of the corresponding areas The stability of the films obtained in the above investigations is not discussed.

The possibility of the formation of a film as a result of the spreading of the substance from the bulk phase is regulated by the Young–Dupré relation

$$\sigma_A > \sigma_B + \sigma_{AB},$$

where σ_A, σ_B, and σ_{AB} are the interfacial tensions at the air–water, air–polymer, and polymer–water interfaces respectively.

The question of the thermodynamic stability of the film can be elucidated by comparing the free surface energies of the film and the close-packed monolayer. [52, 240, 245]

The specific free surface energy (F_s) for the phase state of the substance on a liquid surface is defined as $F_s = F_s^0 = \sigma_B + \sigma_{AB}$. With decrease in the film thickness (h), F_s becomes a function of h.

If the film is stable for all thicknesses up to and including the phase state, the following condition should hold:

$$\frac{dF_s}{dh} \leqslant 0.$$

The change in F_s can be calculated from the change in the surface pressure as a function of h. Fig. 45 (curve *2*) illustrates for cholanic acids [252] a typical F_s–h relation for films of low-molecular-mass crystalline compounds on the surface of water. Other traditional surfactants, for example cetyl alcohol and stearic acid, give rise to curves of similar shape. It is seen from Fig. 45 that, for a cholanic acid film, the stability condition holds only up to h = 20 Å. With further increase in thickness, the film collapses with formation of the bulk phase of the test substance in equilibrium with the monolayer. The difference between F_s corresponding to the plateau and the minimum value of F_s yields the energy expenditure in the transfer of the substance from the two-dimensional state (monolayer) to the three-dimensional state.

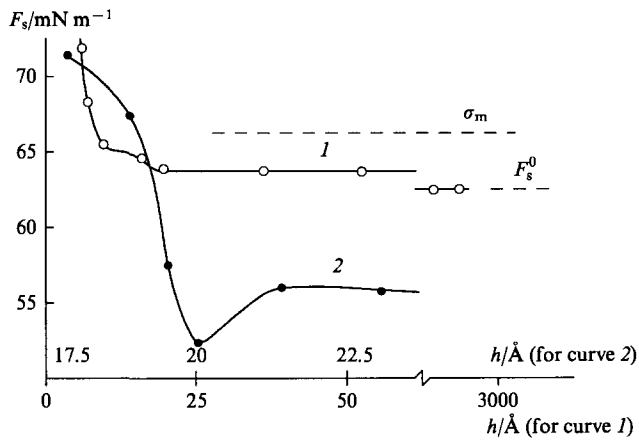

Figure 45. Dependence of the free surface energy (F_s) on the thickness (h) of PDMS (curve *1*) and cholanic acid (curve *2*) films on the surface of water. [240]

For a PDMS film on the surface of water (Fig. 45, curve *1*) we have for all values of h

$$\frac{dF_s}{dh} \leqslant 0.$$

However, if the F_s–h relation is plotted for liquid low-molecular-mass surfactants of the type of oleic acid, then the stability condition will also hold for them over a wide range of thicknesses but not for all thicknesses. When a layer of substance constituting a phase is formed on the surface of the support, i.e. $h \to \infty$, then

$$\frac{dF_s}{dh} > 0.$$

For such systems, it is convenient to consider the relation between the free surface energy of the film and the surface tension of the subphase coated by a close-packed monolayer (σ_m).

If the difference

$$\sigma_m - F_s^0 = S_f^0 ,$$

called by Harkins the finite spreading coefficient, is less than zero, then films thicker than the monomolecular film are unstable. In the opposite case ($\sigma_m - F_s^0 > 0$), the formation of a multimolecular film is energetically more favourable.

Evidently, the formulation

$$\sigma_m - F_s = S_f$$

is more general. In this case, the finite spreading coefficient is the limiting value of S_f, i.e. at $h \to \infty$, we have:

$$\lim_{F_s \to F_s^0} S_f = S_f^0$$

All the systems considered by Harkins[41] had $S_f^0 < 0$. In particular, $S_f^0 = -6$ mN m^{-1} for oleic acid on the surface of water. The results obtained for low-molecular-mass surfactants, the behaviour of which in monolayers differs from that of macromolecules, did not provide grounds for their formal transfer to surface layers of high-molecular-mass compounds.

We may also note that, according to the data of Joany and De Gennes,[253] the 'equilibrium thickness of the film deposited on a large area exceeds the monolayer thickness if the spreading coefficient (the initial spreading coefficient is considered) is sufficiently small'. This can be explained by the competition between the long-range forces, which endeavour to keep the film thicker, and spreading. A fairly low spreading coefficient is too weak a source of energy to transfer the molecules to the monolayer. Although these ideas of the above authors[253] refer to the initial spreading coefficient and not to the final one, the essence of the considerations which they express and which were described above does not change.

We now return to Fig. 45. The dashed line corresponds to the value of σ_m for a close-packed PDMS monolayer on the surface of water. The fact that the values of F_s for large thicknesses of the PDMS film (curve *1*) lie below the dashed line (the values of σ_m) indicates the stability of the film for all values of h. Fig. 45 also indicates the value of F_s^0 for PDMS on the surface of water.

We shall now consider the relation between the ability of PDMS to form thin stable films and the surface tension of the subphase.[240] Solutions of dioxane in water were used as the subphase. The values of σ_{AB} were calculated from the wetting angles (θ) for drops of these solutions on the surface of the polymer by the formula

$$\sigma_{AB} = \sigma_A - \sigma_B \cos\theta .$$

The results of the calculations (in mN m^{-1}) are compiled in Table 5, from which it is seen that the film stability condition ($S_f^0 > 0$) holds until the surface tension of the subphase is greater than 58.8 mN m^{-1} (5% solution of dioxane in water). The extremely interesting correlation between the stability of PDMS films and the two-dimensional discs – helices conformational transition is noteworthy: the PDMS films on the liquid surface are stable until there remains a possibility of the retention of the planar conformation, which occurs on subphases with $\sigma_A > 58.8$ mN m^{-1}.

In connection with the stable existence of PDMS films of different thickness on the surface of a liquid, the properties of the transitional region between the monolayer and the bulk state of the polymer were investigated. Fig. 46 illustrates the dependence of the surface pressure, the surface viscosity, and the resistance to the evaporation of water on the thickness of the PDMS film. Despite the high molecular mass of the polymer (1.25×10^6), the viscosity of its film for small thicknesses is low and varies only slightly with increase in thickness. The low values of η_s in the region of low h reflect the structure of the film, which consists of helical molecules, the cohesive interactions between which are weak, while the length of the sections of the chains displaced from

Table 5. The influence of the surface tension of the subphase on the finite spreading coefficient of PDMS.

Dioxane concentration in water (vol.%)	σ_A	σ_{AB}	F_s^0	σ_m	S_f^0
0	72.5	42.5	62.5	66.5	4.0
1	68.7	42.2	62.2	63.7	1.5
2	66.4	41.3	61.3	62.4	1.1

5	58.8	35.3	55.3	55.0	−0.3
10	55.5	33.0	53.0	52.0	−1.0

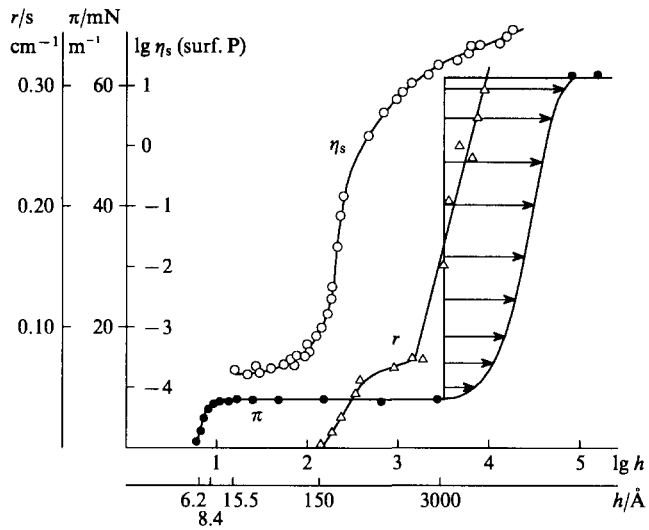

Figure 46. Dependence of the surface pressure (π), surface viscosity (η_s), and the resistance to the evaporation of water (r) on the thickness (h) of PDMS films on the surface of water.[240]

the surface is insufficient for intertwining. The absence of a measureable resistance of the film to the evaporation of water for small film thicknesses confirms this view. For h = 130 – 150 Å, the surface viscosity increases sharply and an appreciable increase in the protecting effect of the film against the evaporation of water is observed. This characteristic range of PDMS film thicknesses can be related to the formation of a monolayer from statistic coils. Calculation shows that the diameter of a dense statistical coil for a molecular mass of the polymer of the order of one million is 140 Å. The nature of the variation of lg η_s in the region where $h > 150$ Å shows that the increase in viscosity is caused by the intertwining of the chains of the macromolecules rather than by the increase in the number of layers in the film (in this case, the viscosity would have varied in proportion to the thickness). In the region where h = 3000 Å, the film viscosity becomes equal to the bulk viscosity: $\eta_0 = \eta_s/h$. The existence of a critical thickness of the transitional region in thin PDMS films has been confirmed in a study of the flow of the polymer into the pores of nuclear Lavsan ultrafilters.[254]

Starting with h = 3000 Å, the surface pressure rises sharply and π begins to depend on the rate of compression. If a load is applied instantaneously to the film perimeter, then π changes abruptly to 62 mN m^{-1} (the Langmuir method), remaining constant on further increase in thickness.[240] The increase in surface pressure in this region cannot be described by the equation

$$\pi = \sigma_A - (\sigma_B + \sigma_{AB}) .$$

Calculation of the correction term for this equation shows that its value (54 mN m^{-1}) is close to that of the thermodynamic work of adhesion of PDMS to water (52 mN m^{-1}). The equation presented above must be rewritten, adding to its right-hand side a correction term equal to the work of adhesion.

Thus there is a transitional region in stable films, the properties of which differ from those of the polymer in bulk, between the monolayer and the PDMS bulk phase on the surface of the liquid. These films, transferred by the Langmuir–Blodgett method onto the surface of mica, have a homogeneous structure according to data obtained by transmission electron microscopy.[52]

On the other hand, recent studies on PDMS monolayers by Brewster angle microscopy have shown[255] that the monolayers on the surface of water have a domain structure also for areas corresponding to the expanded state and to the collapsed film. The relaxation times for the deformation of the domains, agreeing with the extremely low linear tensions of the domain boundaries ($\sim 10^{-13}$ N), have been determined[255] and it has been noted that the relaxation times depend only slightly on the molecular mass of the polymer. This means that the polymer chains are not intertwined on the surface of water and that the interactions between them, determining the viscosity of the monolayer, take place via monomer units. The observed domain structure of the monolayer for large areas does not conflict with the ideas described above. However, the mechanism of the behaviour of the film after the collapse of the monolayer requires further refinement.

The possibility of the formation of stable thin films of polyphenylmethylsiloxane has been discussed[256] in connection with the unusual temperature variation of the surface pressure of its oligomers (Fig. 47). For the monolayer of a polymer with a molecular mass of 2240, π diminishes with increase in temperature and at 37 °C becomes zero. A similar trend has been observed for a polymer with a lower molecular mass and also for the temperature variation of the equilibrium spreading pressure. In the latter case, $\pi = 0$ at 55 °C. Such behaviour of the systems can be accounted for by the decrease in the initial spreading coefficient with increase in temperature, leading to the formation of stable thin films on the surface of a liquid.

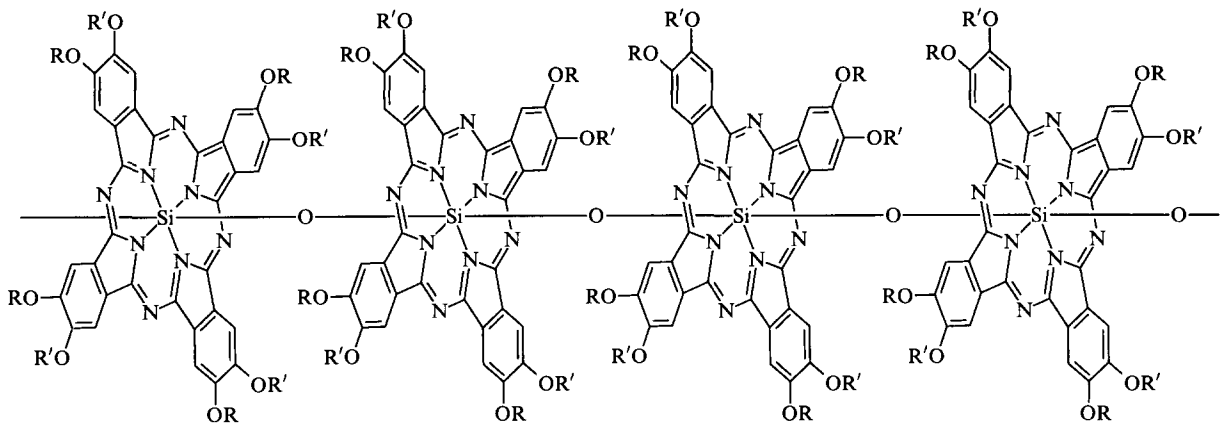
c. Monolayers of certain other polyorganosiloxanes

The replacement of the methyl groups in PDMS by ethyl or phenyl groups weakens appreciably the ability of these polymers to form stable monolayers on the surface of water.[52] On the other hand, ladder polymers—polyphenylsilsesquioxane and polyethylsilsesquioxane—form stable viscous monolayers with high collapse pressures. For example, the collapse pressure for polyethylsilsesquioxane is higher by a factor of four than for PDMS.

The acid groups $(CH_2)_{10}COOH$ introduced into the side chains of polydimethylsiloxane and polyhydromethylsiloxane promote an increase in the surface activity of the polymers and in the collapse pressure (>30 mN m^{-1}). The monolayers are transferred quantitatively onto solid supports by the Langmuir–Blodgett method. Analysis of the electrical properties of alternating LBF of these polymers and eicosylamine showed that they are promising for use in pyroelectric devices.[257]

Monolayers of rod-shaped siloxane polymers—phthalocyaninatosiloxanes **30**—have been investigated.[258–261]



On compression of monolayers of polymer **30** with R = CH_3 and R′ = $(CH_2)_7CH_3$, the cylindrical molecules undergo a reorientation from the horizontal to the vertical position. The interactions between the polymer molecules and the aqueous subphase, which are responsible for the high stability of the monolayers, have been discussed resorting to ideas concerning the polarisation of the central aromatic nucleus, the proton exchange between the subphase and the monolayer, and the oxidation-reduction activity of the phthalocyanine group.[259] The way in which the molecules of compound **30**, containing unsaturated bonds in the peripheral chains, undergo reorientation changes on compression of the monolayer. In this case, the molecules creep onto one another, retaining the orientation parallel to the subphase. The process involving the aggregation of the molecules to microcrystallites has been investigated by transmission electron microscopy for monolayers having different areas transferred onto a carbon support by the Langmuir–Schaefer method.[261]

The diblock copolymers of dimethylsiloxane with methyl methacrylate and bisphenol A carbonate have been investigated in monolayers on the surface of water.[262,263] In both cases, blocks of the second type exert a condensing effect on the PDMS monolayers. It is of interest that the compression isotherms for the block copolymer and the mixed monolayer of the homopolymers (PDMS and PMMA) do not differ greatly from one another but do differ significantly in shape from the additive curve and deviate from the latter.[30] Analysis of the behaviour of binary mixed monolayers of PDMS and polymethylphenylsiloxane with oleic acid showed that the reconstruction of the surfactant monolayer in the presence of the polymer increases the collapse pressure.[264] For mixed monolayers of PDMS with palmitic acid and cetyl alcohol, this effect is manifested to a much lesser extent.[265]

Thus monolayers of polyorganosiloxanes possess a series of interesting features. Despite the low collapse pressure, the PDMS monolayers are stable on the surface of water. An increase in the length of the side chains in polyorganosiloxanes does not lead to the formation of more expanded monolayers and to an increase in the collapse pressure, in contrast to the acrylic and methacrylic polymers. The conversion of the PDMS macromolecules into the helical form, which can be regulated by varying the area of the monolayer or the surface energy of the subphase, is an important structural transition, the dynamics of which require detailed analysis. Polydimethylsiloxane forms stable thin films on the surface of a liquid. Questions concerning the transfer of these films onto solid supports and the study of their structure and properties have not so far been investigated.

Ladder polymers and functionalised polyorganosiloxanes form stable monolayers with high collapse pressures. The properties of the monolayers of these polymers depend to a large extent on the substituents in the side chain.

The nontoxicity and thermal stability of polyorganosiloxanes as well as the large set of functionalised polymers of this class[266] give rise to the hope that they will be investigated more vigorously in monolayers and LBF.

XI. Polysaccharides

Cellulose ethers and esters are classical objects with which systematic studies on polymer monolayers began. It has been shown[267] that cellulose acetate **31a** (n = 0) does not form a stable monomolecular film on the surface of water but a monolayer is formed on the siloxane–water interface, its limiting area corresponding to the model in which the average plane of the glucose rings is arranged parallel to the surface. The influence of molecular mass on the compression isotherms for cellulose acetate has been studied.[33] Despite the fact that the limiting areas of the monolayers of three different fractions of cellulose triacetate were only $^1/_7-^1/_{10}$ of the values of A_0 specified by the high-molecular-mass model, the authors[33] calculated their molecular masses from the $\pi A-\pi$ relations. The molecular masses extrapolated from the region of low π were 3–6 times greater than the control values (57000, 45000, and 29000), while on extrapolation from the region π = 2–6 mN m^{-1} the molecular masses of the first two fractions proved to be close to the control values. The authors explained the better agreement in the latter case by the fact that, in contrast to a domain monolayer (for low values of π), in a dense monolayer account is taken of the contribution of the vibrational motions of the macromolecules to π.

31a: R = $-\overset{\overset{O}{\|}}{C}-(CH_2)_nCH_3$

31b: R = $-(CH_2)_3-OH$.

31c: R = $-(CH_2)_2-OH$.

31a–c

Recently this problem again attracted attention as a result of a study[268] in which monolayers and adsorption layers of hydroxypropylcellulose **31b** with molecular masses of 60000, 100000, 300000, and 1000000 and of hydroxyethylcellulose **31c** with molecular masses of 100000 and 900000 were investigated. Fig. 48 presents the dependence of the surface pressures of the monolayers of these polymers on the monolayer concentration. The molecular mass does not affect the compression isotherms for both polymers, while an increase in the length of the side chain by one CH_2 group increases the value of π corresponding to the plateau from 7 mN m^{-1} for compound **31c** to 28 mN m^{-1} for compound **31b**. It is of interest to note that this plateau is

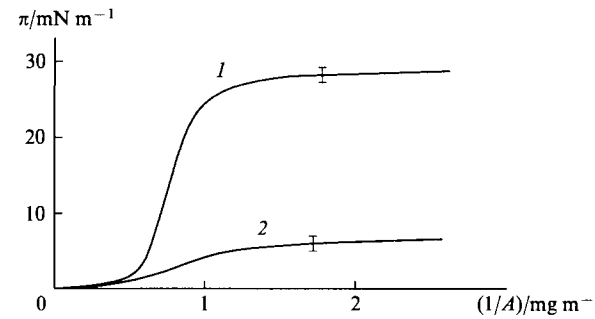

Figure 48. Dependence of the surface pressure (π) on the surface concentration ($1/A$) of monolayers of hydroxypropylcellulose (curve *1*) and hydroxyethylcellulose (curve *2*) specimens with different molecular masses, obtained by spreading from a solution at 25 °C.[268]

reproduced also for adsorption layers of polymers: after a change in concentration by a factor of 300–600, the surface pressure changes by not more than 5%. According to light scattering data, the viscoelastic properties of the monolayers and adsorption layers are also identical.

The importance of these results consist in the fact that they apparently demonstrated clearly for the first time the similarity of the structures and properties of polymers in monolayers obtained by a forced organisation procedure (compression) and in self-organised adsorption layers on the surface of water.

The compression isotherms for cellulose ethers (esters) with different lengths and numbers of side chains are presented in Fig. 49.[269,270] Cellulose triacetate **31a** (n = 0) and cellulose tripalmitate **31a** (n = 14) form condensed monolayers. The limiting area of cellulose triacetate (54 Å^2 per residue) is greater than the value 40–48 Å^2 per residue obtained by Zografi and coworkers[58,268] but is smaller than for compounds **31b** (119 Å^2 per residue) and **31c** (137 Å^2 per residue).[271] For ester groups of moderate length [in the trioctanoate **31a** (n = 6), tridecanoate **31a** (n = 8), and trilaurate **31a** (n = 10)], the liquid-expanded state obtains. The transition from this state to the condensed state is characterised by the constancy of the surface pressure. Monolayers of diesters (cellulose dilaurate) are more compressible and have smaller areas in the expanded and condensed states compared with the triester analogues (Fig. 49, curve *5*). The increase in secondary cohesion in the monolayer with increase in the length of the side chain to 16 carbon atoms (cellulose tripalmitate) leads to the formation of a condensed monolayer in which the glucose residues are arranged parallel to the surface of water, while the hydrocarbon chains are

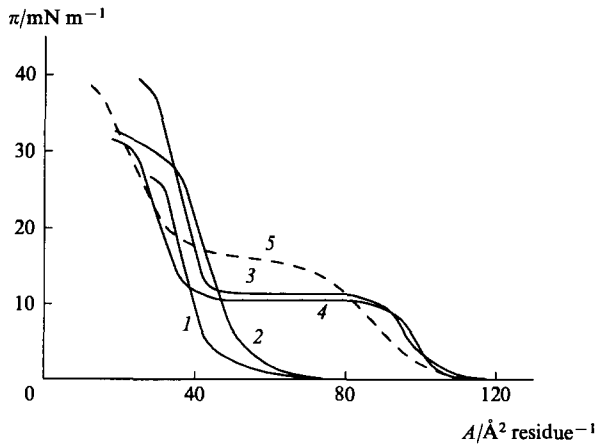

Figure 49. Compression isotherms for the triesters (curves *1*–*4*) and diester (curve *5*) of cellulose **31a**.[269] *n*: (*1*) 0; (*2*) 14; (*3*) and (*5*) 10; (*4*) 6 and 8.

arranged perpendicular to the surface of the subphase. Cellulose trioctadecanoate forms a condensed monolayer with a limiting area of 71 Å^2 per residue.[272]

The LBF films of cellulose esters are formed by the horizontal transfer method. X type cellulose trilaurate films with up to 60 layers have been obtained[269] from both expanded (9.5 mN m^{-1}) and condensed (20 mN m^{-1}) regions of the monolayer. Although the authors note that the cellulose trilaurate monolayers were too brittle to be transferred onto a solid support, in another study[272] it proved possible to obtain 10-layer Y type LBF from cellulose trioctadecanoate with even longer chains (horizontal transfer). For LBF of the same polymers into the side chains of which pyrene labels had been introduced, it was shown by fluorescence analysis that energy transfer or the formation of excimers within or between the layers are not observed in films containing up to 7% (percentage substitution of the side groups) of the label. This is associated with the fact that the thickness of the layers (24 Å) is smaller than the Forster radius between the pyrenyl groups localised in the middle part of the LBF layers. If the concentration of the pyrenyl fragments exceeds 7%, then the formation of two types of excimers with different structures and emission times can be detected by time-resolved fluorescence spectroscopy.

The change in the β-structure of the elementary unit of cellulose to the α-glucoside structure leads to amylose derivatives. Extensive studies on amylose esters have been carried out.[273] Monolayers and LBF of amylose acetate, propionate, butyrate, laurate, and palmitate were investigated. The compression isotherms for these polymers up to a degree of substitution in excess of 2.6 are presented in Fig. 50. It is seen that polymers with short, moderately long, and long side chains correspond to three types of isotherms. For short-chain derivatives, neither the temperature (10–37 °C) nor the rate of compression of the monolayer (1–10Å^2 per residue per minute) affect the compression isotherms in the region $\pi \leqslant 10$ mN m^{-1}. Comparison of model and experimental areas per elementary unit and also allowance for data[274] on the crystal structures of the homologous series of amylose esters led the authors[273] to the conclusion that mono-layers comprising helices are formed by short-chain amylose esters. In the region of the plateau, there is a transition from the helical monolayer to a bilayer. Unfortunately, the bilayers decompose on transfer of the film to a solid support and it was therefore not possible to determine their structural parameters.

An amylose ester with side chains of moderate length (laurate) also formed layers comprising helices on the surface of water. Finally, amylose palmitate, the long side chains of which are capable of crystallising, formed a true monolayer with a vertical disposition of the hydrocarbon chains.

Thus the properties of amylose ester monolayers with short side chains are determined by the conformation of the main chain, while those of the compounds with ester alkyl groups of moderate and great lengths are determined by the side chains. Comparison of the data in Figs 49 and 50 for monolayers of isotypical cellulose and amylose esters shows that both series of derivatives form expanded and condensed monolayers, but in the case of amylose esters the isotherms are displaced towards smaller areas.

Furthermore, in contrast to LBF of cellulose esters, those of amylose ester (up to 50 monolayers) can be obtained on solid hydrophobic surfaces by the vertical transfer method. In the case of amylose triacetate molecules, *Z*-layers are then formed whereas *Y*-layers are produced for other homologues. Amylose palmitate can be transferred only from the liquid state, the product being disubstituted derivatives. The arrangements of the LBF comprising monolayers of amylose esters with short and long side chains are compared in Fig. 51. These arrangements were obtained on the basis of polarisation IR spectroscopic, X-ray diffraction, and ellipsometric studies.[273]

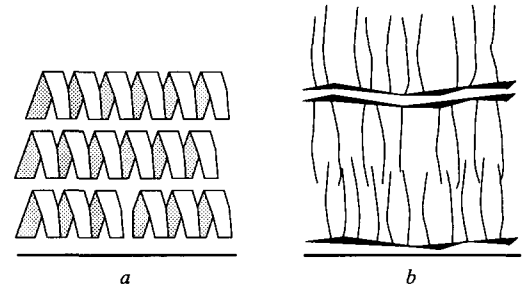

Figure 51. Schematic illustration of the arrangement of LBF of amylose esters with short (*a*) and long (*b*) side chains.[273]

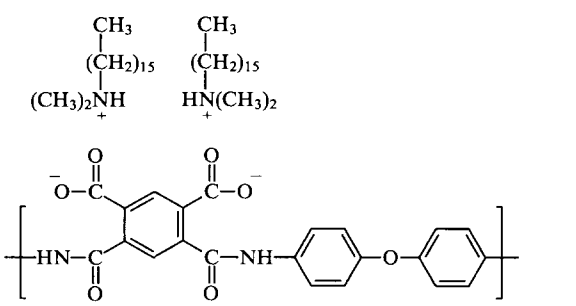
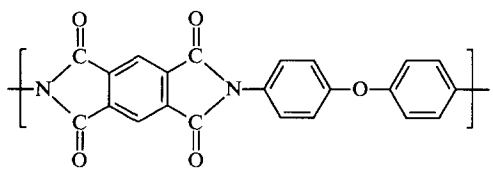


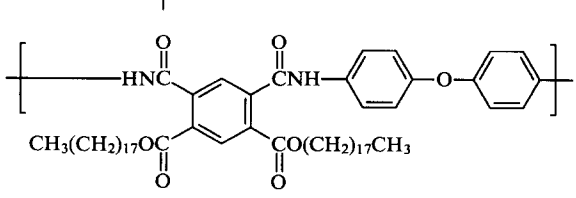
It has been suggested that amylose triacetate monolayers be used[275] as matrix layers for the immobilisation of a chromophore—the active element in a nonlinear optical system. A specially synthesised dye, the ester of palmitic acid and 4-nitro-4′(3R-hydroxypyrrolidino)-1,1′-azobisbenzene, does not afford at 23 °C stable monolayers on the surface of water suitable for use in LBF. Mixed monolayers of the dye and amylose triacetate are stable for a high dye content (up to 50%) and can be transferred onto solid supports by the horizontal and vertical methods. The mixed monolayers consist of amylose acetate domains and two-dimensional dye crystallites. The interfaces between the two types of structures play an appreciable role in increasing the stability of the monolayers. It is of interest that the

stabilisation of monolayers of the above dye by the formation of its mixed monolayers with other amylose esters cannot be achieved. On heating the LBF above the melting point of the dye (129 °C) and subsequent cooling to room temperature, the layered structure becomes more pronounced and virtually all the dye molecules are arranged in hydrogen-bonded aggregates.[276]



Thus, in relation to esters of cellulose and amylose, it is possible to follow the evolution of views on monolayers of these polymers and to demonstrate yet again the existence of discrepancies between data obtained by different workers in the study of identical polymers. The most interesting results presented in this section are the differences in the behaviour of monolayers of identical cellulose and amylose esters differing only in the configuration of the junctions between the glucose units and the similarity of the properties of monolayers of hydroxyalkyl derivatives of cellulose formed by spreading from solution and by adsorption from the subphase.

XII. Polyimides



The effective dielectric and mechanical characteristics and the chemical and mechanical stabilities of polyimides have led to their extensive application in various branches of engineering and primarily in electronics.[277] The minimum thickness of films of polyimides obtained on a rotating support from solutions of a polyamidoacid with subsequent thermal or chemical conversion into the imide form is 25 Å.[278] Polymer films with a thickness from 4–6 to 1000 Å can be obtained with the aid of monolayers and LBF. Owing to the insolubility of polyimides in organic solvents, the LBF are formed in several stages. Monolayers of the alkylammonium salt of the polyamidoacid **32** or its long-chain ester **33** are obtained initially on the surface of water. After their transfer to a solid support, they are converted into the imide form by the thermal (~300 °C) or chemical (with a mixture of acetic anhydride and pyridine) methods. LBF of poly[*N,N'*-bis(phenoxyphenyl)pyromellitimide] **34** have been investigated most fully.[279–284]

32

34

33

The salt **32** forms stable monolayers of the liquid-expanded type on the surface of water. The limiting area of the monolayer (138 Å^2 per residue) agrees well with the area calculated from a model,[279] while the thickness of one layer, found ellipsometrically for a 50-layer LBF, is 16.5 Å.[285] The quantitative transfer of the polyamidoacid onto the solid support (Z type LBF) is indicated by the degree of transfer, which is unity, and also by the linearity of the dependences of the optical absorption and the reciprocal of the capacity on the LBF thickness. According to IR spectroscopic data for 200-layer LBF, the chemical imide formation process goes virtually to completion and aliphatic products are eliminated from the film. After this, the thickness of a single polyimide monolayer is 4 Å.[279]

The imide formation process depends on the type of the ammonium component of the salt, on the solvent in which the imide formation is carried out, and on the support on which it takes place. It has been shown with the aid of a piezoquartz microbalance that higher-quality Y type LBF are formed when *N,N*-dimethyloctadecylamine is used instead of *N*-octadecylpyrrolidine. The initial rate of imide formation, carried out using acetic anhydride and pyridine, is higher in hexane than in benzene, but the conversion is more complete in the latter.[286]

The structure and conformation of the main chain, the number of hydrophobic side chains, and the way in which they are attached to the main chain exert a significant influence on the arrangement of the molecules in the LBF. In particular, the presence of only one hydrocarbon chain in the unit does not allow the formation of an ordered LBF from the polyimide, while two hydrophobic chains attached to different parts of the polymer unit increase the capacity of the polymer for being ordered so much that the layered structure of the polyimide persists also on deposition of the polyamidoacid salt by casting from solution.[287] The influence of the chemical structure and of the flexibility of the main chain of the polyimide on the properties of the LBF has also been investigated by Nishikata et al.[288] LBF of the polyimide **34**, having a zigzag configuration, and also of a rigid linear polyimide containing the phenylenediamine group instead of the oxydianiline group have been investigated by scanning tunnelling microscopy (STM).[281–283,289] Individual polymer chains and their fragments were identified with the aid of STM. The LBF of both polyimides have an ordered structure. The geometrical parameters of the film structure on the surface of highly oriented pyrolytic graphite, evaluated with the aid of STM, agree with data on the orientation of the molecules and their fragments obtained by the molecular dynamics method[289] and EXAFS spectroscopy.[283]

Interesting data concerning the influence of the nature of the support and of the thickness of the LBF on the degree of imide formation have been published.[290] The authors established that the first monolayer of the octadecylammonium salt of the polyamidoacid interacts chemically with the surface of silicon and its molecules are not involved in the imide formation process. According to X-ray electron spectroscopy, the degree of conversion is fairly high in thicker three- and five-layer LBF, although alkyl chains still remain in the film up to 300 °C (annealing for 15 min *in vacuo*). The inhibition of imide formation in thin films of the polyamidoacid, obtained from solution on the surface of nickel and chromium, has been explained by the intense adhesion interactions between the carboxy-groups and the surface. The SiO_2 surface does not hinder the imide formation reaction.[278]

The disordered arrangement of the alkylammonium hydrocarbon chains of the polyamidoacid salt in the LBF and also the retention of these chains in the film at high annealing temperatures[290] are closely related to the question of the defectiveness of the polyimide films arising as a result of the removal of the initial hydrocarbon components. These problems are of key importance in the preparation of high-quality polyimide LBF and require further study.

The change in the orientation of the hydrocarbon chains in the monolayer of the dimethyloctadecylammonium salt of the polyamidoacid has been investigated[291] by the method based on the measurement of the displacement current generated on compression of the monolayer.[292,293] Fig. 52 presents the dependence of the surface pressure, the displacement current, and the dipole moment calculated[294] with its aid on the area of the polyamidoacid salt monolayer. Two peaks may be identified on the $I-A$ relation: one in the region of zero surface pressure and the other in the region of increasing π. With increase in the first peak in I, the dipole moment also increases. Both displacement current peaks can be accounted for by condensation of the polymer molecules in the monolayer.

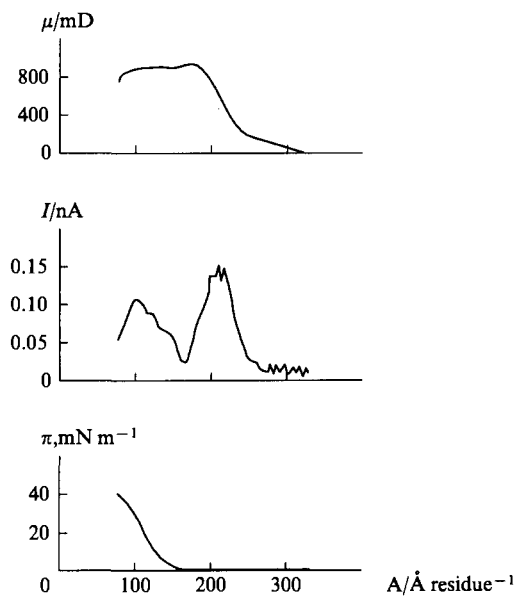


Figure 52. Dependence of the dipole moment (μ), the displacement current (I), and the surface pressure (π) on the area of a monolayer of an alkylammonium salt of a polyamidoacid on the surface of water.[291]

The photoinduced molecular 'switching' in monolayers of the polyamidoacid salt containing the azobenzene group instead of the phenoxyphenyl group has been detected from measurements of the displacement current.[259–297] It was established from molecular spectroscopic data that, on irradiation of the monolayer with UV light (λ_1 = 380 nm), the *trans–cis* isomerisation of the azobenzene group is observed, while on subsequent irradiation with visible light (λ_2 = 450 nm) the reverse *cis–trans* transition occurs. Fig. 53 presents the time variation of the displacement current and of the charge generated for the monolayer on the surface of water. It is seen that the photoisomerisation induces a sharp alteration of the displacement current. The absence of a displacement on irradiation of the monolayer with visible light alone shows that the current is generated precisely by the *trans–cis* isomerisation. Single-layer LBF of the same polyamidoacid salt deposited onto a mixed indium oxide–tin oxide electrode behave similarly.[298] Evidently these results are likely to find a practical application in molecular electronics.

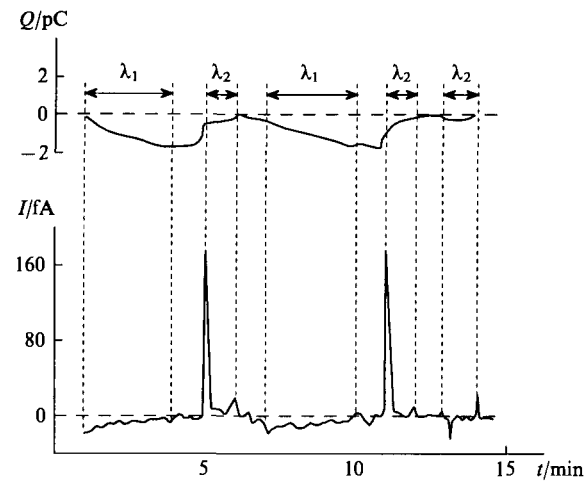

Figure 53. Time variation of the displacement current (I) and the charge (Q) for a monolayer of an alkylammonium salt of a polyamidoacid, containing azobenzene groups, on the surface of water.[295] The time intervals during which the specimen was irradiated with light at wavelengths of 380 nm (λ_1) and 450 nm (λ_2) are indicated.

A design has been proposed for a three-layer photodiode, each layer of which is a polyimide LBF.[299] The donor layer (D) consists of a polyimide containing triphenylamine groups. The sensitiser layer (S) incorporates tetraphenylporphyrin groups. The polyimide **34** LBF was used as the acceptor layer (A). Two types of photodiodes, differing in the position of the layers relative to a semitransparent gold electrode (E), were formed: E/D/S/A and E/A/S/D. The principle of the operation of such photodiodes is as follows: on irradiation with light, the excited electrons are transferred from the sensitiser layer S to the acceptor layer A; the electron deficiency in the S layer is made good from the donor D layer. Z Type LBF were formed in each layer in conformity with the procedure described above, i.e. from monolayers of polyamidoacid salts with subsequent chemical conversion into the imide form. The number of monolayers in each LBF was varied from 0 to 12. It was established that, on irradiation with monochromatic light at a wavelength of 430 nm, cathodic and anodic currents are generated in the photodiodes of the first and second types respectively. With increase in the number of monolayers in each LBF, the current also increases but that for the D layer reaches saturation while the current for the S and A layers passes through a maximum. On the basis of these data as well as the quantum yields, it was concluded that the D layer exhibits a high hole mobility and that the electron mobilities are low in the S and A layers.

LBF comprising the salt of a polyamidoacid based on pyromellitic dianhydride and bis(4-aminophenyl)tetramethyldisilane can be used as positive resists.[300] The quality of the LBF then depends significantly on the type of alkylamine used to obtain the polyamidoacid salt. Among the four dialkylamines selected for this purpose, a high-quality Y type LBF, containing 101 monolayers, could be formed only with *N*-eicosylpyrrolidine. With the aid of the three other alkylamines (*N,N*-dimethyloctadecylamine, *N*-octadecylpyrrolidine, and *N*-octadecylmorpholine), it is possible to obtain LBF the thickness of which does not exceed ten monolayers. After chemical or thermal conversion into the imide form, the LBF were irradiated with UV light through a photomask and were then treated in a mixture of organic solvents. The irradiated sections of the LBF were fully removed, whereas the polyimide on the covered sections of the LBF did not swell and did not dissolve. The use of such a LBF as a positive resist makes it possible to obtain a lithographic picture with a resolution of 0.25 μm.

The polyamidoacid ester **33** has also been used for photolithographic purposes.[301] A 31-layer LBF comprising mixed 1 : 1 monolayers of compound **33** and stearyl alcohol was formed on a silicon surface which had been rendered hydrophilic. The image was created by irradiating the LBF with UV light (254 nm) through a template followed by treatment in 2% KOH solution. The sensitivity, contrast, and resolution of the positive resist were 3.5 J cm^{-2}, 5.5, and 0.4 μm respectively. A characteristic feature of this resist is a low rate of etching in a CF_4/O_2 plasma and a high thermal stability (400 °C). The rates of etching of the LBF and of the silicon support were 1 and 350 nm min^{-1}. The high resistance of the polyamidoacid ester to etching can be accounted for by the presence of aromatic groups in the polymer and the perfection of the LBF structure. Unfortunately, Uekita et al.[301] do not consider the influence of stearyl alcohol, which may be washed out of the LBF on treatment in the liquid and may be desorbed during heat treatment. This should result in an increase in the effectiveness of the LBF and in the impairment of its structure.

Polyimide LBF are used as orienting layers in liquid crystal cells.[302, 303] In this case, the liquid crystals are oriented parallel to the direction of transfer of the monolayers from the surface of water onto the supporting surfaces of the cells; rubbing of the film is not then required.

A combination of conducting and orienting properties has been achieved recently on pyrolysed polyimide LBF based on biphenyl dianhydride [biphenyldicarboxylic acid dianhydride? (Translator)] and oxydianiline.[304, 305] The pyrolysis of the 31-layer Y type LBF was carried out under a nitrogen atmosphere for 60 min. Fig. 54 illustrates the dependence of the conductivity of the specimens obtained on the pyrolysis temperature. The sharpest increase in conductivity is observed for specimens obtained in the temperature range up to 800 °C. At 1000 °C, the conductivity of the LBF reaches 120 S cm^{-1}. The orienting properties of the films obtained were determined in a liquid crystal cell, arranging the supporting surfaces in such a way that the directions of transfer of the monolayers on them made an angle of 90° ('twist' structure). The cell was filled with a nematic liquid crystal and the optical and electrooptical properties of the system were analysed with the aid of a polarisation microscope. Fig. 55 presents the dependence of the transmittance on the angle between the analyser and the polariser for the twisted nematic structure in liquid crystal cells with supporting surfaces in the form of untreated quartz plates, a rubbed polyimide film, and a pyrolysed polyimide LBF. It is seen that the pyrolysed and rubbed polyimide films have similar orientation properties. However, the mechanism of the orienting effect of the pyrolysed LBF still remains obscure, since, according to polarisation optical spectroscopic data, the film has no planar anisotropy.[304]

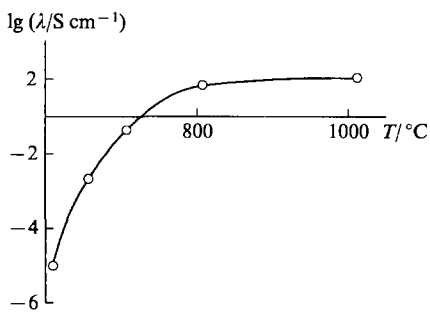

Figure 54. Dependence of the conductivity of specimens of pyrolysed polyimide LBF on the pyrolysis temperature.[305]

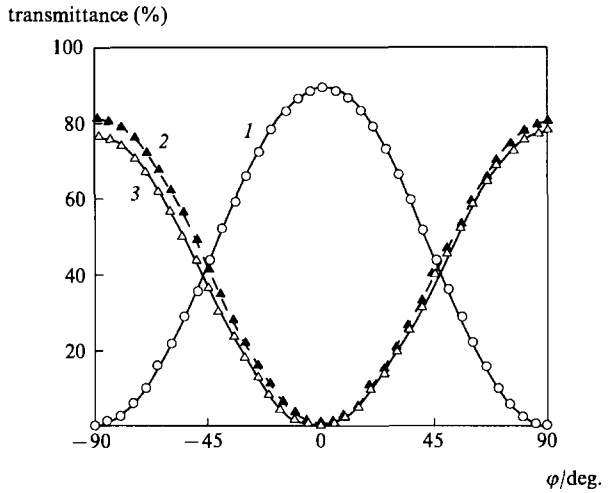

Figure 55. Dependence of the transmittance on the angle between the analyser and the polariser (φ) for a twisted nematic structure in liquid crystal cells with supporting surfaces in the form of untreated quartz plates (curve *1*), a rubbed polyimide film (curve *2*), and a pyrolysed polyimide LBF (curve *3*).[304]

The electrooptical properties of two liquid crystal cells with supporting surfaces comprising pyrolysed LBF and rubbed polyimide film are presented in Fig. 56. Both cells have similar characteristics. The response times to the switching on and switching off of an alternating potential are respectively 200 and 200 ms for the pyrolysed polyimide LBF and 100 and 200 ms for the rubbed film. Consequently, pyrolysed polyimide LBF can be used as more effective orienting layers and transparent electrodes in liquid crystal cells and also in ferroelectric liquid crystal cells.[304, 306]

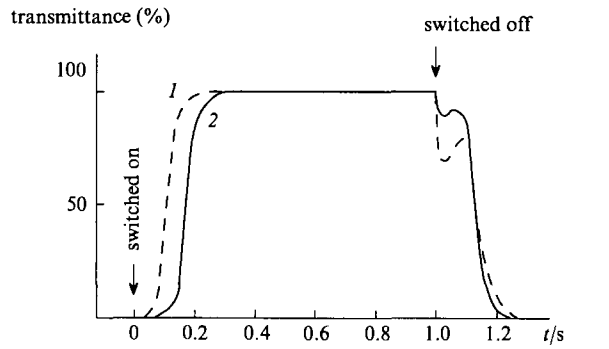

Figure 56. The electrooptical properties of a twisted nematic structure in liquid crystal cells with supporting surfaces comprising a rubbed polyimide film (curve *1*) and a pyrolysed polyimide LBF (curve *2*).[304]

Thus the possibility of obtaining insoluble polymer LBF has been demonstrated in relation to polyimides. In contrast to insoluble polymer LBF obtained by polymerising monomer and oligomer monolayers on a solid support, in the present instance the polymer retains the degree of polymerisation of the prepolymer — the polyamidoacid salt or ester. The imide formation process and the arrangement and quality of the LBF obtained depend on the type of amine component of the polymeric acid, on the solvent in which the chemical imide formation is carried out, and on the nature of the solid support.

The photoswitching effect, based on the *trans – cis* isomerisation of the chromophoric fragment of the main chain, can be achieved with the aid of LBF comprising polyimides containing the azobenzene group. There are also prospects for the application of polyimide LBF as positive photoresists, photodiodes, and orienting layers in liquid crystal cells.

XIII. Conclusion

On the basis of the above analysis of the behaviour of polymer monolayers and LBF, it is possible to arrive at general conclusions concerning the present state of this field of study and the trends in its development.

Among the theoretical aspects, questions concerning the two-dimensional state of macromolecules and the phase and structural transitions in systems with a reduced dimensionality are of greatest current interest. Unfortunately, it must be admitted that there has been no appreciable progress in the study of these fundamental problems of the two-dimensional state of macromolecules. The experimental studies on homopolymer and copolymer monolayers and mixed monolayers comprising polymers and low-molecular-mass compounds are developing more successfully. These involve the investigation of the packing of macromolecules on the surface of a liquid and the influence of the size and orientation of the side groups on the state of the monolayers, the elucidation of the structural correspondence between the components of the mixed monolayers, and the determination of the stability of monomolecular films. However, whereas previously these studies, traditional for monolayers, were of independent character and were sufficiently detailed, in recent years they have played an auxiliary role in most cases and reduce to the determination of the compression isotherms as an essential stage in the formation of LBF. Specific conclusions for each type of polymers considered, based on the results of these investigations, were presented in the appropriate sections of the review. These also contain information about the prospects for the practical employment of polymer LBF. The use of polymer LBF is based, as in the case of LBF comprising low-molecular-mass compounds, on the possibility of assembling multilayer planar structures with a controllable film thickness and orientation of the molecules in layers. Together with the independent role of functionalised polymer LBF in molecular devices, they can be used as matrices for the immobilisation of low-molecular-mass compounds (necessarily diphilic) carrying a specified physical function.

In order to realise these possibilities, it is essential to carry out extensive studies on polymer monomers and LBF, among which the following are of greatest current interest: the determination of the viscoelastic and relaxation properties of polymer monolayers, the establishment of criteria for the preparation of LBF of a specified type, the study of the structural-chemical correlations in the arrangement of monolayers on liquid and solid surfaces.

In conclusion we may note that the studies on monolayers and LBF are not restricted to the objects considered in the present review. Other polymers, the properties of the monolayers and LBF of which the author proposes to consider in subsequent publications, will include conducting high-molecular-mass compounds, water-soluble ionogenic polymers, and certain other functionalised polymers.

This review has been written with the financial support of the Russian Fundamental Research Fund (project code 93-03-5659).

Thermal, photolytic, and oxidative reactions of the homoligand carbonyls of metals in Groups VI – VIII

I V Spirina, V P Maslennikov

Contents

I. Introduction	41
II. Thermal decomposition of the carbonyl complexes of metals	41
III. Mechanisms of the photolytic breakdown of the carbonyls of the elements	44
IV. Oxidation of the metal carbonyls by oxygen, ozone, and peroxides	47
V. Conclusions	51

Abstract. The mechanisms of thermal, photolytic, and oxidative transformations of metal carbonyls into highly dispersed metallic and oxidic phases are discussed. The bibliography includes 142 references.

I. Introduction

The widespread use of the carbonyls of Group VI – VIII metals in the preparation of metal and oxide powders, films,[1,2] and catalysts for various chemical processes[3] has created a need for a detailed study of the mechanisms of the chemical transformations of the carbonyl complexes of the elements. The most recent reviews[3–5] which include a substantial volume of information on the synthesis and properties of metal carbonyls were published more than 10 years ago. However, during that period many new studies of the reactivity of the carbonyl complexes of Group VI – VIII metals towards thermal, photolytic, and oxidative transformations have been reported. They are discussed in the present review.

II. Thermal decomposition of the carbonyl complexes of metals

Most of the recent work on the thermal decomposition of the metal carbonyls is aimed at the preparation of metallic powders, films, and coatings.[1–3,6,7]

One method of preparing catalysts having a high activity and selectivity relies on the decomposition of metal carbonyls deposited on the surface of a solid support.[6,7] Depending on the properties of the surface and on the nature of the carbonyl we may observe the following processes: physisorption,[6–14] chemisorption with formation of various surface organometallic compounds,[6,10–18] and the decomposition of the starting compounds into polynuclear clusters.[13,19,20]

The interaction of pentacarbonyliron with the surface of silicon and of platinum monocrystals at 110 – 185 K results in the molecular adsorption of $Fe(CO)_5$.[8,9] It has been suggested that the adsorption is accompanied by a change in the molecular geometry of the pentacarbonyliron from a trigonal bipyramid to a square pyramidal form. Above 185 K we observe decarbonylation of the $Fe(CO)_5$, and a thin film of metallic iron is formed on the surface of the monocrystal. A similar process takes place during the photolysis of $Fe(CO)_5$ adsorbed on these supports[8,9] at 170 K, and during the thermal decomposition of pentacarbonyliron on the surface of graphite[6] and of dehydrated NaY zeolite.[14]

Highly dispersed metallic catalysts are prepared by thermal decomposition of the carbonyls $Fe_3(CO)_{12}$, $Ru_3(CO)_{12}$, and $Os_3(CO)_{12}$ supported on a clean carbon surface in a hydrogen or helium atmosphere.[21]

We know that when the surface of zeolites or of metal oxides is dehydroxylated by heat treatment under reduced pressure[7,14] the coordinatively unsaturated ions of the elements (Lewis acids) or the oxygen anions in the crystal lattice (Lewis bases) can act as adsorption centres. Depending on the reactivity of the carbonyl and on the nature of the surface, physisorption or chemisorption can be observed even at room temperature. A further increase in temperature results in the full decarbonylation of the initial compound.[6,7,10–15,22–27]

The decomposition of pentacarbonyliron in the micropores of NaY zeolite at 473 K and above produces the subcarbonyls $[Fe(CO)_{5-x}]_{ads}$, $[Fe(CO)_4]^{2-}$, and $[HFe_3(CO)_{11}]_x^-$.[6,14,23,24] The slowest step in the process is the removal of the last CO ligand from one of these species. The presence of small iron clusters in the pores makes possible the complete conversion of the pentacarbonyliron into metal-containing forms of zeolite.[24] The thermal dissociation of $Fe(CO)_5$ includes the disproportionation of CO to CO_2.

The decomposition of $Mo(CO)_6$ in the cavities of NaY zeolite takes place in two steps.[12,25,26] During the first step (at 373 K) we observe changes in the mass of the sample, corresponding to the loss of two carbonyl groups with formation of $Mo(CO)_4$. However, the IR spectrum of the reaction mixture in the 2000–1700 cm^{-1} region contains several ν_{CO} bands which suggest the presence[26] among the reaction products [in addition to $Mo(CO)_4$] of an unidentified molybdenum compound, possibly $[Mo_2(CO)_8Z_x]^{2-}$ (where Z_x is an adsorption centre). Heating the sample above 473 K results in the irreversible decarbonylation of the starting $MO(CO)_6$ with formation of metallic molybdenum within the zeolite lattice. Introducing H^+ ions into the NaY lowers the decomposition temperature of the molybdenum carbonyl to 333 K and produces more finely divided metal particles.[27] $Cr(CO)_6$ physisorbed on silicalite,[11] $Ru(CO)_{12}$ on V_2O_5, MgO, ZnO, and La_2O_3,[12,18] $Mn_2(CO)_{10}$ on NaY zeolite,[13] and $Mo(CO)_6$

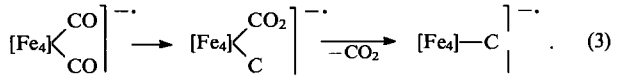
on dehydroxylated Al_2O_3 [22] all undergo similar types of decomposition.

In the thermal decomposition of metal carbonyls on HY zeolite we observe the formation of hydridocarbonyl surface species, $[HM(CO)_m]^+$, which ultimately dissociate with formation of metallic clusters.[11,15,16,28]

On the surface of metal oxides containing hydroxyl groups the carbonyl complexes undergo nucleophilic attack from the side of the OH groups and are converted into compounds of the $[M_n(CO)_{m-x-y}(OH)_x(OZ)_y]\cdot n[HM_n(CO)_{m-1}]$ type, where Z is a metal ion in the corresponding oxide.[10,12,17,18,22] Further decarbonylation leads to the formation of oxidised forms of the metal with evolution of hydrogen.

Octacarbonylcobalt sublimed on to the surface of various zeolites is converted even at room temperature[13,19,20] into the polynuclear clusters $Co_4(CO)_{12}$ and $Co_6(CO)_{16}$. In this case the final product of the thermal decomposition are metal particles 10–15 Å in diameter.

Thus the nature of the surface of the solid phase plays an important role in determining the purity and the disperseness of the metallic powders prepared by the thermal decomposition of metal carbonyls. The reactivity of carbonyl compounds is unaffected by their physisorption on the clean surfaces of inert supports such as active carbon and monocrystalline silicon or platinum.[8,9,21] Metal oxides and zeolites of the NaY type interact with carbonyl complexes through coordinatively unsaturated ions of their elements or through the oxygen anions of the crystal lattice.[6,7,10–15,22–27] The HY zeolites and the oxides containing hydroxyl groups form surface compounds with the carbonyl complexes.[10–12,15–17,22,28] The detailed mechanism of the thermal decomposition of metal carbonyls on solid surfaces has not yet been investigated.



The synthesis of metallic powders and films by the thermal decomposition of metal carbonyls in the gas phase is widely used in industry.[1–3] A study of its mechanism by the fast IR spectroscopy method showed the presence of coordinatively unsaturated metal carbonyls in the reaction mixtures.[29] Depending on the experimental conditions the decomposition of the carbonyl complexes produces powders, films, or metal whiskers.[1–3,30–32] The solid products contain oxide and carbide impurities. Experiments with labelled atoms showed that the oxygen used to form oxides in the resulting solid phase is provided by the carbonyl ligand.[32]

A study by EPR of the thermal decomposition of pentacarbonyliron[33] established that the process takes place on the surface of the reaction vessel by a chain ion–radical clusterisation mechanism:

$$Fe(CO)_4^{-\cdot} + Fe(CO)_5 \longrightarrow Fe_2(CO)_8^{-\cdot} + CO, \quad (1)$$

$$Fe_2(CO)_8^{-\cdot} + Fe(CO)_5 \longrightarrow Fe_3(CO)_{12}^{-\cdot} + CO. \quad (2)$$

This mechanism describes the formation of anion-radical iron carbonyl clusters on the growing iron surface. When the number of nuclei in the cluster reaches four the carbon monoxide group in the coordination sphere of the anion radical undergoes disproportionation according to the Bell–Boudart scheme[33]

(3)

In the presence of an excess of $Fe(CO)_5$ vapour the $[Fe_4]-C^{-\cdot}$ clusters are further converted into clusters with 5 or 6 nuclei. Different ways of generating ion-radical centres on the growing surface by chemisorption, photo-ionisation, and other means have been suggested.[33]

In the thermal decomposition of pentacarbonyliron in the gas phase the formation of new metallic particles is observed mainly during the first stages. Thus, ~80% of all the particles have already been formed when 50% conversion of the $Fe(CO)_5$ is reached.[34]

Carlton and Oxley[35] have shown that the initial rate of decomposition of tetracarbonylnickel vapour at 373 K is proportional to its concentration, and that the resulting carbon monoxide limits the rate of the reaction. They proposed the following scheme for the reaction:

$$Ni(CO)_4 \rightleftharpoons Ni(CO)_3 + CO, \quad (4)$$

$$Ni(CO)_3 \xrightarrow{-CO} Ni(CO)_2 \xrightarrow{-CO} \quad (5)$$

$$\longrightarrow Ni(CO) \xrightarrow{-CO} Ni\ .$$

The activation energy for the thermal decomposition of nickel carbonyl in the gas phase[35] is 91.1 kJ mol^{-1}. The dissociation energy of the first Ni–CO bond in the $Ni(CO)_4$, calculated from quantum chemical[36] and from thermochemical data,[37] is 201.6 and 154.1 kJ mol^{-1} respectively. These values are substantially higher than the activation energy measured[35] for the decomposition of $Ni(CO)_4$: this is probably due to the catalytic effect of the resulting metal particles on the thermal decomposition of tetracarbonylnickel.

The decarbonylation of the tetranuclear clusters $Rh_4(CO)_{12}$, $Rh_2Co_2(CO)_{12}$, $RhCo_3(CO)_{12}$, and $Co_4(CO)_{12}$ has been studied[38] by the programmed decomposition temperature method in a hydrogen stream. The quantity of CO evolved during the complete conversion of $Rh_4(CO)_{12}$ suggests the formation of the $Rh_6(CO)_{16}$ complex, which is relatively stable under the chosen thermal decomposition conditions:

$$3\,Rh_4(CO)_{12} \longrightarrow 2\,Rh_6(CO)_{16} + 4\,CO. \quad (6)$$

The decarbonylation of $Co_4(CO)_{12}$ was completed by the formation of a mirror of metallic cobalt on the walls of the reaction vessel, whereas solid deposits of the powdered metal were obtained[38] from $RhCo_3(CO)_{12}$, $Rh_2Co_2(CO)_{12}$, and $Rh_4(CO)_{12}$.

A flow system with a differential reactor has been used[39–41] to study the kinetics of the gas-phase decomposition of the hexacarbonyls of metals in the chromium subgroup, and the effective activation energies of the processes have been determined: 45.8 and 54.6 kJ mol^{-1} for $Mo(CO)_6$ and $W(CO)_6$ respectively. The low values of the effective activation energy (as compared with the energy required to remove a single CO ligand[42]) suggest a complex process in the thermal decomposition of $M(CO)_6$, probably not involving catalytic stages.

By using pulsed laser photolysis, which suppresses heterogeneous reactions, Lewis et al.[43] studied the homogeneous gas-phase decomposition of mononuclear metal carbonyls (Fe, Cr, Mo, W). Dissociation energies of 171.4, 134.7, 167.2, and 191.5 kJ mol^{-1} for the first metal–ligand bond were obtained for $Fe(CO)_5$, $Cr(CO)_6$, $Mo(CO)_6$, and $W(CO)_6$ respectively. These values are close to those obtained in thermochemical experiments.[42] It was established[43] that additions of equimolar quantities of carbon monoxide do not affect the rate of the gas-phase decomposition of these metal carbonyls. For the iron, molybdenum, and tungsten carbonyls the rate-determining step of the process is the removal of the first CO ligand. In the thermal decomposition of $Cr(CO)_6$ the fast (equilibrium) elimination of the first CO ligand is followed[43] by the slower (but still at equilibrium) stage of the dissociation of $Cr(CO)_5$ to $Cr(CO)_4$.

Thus the thermal decomposition of the metal carbonyls in the gas phase involves the participation of coordinatively unsaturated species. The process is often retarded by the gaseous product (carbon monoxide),[29,33,35,43] and is catalysed by the resulting metallic phase used for the nucleation and growth of the carbonyl anion radicals.[33] The products of the reaction (metallic powders, whiskers, and films) contain oxide and carbide impurities.[32,33]

Particles of highly dispersed metals, having an average diameter of 63–110 Å, have been prepared[44,45,47] by the decomposition of metal carbonyls in liquid media. The thermal dissociation of $Fe(CO)_5$ and $Co_2(CO)_8$ in solutions of surface-active substances has yielded stable colloidal suspensions (ferromagnetic liquids).[45,46]

The decomposition of penta- and nonacarbonyliron in a closed system takes place by the reversible reaction

$$Fe_n(CO)_m \rightleftarrows Fe_n(CO)_{m-1} + CO, \quad (7)$$

and is rate-limited by the evolved carbon monoxide.[47] The coordinatively unsaturated carbonyl $Fe_n(CO)_{m-1}$ which is produced dissociates according to the scheme

$$Fe_n(CO)_{m-1} \rightleftarrows Fe_n(CO)_{m-x-1} + x\,CO; \quad (8)$$

$Fe_n(CO)_m = Fe(CO)_5$ or $Fe_2(CO)_9$.

The thermal decomposition of nonacarbonyliron produces $Fe(CO)_5$, which is relatively stable under the conditions of the experiment.[47] Dodecacarbonyliron decomposes in undecane at 353–383 K by the reaction

$$2\,Fe_3(CO)_{12} \longrightarrow 2\,Fe(CO)_5 + Fe_2(CO)_9 + 5\,CO + 2\,Fe. \quad (9)$$

The rate of the thermal decomposition of the iron carbonyls in paraffins is described by a kinetic equation of the first order with respect to the initial concentration of $Fe_n(CO)_m$. The dissociation of dodecacarbonyliron also obeys the first-order kinetic equation with respect to the time-dependent concentration of $Fe_3(CO)_{12}$ up to a 90% extent of reaction.[47]

The thermal stability of the carbonyl complexes of iron increases in the sequence $Fe_3(CO)_{12} < Fe_2(CO)_9 < Fe(CO)_5$. The rate constants for the dissociation of the iron carbonyl complexes in solution have been determined,[47] and in the case of $Fe(CO)_5$ the equilibrium constants and the rate constants of the recombination reaction are also known.

Octacarbonylcobalt is almost quantitatively converted into the dodecacarbonyl after 5 h at 363 K in toluene or in heptane.[48,49] The rate of the process is described by a second-order kinetic equation with respect to $Co_2(CO)_8$. At 363 K the rate constant is 5.27×10^{-6} dm^3 mol^{-1} s^{-1}:

$$\frac{d[Co_4(CO)_{12}]}{dt} = k\frac{[Co_2(CO)_8]^2}{[CO]^n} \quad (10)$$

The nature of the solvent has a powerful effect on the kinetics of the formation of dodecacarbonylcobalt. Thus, in heptane the parameter n in the expression for the rate of accumulation of $Co_4(CO)_{12}$ [Eqn (10)] is two, but when toluene is used $n = 4$. The following scheme has been proposed[48] to describe the process:

$$Co_2(CO)_8 \rightleftarrows Co_2(CO)_7 + CO, \quad (11)$$

$$Co_2(CO)_7 \rightleftarrows Co_2(CO)_6 + CO, \quad (12)$$

$$2\,Co_2(CO)_6 \longrightarrow Co_4(CO)_{12}, \quad (13)$$

$$Co_2(CO)_8 + Co_2(CO)_6 \longrightarrow Co_4(CO)_{12} + 2\,CO. \quad (14)$$

It is assumed that the main contribution to the formation of dodecacarbonyltetracobalt is provided by reaction (13) in heptane and by reaction (14) in toluene.

The thermal decomposition of tetracarbonylnickel in undecane at 323–353 K is slow, and yields the carbon oxides CO and CO_2.[50] After complete decomposition of the $Ni(CO)_4$ the yield of the two gaseous products is 3.2 and 0.4 mol per mole of converted carbonyl for CO and CO_2 respectively. Metallic nickel and nickel carbide can also be detected among the reaction products. Addition of CO to the reaction mixture before the start of the reaction suppresses the thermal decomposition of $Ni(CO)_4$. The rate of the thermal dissociation of tetracarbonylnickel in solutions is described by a first-order kinetic equation. The following scheme has been suggested:[5,50]

$$Ni(CO)_4 \rightleftarrows Ni(CO)_3 + CO, \quad (15)$$

$$Ni(CO)_3 \xrightarrow[-CO]{} Ni(CO)_2 \xrightarrow[-CO]{} NiCO \xrightarrow[-CO]{} Ni, \quad (16)$$

$$Ni(CO)_3 \longrightarrow Ni + (C) + CO + CO_2. \quad (17)$$

The rate constants for the removal of the first CO ligand (k_{15}) and those for the recombination of $Ni(CO)_3$ and CO(k_{-15}) have been determined.[50]

The thermal decomposition of pentacarbonylruthenium in a cyclohexane solution at 298–303 K leads to the formation of $Ru_3(CO)_{12}$. The conversion of $Ru(CO)_5$ into $Ru_3(CO)_{12}$ is the result[51] of the primary fission of a Ru–CO bond with formation of $Ru(CO)_4$:

$$Ru(CO)_5 \rightleftarrows Ru(CO)_4 + CO. \quad (18)$$

The tetracarbonylruthenium interacts with the $Ru(CO)_5$, ultimately giving $Ru_3(CO)_{12}$. The activation parameters of the process have been obtained, and the equilibrium constant of reaction (18) has been calculated: 3.0×10^6 mol dm^{-3} at 298 K.

Tunik et al.[52] have studied the kinetics and the mechanism of the conversion of dodecacarbonylrhodium into hexadeca-carbonylrhodium in heptane:

$$3\,Rh_4(CO)_{12} \longrightarrow 2\,Rh_6(CO)_{16} + 4\,CO. \quad (19)$$

The reaction takes place by two independent parallel paths—a dissociative and a nondissociative path—and it goes to completion even at pressures of carbon monoxide in the 360–420 bar range.

The dissociative path [process (20)–(23)] includes the reversible elimination of two molecules of carbon monoxide from the $Rh_4(CO)_{12}$, followed by the rate-limiting step, described[52] as the isomerisation of the cluster skeleton to give a cluster nucleus having a new and very different structure. A typical example of this stage is the conversion of the nucleus of the Rh_4 cluster from a tetrahedral configuration into a 'butterfly' configuration.[52] The nondissociative path [processes (24) and (25)] stipulates the activation of the initial cluster by a similar mechanism but without the preliminary dissociation of the CO ligands. The presence of carbon monoxide has no effect on the rate of this process.

$$Rh_4(CO)_{12} \rightleftarrows Rh_4(CO)_{11} + CO \quad (20)$$

$$Rh_4(CO)_{11} \rightleftarrows Rh_4(CO)_{10} + CO \quad (21)$$

$$Rh_4(CO)_{10} \longrightarrow [Rh_4(CO)_{10}]^* \quad (22)$$

$$[Rh_4(CO)_{10}]^* + 2\,Rh_4(CO)_{12} \xrightarrow{fast} 2\,Rh_6(CO)_{16} + 2\,CO \quad (23)$$

$$Rh_4(CO)_{12} \longrightarrow [Rh_4(CO)_{12}]^* \quad (24)$$

$$[Rh_4(CO)_{12}]^* + 2\,Rh_4(CO)_{12} \xrightarrow{fast} 2\,Rh_6(CO)_{16} + 4\,CO \quad (25)$$

Thus in most cases the first step in the decomposition of metal carbonyls in the liquid phase is the equilibrium elimination reaction of a CO ligand. The thermal stability of the carbonyl complexes is strongly influenced by the nature of the metal atom and by the structure of the resulting polynuclear clusters.[37]

III. Mechanisms of the photolytic breakdown of the carbonyls of the elements

The earliest information[1] on the decomposition of the metal carbonyls (in particular, pentacarbonyliron) under the influence of solar radiation appeared at the beginning of the 20th century, but the systematic study of the photolytic breakdown of pentacarbonyliron began in the late 1930s.[53-55]

It was established[53] that the quantum yield of the formation of CO during the decomposition of $Fe(CO)_5$ vapour (at an initial pressure of 5-15 Torr) under the influence of radiation (366, 405, and 465 nm) is 1.16. Additions of various gases (H_2, CO, CO_2, N_2, Ar) in amounts ranging from values close to the concentration of the pentacarbonyliron to a six-fold excess suppressed[35] the decomposition of the $Fe(CO)_5$ by up to ~50% and lowered the quantum yield of the formation of CO to 0.5. In the mechanism proposed to explain these effects the retardation by gaseous additives was ascribed to the deactivation of the excited $[Fe(CO)_5]^*$ molecules:

$$Fe(CO)_5 \xrightarrow{h\nu} [Fe(CO)_5]^*, \quad (26)$$

$$[Fe(CO)_5]^* + Fe(CO)_5 \longrightarrow Fe_2(CO)_9 + CO, \quad (27)$$

$$[Fe(CO)_5]^* + Q \longrightarrow Fe(CO)_5 + Q; \quad (28)$$

$Q = H_2, CO, CO_2, N_2, Ar.$

However, this mechanism was not confirmed by later work.

The absorption spectra of $Fe(CO)_5$ and $Ni(CO)_4$ vapour[55] consist of continuous curves at wavelengths below 410 nm for $Fe(CO)_5$ and 315 nm for $Ni(CO)_4$. This type of spectrum suggests that the potential energy curve of the excited state does not have a minimum, and therefore the excited $[Fe(CO)_5]^*$ and $[Ni(CO)_4]^*$ molecules are unstable and should dissociate. Thus the primary act of the photolysis is the dissociation of the activated $[Fe(CO)_5]^*$ or $[Ni(CO)_4]^*$ molecule to give $Fe(CO)_4$ or $Ni(CO)_3$.

The accumulation of $Fe(CO)_4$ or $Ni(CO)_3$ during the photolysis of $Fe(CO)_5$ or $Ni(CO)_4$ in inert gas matrices at 20 K and in hydrocarbon glasses at 70 K has been confirmed by IR spectroscopy.[56-60] The coordinatively unsaturated metal carbonyl can react reversibly with the matrix to give $[M(CO)_{n-1}]^*Q$ complexes (Q = H_2, Ne, Ar, Xe, CH_4; M = Fe, Ni; n = 5, 4).[57,60]

$$M(CO)_n \xrightarrow{h\nu} [M(CO)_n]^* \underset{-CO}{\rightleftharpoons} \quad (29)$$

$$\rightleftharpoons [M(CO)_{n-1}]^* \xrightarrow[\lambda > 357\ nm]{Q} [M(CO)_{(n-1)}]^*Q$$

By using the pulsed UV photolysis method with fast recording in the IR region it was shown[61,62] that processes like (29) can take place in gas and in liquid phases as well as in a solid matrix.

According to the above arguments the primary reactions taking place during the photolysis of pentacarbonyliron are described by the equations

$$Fe(CO)_5 \xrightarrow{h\nu} [Fe(CO)_5]^*, \quad (30)$$

$$[Fe(CO)_5]^* \longrightarrow Fe(CO)_4 + CO, \quad (31)$$

$$Fe(CO)_4 + Fe(CO)_5 \longrightarrow Fe_2(CO)_9. \ ^\circ C. \quad (32)$$

The photodissociation of pentacarbonyliron has been studied[63-65] in the gas phase with excitation by laser radiation of wavelength 193, 248, and 352 nm in the presence of PCl_3, PF_3, or SF_6, keeping the total pressure in the system below 200 Torr. Additions of PCl_3 and PF_3 or SF_6 were used to identify the carbonyl fragments produced by the reaction. The energy of the laser radiation and the irradiation time were chosen so as to exclude multiple absorption of photons, and the conversion of the $Fe(CO)_5$ was kept below 10%. It was shown that the absorption of one photon by a molecule of pentacarbonyliron in the gas phase leads to the formation of $Fe(CO)_{5-x}$ primary fragments, where x = 1-4, with an overall quantum yield close to unity. The degree of fragmentation of the pentacarbonyliron increases with the energy of the absorbed photon. The mechanism of the photodissociation is described by the scheme

$$[Fe(CO)_5]^* \longrightarrow [Fe(CO)_4]^{**} + CO, \quad (33)$$

$$[Fe(CO)_4]^{**} \longrightarrow [Fe(CO)_3]^{**} + CO, \quad (34)$$

$$[Fe(CO)_3]^{**} \longrightarrow [Fe(CO)_2]^{**} + CO, \quad (35)$$

$$[Fe(CO)_2]^{**} \longrightarrow [Fe(CO)]^{**} + CO. \quad (36)$$

The pentacarbonyliron molecule excited by the absorption of a photon, $[Fe(CO)_5]^*$, loses CO groups successively and forms coordinatively unsaturated intermediates which are in electronically and vibrationally excited $[Fe(CO)_{5-x}]^{**}$ states.[63,64]

In contrast to the photodissociation reaction induced by irradiation with a mercury lamp tetracarbonyliron formed under laser or flash photolysis from pentacarbonyliron retains up to 65% of the absorbed energy in the form of an electronic or a vibrational component, and is therefore very unstable.[64]

According to SCF MO LCAO calculations[66-68] the photochemical excitation of $Fe(CO)_5$ produces a spin-allowed transition to an excited singlet state. Spin-orbit interaction then populates the triplet state, from which the $[Fe(CO)_5]^*$ dissociates with formation of $Fe(CO)_4(T_i)$ and $CO(S_0)$. The calculated enthalpy of the reaction is 178.8 and the experimental value is 246.4 kJ mol^{-1}.[69]

A detailed study of the composition of the products and of the kinetic features of the photolytic decomposition of the iron carbonyls in solutions under the influence of radiation with wavelengths of 253.7 and 366 nm has been reported.[70] In hydrocarbon solutions pentacarbonyliron dissociates photolytically with formation of a mixture of carbon monoxide and of nona- and dodecacarbonyliron. The relative abundance of the polynuclear carbonyls shows that the dodecacarbonyl is produced by the photolytic decomposition of nonacarbonyliron. The photolysis of $Fe_2(CO)_9$ in solution leads to the formation of $Fe_3(CO)_{12}$, CO, and $Fe(CO)_5$. The decomposition of $Fe_3(CO)_{12}$ in octane under the influence of UV radiation is accompanied by the evolution of carbon monoxide, of penta- and of nonacarbonyliron, and also of metallic iron. The quantum yields for the conversion of the initial carbonyl complexes and for the accumulation of their decomposition products suggests that the processes are described by the following equations:

$$2\,Fe(CO)_5 \xrightarrow{h\nu} Fe_2(CO)_9 + CO, \quad (37)$$

$$2\,Fe_2(CO)_9 \xrightarrow{h\nu} Fe(CO)_5 + Fe_3(CO)_{12} + CO, \quad (38)$$

$$2\,Fe_3(CO)_{12} \xrightarrow{h\nu} 2\,Fe_2(CO)_9 + Fe(CO)_5 + Fe + CO. \quad (39)$$

The pentacarbonyliron formed by the decomposition of the nona- and dodecacarbonyls again undergoes photolysis by reaction (37). The nonacarbonyl formed by the photolysis of $Fe_3(CO)_{12}$ contributes to reaction (38). Thus the photolytic transformation of pentacarbonyliron in octane is a complex multistep process including the formation and decomposition stages of polynuclear iron carbonyls.

The synthesis of $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ takes place also during the photolysis of $Fe(CO)_5$ in inert gas matrices containing pentacarbonyliron in a proportion of 1:1000 relative to the inert matrix.[57,71] The photodissociation of $Fe(CO)_5$ adsorbed on Vycor porous glass or on zeolites produces polynuclear iron compounds.[72,73]

It has been shown [70] that the quantum yield of the formation of CO during the photolysis of the iron carbonyls in solution is unaffected by changes in the wavelength of the light between 253.7 and 366 nm. The rate of decomposition of the iron carbonyls in octane in concentrations below 5×10^{-4} mol dm^{-3} is described by a first-order kinetic equation. The mechanism of the photolysis of the iron carbonyls in solutions is consistent with the following scheme:

$$Fe_n(CO)_m \xrightarrow{h\nu} [Fe_n(CO)_m]^*, \quad (40)$$

$$[Fe_n(CO)_m]^* \longrightarrow Fe_n(CO)_m + h\nu, \quad (41)$$

$$[Fe_n(CO)_m]^* + RH \longrightarrow Fe_n(CO)_m + RH, \quad (42)$$

$$[Fe_n(CO)_m]^* \longrightarrow Fe_n(CO)_{m-1} + CO, \quad (43)$$

$$[Fe_n(CO)_m]^* + Fe_n(CO)_{m-1} \longrightarrow \text{products}; \quad (44)$$

RH is the solvent.

Several workers have reported [66, 69, 74] the formation of the $Fe_n(CO)_{m-1}$ fragment during the irradiation of penta- and nonacarbonyliron in inert gas matrices.

We know that the rates and the quantum yields of photochemical reactions are relatively insensitive to temperature, [75] which usually affects only the dark reactions. The activation energies reported [70] for the evolution of CO in the photolysis of octane solutions of iron carbonyls show that the formation of carbon monoxide by the scheme (40)–(44) during the decomposition of $Fe_n(CO)_m$ is accompanied by a process in which the photochemical act is the bimolecular interaction of an activated with a non-activated molecule of the carbonyl [Eqn (45)]. In this case the scheme of the photodissociation should include the steps (40)–(42), (45) and the deactivation of $[Fe_n(CO)_m]^*$ on other molecules of the carbonyl:

$$[Fe_n(CO)_m]^* + Fe_n(CO)_m \longrightarrow \text{products}, \quad (45)$$

$$[Fe_n(CO)_m]^* + Fe_n(CO)_m \longrightarrow 2\,Fe_n(CO)_m. \quad (46)$$

A kinetic analysis of the mechanism of photolysis of iron carbonyls in solutions shows [70] that the process can follow either of the suggested schemes. In the case of reactions (40)–(44) the quantum yield of the photodissociation of the iron carbonyls (φ_1) is independent of the initial concentration of $Fe_n(CO)_m$ [Eqn (47)]. If the photolysis of the carbonyl complexes takes place according to the scheme (40)–(42), (45), (46) the quantum yield of the reaction (φ_2) becomes a function of the concentration of the carbonyl:

$$\varphi_1 = \frac{2k_{43}}{k_{41}} + k_{42}[RH] + k_{43}, \quad (47)$$

$$\varphi_2 = \frac{2k_{45}[Fe_n(CO)_m]}{k_{41}} + k_{42}[RH] + k_{45}[Fe_n(CO)_m] + k_{46}[Fe_n(CO)_m]. \quad (48)$$

Since the quantum yield of the elimination of CO in the photolytic dissociation of $Fe(CO)_5$ at 293 K is not affected by changes in the initial concentration of the carbonyl we may conclude that under these conditions the photolysis of pentacarbonyliron takes place mainly by the mechanism described by Eqns (40)–(44). At 373 K the dependence of the reciprocal quantum yield on the concentration is described by the expression

$$\varphi_2^{-1} = \frac{k_{45} + k_{46}}{2k_{45}} + \frac{k_{42} + k_{45}[RH]}{2k_{45}[Fe_n(CO)_m]}. \quad (49)$$

A similar dependence is observed in the photolysis of $Fe_2(CO)_9$ in octane at 293 K. Therefore increasing the temperature of the reaction and changing from penta- to nonacarbonyliron increases the contribution of the path described by Eqns (40) to (46) to the photolytic breakdown of the carbonyl complexes of iron.

The photolysis of $Co_2(CO)_8$ and $Co_4(CO)_{12}$ is nonane under the influence of UV light produces a colour change in the solution, accompanied by the evolution of carbon monoxide. [76] An analysis of the spectra of the reaction mixtures obtained during the irradiation of $Co_2(CO)_8$ showed that octacarbonylcobalt is converted into $Co_4(CO)_{12}$ by the photolysis.

The initial rate of accumulation of CO in the photodissociation of the cobalt carbonyls is directly proportional to the number of quanta absorbed, and an increase in the wavelength of the light from 253.7 to 366 nm has almost no effect on the quantum yield of the formation of carbon monoxide. The quantum yield for the decomposition of octacarbonylcobalt (2.9×10^{-3}) and for the formation of the reaction products $Co_4(CO)_{12}$ (1.5×10^{-3}) and CO (6.0×10^{-3}) suggest that the photolysis of $Co_2(CO)_8$ is described by the equation

$$2Co_2(CO)_8 \xrightarrow{h\nu} Co_4(CO)_{12} + 4\,CO. \quad (50)$$

The kinetic order of the decomposition of $Co_2(CO)_8$ in nonane under the influence of UV radiation is close to unity; increasing the temperature from 293 to 313 K has no effect on the quantum yields of the photodissociation of the cobalt carbonyls.

The changes in the spectra recorded during the photolysis of $Co_4(CO)_{12}$ show that under the influence of radiation dodecacarbonylcobalt is converted into $Co_6(CO)_{16}$: [76]

$$2\,Co_4(CO)_{12} \xrightarrow{h\nu} Co_6(CO)_{16} + 8\,CO + 2\,Co. \quad (51)$$

The order of the reaction leading to the photolytic dissociation of $Co_4(CO)_{12}$ in nonane is close to unity.

The scheme of the photolytic dissociation of octacarbonylcobalt in solution is analogous to the photolysis mechanism of the iron carbonyls [Eqns (40)–(44)]. [76] A kinetic analysis of this scheme and the experimental dependence of the reciprocal quantum yield for the photolysis of $Co_2(CO)_8$ on its reciprocal concentration, described by Eqn (49), show that the elimination of a CO ligand from the excited carbonyl molecule plays only a minor role in this process. On the other hand, in the thermal dissociation of $Co_2(CO)_8$ in solutions it is the rate-determining step. [48] An electronically excited state relatively stable towards decarbonylation is probably created as a result of the absorption of a light quantum by octacarbonylcobalt. This effect can be attributed to the presence of a large number of bonds in $Co_2(CO)_8$, which allow the energy of the absorbed quantum to be redistributed. [76] As a result most of the activated carbonyl molecules are deactivated by processes such as (41), (42), and (46), leading to low values of the quantum yields in the photolysis of $Co_2(CO)_8$. A graphical analysis of the dependence of the reciprocal quantum yield on the reciprocal concentration of $Co_2(CO)_8$ suggests that the ratio of the rate constants of the bimolecular deactivation of the excited $Co_2(CO)_8$ molecule [Eqn (46)] and of the direct photochemical reaction [Eqn (45)] can be as high as 30. [76]

Early studies of the photolysis of tetracarbonylnickel in a CCl_4 solution [55] and in the gas phase [77] had established that this process results in the formation of four moles of CO. As in the case of pentacarbonyliron the primary act of the photolysis is the absorption of a light quantum and the conversion of the molecule into the excited $[Ni(CO)_4]^*$ state, from which it decomposes with the elimination of one CO group. The resulting $Ni(CO)_3$ is unstable and decomposes to the metal and carbon monoxide. Additions of CO suppress the decomposition of

$Ni(CO)_4$ in both the gas phase [77] and the liquid phase.[50] The observed[77] lifetime of the activated $[Ni(CO)_4]^*$ molecule was 7×10^{-9} s. The quantum yield of the photolytic decomposition of the tetracarbonyl in solution irradiated with 313 nm light was 1.8; the order of the photolysis reaction was close to unity.[50] According to a number of reports[50,55,77] the photolysis of nickel carbonyl takes place by an induced mechanism which includes reversible stages:

$$Ni(CO)_4 \xrightarrow{h\nu} [Ni(CO)_4]^*, \quad (52)$$

$$[Ni(CO)_4]^* \rightleftharpoons Ni(CO)_3 + CO, \quad (53)$$

$$[Ni(CO)_4]^* + M \longrightarrow Ni(CO)_4 + M, \quad (54)$$

$$Ni(CO)_3 \xrightarrow[-CO]{} Ni(CO)_2 \xrightarrow[-CO]{} \longrightarrow NiCO \xrightarrow[-CO]{} Ni, \quad (55)$$

$$Ni(CO)_4 + Ni(CO)_2 \longrightarrow 2\,Ni(CO)_3; \quad (56)$$

M = RH, CO.

The effective rate constant of the photolysis of tetracarbonylnickel in undecane was found to be[50] 1.47×10^{-5} s^{-1}.

Studies by IR spectroscopy of the photolysis of $Ru(CO)_5$ and $V(CO)_6$ in the gas phase revealed coordinatively unsaturated fragments, highly reactive towards the starting carbonyls with which they form binuclear complexes.[78,79] The mechanism of the process has not been studied in detail.

The photolysis of the carbonyls of the chromium subgroup in the gas phase, initiated by laser radiation with wavelengths of 351, 308, and 248 nm, takes place by the successive elimination of the CO ligands from the excited carbonyl molecule.[80–85] The number of particles into which the original carbonyl molecule becomes fragmented depends on the energy of the absorbed photon. Photolysis with light of 351 and 308 nm produces only $M(CO)_5$ molecules, whereas light of 248 nm wavelength generates mainly $M(CO)_4$.[80,83] $M(CO)_5$ and $M(CO)_4$ are both very reactive, and they readily attack the initial $M(CO)_6$ molecule or the CO in the gas phase.

The irradiation of metal hexacarbonyls isolated in a matrix (N_2, Ar, CH_4, petroleum jelly) at 12–293 K with UV or visible light leads to the reversible elimination of one carbonyl group with formation of a relatively unstable pentacarbonyl of the metal, which interacts with the material of the matrix:[85–87]

$$M(CO)_6 \xrightarrow{h\nu} [M(CO)_6]^* \xrightarrow[-CO]{} \longrightarrow [M(CO)_5]^* \xrightarrow{Q} [M(CO)_5]^*Q; \quad (57)$$

M = Cr, Mo, W; Q = N_2, Ar, CH_4, petroleum jelly.

Complexes with organic and with inorganic ligands are formed also during the photolysis of the carbonyls of the chromium subgroup in the gas phase in the presence of various gaseous additives[81,88] or in solutions.[89–92] The coordinatively unsaturated carbonyl $M(CO)_5$ is generated as two structures: square pyramidal (C_{4v}) and trigonal bipyramid (D_{3h}), with a lifetime not greater than 20 μs.[89–91] During this time the carbonyl forms complexes with the solvent or with the additive, the rate of interaction of the triplet (D_{3h}) form being 2.3 times greater than that of the reaction of $M(CO)_5$ in the square pyramidal (singlet) form.[91] In the solvated $[M(CO)_5]^*Q$ complexes (where Q is an alcohol or an alkane) coordination takes place at the alkyl group.[90]

Thus the primary stage in the photolysis of the hexacarbonyls of chromium, molybdenum, and tungsten, and of tetracarbonylnickel (in condensed and in gaseous media) is the reversible elimination of one CO ligand and the formation of a coordinatively unsaturated metal carbonyl. The photolytic decomposition of the iron and cobalt carbonyls includes, in addition to the unimolecular decomposition of $[M_n(CO)_m]^*$, the interaction of this species with a non-excited carbonyl molecule. The contribution from the bimolecular reaction increases with increasing temperature, and also on changing from $Fe(CO)_5$ to $Fe_2(CO)_9$, and it becomes predominant in the case of $Co_2(CO)_8$. The photolysis of polynuclear metal carbonyls has been studied most fully[93–99] for the decacarbonyls of manganese and of rhenium, and for their mixed derivatives.

The primary stages in the decomposition of the $M_2(CO)_{10}$ complexes (M = Mn, Re) have been studied[93–98] by pulsed laser photolysis in the gas phase, in an argon matrix, and in solutions in hydrocarbons. It has been established that the electronic excitation of the decacarbonyls of these metals induces two types of primary reaction: (1) the breaking of the metal–metal bond, with formation of $M(CO)_5$ species, and (2) the elimination of one CO group, with formation of an $M_2(CO)_9$ species containing a bridging carbonyl group:

$$M_2(CO)_{10} \xrightleftharpoons{h\nu} 2\,M(CO)_5, \quad (58)$$

$$M_2(CO)_{10} \xrightleftharpoons{h\nu} (CO)_4M(\mu\text{-}CO)M(CO)_4. \quad (59)$$

The relative yield of $M_2(CO)_9$ increases with the quantum energy of the chosen radiation. Thus, for $Mn_2(CO)_{10}$ in cyclohexane the ratio of the quantum yields of reactions (58) and (59) was found to be 0.21, 0.37, and 0.74 at wavelengths of 266, 337, and 355 nm respectively. For decacarbonylrhenium the ratio of the quantum yields for the photolytic decomposition by these two channels is 0.13 at 355 nm.[94,95] Particles of $M(CO)_5$ and $M_2(CO)_9$ are removed in the reverse reactions (58) and (59), with rate constants of 8.8×10^8 and 3.6×10^9 dm^3 mol^{-1} s^{-1} for $Mn(CO)_5$ and $Re(CO)_5$ respectively, and 1.2×10^5 and 4.4×10^4 dm^3 mol^{-1} s^{-1} for $Mn_2(CO)_9$ and $Re_2(CO)_9$ respectively.[94,95] The free-radical nature of the carbonyls $Re(CO)_5$ and $Re_2(CO)_9$ formed in the photolysis of $Re_2(CO)_{10}$ in CH_2Cl_2 has been demonstrated by the ESR method using spin traps.[99]

Information on the photochemical reactions of the binuclear carbonyls of metals of the iron subgroup [except $Co_2(CO)_8$] is scarce and fragmentary. Thus, it has been shown by the matrix isolation method[74,100] that the primary photochemical reaction of the iron and osmium nonacarbonyls is the dissociation of the excited molecule with formation of the $M_2(CO)_8$ fragment:

$$M_2(CO)_9 \xrightarrow{h\nu} [M_2(CO)_9]^* \longrightarrow M_2(CO)_8 + CO; \quad (60)$$

M = Fe, Os.

The coordinatively unsaturated iron carbonyl $Fe_2(CO)_8$ can exist in two forms: bridged and nonbridged.[74] Octacarbonylosmium does not contain bridging carbonyl ligands, probably because the Os–Os bond is much longer than the Fe–Fe bond and therefore hinders the bridging coordination of the carbonyl ligand.[100] Lengthy photolysis of nonacarbonylosmium isolated in an argon matrix results in cleavage of the metal–metal bond, with accumulation of the mononuclear carbonyl $Os(CO)_5$ among the final products.[100] Homolytic cleavage of the iron–iron bond has not been observed.[74]

Very little has been published on the photochemistry of clusters containing three or more metal atoms.[70,76,101–106] It has been shown[101–105] that after the absorption of a photon the $M_3(CO)_{12}$ carbonyl clusters of the iron subgroup can undergo two types of change. When the energy of the absorbed quanta is high we observe elimination of one of the carbonyl ligands from the initial complex, with formation of an intermediate which can add on another ligand or a solvent molecule. At low photon energies the excited $[M_3(CO)_{12}]^*$ molecule

undergoes isomerisation into a nonradical cluster, different from the initial structure, which then suffers fragmentation:

$$M_3(CO)_{12} \xrightarrow[\lambda > 420\ nm]{h\nu} [M_3(CO)_{12}]^* \longrightarrow \quad (61)$$

$$\longrightarrow [M_3(CO)_{12}] \xrightarrow{L} M(CO)_4L + M_2(CO)_8L;$$

L = CO, C_2H_4.

$$M_3(CO)_{12} \xrightarrow[\lambda > 420\ nm]{h\nu} [M_3(CO)_{12}]^* \xrightarrow{-CO} \quad (62)$$

$$\longrightarrow [M_3(CO)_{11}] \xrightarrow{Q} [M_3(CO)_{11}]^*Q;$$

Q is the solvent [PPh_3, $P(OM_3)_3$, etc.]

Cleavage of one of the metal–metal bonds and changes in the cluster skeleton were observed also in the photochemical initiation ($\lambda > 340$ nm) of the reaction of dodecacarbonylcobalt with alkynes.[106]

After irradiation with visible or UV light, metal carbonyl molecules are converted into an unstable electronically excited state. The next stage is the elimination of one CO ligand by a unimolecular or bimolecular reaction. The resulting coordinatively unsaturated fragment can recombine with CO or with the initial carbonyl molecule, or it can form a complex with a solvent molecule or with another ligand. Binuclear and polynuclear carbonyl compounds also undergo fragmentation with cleavage of the metal–metal bond: in polymetal carbonyls this stage is followed by isomerisation of the cluster skeleton.

IV. Oxidation of the metal carbonyls by oxygen, ozone, and peroxides

1. Oxidation of the metal carbonyls by oxygen

The earliest information on the oxidation reactions of metal carbonyls was published with the first reports of the synthesis of these compounds. The reaction of carbonyl complexes with oxygen is used at present to prepare various oxide materials, including ferromagnetics.[1-3]

The mechanism first put forward[35,53,107-110] to explain the decomposition of pentacarbonyliron in the presence of oxygen postulated the conversion of the primary photolysis product of the $Fe(CO)_5$ [the nonacarbonyl $Fe_2(CO)_9$] into iron oxide:

$$Fe(CO)_5 \xrightarrow{h\nu} [Fe(CO)_5]^* \longrightarrow Fe(CO)_4 + CO, \quad (63)$$

$$Fe(CO)_4 + Fe(CO)_5 \longrightarrow 2\,Fe_2(CO)_9, \quad (64)$$

$$Fe_2(CO)_9 + \left(3+\frac{x}{2}\right)O_2 \longrightarrow Fe_2O_3 + (9-x)CO + x\,CO_2. \quad (65)$$

A detailed study[76,111] of the photochemical interaction of $Fe_n(CO)_m$ (n = 1, 2, 3; m = 5, 9, 12) with oxygen in hydrocarbon solvents failed to confirm this scheme. The photooxidation of these iron carbonyls in solutions is accompanied by the evolution of the carbon oxides CO and CO_2 and by the formation of a highly dispersed, X-ray amorphous form of Fe_2O_3 containing iron compounds characterised by the Fe–CO bond.[76,111] Accumulation of gaseous products takes place at the same time as the disappearance of the initial iron carbonyl from the reaction mixture. The relative yields of CO and CO_2 remain constant up to a 70%–80% conversion of the initial carbonyl. The quantum yields of the formation of products and of the disappearance of the $Fe_n(CO)_m$, calculated from the initial rates of the appropriate reactions, have been reported.[76,111] The interaction of $Fe_n(CO)_m$ with oxygen, initiated by UV radiation, is described by the equations

$$2\,Fe(CO)_5 + \tfrac{5}{2}O_2 \xrightarrow{h\nu} Fe_2O_3 + 8\,CO + 2\,CO_2, \quad (66)$$

$$Fe_2(CO)_9 + 2\,O_2 \xrightarrow{h\nu} Fe_2O_3 + 8\,CO + CO_2, \quad (67)$$

$$2\,Fe_3(CO)_{12} + \tfrac{11}{2}O_2 \xrightarrow{h\nu} 3\,Fe_2O_3 + 22\,CO + 2\,CO_2. \quad (68)$$

The initial rate of the photo-oxidation of these iron carbonyls is directly proportional to the number of quanta absorbed, and is independent of temperature between 278 and 313 K. The photo-initiated oxidation of $Fe_n(CO)_m$ by molecular oxygen in nonane is kinetically of first-order with respect to the initial iron carbonyl. In the case of pentacarbonyliron the order of the reaction with respect to oxygen is zero. For the nona- and dodecacarbonyls the rate of the photooxidation decreases with increasing oxygen pressure.

A spectrophotometric analysis of the reaction mixtures carried out during the oxidation showed the absence of photolysis products of the initial iron carbonyls. This suggests that the initial rates of the photochemical interaction of $Fe_n(CO)_m$ with O_2 are approximately an order of magnitude greater than the initial rate of the photolysis.[76,111] Since the concentrations of the carbonyl solutions did not exceed 10^{-4} mol dm^{-3}, and since the quantum yields of the oxidation of $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ are much lower than unity, the presence of chain reactions in the oxidation process seems unlikely. In keeping with these results the following mechanism has been proposed[76] for the photochemical oxidation of $Fe(CO)_5$ by oxygen through the formation of oxo and peroxo complexes of iron:

$$Fe(CO)_5 \xrightarrow{h\nu} [Fe(CO)_5]^*, \quad (69)$$

$$[Fe(CO)_5]^* \longrightarrow Fe(CO)_5 + h\nu, \quad (70)$$

$$[Fe(CO)_5]^* \longrightarrow Fe(CO)_4 + CO, \quad (71)$$

$$[Fe(CO)_5]^* + M \longrightarrow Fe(CO)_5 + M, \quad (72)$$

where M = $Fe(CO)_5$, O_2, RH.

$$[Fe(CO)_5]^* + O_2 \longrightarrow (CO)_3Fe\begin{matrix}O\\|\\O\end{matrix} + 2\,CO, \quad (73)$$

$$[Fe(CO)_5]^* + O_2 \longrightarrow (CO)_3Fe{=}O + CO + CO_2, \quad (74)$$

$$Fe(CO)_4 + O_2 \longrightarrow (CO)_3Fe\begin{matrix}O\\|\\O\end{matrix} + CO, \quad (75)$$

$$Fe(CO)_4 + O_2 \longrightarrow (CO)_3Fe{=}O + CO_2, \quad (76)$$

$$(CO)_3Fe\begin{matrix}O\\|\\O\end{matrix} + (CO)_3Fe{=}O \longrightarrow Fe_2O_3 + 6\,CO. \quad (77)$$

A kinetic analysis produced a satisfactory correspondence between the proposed scheme and the experimental data. The formation of oxo and peroxo complexes of iron has been observed during the oxidation of the $Fe(CO)_5^-$ anions by oxygen in the gas phase and in the interaction of iron atoms with O_2 in argon matrices at 15 K.[113]

The experimentally observed negative kinetic order with respect to oxygen in the photooxidation of nona- and dodecacarbonyliron suggests that the mechanism of the process includes the reversible formation of a complex between an excited carbonyl molecule and oxygen, and the dissociation of this complex as a result of bimolecular reactions with O_2 and with the solvent.[111]

$$Fe_n(CO)_m \xrightarrow{h\nu} [Fe_n(CO)_m]^* \quad (78)$$

$$[Fe_n(CO)_m]^* \xrightarrow[\text{non-radiative deactivation}]{\text{radiative and}} Fe_n(CO)_m \quad (79)$$

$$[Fe_n(CO)_m]^* + O_2 \rightleftarrows [Fe_n(CO)_m^*O_2]^* \quad (80)$$

$$[Fe_n(CO)_m^*O_2]^* \longrightarrow \text{products} \quad (81)$$

$$[Fe_n(CO)_m^* O_2]^* + RH \longrightarrow Fe_n(CO)_m + O_2 + RH \quad (82)$$

$$[Fe_n(CO)_m^*O_2]^* + O_2 \longrightarrow Fe_n(CO)_m + 2O_2 \quad (83)$$

This mechanism provided a basis for the mathematical modelling of the kinetics of the oxidation of nona- and dodecacarbonyliron by oxygen.[111] The solution of the direct kinetic problem gave the time dependences of the concentrations of $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ during the photooxidation. Comparing the calculated concentrations with experimental values gave a satisfactory agreement.[111] The effect of the initial concentrations of the reactants on the rate of the photooxidation of the carbonyls was also satisfactorily consistent with experiment.

We have studied the possibility of complex formation between pentacarbonyliron and oxygen by measuring the specific heat and the IR spectra of a mixture of reactants at 150–273 K.[114] It was found that the structure of the absorption bands of the Fe–CO bending vibrations in the pure pentacarbonyliron and in its mixtures with oxygen is strongly affected by replacing the gas phase by a solid phase (or vice versa). No difference was detected between the spectra of the pure pentacarbonyliron and those of $Fe(CO)_5$ with additions of O_2. The temperature dependence of the specific heat of the carbonyl complex deviates from a monotonic curve at 153–175 K, both with and without oxygen additions. However, the $C_p = f(T)$ curves of mixtures of these reactants and those of pure $Fe(CO)_5$ are almost identical.

The observed changes in the IR spectra of $Fe(CO)_5$ and in the temperature dependence of its specific heat at 150–190 K suggest the occurrence of specific processes in the substance during heating. The enthalpy of the process observed in this work was 16.22 ± 0.02 kJ mol^{-1}. These effects could be due to changes in the symmetry of the molecular structure of the pentacarbonyliron (for example, a transition from a configuration with D_{3h} symmetry to one with C_{4v} symmetry). Calculations[114] suggest that the ground state of $Fe(CO)_5$ is a singlet with a configuration of D_{3h} symmetry. An assessment of the possibility of finding pentacarbonyliron in a tetragonal bipyramid form (C_{4v} symmetry) gave a difference in energy $E(C_{4v}) - E(D_{3h}) =$ 22.5 kJ mol^{-1}. The calculated value is substantially greater than the experimental enthalpy of the process. The discrepancy arises partly from the seriously overestimated energy of the transition of the $Fe(CO)_5$ molecule from a D_{3h} to a C_{4v} state, due to the chosen method of calculation, and partly from the possibility of a more radical change in the structure of the $Fe(CO)_5$ molecule while only a slight deformation is observed owing to the distortion of the Fe–C–O angles.

Thus the IR spectroscopic and calorimetric studies of the interaction of pentacarbonyliron with oxygen at 150–273 K have failed to establish unambiguously the formation of donor–acceptor complexes between the reactants. However, the possible existence of these complexes has been suggested by the quantum chemical method. Calculations of the potential energy curve for the interaction between pentacarbonyliron and oxygen[114] show that the $Fe(CO)_5 + O_2$ system can be stabilised by the formation of the $Fe(CO)_5O_2^*$ complex, whose energy of dissociation into separate molecules is 20–30 kJ mol^{-1}. This result indicates only a tendency towards complex formation betwen $Fe(CO)_5$ and O_2. The calculated dissociation energy of $Fe(CO)_5O_2^*$ is extremely high.

We know[5] that the crystalline cobalt carbonyls $Co_2(CO)_8$ and $Co_4(CO)_{12}$ are converted into the blue carbonates when stored in air. The oxidation of $Co_2(CO)_8$ by oxygen in toluene was shown[115] to be autocatalytic, leading to the formation of $CoCO_3$, CO, and CO_2:

$$5\,Co_2(CO)_8 + 13\,O_2 \longrightarrow 10\,CoCO_3 + 24\,CO + 6\,CO_2. \quad (84)$$

It was suggested[115] that the interaction of octacarbonylcobalt with oxygen is a chain reaction in which the active species are the $Co_2(CO)_7$ particles formed by the thermal dissociation of $Co_2(CO)_8$. A study of the interaction of $Co_2(CO)_8$ with oxygen in nonane[116] failed to confirm this hypothesis.

The oxidation of the octa- and the dodecacarbonyl of cobalt in solution was found to be accompanied by the formation of carbon oxides and by the deposition of a solid phase containing $CoCO_3$, Co_2O_3 and CoO. The composition of the solid phase depends on the nature of the carbonyl and on the ratio of the initial concentrations of the reactants.[116] The kinetic order of the reaction of octacarbonylcobalt with oxygen in nonane with respect to the initial concentration of the carbonyl is close to unity. Changes in the oxygen pressure over the solution from 300 to 500 Torr do not affect the rate of oxidation. The activation energy of this process is 56.9 ± 2.0 kJ mol^{-1} (in the range of 283–313 K). Additions of CO at the start of the reaction lower the rate of oxidation.

Irradiation of a solution of $Co_2(CO)_8$ with UV light having a wavelength of 366 nm accelerates the oxidation of the cobalt carbonyl. The quantum yield of this process is much higher than unity ($\varphi = 5$), which suggests a chain mechanism for the reaction. Since the formation of $Co_2(CO)_7$ by the photolysis of $Co_2(CO)_8$ in solution has a low probability[76] it has been suggested that the $^{\cdot}Co(CO)_4$ radicals behave as active intermediates in the oxidation of octacarbonylcobalt by oxygen.[116] The energy of the metal–metal bond has been reported by various workers to be in the range between 48 and 125 kJ mol^{-1}, which is much lower than the energy needed to break the Co–CO bond (134.9 kJ mol^{-1}).[37] The $^{\cdot}Co(CO)_4$ radicals were detected by EPR during the sublimation of $Co_2(CO)_8$ on to a surface cooled to 77 K. Carrying out this process in the presence of oxygen produces[117] $(CO)_4CoOO^{\cdot}$ peroxide radicals. The creation of active intermediates during the oxidation of $Co_2(CO)_8$ by oxygen in a polystyrene matrix is also indicated by the partial decomposition of the polymer.[118]

As reported,[116] peroxide radicals are formed during the oxidation of $Co_2(CO)_8$ in solutions. However, the application of various physicochemical methods of detecting free-radical species during the interaction of octacarbonylcobalt with oxygen in nonane (EPR, spectrophotometric analysis of the aqueous phase after hydrolysis of the reaction mixture in the presence of H_2O_2, effect of ionol additions on the rate of the process) produced ambiguous results. Nevertheless the accurately determined quantum yields of these reactions confirm that a chain mechanism is involved:[116]

$$Co_2(CO)_8 + h\nu\,(\Delta) \longrightarrow [Co_2(CO)_8]^*, \quad (85)$$

$$[Co_2(CO)_8]^* \longrightarrow 2\,^{\cdot}Co(CO)_4, \quad (86)$$

$$^{\cdot}Co(CO)_4 + O_2 \longrightarrow {}^{\cdot}OOCo(CO)_4, \quad (87)$$

$$^{\cdot}OOCo(CO)_4 \rightleftarrows [OOCo(CO)_{4-x}] + x\,CO, \quad (88)$$

$$[OOCo(CO)_{4-x}] + Co_2(CO)_8 \longrightarrow$$
$$\longrightarrow (CO)_{4-x}CoOOCo(CO)_4 + {}^{\cdot}Co(CO)_4, \quad (89)$$

$$[OOCo(CO)_{4-x}] \longrightarrow CoO + CO_2 + (3-x)CO, \quad (90)$$

$$(CO)_{4-x}CoOOCo(CO)_4 \xrightarrow{} 2\,CoO + (8-x)CO \quad (91)$$
$$\xrightarrow{O_2} 2\,CoCO_3 + (6-x)CO \quad (92)$$
$$\xrightarrow{O_2} Co_2O_3 + CO_2 + (7-x)CO. \quad (93)$$

In addition to reactions (85)–(93) the deactivation of the excited $[Co_2(CO)_8]^*$ also takes place (on the solvent molecules, and on the reactants) during the photooxidation of $Co_2(CO)_8$.

The dependence of the composition and yield of the oxidation products of octacarbonyldicobalt on the initial concentrations of $Co_2(CO)_8$ and O_2 is due to reactions (89) – (93). Thus, increasing the oxygen pressure increases the amount of Co_2O_3 and CO_2 in the product, whereas an increase in the concentration of the carbonyl increases the amount of carbonate in the deposit, owing to the increased contribution of reaction (92).[116]

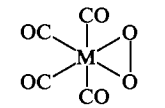
The interaction of dodecacarbonylcobalt with oxygen in nonane is slower (by a factor of 10) than the oxidation of $Co_2(CO)_8$, but it is accelerated by the action of UV radiation. The order of the reaction with respect to the initial concentration of the carbonyl is close to unity. Increasing the oxygen pressure over the solution has no effect on the rate of the process. The activation energy of the oxidation of $Co_4(CO)_{12}$ in solution is 74.6 ± 3.0 kJ mol^{-1} (at temperatures between 278 and 313 K). Additions of carbon monoxide to the gas phase at the start of the reaction do not affect the reaction rate. The quantum yield of the oxidation of $Co_4(CO)_{12}$ by oxygen, initiated by UV light having a wavelength of 366 nm, is 0.3. These results led to the conclusion[116] that the reaction of dodecacarbonylcobalt with oxygen does not involve a chain mechanism.

The oxidation of tetracarbonylnickel by oxygen has a period of induction and critical pressure limits, depending on the pressure and on the diameter of the vessel.[35] These observations suggest that the $Ni(CO)_4$ is oxidised by oxygen in the gas phase by a chain mechanism with chain breaking on the walls of the vessel.[35] The initial stage of the process is the elimination of one CO ligand from the excited carbonyl molecule, and the final products of the reaction are the carbon oxides CO and CO_2 and nickel oxide containing unchanged carbonyl.[107]

The oxidation of tetracarbonylnickel by oxygen in solutions is relatively slow.[50] Thus, at 293 K only 10% of the initial carbonyl is oxidised in 5 h. Irradiation of the reaction mixture with 313 nm light increases the rate of interaction of the $Ni(CO)_4$ with oxygen. The quantum yield of the oxidation of the nickel carbonyl is 1.12. Each mole of converted $Ni(CO)_4$ produces 2.92 mol of CO and 0.96 mol of $NiCO_3$. The kinetic order of the reaction with respect to the carbonyl compound is 1.2. A change in the pressure of oxygen over the solution from 300 to 500 Torr has no effect on the initial rate of the process. Adding the solid products of the oxidation of carbonylnickel to the reaction mixture has no effect on the rate of the interaction with oxygen. However, adding carbon monoxide before the start of the reaction lowers the rate of oxidation of the carbonyl complex. The experimental results are consistent with the following mechanism for the oxidation:[50]

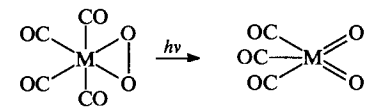
$$[Ni(CO)_4]^* \rightleftharpoons Ni(CO)_3 + CO, \quad (94)$$

$$Ni(CO)_3 \xrightarrow{-CO} Ni(CO)_2 \xrightarrow{-CO} \longrightarrow Ni(CO) \xrightarrow{-CO} Ni, \quad (95)$$



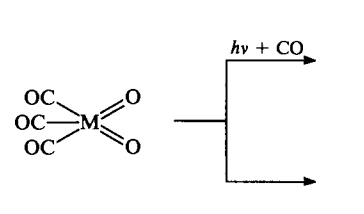
$$Ni(CO)_3 \longrightarrow Ni + (C) + CO + CO_2, \quad (96)$$

$$Ni(CO)_3 + O_2 \longrightarrow NiCO_3 + 2\,CO. \quad (97)$$



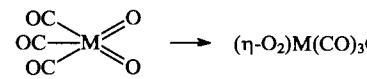
The interaction of the nonexcited $Ni(CO)_4$ molecule with O_2 can be ignored because the rate of the dark process is much lower than the rate of the photooxidation. A kinetic analysis of Eqns (94) – (97) showed that these reactions are consistent with experimental data. The effective rate constant for the oxidation of $Ni(CO)_4$ by oxygen at 293 K was 1.41×10^{-4} s^{-1}, which exceeds by an order of magnitude the rate of its photolytic decomposition.[50]

The oxidation of the carbonyls of the chromium subgroup in inert gas matrices has been studied by Almond et al.,[119–122] who showed that the primary stage of the process was the decomposition of an activated molecule of the carbonyl with formation of the pentacarbonyl of the metal and carbon monoxide. Further photolysis of the matrix leads to mixed carbonyl complexes which ultimately give the metal oxides MO_3 (or MO_2), CO, and CO_2.



$$M(CO)_6 \xrightarrow[CH_4,\ Ar,\ 12\ K]{h\nu + O_2} M(CO)_5 + CO \xrightarrow{h\nu + O_2}$$

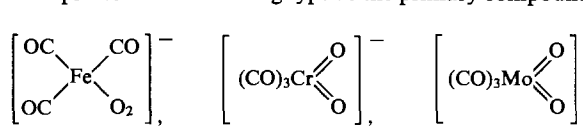
$$+ CO \quad (98)$$



$$+ CO \quad (99)$$

$$(100)$$

$$(101)$$



$$\longrightarrow (\eta\text{-}O_2)M(CO)_3O_2 \xrightarrow{h\nu} \quad (102)$$

$$\longrightarrow MO_3 + CO_2 + 2\,CO$$

The structure of the intermediate carbonyl–oxygen complexes was determined by IR spectroscopy, using the ^{18}O oxygen isotope.[120] It was shown by the isotope substitution method[122] that the MO_3 molecules (M = Mo, W) are formed from the peroxide $(\eta^2\text{-}O_2)M(CO)_3O_2$, which decomposes under the influence of the UV radiation to give MO_3 and oxygen atoms in the excited ^1D state. A sample of chromium dioxide having ferromagnetic properties and metallic conduction was obtained[121] by the photolysis of carbonylchromium in an argon matrix with O_2 additions.

It has been reported[123,124] that the arenetricarbonyls of metals (chromium, molybdenum, and tungsten) react with oxygen by previous coordination of the reactants.

The interaction with oxygen, in the gas phase and at room temperature, of the transition metal carbonyls $M(CO)_n^-$ (where M = Cr, Mo, W, Mn for $n = 5$; M = Fe, Co for $n = 4$), prepared by the electron impact method, leads to the formation of complexes of the following type as the primary compounds:

which are then converted into the metal oxides.[112,125]

Radicals of the peroxides $Re(CO)_5O_2^{\bullet}$ and $Mn(CO)_5O_2^{\bullet}$ were detected by EPR by using spin traps during the photolysis of $Re_2(CO)_{10}$ and $Mn_2(CO)_{10}$ in CH_2Cl_2 solutions in the presence of oxygen.[99,126] The active $Re(CO)_5O_2^{\bullet}$ species detach a hydrogen atom from a solvent molecule and form a hydroperoxide which dissociates further to give the radicals $Re(CO)_5^{\bullet}$ and $HOO^{\bullet}$.

Thus the oxidation of the carbonyl complexes of elements of Groups VI – VIII by oxygen in gaseous or liquid media is accompanied by the formation of the oxides and of the carbonate of the metal, and of carbon oxides. The composition and the yield of the reaction products are strongly dependent on the nature of the carbonyl complex and on the condition used for the oxidation. The process is accelerated under the influence of irradiation, and it can be hindered by additions of CO. The mechanism of the reaction includes the formation of intermediate carbonyl complexes of the metal in both radical and nonradical forms.

2. Oxidation of metal carbonyls by ozone

Data on the interaction of metal carbonyls with ozone are few. A study of the oxidation of pentacarbonyliron vapour by ozone–helium mixtures at room temperature and low pressure has been reported.[127] The product of the reaction was a highly dispersed diamagnetic aerosol of Fe_2O_3, formed according to the scheme

$$Fe(CO)_5 + O_3 \longrightarrow Fe(CO)_4 + CO_2 + O_2, \quad (103)$$

$$Fe(CO)_4 + O_3 \longrightarrow FeO + 4\,CO + O_2, \quad (104)$$

$$FeO + O_3 \longrightarrow Fe_2O_3 + O_2. \quad (105)$$

The oxidation of $Fe(CO)_5$ and $Ni(CO)_4$ vapours by ozone is accompanied by chemiluminescence in the 500–600 nm region,[128] due to the emission of light quanta by the excited FeO and NiO molecules formed in the exothermic reaction of the metal carbonyl with ozone. The oxidation of tetracarbonylnickel by ozone has been used in the purification of industrial effluents.[129]

Studies of the composition of the products and of the kinetics in the reaction of iron, cobalt, and nickel carbonyls with ozone in organic solvents have been reported.[50,130,131] The carbonyls of the iron subgroup were oxidised by an ozone–oxygen mixture by bubbling the gases through the liquid at 223–293 K. The final products of the reaction were the oxide and carbonate of the metal and the oxides of carbon; their composition and yield depended on the nature of the carbonyl complex.[50,130,131] The transformation of the metal carbonyl is accompanied by oxidation of the solvent. The rate of oxidation of pentacarbonyliron, octa- and dodecacarbonylcobalt, and tetracarbonylnickel in the liquid phase is determined by the rate of diffusion of ozone from the gas phase into the solution. The interaction of dodecacarbonyliron with ozone in nonane is activation-controlled, with an activation energy of 24.2 ± 5.3 kJ mol^{-1} at 255–293 K. The number of moles of ozone used to oxidise one mole of the carbonyl complex varies between 1 and 14, depending on the nature of the metal in $M_n(CO)_m$. In some cases (dodecacarbonyliron, tetracarbonylnickel) this number is smaller than the value calculated from the yield of oxygen-containing products. This is due to the contribution of oxygen to the oxidation of the metal carbonyl.[50,131]

The kinetic features of the interaction of metal carbonyls with O_3 in the liquid phase[132] and the increase in the reaction rate produced by increasing the polarity of the medium show that the rate-limiting step of the process is the attack of the metal–ligand bond by the ozone molecule.

Unlike the oxidation of metal carbonyls by oxygen, the interaction of $M_n(CO)_m$ with ozone is relatively fast and produces a large yield of CO_2 and of carbonate anions. The detailed mechanism of this process has not yet been established.

3. Oxidation of the metal carbonyls by peroxides

Pentacarbonyliron reacts violently with hydroperoxides to give iron(III) oxide and carbon monoxide.[133] Di(*tert*-butyl) peroxide oxidises the iron and cobalt carbonyls to $Fe(OBu^t)_3$ and $Co(OBu^t)_3$ (Schott and Wilke[134]). The kinetics and the mechanism of the interaction of $Co_2(CO)_8$, $Mn_2(CO)_{10}$, and $Fe(CO)_5$ with dibenzoyl peroxide in toluene at 293–333 K have been studied by volumetric and IR spectral methods.[135] The reaction is of the first order with respect to the cobalt and manganese carbonyls and to the peroxide. The interaction of $Fe(CO)_5$ with benzoyl peroxide is autocatalytic. Additions of styrene and of carbon monoxide suppress the oxidation of the manganese and iron carbonyls. The process is described by the reactions

$$Co_2(CO)_8 + 2\,PhC(O)OOC(O)Ph \longrightarrow 2\,Co(OOCPh)_2 + 8\,CO, \quad (106)$$

$$Mn_2(CO)_{10} + 2\,PhC(O)OOC(O)Ph \longrightarrow 2\,Co(OOCPh)_2 + 8CO, \quad (107)$$

$$Fe(CO)_5 + 1.5\,PhC(O)OOC(O)Ph \longrightarrow Fe(OOCPh)_3 + 5\,CO. \quad (108)$$

The formation of free-radical species during the oxidation of metal carbonyls by benzoyl peroxide has been suggested.[135] The rate-limiting step of the interaction of $Fe(CO)_5$ with PhC(O)OOC(O)Ph is the conversion of the carbonyl complex into iron(II) compounds, followed by their fast oxidation to $Fe(OOCPh)_3$.

Complexes of zero-valent nickel are oxidised by dibenzoyl peroxide and by di(*tert*-butyl) peroxide, giving nickel benzoate and *tert*-butoxide.[134] Studies[136] of the interaction of chromium, molybdenum, tungsten, and iron carbonyls with organosilicon peroxides suggest that the primary stage in the reaction of $Fe(CO)_5$ with $Me_2Si(OOBu^t)_2$ is the coordination of two molecules of the peroxide to the carbonyl ligands of the pentacarbonyliron. The interaction of $Mo(CO)_6$ with cyclohexyl and 1-methylcyclohexyl peroxides in heptane also leads to the formation of out-of-sphere complexes with an enthalpy of formation of 6.3 kJ mol^{-1}.[137]

Hexacarbonylmolybdenum is oxidised by *tert*-butyl and cumyl hydroperoxides in alkanes at temperatures above 373 K.[138] The use of an aromatic hydrocarbon as the solvent increases the rate of the oxidative degradation of the $Mo(CO)_6$ by hydroperoxides because of the conversion of the initial metal complex into an arenemolybdenumtricarbonyl complex. The latter species is readily oxidised to molybdenum oxides and peroxides. The hydroperoxides are catalytically decomposed on these products, and the resulting intermediates interact with the $Mo(CO)_6$.[138]

The EPR method with spin traps has been used[139] to study the free-radical dissociation of Bu^tOOBu^t in the presence of various metal carbonyls in hydrocarbon solutions. The formation of adducts of $Bu^t\dot{O}$ radicals with the spin traps was demonstrated, and a scheme which included an initial electron transfer from the carbonyl to the peroxide was proposed.

The writers have studied[140,141] the oxidation of the carbonyl complexes of the elements of the iron subgroup by *tert*-butyl and cumyl hydroperoxides and by *tert*-butyl peroxide in paraffin solutions, and by hydrogen peroxide in water. The reaction is very fast at room temperature, and is accompanied by the formation of solid deposits, carbon oxides, and transformation products of the peroxide fragments. The solid phase precipitated from the reaction mixture is an oxide or carbonate of the metal, or a mixture of the two compounds, containing adsorbed molecules of the solvent or of water. In the case of pentacarbonyliron the precipitate contains (in addition to iron oxide) iron compounds in which the metal atom is attached to CO groups.[141]

Complete conversion of $M_n(CO)_m$ (where M = Fe, CO) is achieved with an excess of hydroperoxide (6-fold and 30-fold for the iron and the cobalt carbonyl respectively). The excess of hydroperoxide in comparison with the stoichiometric amount is attributed to the catalytic decomposition of the peroxidic compound into products containing metal atoms in different states of oxidation. The interaction of $M_n(CO)_m$ with the organic hydroperoxides is accompanied by the oxidation of the paraffin used as solvent to a mixture of secondary alcohols in a yield of up to 10% relative to the ROOH consumed.[141]

The reactivity of the metal carbonyls towards organic hydroperoxides decreases as the nucleus of the cluster is increased in the sequence $Fe(CO)_5 > Fe_2(CO)_9 > Fe_3(CO)_{12}$ and $Co_2(CO)_8 > Co_4(CO)_{12}$. The reaction of $M_n(CO)_m$ with hydroperoxides is accompanied by oxidation of the central atom and of the ligands. Inner sphere changes in the ligands probably take place, as suggested by the presence of an oxalate ester among the reaction products.[141]

EPR studies of the oxidation of metal carbonyls by peroxidic compounds have shown that the spectra of a reaction mixture of pentacarbonyliron or its monotriphenylphosphine derivative with organic hydroperoxides in hexane or toluene at 203–293 K include signals from paramagnetic species, in particular from $Fe(CO)_5^{+\cdot}$ or $Fe(CO)_4PPh_3^{+\cdot}$. A signal from the $RO_2^{\cdot}$ radical has also been detected in the EPR spectrum of the products of the interaction of *tert*-butyl or cumyl hydroperoxide with the carbonyl derivatives of iron. This radical is generated by the catalytic decomposition of alkyl hydroperoxides. By using the 2- methyl-2-nitrosopropane spin trap in these measurements the writers established the presence of adducts with RO$^{\cdot}$ radicals.[141]

The oxidation of the carbonyls of metals in the iron subgroup by peroxidic compounds can be described by taking pentacarbonyliron as an example:

$$Fe(CO)_5 + ROOH \longrightarrow \{HO^-, Fe(CO)_5^{+\cdot}, RO^{\cdot}\} \longrightarrow \quad (109)$$

$$\longrightarrow RO^{\cdot} + [HO^-, Fe(CO)_5^{+\cdot}],$$

$$[HO^-, Fe(CO)_5^{+\cdot}] \longrightarrow [(CO)_4Fe{-}OH]^{\cdot} + CO, \quad (110)$$

$$[(CO)_4Fe{-}OH]^{\cdot} + ROOH \longrightarrow [(CO)_4Fe{-}OOR]^{\cdot} + H_2O, \quad (111)$$

$$[(CO)_4Fe{-}OOR]^{\cdot} \longrightarrow 4\,CO + FeO + RO^{\cdot}, \quad (112)$$

$$[(CO)_4Fe{-}OOR]^{\cdot} \longrightarrow CO_2 + [(CO)_3Fe{-}OR]^{\cdot}, \quad (113)$$

$$[(CO)_4Fe{-}OOR]^{\cdot} \longrightarrow [(CO)_3Fe{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{O}{\|}}{C}{-}OR]^{\cdot}, \quad (114)$$

$$[(CO)_3Fe{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{O}{\|}}{C}{-}OR]^{\cdot} + OR^{\cdot} \longrightarrow (CO)_2Fe\begin{array}{l}\diagup C(O)OR \\ \| \\ O \\ \diagdown C(O)OR\end{array} \longrightarrow$$

$$\longrightarrow \begin{array}{l}C(O)OR \\ | \\ C(O)OR\end{array} + FeO + 2\,CO, \quad (115)$$

$$[(CO)_nFe{-}OH\ (\text{or } OR)]^{\cdot} + {}^{\cdot}OR \longrightarrow$$

$$\longrightarrow n\,CO + FeO + ROH\ (\text{or } ROR), \quad (116)$$

$$2\,[(CO)_nFe{-}OH\ (\text{or } OR)]^{\cdot} \longrightarrow$$

$$\longrightarrow H_2O\ (\text{or } ROH) + CO + [(CO)_3FeOFe(CO)_3]; \quad (117)$$

$n = 3, 4.$

$$2\,[(CO)_4Fe{-}OOR]^{\cdot} \longrightarrow (CO)_2Fe\begin{array}{l}\diagup C(O)OR \\ \diagdown C(O)OR\end{array}{-}\underset{\underset{O}{\|}}{C}{-}OFe(CO)_4 \longrightarrow$$

$$\longrightarrow \begin{array}{l}C(O)OR \\ | \\ C(O)OR\end{array} + 4\,CO + [(CO)_2FeO\underset{\underset{O}{\|}}{Fe}], \quad (118)$$

$$Fe^{n+} + ROOH \longrightarrow RO^{\cdot} + Fe^{(n+1)+} + HO^-, \quad (119)$$

$$Fe^{(n+1)+} + ROOH \longrightarrow RO_2^{\cdot} + Fe^{n+} + H^+; \quad (120)$$

Fe^{n+} denotes any oxidised form of the carbonyl complex.

$$RO^{\cdot}(\text{or } RO_2^{\cdot}, [Fe]^{\cdot}) + SH \longrightarrow$$

$$\longrightarrow ROH\ (\text{or } ROOH, [Fe]H) + S^{\cdot}. \quad (121)$$

SH is the solvent.

The primary step in this process is the transfer of an electron from the carbonyl to the peroxide with formation of an ion–radical pair. This reaction may be preceded by complex formation between the reactants, as was shown for the hexacarbonyls of the Group VI metals.[136, 137] The subsequent transformation of the ion–radical pair and the interaction of the resulting species with a molecule of the peroxide cause the accumulation of oxygenated iron compounds, carbon oxides, and oxalate esters. The appearance of oxidised forms of iron in the system is responsible for the catalytic decomposition of the hydroperoxide.

The interaction of metal carbonyls with peroxidic compounds is a complicated process with a radical-chain mechanism. Its primary stage is the transfer of an electron from the carbonyl to the peroxide with formation of cation-radical carbonyls of the metals.

V. Conclusions

The thermal, photolytic, and oxidative degradation processes of the carbonyl complexes of metals are widely used in the preparation of highly dispersed powders and of films. The great diversity of the known metal carbonyls makes it impossible to describe their thermal, photolytic, and oxidative transformations in terms of a single mechanism.

However, in most cases of the thermal and the photodecomposition of metal carbonyls the primary stage consists in the elimination of one CO ligand from a thermally or photochemically activated $[M_n(CO)_m]^*$ molecule with formation of a coordinatively unsaturated fragment. During thermal decomposition this stage is at equilibrium, and the rate of the process is suppressed by additions of carbon monoxide for many typical compounds in this class. In contrast to the thermal processes, in the photolysis of the metal carbonyls the contribution of the recombination of the coordinatively unsaturated fragment with the carbon monoxide is insignificant, since for the majority of metal carbonyls this interaction is formally spin forbidden. The coordinatively unsaturated fragment dissociates by further elimination of CO radicals, or alternatively it can react with the initial molecule (producing a binuclear carbonyl) or form a solvato complex.

Instead of the removal of one CO ligand from the excited carbonyl complex of the metal the primary photochemical act leading to the observed products may consist in the bimolecular interaction of an activated $[M_n(CO)_m]^*$ molecule with a nonactivated molecule. In binuclear and polynuclear metal carbonyls another possibility is fragmentation with breaking of a metal–metal bond, preceded in some cases by the isomerisation of the skeleton of the complex.

The stability of the iron carbonyls towards thermal decomposition decreases in the order $Fe(CO)_5 > Fe_2(CO)_9 > Fe_3(CO)_{12}$. In the photolytic decomposition the same compounds are arranged in the opposite stability sequence. Evidently the photochemical excitation of the dodeca- and nonacarbonyliron to the triplet state (from which the initial compound can dissociate) requires a greater expenditure of energy than the activation of $Fe(CO)_5$. This difference is due to the presence (in the former compounds) of many bonds over which the energy of the absorbed photon has to be redistributed.

The thermal and the photolytic decomposition of the carbonyl complexes are complicated by catalytic reactions on the resulting metallic surface, which adsorbs pentacarbonyliron and assists the nucleation of anion radicals. The latter interact with the initial molecule of the carbonyl complex and are converted into polynuclear anion radicals which ultimately decompose and contaminate the metal with carbide and oxide impurities. In some cases CO molecules are incorporated into the metallic phase.

The interaction of metal carbonyls with oxygen, ozone, and peroxides is accompanied by the formation of oxides and carbonates of the metals and by the oxidation of CO to CO_2. The reaction of $M_n(CO)_m$ with O_2 is initiated by UV radiation. The rate of the photo-oxidation of the carbonyls of Group VIII metals is approximately an order of magnitude greater than the rate of their photochemical decomposition. This is probably because the reaction between the coordinatively unsaturated carbonyl $M_n(CO)_{m-1}$ (or the metal carbonyl radical) and oxygen is spin-allowed and fast.[142] The reverse recombination of $M_n(CO)_{m-1}$ and CO is forbidden. The photolysis of the carbonyls of Group VI metals takes place through the reversible elimination of one carbonyl group.

The competition between CO and O_2 for the reaction with $M(CO)_5$ is apparently responsible for the lower reactivity of the chromium, molybdenum, and tungsten carbonyls towards the oxidation by oxygen. The mechanism of the oxidation of the carbonyl complexes is strongly dependent on the nature of the resulting intermediate species, varying from a radical mechanism (peroxidic metal carbonyl radicals of cobalt, manganese, etc.) to a molecular mechanism (carbonyl–oxygen complexes of iron, chromium, molybdenum, tungsten, etc.).

The reaction of the carbonyls of Group VIII metals with peroxidic compounds is a free-radical chain process in which the primary stage is electron transfer from the metal carbonyl to the peroxide, with formation of cation radicals of the metal carbonyls. It may be assumed that a stage of complex formation between the reactants occurs before the electron transfer. In conclusion we should note that in spite of some useful advances in identifying the products of the oxidative reactions of the carbonyls of elements in Groups VI–VIII, their kinetic features, and the influence of the medium and of other factors, the detailed mechanisms of these processes have not yet been established.

Abstract. Experimental and theoretical data on the structure of clusters of Group IIA and IIIA metals are summarised. General trends in the properties of the clusters as a function of nuclearity are outlined, and special points on the dependences, corresponding to the so-called magic numbers, are identified. Data on the reactivity of clusters in the gas phase are used to establish the anomalies corresponding to these points. It is shown that the reactivity of mixed clusters obeys more complex relationships, determined by their electronic structure and geometry. A new type of organomagnesium cluster is described, and shown to be promising as a component of catalytic systems. The cryochemical synthesis of giant clusters of transition metals, which offer a high reactivity and catalytic activity, is described. The bibliography includes 176 references.

I. Introduction

Metal clusters occupy an intermediate position between metal atoms (which display the greatest possible dispersion) and bulk metals, and they constitute a new type of metallic state. According to the generally accepted terminology[1] clusters are species containing between 2 and 10^5 interconnected metal atoms, of size varying from 0.5 to several tens of nanometres. The boundary between the cluster and the metallic state is hard to define. Ultradispersed powders, and especially colloidal metals with a particle size of $10-10^3$ nm, show marked differences from bulk metals. They are often called giant or supergiant clusters. This terminology will be adopted here.

The special properties of the cluster state and the wide range of potential applications of clusters and colloidal metals in various areas of science and technology have stimulated an intense interest in this field of research. The results have been discussed in monographs[1-4] as well as in research papers. However, until recently most of the work had been aimed at clusters of the transition metals, and an interest in clusters of the typical (non-transition) elements has become evident only in the last few years. This new topic has come to the fore because of recent advances in experimental and (even more so) in computational methods, which have made the clusters of typical metals a promising field of study. Because of the great experimental difficulty met in the preparation and study of clusters we have witnessed an unusual state of affairs in which theoretical studies have outstripped the experimental work.

This review is aimed at clusters and colloidal solutions of metals from Groups IIA and IIIA. It does not attempt to provide comprehensive information on the physics and the physical chemistry of these materials: its object is to draw attention to the least fully investigated and yet the most interesting aspect of the problem: the chemical properties and the likely applications of clusters of typical metals.

II. Preparation of clusters in solution

The characteristic properties of the metals in Group IIA are the presence of an occupied *s* shell and the absence of *p* electrons. In terms of the general propositions of the theory of valence the bond of the M_2 dimer is not likely to be strong: occupied bonding and antibonding σ MO are formed from the two *s* AO. Not surprisingly, therefore, no successful attempts to prepare homonuclear clusters of IIA group metals by 'classical' methods have so far been reported. Only one paper[5] describes the reduction of the tetramer of *o*-phenylmercury by magnesium in tetrahydrofuran (THF), which gave a crystalline complex of the tetramer of *o*-phenylmagnesium with THF. Each magnesium atom in the complex contributes to the formation of one σ bond and two bridging δ bonds with the phenyl radicals, and it is also coordinated with one molecule of THF. Under these conditions the distance between the magnesium atoms lies between 3.546 and 2.804 Å. The latter value formally justifies the assignment of this compound to the cluster type. However, the lack of data on the direct interaction between the magnesium atoms makes this assignment ambiguous.

A different state of affairs is found with the Group IIIA metals. The presence of a valence *p* electron allows the formation of a covalent metal–metal bond, and the preparation of cluster compounds by conventional chemical methods seems more likely. Significant differences are noted between aluminium, which has a stable (3+) and an unstable (1+) oxidation state,

and gallium and indium. The latter metals have, in addition, an even less stable state (2+). The synthesis of their cluster compounds by the dimerisation of derivatives of the bivalent metals immediately suggests itself:

$$2MX_2 \rightleftharpoons X_2M{-}MX_2.$$

In reality the dimers of the halides of bivalent indium and gallium are ionic species, $M^+[MX_4]^-$, and do not contain metal–metal bonds.[6] There are two methods of stabilising the cluster halides of indium and gallium. The first consists in complex formation with dioxan or other organic donors. In the resulting complexes of composition $M_2X_4 \cdot 2D$ (where D is a donor) the length of the Ga–Ga bond[7–9] is 2.40 ± 0.02 Å, and that of the In–In bond[10] is 2.775 Å. The cluster nature of these compounds was confirmed by X-ray diffraction and from their vibrational spectra. Complexes can also be prepared by the interaction of suitable donors with the metal dihalides in a hydrocarbon medium (for example, in benzene). Anion salts ($M_2X_6^-$) are another type of compound of these metals. Thus, in the ammonium salts $[R_4N]_2^+Ga_2Cl_6^{2-}$ the Ga–Ga distances are 2.39 Å (R = Me)[11] and 2.42 Å (R = Pr^i),[12] and in the triphenylphosphonium salts[13] they are 2.407–2.415 Å. In spite of the short interatomic distance the metal–metal bonds are weak, as shown by the low frequencies of the stretching vibrations (between 122 and 235 cm^{-1} in the case of gallium[14] and between 120 and 150 cm^{-1} for indium[15]). The dissociation energy of the metal–metal bond in these cluster halides was estimated[6] to be 25–35 kcal mol^{-1}. Another example of compounds containing a metal–metal bond are the gallium and indium chalcogenides, in which the Ga–Ga distance is 2.4–2.5 Å and the In–In distance is 2.75 Å. These compounds can be treated as salts of the simplest (M_2^{4+}) cluster cation.[16]

Only the simplest binuclear compounds have been obtained using classical methods of synthesis,[17] though the $In_6(C_5Me_5)_6$ hexamer (which is formally a cluster with an octahedral In_6 metal core) has been synthesised by the reaction between InCl and $Li(C_5Me_5)$. However, the In–In distances in this compound are so large (3.9 Å) that there is no justification for assuming the formation of metal–metal bonds. Even at 55 °C this product sublimes exclusively as a monomer.

Many attempts to prepare cluster compounds of aluminium in solutions have been reported. The formation of Al–Al bonds has been suggested, for example, in a mixed alkyl derivative of boron and aluminium synthesised by the reaction between Al_2Me_6 and $B_2(Me_4N)_4$, but no strict proof of this claim was advanced.[18,19] The same is true of the compound $[Bu^i_2Al]_2$, prepared[20] by treating Bu^i_2AlCl with potassium.

X-Ray confirmation of the structure of the cluster compounds of aluminium synthesised under normal conditions has only recently been obtained. The reduction (with potassium) of the compound $[(Me_3Si)_2CH]_2AlCl$ gives a binuclear product with an Al–Al bond.[21] The reaction of the tetrameric complex of aluminium(I) chloride with $Mg(C_5Me_5)_2$ at −78 °C in the absence of water vapour and oxygen gave[22] the product $[Al(C_5Me_5)]_4$, containing a tetrahedral metallic core with an Al–Al distance[22] of 2.773 Å. The synthesis of a salt of composition $K_2[Al_{12}Bu^i_{12}]$, stable up to 150 °C and containing a metal core consisting of the Al_{12} icosahedron (Al–Al distance 2.679 and 2.696 Å), has been reported.[23] This example offers the hope of a synthesis (in the near future) of cluster compounds of Al with metal cores in the form of regular polyhedra. One further example is provided by melts (prepared in a corundum crucible) of crystalline Al_7Te_{10}, in which the metal–metal distance (2.6 Å) is shorter than in the organic clusters.[24] However, the limitations of the classical approach cannot be ignored: there have been only two reports of the synthesis of cluster compounds with a substantial metal core, and there are no prospects to date of preparing ligand-free clusters by this method.

III. Synthesis and properties of clusters in the gas phase

Fully developed methods of preparing and studying metal clusters in the gas phase are now available. The key stage in these methods is the flash evaporation of a relatively large amount of the metal, achieved (for example) by ion or electron bombardment. More recently, powerful laser pulses have been used for the same purpose. The evaporated atoms and ions are entrained in a stream of inert gas in which the clusters are formed. The temperature of the particles can be rapidly lowered to room temperature by suddenly expanding the flow. If necessary the ions can be selected by means of a quadrupole mass spectrometer. The final stage consists in the mass spectrometric detection of the particles, either directly or after appropriate physical or chemical perturbations.

Clusters of the Group IIA metals have not been studied extensively. For Be the dissociation energy of the dimer (0.1 eV) has been determined.[25] For Mg_2 the absorption spectra have been measured,[26] and a dissociation energy of 0.05 eV has been reported.[27] It was also shown that the ionisation potential of Mg_2 is 6.7 eV, which is much lower than for atomic magnesium, and that the dissociation energy of the charged Mg_2^+ ion is close to 1 eV.[28] Thus the removal of one electron strengthens the magnesium–magnesium bond quite substantially.

Aluminium clusters have been studied in greater depth. Experiments with ionised clusters have yielded reliable data on their electron affinities (EA) and ionisation potentials (IP), shown in Table 1. It can be seen that the ionisation potential increases significantly on going from the atom (6.0 eV) to the small clusters, but then gradually decreases. For $N > 14$ it falls below the value for the atom. However, it is still far from the electronic work function for the compact metal (4.24 eV). Even for $N = 55$ the IP stays at 4.95 eV.[29]

Table 1. Electron affinity and ionisation potentials of Al_N clusters.

N	IP/eV	EA/eV	Ref.
2	5.9–6.3	–	29–31
3	6.4–7.2	–	29–31
3	–	1.4–1.9	32–34
4–6	6.0–6.5	–	29–31
4–6	–	1.74–2.7	32, 33
7	6.0	–	29
7	–	2.0–2.6	32, 33
8–12	6.2	–	29
8–12	–	2.2–3.2	29, 32–34
13	6.4	–	31
13	–	2.8–3.5	32–34
14–22	⩽ 5.5	–	29, 31
14–22	–	2.5–2.8	32, 33
23	–	2.86	32
24–25	–	2.75	32
26–32	–	2.8–2.85	32
55	4.95	–	29

The electron affinity, which is negative for the atom, increases rapidly for $N = 2–3$, but beyond this point the growth becomes slower. In clusters with 24–32 atoms the EA increases at the rate of 0.1 eV per 8–10 metal atoms in the cluster.

The most interesting observation is the presence of several special points in the dependence of these parameters on the size of the cluster. Thus the electron affinity of Al_6, Al_{23}, and especially Al_{13} is significantly higher than for their neighbours. The low ionisation potential of the Al_7 cluster is also noteworthy. This implies an abnormally high stability for the Al_6^-, Al_7^+, Al_{13}^-, and Al_{23}^- systems, which contain 19–20, 40, and 70 valence electrons. This is an example of the law of magic

numbers, well known in the chemistry of clusters, according to which systems having certain numbers of valence electrons have anomalously high stabilities.

Experimental tests of the magic numbers in terms of the dissociation energies of neutral clusters have not yet been carried out. We only know that the dissociation of Al_2 requires[35] an energy of 1.34 eV. More data are available for charged clusters. The high thermal stability of several Al_N^+ clusters, including easily identifiable clusters with 20 valence electrons (of composition Al_7^+),[36] has been demonstrated. A similar result has been reported[29,37] for cationic clusters of aluminium, which show a tendency for an increase in stability with nuclearity: anomalously high stabilities were found in the clusters with 7, 13, 14, and 23 aluminium atoms, containing 20, 38, 41, and 68 valence electrons respectively. This is consistent with data on clusters obtained[38] by bombarding an aluminium target with Xe^+ ions having an energy of 9 eV: in this case a stability maximum was again observed for the clusters with 7, 14, and 23 metal atoms. Less striking examples of the same effect were found in trinuclear clusters (8 electrons). Detailed studies of the photodissociation of Al_N^+ clusters revealed the existence of two main dissociation paths:

$$Al_N^+ \longrightarrow Al^+ + Al_{N-1}, \quad (1)$$

$$Al_N^+ \longrightarrow Al_{N-1}^+ + Al. \quad (2)$$

Path (1) is more typical of clusters with 5–7 and with 9 atoms; path (2) usually corresponds to 8 or 10–17 metal atoms.[39] The dissociation energies vary between wide limits (from 1.5 to 2.6 eV) and are anomalously high (3.1 eV) in cationic clusters with 7 and 13 aluminium atoms. Data[30] for small clusters ($N \leqslant 7$) differ quantitatively from other reports,[39] but they also point to a large increase in the strength of the bond on going from $N = 6$ ($E_{diss} = 1.55$ eV) to $N = 7$ (2.25 eV). Surprisingly, the elimination of Al^+ or Al from Al_3^+ ($E_{diss} = 1.3$ or 1.12 eV) is more difficult than the dissociation of Al_2^+ or Al_4^+.

The existence of magic numbers has been confirmed also for anionic clusters. In a mass spectrometric study of anionic clusters of aluminium containing up to 70 atoms the species Al_{13}^- (40 electrons) was found to have a very high stability, and a jump was noted also for Al_{13}^- (70 electrons).[40]

Gallium and indium clusters show the same magic numbers as the aluminium clusters, the effect being most marked for the M_7^+ clusters.[36]

The experimental determination of the electronic state of the clusters is a difficult problem. Measurements[41] of the magnetic moments of Al_N particles ($N = 2-25$) led to the conclusion that these clusters are in low-spin states: doublet for odd N and singlet or triplet for even N. In ESR studies of the Al_3 trimer (prepared by condensation of aluminium from the gas phase into an adamantane matrix[42]) it was found that the spectrum corresponds to a particle having the form of a regular triangle and in a quartet state. The state of the simplest (Al_2) particle is also not entirely clear. An analysis of the electronic spectra of the aluminium, indium, and gallium dimers, which have (when in a matrix) two groups of bands at $(1.3-1.5) \times 10^4$ and $(2.4-3.0) \times 10^4$ cm^{-1}, led to the assignment of both groups of bands to transitions from a $^1\Sigma_g^+$ state.[43] However, an analysis of the vibrational spectra and of the emission spectra suggests that the ground state is $^3\Sigma_g^-$.[44] We shall show in the next section that this ambiguity arises from the existence of several almost degenerate states.

IV. Structure and properties of clusters from quantum chemical calculations

Most of the currently available information on the clusters of typical metals has been obtained by quantum chemical methods. Let us examine the results in some detail.

Theoretical studies can be subdivided into two groups: quantitative calculations and calculation of a qualitative or semiquantitative character, based on the spherical shell model.

The spherical shell model[44,45] starts from the assumption that the metal core is most closely packed when in a spherical symmetry. The whole system is divided into two spheres: an inner (core) and an outer sphere (shell). The core includes the nucleus and all the electrons except the valence electrons, and the shell includes the valence electrons. It can easily be seen that in the case of a spherical symmetry this description is formally identical to the description of an atom in the one-electron approximation. Therefore the wave functions of the electrons in the shell can be split into a radial and an angular part. Like the spherical harmonics of the atom the angular functions will have s, p, d, f AO symmetry depending on the orbital angular momentum. The maximum numbers of electrons in the subgroups of this pseudoatom are the same as the typical numbers for atoms: 2, 6, 10, 14, etc. However, the greater diffuseness (as compared with the AO) of the cluster functions results in a number of differences. In particular, the normal sequence of increasing energies for the AO,

$$ns < np < (n+1)s \approx nd < (n+1)p < (n+1)d \approx nf$$

is replaced by

$$ns < np < nd < (n+1)s < nf < (n+1)p < ng < (n+1)d.$$

The following electron configurations are the most stable in this model: $1s^2p^6$, $1s^2p^6d^{10}2s^2$, $1s^2p^6d^{10}f^{14}2s^2p^6$, $1s^2p^6d^{10}f^{14}g^{18}2s^2p^6$, $1s^2p^6d^{10}f^{14}g^{18}2s^2p^6d^{10}3s^2$, containing 8, 20, 40, 58, and 70 electrons respectively. We can easily see that these are the same magic numbers as those which had been discovered experimentally. According to the model the species Al_3^+, Al_7^+, Al_{13}^-, Al_{19}^-, and Al_{23}^- should be the most stable. This is consistent with the IP and EA data quoted above, and with the corresponding cluster stabilities. The increased stability of Al_{14}^+, Al_{23}^+, etc. can be attributed to the fact that the occupancy of their electron shells is the closest to the stable configuration in the Al_N^+ series.

The simple and objective description of the clusters, and especially the possibility of predicting the magic numbers, are the strong points of the spherical shell model. Its limitations, however, are equally obvious. For small N values the real symmetry of the core is far from spherical. In general, as was pointed out by DeHeer et al.,[45] the predictions of the model are satisfactory for $N > 40$. The most serious limitation arises from the failure of the model to take account of the real geometry of the cluster. This limitation can be partially eliminated by adopting a variant of the theory which offers a compromise: the stipulation of a spherically symmetrical potential is retained, and departures of the geometry from the ideally spherical are treated as perturbations. Thus, the geometry of the sodium, magnesium, aluminium, and lead clusters has been optimised[46] by treating the ions of the core as exposed to a spherically averaged potential not identical to the potential of the simplest model.

Most of the cluster calculations were carried out by *ab initio* methods at various levels, or in the approximation of the local density functional (LDA). The electron correlation was allowed for by the Møller–Plesset theory at different levels (MP-2, MP-4, etc.) or by introducing the configurational interaction (CI) with allowance for singly and doubly perturbed states (CISD), as well as the CI for different initial configurations (MRCI, MRCI-SD).

1. Be clusters

The main result obtained at the SCF level was that the stability of the Be_2 dimer is very low and that the dissociation energy increases rapidly with N. Whereas the atomisation energy of one metal atom (D/N) at this level of calculation is only 0.05 eV for Be_2, in Be_3 it already has double that value and in Be_4 D/N is 0.43 eV.[47] This is explained by the rapid growth of the degree of sp hybridisation attributed to the relatively similar sizes of the $2s$

and $2p$ AO, which favour the formation of hybrid sp AO. SCF calculations also point to a large increase of the electron affinity with increase of N in the Be_N clusters. Even in the tetramer we find[48] EA $\approx$ 1 eV. For the neutral tetrahedral Be_4 molecule at the SCF (or a more precise) level a D/N value of 0.6 eV has been calculated,[47] with an interatomic distance of 2.08 Å.

Calculations allowing for electron correlation[49-54] have identified a series of important properties of the structure of Be clusters: a rapid increase in D/N with N (up to a value in excess of 0.9 eV for Be_{13}) with approximately constant values of Be–Be distance (2.0–2.2 Å) in the clusters, a similarity in the energies of different isomers (for example, the Be_{13} clusters of D_{3h} and D_{3d} symmetry differ by 5% in energy), and a singlet ground state. All the published papers have stressed the important role of the electron correlation, but according to Rubio et al.[51] in the case of large clusters ($N \geqslant 7$) good qualitative results can also be obtained without allowing for CI.

Small Be clusters ($N = 3-7$) have been studied[55-57] in great detail in recent years. The structures illustrated in Fig. 1 are available to these species. We can see that regular polyhedra of the highest possible symmetry are characteristic for Be. The bond length is 2.50 Å in the dimer, 2.23 Å in the trimer, and less than 2.10 Å in the Be_4 tetramer. The dissociation energies calculated per atom are 0.3, 0.8, and 0.9–1.0 eV for Be_3, Be_4, and Be_5 respectively. Thus even relatively small Be clusters can be treated as stable molecules.

Unlike other metals of interest in the present discussion Be has been the object of nonempirical calculations[58,59] for relatively large clusters (from Be_{51} to Be_{69}). However, in this case electron correlation effects were ignored. As we have already pointed out, in large clusters this omission is unimportant. The clusters are in a singlet ground state, with a bond energy (not allowing for correlation effects) of about 1.1 eV per atom for $N = 51$, 57, and 63 and about 1.2 eV per atom for $N = 69$. Allowing for correlation would bring these values to about 1.4–1.5 eV. A large decrease in the ionisation potential as compared with that of the atom and of the small clusters (IP = 3.62 eV) has been pointed out. As could have been expected, in large clusters a very effective sp hybridisation takes place: even in Be_{51} more than one electron of the central atom is transferred from a $2s$ AO to a $2p$ AO. Unlike the atoms of the outer layer, the central atoms of these clusters can be treated as indistinguishable from atoms in the bulk state.

2. Mg clusters

Magnesium clusters have a low bond energy. Calculations not allowing for correlation give a negative stabilisation energy for the dimer and the trimer, and a negligibly small stability (0.03 eV) for the tetramer.[48,60,61] The results of detailed calculations for neutral Mg clusters are summarised in Table 2.

All the Mg_N clusters with $N \leqslant 13$ are in a singlet state.[63-66] It can be seen from Table 2 that the tendency to form regular polyhedra is suppressed even for $N = 5$, and clusters with $N \geqslant 8$ have a low symmetry. Their geometry is determined by two opposing tendencies. Regular polyhedra are the best configuration for maximising the number of covalent bonds and for optimising the conditions leading to sp hybridisation. However, a high symmetry unavoidably produces degenerate electronic states which destabilise the molecule through the Jahn–Teller effect. In Mg_N clusters the stability of the M–Mg covalent bond is low, the role of this effect should be small, and the departures from the 'ideal' geometry are not very substantial.

We also see from Table 2 that the normal dependences of various properties on N are also displayed by Mg_N: an increase in the stability and in the electron affinity with N, and a decrease in the IP. Calculations can predict small peaks corresponding to the magic numbers on these otherwise monotonic curves. In particular, a marked increase in stability is found on passing from Mg_3 to Mg_4 (8 electrons). The magic number 20 is not so clearly recognisable, but nevertheless the stability of Mg_{10} ($D/N = 0.83$ eV) is higher than that of Mg_9 (0.78 eV) and of Mg_{11} (0.79 eV).[66] Calculations reveal a correlation between the stability and the population of the $3p$ level. For $N \leqslant 13$ the maximum p population corresponds to $N = 10$ (0.3); a second local maximum (0.2) corresponds to $N = 4$. It should also be noted that the stability of the clusters is relatively low for $N \leqslant 8$.

In spite of the small bond energy the excitation of Mg_N produces long-lived excited states. The thermal decomposition of Mg_N^* requires surmounting a high activation barrier[67] ($\geqslant 0.4$ eV in the case of Mg_2). Excitation can be induced by exposure to

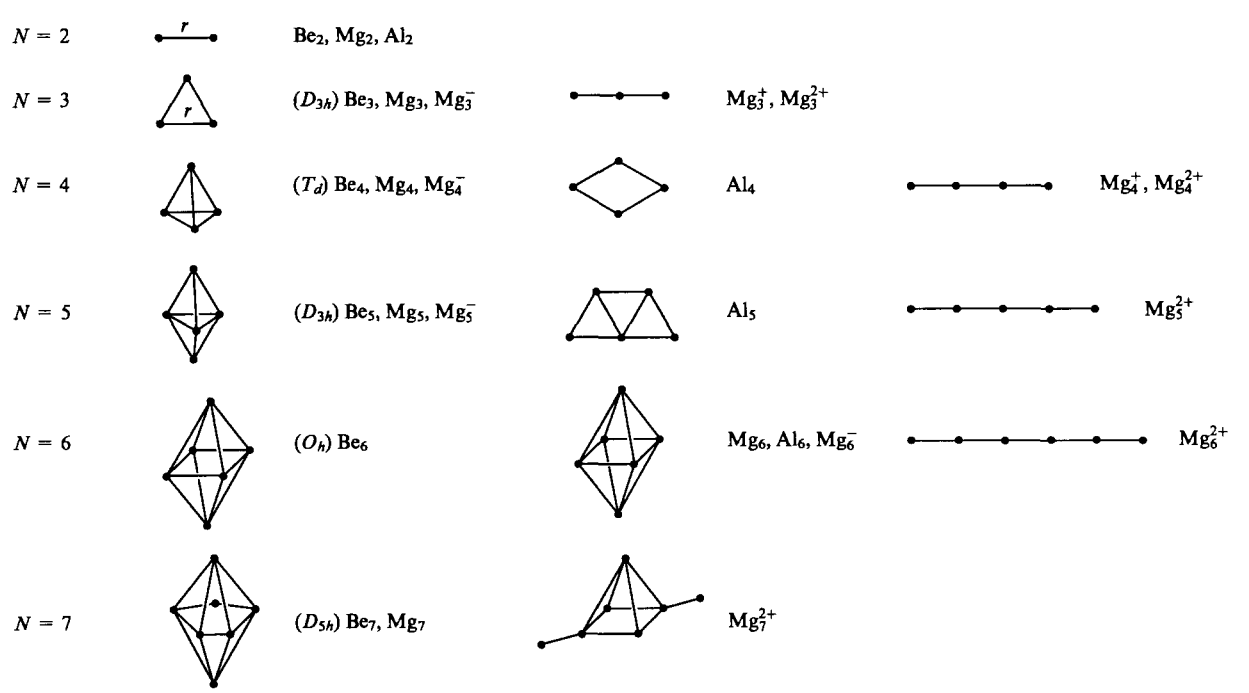

Figure 1. Typical geometric forms of small clusters of Group IIA and IIIA elements.

light or by chemical action (for example, with sulfur atoms). As has been pointed out,[67] the stability of the excited states of Mg clusters suggests the possibility of developing a new type of laser based on this material.

Neutral and anionic magnesium clusters decompose by splitting off one metal atom:[64]

$$Mg_N \longrightarrow Mg_{N-1} + Mg,$$

$$Mg_N^- \longrightarrow Mg_{N-1}^- + Mg.$$

The geometry of the anionic clusters is similar to that of the neutral clusters. The interatomic distances in the anionic clusters are slightly smaller than in the neutral species, and the bond energy per single atom is approximately 0.2 eV higher.[63,64]

The highest singly occupied MO in Mg_N^- have a completely p character for $N = 2$, 3, 6, and 7, and an approximately 67% p character for $N = 4$ or 5.[64]

Removing one electron alters the geometry of the cluster. Thus, the structure of Mg_3 and Mg_3^- is an equilateral triangle, whereas that of Mg_3^+ is linear. The D_{3h} symmetry characterises a saddle point rather than a minimum on the potential energy surface (PES) of Mg_3^+.[62] Two structures have been proposed for Mg_4^+; an approximately square structure and an equilateral triangle with a central atom.[68] A calculation allowing for CI suggests that the energies of these molecules are equal: 0.51–0.53 eV per atom.[69] An analysis in the approximation of the valence bond method showed that the presence of many isomers with approximately equal energies is a distinguishing feature of the cationic Mg clusters.[62]

The geometry calculated for Mg_4^+–Mg_6^+ in the local spin density functional approximation[63,64] is different from the value calculated by Durand.[62] These results are compared in Table 3. They all suggest[62–64] that the singly charged clusters are much more stable than the neutral clusters, especially for small N. As for Mg_N^- and Mg_N their decomposition takes place by the detachment of one Mg atom. Small Mg_N^{2+} clusters are thermodynamically unstable, and undergo the so-called coulombic explosion: a decomposition induced by the coulombic repulsion of the nuclei.

Table 3. Cationic Mg_N^+ clusters.[63,64]

N	Geometry	(D/N)/eV	r_{Mg-Mg}/Å
2	$D_{\infty h}$ (linear)	0.76	2.98
3	"	0.85	2.99
4	"	0.83	2.96
5	D_{3h} (trigonal bipyramid)	0.93	3.04 (3.01)[a]
6	Rectangular bipyramid	0.84	3.54, 4.07 (3.06)[a]
7	Distorted pentagonal bipyramid	0.90	2.96 – 4.10[a]

[a] The Mg–Mg distance in the base is shown without parentheses; that in the edges is shown in parentheses.

A calculation in the LDA approximation[70] showed that Mg_N^{2+} clusters are stable only for $N > 14$. An alteration effect has been noted: the maxima in the curves of energy against number of atoms correspond to N values of 5, 10, 18, 21, 30, and 35 (with 8, 18, 34, 40, 58, and 68 electrons respectively), i.e. the number of electrons is equal or close to the magic numbers. The simplest decomposition scheme,

$$Mg_N^{2+} \longrightarrow Mg^+ + Mg_{N-1}^+.$$

takes place only in special cases. The general rule is that the preferred decomposition is the process in which both fragments have a number of electrons differing by unity from the magic number (an exact correspondence is impossible because the number of electrons in Mg_N^+ is odd).

Table 4. Decomposition of the Mg_N^{2+} clusters.[64]

N	Decomposition scheme	Energy barrier/eV
2	$Mg_2^{2+} \rightarrow 2Mg^+$	0.48
3	$Mg_3^{2+} \rightarrow Mg_2^+ + Mg^+$	0.77
4	$Mg_4^{2+} \rightarrow 2Mg_2^+$	0.90
5	$Mg_5^{2+} \rightarrow Mg_3^+ + Mg_2^+$	0.98
6	$Mg_6^{2+} \rightarrow 2Mg_3^+$	1.03

The coulombic repulsion favours the linear Mg_N^{2+} structure with positive charges located mainly at the chain ends.[63,64] Clusters with $N \leqslant 6$ are linear, but for $N = 7$ the structure becomes a pentagonal bipyramid. The linear molecule has an energy only 0.08 eV higher. The potential energy curves for the dissociation have also been calculated;[64] the results are summarised in Table 4. Because of their kinetic stability the unstable Mg_N^{2+} clusters can play an important role as intermediates in the reactions of neutral magnesium clusters.

3. Ca clusters

The energy gap between the 4*s* and 4*p* shells of Ca is smaller by a factor of 1.5 than the gap between the *s* and *p* valence shells of Be and Mg. This should favour *sp* hybridisation, but at the same time the more diffuse structure of the 4*p* AO suppresses the hybridisation. The compensation of these opposing factors should make the properties of the Ca clusters similar to those of the Mg clusters. Few calculations on the Ca clusters have been reported. At the SCF level a dissociation energy of about 0.2 eV per atom has been obtained for Ca_4. This is greater than for Mg_4 but smaller than for Be_4.[61] The Ca_3 trimer is even less stable ($\sim$0.11 eV per atom for an internuclear distance of $\sim$4 Å).[71]

No calculations have been reported for Ba or Sr.

4. Al clusters

The valence shell of Al contains an unpaired *p* electron which permits the formation of a σ bond with *sp* hybridisation. A relatively high stability can therefore be expected for the small Al clusters. This has been confirmed experimentally and by quantum chemical calculations.

The presence of isomers having similar energies and the small depth and large width of the minima in the PES make it difficult to obtain reliable calculated results. A recent analysis[72] has shown that in order to give an adequate description of Al_N clusters the chosen basis should include the *d* AO. Electron correlation effects account for up to one half of the stabilisation energy of the cluster, but their inclusion does not markedly affect the calculated geometry.[73] The main difficulty is the presence of several almost degenerate states having different geometries and multiplicities.

Specially meaningful results were obtained in calculations on the Al_2 dimer. Different ground states had been suggested for this species: $^1\Sigma_g^+$, $3\Pi_g$ (see Ref. 50) and $^3\Sigma_g^-$ (see Ref. 74), but more recently it was shown that this state is $^3\Pi_u$ (see Refs 75 and 76). This state is almost degenerate with $^3\Sigma_g^-$ ($\Delta E = 174$ cm^{-1}), and the $^1\Sigma_g^+$ energy is substantially higher (by 2000 cm^{-1}).[77] A similar state of affairs was noted for Al_3 (see Refs 78–81). The results of calculations for small Al clusters are shown in Table 5: we can see that Al_N clusters show a number of special features in addition to the more general properties such an increase in EA and in stability with increasing N. The most striking of the special features is a tendency to form planar structures (except in the case of Al_6). This is probably a consequence of the absence of *sp* hybridisation during cluster formation, which can destabilise the molecule. Therefore the three-dimensional structures most conducive to the formation of *sp* hybrid orbitals are difficult to produce. It should be noted that a planar structure is not consistent with the close packing postulated in the spherical shell model. Nevertheless, as was pointed out above, the model can successfully predict (at the qualitative level) many important properties of the clusters, and departures from the spherical symmetry can be treated as perturbations while retaining the model.[78]

The similarity in structure between the Al clusters and the crystalline metal have been analysed at the LDA level.[62] In the metal the cubo-octahedron can be chosen as the structural unit. In clusters, even when large, a packing based on the icosahedron as the structural unit is more stable. It is replaced by the cubo-octahedron only for $N > 2000$. The energy differences between the corresponding isomers calculated for $N = 13-55$ were found to be very small: not more than 2% of the total energy. Calculations of the IP[82] show that even for $N = 19$ the value obtained for the cluster (6.18 eV) is higher than for the Al atom (5.77 eV), and that it becomes significantly lower (5.04 eV) only for $N = 55$. Experimental results give a similar dependence of the IP on N, but the equality of the IP values for the atom and the cluster is seen at $N \approx 19$.

5. Ga and In clusters

Experimental data on Ga and In clusters are adequately consistent with the predictions of the spherical shell model.[83] A strict calculation allowing for the CI has been reported only for the Ga dimer.[84] The ground state of the dimer is $^3\Pi_u$ (r_{Ga-Ga} = 2.762 Å), with a dissociation energy of 1.4 eV, and a $^3\Sigma_g^-$ state lying close to it (IP of the dimer 5.62 eV, EA = 1.04 eV). The anion of the dimer is more stable, with a dissociation energy of 2.2 eV, r_{Ga-Ga} = 2.562 Å, ground state $^4\Sigma_g^-$. The stability of the Ga_2^+ cation in the $^2\Sigma_g^+$ ground state is close to that of Ga_2 (1.5 eV, r_{Ga-Ga} = 3.24 Å).

V. Semiempirical and empirical calculations on clusters

Nonempirical calculations in wide basis sets which allow for electron correlation offer adequate descriptions of small clusters. However, in the case of large clusters their requirements of computer time are excessive. Therefore the search for promising methods of calculating the structure and the characteristics of these clusters by semiempirical approaches is now an urgent problem.

We are not aware of any successful attempts to describe clusters of Group IIA metals by these methods. Reported calculations of Mg_N clusters by the MNDO and CNDO/2 methods (*sp*, *spd*, and split *spd* basis sets) did not give satisfactory results: the bond energies were unacceptably high and the internuclear distances were too short.

Table 6. Calculation of Al clusters by semiempirical methods.

N	Method	Geometry	*s*	(*D*/*N*)/eV	IP/eV	Ref.
2	CNDO/2	$D_{\infty h}$	3	1.0	7.21	84
	MNDO	–	–	0.66	5.57	85
	INDO	$D_{\infty h}$	–	0.67	6.37	–
3	CNDO/2	$C_{2v} \sim D_{3h}$	2	2.04	7.18	84
	MNDO	–	–	0.8	6.15	–
	INDO	D_{3h}	–	1.12	6.13	85
4	CNDO/2	$C_{2v} \sim D_{4h}$	1	2.43	7.75	84
	MNDO	–	–	0.9	6.2	–
	INDO	Rhombus	–	1.37	6.44	85
5	CNDO/2	C_{4v}	2	2.60	7.12	84
6	CNDO/2	O_h	1	2.97	7.51	84

Better results were obtained for Al clusters. The results of a calculation[84] by the CNDO/2 method using corrected parameters are summarised in Table 6. As can be seen, the calculation gave reasonable values of the parameters *D*/*N* and IP, and it offers a correct description of the geometry of these clusters. However, a comparison with the data of Table 5 shows some quantitative discrepancies, less marked in the case of the MNDO calculations. Thus the shortcomings of these methods include a 10%–20% reduction of the internuclear distance as compared with the *ab initio* calculations.

Satisfactory results were obtained[85] by a special modification of the INDO method which gives internuclear distances and structures in good agreement with experiment.[82] It was used[85] in calculations for large clusters with $N \leqslant 49$. In clusters with $N \leqslant 43$ good results were obtained by the SINDOI method.[86] Thus the use of semiempirical methods in conjunction with special parametrisation provides an adequate description of Al clusters. Evidently, suitable alternative parametrisations can be produced also for other metals.

The low bond strength and the important role of the van der Waals interactions justify the use of empirical potentials for the intermolecular interactions when considering the structure and properties of the clusters. Thus, Halicioglu and Pamuk[87] have used a modified Lennard–Jones potential which gave stabilisation energies (1.226 and 1.274 eV per atom for Al_4 and Al_5 respectively) in good agreement with the results of nonempirical calculations. The same potential was used to calculate the activation energies of the regrouping of isomers. The activation barrier to the rearrangement of the tetrahedral Al_4 cluster into a rhombic cluster was 12.5 kJ mol^{-1}. In the case of Al_5 the conversion of a trigonal bipyramid into a square bipyramid requires surmounting a barrier of ~4 kJ mol^{-1}. These calculations[87] suggested the initial formation (in the gas phase) of the less stable Al_4 and Al_5 clusters, which are then transformed into the more stable planar structures. Thus the use of empirical potentials in calculations of the dynamics of the regrouping of small clusters can give satisfactory results. The conclusion that the barriers to isomeric regrouping are small has been shown[88] to apply also to magnesium.

VI. Reactions of clusters in the gas phase

The reactions of clusters have attracted great interest among research workers as models of the elementary stages of processes in heterogeneous catalysis. They are also of interest from the standpoint of the synthesis of unusual chemical compounds containing weak metal–metal bonds.

The interaction of Al_N^+ with oxygen destroys the cluster.[89] Most of the oxygen interacts with the uncharged core of the cluster to form particles of the Al_5O_2 and Al_4O_2 type. Products of the interaction of the charged core of the clusters with oxygen have also been detected: the Al_2O^+ and Al_3O^+ cluster oxides. The order of the changes in reactivity of neutral and cationic clusters of aluminium towards the reaction with oxygen has been established:[90] the reactivity decreases in the sequence dimer > atom > trimer. The rate of the process was slowest with Al_3^+, probably because of the stability of the 8-electron shell present in this species. Studies of the reactions of O_2 with neutral Al_N particles also revealed a high reactivity of the dimer, decreasing in the series $Al_2 > Al_3 > Al_4$ (Cox et al.[91]). Beyond this point the reactivity begins to increase again with the nuclearity. Notwithstanding the generally held view that the highest activity of a metal is found in the atomic state the reactivity of the clusters was found to be even higher.[92] Thus, the Al^+ and Al_N^+ ions (N = 2–8) require collision energies of 3.5 and 0–0.25 eV respectively to react with oxygen.[92]

The nonmonotonic dependence upon nuclearity of the activity of clusters towards the reaction with O_2 is clearly seen in the anionic Al_N^- clusters. In keeping with the spherical shells model the most stable and unreactive clusters are Al_7^-, Al_{23}^-, and Al_{43}^- (see Refs 93 and 94).

It is interesting to note that the reactivity of Al_N^- and Al_N^+ towards reactions with oxygen is weakly dependent on the sign of the charge, and that according to kinetic data[95] the effect of nuclearity in a series of clusters carrying the same charge is markedly stronger. For Al_N^+ with N between 1 and 33 the following oxygenated products have been obtained: AlO_x^+, $Al_2O_x^+$, $Al_3O_x^+$, $Al_3O_3^+$, and $Al_5O_2^+$. The rate constants k_2 of these reactions lie in the range of (1–2) × 10^{-12} cm^3 s^{-1} for N = 2, 3, 5, 9, 10, 17–33, and for N = 4, 8, and 14–17 they are 1.5–5.0 times lower. For Al^+, Al_6^+, and Al_7^+ the reaction is totally suppressed ($k_2 < 10^{-16}$ cm^3 s^{-1}).

Anionic clusters react by the scheme

$$Al_N^- + O_2 \longrightarrow \begin{cases} Al_{N-2}^- + Al_2O_2 \\ Al_{N-1}^- + AlO_2^- \\ Al_{N-1}O + AlO^- \end{cases}$$

The rate constants k_2 lie between 10^{-13} and 10^{-11} cm^3 s^{-1}. No interaction was detected for the magic clusters Al_{13}^- and Al_{23}^-.

The reactions of aluminium clusters with other molecules have been studied in less depth. The interaction with hydrogen (and deuterium) is hindered, and its rate is measurable only for

clusters with $N = 6-8$ ($Al_6 \gg Al_7 \gg Al_8$). The process probably takes place in two stages: [91]

$$Al_N + D_2 \longrightarrow Al_ND_2,$$

$$Al_ND_2 + Al \longrightarrow Al_ND + AlD.$$

The reactivity of the D_2 molecule towards the interaction with Al_6 is 1500 times lower than that of O_2.

The reactions of aluminium clusters with hydrogen have been analysed in terms of the modified spherical shells model.[96] Two factors play an important role: the stability of the cluster (magic numbers) and its structure (from the point of view of inserting a hydrogen atom into it). The icosahedral Al_{12} cluster has an internal cavity large enough to accept a hydrogen atom. On the other hand in the case of Al_{13}, in which the insertion of hydrogen seems even more favourable (since the total number of electrons in this case increases to the magic value), the cavity is absent and the hydrogen can be accommodated only with great difficulty.

The interaction of the lower Al clusters with molecular hydrogen has been examined theoretically in an *ab initio* study[97] of the heat of dissociative chemisorption of H_2 on Al_N. According to these calculations the process is endothermic for $N \leqslant 5$, and a small energy gain (approximately 5 kJ mol^{-1}) is observed only for $N = 6$. This effect can be treated in terms of the spherical shell model as a manifestation of the filling of the valence shell of the cluster superatom: in Al_6H_2 we reach the magic number of electrons (20). The results of the calculation agree satisfactorily with experimental data.[91]

Aluminium clusters (Al_N) can react with compounds containing a hydroxyl group. With methanol they give the adducts $Al_N(CH_3OH)_m$, where $m = 1-3$, the reactivity being a maximum for $N = 16$, 17, with a minima at $N = 7$, 14, 23. The rate of the reaction with methanol is only slightly lower than the rate of the reaction with oxygen.[91] It is interesting to note that water is approximately an order of magnitude less active than methanol. Adducts with the same composition as those formed with methanol are obtained with D_2O. The formation of oxides or hydroxides has not been observed.[91] The lower neutral clusters ($N = 2-7$) react with water to a negligible extent, whereas the cationic Al_N^+ clusters ($N = 1-3$) react with water, with formation of cluster hydroxides and evolution of hydrogen.[90]

In addition to the above, reactions of the Al_N clusters with carbon monoxide[91] and with acetone[98] have been observed. In the latter case particles of Al_NMeCO ($N = 1-15$) are formed as well as the Al_NMe_2CO adducts. The interaction of Al_N^+ ($N = 1-3$) with ethylene breaks down the hydrocarbon molecule:

$$Al_N^+ + C_2H_4 \longrightarrow Al_NCH_2^+ + \dot{C}H_2.$$

The Al^+ and Al_2^+ ions are much more active than Al_3^+.[90] With ammonia the Al_N clusters give the adducts $Al_N(NH_3)_m$, $m = 1-3$. Under the influence of radiation the ammonia is desorbed without dissociation of the cluster.[31] Aluminium clusters do not react with methanol in the gas phase.[91]

There have been effectively no studies of the gas-phase reactions of clusters of other metals of Groups IIA and IIIA. Only theoretical calculations have been carried out for some systems. The structures and energies of the Be_NH cluster hydrides have been calculated at the SCF level (without allowing for CI).[71] These molecules are much more stable than the corresponding Be clusters. The binding energy of the hydrogen increases rapidly with the nuclearity N: even for $N = 4$ it is close to the energy of sorption on the bulk metal. *Ab initio* calculations of the complexes of Be_2^{2+} with molecular hydrogen[99] identified two stable complexes formed by the reactions:

$$Be_2^{2+} + 2H_2 \longrightarrow \left[H_2\text{---}Be\text{—}Be\text{---}H_2\right]^{2+}, \quad (+2.45\ eV)$$

$$Be_2^{2+} + 4H_2 \longrightarrow \left[(H_2)_2\text{---}Be\text{—}Be\text{---}(H_2)_2\right]^{2+}. \quad (+3.27\ eV)$$

In these complexes the hydrogen is not dissociated: the H_2 molecules are located at right angles to the Be—Be bond. These complexes may be formed as intermediates in the interaction of charged Be clusters (and probably also Mg and Ca clusters) with molecular hydrogen.

Theoretical studies of the cluster compounds of magnesium[100-102] have shown that the addition of an Mg_2 dimer to F—F, Cl—Cl, H—H, and H—F bonds is more favourable than the addition of an Mg atom. The gain in energy is between 2 and 12 kJ mol^{-1}. For Ca the calculation also predicts the possibility of forming cluster compounds of the F—Ca—Ca—F type. As reported,[102] the interaction of the Mg_2 cluster with HF can take place through a four-atom transition state to give the cluster compound HMgMgF. However, in every case the calculated difference between the heats of reaction of Mg and Mg_2 is not large. It should not be forgotten that the calculation[100-102] can give erroneously low results for the clusters because of the failure to allow for electron correlation effects. The results of calculations on the magnesium—methyl halide system are discussed below, because this reaction has been observed in a condensed but not in a gaseous phase.

Only fragmentary information on the structure, properties, and reactivity of the clusters in the gas phase is available at present. Nevertheless we can formulate some general conclusions. The clusters of all metals in Groups IIA and IIIA are labile formations, with bonds having a strength intermediate between the weak van der Waals bonds and covalent bonds. The presence of numerous geometric isomers and of electronic states with similar energies leaves little doubt that clusters can easily become rearranged into a structure more favourable to the reaction. The low stability of the M—M bond allows us to observe both processes without decomposition of the cluster core (reactions with H_2, MeOH, CO) and reactions with dissociation (with O_2) under conditions of low activation energy. Two problems are still controversial. Firstly, it is not clear whether homogeneous gas-phase catalysis involving clusters is possible. The Be, Mg, and Al clusters can activate and split bonds with low reactivities such as H—H, C—C, etc. However, there is no evidence of the regeneration of the clusters from the resulting adducts. Secondly, the reaction mechanisms have not been made clear. In an attempt[91] to treat these reactions as one-electron processes the reactivity was correlated with the reciprocal energy difference between the HOMO of the donor and the LUMO of the acceptor. However, the arguments put forward are not entirely convincing. For example, in this approach methane could be said to be more active than hydrogen. Furthermore the low reactivity of the Al atoms as compared with their small clusters (which have a high IP) is difficult to understand. We believe that the high reactivity of the clusters arises from the possibility of simultaneous interaction of a cluster with several atoms of the substrate molecule. Under these conditions the activation may be associated with both an electron transfer and a synchronous bond breaking act in the substrate, with formation of substrate—metal bonds. The thermodynamic characteristics and the activation parameters are found (as could have been expected) to be sensitive to the electronic state of the cluster. The magic clusters have a low reactivity (at least, in reactions involving the breakdown of the metal core).

VII. Heteronuclear clusters

Metals of Groups IIA and IIIA can form heteronuclear as well as homonuclear clusters. The mixed clusters K_NMg were studied by Kappes et al.,[103] who found that these compounds did not satisfy the formal rules of the spherical shell model. In spite of

having eight valence electrons K_6Mg does not show an enhanced stability, as observed in the 10-electron K_8Mg cluster. The $MgLi^+$, $MgLi^{2+}$, Mg_2Li^+ clusters have been prepared by evaporation of the metals from the liquid phase using electron bombardment.[104] Experimental data on clusters of this type are few, and do not allow definite correlations to be identified. Theoretical studies have greatly outstripped the experimental work.

Mixed clusters containing Be and Mg are characterised by a moderately high symmetry and a tendency to form planar structures at low values of N. Typical geometric forms of Li_NBe clusters[105] are shown in Fig. 2. Three-dimensional structures are first encountered with Li_5Be in neutral clusters and with Li_6Be^+ in charged clusters. The bond is stronger in $LiBe_N$ clusters than in Be_N. The bond energies per atom are 0.25 eV in LiBe and 0.45 eV in Li_2Be. Similar effects were observed[106] for Li_NMg, the only difference being that Li_3Mg has the form of a centred triangle. The introduction of Mg or Al as adatoms into Li_N clusters produces a large increase in the stability of the cluster as a whole, with a corresponding decrease in the ionisation potential.[107]

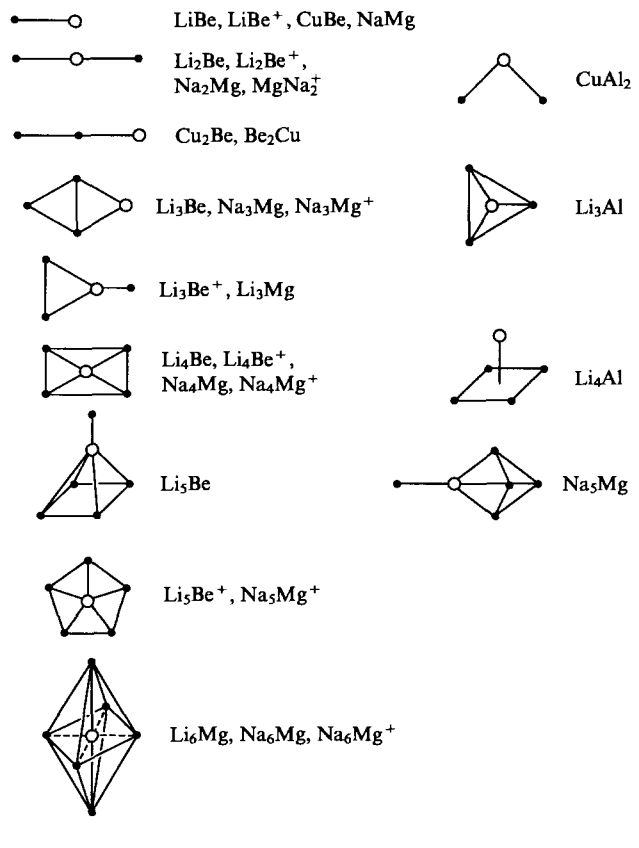

Figure 2. Typical forms of mixed clusters.

The Na_NMg and Li_NMg clusters were studied in great detail by Fantucci et al.,[108] who made *ab initio* calculations over a wide basis set allowing for CI. Though the geometry obtained for Li_NMg was similar (on the whole) to previous reports[106] the D/N and IP values were quite different. It was suggested[108] that the STO-6G basis used in the previous work[106] is inappropriate in this case and leads to unreal values of the energy. The MgNa and MgLi clusters are characterised by weak M – M′ bonds with $D/N < 0.1$ eV and internuclear distances of 3.59 and 3.2 Å. The stabilisation energy increases with N. The cations are much more stable. For example, the bond breaking energy is 0.87 eV in $MgNa_N^+$. The properties of the mixed clusters vary non-monotonically with N. In $MgLi_N^+$ and $MgNa_N^+$ even values of N correspond to a stabilisation energy greater than in the odd values. The ionisation potential of clusters with even N is also higher than that of their neighbours with odd N. The magic numbers expected on the basis of the spherical shell model are not clearly observed. In the neutral clusters an enhanced stability is found for 8, 9, and 10 electrons, and in the cationic clusters for 5, 7, and 9. This effect is probably due to the large departures of the geometry of the small MgM_N and MgM_N^+ clusters from the spherical form.

The theoretical model was modified as follows in order to provide a satisfactory explanation of the experimental data.[109,110] It is assumed that the additive atom is located at the centre and creates a region in which the charge density is different from the density in the remainder of the core. With a reasonable choice of parameters the resulting model of 'a sphere within a sphere' provides a sequence of energy levels different from that given by the simplest model: $1s < 1p < 2s < 1d$ etc. In this case even a configuration of 10 electrons produces a closed shell: $1s^2p^62s^2$. Under these conditions the stability of the 10-electron cluster K_8Mg is not surprising. The stipulation of a central location of the additive atom is clearly justified (see Fig. 2), as is also the assumption of a different charge density in the central region. For example, in the Li_NMg clusters the central Mg atom carries a greater positive charge (1.1 – 1.33), and in the Li_NAl clusters the charge on the Al atom is also greater than +1 (see Rao and Jene[107]). At the same time the departures from spherical symmetry become substantial.

The Al – B and Al – C mixed clusters are of interest from the standpoint of the spherical model. The clusters $Al_{12}B^-$, $Al_{22}B^-$, and $Al_{21}B_2^-$ have been shown (experimentally) to have a high stability.[111] Because B and Al are isoelectronic these clusters are analogues of the magic clusters Al_{13}^- and Al_{23}^-. The low stability of the $Al_{11}B_2^-$ cluster, which is isoelectronic with Al_{13}^-, seems inexplicable at first sight. Allowing for the geometric factor now becomes important. Thus, Al_{13}^- is an icosahedron with one central atom which can be replaced by B without substantial changes in geometry. On the other hand replacing a second atom in the outer sphere infringes the symmetry of the system and destabilises it. Two central atoms are present in Al_{23}^-, and both can be replaced without perturbing the structure: $Al_{21}B_2^-$ is therefore a very stable system.

The C atom differs little in size from the Al atom. Results analogous to those obtained[111] for the Al – B system could have been expected for Al_NC^-. However, a study of Al_NC^- clusters with $5 \leqslant N \leqslant 38$ gave unexpected results: a high stability was observed[40] for $Al_7C_4^-$ and $Al_{24}C^-$. These clusters contain a nonmagic number of electrons: 26 and 77. Their stability was ascribed[40] to the formation of tightly bound AlC subunits in the cluster, which do not contribute to the formation of a valence shell. These clusters should be treated as $Al_6^-(AlC)$ and $Al_{23}^-(AlC)$ respectively, with shells of 19 and 70 electrons, in complete agreement with the model. The absence of a stable $Al_{13}^-(AlC)$ cluster can be attributed to the same effects as the absence of $Al_{11}B_2^-$. The Al_{13}^- centred icosahedron simply does not have unoccupied sites for the interaction with an AlC subunit.

Mixed clusters containing transition and typical metals are of interest as models of new types of heterogeneous catalysts. They can be prepared in the gas phase or in solution. The reaction between diphenylmagnesium and CuBr in diethyl ether gave the $Cu_4Mg(C_6H_5)_6$ cluster, with a metal core consisting of a trigonal bipyramid having three Cu atoms at the base and Cu and Mg atoms at the apices.[112] The Mg – Cu distances are 2.75 Å, and the tetrahedral Mg configuration is produced by the coordination of ether molecules.

Ab initio calculations allowing for correlation[113] have been carried out for clusters containing Cu, Be, and Al. The CuBe cluster is much more stable than Be_2 ($D/N = 0.385$ eV), and CuAl has the same bond energy as Al_2. Both these clusters are almost nonpolar. It is interesting to note that asymmetric structure correspond to the more stable isomers of the linear

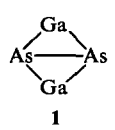
Cu_2Be and Be_2Cu clusters (see Fig. 2). The interaction of Be_2 with Cu greatly increases the stability of the Be–Be bond (dissociation energy 0.56 eV). The $CuAl_2$ cluster has a triangular structure; the energy needed to split off an atom is 2.28 eV for a Cu atom and 1.56 eV for an Al atom.

The reactivity of the mixed Al clusters has been studied for their interaction with hydrogen and oxygen. Hydrogen is not chemisorbed on solid Al, and does not react with Al atoms or clusters (except Al_6–Al_8). However, Co clusters are activated by introducing Al into them. Thus, the following activity series were obtained[114,115] for mixed Co–Al clusters with identical numbers of Co atoms:

$$Co_6 \approx Co_6Al \ll Co_6Al_2 > Co_6Al_3\,;$$

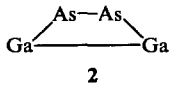
$$Co_8 \ll Co_8Al < Co_8Al_2 > Co_8Al_3\,.$$

Even one Co atom causes marked activation of the Al clusters. Thus, the $Al_{10}Co$ cluster has a high activity.



A different state of affairs is seen for Nb_N clusters. The activity of small Nb clusters with $N = 4-7$ falls off steeply when Al is introduced. For example, Nb_4Al_2 reacts with H_2 to a negligible extent, whereas Nb_4 is quite active. On the other hand the deactivation of Nb_N clusters with $N = 8-12$ by aluminium is relatively weak.

The effect of Al on the reactivity of Co_N clusters has been ascribed[114] to a decrease in the IP. However, direct measurements of the IP of mixed clusters failed to detect a decrease when the number of Al atoms was increased, or a correlation with the reactivity of the cluster.[116] The activation of the Co clusters by aluminium is probably caused by electron transfer within the metal core from the Al to the Co.



The reactivity of Nb clusters towards the reaction with H_2 is not correlated with the IP,[117] and the electronegativities of the Al and Nb atoms are not very different. The deactivation of small Nb_N clusters by aluminium has been attributed to the structural blocking of the most reactive atoms of the transition metal. At high N values the contribution from this effect is small.

A phenomenon analogous to the magic numbers effect has been observed for anionic Al clusters in the reactions of VAl_N^-, $NbAl_N^-$, and $VNbAl_N^-$ with oxygen.[94,118] It was found that $NbAl_4^-$ and VAl_6^- have an anomalously low reactivity. Any attempt to reconcile this result with the spherical shell model must take account of the number of electrons contributed by the transition metal. The valence shell of V and Nb have the $3d^34s^2$ and $4d^45s^1$ structure. It is not clear whether the d electrons are correlated in the cluster. In the case of $NbAl_4^-$ the participation of all the electrons produces a stable 18-electron shell. In this case we obtain a 24-electron configuration for VAl_6^-, which is far from the magic number. It may be assumed that only the s electrons are involved (or, more strictly, one s electron). The prospects of describing the reactions of mixed clusters containing transition and typical metals in terms of simple models are not favourable at present.

Before proceeding to other topics we should mention the mixed clusters of gallium and arsenic. Interest in these species was stimulated by their possible application in the production of gallium–arsenic semiconductor materials. Clusters of this type are prepared by the laser evaporation of gallium arsenide.[119] The ground state of GaAs is $^3\Sigma^-$, that of $GaAs^+$ is $^4\Sigma^-$ (see Knight and Petty[120]). The most stable of the binary clusters[121] is $GaAs^-$. The Ga_NAs_M clusters are characterised by the presence of several isomers with similar energies.[122] For example, in Ga_2As_2 we find the structures **1** and **2**, both unstable (though structure **1** is relatively more stable). The energy of the dissociation of cluster **1** into two GaAs molecules is greater than 3 eV (*ab initio* + MRCISD).[123]

1

2

These results exemplify the multiplicity of structures and of composition available to the mixed clusters. It is not unreasonable to suggest the possibility of preparing these compounds for any pair of metals and for many metal–nonmetal combinations.

VIII. Preparation of clusters and their reactions at low temperatures

So far we have dealt with clusters prepared and studied in the gas phase. Another, no less important approach to the problem relies on the cryochemical synthesis of cluster compounds.

Metal clusters can be prepared by the aggregation of atomic metal being condensed from the gas phase. Their stabilisation in a matrix or on a solid carrier surface allows their chemical properties to be studied. The nuclearity of the clusters is difficult to establish in solid-phase experiments because mass spectrometric detection is not available.

Studies in which the clusters are prepared by condensation from the gas phase can be divided into two groups: studies of small clusters and studies of giant clusters and of even larger species. The preparation and the chemical properties of moderately large clusters (tens of hundreds of atoms) have received little attention because of the difficulty of identifying these species in condensed phases. Let us examine the case of small clusters.

The spectra of small clusters of calcium and magnesium have been studied by Klabunde and coworkers.[124,125] For example, for Ca the following bands were observed: 374 (Ca_2, $^1\Pi_u \leftarrow {}^1\Sigma_g^+$), 415 (Ca, $^1P_1 \leftarrow {}^1S_0$), 448 (Ca, $^1D_2 \leftarrow {}^1S_0$), 470 (Ca_x, $x > 2$), 505 (Ca_2, Ca_x), 550 (Ca_x), 648 nm (Ca_2, $^1\Sigma_u^+ \leftarrow {}^1\Sigma_g^+$). Bands corresponding to clusters with N between 1 and 4 can be resolved for Mg; total absorption was observed for clusters with $N \geqslant 5$. The spectra of Al, Ca, and In dimers were reported by Douglas et al.[43]

The study of the reactivity of Al clusters is complicated by the very high activity of Al atoms towards the majority of reactants in the solid phase. At temperatures of about 77 K Al atoms react with ethylene,[126] propene,[127] butadiene,[128] tetrahydrofuran and halogen derivatives,[129] benzene,[130] and even methane.[131] Nevertheless the cluster halide Al_2Cl_4 was prepared by the simultaneous condensation of aluminium and chlorine in an inert matrix: the structure of its Al–Al bond was established by IR and ESR spectroscopy and by quantum chemical calculations.[132]

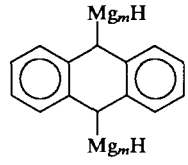
The cryochemical reactions of the elements of Group IIA, whose atoms are less reactive than those of aluminium, are of special interest. The formation of organomagnesium compounds (OMC) by the simultaneous condensation of Mg and organic halides was established 20 years ago.[133] More recently reactions between Mg clusters and relatively unreactive molecules such as C_6H_5F and CCl_4 (Refs 134 and 135) have been carried out. Similar reactions have been observed[136] also for Ca and Sr. In the course of this work it was shown that the formation of OMC is favoured by the same conditions as the aggregation of Mg atoms.[137] Furthermore, products of the Wurtz reaction can be obtained instead of the OMC under conditions conducive to the isolation of atoms.[138] This underlines the important role of the aggregation of metals in the synthesis of OMC. Strict proofs of these conclusions have been formulated[139,140]. It was shown that in an Ar matrix the Ca clusters (but not the Ca atoms) react with CH_3Br and CH_3I, and that only the Mg_N clusters with $N \geqslant 4$ react with CH_3F.

The low reactivity of Mg and Ca atoms can be understood by considering the mechanism of formation of the OMC. The direct addition of the atoms to the carbon–halogen bond is symmetry forbidden,[141] and the activation energy of the process should be at least 30–40 kJ mol^{-1} (see Davis[142]). Typically, in the gas phase the Mg atoms do not react with RCl molecules, irrespectively of the nature of R; radical detachment of Cl with formation of MgCl is observed only in the reaction with Cl_2.[143]

The formation of OMC requires an intermediate one-electron transfer whose possibility is determined by the ionisation potential of the metal-containing particles. As was pointed out above, the IP of Mg_N clusters decreases with increasing nuclearity, and the reaction becomes possible above a certain value of N. By starting from this simple scheme we can propose an alternative role for the aggregation in the case of Al. In the Al clusters the IP initially increases with increasing nuclearity, and small clusters can have a low activity towards reactions with RCl.

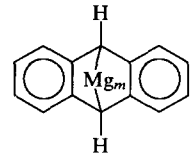
The addition of Mg_N to the bonds of organic halogen derivatives (RX) should lead to the formation of cluster compounds which we can call organopolymagnesium halides (OPMH). It has been suggested[140] that these compounds cannot be stable, and that they should decompose or react with the excess of RX when the matrix is allowed to warm up. Indeed, as reported,[101,102] the additional stabilisation energy of the OMC clusters (as compared with the Grignard reagent) is not more than 24.8 kJ mol^{-1}, and falls to zero as N increases to 5. We consider these conclusions[140] premature. Firstly, as can be seen from the calculated potential energy surfaces for Mg* and Mg^{2+}, these species should have a high kinetic stability. The activation energy for their decomposition could be quite large. Secondly, the published calculations[101,102] do not allow for electron correlation effects, which can predominate in the stabilisation of cluster compounds. For example, the *ab initio* calculation of the stable cluster tetramer $Al_4(C_5Me_5)_4$ isolated in a pure form[22] suggests that this species cannot be prepared.[144] This conclusion is quite correct, in spite of the neglect of correlation effects, but for Mg_N the correlation effects may be more important than for Al. Therefore the reported[101,102] stability of OMC clusters of the RMg_NX type appears to be too low.

The stability of OPMH under normal conditions has now been confirmed experimentally in the case of phenylpolymagnesium halides.[145,146] These compounds, of the general formula $PhMg_NX$ ($N = 2-4$; X = F, Cl, Br, I), can be prepared by cryochemical synthesis and are stable in solution for many weeks at 295 K: they can be isolated in a polycrystalline form and analysed. The effective state of oxidation of the Mg is less than 2. The action of water on OPMH causes hydrogen evolution according to the equation



$$PhMg_NX + (2N-1)D_2O \longrightarrow$$

$$\longrightarrow PhD + MgX(OD) + (N-1)Mg(OD)_2 + (N-1)D_2.$$



The decomposition of $PhMg_NX$ requires a temperature close to 100 °C. Compounds with alkyl substituents are less stable, and their structure is not entirely clear.[147]

The composition of RMg_NX is determined by the nature of the reagent X, and to a large extent by the stability of the C–X bond. Allyl bromides, which have the weakest bonds, give the classical Grignard reagents C_3H_5MgX ($N = 1$). With the stronger C–Br and C–I bonds, and also C–C, the parameter N takes the value 2 (on average). Lastly, from PhCl and PhF we obtain $PhMg_NX$ compounds in which the average value of N is 3–3.5 (X = Cl), and even 4 (X = F). The dependence of the nuclearity of the OPMH on the strength of the C–X bond is due to the competition between the metal aggregation process and the addition at the C–X bond. In C_3H_5X the bond is very weak, and the Mg atoms arriving from the gas phase react with the organic molecule faster than they can aggregate. The reaction probably takes place by a radical mechanism with intermediate removal of a halogen atom. Dimers and trimers react with the stronger C–Br and C–Cl bonds, whereas only the tetramers of larger particles can react with the strongest bonds (H–F). This explains the selectivity of the clusters in terms of activity as a function of the stability of the C–X bond.

The formation of cluster compounds of Group IIA is not confined to halogen derivatives. There is strong evidence for the existence of compounds of the RMg_NH type, formed by the simultaneous condensation of the metal and of aromatic hydrocarbons. Under these conditions, Al, Ca, and Mg form bright green condensates which become black when heated. It is assumed that complexes are formed in the first stage, and are then decomposed with formation of the dispersed metal.[129,148] However, in addition to this process we observe the activation of the C–H bonds of the aromatic with formation of hydride derivatives. The yield of hydrides during the interaction of alkylaromatic compounds with magnesium was thought to be a few per cent.[149] During the interaction of calcium with benzene a quantitative yield of hydrides is formed,[150] but their nature is not entirely clear. By analogy with the formation of organopolymagnesium halides we may suggest the addition of magnesium clusters to strong C–H bonds. More definite data are available for the magnesium–anthracene system. In this case a solid product of composition $C_{14}H_{10}Mg_N$ was obtained on removing the excess of ligand, with N varying between 4 and 8. Hydrolysis of these materials produces hydrogen, anthracene, and 9,10-dihydroanthracene, which suggests[151] the formation of the compounds **3** and **4**:

3

4

$m \approx 4$.

The cluster compounds of Mg are more reactive than their mononuclear analogues. For example, the cross-combination of the $PhMg_2X$ (X = I, Br) compounds with allyl bromide is faster by an order of magnitude[145] than the reaction of PhMgX. The course of the reaction is also different. The compounds $PhMg_3Cl$ and $PhMg_4F$ ($N = 3$ and 4) react with allyl bromide by exchanging organic radicals, and under these conditions cross-combination is almost never observed.

The high reactivity of organopolymagnesium halides can be attributed to a number of causes. These compounds contain the relatively weak Mg–Mg bonds, whose homolysis can lead to reactions which lower the nuclearity of the cluster. This could be the mechanism of the thermal breakdown of the cluster compounds at high temperatures. We should stress that the ionisation potential of the cluster OMC can be much lower than in RMgX, as shown by semiempirical calculations for model compounds.[146] One-electron transfer plays a fundamental role in many reactions of organomagnesium compounds.[152] Therefore a decrease in the IP should produce a strong activation of the molecule. Furthermore the coordination of the reacting molecules at several centres of the cluster simultaneously can be important, as it is in gas-phase reactions. For example, in the RMg_4X compounds all the magnesium atoms are coordinationally unsaturated, and the unsaturation persists even after dimerisation of these cluster molecules. In the absence of donor solvents these species will be reversibly coordinated to reagents which favour their interaction. From this point of view the exchange reaction discussed above can be represented by the scheme:

$$RMg_NX + R'Y \rightleftharpoons \begin{matrix} R & & Y \\ & Mg_N & \\ X & & R' \end{matrix} \rightleftharpoons R'Mg_NX + RY.$$

The high activity of cluster compounds offers new possibilities in organometallic synthesis. However, the use of these compounds in catalysis has attracted the greatest interest. The reversible coordination of the cluster core to various reagents creates the possibility of obtaining catalytic cycles. Thus, in the $C_6H_5F-n\text{-}C_8H_{17}Cl-C_6H_5Mg_4F$ system the yield of chloro-benzene and octyl fluoride exceeds the molar amount of magnesium by a substantial factor, suggesting a catalytic process.

Cluster organometallic hydrides are of special interest from the viewpoint of catalysis. The magnesium–anthracene system discussed above can be used as a hydrogen transfer system. In the presence of hydrogen donors such as alkylaromatic hydrocarbons the yield of $CHCl_3$ in reactions with CCl_4 exceeds the amount of magnesium by an order of magnitude or more.[151] Evidence of a high catalytic activity towards the polymerisation, alkylation, and isomerisation of olefins in the combined condensates of magnesium with aromatic hydrocarbons and $TiCl_4$ has recently been obtained.[153] In the absence of the aromatic hydrocarbon the activity of the catalyst is much lower, or completely absent.

The cluster compounds of nontransition metals are of considerable interest as the components of homogeneous catalytic systems. From the standpoint of heterogeneous catalysis the giant and supergiant clusters are the most promising. These are similar in size to the powders obtained by dispersing metals or by reducing their salts in solutions. However, the giant clusters prepared by the cryochemical method have a number of distinguishing features, not found in ordinary metals, which justify a separate discussion within the present review.

IX. Giant clusters prepared by cryosynthesis

In the previous section we discussed the interaction of small metal clusters with reactive matrices, leading to the formation of cluster compounds. The use of relatively inert matrices, and of compounds giving only low-stability metal adducts, offers a new pathway for the reaction: the aggregation of the metal with formation of giant clusters.

The most important methods of studying these systems include electron microscopy and UV and IR spectroscopy. Various theoretical models (Maxwell–Garnet, Drude, etc.[154, 155]) have now been developed to describe the spectra of highly dispersed metals. However, even by allowing for the cluster nature of the absorbing species these models fail to describe their IR spectra exactly.[156] A satisfactory quantitative description of the spectra is obtained by abandoning the use of all parameters relating to the bulk metal and allowing for the quantum effects associated with the small size of the absorbing species.[157] This model can be used to describe the spectra of large clusters of Al and other metals in the gas and the condensed phase.[158, 159]

Electron microscopic and spectral data show that ultradispersed particles of practically any size can be obtained by varying the condensation regime and the metal : inert matrix ratio. Under typical conditions (pressure of metal vapour ~ 0.1 Torr and metal : Ar matrix ratio ~ 10) almost all metals give particles having a diameter of the order of 1000 nm.[160] The particle size depends (among other factors) on the nature of the matrix and of the diluent gas. As a function of the latter factor it increases in the sequence: He < Ar < Xe (see Wada [161]). By varying the preparation regime of Mg clusters in the presence of tetrahydrofuran and of inert gases the size of the clusters can be varied between 2 and 100 nm or more (i.e. from 10^2 to 10^7 atoms).[162] Particles of about the same disperseness can be produced also without using inert matrices. Thus the condensation of Al vapour, both with and without hydrogen, gives crystalline particles of octahedral, cubo-octahedral, and trigonal bipyramid form having an average size of 40–200 nm.[163]

The giant clusters prepared by condensation in an inert gas matrix or on the surface of an inert carrier are similar in properties to the massive metals, the only difference being a very large specific surface area. The situation is entirely different for the products of the simultaneous condensation of the metal and of a formally inert organic compound. After removal of the excess of organic compound cocondensates of Mg with hexane and tetrahydrofuran are deeply coloured pyrophoric powders much more reactive than the Mg powders obtained by traditional methods.[164] The corresponding Ca condensates have been used [165] to prepare Ca analogues of the Grignard reagents.

Studies by electron microscopy of simultaneous condensates of Mg and tetrahydrofuran (after removing the excess of the latter) showed the formation of clusters approximately 35 nm in diameter. These condensates can absorb hydrogen at 200 °C, whereas dispersed magnesium prepared by any other method absorbs only at 350–450 °C. Treating the condensate with perylene increases the rate of sorption of hydrogen more than 10-fold.[166] This large increase in activity is due (at least in part) to an almost fourfold increase in specific surface area as compared with the most active samples of the compact metal. However, the main role is played by the specific structure of the clusters, resulting from the high proportion of organic substance. The condensate has the overall formula $Mg(C_xH_yO_z)_{0.0274}$, where $x:y = 3:1$.[167] The high catalytic activity of the condensate towards the H–D exchange reaction is observed even at 0 °C.[168] The sorption activity depends on the condensation conditions and on the shape and size of the clusters. Though in every case the arrangement of Mg atoms in the condensate corresponds to a hexagonal lattice, the morphology of the clusters is different: layered aggregations are formed in THF, whereas in a diethyl ether matrix the aggregates are columnar. A substantial activation of the condensate is achieved by adding 1%–2.5% of copper. Under these conditions the specific surface is increased by 1–2 orders. The copper is finely dispersed in the excess of magnesium and accelerates the sorption of hydrogen.[169] Similar results were obtained with cocondensates of magnesium and nickel. The nickel forms clusters 0.8–3.5 nm in diameter enclosed within larger aggregations containing an organic Mg species.[170]

The giant metal clusters obtained by cryochemical condensation have the size of colloidal particles. Therefore colloidal solutions are often produced by dissolving these condensates.[171] Giant clusters can also be synthesised by passing a flow of metal clusters or atoms in a stream of inert gas through a liquid solvent.[172] The possibility of formation and the stability of the colloidal metals obtained in this way are determined by the character of the interaction of the surface of the ultradispersed metal with the medium.

The colloidal solutions of aluminium have been studied in most detail. Thus, the dark blue solution in ethanol contains particles 30 nm in diameter. Bands at 215, 250, and 550 nm have been identified in its spectrum.[172] The solution is stable for one month: this has been attributed to the formation of a stabilising oxide film on the metal surface. The nature of the stability of the colloid is the same as in the Al colloid prepared by the aerosol method.[173]

The more active Ca metal also forms a light blue colloidal solution in ethanol. However, its lifetime is not more than 10–12 min, possibly because of the low strength of the oxide film. Stable colloids are not obtained even when the metal particles are combined with paraffins.

The mechanism of the stabilisation of colloids of typical metals prepared by cryochemical synthesis is not completely understood at present. Firm criteria defining their optimum formation conditions have not been formulated. It may be assumed that reactions on the surface of the initial clusters play a dominant role. Clearly, if the matrix is very active and reacts with atoms and small clusters in the solid phase a colloidal solution cannot be formed: for example, in calcium (or magnesium)–hydrocarbon halide systems. As in the case of the alkanes, inertness of the matrix does not stabilise particles of

colloidal dimensions because of coagulation and sintering effects. The best matrices have a moderately high reactivity: they are inactive during the preparation of the solid sample at low temperatures, and do not suppress the primary aggregation process in the solid phase, but they block the surface of the giant cluster by reacting with it near the melting point.

This simple criterion has been used in the synthesis of stable colloidal solutions of Mg in amines (triethylamine, dimethylamine, etc.[174,175] Heating the cocondensates of Mg and amines leads to the formation of coloured or colourless solutions containing (according to measurements by UV spectroscopy and electron microscopy) particles having dimensions between 30 and several hundred nanometers, depending on the amine. The interaction begins in the solid phase with formation of ion–radical particles, as shown by the characteristic ESR signal, which disappears upon heating the sample. Two competing processes apparently take place under these conditions: the aggregation of the small clusters formed during the condensation into larger formations and the conversion of the ion–radical species into compounds with stable chemical bonds. As a result we obtain relatively large metal particles with a surface coating of organometallic compounds. The formation of strong bonds is confirmed by the detection of up to several per cent of the organic component after pumping out the amine and lengthy vacuum heat treatment of the residue.

A slightly different stabilisation mechanism takes place in the magnesium–pyridine system. In this case very large aggregates (up to 2000 nm) are present in the solution. A strong ESR signal persists after the sample is melted. Pyridine has a high electron affinity, and therefore the ion radicals are reasonably stable on the metal surface. The resulting electric double layer stabilises the particles and prevents their coagulation. Oxygen additions cause the breakdown of this layer and destroy the colloidal solution.

Mg colloidal solutions have a high reactivity. They can be used in preparative work as a source of very active magnesium. However, their catalytic and initiating properties are the most interesting. They can activate various organic molecules, including hydrocarbons. In the presence of colloidal magnesium the catalytic migration of the double bond in olefins takes place effectively at room temperature. Normal alkanes are isomerised into isoalkanes, but the extent of reaction does not exceed 2%–4%. Colloidal magnesium is used as a powerful initiator of the radical addition of polyhalogenomethanes (CCl_4, $CHCl_3$, etc.) to the multiple bonds in olefins. The yield of product at 80 °C can be as high as 400 mol per mole of Mg per hour.[176] We note for comparison that the activity of one of the best initiators of this process (magnesium decacarbonyl) is several times lower at 120 °C and high pressure.

* * *

The study of the chemical reactions of clusters of the transition metal in the condensed phase and of the reactivity and catalytic properties of the resulting cluster compounds is only beginning. However, it is already evident that this work will generate new and very active homogeneous and heterogeneous catalysis systems. The stability of many cluster compounds of the transition metals in solutions opens new pathways to the realisation of unusual transformations and to the synthesis of new types of organometallic derivatives. Complex systems containing both clusters of the transition metals and compounds of these metals are of special interest. In this case we can expect the achievement of very high catalytic activities. The number of publications in this field will undoubtedly continue to increase.

Derivatives of trivalent phosphorus in the synthesis of glycerophosphatides and related phospholipids

E E Nifant'ev, D A Predvoditelev

Contents

I. Introduction	71
II. Phosphorylation of glycerol and related oligool derivatives by trivalent phosphorus reagents	71
III. Synthesis of phospholipids from glycerophosphorus acid esters and amides	75
IV. Conclusion	87

Abstract. The review is devoted to the analysis of one of the new trends in phospholipid synthesis. An attempt is made to demonstrate the likely usefulness of studies designed to establish an interdisciplinary field combining the interests and possibilities of the chemistry of lipids and the chemistry of trivalent phosphorus. The bibliography includes 218 references.

I. Introduction

Natural glycerophospholipids and their synthetic analogues, in the molecules of which phosphorus-containing functional groups have been modified, constitute a large group of compounds with a complex structure. Since many of these substances are very important for the development of physicochemical biology as well as certain modern branches of medicine and engineering, much attention is being devoted nowadays to their synthesis.[1–10]

Among other problems solved in the synthesis of glycerophospholipids and their analogues, the most difficult is that of the formation of the phosphorus-containing unit in these complex polyfunctional systems. For a long time, only pentavalent phosphorus reagents have been used in all the world research centres for the synthesis of phospholipids; we may note that a similar strategy was applied also in the synthesis of nucleic acids and certain other phosphorus-containing natural products. This situation can be accounted for by the relatively ready availability of pentavalent phosphorus-containing reagents, the knowledge of the compounds at the time, and the fact that their application in fine organic synthesis appeared evident. Nevertheless, these reagents frequently suffered from significant disadvantages. Thus they ensured only low rates of phosphorylation and exhibited a tendency to alkylate the electrolytes present in the reaction system and to undergo other side reactions. Furthermore, only a narrow range of synthetic possibilities is associated with pentavalent phosphorus-containing reagents.

In view of the foregoing, a trend has gradually arisen in the chemistry of phospholipids to change over to reagents containing trivalent phosphorus, which differ from the corresponding oxidised forms by a much higher phosphorylating capacity, better preparative results, and more extensive design possibilities. A very important factor is that specialists working actively in the chemistry of trivalent phosphorus have begun to be involved during the recent period in the study of problems in the chemistry of phospholipids of current interest. They were able to find a series of novel and fruitful solutions during a comparatively short period.

The first results of studies by methods from the chemistry of trivalent phosphorus in the synthesis of glycerophosphatides and their phosphorothioate, phosphoroselenoate, and other analogues were compiled and discussed by the authors of the present review at the beginning of the 1980s.[11,12] In the subsequent period, the interest in this problem increased sharply and a need therefore arose to return to this topic in order to survey the authors' own and literature data and to deduce the trends which have reliably arisen.

Analysis of the scientific facts published during recent years demonstrates not only quantitative but also qualitative changes in the overall series of studies being prosecuted. This factor necessitated a revision of the previous structure used in considering the available data. In the present review, we have differentiated two main problems. The first involves the phosphorylation of glycerol derivatives and related polyols using trivalent phosphorus-containing reagents. Here one may include also certain other reactions of trivalent phosphorus derivatives leading to the introduction of the phosphoryl functional group into the glycerol system. The second involves the conversion of the phosphites obtained into natural phospholipids or their analogues via reactions involving trivalent phosphorus atoms.

II. Phosphorylation of glycerol and related oligool derivatives by trivalent phosphorus reagents

The introduction of trivalent phosphorus reagents into the synthetic chemistry of lipids was initially problematical for several reasons. Thus reliable information concerning the use of phosphorous acid and other trivalent phosphorus acid derivatives for the phosphorylation of polyfunctional systems was lacking in the literature. There was also no experience in the identification and isolation of glycerophosphatides and related compounds with a complex structure. Finally, one had to be on one's guard against the ready disproportionation of asymmetric glycerophosphites similar to that occurring in studies with the simplest asymmetric phosphites.[13] In view of the foregoing, in the first stages of the investigation predominantly model systems were used, in which the necessary methodological problems were worked out. 1,2-*O*-Isopropylideneglycerol and other similar acetals were usually employed as models of this kind. A very

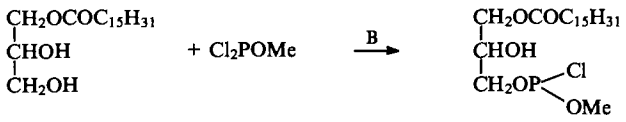
Uspekhi Khimii **63** (1) 73–92 (1994); translated by A K Grzybowski

important factor is that subsequently a rational procedure was found for the conversion of these acetals,[14-16] as well as cyclic orthoesters[17] and oxazolidines,[18] into phospholipid systems.†

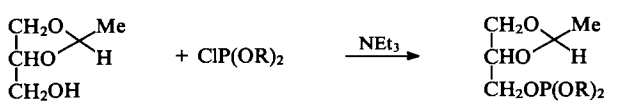


Various derivatives of tricoordinate phosphorus and hydrophosphoryl compounds were used as phosphorylating agents in the studies carried out.[21] Since each of the classes of these two types of reagents frequently exhibited significant chemical characteristic features, in the present review we have endeavoured to discuss topically the published data and to demonstrate the characteristics of the most important phosphorylating agents.

1. Phosphorylation by neutral derivatives of phosphorous acid

a. Phosphorylation by acid chlorides

In the synthesis of the simplest neutral esters of phosphorous acid, phosphorus trichloride and phosphorochloridites are usually employed as phosphorylating agents. These substances have been used also in the phospholipid synthesis. Thus diarylglycerols[22] and diacylglycerols[23-25] were treated with phosphorus trichloride to form glycerophosphorodichloridites. Unfortunately, the products of these reactions could not be isolated in a pure form and they were hydrolysed to the corresponding primary phosphites. Difficulties with isolation were noted also in the phosphorylation of diacylglycerols by 2,6-di-*tert*-butyl-4-methylphenyl phosphorodichloridite[26] and dimethyl and diphenyl phosphorochloridites.[27,28] In these cases, the primary reaction products were immediately converted by oxidation and subsequent hydrolysis (alcoholysis) into the corresponding phosphates. Unfortunately we must note that the use of phosphorochloridites for the synthesis of complex lipid systems has not always been carried out using well-founded schemes and in a number of instances was not accompanied by the demonstration of the structure. Thus the interaction of α-monopalmitoylglycerol with methyl phosphorodichloridite has been described.[27] The authors specify the mode of monophosphorylation, involving the formation of an alcohol-acid chloride (Scheme 1).



Scheme 1

It is most likely that such a product should either cyclise with formation of a 1,3,2-dioxaphosphorinane or should be converted into an oligophosphite. Therefore the probability that the above acid chloride exists for any [significant] period and then phosphorylates an extraneous nucleophile, as claimed by the authors,[27] is low.

More definite results were achieved using phosphoromonochloridites. The first investigation on these lines was carried out by Arbuzov and Yarmukhametova,[29] who synthesised dialkyl glycerophosphites from 1,2- and 1,3-*O*-ethyleneglycerols and dialkyl phosphorochloridites (Scheme 2).

Scheme 2

It was subsequently shown that phosphorylation yields better results when phosphoramidochloridites[30-37] as well as the readily available and experimentally more convenient cyclic acid chlorides—alkylene phosphorochloridites,[38-51] alkylene phosphoramidochloridites,[52-54] alkylene phosphorodiamidous chlorides,[54] and salicyl phosphorochloridites[55]—are employed. In this case, it was possible to obtain in satisfactory yields a series of neutral phosphites and phosphoramidites of the acetal and diacyl derivatives of glycerol[38-50,52-55] and thioglycerol.[51]

There are literature data concerning the analogous syntheses of phospholipids from etriol [2-hydroxymethyl-2-ethylpropane-1,3-diol (Translator)],[56] pentaerythritol,[57] ascorbic acid,[58] glycols,[59-61] higher aliphatic alcohols,[62-65] sphingophospholipids,[66-68] and fragments of lipid A.[69]

The use of phosphorus trichloride and phosphorochloridites in fine organic synthesis is not always justified. When complex lipid systems are synthesised, the application of reagents the use of which involves the evolution of hydrogen chloride is risky, because in this case there is a possibility of isomerisation, degradation of labile bonds, and other unfavourable processes. Furthermore, certain phosphorochloridites, for example those containing benzyl groups, exhibit a tendency to undergo rearrangements; the employment of such reagents may lead to explosions.[70] In view of the foregoing, a trend has recently arisen to employ mild phosphorylating agents in the synthesis of polyfunctional phosphorus-containing natural products, including phospholipids.

b. Phosphorylation by esters

The first experiments on this problem were carried out with model phosphorylating agents—phosphinous acid esters containing only one phosphorylating functional group. It was established that phosphinites are readily and effectively transesterified by 1,2- and 1,3-alkylideneglycerols.[71] Subsequently triphenyl[72] and triethyl phosphites[14-16,73,75] were transesterified.

Scheme 3

R = $C_{17}H_{35}$.

Phosphorylation by triethyl phosphite has been used for 1,2-diacylglycerols (Scheme 3).[74]

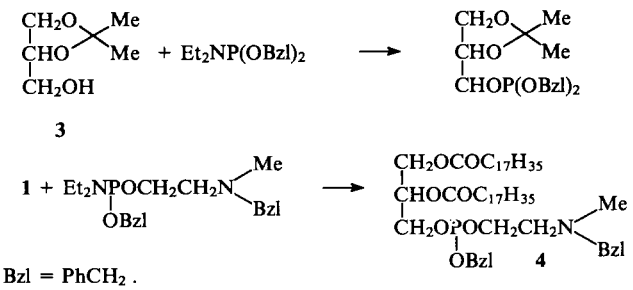
Transesterification has been used also for the synthesis of the phosphites of certain other polyols (see, for example, Petrov et al.[72]).

The transesterification method is also milder compared with the acid chloride method, but it too suffers from preparative disadvantages. Thus, in studies with partially acylated oligools, this procedure may be accompanied by side migrations, for example acyl migrations, owing to the high temperature of the main reaction. Investigators have therefore concentrated attention on the search for new phosphorylation procedures. The optimum procedure of this kind is examined below.

c. Phosphorylation by amides and amidoesters

Amides and amidoesters proved to be especially mild and convenient to use. Their employment ensured the maximum specificity and effectiveness of the phosphorylation reaction. We may also note that, when phosphoramides are used, amines are formed apart from the target esters. The amines can be readily evacuated from the reaction mixture and do not degrade the starting materials and reaction products (Scheme 4).[13]

Scheme 4

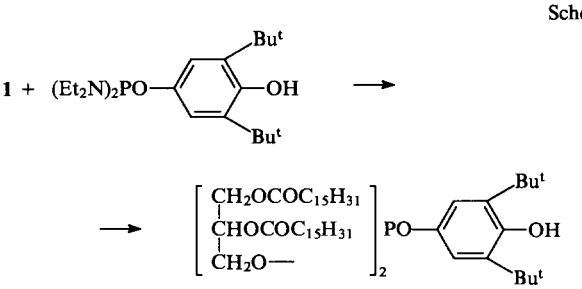


† In naming the phospholipids, we have employed, with some simplifications, the rules formulated by the IUPAC-IUB Commission on Chemical Nomenclature.[19,20]

We should draw attention to yet another factor. It has been shown that the rate of phosphorylation of nucleophiles by phosphorous acid amides can be regulated by catalysts. It has been proposed that amine hydrochlorides,[76,77] salts of dialkyldithiocarbamic acids,[78,79] and weak acids, for example tetrazole,[25,28,30–32,34–37,66–68,80–82] be used as catalysts of this kind. It has been stated that small amounts of added iodine have an activating effect in the phosphorylation reaction;[83–85] apparently hydrogen iodide and then its ammonium salts, which are in fact the catalysts, appear in the reaction mixture in such experiments.

Phosphoramides are used nowadays in syntheses of various lipid systems. Thus it has been suggested that phosphorous monoamides be used for the phosphorylation of glycerol acetals[26,74,86,87] and the corresponding esters[25,26,46,74,80,87] (Scheme 5).

Scheme 5

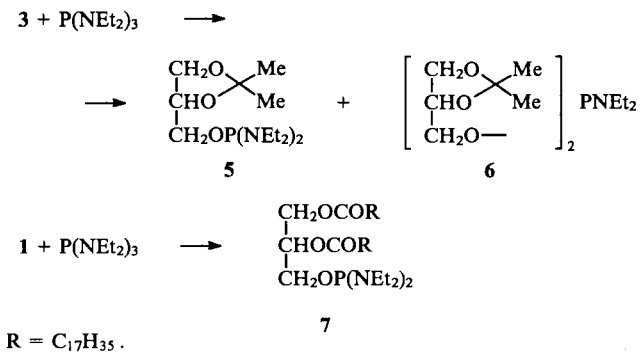


Bzl = $PhCH_2$.

The amides of cyclic phosphites and phosphoramidites are especially convenient to use and are promising for further reactions. A series of reactions with the amino-derivatives of phospholans,[88,89] phosphorinanes,[43,45,90] and phosphepans,[91,92] as well as oxazaphospholans[93–96] and oxazaphosphorinanes[52] have now been investigated.

Phosphorous diamides are even more widely used and it has been suggested that phosphomonoglycerides[26,74,86,87,97–102] and phosphodiglycerides[26,87] be obtained from them. We shall illustrate the latter possibility by the synthesis of a compound the structure of which includes a sterically hindered phenol fragment (Scheme 6).[26]

Scheme 6



R = $C_{15}H_{31}$.

These and other similar compounds can be built into biological membranes and can protect the latter from homolytic oxidation.[103]

It has been suggested that phosphorous acid triamides be also employed as phosphorylating agents. Depending on the reactant ratio, it is possible to obtain in this case mono- or diglycerophosphoramidites (Scheme 7).[74,85,88,94,95,104,105]

In the course of the study of the phosphoramide method for the phosphorylation of diacylglycerols, fears arose concerning the possibility of acyl migrations. Indeed, as a strong nucleophile, the secondary amine produced should at least partially add to the carbonyl groups of the esters, which generally speaking can lead to rearrangements. Experimental data have confirmed the validity of such fears: in some

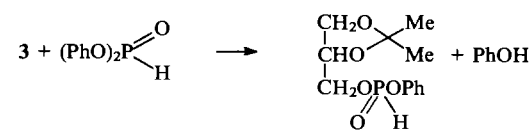
Scheme 7

R = $C_{17}H_{35}$.

experiments with 1,2- and 1,3-diacylglycerols isomerisations involving up to 10% of the starting materials were observed. Taking into account the foregoing considerations concerning the possible nature of the migrations, a study involving the search for optimum phosphorylation conditions was undertaken and it was observed that phosphorylation in a low vacuum (300 torr) makes it possible to achieve the timely evacuation of the amine produced and to protect the acylglycerol system against side reactions.[107]

Phosphorous acid amides have been used successfully in the synthesis of nonglycerol phospholipids—derivatives of ascorbic acid,[108] 1,1,1-tri(hydroxymethyl)alkanes,[18,56] pentaerythritol,[17,57,109] glycols,[78,79,83,110] fragments of lipid A,[69] and ceramide.[68,81,82]

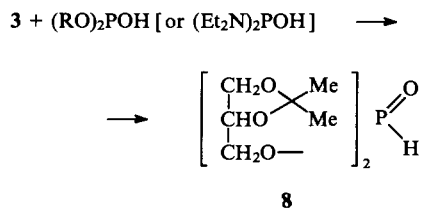
The phosphoramidites and phosphorodiamidites of oligools have attracted attention not only in connection with their ready availability but also because they are convenient to use. They are optimum intermediates for the synthesis of a wide range of phospholipids, because they effectively phosphorylate the nucleophiles forming part of phospholipid systems—the choline, aminoalkyl, carbohydrate, acylglycerol, aminoacid, and other important synthons. This aspect of the problem will be considered below.



In conclusion of this section we shall deal with the problems of the stability of glycerophosphites and also with certain features of the experiments involving them. Depending on the molecular mass and nature of the glycerophosphites formed, the latter can be isolated by vacuum (high vacuum) distillation or chromatographically. However, in most cases this is superfluous. Bearing in mind the high phosphorylating capacities of trivalent phosphorus derivatives, the mild conditions, and hence the high effectiveness of the processes considered, it is useful to introduce glycerophosphites immediately into subsequent reactions without isolating them. An important preparative feature of glycerophosphites is noteworthy. In contrast to simple symmetric derivatives of phosphorous acid,[13] these compounds are thermally stable, i.e. are only poorly symmetrised on heating.

2. Phosphorylation by acid derivatives of phosphorous acid

a. Phosphorylation by diesters and diamides

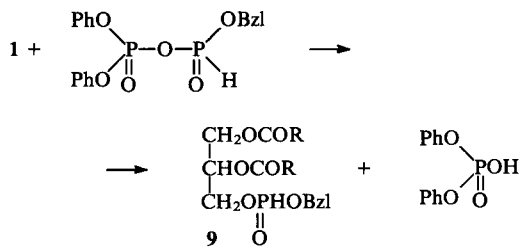


The possibility, in principle, of using the transesterification method for the synthesis of symmetrical and asymmetric disubstituted phosphites containing glycerol fragments in their structure has been demonstrated in the literature. Thus phenyl glycerophosphite has been synthesised from 1,2-*O*-isopropylideneglycerol **3** and diphenyl phosphite (Scheme 8).[72]

Scheme 8

Isopropylidenemetriol reacts similarly with diphenyl phosphite.[72] Subsequently the reaction was extended to aliphatic phosphites. The complete transesterification of dimethyl(ethyl) phosphite with 1,2-*O*-isopropylideneglycerol may serve as an example of the synthesis of symmetrical diglycerophosphites.[45,75,111,112] It was shown that the transesterification is accelerated by orthotitanic acid derivatives (Scheme 9).[112]

Scheme 9



8

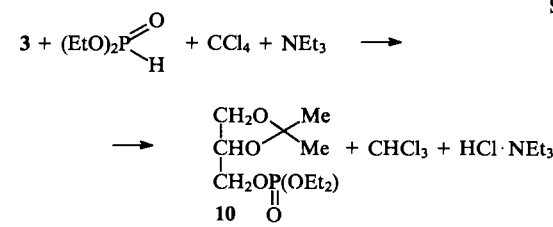
A similar result was obtained when phosphorus tetraethyldiamide was used.[111] Owing to the presence of two chiral centres and a pseudochiral centre in the molecule, the ^{31}P NMR spectra of diglycerophosphite **8** are relatively complex. It is noteworthy that the above compound was the first among hydrophosphoryl products in the molecules of which a pseudochiral phosphorus atom was detected.[75]

b. Phosphorylation by phosphorous acid monoesters

A promising method of synthesis of complex disubstituted phosphorous acid esters is based on the use of primary phosphites. The idea of this method is as follows. Primary phosphite salts, which are readily available and are convenient to use, are treated with strong electrophiles, usually the halides of organoelement and carboxylic acids. The alkyl phosphites are activated as phosphorylating agents as a result of the formation of mixed anhydrides. On contact with alcohols, the latter afford secondary phosphites. The practical application of the chlorides of organoelement acids was initiated by Corby et al. in relation to diphenyl phosphorochloridite.[113] This version of the phosphorylation method has been used in the chemistry of natural products, including lipids. As an illustration, we present the following example which resulted in the formation of benzyl 1,2-diacylglycerophosphite **9** (Scheme 10).[114–117]

Scheme 10

The application of carboxylic acid chlorides for the activation of monoalkyl phosphites has been proposed by Rogovin and the authors of the present review.[118,119] This version is apparently especially interesting for the chemistry of natural products.‡ It has already proved very useful in the synthesis of phosphorylated cellulose,[118,119] nucleic acids,[120–122] and sugar glycosyl phosphates.[123] At the present time, the above approach is one of the procedures in the chemistry of phospholipids for the phosphorylation of glycerols by primary phosphites of different nature and for the phosphorylation of the constituents of complex phospholipids by glycerophosphites (see Section III).

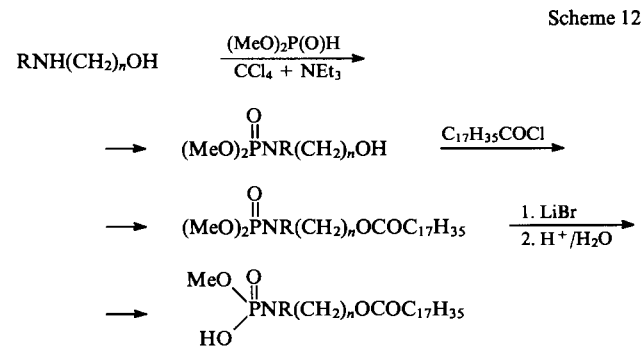


‡ This method is sometimes referred to in the literature, not entirely accurately, as the 'H-phosphonate' method. A more accurate term may be the 'hydrophosphoryl' method.

3. The use of trivalent phosphorus reagents for the oxidative introduction of phosphorus into the glycerol and related oligool systems

The direct phosphorylation reactions described above do not exhaust all the possibilities for the employment of trivalent phosphorus reagents in the synthesis of phosphoglycerol structures. Together with these reactions, studies have also been made on oxidation processes based on the use of phosphorous acid diesters and triesters, which made it possible to obtain glycerophosphates, glycerophosphorothiolates, and glycerophosphonates by a simple procedure.

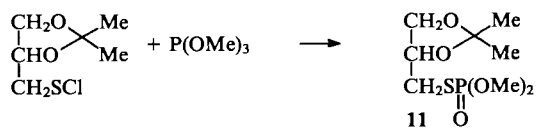
The Todd–Atherton reaction is of great synthetic importance.[124] It has been studied in detail in relation to the phosphorylation of 1,2-*O*-isopropylideneglycerol **3** and 1,3-*O*-benzylideneglycerol by diethyl(methyl) phosphites in the presence of carbon tetrachloride.[14,15,74] As an example, we present the synthesis of diethyl 1,2-isopropylideneglycerophosphate **10** (Scheme 11).



Scheme 11

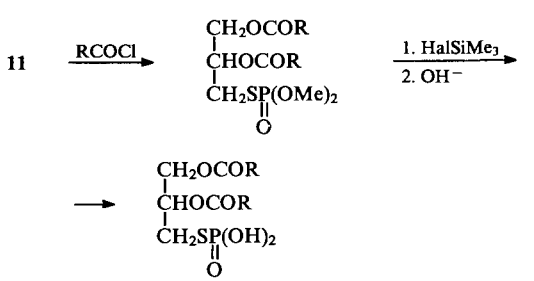
The process is based on the use of readily available starting compounds, is carried out under mild conditions, and gives rise to high yields of the target products. In considering the Todd–Atherton reaction, one should bear in mind its extensive synthetic possibilities. We may point out that, in the oxidative phosphorylation of glyceroacetals and diacylglycerols, good results have been obtained not only with aliphatic but also with aromatic phosphites.[14] Furthermore, alkylene phosphites,[45] alkylene phosphorothioites,[40] and alkylene phosphoramidites[125] have been used in preparative practice. On the other hand, instead of glycerol derivatives it is possible to employ glycols and obtain diol phospholipids and their diphosphorus analogues.[56–61,126]

Important results have been achieved also in the phosphorylation of primary and secondary aminoalcohols.[127] This reaction made it possible to put forward a new strategy for the synthesis of the important, although nowadays little investigated, class of phospholipids (Scheme 12).



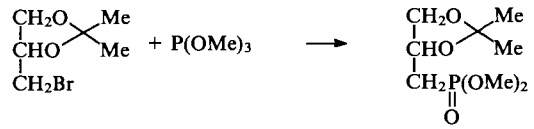
Scheme 12

n = 2, 3; R = H, Me.



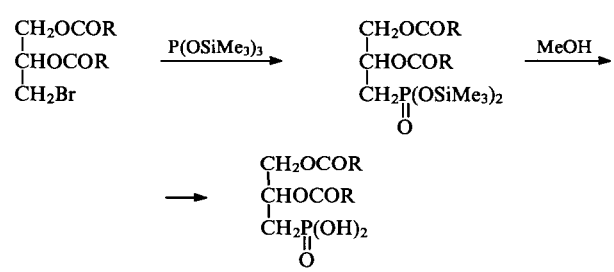
An elegant synthesis of lipids otherwise difficult to obtain, for example dimethyl 1,2-isopropylidenethioglycerophosphorothiolate **11**, has been described by Mlotkovska and Markovska,[128-130] who resorted to the reactions of sulfonyl chlorides derived from glycerol with neutral phosphites (Scheme 13).

Scheme 13



Analogues of natural phosphoglycerols can be readily obtained from such phosphoacetals.[14-16] In the molecules of phosphoglycerols, the glycerol residue is joined to the phosphorus atom via a labile thiol 'inset', which is of great interest for enzymological research for example (Scheme 14).[128]

Scheme 14

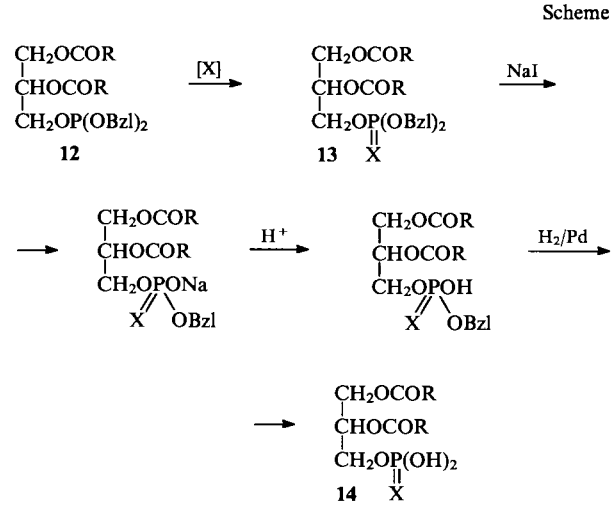


It has been suggested that the novel systems in the molecules of which the deoxyglycerol fragment is joined directly to the phosphorus atom be synthesised via the Arbuzov reaction (Scheme 15).

Scheme 15

Special reviews have been published on questions concerning the use of this reaction,[5,131,132] which makes it unnecessary to quote in detail the relevant studies in the present review. We shall only note the particularly good prospects for the use of trisilyl phosphites as the phosphorous component. This version of the reaction takes place particularly readily because of the high nucleophilicity of the silyl phosphites and makes it possible to obtain in the concluding stage the phosphono-analogues of phosphatidic acids by means of simple alcoholysis (Scheme 16).[133-135]

Scheme 16



III. Synthesis of phospholipids from glycerophosphorous acid esters and amides

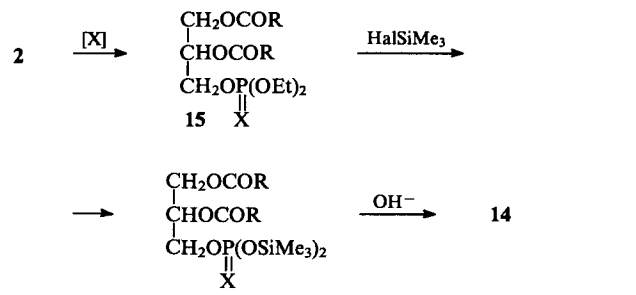
In this section, the literature data are discussed in three subsections. Each of them is devoted to the reactions of the most important classes of derivatives of glycerophosphorous acids which occur as key substances in lipid syntheses: neutral glycerophosphites, acid glycerophosphites, and glycerophosphoramidites. Sometimes the types of compounds considered are linked to one another by simple reactions which will be specially indicated.

1. Reactions of neutral glycerophosphites

In the first place, we shall consider the phospholipid syntheses based on neutral monoglycerophosphites.§ It has been suggested that the simplest of these compounds — acyclic esters — be used to synthesise phosphatidic acids.[74] Thus dibenzyl 1,2-diacylglycerophosphites **12** are oxidised¶ by nitrogen oxides or iodosobenzene with formation of the corresponding dibenzyl phosphates **13** (X = O), which were obtained previously via a much more complex scheme: by the reaction of the silver salts of dibenzylphosphoric acids with glycerol 1,2-diacylhalohydrins which are difficult to obtain and inconvenient to work with.[1,3,8,10] Dibenzyl phosphates **13** (X = O) are subsequently converted into the phosphatidic acids **14** (X = O). At the same time, it was shown that dibenzyl 1,2-diacylglycerophosphites **12** combine smoothly with sulfur and are converted into the phosphorothioates **13** (X = S), which are debenzylated to the thiophosphatidic acids **14** (X = S) (Scheme 17).

Scheme 17

R = $C_{15}H_{31}$, $C_{17}H_{35}$; X = O, S.



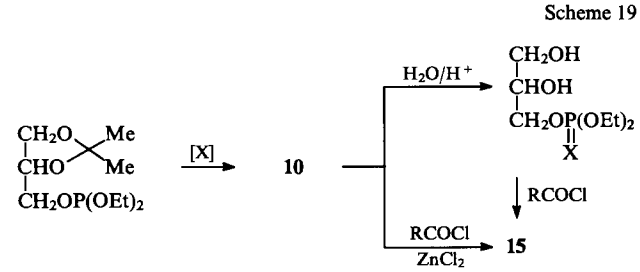
Another, apparently more promising version of the synthesis of phosphatidic acids **14** is based on the use of the glycerophosphates **2** with ethyl protecting groups in the phosphorus-containing functional group.[14-16,73] Diethyl 1,2-diacylglycerophosphites **2** are oxidised without complications to the phosphates **15** by a procedure similar to that used for the dibenzyl esters **12** already mentioned. Next the ethyl protecting groups are removed by silylation by a procedure similar to that used for the simplest phosphoric acid esters.[137-141]

§ Certain reactions of phosphoroamidites, in which only the valence state of the phosphorus atom changes, are also considered in this subsection. Subsection 3 is devoted to reactions involving the P–N bond.

¶ A method involving the selective development of trivalent phosphorus compounds in thin layer chromatography with the aid of a ninhydrin solution has been recommended for the monitoring of the oxidation reactions and also for the recognition of substances with similar R_f values.[136]

The scheme terminates with the hydrolysis of the trimethylsilyl derivatives of phosphatidic acids (Scheme 18).

Scheme 18



R = $C_{15}H_{31}$, $C_{17}H_{35}$; X = O, S.

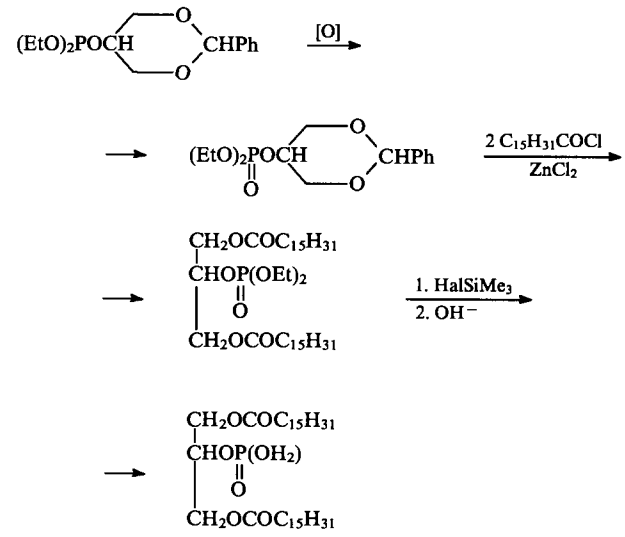
The phosphatidic acids **14** have been obtained in a better yield (up to 56%) by using a solution of equimolar amounts of chlorotrimethylsilane and sodium iodide.

We may note that previously alkyl groups had already been considered for the temporary protection of acid hydroxyls in certain lipid syntheses. It was suggested that they be removed under severe conditions, for example by hydrolysis with lithium hydroxide, which involves considerable complications.[142,143] The new method—deethylation with the aid of halotrimethylsilanes—is carried out under mild conditions and ensures satisfactory yields of the lipids. It has therefore come to be widely used nowadays in many laboratories.[14-16,60,73,75,106,128,144-149]

The phosphatidic esters **15** can be obtained using diethyl (1,2-*O*-isopropylidene-3-glycero)phosphite by its oxidation or sulfurisation to phosphates (phosphorothioates) **10**, mild hydrolysis of the acetone protecting group, and acylation of the resulting phosphodiols.[14-16,73] Further progress on these lines was determined by the discovery of fundamentally new procedures for the acylation of the glycerophosphoacetals **10**, which markedly simplified the method of synthesis (Scheme 19).[14-16,73]

Scheme 19

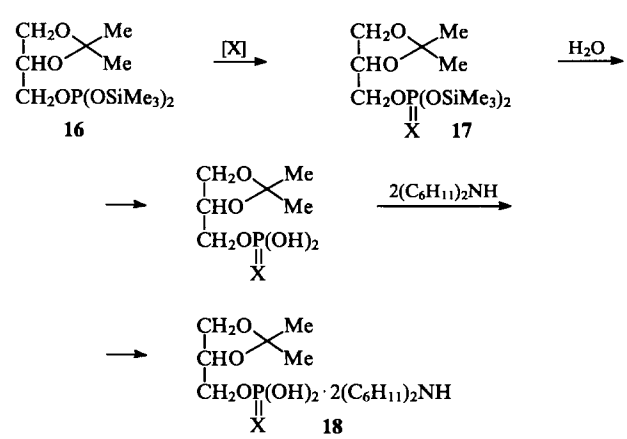
The reaction presented in Scheme 19 (X = S) is an example of a convenient preparative method of synthesis of thiophosphatidic acids.



The version examined may be extended also to the synthesis of little investigated β-phosphatidic acids (Scheme 20).[14,15]

The series of studies on the acylation of 1,2- and 1,3-acetals with glycerols was completed by demonstrating the absence of acyl migrations in these decisive stages of the synthesis.[15]

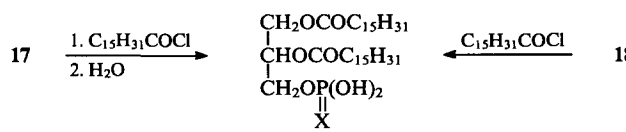
The new method for the acylation of glyceroacetals probably merits extensive use. It has already been applied successfully in the synthesis of a series of ester phospholipids.[14-16,26,45,56,57,73,75,87,91,92,106,109,128,150-155]



An even simpler version of the synthesis of phosphatidic acids, their thio-analogues, and also their previously unknown seleno-analogues is based on the use of the available bis(trimethylsilyl) 1,2-*O*-isopropylidene-3-glycerophosphite **16** (see below). This silyl phosphite was converted by oxidation (by the addition of oxygen, sulfur, and selenium) into the

Scheme 20

corresponding phosphates, phosphorothionates, and phosphoroselenonates **17**. Compounds **17** were isolated by high-vacuum distillation in yields up to 81%. Acid glycerophosphates and then their salts **18** were obtained by the hydrolysis of the neutral silyl esters **17** (Scheme 21).[106,156]

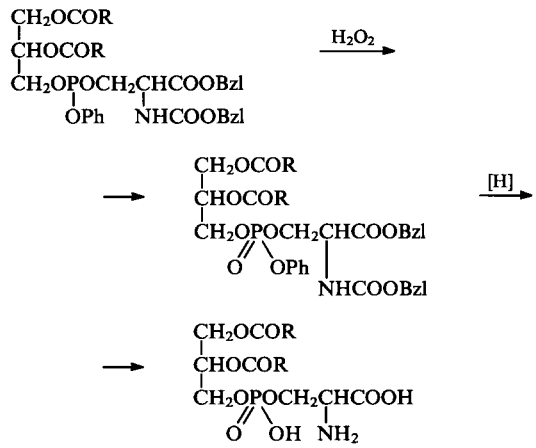


Scheme 21

X = O, S, Se.

The salts (or silyl phosphates) obtained are readily acylated and are converted ultimately into phosphatidic acids (Scheme 22).

Scheme 22

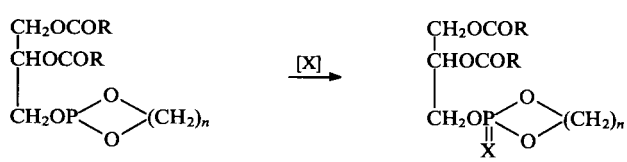


According to ^{31}P NMR data, thio- and seleno-phosphatidic acids exist in chloroform solutions in the thiono- and selenonophosphoryl forms. A similar conclusion concerning the structure of the seleno-acids was also reached from analysis of the direct $^{77}Se-^{31}P$ spin–spin coupling constants.

The method of synthesis of phosphatidic acids and their chalcogen analogues examined above was used to synthesise an optically active product—1,2-dipalmitoyl-*sn*-(3-glycero)-phosphate; in this case, the starting compound was 1,2-isopropylidene-*sn*-glycerol.[106]

The thionophosphatidic acids obtained in accordance with the schemes proposed immediately found applications in lipidology. Thus the use of a thionophosphatidic acid as a $^{31}P-\{^1H\}$ NMR probe (δ_P = 59 ppm) made it possible to investigate the polymorphic transformations of phosphatidic acids and of the phospholipid mixtures incorporating them.[157-161] Thionophosphatidic acids have also proved useful in the study of the permeability of bilayer lipid membranes in phase transitions and in the solution of other biophysical problems.[162-164] In connection with their spectroscopic characteristics, selenonophosphatidic acids (δ_P = 55 ppm) can also be used as ^{31}P NMR probes in the study of membranes. Additional information about the structure of the membranes can then be obtained by recording the satellites induced by the spin–spin splitting of the $^{31}P-^{77}Se$ signal. Selenonophosphatidic acids may be of interest as carriers which transfer selenium into biological membranes and also for the solution of other problems in physicochemical biology.[165,166]

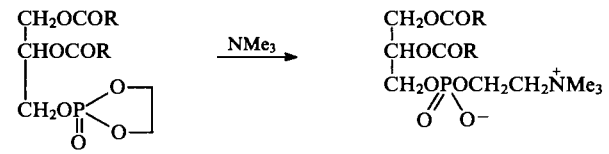
The oxidative reactions of neutral glycerophosphites have been used in various laboratories also for the synthesis of diester phosphatides. Thus the oxidation of aminoalcohol and aminoacid glycerophosphites using hydrogen peroxide has been described (Scheme 23).[27,28]



Scheme 23

As shown in the scheme presented above, the removal of the phenyl protecting group from the phosphate centre does not always yield satisfactory results. Therefore nowadays investigators usually select alternative solutions, including the formation of neutral glycerophosphites, the molecules of which contain β-cyanoethyl[60,69,167] or methyl[28,60,127] groups. After the oxidation of the phosphites to the corresponding neutral phosphates, these groups are readily and selectively removed by methods which have been thoroughly developed in the chemistry of nucleic acids.

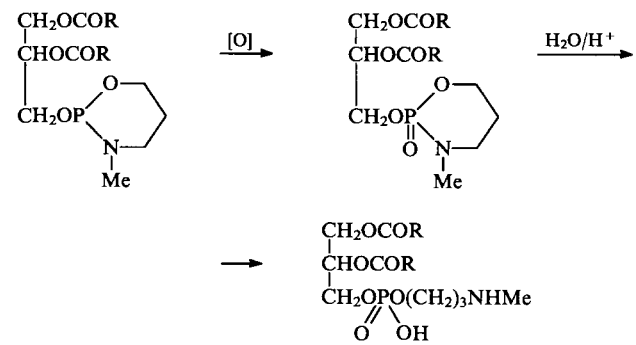
The use of cyclic phosphites has proved particularly promising in oxidation reactions. They react smoothly and effectively with nitrogen oxide and dioxide, oxygen, ozone, iodosobenzene, sulfur, and selenium, forming cyclic phosphates, phosphorothionates, and phosphoroselenonates (Scheme 24).[41-46,47,49,51,88,150,168]



Scheme 24

n = 2, 3, 4; X = O, S, Se.

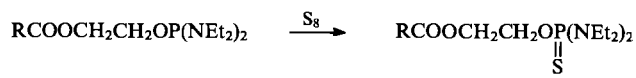
Owing to these processes, the attention of specialists in the chemistry of phospholipids has been fixed on cyclic phosphoglycerols. This trend proved to be extremely fruitful. It was established that the 1,3,2-dioxacyclanes synthesised are extremely useful alkyl donors, capable of novel reactions leading to conversion into most important classes of phospholipids. We shall illustrate the foregoing by a very simple synthesis of phosphatidylcholines (Scheme 25).[41,43,44,46,47,49,50,88,89,169,170]



Scheme 25

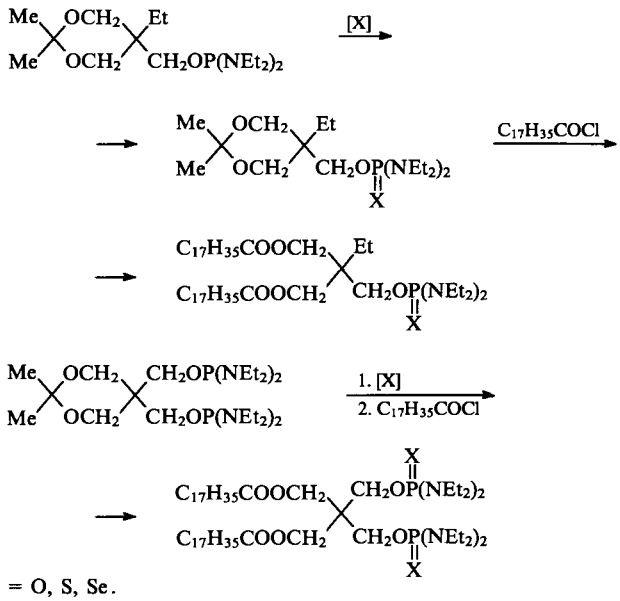
Acetals can also be used in such reactions. They are converted into the required ester systems in the most convenient stages of the synthesis.[38-40,45,49,88,91,150,152-154,171,172] It is significant that alkylation has been used for the synthesis of nonglycerol phospholipids, for example diol,[59-61] etriol,[56,109] etc.[17,18,57,58,62,108,167] phospholipids.

The oxidation reactions of cyclic phosphoramidates[52,54,64,65,93,95,125,173-178] and cyclic phosphorodiamidates[54,63] have now been investigated. The phosphaza-derivatives of pentavalent phosphorus are also very promising for subsequent reactions. For example, they can be hydrolysed with formation of phosphatidylaminoalkanols, which are otherwise difficult to obtain and which are of great interest for lipidology (Scheme 26).[54,63]



Scheme 26

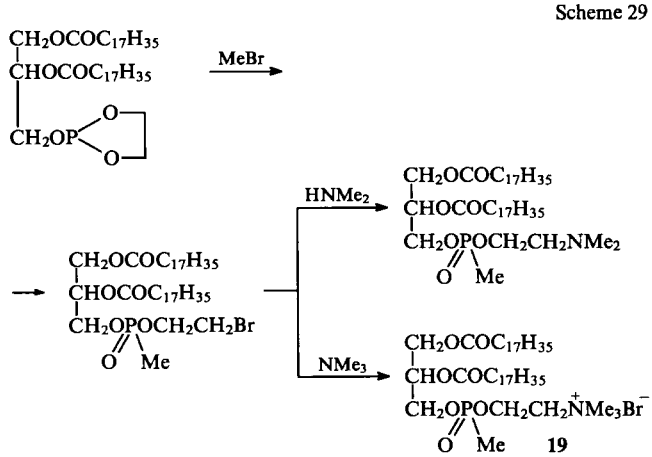
The first studies on the use of cyclic phosphates and cyclic phosphoramidates in the synthesis of lipid systems were soon continued in various scientific centres and have been described in numerous publications which we shall not discuss in the present review.



Oxidation reactions similar to those described above have been used also for the conversion of phosphites belonging to other classes of phosphorylated oligools. The phosphorodiamidites derived from monoacylglycols were sulfurised in this way (Scheme 27).[78,79,83,110]

Scheme 27

The possibilities in the use of etriol and pentaerylthritol phosphorodiamidites have been investigated in greater depth. Here is was possible to combine different new synthetic methods, for example those presented in Scheme 28.[56, 57, 109]



Scheme 28

X = O, S, Se.

A specific aspect of the use of cyclic glycerophosphatee is their involvement in the Arbuzov reaction. In this case, the main pathway in the process is the opening of the ring and the formation of the glycerophosphonate system. Attention should be drawn to the fact that phospholan glycerides react much more readily than phosphorinane glycerides, which can apparently be accounted for by the greater tendency of the five-membered ring to be opened in the second stage of the reaction. It has been suggested that the halo-derivatives formed initially be used for the preparation of the corresponding phosphonate analogues of phosphatidyldimethylethanolamine and phosphatidylcholine (Scheme 29).[39, 88]

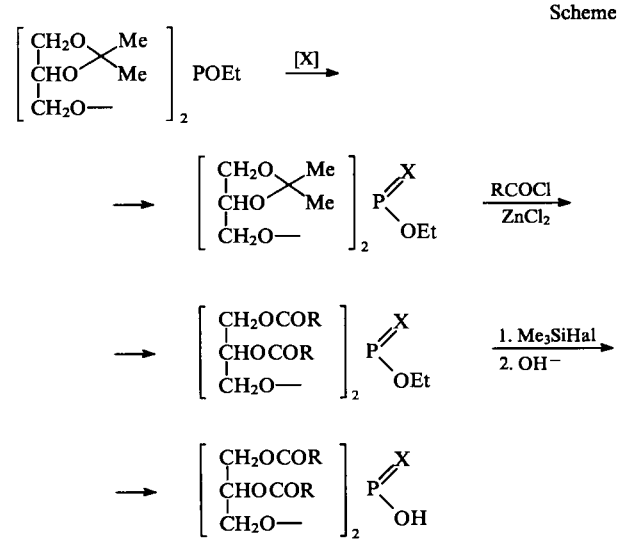
Scheme 29

It is significant that, when the Arbuzov reaction is carried out, a second chiral centre—the phosphorus atom—is generated in the molecules of racemic glycerophosphonates. This results in the appearance of a mixture of two pairs of diastereoisomers, which are manifested separately in the $^{31}P-\{^{1}H\}$ NMR spectra.

It is noteworthy that a group of unique lipids **19**, having an electropositive molecular skeleton, have been obtained via the Arbuzov alkylation reaction. On the other hand, the natural products and synthetic compounds of this type obtained previously have an electronegative or neutral molecular skeleton. The lipids described are therefore of interest as carriers of biologically active compounds and also for the creation of selectively conducting membranes. For example, anion-selective channels were first detected in planar lipid bilayer membranes formed from compound **19**.[179]

For purposes of phospholipid chemistry, a study has been made of the interaction of the neutral phosphite of an important oligool (etriol) with carboxylic acid halides. Processes of this kind were investigated previously by Kabachnik, but he used trialkyl phosphites.[180] He showed that the phosphorus atom is subjected to electrophilic attack in the acylation reaction and that α-ketophosphonates are formed. It is very interesting that etriol phosphite behaves in an unusual way in the acylation reaction: electrophilic attack is directed not to the phosphorus atom but to an oxygen atom, which results in the formation of an ester with a phosphor(III)inane substituent (Scheme 30).[181]

Scheme 30



R = Me, $C_{17}H_{35}$.

Further reactions made it possible to obtain from this product unusual phospholipid compounds the molecules of which include a phosphorus-containing ring with a pentavalent phosphorus atom.

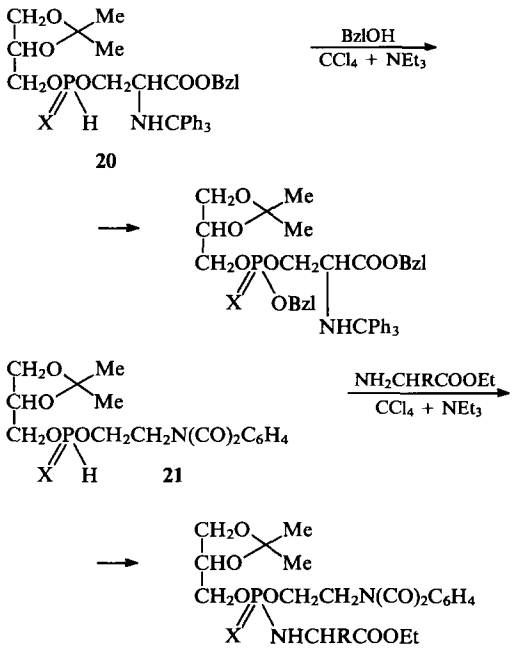
Neutral diglycerophosphites have also begun to be used for the synthesis of phospholipids. Thus a convenient method of synthesis of bisphosphatidic and previously unknown thiobisphosphatidic acids from ethyl diglycerophosphite has been developed with the aid of the fundamentally new synthetic solutions examined above [acylation of glycerol derivatives via the acetal bonds and the removal of the alkyl protecting groups by silylation and subsequent hydrolysis (Scheme 31)].[75]

Scheme 31

R = $C_{13}H_{27}$; $C_{17}H_{35}$; X = O, S; Hal = Br, Cl.

The influence of temperature and of the type of solvent on the effectiveness of the acylation of phosphobisglyceroketals and other stages of the synthesis was investigated in detail in the above study.

In the present review, we have already considered the acylation of phosphoglycerols the molecules of which contain only one glyceroketal fragment. The data illustrated by the last equation have significantly expanded the limits of the application of the new method of synthesis of ester derivatives of glycerol.

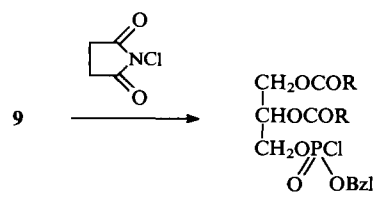


2. Reactions of acid glycerophosphites

The use of acid glycerophosphites has led to interesting prospects for phospholipid synthesis. Phosphorus as well as phosphorothious mono- and di-esters were usually assigned to this group of compounds.

Among these compounds, initially most attention was devoted to the diesters (secondary phosphites) which can be usefully subdivided into two groups—mono- and di-glyceroesters. We shall deal with these substances in the same sequence in considering their reactions.

Various types of secondary monoglycerophosphites are known at present: their molecules contain the residues of diacylglycerols, alkylglycerols, and the corresponding acetals. The structural characteristics of the systems listed above do not affect significantly their reactions, i.e. they all have the general properties of hydrophosphoryl compounds. Thus acetal systems enter widely into the Todd–Atherton oxidative phosphorylation.[124] As an example, one may quote the syntheses of lipids of different complexity: tri- and di-ester phosphoramidates based on isopropylideneglycerophosphites **20** and **21** (Scheme 32).[94,182–184]

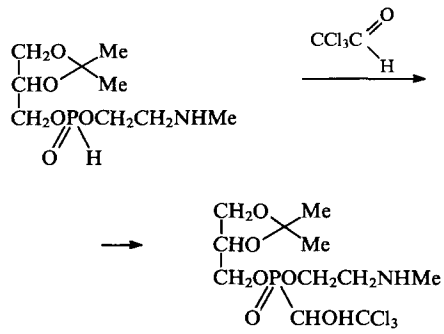


Scheme 32

R = H, Me; X = O, S.

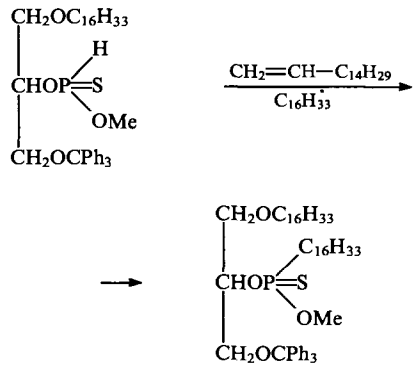
When necessary, the Todd–Atherton reaction can be arrested in the intermediate stage involving the formation of phosphorochloridates.[104] It has been suggested that the phosphorochloridates be obtained also by chlorinating phosphites with *N*-chlorosuccinimide (Scheme 33).[114–117]

Scheme 33



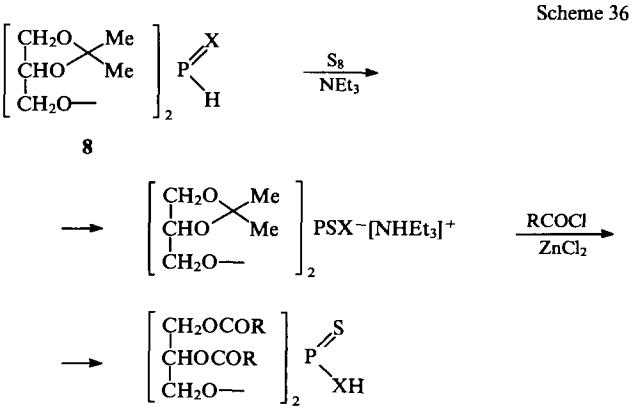
The phosphorochloridates obtained are usually employed without isolation to phosphorylate various nucleophiles, which affords, after debenzylation, phosphatidic acids, phosphatidylethanolamines, phosphatidylserines, phosphatide analogues of aminoacids phospholipids, and other important types of phospholipids.[114–117]

The oxidation reactions presented above began to be investigated also in relation to monoglycerophosphorothioites, which opens a simple path to the synthesis of neutral lipid phosphorothioates and phosphoramidothioates.[184,185]



It has been suggested that α-hydroxyphosphonates be obtained from acid glycerophosphites by means of the Abramov reaction (Scheme 34).[174,186]

Scheme 34

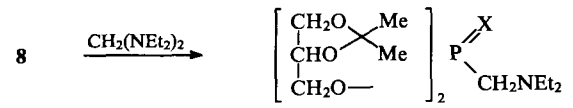


The phosphorus–carbon bond in the lipid systems can be formed also via the free-radical thiohydrophosphorylation of olefins for example (Scheme 35).[33]

Scheme 35

Secondary diglycerophosphites and their thio-analogues, represented by the 1,2-*O*-isopropylidene- and 1,3-*O*-benzylidene-derivatives, have been investigated in the Todd–Atherton oxidative phosphorylation reactions in greater detail than the monoglycerophosphites. A wide range of neutral ester diglycerophosphatides and thiophosphatides[104,111] and α- and β-bisphosphatidic acids[105] have been obtained from them. The thiophosphatides can also be obtained by direct sulfurisation (Scheme 36).[75]

Scheme 36

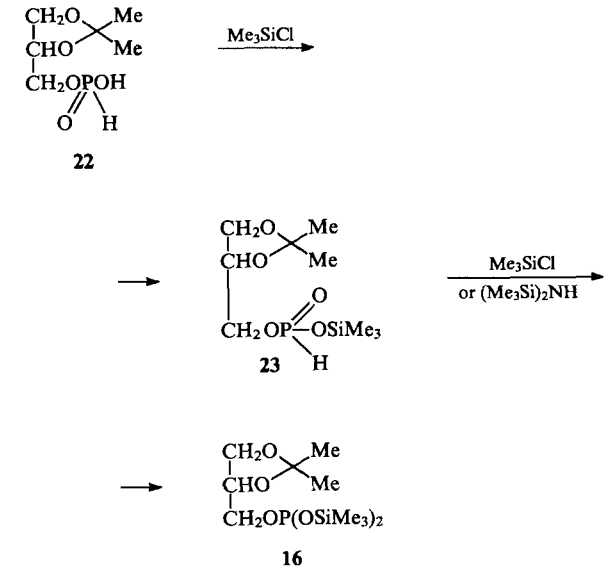


R = $C_{13}H_{27}$, $C_{17}H_{35}$; X = O, S.

Like the thio-analogues of other phospholipids, thiobisphosphatidic acids are promising substances in biochemical and biophysical research, since their resonance region in ^{31}P NMR spectroscopy is significantly different from that of natural phospholipids (δ_P = 65 and 97 ppm respectively).

The Kabachnik–Fields aminomethylation of diglycerophosphites, which makes it possible to obtain simply phospholipids belonging to the class of α-aminophosphonates and α-aminophosphonothioates, apparently merit much attention (Scheme 37).[48,104,185]

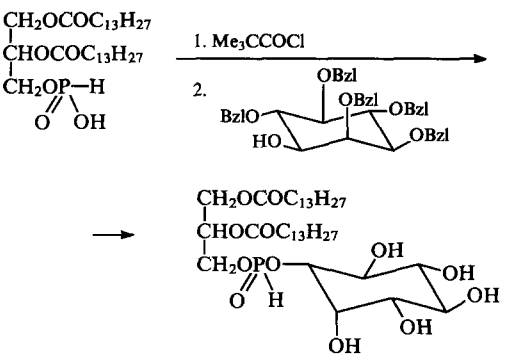
Scheme 37



X = O, S.

The compounds obtained, which are effective chelating agents, can regulate the transport of certain metals in biological membranes. Furthermore, they can fix metals which are initiators of free-radical reactions in lipid compositions and thereby stimulate, when necessary, their oxidation and certain other reactions.

Studies on primary glycerophosphites from the standpoint of the interests of glycerophosphite chemistry are only just beginning. Nevertheless, here too important results have already been obtained and there are good prospects for the wide scale preparative application of these compounds. Thus it has been shown that 1,2-isopropylideneglycerophosphite **22** is readily converted into trimethylsilyl glycerophosphite **23** on treatment with chlorotrimethylsilane, while further silylation affords a satisfactory yield of bis(trimethylsilyl) glycerophosphites **16** (Scheme 38).[106,156]



Scheme 38

As already stated in the discussion above, derivatives of tricoordinate phosphorus **16** are converted by means of simple reactions into phosphatidic acids and their thio- and seleno-analogues.

It has been suggested that primary glycerophosphites be made to react with pivaloyl chloride or other similar electrophiles to form highly reactive phosphorylating agents. The latter phosphorylate derivatives of aminoalcohols[23] and other biogenic nucleophiles,[23–25] which makes it possible to obtain rapidly valuable phosphite lipids (Scheme 39).

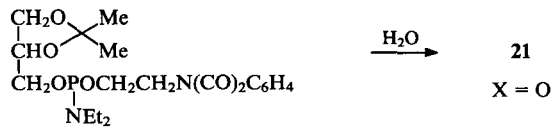
Scheme 39

This and similar phosphites were oxidised or were introduced into other oxidation reactions, which made it possible to obtain effectively a wide variety of phospholipids and their chalcogen analogues. We may note that similar syntheses also of other types of complex phospholipids have been achieved, for example the synthesis of sphingophospholipids — dihydrosphingomyelin and its *N,N*-dimethyl analogues from the primary phosphite of 3-benzoylceramide.[68,81]

3. Reactions of phosphoramidites

Recent years have been marked by the active employment of the phosphoramidites of glycerol (and other polyols) in phospholipid syntheses. Extensive data have accumulated in this field, their amount increasing steadily as a result of the appearance of new ones. We have already considered above certain reactions of glycerophosphoramidites, for example oxidation, the addition of sulfur, and alkylation, i.e. processes involving only the trivalent phosphorus atom and sometimes the P–O fragment. In the present subsection, attention will be concentrated on the reactions involving the dissociation of one or two P–N bonds, i.e. on the phosphorylation of nucleophiles (Scheme 40).

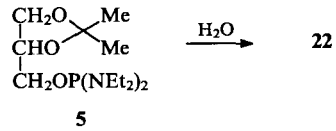
Scheme 40



By virtue of the effectiveness and mildness of this reaction and its successful combination with the necessary 'routine' reactions (oxidation, removal of protecting groups, acylation, etc.), glycerophosphoramidites are readily converted into many complex substances, including those which are difficult to obtain by other popular methods of synthesis. We may note that the initial glycerophosphoramidites are readily available, are stable during storage, and are convenient to use. Thus they may prove to be valuable key products in the synthesis of phospholipids of different types.

The phospholipid syntheses from glycerophosphoramidites, described in the literature, have two aspects. The first of these concerns the phosphorylation of nucleophiles as a result of the selective removal of one amido-group or the successive removal of two amido-groups from the phosphorus atom. The second concerns the phosphorylation of bifunctional nucleophiles — glycols and aminoalcohols — with formation of cyclic phospha-compounds.

Natural diglycerophosphoramidites with different chemical structures can be selectively hydrolysed by cleaving only the P–N bond with the formation of the corresponding phosphites.[104,111,156]



The hydrolysis of asymmetric phosphorus acid diesteramides is more complex (Scheme 41).[182–184]

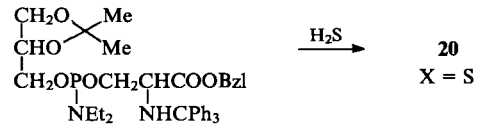
Scheme 41

The diamides of glycerophosphorus acids are hydrolysed similarly. In this case, two phosphoramide bonds are cleaved and monosubstituted phosphites are formed, for example compound **11** (Scheme 42).[106, 156]

Scheme 42

5

The hydrolysis of phosphoramidites is accelerated by inorganic and organic acids and in this version is carried out without heating. This reaction is in fact the best method of synthesis of such acid phosphites.

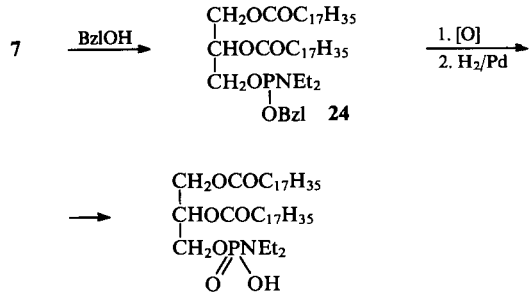


The sulfhydrolysis of glycerophosphoramides, which so far belongs to the class of little investigated reactions, also has considerable preparative prospects (Scheme 43).

Scheme 43

The cleavage of the P–N bond by treatment with hydrogen sulfide was discovered in the simplest of examples.[187, 188] Subsequently this reaction was investigated in more complex cases in our laboratory, where it was possible to introduce it into practical phospholipid syntheses.[40, 104, 184, 190] The possibilities of experiments with systems the structure of which includes acetal, ester, and trityl protecting groups were thus demonstrated (Scheme 44).[184]

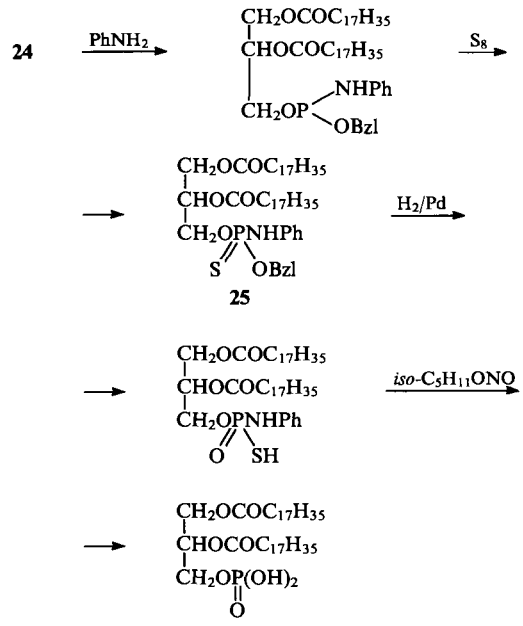
Scheme 44



The thiohydrophosphoryl fragment in this and similar compounds exhibits a high chemical reactivity, for example in oxidative phosphorylation and in combining with sulfur.[40, 75, 104, 184, 185, 190]

Subsequently it was possible to achieve the sulfhydrolysis of phosphorous acid diamides accompanied by the cleavage of two P–N bonds, leading to the formation of phosphorodithioites which are difficult to obtain in other ways.[189] These compounds can be used to synthesise completely new types of phospholipids.

A special series of studies was devoted to the benzylolysis of glycerophosphoramidites and glycerophosphorodiamidites. These studies were mainly combined with those designed to obtain phosphatidic and other lipid acids. Thus it has been shown that the tetraethyldiamide derivative of 1,2-distearoylglycerol **7** is readily converted on treatment with two equivalents of benzyl alcohol into the neutral phosphite **12**, which is readily converted into the phosphatidic acid (see above).[74]

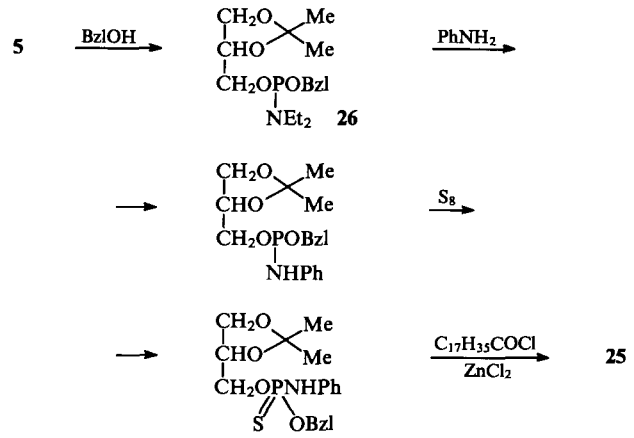


If the benzylolysis of the phosphorodiamidite **7** is carried out using an equivalent amount of alcohol, then selective monophosphorylation takes place. After oxidation and the removal of the protecting group, the product **24** was converted into an acid phosphoramidate—a representative of a rare class of phospholipids (Scheme 45).[74]

Scheme 45

Readily available and effective reagents—nitrogen(II) oxides and iodosobenzene—were used as oxidants in the schemes described above. Unfortunately they are not always convenient to use. A different way of converting glycerophosphoramidites into phosphatidic acids was therefore proposed. The idea of the synthesis consists in the fact that the benzyl glycerophosphorimidate, for example compound **24**, is transamidated with aniline† to form an anilide, which rapidly combines with sulfur, producing the neutral phosphoranilidothionate **25**. By means of a combined catalytic debenzylation and oxidative deamination, this compound is converted into a phosphatidic acid (Scheme 46).[99]

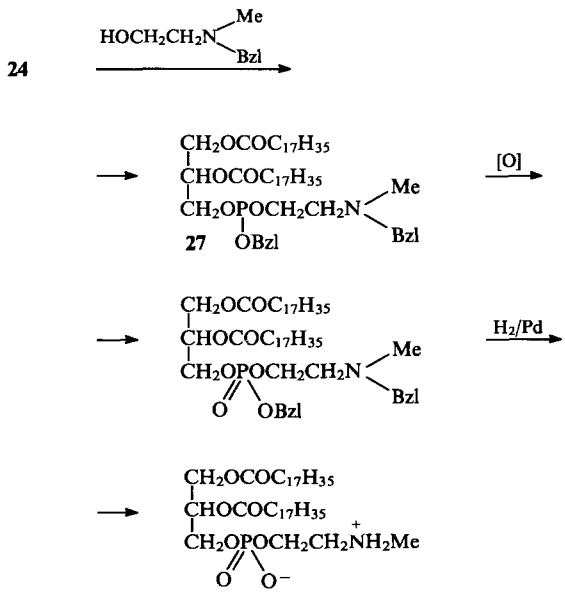
Scheme 46



The somewhat longer synthesis in this case compared with the previous one is fully compensated by experimental convenient. It is also significant that the latter scheme affords good results when isopropylideneglycerophosphoramidites **5** are used as the starting materials (Scheme 47) (see over).[99]

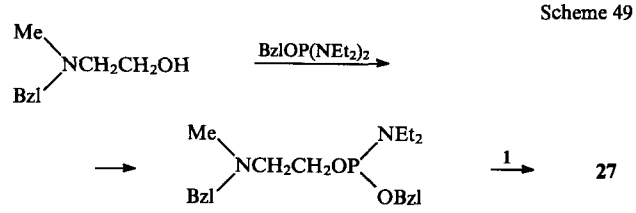
Yet another factor is striking in the present instance: acylation of the acetals of the phosphorothioic derivative of glycerol is more effective than acylation of the corresponding phosphoryl product.[14, 16, 73] Thus yet another argument may be put forward in support of the second scheme.

Extremely varied and chemically significant syntheses of phospholipids consist in the stepwise interaction of glycerophosphorodiamidites with two different alcohols. The following strategy is often used in this case: instead of one of the amido-groups, an aminoalcohol, hydroxyaminoacid, substituted glycerol, carboyhydrate, or inositol residue, or one comprising



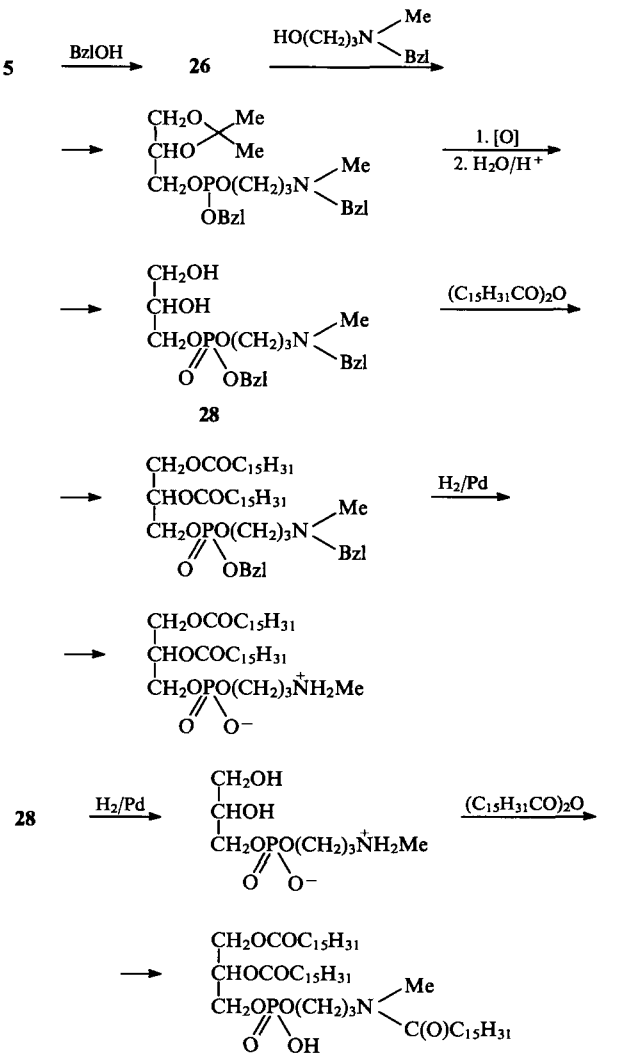
† The transamidation of the simplest phosphorous acid dialkylamides with aniline has been described.[191]

Scheme 47



other important components of the complex natural lipids or related synthetic substances is introduced initially. Next, instead of the second amido-group, a new group protecting the hydroxyl is introduced. In many instances the opposite sequence of operations in the phosphorylation process is also employed. In some experiments primary phosphorylation of the alcohol component with subsequent condensation of the resulting phosphoromonoamidite and the glycerol derivative has been used too. All the syntheses listed above are terminated by oxidation processes, the removal of protecting groups, and, when necessary, a molecular reorganisation of the type involving the replacement of acetal fragments by ester fragments. We shall consider the most important data concerning these reactions. The use of glycerophosphoroamidites for the synthesis of phosphatidylaminoalcohols, for example phosphatidyl-*N*-methylethanolamine, has been described in detail in the literature,[46, 104, 175, 176, 182] For this purpose, the phosphatide **7** (a key compound) is converted by reaction with benzyl alcohol into the monoamide **24**, which is treated with benzylmethylethanolamine. After this the intermediate neutral phosphite **27** is oxidised and debenzylated twice (Scheme 48).[46]

Scheme 48

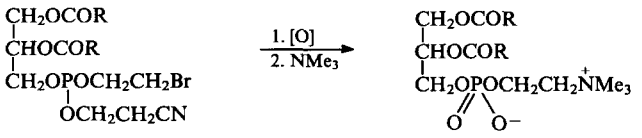


We may note that an alternative scheme, involving the initial phosphorylation of benzylmethylethanolamine with phosphorous acid diamine has certain preparative advantages (Scheme 49).[46]

Scheme 49

A fundamentally different method of synthesis of phosphatidylaminoalcohols presupposes the use of 1,2-*O*-isopropylideneglycerophosphorodiamidites **5** as the starting material. Experiments involving the hydrolysis of 1,2-isopropylideneglycerophosphate to the phosphate **28** unsubstituted in the glycerol residue and its subsequent acylation (Scheme 50) have been carried out for this purpose.[175, 176]

Scheme 50

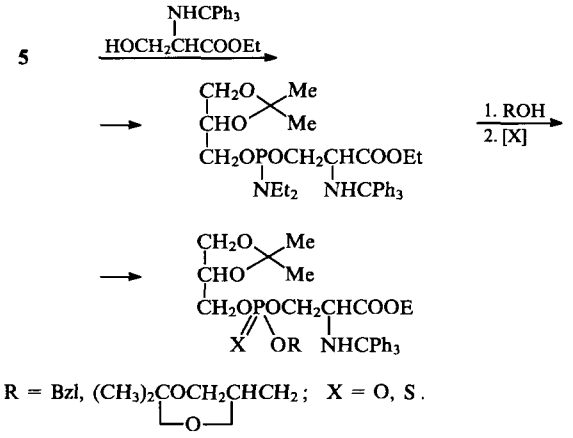


Unfortunately, nobody has investigated previously the possibility of using in this instance the acylation of a phosphorus-containing acetal with formation of ester systems, bypassing the diol stage.

In relation to the synthesis of the aminoalcohol lipids examined above, a number of workers have improved the classical scheme by a useful new feature—methyl phosphite derivatives were used as the reactants instead of benzyl phosphite derivatives. The former are readily oxidised to methyl phosphates, which exhibit an excellent methylating activity and readily lose the methyl group on treatment with, for example, ammonia in toluene or another nucleophile.[30–32]

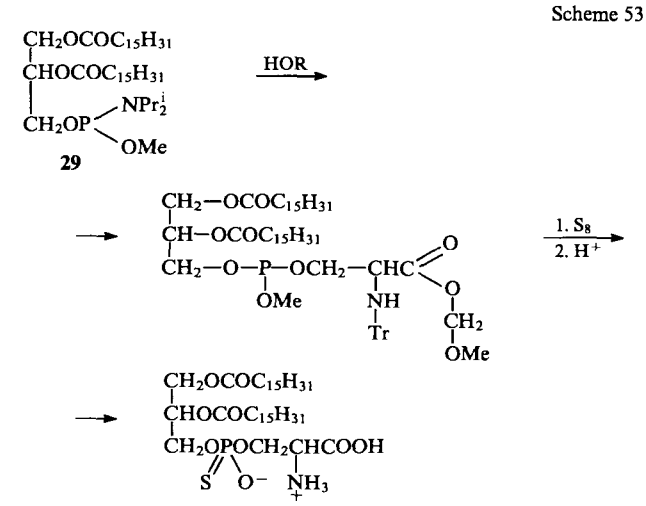
Aminoalcohol derivatives of thiophosphatidic acids, including reactions where they were obtained as individual stereoisomers with chiral phosphorus atoms, have been obtained using this version of the synthesis.[32] These stereoindividual thiophospholipids are nowadays actively employed in biochemical research to elucidate the mechanism of the action of phospholipases.[32, 192–194]

There exists yet another version of the method described above. It differs by the use of neutral phosphites with a protecting β-cyanoethyl group. This protecting group is removed under milder conditions than the methyl group, which is the reason for the interest in the proposed modification. Phosphatidylcholine was obtained by this procedure. An additional advantage of the above scheme is the simultaneous occurrence of two reactions with trimethylamine: the removal of the cyanoethyl group and the formation of the ammonium group (Scheme 51).[60, 69, 80, 167]



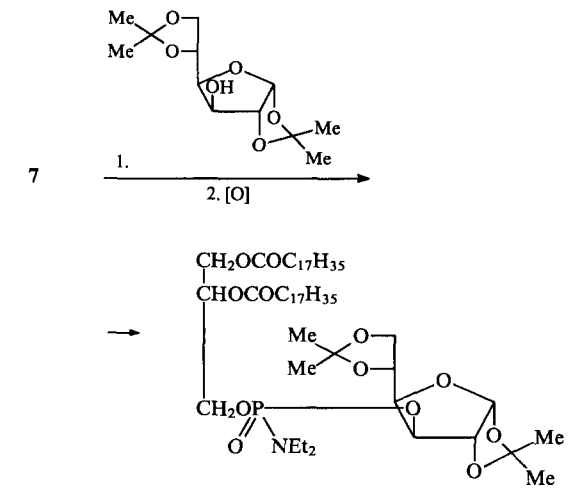
Scheme 51

The above schemes have also been used to synthesise sphingolipids.[66–68, 81, 82]



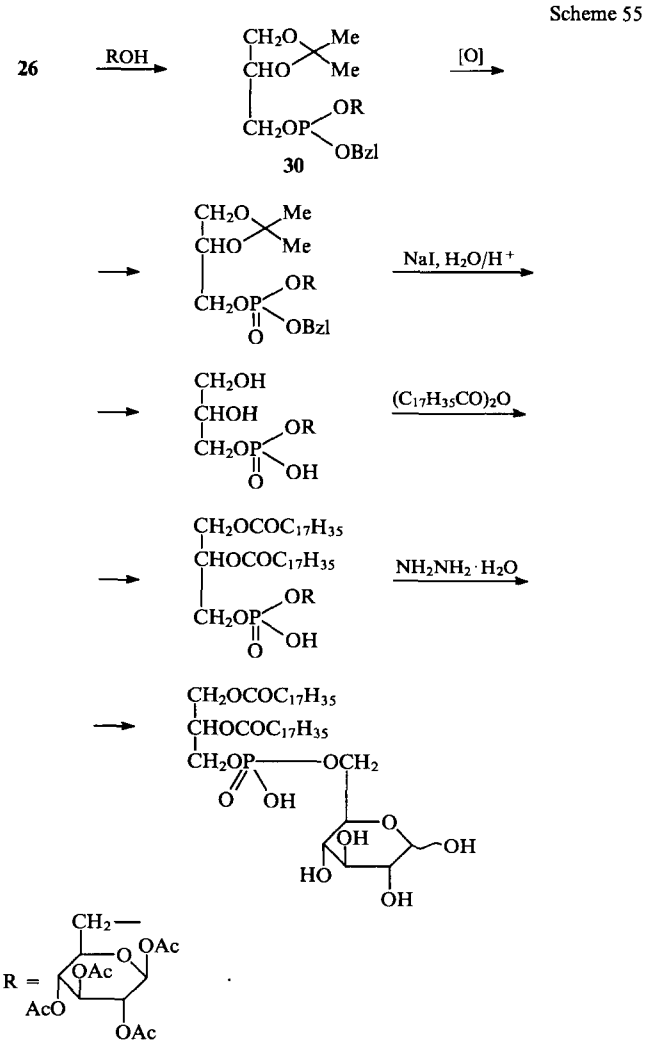
The phosphoroamidite method has been used to obtain models of lipids containing aminoacid, for example serine, residues (Scheme 52).[100, 183, 184]

Scheme 52



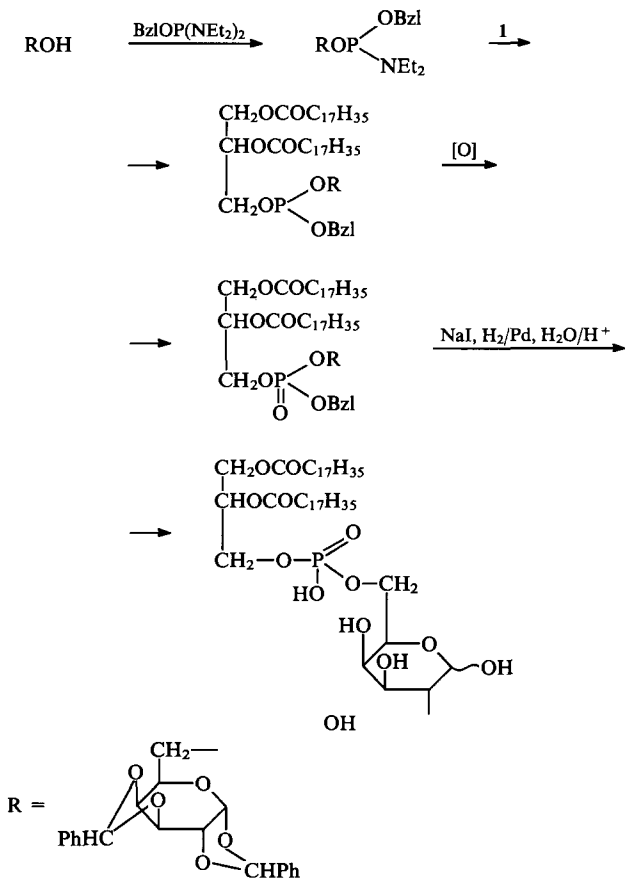
Similar reactions have been carried out also using *N,N*-diisopropyl-1,2-dipalmitoylglycerophosphoramidite **29** (Scheme 53).[35]

Scheme 53



The use of glycerophosphoramidiates for the synthesis of carbohydrate-containing phospholipids, which have been recently attracting increasing attention, is especially valuable.[90, 195, 196] The reaction indicated in Scheme 54 indicates a simple path to these systems.[90, 96, 197, 198]

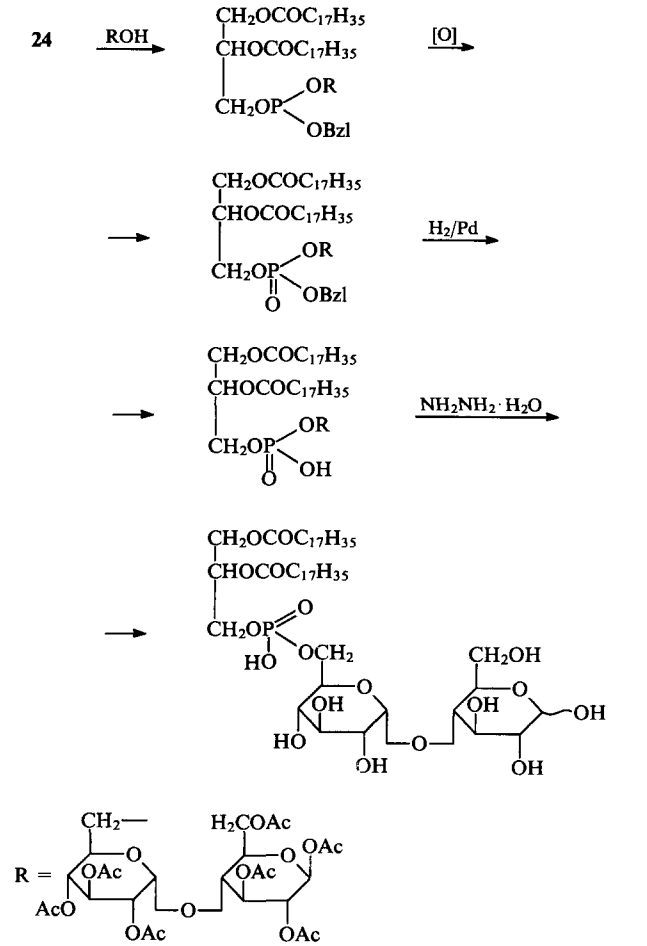
Scheme 54



Another version of the synthesis of the complex lipid phosphatidyl-6-glucose is based on the employment of 1,2-*O*-isopropylideneglycerophosphoramidite **26** and 1,2,3,4-tetra-*O*-acetyl-β-D-glucopyranose as the starting compounds (Scheme 55).[86]

Scheme 55

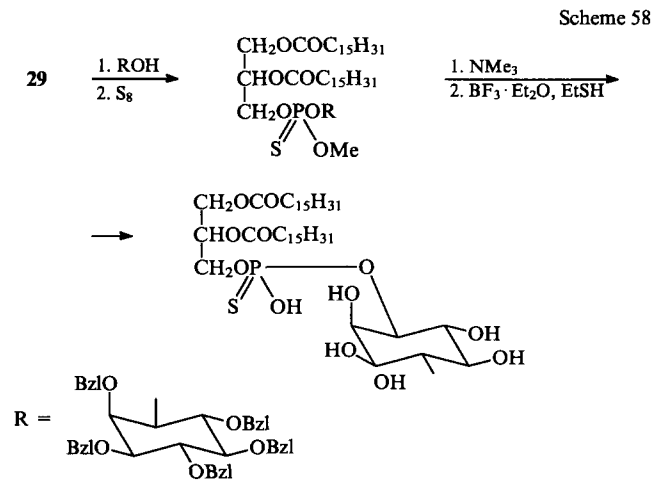
The asymmetric benzyl glyceroglycophosphite **30**, used in the above study, can be obtained also by the initial phosphorylation of the sugar with benzyl *N,N,N',N'*-tetraethylphosphorodiamidite and subsequent incorporation of the 1,2-*O*-isopropylidene-glycerol residue in the phosphorus unit. When a sugar with acetate protecting groups is used, this phos-phorylation sequence is less preferable, since it involves prolonged heating of the reaction mixture and this leads to appreciable charring and hence to a decrease in the yield of the asymmetric phosphite. On the other hand, the above method can be usefully employed in the synthesis of glycophospholipids based on stable benzylidene derivatives of sugars, for example, 1,2,3,4-di-*O*-benzylidene-α-D-galactopyranose, because in this case the labile diglyceride fragment is phosphorylated last and is less subject to thermal and chemical influences. A similar solution is used in the total synthesis of phosphatidyl-6-galactose (Scheme 56).[97]



Scheme 56

The use of the synthetic ideas described above has led to the availability also of the very important disaccharide derivatives of glycerophospholipids.[199,200] We shall demonstrate this in relation to the synthesis of 6'-(1,2-distearoyl-3-glycerophospho)-maltose (Scheme 57).[198]

The methods of synthesis of glycophospholipids examined in the present subsection are distinguished by their simplicity. The main advantage of the 'phosphoramidite' method of synthesis of the phosphorus-containing unit compared with the commonest classical 'silver salt' method is the small number of stages. Thus, in order to phosphorylate a diglyceride or a partly protected carbohydrate with a free hydroxy-group by the 'silver salt' method, it is necessary to convert them in a preliminary step into halodeoxy-compounds. The yield of deoxy-derivatives usually does not exceed 50%. Furthermore, the alkyl dibenzyl phosphates used as phosphorylating agents must be converted by complex procedures into silver salts of monobenzyl phosphates.[1,195,196] The phosphoramidite method makes it



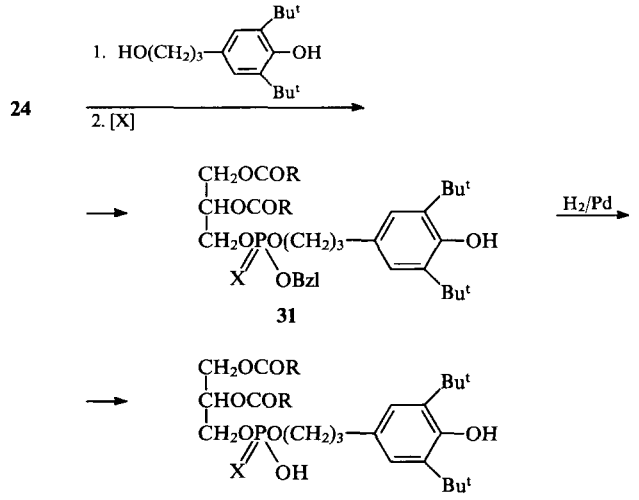
Scheme 57

possible to achieve directly the phosphorylation of diglycerides and of partly protected carbohydrates by phosphoramidites under mild conditions and with high yields in the decisive stages.

The phosphoramidite method has been recently used to synthesise inositylthiophosphatides. As in the synthesis of nitrogen- and carbohydrate-containing glycerophospholipids, in this case the synthesis is based both on the glycerophosphor-amidites **29** and myoinositol derivatives (Scheme 58).[34,36,37]

Scheme 58

The signals due to two diastereoisomers were detected in this instance in the $^{31}P-\{^{1}H\}$ NMR spectra for the optically active glycerol when a neutral phosphorothioate was used. These substances were resolved chromatographically. Their structure was demonstrated by enzyme analysis.

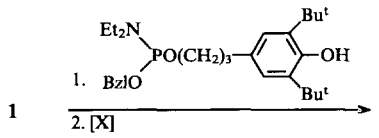


Neutral phosphoramidites with benzyl protecting groups, similar to those described above, have been used as the starting materials for the synthesis of the optically active natural phosphatidylinositol diphosphate and a fragment of a microbacterial phospholipid—phosphatidylmannomyo-inositol.[101,102]

The phosphoramidite method has been used also to synthesise other related complex lipids, for example ceramide phosphoinositol and its thio-analogue,[68,81,82] and in addition diolphospholipids containing cholesterol and certain other steroids.[78,84,110]

The following aspect of the use of phosphoramidites has been applied to the synthesis of lipid antioxidants. Such compounds can be obtained by the chemical combination of sterically hindered phenols and phosphatidic acids. We may note that previously a number of investigators demonstrated in studies on the peroxide oxidation of lipids that natural inhibitors of radical reactions play a significant role in the regulation of this process. These natural bioantioxidants initially contain the residues of sterically hindered phenols as protecting groups.[201-206] It was of interest to investigate the regulation of the peroxide oxidation of lipids in the presence of synthetic anitoxidants which are also derivatives of sterically hindered phenols. Such studies have been carried out in different laboratories and, in the case where ionol was used, led to positive results.[201-204,206-210] Unfortunately ionol and its analogues are not chemically related to lipids, which prevents the ready transport of the antioxidants into the membrane.[206,211] Taking into account the foregoing, the synthesis was undertaken of membrane-addressed antioxidants containing phosphatide groups and residues of sterically hindered phenols: 2,6-di-(*tert*-butyl)-4-(γ-hydroxypropyl)phenol, 2,6-di(*tert*-butyl)-hydroquinone, and ionol.

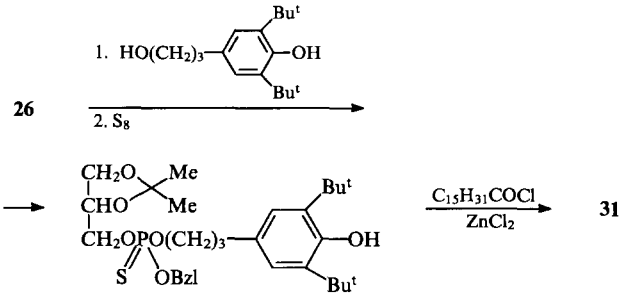
In the search for a convenient preparative method of synthesis of phosphatidyl(hydroxalkyl)phenols, various synthetic procedures were investigated. One of the schemes employed included the phosphorylation of γ-hydroxy-propylphenol by the phosphoramidites **24** (Scheme 59).[87]



Scheme 59

R = $C_{15}H_{31}$, $C_{17}H_{35}$; X = O, S.

Of the two hydroxyls of the substituted phenols, the alcoholic hydroxyl reacts with the phosphoramidite.[212] In the second version, the key compounds **31** were obtained by phosphorylating 1,2-diacylglycerols **1** with benzyl γ-(di-*tert*-butylhydroxyphenyl)propyl *N,N*-diethylphosphoramidite (Scheme 60).



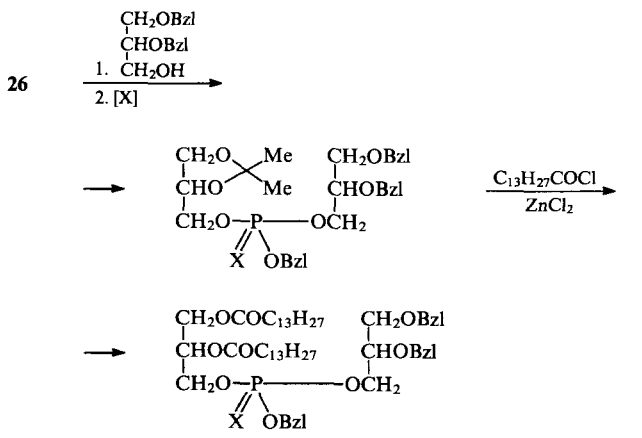
Scheme 60

R = $C_{15}H_{31}$, $C_{17}H_{35}$; X = O, S.

The lipid antioxidant has also been synthesised using the readily available 1,2-*O*-isopropylideneglycerophosphoramidite **26** instead of the phosphoramidite **24** as the starting compound (Scheme 61).

Scheme 61

The most important feature of the synthesis is the specificity of the acylation of the phenol-substituted phosphoacetal. It was shown that, on acylation with two moles of palmitoyl chloride, the phenolic hydroxyls are unaffected.



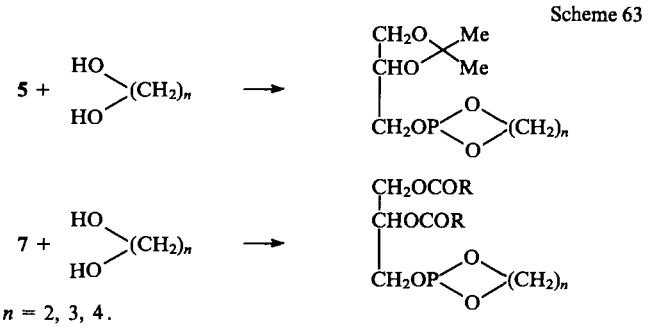
The synthesis of lipid antioxidants containing the 2,6-di-(*tert*-butyl)hydroquinone residue has also been investigated. The schemes presented above were used for this purpose.[26]

It was found that lipid antioxidants containing sterically hindered phenol residues have effective antioxidant properties.[103] There is therefore a prospect of formulating with the aid of these phospholipids (antioxidants) new problems in the study of the peroxide oxidation of membranes.

The phosphorylation of tocopherol, which is a carrier of antiradical properties, by *N,N,N',N'*-tetraalkylphosphorodiamidites is of definite interest for the synthesis of a new type of antioxidants.[78,83,110]

A very interesting fact was established in the search for lipid anitoxidants. It was found that certain glycerides containing phosphorothioic acid residues are also inhibitors of free-radical reactions.[103] Apparently, after a deeper investigation of such phosphorothioates, the procedures available in lipidology will be expanded by the inclusion of a new class of readily available antioxidants which are convenient to use.

Scheme 62



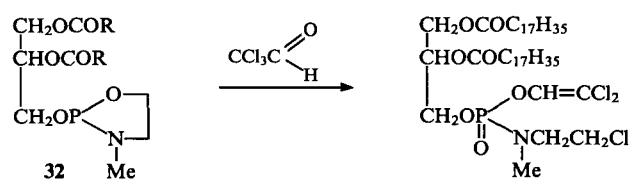
X = O, S.

We examined above the employment of monoglycerophosphoramidites for the synthesis of glycerophosphatides, the molecules of which contain one glycerol residue. We shall now proceed to the discussion of the syntheses of phospholipids containing two glycerol residues.[30,75,105] Thus phosphoramidites have been used to synthesis phosphatidylglycerols (Scheme 62) (see previous page).[75]

The neutral benzyl esters of phosphatide and thionophosphatide can be converted into phosphatidylglycerol (thiophosphatidylglycerol) by total debenzylation taking into account the results of other investigations.[1,3,8,10]

Another aspect of the synthetic application of glycerophosphoramidites concerns studies on the cyclophosphorylation of bifunctional nucleophiles, in the first place glycols (Scheme 63).

Scheme 63



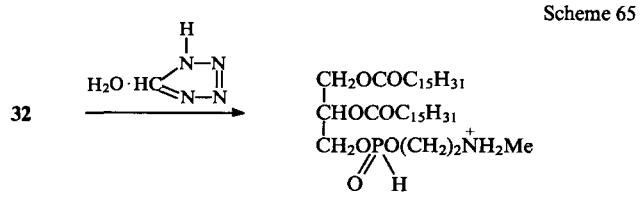
n = 2, 3, 4.

The choice of the diol has a considerable influence on the effectiveness of the cyclisation; 1,2- and 1,3-glycols react in accordance with the scheme presented and afford high yields of alkylene glycerophosphites (up to 70%).[46,88] Butane-1,4-diol is also converted into the expected glycero-1,3,2-dioxaphosphepan in 55% yield in the reaction with the diamine **5**. However, in this case a mixture of cyclic oligomers is formed simultaneously, but these can be readily separated from the target product.[91,92] It is of interest that the glycerophosphepan is a stable compound, while its analogues, containing chlorine, dialkylamino-groups, and other very simple substituents at the phosphorus atom, are very labile and readily oligomerise.[214-218] The last factor explains the low effectiveness of the synthesis of glycerophosphepans via an alternative scheme consisting in the phosphorylation of substituted glycerols by the chloro- and dialkylamino-phosphepans already mentioned.[91,92]

Glycerophospho(III)cyclanes are promising intermediates in the synthesis of different types of phospholipids. Data on this question have already been examined above in subsection 1 in the present section.

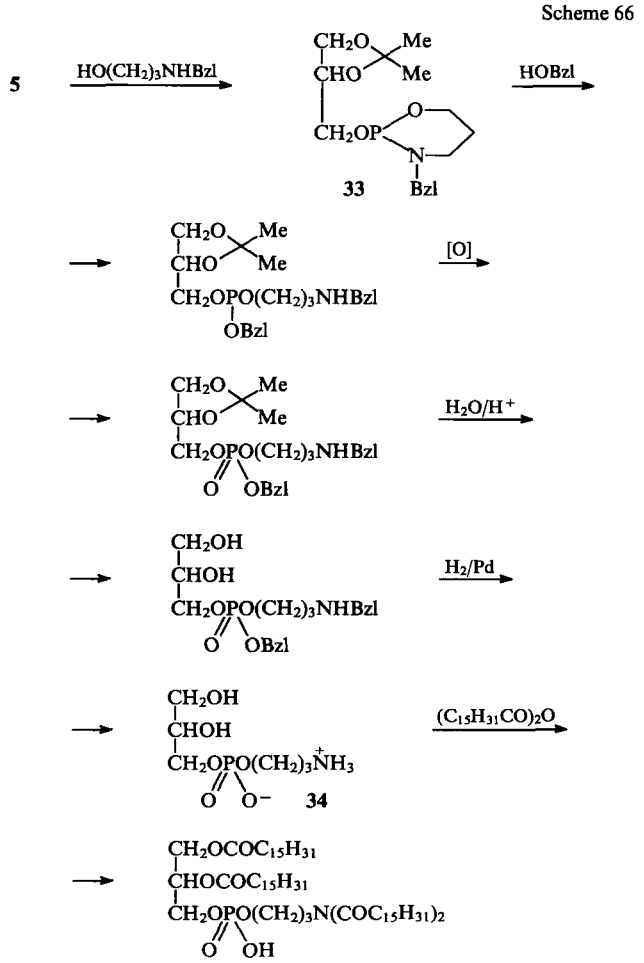
It has been suggested that cyclic glycerophosphoramidites — glycero-derivatives of oxazaphospholans[94,177,183] and oxazaphosphorinanes[52,175] — be synthesised via Scheme 63 but this time also using aminoalcohols.‡ These substances have already been used in oxidation reactions (see above) and in certain other syntheses. Thus treatment of glycerooxazaphospholans **32** with chloral in accorance with the Perkow procedure results in their conversion into unusual lipids belonging to the class of enol phosphates (Scheme 64).[95,186]

Scheme 64



‡ The possibility of using also hydroxyaminoacid esters, for example serine, in such cyclisations has been demonstrated.[183]

The phosphorus centre in the molecules of enol glycerophosphates combines the structural features of the molecules of familiar alkylating ($\geq NCH_2CH_2Cl$) and phosphorylating [$\geq P(O)OCH=CCl_2$] preparations. Lipids, which contain such a functional group, can probably be regarded both as antitumour agents and as instruments for the study of the structures and functions of biological membranes. Phospholipids containing alkylating groups have also been obtained by the Arbuzov reaction between glycerophosphoramidites and methyl iodide.[186]



Another possible synthetic use of glycerophosphoramidites involves their reactions via the labile P—N bond. In this case, the fragment concealed by phosphorylation is immediately 'bared'. The simplest version of the cleavage of the P—N bond is acid hydrolysis, for example by monohydrates of sulfonic acids[52,173] or tetrazole,[53] and sulfhydrolysis,[185] which lead to hydrophosphoryl(thiohydrophosphoryl) analogues of phosphatidylaminoalcohols (Scheme 65).[53]

Scheme 65

The cyclic phosphoramidites examined above react satisfactorily also with alcohols of different chemical nature, which permits the solution of novel chemical problems. Thus the benzylolysis of glycerooxazaphosphorane **33** results in the formation of a neutral phosphite, the oxidation and deblocking of which lead to glycerophosphohomoethanolamine **34**. This

Scheme 66

polyfunctional product was acylated with palmitic acid anhydride, affording the tetrapalmitoyl derivative of a phospholipid which is difficult to obtain by other procedures (Scheme 66).[54, 176]

Alcoholysis can be used also to synthesise unusual neutral phosphites in the molecules of which the phosphorus atom is surrounded by residues of glycerol, aminoalcohols, and the reagent employed (carbohydrate, hydroxyaminoacid, glycerol derivative, etc.). The neutral phosphites obtained can be stabilised in either the phosphate or the phosphorothionate forms.[96, 184, 196] Such derivatives have been discussed in the literature in connection with the elucidation of the structures of natural complexes incorporating in their structure biopolymers and lipids.[8] Previously they were synthesised only by methods of classical phospholipid chemistry. The new suggestions based on the use of effective phosphorylation procedures apparently merit extensive use and can lead to progress in the study of such complex systems.

IV. Conclusion

The data presented have acquainted readers with the way in which the idea of replacing, in the intermediate stages of phospholipid syntheses, pentavalent phosphorus reagents by previously hardly used trivalent phosphorus reagents is applied. The application of this new synthetic strategy has entailed the vigorous utilisation of the possibilities of modern organophosphorus chemistry for the solution of problems in phospholipid chemistry of current interest and subsequently in membranology. On the other hand, further development of traditional studies on trivalent phosphorus derivatives has been greatly stimulated. All these factors suggest that a trend has arisen towards the establishment of a new interdisciplinary field of science.

Overall, the studies described demonstrate the necessity for their further expansion and deepening. Thus the absence of attempts to synthesis hypophosphite glycerolipids appears strange because all the previously investigated hypophosphites proved to be valuable key substances in the synthesis. Furthermore, hypophosphite glycerophospholipids as components of membranes can protect the latter against oxidation and other undesirable processes. The development of simple and effective methods of synthesis of glycerophosphites and similar compounds makes it necessary to undertake studies also on the corresponding metal complexes including transition metal complexes. Such coordination systems can play the role of a kind of carrier and can ensure the transport of metals into membranes. The distribution of metals in the lipid phases of membranes will clearly prove to be of fundamental importance since it will enable a series of important problems to be solved, for example that of the regulation of homolytic reactions in membranes or the binding to one another of individual lipid molecules as a result of the oxidative addition of C–H bonds to the metal.

Immunoassay of low-molecular-mass physiologically active substances of plant and microbial origin encountered in plants

S K Volkov

Contents

I. Introduction 91
II. Immunoassay 91
III. Conclusion 99

Abstract. The application of immune methods for the assay of both endogenic and exogenic low-molecular-mass physiologically active substances encountered in plants is considered. The bibliography includes 161 references.

I. Introduction

The determination of the content of biologically active substances in plant tissue constitutes one of the most important parts of the science of medicinal plants. The content of physiologically active substances in plant raw material determines not only the economic parameters of the manufacture of a number of medicinal preparations but also their quality.

Selection of the most productive types of plants is based on the quantitative assay of biologically active substances in various parts of plants. The development of biotechnological methods for the cultivation of plant cells and tissues likewise cannot take place without the quantitative assay of biologically active substances. Since many biologically active compounds of plant origin are narcotics, their quantitative determination is important from the criminological point of view.

The most important groups of biologically active substances of plant origin are alkaloids, including a series of narcotic substances, terpenoids, flavonoids, anthrones, steroids, plant growth and development regulators, and certain others. Certain substances which are not endogenic but enter the plant material from outside frequently have to be determined in plant tissues, particularly those used as food by man and as cattle feed. These include antibiotics and mycotoxins.

This review constitutes a continuation of the previously published article on the immunoassay of alkaloids [1] and for this reason alkaloids will not be considered here except for those groups of alkaloids which were not dealt with in the previous review. For the same reason, narcotic alkaloids (opiates and cocaine group alkaloids) will not be considered here either.

The principal advantages and disadvantages of the immune methods for quantitative assay, the approaches to the immunoassay of low-molecular-mass compounds, and the commonest methods of immunoassay were also examined in fair detail in the previous review.

II. Immunoassay

1. Narcotic substances

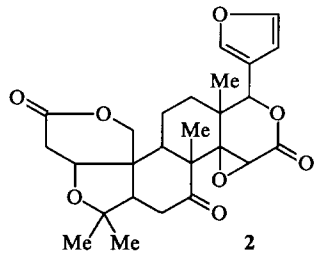
Narcotics of plant origin include not only many alkaloids but also a series of nonalkaloid compounds with biological activity. Biologically active substances of hemp (cannabinoids) occupy a by no means unimportant place among them.

Cannabinoids constitute a group of powerful narcotics — hallucinogens. Among cannabinoids, tetrahydrocannabinols are particularly dangerous. Thus Δ^9-tetrahydrocannabinol **1** (or Δ^1-tetrahydrocannabinol when a different system for the numbering of atoms is used) is the principal component of hashish and marijuana, which are prepared from Indian hemp (*Cannabis sativa*). When it acts on the organism in doses of the order of 10^{-5}–10^{-6} g (kg body weight)$^{-1}$, compound **1** induces a psychiatric disorder, a decrease in blood pressure, and a decrease in sensitivity to pain.

1

Several methods exist at present for the immunoassay of compound **1**. The fluorescence polarisation method is simple and convenient in the assay of a large number of specimens, but its sensitivity (5×10^{-5} g L^{-1}) is not always adequate. [2] The immunofluorescence method using antibodies bound covalently to magnetic particles, which makes it possible to carry out easily the stage involving the separation of the bound and free antigens, is more sensitive; as a result of the above features of this method, its sensitivity reaches 5×10^{-6} g L^{-1}. [2]

There exist also a homogeneous immunoenzyme method for the determination of cannabinoids, [3] the sensitivity of which is $(1.5-2.5) \times 10^{-2}$ g L^{-1}, and a solid-phase heterogeneous immunoenzyme method. [4] In the latter case, the immunogenic conjugate was obtained by oxidising compound **1** with potassium hexacyanoferrate(III) and conjugating the derivative obtained with the protein. The sensitivity of the solid-phase immunoenzyme method reaches 10^{-4} g L^{-1}.



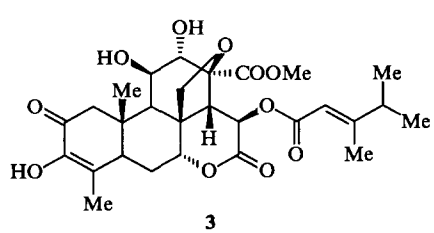
Diagnostic sets produced by the Abbot Company (UK) enable detection of **1** at a concentration of 9×10^{-6} g L^{-1}.

The immunoassay methods have been used hitherto only in the determination of cannabinoids and their metabolites in human biological liquids [6,7] but not for the quantitative assay of cannabinoids in plants.

2. Terpenoids

The class of terpenoids or isoprenoids, the first representatives of which were isolated from turpentine, constitute a large group of biologically active compounds of plant and animal origin. Terpenoids include certain natural glycosides (saponins), yellow and orange plant pigments (carotenoids, xanthophylls), natural rubber, products derived from pine resin, and a number of other substances.

Limonin 2. This triterpene is concentrated in the seeds of many types of plants of the genus *Citrus* (*Rutaceae*) and when it contaminates lemon juice it imparts an excessively bitter flavour to the latter. Since the amount of compound **2** in the plant can differ greatly from batch to batch, its content must be monitored, since the bitterness of the juice increases sharply in the range of concentrations of compound **2** from 10^{-7} to 10^{-6} g L^{-1}. This requirement has led to the development of a series of methods for the immunoassay of compound **2**.



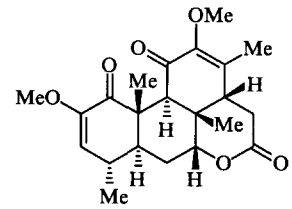
2

In order to obtain an immunogenic conjugate, compound **2** was attached to bovine serum albumin (BSA) with the aid of aminooxoacetic acid. The antiserum to this conjugate was used to develop radioimmunoassay methods using the conjugate of the methyl ester of 7-(*O*-carboxymethyl)limonin with the ^{125}I-labelled aminooxo-derivative of tyrosine[8] and also ^{3}H-labelled limonol.[9] The same antiserum has been used for the development of an immunoenzyme assay method using the 7-(*O*-carboxymethyl)oxime of compound **2** conjugated with alkaline phosphatase by the carbodiimide method.[10] Radioimmune methods using ^{125}I- and ^{3}H-labelled compounds make it possible to determine compound **2** in the ranges $10^{-10}-10^{-7}$ and $5 \times 10^{-10}-10^{-7}$ g respectively. Although the immunoenzyme method is somewhat less sensitive (the range of the determination is $10^{-9}-10^{-7}$ g), nevertheless it makes it possible to work with more stable substances and to carry out the assay in 1 h.

The radioimmune method has been used to investigate the distribution of compound **2** in the tissues of *Citrus paradisi*.[8] The immunoenzyme method has been applied to the assay of specimens of lemon juice and a satisfactory agreement has been observed with the results of assay by the HPLC method, but the immunoenzyme method does not require special preparation of the specimen and takes less time.[10]

A set for the immunoenzyme assay of compound **2** is manufactured by the Idetek Company (USA).[11]

Bruceantin 3. This secotriterpenoid, isolated from *Brucea antidisenterica* (*Simaroubaceae*), exhibits an appreciable antitumour activity. As for other medicinal drugs, immunoassay methods greatly facilitate the study of the pharmacological properties of compound **3**.



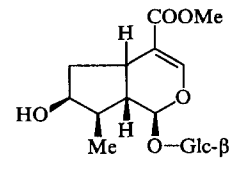
3

In the development of the radioimmunoassay method, compound **3** was conjugated with BSA with the aid of succinic anhydride, and an antiserum to this conjugate was obtained.[12] Radioimmunoassay with the use of [^{3}H]acetylbruceantin, obtained by treating compound **3** with [^{3}H]acetic anhydride, makes it possible to determine compound **3** in the range 5×10^{-10} to 5×10^{-8} g.[12]

The method has been used to study the distribution of compound **3** in mouse body tissues and for its removal from the dog; immune methods have not been applied to the assay of compound **3** in plants.

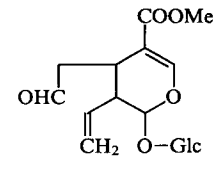
Quassin 4. This secotriterpenoid, which has an extremely bitter taste, has been isolated from *Quassia amara*. It is used to impart a bitter flavour in the food industry. Methods for the immunoassay of compound **4** have been developed in order to monitor the manufacture of products and also for the analysis of plant cell clones.

4



In devising an immunoenzyme method, the δ-lactone of quassin was converted into a derivative with a free carboxy-group, which was stabilised by epimerisation to form isoquassinic acid.[13] Isoquassinic acid was conjugated with BSA by the mixed anhydride method and a rabbit was immunised with the conjugate. The competing conjugate of compound **4** with the haemocyanine of the edible snail (KLH) was obtained by the carbodiimide method. The immunoenzyme method using goat antibodies to rabbit immunoglobulins G (Ig G), conjugated to alkaline phosphatase, makes it possible to determine the concentration of compound **4** in the range $2 \times 10^{-9}-2 \times 10^{-7}$ g. Appreciable cross-reactions were noted for methyl isoquassinate, α- and β-neoquassin, 14,15-dehydroquassin, 12- and 18-hydroxyquassin, and also nigakilactones and picrasin A from *Picrasma excelsa*.

Another method is based on the application of the antiserum to 18-hydroxyquassin conjugated with BSA by means of succinic anhydride. In other respects, the method is similar to the previous one and makes it possible to determine quassin in the range $5 \times 10^{-9}-10^{-7}$ g.[14] The method has been used to investigate the distribution of immunoresponsive substances in the tissues of *Q. amara*, *Q. indica*, and *P. excelsa*.[14]



The immunoenzyme method for the determination of quassinoids has been used in the study of the tissues and cell cultures of *Ailanthus altissima*.[15]

3. Iridoid glycosides

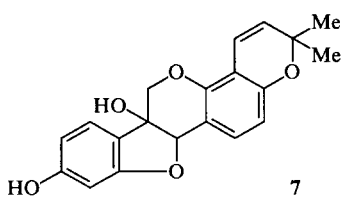
The monoterpene glycosides loganin **5** and secologanin **6** are intermediates in the biosynthesis of many alkaloids.

5

6

Radioimmunoassay methods have been developed for the investigation of the biogenetic transformations of compounds **5** and **6**.[16] Loganin was converted into the 6′-carboxy-derivative involving the glucose residue and was conjugated with BSA by the carbodiimide method. The radioimmune method using the ^3H-labelled derivative, obtained by the periodate cleavage of compound **5** and subsequent reduction by NaB^3H_4, makes it possible to determine compound **5** in the range 5×10^{-10} to 10^{-7} g. Cross reactions with compound **6** (0.07%) and the aglycone of compound **5** (30%) have been noted.

The method was used to determine compound **5** and to investigate its conversion into compound **6** in *Weigela gigantiflora* and *Lonicera tatarica* cell cultures.[16]



4. Sesquiterpenes

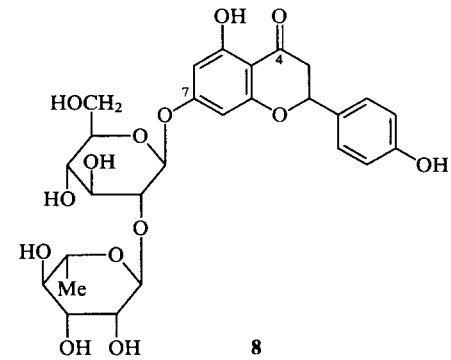
Sesquiterpenoid compounds are contained in various plant essential oils and resins (balsams). The group of sesquiterpenes includes substances such as juvenile hormones, perfumes, sesquiterpene lactones and phytoalexins, as well as ichthyotoxins.

5. Phytoalexins

The group of phytoalexins includes highly reactive compounds which protect plants against disease. They are synthesised by plants only in response to tissue trauma and for this reason they are also referred to as stress metabolites. The system for the production of phytoalexins by plants is sometimes referred to as the immune system of plants. Phytoalexins possess antimicrobial properties.

Glyceollin I (compound 7) is the main phytoalexin accumulating at the sites of tissue trauma or infection of soya bean (*Glycine max L. Merrill*).

7



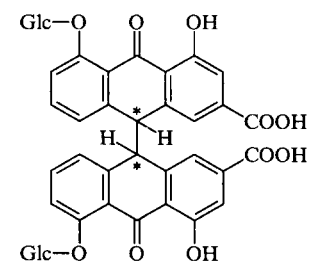
In the synthesis of the immunogenic conjugate of compound **7**, the BSA derivative of *p*-aminohippuric acid was obtained initially. For this purpose, a mixture of *p*-aminohippuric acid and BSA at pH 6.4 was treated with the hydrochloride of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide.[17] The derivative obtained was treated with $NaNO_2$ at pH 1.5 at 0 °C (the excess $NaNO_2$ was decomposed with ammonium sulfamate) and was then conjugated with compound **7** at pH 9.0 at 0 °C.[18]

The antiserum to the resulting conjugate is highly specific to compound **7**. Structural isomers of compound **7** — glyceollin II and glyceollin III — are fairly poorly recognised by the antiserum: 5.7% and 1.0% respectively. The radioimmunoassay method using [^{125}I]glyceollin I makes it possible to determine compound **7** at a concentration of 1×10^{-5} M.[19] The method has been used to determine compound **7** in soya bean tissues.

6. Flavonoids

The group of flavonoids combines the hydroxy-derivatives of flavanone, flavanonol, catechins, flavone, flavonol, and anthocyanins. These substances are present in many plants and exhibit vitamin P activity.

A series of bitter flavonoid 7-*O*-neohesperidosides have been detected in *Citrus* (*Rutaceae*) fruits. The main one is **naringin 8**. The content of compound **8** in the grapefruit (*C. paradisi*) can reach a level such that both the fruits themselves and the juice obtained from them acquire an excessively bitter flavour. Two radioimmunoassay methods for compound **8** have been developed for the rapid monitoring of the quality of the produce. In the synthesis of the immunogenic conjugate, the amino-groups of BSA were modified with *p*-aminohippuric acid and were then attached to compound **8** by diazotisation. The radioimmunoassay method using a ^{125}I-labelled competing conjugate makes it possible to determine compound **8** in the range $5 \times 10^{-9} - 2 \times 10^{-7}$ g. The method is very sensitive to the nature of the sugar residue in the 7-position, but is insensitive to changes in the aromatic ring. All the flavonoid 7-*O*-neohesperidosides are recognised by the antiserum to the same extent.[20]



8

In another instance, the immunogenic conjugate was synthesised by activating the 4-oxo-group in compound **8** with aminooxoacetic acid and was attached to BSA by the mixed anhydride method. The ^3H-labelled conjugate was obtained by condensing the (4-*O*-carboxymethyl)oxime of compound **8** with 5-aminolevulinic acid by the mixed anhydride method and by the reduction of the side chain with NaB^3H_4. The radioimmunoassay method permits the determination of compound **8** in the range $5 \times 10^{-10} - 5 \times 10^{-8}$ g.[21]

Both these methods have been used to determine the content of flavonoid 7-*O*-neohesperidosides in grapefruit juice and in the study of the distribution of immunoresponsive substances in grapefruit tissues.[21] It was shown that the data obtained by the radioimmune method agree well with the results of the assay by the HPLC method. The second method has been used also to analyse grapefruit juice under the conditions of large scale production.

7. Anthrones

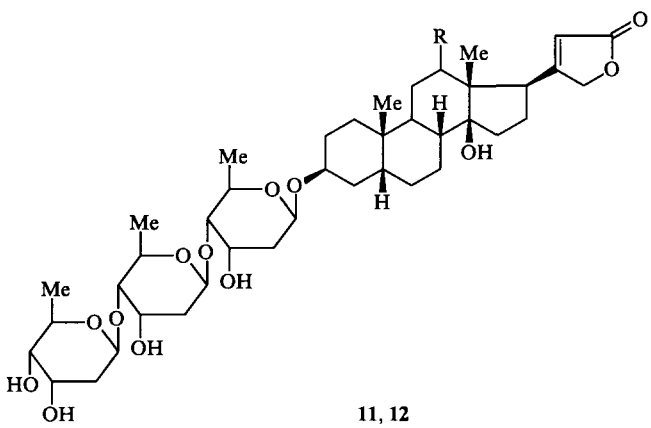
Isomeric dianthrone glucosides — **sennosides A (compound 9)** and **B (compound 10)** isolated from a series of *Cassia* (*Caesalpinaceae*) species — are highly active laxatives and constitute one of the classes of substances of plant origin most widely used in pharmaceutical practice. This stimulated the development of a method for the radioimmunoassay of dimeric glucosides.[22]

9, 10

In order to obtain the immunogenic conjugate, compound **10** was attached to BSA by the carbodiimide method. The radioimmune method using [^{3}H]-8-glucosidorheinanthrone, obtained by reducing compound **10** with NaB^3H_4, makes it possible to determine compound **10** in the range $4 \times 10^{-10} - 8 \times 10^{-9}$ g. Cross reactions have been noted for compound **9** (75%), sennoside C (100%), 8-glucosidorheinanthrone (55%), and sennidins A (25%) and B (10%).

The method has been used to investigate the distribution of compounds **9** and **10** in various parts of *Cassia augustifolia*.

8. Steroids



A large group of steroid glycosides of plant and animal origin is combined under the general name cardioactive or cardiotonic substances. At low concentrations, they normalise the working of the heart muscle, whilst in large doses they induce cardiac arrest in the systolic period. In contrast to their aglycones, cardiac glycosides are concentrated in heart muscle and their content in the latter is 10–40 times greater than in other tissues of the organism.

a. Digitalis cardenolides

The myocardium-stimulating digoxin and digitoxin are isolated from the leaves of *Digitalis lanata* (*Scrophulariaceae*), where they accumulate together with related glucosides.

Digoxin 11 (R = OH) is one of the substances of plant origin for the assay of which immune methods are used very widely.

The first attempts to devise an immunoassay method for compound **11** date back to 1967 when antibodies specific to compound **11** were obtained.[23] A method for the radioimmunoassay of compound **11** for use under clinical conditions was developed in 1970[24,25] and subsequently methods suitable for the determination of compound **11** in plant tissues were developed.[26–28] All these methods employ the rabbit antiserum to the conjugate of compound **11** with BSA or human serum albumin (HSA) obtained by the periodate oxidation method. The range of the determination of compound **11** is 8×10^{-10} to 4×10^{-8} g when [^{3}H]digoxin is used[25] and 5×10^{-10} to 5×10^{-9} g when the methyl ester of digoxin-[^{125}I]tyrosine is employed.[26] The study of cross-reactions with a large number of related structures showed that the serum obtained makes it possible to determine the sum of the digitoxigenin glycosides in extracts from *D. lanata*.

11, 12

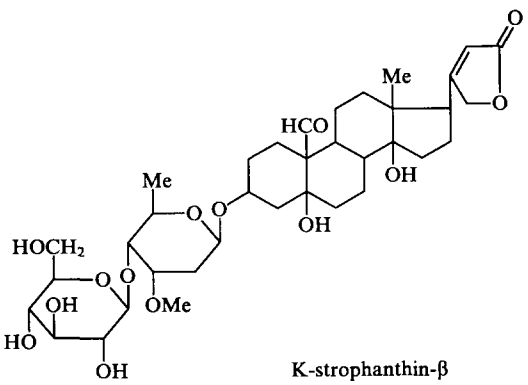
Immune methods have been used to determine the level of compound **11** in the serum of blood from patients[25] and also for the investigation of the distribution of compound **11** in the tissues of *D. lanata*.[26,27] It was established that the main bulk of compound **11** accumulates in leaves after 8–12 weeks. The radioimmune method makes it possible to determine the optimum period for the harvesting of leaves. The same method has been applied in the selection of plants most productive as regards compound **11**.[28] The content of compound **11** in the tissues of *D. lanata* and *D. purpurea* was determined with its aid during the growth of these plants.[29]

In subsequent years, many immunoassay methods for compound **11** were developed: radioimmune,[30–32] immunoenzyme,[29,32–34] immunoluminescence,[29,35] and fluoroimmune[36] methods, a combined liquid chromatographic-immune method,[37] immune methods involving the measurement of the degree of polarisation of fluorescence,[32,38–43] an immune method using particles of polystyrene latex,[44] a chemiluminescence immunoenzyme method,[45] a heterogeneous competitive immunoenzyme method with electrochemical detection,[46] a fluorescence method with transfer of excitation energy,[32,47–49] and a number of others.[42,50] The methods developed have been used to assay compound **11** in the serum,[32,33,42,47–49,51–58] plasma,[30,39,42,49,59] urine,[30] saliva,[31] and blood of patients[60] and also for the investigation of the pharmacokinetics of compound **11**.[61] Only one of these methods has been applied to its determination in the cell culture of *D. lanata* roots.[33]

Comparison of the immune methods with one another and also with methods based on high performance liquid chromatography showed that many substances related to digoxin, frequently present in the specimen, as well as certain metabolites of compound **11** affect appreciably the results of the determination of compound **11** by immune methods.[30,32,38–40,51–57,62,63] The attempts to eliminate this influence led to the appearance of immune methods based on monoclonal antibodies[58] and to the introduction of stages involving additional purification of the specimens analysed.[37,43,44,64]

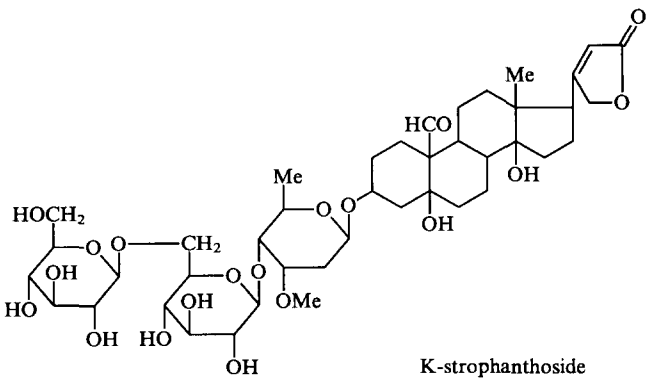
Many Companies manufacture sets for the immunoassay of compound **11**. The sets produced by Companies such as Syva Corporation, E.I. du Pont de Nemours, New England Nuclear, Amersham Corporation (USA), and a number of others have come to be most widely used. These sets are widely employed in clinical and laboratory practice for the determination of compound **11** in blood plasma and serum, in urine, and in other physiological liquids. A method for the radioimmunoassay of the total digoxigenin glycosides in the *D. lanata* plant has been developed on the basis of one of such sets — the 'Digoxin RIA kit' produced by the Farmos Diagnostica Company (Finland).[64]

Digitoxin 12 (R = H). An antiserum to the conjugate of digitoxigenin (aglycone) with BSA, obtained by 3-*O*-succinylation and carbodiimide condensation, was isolated in 1968 from rabbit.[65] The radioimmune method using the conjugate of the methyl ether of 3-*O*-succinyldigitoxigenin with [^{125}I]tyrosine makes it possible to determine compound **12** in the range 2×10^{-10}–2×10^{-8} g. The contribution of the cross-reaction with compound **11** is 10%. The method has been used to determine the content of compound **12** in the serum of blood from patients.



The method developed subsequently for the analysis of patients' blood, involving the measurement of the degree of polarisation of fluorescence, yielded the same results as the radioimmune method.[66]

The radioimmune method using [^{125}I]digitoxigenin has been applied to the assay of compound **12** in urine specimens after preliminary purification of the extract by reverse-phase HPLC.[67] Immune methods have not so far been applied to the assay of compound **12** in plants.



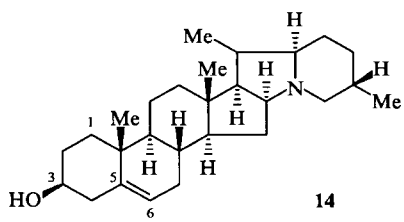
b. K-Strophanthin

K-Strophanthin **13** is a typical representative of cardiac glycosides with a cardenolide aglycone. It is a mixture of the cardiac glycosides K-strophanthin-β and K-strophanthoside. Strophanthin is present in various *Strophanthus* species.

The immunogenic conjugate with BSA was obtained by the periodate oxidation of compound **13**.[68] The use of this conjugate made it possible to obtain antibodies specific to compound **13** and to devise an immunoenzyme assay method whereby it is possible to determine compound **13** in the concentration range 10^{-9}–10^{-3} M.[69] Subsequently immunoenzyme methods were developed for the assay of compound **13** using the antigen immobilised on AH-agarose,[70] on nitrocellulose membranes,[71] and also on activated polystyrene pellets.[72] The latter methods make it possible to determine compound **13** in the concentration range 10^{-8}–10^{-3} M; the sensitivity of the method reaches 10^{-10} M.[71,72] These methods were developed to assay compound **13** in the blood and other biological liquids of patients; immune methods have not so far been applied to the assay of compound **13** in plant tissues.

K-strophanthin-β

K-strophanthoside



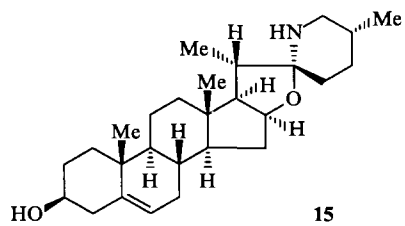
9. Steroid glycoalkaloids in *Solanaceae*

Plants of the genus *Solanum* (*Solanaceae*) produce a series of steroid glycoalkaloids. Certain representatives of *Solanaceae* are of greatest interest from this standpoint.

1. The potato (*S. tuberosum*) contains a number of bitter toxic derivatives of solanidine, mainly α-solanine and α-chaconine. The assay of these compounds is important for work involving selection. Furthermore, during incorrect storage of the tubers or when the potato is grown under unfavourable climatic conditions, the content of these glycoalkaloids can increase greatly, impairing the flavour of the potato.

2. The alkaloid solasodine, which serves as the starting material for the synthesis of a series of steroid preparations (progesterone and corticosteroids), accumulates in the leaves of a series of *Solanaceae* species (*S. laciniatum* and *S. aviculare*).

Glycoalkaloids — glycosidic derivatives of solanidine 14. A radioimmunoassay method for compound **14**, based on the use of the antiserum to compound **14** conjugated with BSA via the 3-hydroxy-group, was developed in 1979.[73] This method makes it possible to determine compound **14** in the range 2×10^{-10} to 5×10^{-8} g. The contribution of the cross-reaction with α-solanine is 28%.



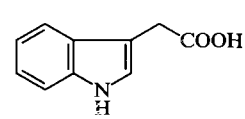
14

The conjugate of α-solanine with BSA was synthesised in 1983 by the periodate cleavage method.[74,75] The rabbit antiserum to this conjugate is equally sensitive to compound **14**, α-solanine, α-chaconine, and demissidine, which is very convenient for the determination of the overall content of glycoalkaloids in potato tubers. The radioimmune method using ^{3}H-labelled compound **14** makes it possible to determine these glycoalkaloids in the range $2 \times 10^{-10}-8 \times 10^{-9}$ g,[76] while the immunoenzyme method permits their determination in the range $10^{-11}-10^{-9}$ g.[75]

The radioimmune method has been used to determine compound **14** in human blood serum.[76,77] The results of assays obtained by the immunoenzyme and chemical methods have been compared. It was established that they agree well, but the immunoenzyme method is simpler, rapid, and less subject to technical errors.[78,79]

Glycoalkaloids — glycosidic derivatives of solasodine 15. The immunogenic conjugate was obtained by subjecting a 2:3 mixture of solasonine and solamargine to periodate cleavage followed by attachment to HSA.[75] The radioimmune method using ^{3}H-labelled glycoalkaloids, based on the application of the rabbit antiserum, makes it possible to determine derivatives of compound **15** in the range $10^{-9}-10^{-7}$ g. Reactions with solasonine (100%), solamargine (110%), and tomatine (104%), as well as the aglycones of tomatidine (21%), soladulcine (5%), and compound **15** (7%) have been noted.

15



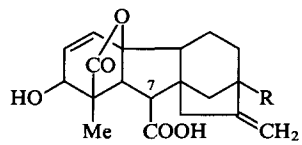
This method has been applied in the study of the content of compound **15** in the tissues of *S. laciniatum* and *S. aviculare*.[75]

10. Plant growth and development regulators

Plant bioregulators are low-molecular-mass products of the secondary metabolism of plants. Phytohormones, natural stimulators, and inhibitors are distinguished among them.

Phytohormones include auxins, gibberellins, abscisic acid, cytokinins, and ethylene. In contrast to other physiologically active compounds, phytohormones are bioregulators common to all plants. They are synthesised in actively dividing cells, after which they are transported to other organs and tissues where they initiate chemically physiological programs. The molecular mechanisms of the action of plant hormones are apparently associated with the regulation of protein synthesis, the activity of enzymes, and transport through a biological membrane.

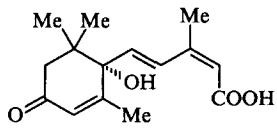
Auxins constitute a group of natural compounds which stimulate cell division (mitosis), root formation, respiration, and the synthesis of protein in plants. The main representative of auxins is indolylacetic acid **16**.



16

The Mannich reaction was used to synthesise the immunogenic conjugate of compound **16** with BSA; compound **16** is linked to the protein via the nitrogen atom.[76]

The formation of the bond via the carboxy-group (the mixed anhydride method) affords more stable conjugates, which induce a somewhat greater immune response both in rabbits[77] and in mice.[78]

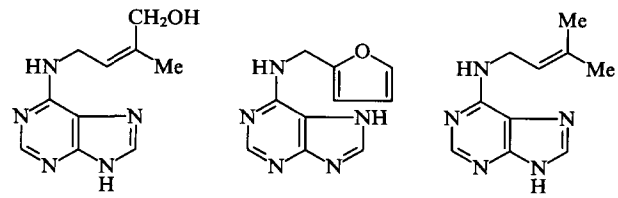


Gibberellins are diterpenoid tetracyclic mono-, di-, and tricarboxylic acids. The mechanism of the biological action of gibberellins has been inadequately investigated. It is known that they alter the properties of membranes and induce the synthesis of α-amylase in barley grains, while in the tissues of other plants they alter the systems comprising RNA and functioning enzymes. About 70 gibberellins have now been found in nature and antisera have been obtained and immunoassay methods have been developed for some of them [including the gibberellins A_3 **17** (R = OH) and A_7 **18** (R = H)].[79–83]

17, 18

The immunogenic conjugates are obtained by forming an amide linkage between the C(7)-carboxy-group of gibberellin and the amino-groups of the protein.[79] Alternatively, the mixed anhydride method is used, but in this case conjugates with a fairly low hapten density are obtained owing to steric hindrance. A spacer is introduced between the hapten and the protein in order to increase the hapten density.[82,83]

Abscisic acid 19 is a highly specific inhibitor of the growth of higher plants. It causes a transition of the plant to the resting state and induces wilting and shedding of leaves and fruit.



19

The conjugates of compound **19** may be synthesised using both the carboxy-group[84,85] and the carbonyl[85] group. In order to obtain a conjugate of compound **19** with a protein via the carboxy-group, a solution of the hapten and the protein in a mixture of dimethylformamide and water at pH 8 is treated with the hydrochloride of 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide.[85] The antiserum to this conjugate interacts with the protonated form of compound **19** and its esters but hardly interacts with the deprotonated compound **19**, which is the main one actually present under the conditions of the immunoassay (pH 7–8).

The conjugate via the carbonyl group is synthesised by carrying out initially the reaction between compound **19** and tyrosine hydrazide in the presence of acetic acid in order to obtain the tyrosylhydrazone of compound **19**. BSA *p*-aminohippurate is obtained simultaneously by the reaction of *p*-aminohippuric acid with BSA in the presence of 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide. The modified protein is treated with $NaNO_2$ at pH 1.5 and ammonium sulfamate and is condensed with the tyrosylhydrazone of compound **19** at pH 9.[85] The antibodies to this conjugate are preferable in those cases where it is proposed to assay compound **19** in the form of the anion. Such antibodies interact very weakly or not at all with the protonated form of compound **19**.

Cytokinins constitute a special group of plant growth and development regulators which stimulate cell division (cytokinesis). This group includes the *N*(6)-derivatives of adenine—zeatin **20**, kinetin **21**, and isopentenyladenine **22**. In plants, they are frequently encountered in the form of the less active ribosides and ribotides and are one of the constituents in the structures of certain transport RNA of plants.

20 **21** **22**

The mechanism of the biological action of cytokinins is apparently associated with the intensification of the biosynthesis of DNA, RNA, and protein and also with their influence on the functioning of biological membranes.

Cytokinins have been traditionally assayed by biological methods, but the sensitivity and selectivity of these is low.[86,88] The physicochemical and immunochemical assay methods are superior to the biological methods as regards sensitivity, specificity, and reproducibility and take less time.[89,90]

The preparation of the immunogenic conjugates of cytokinins is based on the periodate oxidation of the riboside to the corresponding aldehyde, which can interact with the amino-groups of the carrier protein. For this purpose, the cytokinin riboside in methanol was treated with sodium periodate, the excess of which was decomposed with ethylene glycol. A solution of the carrier protein at pH 9.3 was treated with the dialdehyde obtained from the cytokinin riboside; the complex thus produced was stabilised by reduction with tetrahydroborate.[91]

The first radioimmunoassay methods permitting the determination of compound **22** in an amount of about 10^{-8} g were used in the study of plant transport RNA.[92–94] Analysis of the cross-reactions showed that the antiserum obtained to the conjugate of compound **22** with the protein interacts with the phosphate of compound **22** (100%) and with isopentenyladenine (10%).[94] The interaction of the antiserum with compound **21** is weaker by a factor of 100 and that with adenosine is weaker by a factor of 300 000 than the interaction with compound **22**.[94]

The use of the immune method for the assay of cytokinins in plants was described in 1979, but the antibodies to compound **22** interacted strongly with *trans*-zeatin riboside and dihydrozeatin riboside.[95]

A sensitive and specific radioimmune method for the determination of *trans*-**20** was developed in 1980.[96] The limit of the determination of *trans*-**20** amounted to several femtomoles. The antibodies did not interact with *cis*-**20**.

The antisera to compound **22** made it possible to attain a limit in the determination of compound **22** of 5×10^{-11} to 10^{-9} g.[89,97–99] These antisera interact only weakly with cytokinins of the zeatin group, but they do interact appreciably with 6-benzylaminopurine cytokinins.

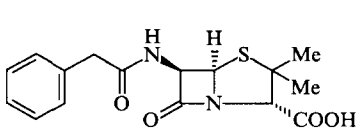
It was established that the interaction of cytokinin molecules with the corresponding antibodies depends mainly on the nature of the substituent at the N(6) atom. Owing to the appreciable cross-interactions, the accurate assay of cytokinins by the immune methods requires the introduction of a stage involving preliminary chromatographic purification.[100] Column chromatography on cellulose phosphate and Sephadex LH-20 is used for this purpose.[100,101] However, these procedures require a fairly long time, so that simpler purification procedures with the aid of thin-layer chromatography (TLC)[99] and HPLC[102] have been proposed. The choice of a suitable sorbent for HPLC makes it possible to attain the complete separation of the cytokinins assayed. As a rule, reversed-phase sorbents are used for this purpose—Bondapak C 18,[102–104] Lichrosorb RP-8,[105] Hipersil ODS,[106,107] and Sep-Pak C 18.[97,108] The preliminary purification of the specimen can be carried out with the aid of an immunoaffine column.[109]

11. Other compounds

Immunoassay methods for compounds which are not endogenic in plants but which it is sometimes necessary to determine in plant material will be examined in this part of the review. In the first place, these are undesirable substances in plants designed for use as food. Such substances are formed on microbial infection of the plant material.

a. Antibiotics

In a number of instances, as a result of the infection of the plant raw material by microorganisms, such material may be contaminated with the antibiotics produced by such microorganisms.



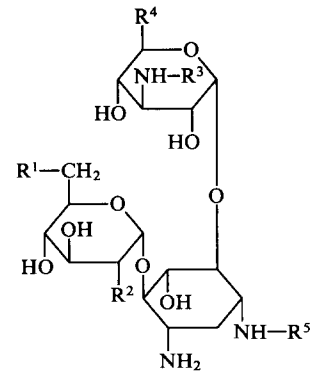
Natural substances and the products of their chemical modification, capable of suppressing at low concentrations ($10^{-6}-10^{-5}$ g L^{-1}) the development of bacteria, lower fungi, protozoa, viruses, and malignant tumour cells, are classified nowadays as antibiotics.

The group of β-lactam antibiotics includes penicillins, cephalosporins, cephamycins, and certain other antibiotics. The mechanism of the action of β-lactam antibiotics involves the suppression of the synthesis of the bacterial cell wall.

Penicillins possess a broad spectrum of antibacterial activity, exhibiting both bacteriostatic and bactericidal activities in relation to many gram-positive microorganisms (staphylococci, pneumococci, and streptococci), certain gram-negative cocci (gonococci, meningococci), Siberian ulcer bacilli, clostridia, spirochaetes, and certain fungi.

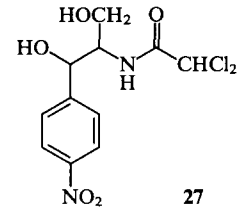
In the immunoassay of penicillins, serious problems, associated with their instability, arise: penicillins readily hydrolyse in aqueous solutions, the hydrolysis products being capable of binding to proteins. Because of this, the sensitivity, the degree of cross-interaction, and the parameters of the binding of antibodies to antigens vary as a function of the degree of hydrolysis of penicillins and the composition of the buffer solution. Hydrolysis of the β-lactam ring of penicillins in 0.1 M NaOH solution or on treatment with β-lactamase also affects these parameters. An additional source of error is the nonspecific binding of penicillins to the proteins present in the specimen assayed.[110]

Despite the complexities in the development and application of immunoassay methods for penicillins, their description is appearing with increasing frequency in the scientific literature. Thus an immunoenzyme method has been developed for the determination of penicillin G **23** and its derivatives in cow's milk and in bovine blood serum.[111]



23

Aminoglycoside antibiotics represent a large family of antibiotics numbering more than 100 natural compounds produced by microorganisms of the genera *Streptomyces, Micromonospora,* and *Bacillus* as well as a large number of semisynthetic analogues. The mechanism of the action of these antibiotics has not been finally established.



A wide range of immunoassay methods are used for the assay of aminoglycoside antibiotics.[112–114] Thus immunoassay methods have been used in the assay of gentamicin **24** (R^1 = OH, R^2 = NH_2, R^3 = Me, R^4 = R^5 = H),[115,117] amikacin **25** [R^1 = NH_2, R^2 = OH, R^3 = H, R^4 = CH_2OH, R^5 = C(O)CH(OH)Pr],[117,118] and tobramycin **26** (R^1 = R^2 = NH_2, R^3 = R^5 = H, R^4 = CH_2OH).[117,119–121] Immunofluorescence methods are also widely used in the assay of these antibiotics.[118,121,122]

The 'Optimate' automatic system, based on the immunofluorescence assay method, is used for the assay of compounds **24** and **25**.

24–26

Chloramphenicol 27 occupies a special place among antibiotics. It proved to be the first preparation active against rickets and intracellular parasites which give rise to diseases such as typhus and spotted fever. Chloramphenicol suppresses also many gram-negative and certain gram-positive bacteria and is effective in the treatment of typhoid fever and infections induced by *Haemophilus influenzae, Klebsiella pneumoniae,* spirochaetes, and especially salmonellas, which are resistant to other antibiotics. The therapeutic use of compound **27** is restricted by allergic reactions and the rare instances where the erythropoiesis in the bone marrow is affected, but it is widely used for the inhibition of the biosynthesis of protein in plant chloroplasts.

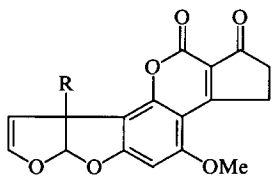
27

Antibodies to the conjugate of compound **27** with bovine γ-globulin, synthesised by the diazotisation method, were obtained in 1966.[123] An immunoenzyme method for the assay of compound **27**, based on the use of the rabbit antiserum to the conjugate of compound **27** with KLH, obtained with the aid of succinic anhydride and carbodiimide, was developed in 1984.[124] The use of goat antibodies to rabbit Ig G conjugated with peroxidase permits the determination of compound **27** in the range $4 \times 10^{-10}-4 \times 10^{-8}$ g.

A radioimmunoassay method has been developed for residues of compound **27** in food products.[125,126] A review on the immunoenzyme and liquid-chromatographic methods for the determination of residues of compound **27** in milk and pig tissues has been published recently.[127] A set for the immunoenzyme assay of compound **27** in human blood serum is manufactured by the Aesculaap BV Company (Holland).[128]

Immune methods have not so far been used to determine antibiotics in plant raw material.

b. Mycotoxins



Certain mould species (*Aspergillus, Penicillium*) produce under certain conditions mycotoxins—highly toxic, sometimes carcinogenic secondary metabolites. A special effort has been made to develop methods for the immunoassay of mycotoxins. There are several reasons for this. Firstly, contaminated batches of products are frequently inhomogeneous, which requires the analysis of a large number of specimens. Secondly, in view of their high toxicity, the toxins must be assayed at a level of 10^{-12} g. Thirdly, owing to the presence of large amounts of chemically related compounds, the methods must be highly specific.

Although several tens of studies on the immunoassay of mycotoxins have already appeared in 1976, very often only a few of the proposed methods have found practical application. This is associated as a rule either with the low quality of the antiserum obtained (small amount, low avidity, poor specificity) or with the unsatisfactory reproducibility of the method.

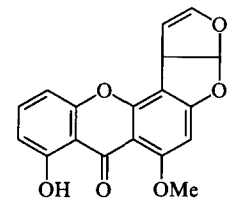
However, the interest in the development of immunoassay methods for mycotoxins has not weakened owing to the large losses of food products due to their contamination by myxotoxins. According to data produced by Biotech Research Company (USA), about 50 million dollars were spent in 1985 on tests for the presence of aflatoxins in food products alone. [129]

There are at present a series of methods for the immunoassay of mycotoxins. [130, 131]

Among the large number of mycotoxins, aflatoxins, which are secondary metabolites produced by *A.flavus* and *A.parasiticus* species, constitute a special danger. [132] Several immunoassay methods for aflatoxins have been developed. [132–136]

28, 29

Aflatoxin B_1 28 (R = H). This mycotoxin is one of the most carcinogenic among substances known at the present time. It is produced by several *Aspergillus* species. It has been shown that compound **28** causes cirrhosis and cancer of the liver in children. When it enters the organism, aflatoxin B_1 is epoxidised by cytochrome P-450 and binds to RNA, which leads to the inhibition of protein synthesis. LD_{50} for compound **28** is $3 \times 10^{-4} - 1.02 \times 10^{-2}$ g (kg bodyweight)$^{-1}$.

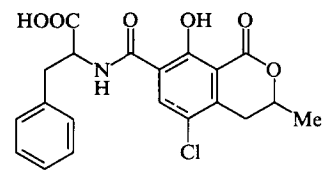


In order to obtain an antiserum aminooxoacetic acid was attached to the keto-group in compound **28** and the resulting derivative was conjugated with BSA by the mixed anhydride method. Polyclonal [138] and monoclonal [139] antisera were obtained on the basis of this conjugate. When used in the immunoenzyme method, both antisera make it possible to attain a limit of determination of 10^{-13} g. They are used to monitor the content of compound **28** in grain and in other food products, for example in groundnut oil. [138, 139]

In another method, the hemiacetal of compound **28** was conjugated by the Mannich reaction with methylalbumin either indirectly or via ε-aminocaproic acid. [140] An immunoenzyme method was developed on the basis of antisera to these conjugates. It makes it possible to determine compound **28** and aflatoxin M_1 **29** (R = OH) in the range $10^{-12} - 2 \times 10^{-10}$ g, aflatoxins P_1 in the range $10^{-11} - 2 \times 10^{-10}$ g, and aflatoxins G_1 in the range $(1-2) \times 10^{-10}$ g.

Sets for the immunoenzyme assay of compound **28** are manufactured by Neogen Corporation, Agritech Systems, Immuno Systems, Biotech Research Laboratories, Biokits (USA), and May and Baker Diagnostics (Great Britain). The URVJT Company (Czechoslovakia) manufactures a set for the radioimmunoassay of compound **28**. [11, 141]

Aflatoxin M_1 29 (R = OH). This aflatoxin is a product of the metabolic oxidation of compound **28** in the cow. On passing with cow's milk into humans, it can be the cause of cancer or cirrhosis of the liver. For this reason, almost all the methods developed for the immunoassay of compound **29** are designed particularly for the analysis of cow's milk. [142–145]

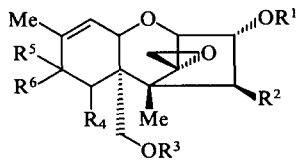


Sterigmatocystin 30. This substance, which is a toxic metabolite of the *Aspergillus* species, exhibits powerful hepatocarcinogenic properties. In view of the sparing solubility of compound **30** in water, a method has been developed for the assay of its hydrolysed derivative.

30

For this purpose, the conjugate of compound **30** with BSA was converted into a hemiacetal with which rabbits were immunised. [146, 147] The immunoenzyme method, developed on the basis of the resulting antiserum, makes it possible to determine compound **30** in the range $10^{-12} - 10^{-9}$ g.

Ochratoxin A 31 is a powerful liver poison, frequently formed during the storage of grain in temperate climatic zones. In order to develop an immunoenzyme assay method, compound **31** was attached to protein via the carboxy-group and an antiserum was obtained, which makes it possible to detect compound **31** in amounts down to 10^{-11} g. A cross-reaction has been noted only for the non-toxic ochratoxin B (0.5%). [148, 149]



31

The method developed has been used in the study of specimens of the kidneys [150] and livers [151] of pigs fed with grain subjected to prolonged storage and also in the assay of compound **31** in the grain itself. [152]

The application of monoclonal antibodies made it possible to devise an immunoenzyme method for the determination of ochratoxin A in the range $5 \times 10^{-13} - 2.5 \times 10^{-10}$ g. [153, 154] Cross-reactions with the ethyl ester of compound **31** and with ochratoxin C have been noted.

Sets for the immunoenzyme assay of compound **31** are manufactured by the AFRC Food Research Institute (Great Britain) and Biokits. The URVJT Company manufactures a set for the radioimmunoassay of compound **31**. [11]

Tricothecene mycotoxins constitute a dangerous group of mycotoxins. They are produced mainly by the toxic fungi of the genus *Fusarium*. The most poisonous are diacetoxyscirpenol **32** ($R^1 = R^4 = R^5 = R^6 = H$, $R^2 = OAc$, $R^3 = Ac$) and the toxin T-2 **33** ($R^1 = R^4 = R^5 = H$, $R^2 = OAc$, $R^3 = Ac$, $R^6 = OCOCH_2C_4H_7$-*cyclo*). The producers of tricothecenes contaminate mainly grain, while in the animals consuming this grain the toxins induce damage to the skin, sepsis and necrosis of the mucous membranes of the intestine, kidneys, lymphatic glands, and bone marrow. In humans, the effect of tricothecenes is believed to be associated with flare-ups of the alimentary-toxic aleukia, the main symptoms of which are necrosis of the tissues of the alimentary tract and leukopenia. The reason for these infections is apparently suppression of protein biosynthesis.

32–34

Immune methods are used fairly widely for the assay of tricothecene mycotoxins. In the preparation of the immunogenic conjugate, compound **32** was converted into the hemiglutarate which was conjugated with BSA. The antibodies formed on immunisation of animals with this conjugate were used to develop radioimmune [155] and immunoenzyme [156,157] methods for the assay of compound **32**.

Using similar procedures, antibodies were obtained and immunoenzyme methods were developed for the assay of compound **33** [158,159] and 3-acetyldeoxynivalenol **34** (R^1 = Ac, R^2 = R^3 = H, R^4 = OH, R^5 + R^6 = O).[160]

III. Conclusion

Immune methods make it possible to assay virtually any low-molecular-mass biologically active substances encountered in plants.[161] These methods are superior to the chromatographic procedures as regards sensitivity and speed of preparation of the assay sample and are hardly inferior to them as regards accuracy and reproducibility.

However, an individual approach to each specific substance is necessary for the development of immunoassay methods and in each case this requires a fairly considerable amount of preparatory work, which depends on the objects of the analysis. From this standpoint, the greatest difficulties are associated with the development of immunoassay methods for objects in which the biosynthesis or biodegradation of the substances assayed takes place, since the specimen then contains a large amount of structurally very similar compounds. Physiologically active substances of plant origin are in fact objects of this kind.

Despite the difficulties associated with the development of immunoassay methods (the main ones of which are the synthesis of the immunogenic conjugate and the preparation of highly specific antibodies), such methods are already widely used in clinical practice for the monitoring of the course of therapy and in studies on the metabolism of physiologically active substances of plant origin.

The use of immune methods in the assay of low-molecular-mass physiologically active compounds in plant cells and tissues is hindered by the presence of a large number of closely related compounds (biogenetic precursors and metabolites), which participate in intense cross-interactions with the antibodies used in the assay. However, the application of immunoassay methods is expanding to an increasing extent in biotechnology in connection with the preparation of plant cell and tissue cultures producing physiologically active substances. Immunoassay methods are also applied on an increasing scale in the cultivation of plants — in the study of the biosynthesis of physiologically active substances and in their assay in plant tissues. Methods developed for use in clinical practice, supplemented by stages involving the preliminary purification of the specimen, are frequently employed.

In recent years, the most vigorously developing field of application of immunoassay methods is the monitoring of the content of substances contaminating plant material (mycotoxins, etc.).

The appearance of automated systems for immunoassays and laboratory work suggests that the application of immune methods will expand.

IV.	Electroluminescent polymer layers	112
V.	Injection of charges into polymer transport layers	120

Abstract. We shall discuss the transport of charge carriers (electrons and holes) in disordered polymeric dielectric matrices and electroluminescence phenomena in transport layers of various structures, and also the injection of charges into transport layers through a boundary bearing a solid layer of a different type. The temperature, field, and concentration dependences of the mobility of the carriers will be considered, as well as the effect of the structure of the polymer matrix and of the transport centres on the mobility. The most reliable theoretical models of charge transport in these media will be examined. The bibliography includes 150 references.

I. Introduction

Significant advances in the study of the electronic properties of organic materials have been made in recent years. Attention has been focussed mainly on the electric conductance and on the electron transport properties of these materials. Some of the studies were aimed at developing organic materials having electronic properties close to those of inorganic semiconductors. Since organic materials (and, principally, polymeric) display a great variety of chemical structures and physico-mechanical characteristics, and since they can be prepared by a variety of methods, an improvement of their parameters to the level achieved in inorganic semiconductors would reveal a new world in microelectronics. The use of organic polymeric photoconductors in electrophotography is the first (and, so far, the only) example of the wide-scale industrial application of these materials in order to exploit their unique electric properties.[1] We need only to note that at present most of the photocopying ('Xerox') devices, laser printers, and other electrophotographic (EP) equipment use organic polymeric photoreceptors as the main active element. These photoreceptors usually consist of two polymer layers: a photogeneration layer and a transport layer. The photogeneration layer, deposited on an electrically conducting substrate, is a dispersion of a pigment in a polymer binder, and the transport layer is an amorphous (polymeric) dielectric containing electron transport centres.[2]

The principle of the operation of these receptors is the following. The surface of the transport layer is negatively charged by a corona discharge. When the sample is exposed through a mask photons are absorbed in the generation layer of the illuminated parts of the photoreceptor, with formation of electron – hole pairs. Free holes are injected into the transport layer and drift through it under the influence of the electric field, discharging the surface of the transport layer. As a result, a potential contour (latent image) is formed on the surface of the transport layer: this is a replica of the spatial distribution of optical density in the original mask.

We should stress that the charges must cross the whole thickness of the layer until they reach the surface, and therefore we are dealing with electron transport not accompanied by mass transport. The quantitative characteristic of this process is the time of flight of the charge carriers t_τ through the transport layer. The time of flight is a critical parameter which determines the operating speed of the whole apparatus, since it must be shorter than the time interval between exposure and development, which is usually a fraction of a second. The fundamental technological problem is to develop organic polymer layers with the smallest possible t_τ.

We should stress that the transfer of a charge between adjacent transport centres during its drift through the film is an elementary redox reaction between a neutral molecule and its cation radical (for hole transport) or its anion radical (for electron transport).[3] Surprisingly, electron transfer can take place between particles not in direct contact (at distances up to 20 Å, determined by the concentration of transport centres in the sample).

However, interest in thin polymer layers showing electronic transport phenomena has been stimulated not only by their transport properties but also by their electroluminescence (EL) properties, which allow them to be used as the elements of flat, flexible colour displays, luminescent and television screens, electrically pumped lasers, etc.[4] Again, the transport of the charge carriers is the factor which determines the effectiveness of the conversion of electric into light energy.

The distinguishing feature of EL layers (as compared with EP layers) is that their transport centres act also as luminescence centres. The essential component of an EL diode is a polymer layer sandwiched between two electrodes, one of which injects holes while the other injects electrons. The injection of charges into the transport layer through a phase boundary is an operating stage common to EP and EL systems.

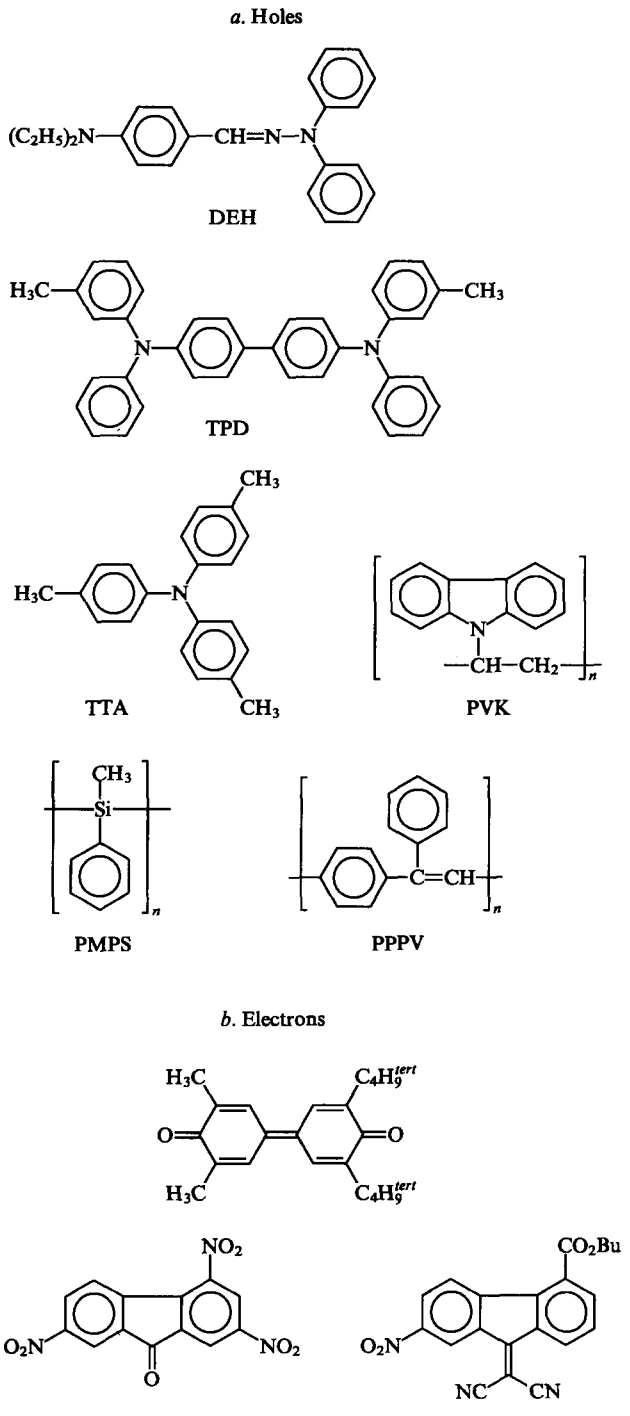

Figure 1. Typical compounds used as transport centres in polymer matrices containing mobile holes or electrons.

Electron transport phenomena in dielectric polymers are also responsible for the photorefractive effect (recently discovered in nonlinear optical polymers doped with molecules having electron transport properties[5-7]). Thus, holograms can be phase recorded by irradiating photorefractive polymer layers in a strong electric field. This four-step process includes: (1) the photogeneration of mobile charge carriers, (2) the transport and separation of charges of opposite sign, (3) the trapping of mobile charges and the generation of a nonuniform electric field by the space charge, (4) the modulation of the refractive index by the nonuniform electric field through the electro-optical effect. Uniform irradiation of the layer with a strong light erases the hologram and makes the recording process reversible.

In the present review we shall discuss only the special features and the mechanisms of charge transfer processes in polymeric transport layers, and also their electroluminescence. Photorefractive polymers lie beyond the scope of this article because their study is only beginning.

In spite of the many recent experimental and theoretical publications on electron transport in dielectric polymers a generally accepted theoretical model able to explain the basic experimental findings is still awaited. We shall examine the most significant experimental results on the temperature, field, and concentration dependence of the carrier mobility, and the effects on the mobility resulting from the structure of the polymer matrix and of the dopants introduced into the polymer and not contributing directly to the carrier transport, from the electroluminescence of transport layers of different structures, from the injection of charges into the transport layer through a boundary with a different solid layer, and also the most reliable theoretical models of charge transport in polymeric dielectric layers, i.e. models able to explain the total fund of experimental results.

II. Main characteristics of the transport of charge carriers

The polymers in which the mobility of the charge carriers can be measured by the direct time of flight method can be classified into the following groups: (1) molecularly doped polymers such as aromatic amines [triphenylamine (TPA), tritolylamine (TTA), etc.] and polyesters; (2) carbon chain polymers with chromophoric aromatic side substituents such as polyvinylcarbazole (PVK) and polyepoxypropylcarbazole (PEPK); (3) polymers with transport centres in the main chain such as polyhydroxyaminoethers (PHAE); (4) σ- and π-conjugated polymers [polysilylenes, polyphenylenevinylenes (PPV), etc.]

Some members of the different classes of transport centre are shown in Fig. 1. In groups 1–3 the localised transport centres are nitrogen atoms conjugated with phenyl groups, whereas in polymers of group 4 the transport centres are ordered parts of the polymer chains or the so-called effectively conjugated segments.[8]

Our discussion of the experimental data will invariably assume (unless accompanied by a statement to the contrary) that the transport of charge carriers is nondispersive, i.e. the injected charges are in thermal equilibrium with the medium, since this hypothesis makes the characteristics of the transport process of interest much easier to extract from the experimental results without complications from complementary factors. Detailed descriptions of dispersive (stochastic) transport can be found in existing reviews and monographs.[9-11]

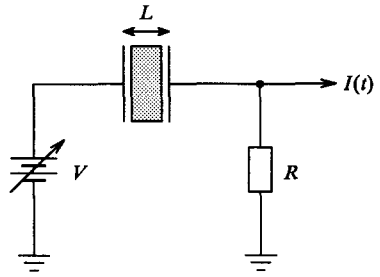

Figure 2. Scheme of the time of flight experiment.

Let us examine the basic information on transport discovered experimentally. The great majority of the data was obtained by the so-called time of flight experiment, shown schematically in Fig. 2. Charge carriers, injected (by a laser pulse or electric discharge) on one side of a flat sample of the dielectric

polymer exposed to a transverse electric field corresponding to a potential difference V, drift towards the opposite electrode. The dependence of the current I of carriers on the time t is determined experimentally. In the ideal case, when all the carriers move at the same speed, the $I(t)$ dependence is stepped: for $t < t_\tau$ the current is independent of time, but for $t > t_\tau$ it decreases rapidly with time. The transport properties of the carriers are usually defined through their mobility μ, where

$$\mu = \frac{L^2}{Vt_\tau}, \tag{1}$$

which in the ideal case is independent of the sample thickness L. The real $I(t)$ dependence has a more complex form: the sharp step is replaced by a shoulder, followed by a more gradual decrease. The latter feature shows that carrier transport in disordered systems is always to some extent dispersive. Nevertheless, when the position of the shoulder (identified with the time t_τ) is linearly dependent on L, we can confidently assume that the transport is mainly nondispersive and can be described in terms of a mobility independent of L.

The most important of the parameters which influence the transport of charge carriers are the temperature T, the electric field strength F, the concentration of transport centres c, and also the structure of the transport centres and of the polymer matrix. Many papers have been published on these topics, and we shall discuss only the most important. For a more detailed description the reader is referred to recent reviews[12-14] and to Borsenberger and Weiss's exhaustive monograph.[1] All the systems listed above have more or less similar dependences of μ on T and F.

Let us first consider the temperature dependence. The great majority of workers conclude that the temperature dependence of the mobility denotes activation control:

$$\ln\mu \propto -\frac{E_a}{T}, \tag{2}$$

where E_a is the activation energy (which we shall express in units for which the Boltzmann constant k_B is unity). However, the problem has not yet been finally solved. Recent publications by Borsenberger and coworkers[15-19] argue that the temperature dependence of the mobility is better described by an equation of the form

$$\ln\mu \propto -\left(\frac{T_0}{T}\right)^2. \tag{3}$$

(The physical significance of T_0 is examined in detail below.) A similar dependence had been proposed earlier,[20] but later work showed[12] that this observation was due to the erroneous inclusion of temperatures above the glass transition temperature, where the activation energy usually decreases steeply without a corresponding decrease in the mobility, thus stimulating a dependence such as Eqn (3). The experimentally accessible temperature range is not usually wide enough to allow an unambiguous distinction between the dependences (2) and (3). Therefore the choice of one of these functional $\mu(T)$ dependences is usually based on other considerations.[15]

In the vast majority of cases the dependence of the carrier mobility on the strength F of the electric field takes the form

$$\ln\mu \sim \text{const} + bF^{1/2}, \tag{4}$$

where b is a temperature-dependent coefficient. This is known as the Poole–Frenkel relationship because it was first proposed by Poole[21] and by Frenkel[22] in an attempt to describe the effect of an external field on the rate of escape of charge carriers from a Coulomb trap. The Poole–Frenkel model ascribes the dependence (4) to a lowering of the activation energy by the external field (Fig. 3), which gives

$$\ln\left(\frac{\mu}{\mu_0}\right) = -\frac{E_0 - \beta_{PF}F^{1/2}}{T},$$

$$\beta_{PF} = 2\left(\frac{e^3}{\varepsilon}\right)^{1/2}, \tag{5}$$

where E_0 is the depth of the potential well (trap) in a zero external field, e is the elementary charge, and ε is the permittivity of the medium. It is now generally thought that the Poole–Frenkel mechanism cannot be realised in disordered organic matrices because of the absence of significant numbers of transport centres in the great majority of organic materials.[13,23-25] Surprisingly, however, the Poole–Frenkel model gives a correct estimate of the proportionality coefficient in Eqn (4) though the experimental values of β are usually 2–3 times lower than those calculated by Eqn (5). Many experimental results show that in the majority of systems with nondispersive charge transport the overall dependence of μ on T and F is satisfactorily described by the equation

$$\mu = \mu_0 \exp\left[-\left(E_0 - \beta F^{1/2}\right)\left(T^{-1} - T_0^{-1}\right)\right], \tag{6}$$

proposed by Gill[26] and (in a slightly different form) by Pfister[27]. According to this equation the temperature dependences of the mobility measured in various electric fields should intersect at the temperature T_0, while the field dependences of μ for different temperatures have the common point $F_0 = (E_0/\beta)^2$. This behaviour has been observed in many systems of the first and second group,[1] in polyhydroxyaminoethers (third group),[28] and also in various polymers with a system of conjugated bonds in the main chain.[29,30]

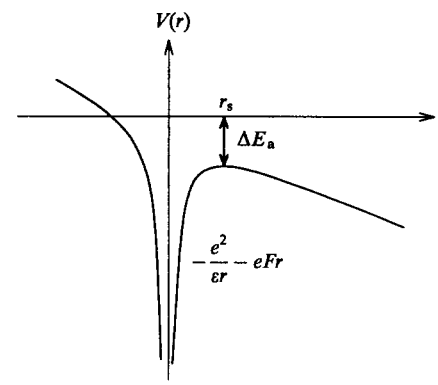

Figure 3. Lowering of the activation energy (ΔE_a) for the emission of a charge from a charged trap in an external electric field (Poole–Frenkel effect). r_s is the position of the saddle point in the potential energy.

An interesting property of Eqn (6) is the presence of the parameter T_0, which usually lies between 400 and 500 K. Formally it follows from Eqn (6) that for $T > T_0$ the mobility should decrease as the field is increased. This behaviour has been observed in recent experiments.[15,31-33] Furthermore, it was found that the mobility can be a nonmonotonic function of the field: it decreases with increasing F in weak fields and begins to increase in stronger fields.[13,34] An atypical variation of the mobility (increasing in moderately strong fields, and decreasing above $F = 10^6$ V cm^{-1}) has been reported.[35] We believe this to be an artefact, arising from the determination of the time of flight by different methods in experimental data for $F > 10^6$ and $F < 10^6$ V cm^{-1}, since the nondispersive component [the

plateau in the $I(t)$ dependence] could not be detected at high fields in those measurements. On the whole, individual instances of unusual field dependences of the mobility have been reported [with a sign inversion of b, or not consistent with Eqn (6)], but according to the Gaussian model (see below) the sign inversion of b at high temperatures and the decrease of μ in weak fields should be a common occurrence. Whether this is the case can be established only when additional experimental information becomes available.

The study of the transport properties of systems of the first group offers a unique opportunity to establish the dependence of the mobility carriers on the concentration of the transport centres, i.e. (effectively) on the average distance between the transport centres centres. It has been established that mobility decreases rapidly as the concentration of transport centres decreases.[36-38] The concentration dependence of the mobility will be discussed in more detail in the description of the various transport models given below.

The completely analogous dependence of the mobility of the two types of carrier (electrons and holes) on the temperature, field, and concentration is a fundamental experimental fact. Since the oxidation products of organic compounds have a relatively high electron affinity and act as deep traps it is easier to obtain polymer systems with hole conduction; nevertheless many systems with electron conduction have been studied in depth. Data on the transport of electrons in matrices with transport centres of the acceptor type (for example, quinone or nitrile derivatives) suggest that Eqn (6) is usually obeyed in these systems.[16,26,39] We can therefore assume that the same mechanism applies to transport by electrons and by holes.

Aromatic molecules containing nitrogen, which have low ionisation potentials (IP), have been used as transport centres for holes (see Fig. 1). A low IP is needed because fortuitous impurities with an even lower IP would act as traps for the holes. Correspondingly, molecules with the highest possible electron affinity are chosen to optimise the electron transport. It can be seen from Fig. 1 that the hole centres usually contain several nitrogen-containing $>N-C_6H_5$ groups. This facilitates the transport of positive charge within the relatively large transport centre. Kitamura and Yokoyama[40] have proposed the concepts of intramolecular and intermolecular charge mobility. The large linear size of the $>N-C_6H_5$ groups increases the intermolecular mobility, because under these conditions the length of the intermolecular jumps for a given concentration of molecules is decreased.[3] The intramolecular 'mobility' is a maximum when the density of positive charge is the same on the two functional groups of the cation radical, i.e. in symmetrical molecules.

Layers with bipolar carrier transport can sometimes be obtained, though the formation of charge transfer complexes (CTC) between donor and acceptor components strongly lowers the mobility. A well known example is PVK doped with trinitrofluorenone (THF).[26] Bipolar conduction has been observed[41] in polycarbonate (PC) doped with an alkyl derivative of diphenoquinone and tetra(*m*-tolyl)-1,3-diaminobenzene. Because of their bulky alkyl substituents the acceptor molecules cannot interact strongly with the donor molecules, and a CTC is not formed. Bipolar transport was observed also[42,43] in poly-[phenylenedi(phenoxyphenol)vinylene] (DPOP–PPV), one of the systems of the fourth group, without the addition of low-molecular-mass dopants. As will be shown below, bipolar transport is responsible for the very efficient electroluminescence of DPOP–PPV layers.

Important information is provided by data on the effect of the polarity of the matrix on the transport characteristics of the charge carriers. The existence of this effect, which shows that the role of the polymer matrix is not confined to providing sites for the transport centres, was first established in our laboratory.[44,45] The polarity of the medium can be varied either by adding chemically inert polar molecules (usually various isomers of dinitrobenzene or dinitrotoluene),[43-49] or be replacing the polymer matrix itself (for example, polystyrene by polycarbonate).[19,49] An increase in the dipole moment (or in the concentration) of the polar dopant usually lowers μ and increases β,[45,47,49] though other situations have also been observed[43,46,48] (usually in cases of strongly dispersive transport of the carriers).

In recent years the effect of the dipole moment of the transport centre on the transport characteristics of the charge carriers has been intensively studied. The most detailed contributions were made by Borsenberger and Fitzgerald[50] and by Sugiuchi and Nishizawa,[51] who studied the properties of fifteen different transport centres with dipole moments between 1.5 and 5.5 D. It was shown that an increase in the dipole moment of the centre lowers the absolute value of the mobility and increases the coefficient β.

III. Models of the transport of charge carriers in disordered organic matrices

Three main models of charge transport in disordered organic matrices have been proposed so far: the model of hopping transport over centres with a Gaussian distribution of energy levels, the polaron model, and the dipolar traps (transport centres) model. The situation is far from clear, and even the nature of the charge carriers in these matrices is still controversial.

1. Hopping transport over centres with a Gaussian distribution of energy levels

Bässler and coworkers[52-57] developed in greath depth the following model for the motion of the charge carriers. The organic matrix with the added transport centres is modelled by a cubic lattice with edge a with a transport centre located at each lattice point. The position of the energy level E involved in the charge transport is an independent, random quantity in each centre because of the random and noncorrelated effect of the surroundings. The corresponding density of states is described by the Gaussian distribution

$$\rho(E) = (2\pi\sigma^2)^{-1/2} \exp\left(-\frac{E^2}{2\sigma^2}\right). \tag{7}$$

Additional grounds for this choice of $\rho(E)$ are provided by the experimentally observed Gaussian form of the absorption and fluorescence bands of many polymers[58,59] and by the assumption that the central limit theorem must apply to some extent: the physical meaning of this model is that the overall energy of the interaction of the centre with the surroundings is the sum of many independent terms having not very different probability densities. The frequency of the jumps between the centres i and j is expressed in the form proposed by Miller and Abrahams:[60]

$$\nu_{ij} = \nu_0 \exp\left(-2\gamma a \frac{\Delta R_{ij}}{a}\right) \begin{cases} \exp\left(-\dfrac{E_j - E_i}{T}\right), & E_j > E_i \\ 1, & E_j < E_i \end{cases}. \tag{8}$$

Here ν_0 is the pre-exponential frequency factor, γ is the decrement of the wave function, and ΔR_{ij} is the distance between the centres. In the case of a nonzero external electric field an electrostatic contribution is included in the energy E_i:

$$E_i = E_i^0 - e\boldsymbol{F}\boldsymbol{R}_i. \tag{9}$$

The function $\rho(E)$ describes the effect of the energy disorder. The geometric disorder can be described phenomenologically by introducing the arbitrary parameter γa. It was assumed that

$$2\gamma a = \Gamma_{ij} = \Gamma_i + \Gamma_j, \tag{10}$$

where Γ_i and Γ_j are independent Gaussian arbitrary quantities having a dispersion σ_Γ, and the dispersion of Γ_{ij} is $\Sigma = 2\sqrt{\sigma_\Gamma}$.

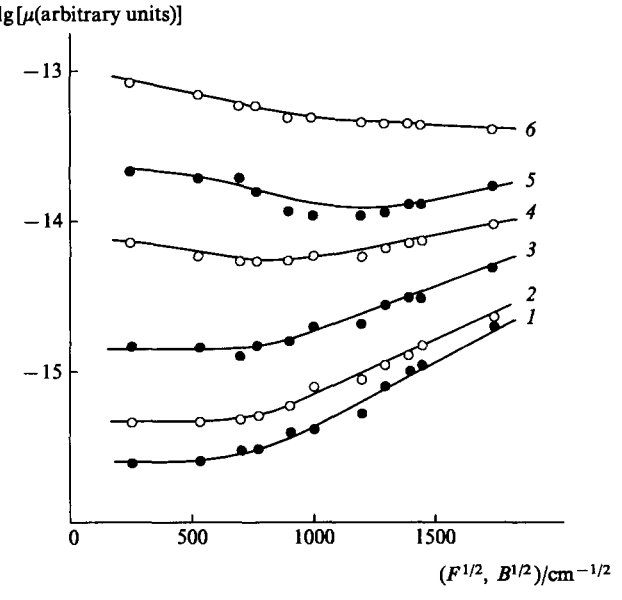

Figure 4. Field dependence of the carrier mobility in the Gaussian model (Monte Carlo calculation).[56] $\sigma/T = 3.0$; Σ: 0.00 (*1*), 1.41 (*2*), 2.12 (*3*), 2.54 (*4*), 2.80 (*5*), 3.26 (*6*).

Specific calculations by this model were possible only by the numerical modelling (Monte Carlo) method. The field dependence of the mobility is S-shaped (Fig. 4), and its middle part corresponds approximately to a linear dependence of $\ln \mu$ on $F^{1/2}$. However, this region is much narrower than the region covered by the experiment. The explanation proposed[61] for this discrepancy in terms of the difference in the definition of the mobility (through the average time of flight in the numerical experiment and through the time for the signal to fall to one half of its value at the plateau, or through the intersection of the corresponding asymptotics in the real experiment) is incompatible with the experimental results, according to which all these times have the same field dependence.[12] The calculation of the geometric disorder ($\Sigma > 0$) in terms of this model produces an interesting corollary: the mobility becomes a nonmonotonic function of the field, decreasing at first and then increasing as the field is increased.[56] This behaviour corresponds to the experimental observations of Borsenberger[34] and of Abkowitz[13].

The temperature dependence of the mobility in a zero field is not of the Arrhenius type, and is described by Eqn (3), with

$$T_0 = \tfrac{2}{3}\sigma . \tag{11}$$

In sufficiently strong fields the overall dependence of μ on T and F for $\Sigma \geqslant 1.5$ can be written[17]

$$\mu = \mu_0 \exp\left[-\left(\frac{2\sigma}{3T}\right)^2\right] \exp\left(-C\left[\left(\frac{\sigma}{T}\right)^2 - \Sigma^2\right]F^{1/2}\right), \tag{12a}$$

and for $\Sigma \leqslant 1.5$

$$\mu = \mu_0 \exp\left[-\left(\frac{2\sigma}{3T}\right)^2\right] \exp\left(-C\left[\left(\frac{\sigma}{T}\right)^2 - 2.25\right]F^{1/2}\right), \tag{12b}$$

where C is a universal constant equal to 2.9×10^{-4} cm$^{1/2}$ V$^{-1/2}$. However, the universality of this constant seems doubtful. In particular, Bässler's most recent paper[14] stresses that the field F should be interpreted as the dimensionless effective field

$$F_{\text{eff}} = \frac{eF\rho}{2T}, \tag{13}$$

where ρ is the average distance between the transport centres of the matrix. This replacement produces a change in the temperature dependence of μ. It is stated[14] that this change is unimportant in relation to the experimentally accessible temperature range. Nevertheless when using formula (12) we must treat the parameter C as a function of temperature rather than as a constant. Since in previous papers[16,34] the satisfactory consistency of the experimental 'constant' C with the calculated value had been repeatedly stressed in the comparisons with experiment the whole of the comparison procedure becomes open to doubt. This is a serious shortcoming, especially because of the recent tendency to treat the model of hopping transport over a system of levels normally distributed in density of states as the most promising candidate for the correct description of the transport of charge carriers in disordered organic matrices. Therefore the following list of the main weaknesses of the model could be useful.

1. The range of fields in which the mobility is linearly dependent on $F^{1/2}$ is much narrower than the experimental range. The suggested explanation[61] of this discrepancy is not consistent with experiment.

2. Nondispersive transport of the carriers is observed experimentally under conditions for which the model predicts dispersive transport (i.e. for $\sigma/T > 4.4$).[12]

3. The temperature independence of the parameter σ at temperatures below the glass transition temperature T_g of the matrix is difficult to understand, especially when σ and T have similar values: for example, $\sigma \approx (6-7) \times 10^{-2}$ eV and $T \approx 300$ K.[48] As expected, for $T > T_g$ the parameter σ begins to increase with T (see Abkowitz et al.[62]).

4. The following is probably the most serious deficiency of the model. The results (temperature and field dependence of the mobility) are to a large extent based on a specific (Gaussian) form of the density of states function. However, if $\sigma/T \gg 1$ (for example, if $\sigma/T \approx 4-6$) the main contribution to the carrier transport is provided by the decrease in the density of states in the region of $E/\sigma \gg 1$. The functional form of the density of states in this region does not have to be Gaussian. Whereas in the neighbourhood of the maximum a Gaussian distribution function can be produced by the central limit theorem, an additional decrease in the density of the distribution usually arises from infrequent fluctuations in the surroundings,[63-66] and the central limit theorem does not apply under these conditions.

Many specific problems of this type are met during familiarisation with the above model. For example, to what extent can the Miller–Abrahams model [Eqn (8)] be justified, and in particular the stipulated temperature independence of the probability of a jump giving a decrease in energy? How valid is the modelling of an organic matrix as a regular cubic lattice with transport centres at the corners? How are the results affected by the specific choice of an expression such as Eqn (10) to describe the geometric disorder?

Nevertheless at present the Gaussian model offers the most correct description of the transport of charge carriers, because it allows an integrated description of all its characteristics, including the transition from nondispersive to dispersive transport induced by a decrease in temperature, and it also allows the direct modelling of the current curve in the time of flight experiment.[34,67] It is interesting to note that the Gaussian model describes the time dependence of the stochastic transition current in a form different from that of the standard Scher–Lax–Montroll theory[68-71] of stochastic transport:

$$I(t) \sim \begin{cases} t^{-(1-\alpha)}, & t < t_\tau \\ t^{-(1+\alpha)}, & t < t_\tau \end{cases} . \tag{14}$$

This difference makes possible, in principle, an additional test of the model, though the experimental precision which has been achieved so far is not yet adequate for such a test.

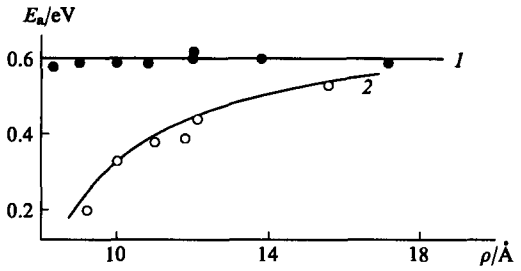

Figure 5. Dependence of the activation energy on the average distance between the transport centres in the DEH/PC (*1*) and TPD/PC (*2*) systems.[72]

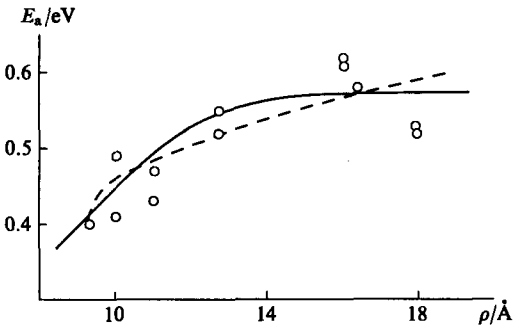

Figure 7. Dependence of the activation energy on the average distance between the transport centres in the TTA–PC system.[74]

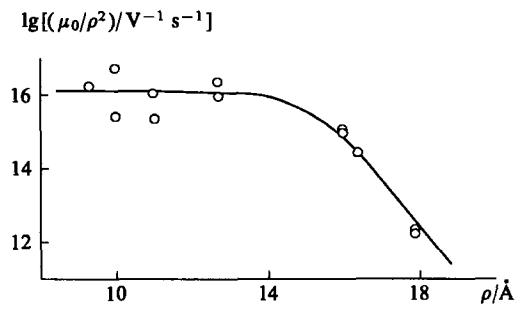

Figure 8. Dependence of the pre-exponential factor in Eqn (15) on the average distance between the transport centres in the TTA–PC system.[74]

2. The polaron model

Schein and coworkers[72–74] have actively developed the concept that the current carriers in disordered organic matrices are small polarons. As we know, the polaron is a bound state of a charge carrier and a vibrational mode (intramolecular, or involving phonons) which can move in a solid as a single entity. Those workers consider that a polaron is formed by the interaction of a carrier with an intramolecular vibrational mode.

A very large number of publications have dealt with the development of a theory of polarons as current carriers in solids of various types, such as semiconductors and organic crystals (see recent reviews, including a monograph[75–78]). In the limit of a weak external field the mobility of a polaron can be expressed as:[79]

$$\mu = \frac{e\rho^2}{T} P \frac{\omega}{2\pi} \exp\left(-\frac{\frac{1}{2}E_p - J}{T}\right), \tag{15}$$

where P is the probability of the transfer of a charge carrier from site to site in the lattice for identical energy levels in the two sites, ω is the frequency of the vibrational mode, E_p is the binding energy of the polaron, and J is the two-centre resonance integral. The function P has a complex form,[76] but a much simpler description can be used in the two limits of large and of small J. In the former (adiabatic regime) we have

$$P = 1, \tag{16}$$

and in the latter (nonadiabatic regime)

$$P \propto J^2 \propto \exp(-2\gamma\rho). \tag{17}$$

As has been pointed out[73] it follows from Eqn (15) that in the former case the activation energy increases with the average distance between centres (since J decreases), and in the latter it is almost independent of the distance (since J is small). An attempt was made to confirm this behaviour experimentally by studying the change in the mobility of the charge carriers in molecularly doped polymeric matrices as a function of the concentration of the dopant. Polycarbonate was used as the matrix, and the dopants included diphenylhydrazone-*p*-diethylaminobenzaldehyde (DEH)[72] and tri-*p*-tolylamine (TTA).[74] Results obtained in earlier work[38] with *N*,*N*′-bis(*m*-tolyl)-*N*,*N*′-diphenyl-1,1′-biphenyl-4,4′-diamine (TPD, see Fig. 1) were also discussed. It was found that in the DEH–PC system the activation energy is independent of the average distance between the transport centres, whereas the parameter P decreases exponentially as ρ increases, whereas in the TPD–PC system the activation energy increases with ρ but (conversely) P is independent of ρ (Figs 5 and 6). This difference was interpreted as a manifestation of nonadiabatic and of adiabatic polaron transport respectively. Since the resonance integral decreases exponentially with increase in ρ it follows that decreasing the concentration of transport centres in any system must sooner or later induce a transition to nonadiabatic transport. Schein et al.[74] claim to have detected this transition experimentally in the TTA–PC system (Figs 7 and 8). The different response observed in DEH, TPD, and TTA to a change in ρ (covering the same range) was ascribed to differences in geometry of the dopant molecules, leading to different packing in the polymer matrix and therefore to differences in the overlap of the π electron systems of the molecules.

Thus the experimental data are formally consistent, as a whole, with a polaron transport scheme. However, there are also some discrepancies. Firstly, the values obtained for J, E_p, and ω [0.25 (or more), 0.5, and 1 eV respectively] are unacceptably high in the case of J and ω. One obvious reason is the failure to allow for the disorder of the system. It was particularly stressed[74] that the concentration dependence of the activation energy and of the pre-exponential in Eqn (15) is explained by the polaron model without explicitly allowing for disorder effects.

The suggested explanation was that the activation energy in Eqn (15) is much greater than typical fluctuations in the position of the levels, i.e. the parameter σ as defined in the language of the Gaussian model. In this sense the suggested approach and the Gaussian model are totally incompatible. Furthermore Eqn (15) is not an exact formula but is essentially an interpolation (qualitative) expression. Kenkre and Dunlap[80,81] looked for a stricter expression for μ which also allowed for disorder effects through fluctuations in the energy levels (but not through fluctuations in the transition probability arising from geometric factors). This gives a slightly different functional dependence of the carrier mobility on the concentration for the TTA–PC system, but still as consistent with experiment as the earlier results[74] (see Fig. 7, broken curve). It was also suggested[80,81] that nonadiabatic polaron transport takes place in all the molecularly doped organic systems examined, since no transition to adiabatic transport was observed in the TTA–PC system. The same workers described[80,81] experimental data for the TPD–PC system by using their model. However, their model fails to describe satisfactorily the DEN–PC system, for which the activation energy is independent of ρ.

The proposed[80,81] modification of the polaron model did not eliminate its initial shortcoming: unacceptably high values of J were still obtained (of the same order as in the previous work[74]). Kenkre and Dunlap[81] stressed the fact that even in organic crystals, where the distance between the molecules is smaller than in molecularly doped polymers, the parameter J is at least an order of magnitude smaller than the values given by the model. Furthermore Bässler[14] correctly points out that the conclusions of Schein et al.[74] on the transitions between adiabatic and nonadiabatic transport regimes are based on the hypothesis of a temperature dependence of the mobility, undoubtedly of the Arrhenius type [see Eqn (2)], though this hypothesis now seems unjustified. For example, it yields (from the experimental data[74]) values of the pre-exponential factor in Eqn (15) of 100 $cm^2 V^{-1} s^{-1}$ and higher, which are unacceptably high for the hopping mechanism of mobility.

A recent paper[82] describes another attempt to choose between the polaron and the Gaussian model on the basis of the effect of small additions of diethylaminobenzaldehyde methylphenylhydrazone (DEMPH) on the transport of holes in the DEH–PC system. The transport level in DEMPH is located just below the corresponding level in DEH, and therefore it was suggested[82] that according to the Gaussian model a small addition of DEMPH should produce only a small widening of the distribution (7), whereas according to the polaron model the DEMPH molecules should act as shallow traps. As reported,[82] the observed increase in the activation energy can be explained only by adopting the polaron model. We do not agree that such an equivocal conclusion is justified, since the appearance of impurity levels in the low-energy region is essential to the transport of carriers in the Gaussian model for $\sigma/T \gg 1$ (see above). We suggest that the assumption of an effective widening of the distribution (7) as the only result of small additions of DEMPH is incompatible with the Gaussian model.

Thus it is impossible at present to produce unambiguous arguments for the occurrence of a transition from adiabatic to nonadiabatic polaron transport upon increasing ρ. The same must be said of the possibility of realising the polaron mechanism in general. The reason is that the main shortcoming of the polaron model (at least, in its present form) is its inability to account for the observed field dependence of the mobility. In the polaron model[79]

$$\mu \propto F^{-1} \sinh\left(\frac{e\rho F}{2T}\right), \tag{18}$$

which is totally incompatible with the experimental dependence (4). We believe that the ability to reproduce the field dependence of the mobility is the decisive test of the validity of any model of charge transport. Indeed, the temperature dependence of the mobility has an Arrhenius or similar form in the majority of the models which have been used, but the narrowness of the experimentally accessible temperature range makes it impossible to distinguish even between dependences of types (2) and (3). Different concentration dependences give an impression of artificiality, and often need to be combined with various extrapolation procedures.[14] Furthermore the extraction of unambiguous information from the concentration dependences is complicated by the frequent presence of large concentrations of dopant (10% or more), which make the separation of the system into transport centres and an inert medium an arbitrary decision. In fact a different effective medium corresponds to each concentration of dopant. Under these conditions the field dependence of the mobility offers a unique opportunity to test various models by a relatively simple experiment, using ranges of field strength covering two orders of magnitude in recent experiments.[23] This is why we believe that the strongest argument against the polaron model of charge transport is its failure to offer a correct description of the field dependence of the mobility.

Vannikov and coworkers[44,45,47] have tried to use the theory of Marcus[83] to describe the transport of charge carriers in polymers. In practice this meant allowing for the interaction of the charge carrier both with the intramolecular vibrations and with the vibrational modes of the medium in the polaron model. This approach allowed the activation energy of the carrier transport process to be related to parameters of the medium, such as the static relative permittivity, and thus to explain the influence of added inert polar molecules of the *o*-dinitrobenzene type on various characteristics of the transport. Unfortunately this variant of the polaron model suffers from the same serious shortcoming: as before, it gives Eqn (18) for the field dependence of the mobility.

3. The dipolar traps (transport centres) method

The dipolar traps method[84–88] is still only in the initial stage of its development. Nevertheless the results so far achieved show considerable promise. The model was first proposed in order to account for the field dependence of the mobility, which neither the Gaussian nor the polaron model could explain. However, it was later found that the new model offers interesting information as well on the temperature dependence of the mobility.

The model is based on the following considerations. Let the mobility be determined by the rate of emission of charge carriers from the traps (the transport centres). This state of affairs can be realised if the transport occurs (for example) by jumps of the carriers in a system of relatively shallow traps, and the rate of emission of the carriers from the transport centres determines their concentration in the mobile 'transport' state. Basically this idea underlies the Poole–Frenkel model,[21,22] but in addition that model also stipulates that the transport centres are charged even in the absence of charge carriers. Unfortunately, in the vast majority of matrices so far examined charged traps cannot exist in significant concentrations. Furthermore, as has been pointed out,[23] the distance from which the carrier is emitted from the charged trap according to the Poole–Frenkel model (i.e. the position of the saddle point in the potential energy surface, which determines the decrease in the activation energy, see Fig. 3) takes values of 50–400 Å in typical fields of 10^4–10^6 V cm^{-1}, i.e. it is unrealistically large. Since the transport traps are usually aromatic compounds or groups containing nitrogen they often possess sizeable dipole moments. Therefore it was suggested[84,85] that the effect of the field on the rate of emission of the charge carriers from a dipolar trap can explain the experimentally observed dependence of the mobility on the field strength. In the simplest case this effect can be evaluated through the lowering of the activation energy barrier to the emission of a carrier caused by an external electric field.

We assume that the carrier emerges from the trap in a region close to the saddle point, where the activation energy is a minimum, so that averaging over the different emergence directions becomes unnecessary, and quantum effects can be ignored. The interaction of a charge with a point dipole is described by the well known expression

$$V(r) = \frac{edr}{\varepsilon r^3} - eFr\,, \tag{19}$$

where d is the dipole moment of the trap. This leads to a dependence of the type

$$\Delta E_0 \propto F^{2/3}\,, \tag{20}$$

and therefore to $\ln\mu \propto F^{2/3}$, which is not consistent with experimental data. However, the decrease in the activation energy ΔE_0 depends also on the mutual orientation of the dipole and the field. By assuming that the orienting influence of the field on the dipolar transport centre is similar to its influence for a free dipole, we obtain the following expression for the mobility after averaging over the orientations of the dipole:

$$\mu = \mu_0 \int_0^{\pi} \sin\alpha \exp\left(-\frac{E_0 + \Delta E_0(\alpha, F) - dF\cos\alpha}{T}\right) d\alpha\,,$$

where

$$\Delta E_0(\alpha, F) = -e\left(\frac{dF^2}{\varepsilon}\right)^{1/3} G(\alpha)\,, \tag{21}$$

$$\begin{cases} G(\alpha) \approx \alpha, & \alpha \to 0 \\ G(\alpha) \approx \dfrac{3}{2^{2/3}}\left[1 - (\pi - \alpha)^2/9\right], & \alpha \to \pi \end{cases},$$

and α is the angle between the vectors d and F. In a weak field this expression gives

$$\ln\mu = \ln\mu_0 - \frac{E_0 - \beta_1 F^{2/3}}{T}\,,$$

$$\beta_1 = \frac{3}{2} e\left(\frac{2d}{\varepsilon}\right)^{1/3}\,, \tag{22}$$

whereas in a strong field

$$\ln\mu = \ln\mu_0 - \frac{E_0 - \beta_2 F^{1/3}}{T}\,,$$

$$\beta_2 = \frac{1}{2} e^2 \left(\frac{1}{d\varepsilon^2}\right)^{1/3}\,. \tag{23}$$

The change from Eqn (22) to (23) is brought about by the orientation of the dipoles in the external field, and takes place in fields of magnitude $F_t \approx 0.01 e^3/\varepsilon d^2$. Thus an increase in the field strength produces a change from the $\ln\mu \propto F^{2/3}$ to the $\ln\mu \propto F^{1/3}$ dependence. In the relatively wide intermediate range of field strength the change in mobility is satisfactorily described by Eqn (5) with

$$\beta = 0.36\beta_{PF}\,. \tag{24}$$

Furthermore the distance between the dipole and the saddle point of the potential surface (19) is 10–40 Å, which is a reasonable value. An attempt[85] to describe the experimental data[23] by means of Eqn (21) gave good agreement between experiment and theory, though the adjustable parameters had to be given unreasonably high values (d_{opt} = 18 D and ε_{opt} = 7.5). In order to resolve this discrepancy an attempt was made[86,87] to allow for the dynamics of the motion of charge carriers in the trap by assuming that the motion is stochastic and can be described by a Markov controlling equation of the form

$$\frac{\partial P}{\partial t} = \int_{E_{min}}^{\infty} \left[K(E, E')P(E', t) - K(E', E)P(E, t)\right] dE' - k_d(E)P(E, t)\,, \tag{25}$$

where $K(E, E')$ is the probability of the transition from a state of energy E' to a state of energy E in unit time, $P(E, t)$ is the distribution function over the energies of a charge bound in a trap, $k_d(E)$ is the rate constant of the dissociation of the bound state of the charge in the trap, and E_{min} is the position of the bottom of the potential well. The nucleus $K(E, E')$ was chosen as a phenomenological Bhatnagar–Gross–Krook (BGK)[89] nucleus, for which in $\Gamma = (\mathbf{r}, \mathbf{p})$ phase space the function $K(\Gamma, \Gamma')$ takes the form

$$K(\Gamma, \Gamma') = \nu\delta(r - r')P_{eq}(p)\,, \tag{26}$$

where ν is the characteristic frequency of the interaction with the external medium, r is the coordinate and p is the momentum of the charged particle, and $P_{eq}(p)$ is the equilibrium distribution function over the momentum. The use of the BGK nucleus implies that every collision leads to a completely stochastic momentum distribution without change in the spatial coordinates. Intuitively this stipulation seems correct in the case of effective collisions of short durations, and therefore the BGK nucleus is often used to analyse and to model the dynamics of various systems.

A solution of Eqn (25) has been obtained[86–88] by two numerical methods: direct modelling of the random walk over energies of a charge carrier in the trap, by using the Monte Carlo method to calculate the rate constant for the dissociation of the bound state through the reciprocal mean time to reach the dissociation threshold, and by the direct calculation of the quasistationary solution of Eqn (25), whose decrement defines the rate of dissociation of the bound state. The latter method can be used for the low-temperature region, which is not accessible to the Monte Carlo method because of its unreasonable requirements of computer time. The two methods gave satisfactorily consistent results. The mobility of the carriers was also calculated by averaging the rate constant $k_e(\alpha)$ over the angle α, using both a chaotic distribution and the distribution corresponding to Eqn (21).

Calculations showed[86–88] that in moderately weak fields the field dependences of the mobility have the typical Poole–Frenkel form (Fig. 9), irrespectively of the assumed distribution of the dipoles over the orientations. This effect is attributed to the fact that the parameter $\ln k_e(\alpha)$ is linearly dependent on $F^{1/2}$ for strong enough fields (Fig. 10). The suppression of the $\ln k_e(\alpha) \propto F^{2/3}$ dependence, indicated by the calculation of the rate constant, can be explained through a decrease in the activation energy. This is because the field F has a double influence on the motion of the charge carrier in the potential well. The strongest effect is a lowering of the activation energy. However, there is also a second effect which limits the space available for the motion of the particle, and therefore the application of a nonzero electric field converts the long-range potential of the dipole into a short-range potential. This ensures that at energies just below the threshold value the particle spends much less time in a state of low kinetic energy (a typical situation for a long-range potential), i.e. the average kinetic energy of the particle (the charge carrier) increases. In our mechanism, which assumes interaction of the particle with the thermal fluctuations of the surroundings, this leads to an increased rate of dissipation

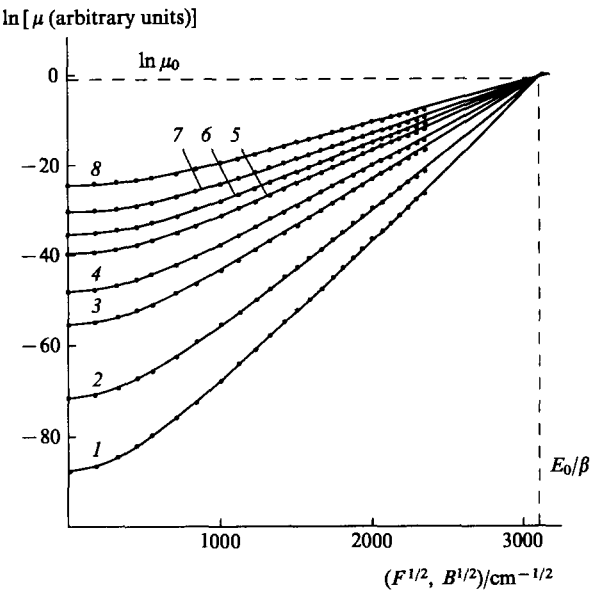

Figure 9. Field dependences of the mobility for different temperatures.[88] T/E_0: 0.01 (*1*), 0.012 (*2*), 0.015 (*3*), 0.017 (*4*), 0.02 (*5*), 0.022 (*6*), 0.025 (*7*), 0.03 (*8*). Calculated for $E_0 = 0.8$ eV, $T = 0.01E_0$, $d = 5$ D, and $\varepsilon = 1$.

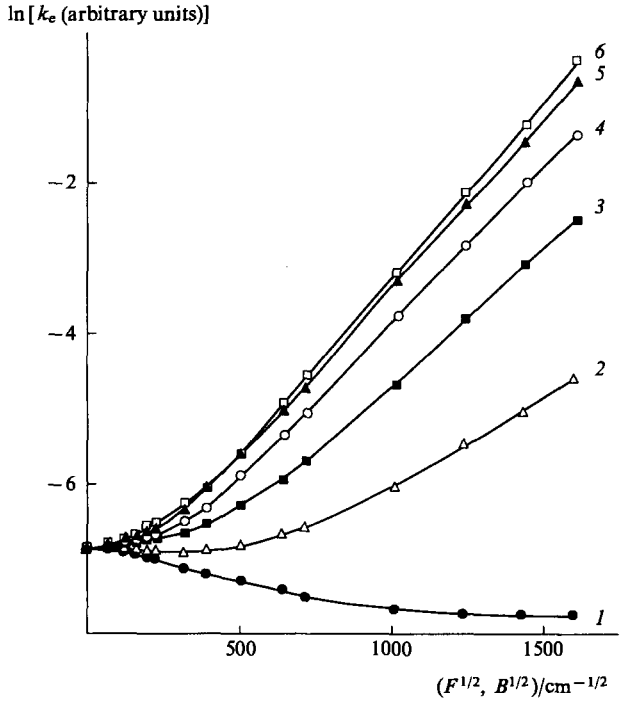

Figure 10. Field dependences of the rate constant k_e for different values of the angle α.[86] α/rad: 0 (*1*), $\pi/5$ (*2*), $2\pi/5$ (*3*), $3\pi/5$ (*4*), $4\pi/5$ (*5*), π (*6*). Calculated for $E_0 = 0.4$ eV and $T = 300$ K, other parameters as in Fig. 9.

of energy for a particular close to the threshold, and therefore to a decrease of $k_e(\alpha)$. This effect is most clearly seen for $\alpha = 0$, when there is no lowering of the activation energy and therefore $k_e(0)$ decreases as F increases.

The temperature dependence of the mobility was shown to be a complex phenomenon of the Arrhenius type at low temperatures and approaching the dependence described by Eqn (3) at high temperatures (where high temperatures are defined by the condition $T/E_0 > 0.03$, Fig. 11). Additional

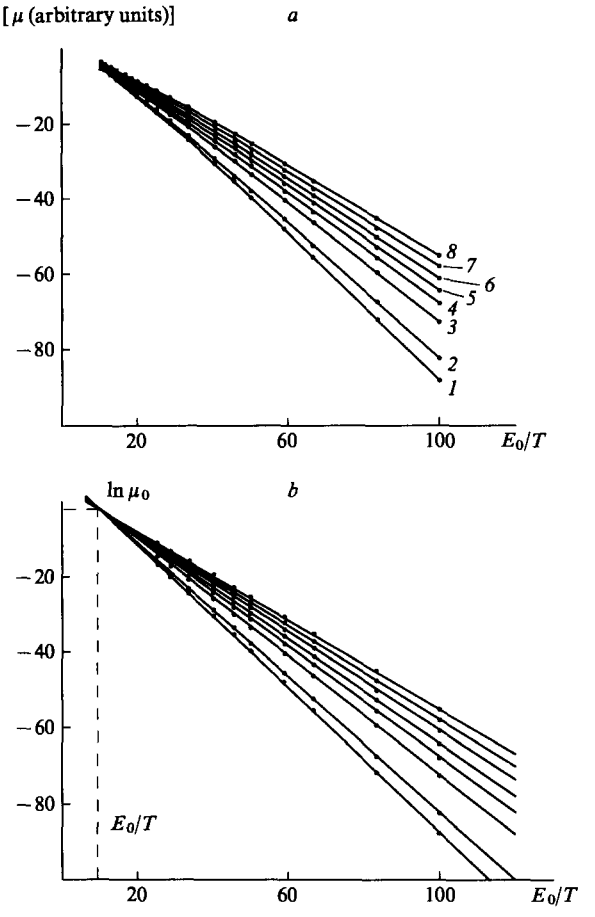

Figure 11. Temperature dependences of the mobility (*a*) for different values of the electric field,[88] and temperature dependences averaged by least squares (*b*) for temperatures not exceeding $0.05E_0$. $(10^{-5}E)$/V cm^{-1}: 0 (*1*), 2 (*2*), 7 (*3*), 10 (*4*), 12.5 (*5*), 15 (*6*), 17.5 (*7*) 20 (*8*). All the other parameters as in Fig. 9.

confirmation of the Arrhenius form of the $\mu(T)$ dependence is provided by the equality of the activation energy and of the depth of the trap (which depends on F).

The overall dependence of μ on F and T in not very weak fields is accurately described by the Gill–Pfister Eqn (5) (see Figs 9 and 11). It follows from Fig. 11 that a crude estimate of the temperature T_0 can be obtained by the formula

$$T_0 \approx 0.1\,E_0\,. \tag{27}$$

Evidence that the temperature T_0 is determined only by the parameter E_0 has been obtained.[88] The estimate (27) agrees reasonably well with experimental data,[24,39,40,90,91] especially if its approximate nature is not forgotten. Another interesting conclusion follows from the calculations: the constant μ_0 of the Gill–Pfister Eqn (5) corresponds approximately to the limit value of the mobility at $T \to \infty$, which is independent of F, whereas it follows formally from Eqn. (5) that

$$\mu(T \to \infty) = \mu_0 \exp\left(\frac{E_0 - \beta F^{1/2}}{T_0}\right). \tag{28}$$

For $F = 0$ we find from Eqns (27) and (28) that Eqn (5) gives a value of the limiting mobility too high by a factor of 2×10^4. Of course, the approximation (27) is quite arbitrary and has a low precision, and it is clear that it overestimates the limiting mobility by several orders of magnitude. Therefore the choice of the dependence (3) [rather than (2)] on the grounds that (2) gives an unreal value of the mobility as $T \to \infty$ is not justified.[15,92]

At the same time, in the light of the dipolar traps model, the relative advantages of the expression (2) or (3) are arguable. Depending on the temperature interval chosen the mobility can be better described by Eqn (2) or by Eqn (3).

To conclude this section we shall discuss the sign inversion at high temperatures[15,31-33] of the coefficient b in the field dependence of the mobility [Eqn (4)], which was mentioned above. This behaviour follows formally from Eqn (5) for $T > T_0$. The dipolar traps model in its most recent variant cannot account for this behaviour, and this is, in fact, its most serious shortcoming. Nevertheless we should stress that the Gill–Pfister formula applies with satisfactory precision to almost all the systems so far examined, whereas in practice the sign inversion has been established experimentally only in a few cases. For the great majority of compounds the temperature T_0 is found to lie well above the glass transition temperature of the matrix, and is therefore not experimentally accessible. Therefore we believe that the temperature T_0 is not directly related to the sign inversion of the coefficient b of Eqn (4), and is only a parameter which describes the deviation of the temperature dependence of the mobility from the Arrhenius form. From our point of view the sign inversion of b must be explained by the action of some specific and (obviously) rarely met mechanism. The same is true of the nonmonotonic field dependence of the mobility.[13,34] This dependence is a very rare exception. Only future work can show whether this is really the case, or whether these effects are unavoidable characteristics of charge transport in disordered organic matrices.

The dipolar traps model also offers a natural explanation of the effect of inert polar additives on the transport of charge carriers. It is reasonable to assume that the dipoles can form aggregates of various compositions and geometries with the transport centres, and that the effective dipole moment of these aggregates can vary within defined limits. Clearly, the dipole moment of the aggregates is directly correlated with the bond energy of the carrier, since the electrostatic interaction of the charge with the dipole adds a substantial contribution to the total energy of the bond. Since the number of carriers is usually small in comparison with the number of traps, the charge transport is dominated by the deepest traps, i.e. by the traps with the largest dipole moment. This decreases the absolute value of the mobility as a result of the increase in E_0, but it also increases β since an increase in d strengthens the long-range interaction of the charge with the dipole, which is responsible for the emission of the charge from the trap.[88] Similar arguments apply to the changes in dipole moment of the transport centre itself.

We note that an increase in d without a change in the depth of the trap results in an increase in μ as a result of the accompanying strengthening of the long-range interaction. This effect can be used to explain an interesting experimental observation:[45] the carrier mobility in the polystyrene–triphenylamine system is decreased by a factor of 320 after doping with *o*-dinitrobenzene, whereas allowing only for the change in the activation energy should lower the mobility by a factor of 5×10^4.

The most characteristic difference between the dipolar traps model and the Gaussian or the polaron models is the substantial role played by the medium (the polymer matrix). The latter two models treat the polymer matrix as a nontransport medium whose function is to accommodate the transport centres at a well defined mutual distance and which affects the transport only indirectly by acting on the parameters of the centres. Transport directly through the polymer matrix is excluded.

In the dipolar traps model the controlling step is the emission of the charge carrier from an isolated transport centre. In this case the transition to a neighbouring centre requires a stage of transport along the polymer matrix. Data on the radiation-induced electric conduction in polymers show that this mode of transport can easily account for the transport of the charge carrier for the required distance. We know that the radiation-induced electric conduction in polymers, which has undoubtedly an electronic nature, includes an instantaneous and a delayed component,[93,94] and that the instantaneous component γ_m (defined by the drift of the charge carrier between its generation and its capture by a trap) bears a direct relationship to the motion of the carriers in the polymer matrix between neighbouring transport centres. The instantaneous component is characterised by the constant K_m. Under these conditions $\gamma_m = K_m R_0$, where R_0 is the dose rate. If γ_m is expressed in C m^{-1}, and R_0 in Gy s^{-1} we can write

$$G\mu_0\tau_0 = 0.1\,\frac{K_m}{g}, \tag{29}$$

where G is the radiation-chemical yield of charge carriers per 100 eV of absorbed energy; μ_0 and τ_0 are the mobility of the carrier in the free state and the time elapsing before its capture by a deep trap; $\mu_0\tau_0$ is the specific path, m^2 V^{-1}; g is the density of the polymer, g cm^{-3}. In organic substances, including polymers, $G = 1$. In polycarbonate, the polymer matrix most often used in electron transport layers, $K_m = 1.6 \times 10^{-15}$ F m^{-1} Gy^{-1}, whence $\mu_0\tau_0 = 1.6 \times 10^{-12}$ cm^2 V^{-1}. The interval usually obtained for the change in F is 10^5–10^6 V cm^{-1}, i.e. the charge carrier travels a distance of 16–160 Å before being captured by a deep trap, whereas the average distance between the transport centres is usually 10–20 Å.

The dipolar traps model in its current form is only a model of a single trap, not a model of the transport process as a whole. Therefore it cannot claim to describe characteristics of the transport such as the various concentration dependences and dispersion phenomena. Nevertheless it can be used to give descriptions of field and temperature dependences in good agreement with experiment.

IV. Electroluminescent polymer layers

In recent years studies of radiative recombination and the preparation of flat, flexible polymer diodes which emit light upon the application of an electric potential difference have become one of the leading new areas in applied science.[4,95,96] The main part of these electroluminescent diodes is a polymer layer located between two electrodes: the cathode injects electrons and the anode injects p-type carriers. Metals having a low work function (ϕ) are used for the cathode (Al, In, Ca, or Mg), whereas the hole-injecting anode is a compound having a high electron affinity: In_2O_3/SnO_2 (ITO), or a polyaniline (PAn) film in the form of the conducting (acid-doped)[97,98] emaraldin salt, or oligothiophen.[99] When a voltage is applied the injected electrons and holes move into the layer from opposite directions and recombine (when they meet) with emission of light:

$$p^{+\cdot} + e^{-\cdot} \longrightarrow {}^{1,3}(p^{+\cdot}\cdots e^{-\cdot}) \longrightarrow$$

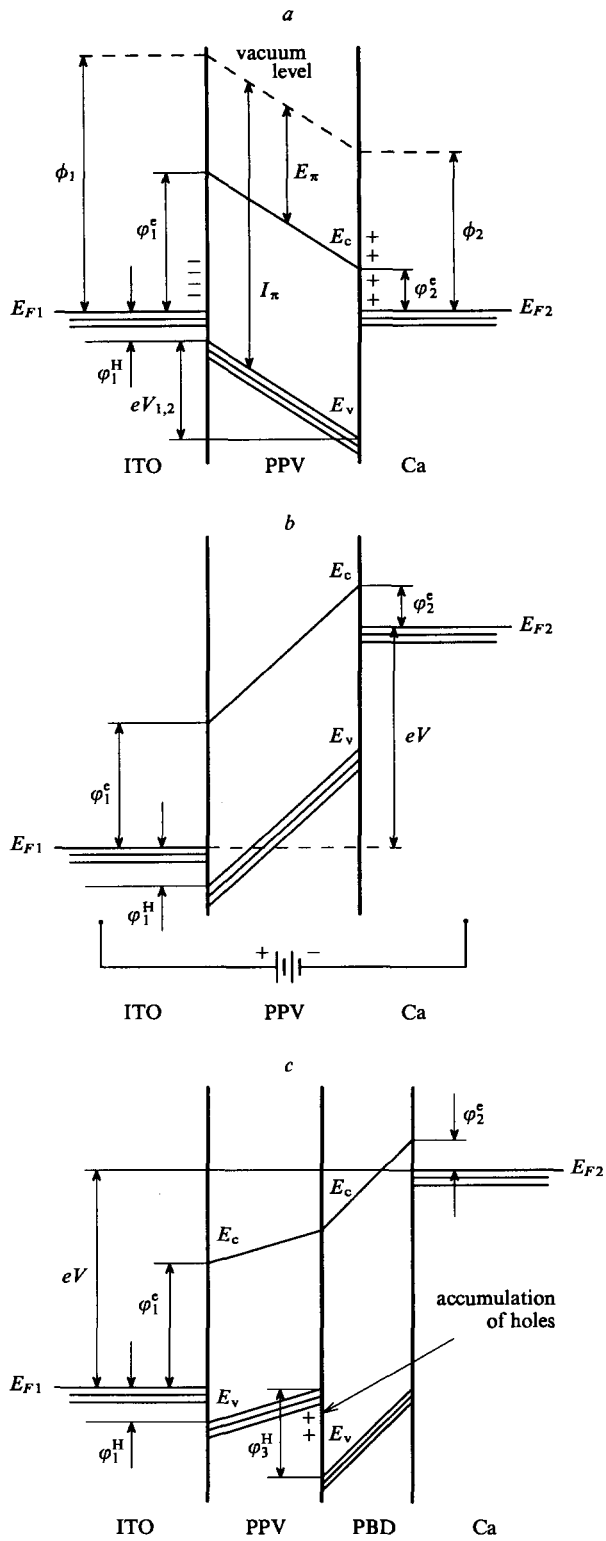
$$\xrightarrow{25\%} S_1 \longrightarrow h\nu^{fl} + S_0 + \text{phonons} \tag{30a}$$

$$\xrightarrow{75\%} T_1 \longrightarrow S_0 + \text{phonons}. \tag{30b}$$

In keeping with the multiplicity of the states S_1 and T_1 25% of the charges which collide in reaction (30) recombine through a singlet excited state, and 75% through a triplet state.[100] Electrophosphorescence was not observed in these diodes. As will be shown below, the triplet excitons T_1 contribute to the electroluminescence by virtue of the reaction (30c) in competing processes:

$$T_1 + T_1 \longrightarrow S_1 \longrightarrow h\nu^{fl} + S_0 + \text{phonons} \tag{30c}$$

$$T_1 + T_1 \longrightarrow S_0 + \text{phonons}. \tag{30d}$$



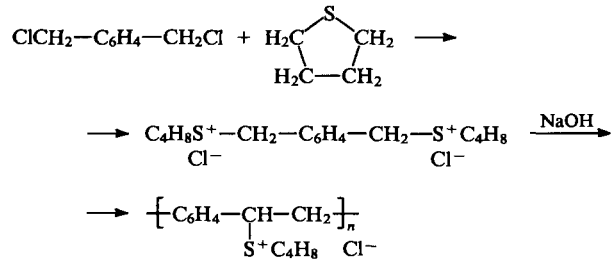


Figure 12. Energy diagram of the processes in single-layer (*a*, *b*) and in bilayer (*c*) electroluminescent diodes (symbols defined in text). Applied potential difference $V = 0$ (*a*), V (*b*, *c*).

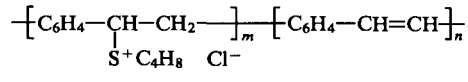
Two types of system have been examined so far. The first type includes single-layer systems with one or more components. The one-component systems rely on polymers with conjugated bonds, in which charge transport and light emission can take place simultaneously (PPV and its derivatives,[4,95,97,98,101-107] poly-3-alkylthiophens,[100,108,109] poly-*p*-phenylene,[110] etc.). A typical example of a single-layer multicomponent system is a composition consisting of PMMA with a dissolved triphenyldiamine additive (TPD, see Fig. 1) responsible for the transport of holes, and the organoaluminium complex (Alq_3), responsible for the transport of electrons and for the emission of light.[112] An energy diagram of the processes in single-layer systems is shown in Figs. 12*a* and 12*b*, where ϕ_1 and ϕ_2 are the work functions of the anode and of the cathode respectively; I_π and E_π are the ionisation potential and the electron affinity of the polymer layer in the solid phase [respectively, the distance from the vacuum level to the upper edge of the valence band (E_v) and to the lower edge of the conduction band (E_c)]. Under these conditions $h\nu^{fl} \approx I_\pi - E_\pi$. In PPV I_π is equal to 6.2 eV and E_π to 2.5 eV.[113] The strength of the EL is determined by the effectiveness of the radiative recombination channel, by the energy barriers which the electrons and holes must overcome before recombining, and also by the transport of electrons and/or holes, all of which contribute to the encounter of electrons and holes in the polymer.

Systems of the second type include structures consisting of two (or more) polymer layers (see Fig. 12*c*), one of which (PPV) is responsible for the transport of holes while the other [PPMA containing 2-(4-biphenyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD)] is responsible for the transport of electrons.[104,114-117] In these systems the emission of light takes place from the contact region of the two layers.[104,114-117] Structures in which the polymeric transport layer is in contact with a sputtered layer of a low-molecular-mass compound have also been prepared. The transmission of electrons through interlayer boundaries is discussed in detail in Section V.



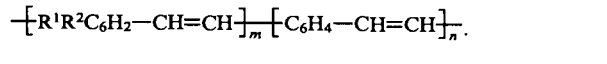
1. Electroluminescence of PPV derivatives

In the method widely used to synthesise PPV its precursor is first obtained from α,α′-dichloro-*p*-xylene in the form of the polyelectrolyte **1**, for example by reaction with tetrahydrothiophen (THT).[118]

1

The polymer **1** is unstable, and conjugated phenylenevinylene portions of the chain are formed in the molecule during lengthy storage at elevated temperatures (160–300 °C).

2



The polymer **2** is completely converted into PPV when stored in vacuum at 300 °C for several hours.[118]

If substituted α,α′-dichloro-*p*-xylenes [$ClCH_2-2\text{-}R^1,5\text{-}R^2.C_6H_2-CH_2Cl$ (R^1 and R^2 = CH_3O, NO_2, or other groups)] are used in the synthesis derivatives of PPV are obtained,

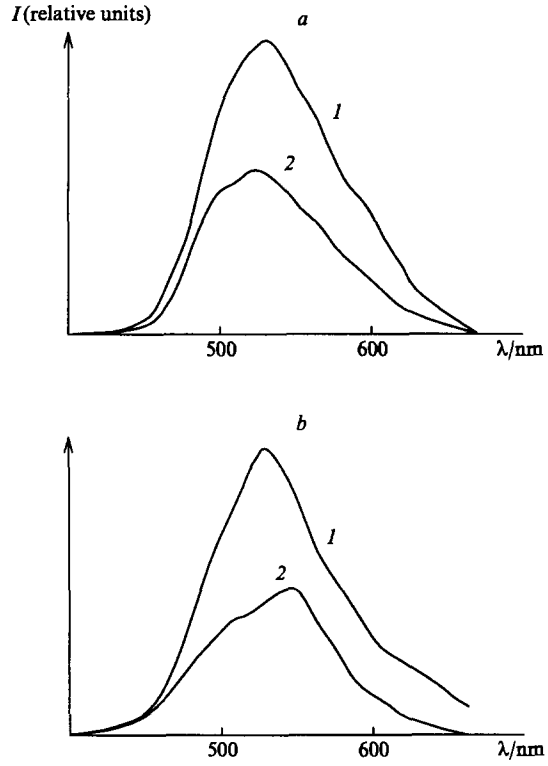
3

or copolymers of the structure

As will be shown below, PPV has a weak EL, and polymer **2** is most often used in the preparation of diodes. Since the conversion of polymer **2** into PPV continues in the prepared diode it is difficult to control the degree of development of the unsaturated chains in PPV. This may be the reason for the large scatter of the characteristics of the EL obtained in different laboratories. Changes in the region of the Schottky barrier caused by the interaction of the cation material (for example, Ca) with the sulfur-containing impurity produced during the conversion of the polymer **2** into PPV also contribute to the scatter of the results.[119]

The position of the EL band is determined mainly by the size of the system of conjugated bonds, and also by the structure of the side substituents in the polymer chain and by other factors which control the position of the energy levels contributing to reaction (30). The optical absorption of the PPV film lies in the energy range above 2.4 eV and has a maximum at ~3.0–3.2 eV (410–390 nm).[118–120] The long-wave threshold of the optical absorption of the polymers **3** is bathochromically shifted by the introduction of donor substituents from ~2.4 eV in PPV ($R^1 = R^2 = H$) to 2.18 eV for R^1 and $R^2 = OCH_3$ and to ~2.1 eV for R^1 and $R^2 = O-(CH_2)_7-CH_3$, or $R^1 = O-CH_2-CH(CH_2CH_3)-C_4H_9$, $R^2 = O-CH_3$; or for $R^1 = R^2 = O-(CH_2)_5-CH_3$.[121] A hypsochromic shift of the spectrum has been observed for the oligomeric analogues of PPV ($n = 3$) with $R^2 = NO_2$.

The EL spectra are usually similar to the photoluminescence (PL) spectra of the polymers. The similarity is due to the fact that in both cases the formation of an exciton is an intermediate stage, and the same excited states take part in the radiative transitions. As an example we show in Fig. 13 the photoluminescence spectra of poly[1,4-phenylene-1,2-di-(4-phenoxy-phenyl)vinylene], DPOP–PPV, measured at room temperature,



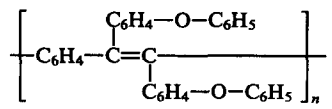


Figure 13. Photoluminescence spectra (*a*) of a layer of DPOP–PPV ($\lambda^{exc} = 370$ nm) and electroluminescence spectra (*b*) of a layer of DPOP–PPV in an ITO/PAn/DPOP–PPV/Al cell ($V = 12$ V) without (*1*) and with 10 wt.% of *o*-DNB (*2*).

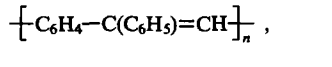


and their electroluminescence spectra, measured in an ITO/PAn/DPOP–PPV/Al cell with an applied voltage of 10–20 V. It can be seen that the EL and PL spectra lie in the same region (450–650 nm) and have a maximum at ~530 nm (2.34 eV) in the absence of additives.[98] The spectral changes produced by the addition of *o*-DNB are discussed below. In cells of this type the brightness of the EL is proportional to the density of the current flowing through the sample when the voltage is applied. The heating of the sample at high current densities shifts the EL spectrum towards shorter wavelengths.[105]

2. Photoluminescence of PPV derivatives

The fluorescence excitation and emission spectra of PPV are similar in form to those of *trans,trans*-1,4-distyryl benzene $C_6H_4(CH=CHC_6H_5)_2$,[123,124] bispropylstilbene[124] $C_3H_7-(C_6H_4-CH=CH)_2-C_6H_4-C_3H_7$ or oligomeric analogues having the structure $H-(C_6H_4-CH=CH)_n-C_6H_5$, $n = 3-7$.[125,126] In all these compounds the PL spectrum has a well resolved fine structure. The energy of the $S_1 \rightarrow S_0$ 0–0 transition (ΔE), measured from the fluorescence spectra in frozen (6 K) solutions of the oligomeric analogues of PPV, depends on the size of the π conjugation system (n) and corresponds to the Kohn potential box model[122,125–127]

$$\Delta E = \Delta E_\infty + \frac{\text{const}}{n}. \qquad (31)$$

An analysis of the optical absorption spectra of polyphenylphenylenevinylene (PPPV),

during the oxidation of the polymer (in contact with $SbCl_5$) showed[127] that, as the polymer was consumed by being converted into the oxidised form, the optical absorption maximum was hypsochromically shifted from 25×10^3 to 30×10^3 cm^{-1}. These changes, which suggest a nonuniform broadening of the spectra, were ascribed[126] to a nondegenerate energy ground state, i.e. to a weak exchange interaction of the overall collection of segments of the polymer with different effective lengths of conjugated bond systems. In this case the nonuniform broadening of the spectrum is due to the contribution of the optical transitions from conjugated segments having different n values [see Eqn (31)]. The longest conjugated segments are oxidised first, because they have the lowest ionisation potential. This results in a lowering of the optical density at the low-energy absorption edge of the initial polymer and in the appearance of three optical absorption bands belonging to the oxidised form. As the oxidation proceeds, increasingly short conjugated chains begin to contribute to the reaction (i.e. n decreases), and this produces a gradual hypsochromic shift of the spectra of both the initial polymer and its oxidation products.

By comparing the ΔE energies in the polymers and the oligomer analogues with the known values of n we can calculate by Eqn (31) the maximum length of the system of conjugated bonds in the polymers: it is found to be $n \simeq 5-7$ in PPPV and ~10 in PPV.[122,126,127] The value $n \simeq 4$ was obtained for the average length of the conjugation chain in PPPV,[127,128] and in other derivatives of PPV,[128] and this was ascribed to a nonplanar structure of the polymer chain. It was suggested[127] that because of the weak exchange interaction the photoexcitation generates a Frenkel exciton, delocalised within one particular conjugated region. During its random motion (spectral diffusion) the exciton

gradually loses energy and migrates towards more extensive regions of effective conjugation: thus, radiative transitions take place with a higher probability from the regions with the highest n value.

These concepts are consistent with the lack of dependence of the maximum in the fluorescence emission spectra on the energy of the exciting light $h\nu^{ex}$, which has been established experimentally for PPV and PPPV, if $h\nu^{ex} \geqslant h\nu^{loc}$, where $h\nu^{loc}$ depends on the morphology of the polymer and lies in the region of 2.5–2.36 eV [$\nu^{loc} \sim (20.2-19) \times 10^3$ cm^{-1}].[126,129] Lowering ν^{ex} into the region below ν^{loc} at 6 K produces uniformly broadened radiative transitions, resulting from the local excitation of the largest π conjugated segments.[126,129] Since the diffusion of low-energy excitons is hindered, the absorption and the emission of light take place in the same fragment. A dependence of the displacement between the maxima of the excitation and radiation PL spectra (Stokes shift) upon the degree of order in the polymer chains has been established for this case. This effect justifies the conclusion that the Stokes shift is determined by a change in conformation of the polymer chain in the photoexcited state[129] rather than by the electron–photon interaction, as had been suggested previously.[126] The Stokes shift is 500 cm^{-1} (0.062 eV) in PPPV, but it depends on the extent of conversion of the polymer **2** into the conjugated PPV, decreasing from ~100 cm^{-1} for $n \simeq 10$ (see Mahrt et al.[125]) to zero for $n \simeq 20$ (see Heun et al.[129]). In the highly oriented PPV crystals the Stokes shift is close to zero,[130] and singlet excitation extends over more than seven monomer units of the chain. These observations led to the conclusion that the electronic excitation in ordered crystalline PPV corresponds to the Wannier type of exciton.[130]

The PL quantum yield in 1,4-distyrylbenzene at room temperature[120,124] is ~94%. It is substantially lowered by changing to polymer analogues, and in PPV it is variously reported to be $\leqslant 0.1\%$ at room temperature[120,123] and ~4%–0.4% in the 10–293 K region.[124] Separating the basic π conjugated chains by introducing bulky side substituents in the change to PPPV increases the quantum yield at 10–293 K to 20%–10%, and if the PPPV is additionally diluted with polycarbonate the yield increases to 32%–25%. On these grounds it was concluded that a competition between radiative and nonradiative recombination is occurring. The nonradiative disappearance of the excitons is due to their capture by randomly distributed traps, formed by the interaction of the π conjugated chains of the polymer. The effectiveness of the capture of excitons by these traps is increased by the increase in their rate of migration at higher temperatures.

The EL and PL spectra of polyphenylenevinylene lie at ~2.6–1.8 eV, with a maximum at ~2.1–2.4 eV,[105,108] and they have similar fine structures with a resolution of ~0.16 eV.[120] However, in the partially conjugated polymer **2**, with segments containing the saturated precursor PPV, the PL and EL emssion spectra were found[118] not to be exactly identical: in particular, differences were noted in the relative intensities of the fine structure bands. These differences were tentatively ascribed to contributions to the PL and EL from different parts of the polymer chain.[118] The main contribution to the PL is provided by portions of the chain with a high content of nonconjugated segments, since on the conjugated segments the emission is preferentially quenched by nonradiative recombination processes. On the other hand, in EL the oppositely charged species can approach each other to within a distance which allows recombination within the conjugated regions, where the charge carriers have their highest mobility.[118]

Measurements of the EL and PL in DPOP–PPV are consistent with these arguments. As is shown in Fig. 13, the addition of *o*-DNB to the polymer (which increases the hole mobility[42]) lowers the intensity of both the EL and the PL, and therefore the *o*-DNB is acting as a quencher of the singlet excitation of the polymer. The suppression of the intensities is accompanied by a hypsochromic shift of the maximum of the PL spectrum and by a bathochromic shift of the maximum of the EL spectrum (see Fig. 13). These changes can be explained in terms of nonuniform broadening of the spectrum. Evidently, the displacement of the PL towards higher energies is associated with preferred interactions giving a CTC of the quencher with the most extensive π conjugation regions, which have the lowest I_π. The bathochromic shift in the maximum of the EL spectrum may be due to a simultaneous increase in the mobility of the charge carriers upon the addition of *o*-DNB, which increases their time of residence in regions with a more developed system of conjugated bonds.

According to published results EL and PL have different characteristic times. Thus, the application of nanosecond voltage pulses to a PPV film produces a decrease in the EL intensity which can be described by two exponentials with time constants of <11 and 60 ns respectively.[105] The slow component is determined by the distortion of the electric pulse by the *RC* constant of the sample, and the fast component by the EL process itself, which suggests the possibility of fabricating fast EL devices by optimising their geometry. Another important result of the pulse measurements was the observation of a proportionality between the current density and the brightness of the EL, up to current densities of the order of 10 A cm^{-2}. In the absence of limitations associated with the geometry of the sample the PL can be measured in the picosecond range. The decay of the PL also involves two components. Initially the PL intensity decreases 2.7-fold in PPV and PPPV at 10 K in ~135 and 430 ns respectively, and at room temperature in ~70 and 120 ns. Diluting the PPPV with polycarbonate increases this time to 780 ns and eliminates the temperature dependence. The slow component has a time constant of 1.1–1.4 ns,[124] which coincides with the 1.3 ns time constant measured in 1,4-distyrylbenzene.

3. Role of the spin constants in electroluminescence

Data on the electronic processes which accompany reaction (30) in EL diodes based on PPV and its derivatives were obtained by measuring the electric conductivity (σ) and the EL,[131] and also the PL [131,132] under conditions of paramagnetic resonance of the species which contribute to the process (electrons, holes, triplet excited states). These characteristics were measured at 20 K in diodes placed in the resonator of an ESR spectrometer, in which the magnetic field was scanned in the region of spin allowed ($\Delta m_s = 1$, $g \approx 2$) and of spin forbidden transitions ($\Delta m_s = 2$, $g \approx 4$). The increase in the PL intensity is accompanied by the appearance of a narrow signal ($\Delta H_{1/2} = 13$ *G*) with a g factor of 2.0023. Under paramagnetic resonance conditions the Boltzmann distribution of the population of Zeeman levels is perturbed as a result of the reorientation of the spins, and the fractional number of charged particles for which the charge recombination process (30a) becomes spin allowed is increased:

$$^3(p^{+\cdot}\uparrow \cdots e^{-\cdot}\uparrow) \xrightarrow{PMR} {}^1(p^{+\cdot}\uparrow \cdots e^{-\cdot}\downarrow) \quad p^{+\cdot} + e^{-\cdot} \qquad (32a)$$

Swanson et al.[131] assume that the increase in the PL under conditions of resonant change in spin orientation is due to the participation in reaction (30a) of the triplet pairs $^3(p^{+\cdot} \cdots e^{-\cdot})$, and that [as shown in the scheme (32a)] under spin forbidden conditions and in the absence of resonance these pairs dissociate into the free current carriers which are responsible for the photoconduction.[133] A broad spectrum (from 2600 to 4200 G) due to the increased fluorescence intensity produced by the reactions of the triplet excitons T_1 is superimposed on the narrow signal. The appearance of this spectrum shows that the probability of reaction (30c) in the competing processes

(30c) and (30d) is increased under paramagnetic resonance conditions.[131,132] For this reason the PL increases also in the region of forbidden transitions with $\Delta m_s = 2$, $g = 4.07$.

In contrast to the PL, a decrease in the electric conductivity σ and in the EL brightness was observed in the region of resonance spin transitions with $\Delta m_s = 1$. This effect is due to the possible existence, in equilibrium with the singly charged particles, of doubly charged particles with zero spin (depending on the chosen model, they have been called PPV^{2-} and PPV^{2+})[122,125-127] or bipolarons[121,131,132] bp^{++} and bp^{--}. As a result of the reorientation of the spins at resonance by the schemes (32b) and (32c) the probability of formation of doubly charged particles by scheme (32d) should increase:

$$p^{+\cdot}\uparrow + p^{+\cdot}\uparrow \xrightarrow{PMR} p^{+\cdot}\uparrow + p^{+\cdot}\downarrow \qquad (32b)$$

$$e^{-\cdot}\uparrow + e^{-\cdot}\uparrow \xrightarrow{PMR} e^{-\cdot}\uparrow + e^{-\cdot}\downarrow \qquad (32c)$$

$$p^{+\cdot}\uparrow + p^{+\cdot}\downarrow \rightleftharpoons bp^{++}$$
$$e^{-\cdot}\uparrow + e^{-\cdot}\downarrow \rightleftharpoons bp^{--} \qquad (32d)$$

According to Swanson et al.[131] the bipolarons have a much lower mobility than the singly charged current carriers, and therefore the decrease in σ and in EL under paramagnetic resonance conditions is interpreted as a confirmation that the reaction (32d) is taking place in the forward direction. In the region of forbidden transitions ($\Delta m_s = 2$) we find marked differences in the dependence of the EL and of σ on the magnetic field. Both these dependences demonstrate the two resonant transitions of the triplet excitons (low-field at 1.61 kG and high-field at 1.63 kG). Whereas σ is increased as a result of the two transitions the EL signal falls in the 1.61 kG region and rises at 1.63 kG. In agreement with reaction (30a) 75% of the charged particles form triplet excited states in their interaction. As in the case of the PL the increase in the EL is due to the increased probability of reaction (30c) under PMR conditions. It is assumed that the low-field triplet excitons with a resonance at 1.61 kG are more localised than the high-field excitons, and therefore that the process (30c) to which they contribute takes place in the immediate vicinity of the cathode surface. The S_1 singlet formed in the interaction with the electrode surface either undergoes nonradiative deactivation or rapidly decomposes into p^+ and e^-, the p^+ being discharged on the electrode. These changes lower the EL and increase σ under resonance conditions at 1.61 kG.[131]

Thus we conclude from the above discussion that the derivatives of PFV are usually characterised by a greater hole mobility, and that the reaction (30a) takes place in the space adjacent to the negatively charged electrode. The most serious problems are the decreased rate of the forward hole discharge reaction on this electrode, the equalisation of the concentrations of electrons and holes injected into the layer, and the limitation by the deactivation of excited S_1 states as a result of interaction with the electrode.

4. Quantum efficiency of the electroluminescence

The quantum efficiency η of the electroluminescence, defined as the ratio of the number of photons $h\nu$[f1] produced by the reactions (30) to the number of injected charges, depends on the mechanism of the motion of the charged particles, and also (as in the case of the PL) on the factors which affect the deactivation of the excited states.

It has been established[118] that the brightness of the EL in the ITO/polymer **2**/calcium cell depends on the degree of conversion of the saturated sulfur-containing precusor **1** into the π conjugated PPV, i.e. it is determined by the temperature and duration of the heat treatment of the precursor during the synthesis of the PPV. The quantum efficiency is 0.08% if the polymer **1** is heated for 2 h at 140 °C. If the temperature of the two-hour heat treatment is increased the efficiency η initially increases to a maximum of 0.75% at 160 °C and then falls again to ~0.05% at 300 °C. Increasing the time of heating at 300° C to 20 h lowers η further to $\leqslant 0.003\%$. The PL intensity shows similar dependences on the temperature and time of the heat treatment. A substantial lowering of the PL and EL intensities upon increasing the length of the conjugated bond system has been ascribed[118,120] to an increase in the rate of diffusion of the excitons and in the mobility of the charge carriers, which increases the probability of their migration to sites responsible for the nonradiative recombination.

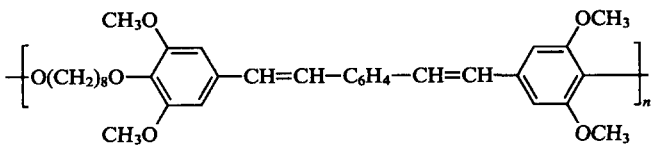
An analysis of the dependence of the mobility of holes on the degree of thermal conversion of the polymer **1** into the π conjugated PPV, or of other precursors in which the $S^+(C_4H_8)Cl^-$ group is replaced by chlorine, dimethyl-, or diethyl sulfide, or by the methoxy or butoxy group, has been reported.[134] In all the polymers prepared by this method, and whatever their degree of conversion, the hole mobility exceeds the mobility of electrons by more than two orders of magnitude. In spite of a marked lack of reproducibility of the results, increasing the number of conjugated segments in the polymer **2** produces an unmistakable increase in the mobility of holes, but this increase is suppressed by lengthy storage of the sample at room temperature or by heat treatment of the precursor above 150 °C.

Antoniadis et al.[134] were unable to detect the motion of charge carriers through a film of polymer having a high level of conjugation prepared by heat treating **2** for 2 h at 250° C. They showed that increasing the heat treatment temperature increases the dispersion of the time of flight of the charge carriers through the sample. These results were ascribed to the formation (after heat treatment at 150 °C) of polymer **2**, in which the regions of π conjugation include 2–3 phenylene-vinylene units. As was pointed out in Section II, the hopping model of transport, characteristic of many amorphous polymers, is applicable to this polymer containing isolated transport centres. As the extent of conversion of polymer **2** into PPV is increased, the size of the system of conjugated bonds also increases, and so does the dispersion of the times of flight through the transport layer, since the longest π conjugated segments (which have the lowest ionisation potentials) are hole traps. Furthermore, segments with a large n tend to form crystalline domains whose inclusion into an amorphous polymer produces an additional increase in the dispersion of the time of flight of the holes.[134]

In the copolymer of phenylenevinylene (PV) and 2,5-dimethoxy-*p*-phenylenevinylene (CH_3O-PV)[102] the EL spectrum is the same as in PPV, but the quantum efficiency increases more than 30-fold, reaching 0.3% for $m:n = 1:9$ in the ITO/copolymer/Al structure. Burn et al. point out[102] that the quantum efficiency can be increased to $\eta > 1\%$ by controlling the $m:n$ ratio during the synthesis through an appropriate choice of components:

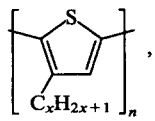
$$-\left[C_6H_4-CH=CH\right]_n-\left[C_6H_2(OCH_3)_2-CH=CH\right]_m-$$

(CH_3O-PV)



The PL radiation from this copolymer is characterised by two spectra with maxima at 555 and 608 nm, resulting from the different emissions of the PV regions in CH_3O-PV. In contrast to the EL, the PL intensity decreases on passing from PPV to the copolymer. As the $m/(m+n)$ ratio is increased from 0 to 0.33 the PL intensity decreases by about a factor of 8 and takes a constant value, characteristic of CH_3O-PV ($n = 0$).[135] It is suggested that the PL quenching in a copolymer is due to the photodissociation of excitons as a result of the transfer of an electron between parts of the chain of different nature.[135]

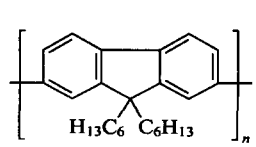
In the copolymer



$$-\left[C_6H_4-CH(OCH_3)-CH_2\right]_m-\left[C_6H_4-CH=CH\right]_n-$$

the conjugated structures are also separated by segments containing different bonds. The maximum of the emission spectrum corresponds to 508 nm (2.44 eV). At this light energy the quantum efficiency of the EL is 0.02% in the ITO/polymer (1000 Å)/Al structure.[103]

The electroluminescence lies in the blue region, and has a maximum near 470 nm (2.64 eV), in a polymer whose chain is divided into short segments of conjugated bonds by longer chains of single bonds:[107]



Attempts to prepare EL diodes on the basis of poly-(3-alkylthiophens) (PAT) have been reported: [100, 108, 109]

where $x = 8$ (see Ref. 100), 12, 18, and 22 (see Refs 108, 109). The electroluminescence is characterised by a broad spectrum with a maximum at 620–640 nm (1.9–2.0 eV). The position of the maximum in this spectrum is unaffected by the size of the neutral C_xH_{2x+1} side groups.[100, 108, 109] In the system based on poly(3-octylthiophen), replacing a Ca cathode by an In cathode increases the voltage needed to generate EL, but this does not affect the quantum efficiency of the reaction (30a) to a significant extent: in the diode based on Ca the parameter η lies in the range $10^{-4}\% - 10^{-3}\%$ [for working strengths of the electric field of $(0.2-0.7) \times 10^6$ V cm^{-1}], whereas in an In diode it lies in the range $(1-3) \times 10^{-3}\%$ [for fields of $(1-3) \times 10^6$ V cm^{-1}].[100] These low values of η were explained in terms of the presence in the final polymer of an impurity of $FeCl_3$, which is used in the synthesis and generates defects leading to the nonradiative recombination of the current carriers. A 4-fold increase of η upon increasing the length of the alkyl side chain x from 12 to 22 has been demonstrated.[108, 109] This observation led to the conclusion that the intermolecular interaction of the main chains containing the conjugated structures, which is weakened by an increase in x, is responsible for the nonradiative recombination of the charge carriers in these polymers as in the case of PPV. In PAT an increase in the applied voltage and in the current flow produce an anomalous superlinear increase in the EL.[108, 109] This effect is attributed to the increase in temperature and to the corresponding (temperature-induced) twist rotations of the main chains, leading to a shortening of the effective conjugation chain. The final result is a weakening of the intermolecular interaction of the main chains and a decrease in the rate of the nonradiative processes.

An electroluminescence with $\lambda_{max} = 470$ nm (2.5 eV) has been measured in a cell based on poly(9,9-dihexylfluorene):[111]

5. Effect of the material of the injecting layer

The efficiency of the EL can be improved by lowering the energy barriers which the electrons and holes have to surmount during injection. The quantum efficiency in single-layer diodes based on the derivatives of polyphenylenevinylene with p-type mobile carriers increases when cathodes such as Al (($\phi_2 = 3.8$ eV, see Fig. 12*a*)[136] or In ($\phi_2 = 4.2$ eV) are replaced by an electrode with a much lower work function, for example Ca ($\phi_2 = 3$ eV).[101] In a diode based on unsubstituted PPV [ITO/PPV (1000Å)/Al] the quantum efficiency (photons per electron) has been variously reported to be 0.01% (Refs 102, 103) or 0.05% (Ref. 100). When the aluminium cathode is replaced by a calcium cathode in this structure the quantum efficiency increases to 0.1%.[104]

In a diode based on poly[2-methoxy, 5-(2-ethylhexoxy)-1,4-phenylenevinylene], MEG–PPV [structural formula **3**, where $R^1 = O-CH_3$, $R^2 = O-CH_2-CH(CH_2CH_3)-C_4H_9$], ITO/MEG–PPV/In(or Ca), an electroluminescence in the spectral region between ~1.6 and 2.3 eV with a maximum at ~2.15 eV (at 300 K) or two maxima at 2.03 and 1.88 eV (at 90 K) is produced at voltages above 1.8 V.[97, 101] For a constant diode current density of 2 mA cm^{-2} the quantum efficiency is 0.05% and 1% (photons per electron) in the case of an In or a Ca cathode respectively.[101] In both diodes the increase in η is due to the fact that lowering the electronic work function strengthens the injection of electrons into the polymer for a constant hole current. It should also not be forgotten that in polymers with mobile carriers of a single sign (holes) the injected electrons are captured in traps directly on the metallic electrode, and recombination with formation of excited states by reaction (30) also takes place on the cathode. Under these conditions the nonradiative dissipation of the exciton energy on the metallic surface can compete effectively with the radiative $S_1 \rightarrow S_0$ transition (30).

Attempts to solve these problems have been made by synthesising derivatives of polyphenylenevinylene in which charge carriers of both signs are mobile,[42, 43, 98, 137, 138] and their recombination by reaction (30a) takes place not only in the immediate vicinity of the electrode but also throughout the polymer layer. For example, charges of both signs are mobile in the polymer DPOP–PPV. At 20 °C the quantum efficiency of reaction (30), measured at the emission maximum (530 nm, see Fig. 13) in ITO (or PAn)/DPOP–PPV (3000 Å)/Al cells for a constant voltage of 20–40 V, was 0.13% in the case of the ITO anode ($\phi_1 = 4.1$ eV,[97] see Fig. 12), and was increased to 0.38% by changing to a PAn anode ($\phi_1 = 4.3$ eV,[97]).[98] In the latter case the energy efficiency of the transformation of electric into light energy is 0.32%. As can be seen, when polymers with mobile carriers of both signs are used the anode material also has a marked effect on the quantum efficiency of the EL. In contrast, in a cell based on the MEG/PPV polymer, in which only the holes are mobile, the quantum efficiency of the EL is unaffected by replacing ITO by PAn: the current through the cell is increased by a factor of 10^3-10^4 for applied voltages below 1.5 V, but it ceases to be a function of the anode material at voltages above 1.8 V, where the EL is produced in the bulk of the polymer.[97] In this case, as was pointed out above, the controlling processes are those taking place directly on the cathode and involving its material.

6. Molecularly doped polymers

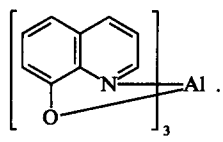
Molecularly doped polymers, in which compounds with both donor and acceptor properties are introduced into the polymer matrix to generate transport at both holes and electrons,[112] are a special class of electroluminescent layer. Poly(methyl methacrylate) (PMMA) is often used as the polymer matrix. Direct measurements of the mobility of the excess charge carriers in PMMA in the absence of additives or in the presence of a donor (triphenylamine, TPA) and an acceptor (chloranil, CA) showed[139] that the polymer matrix itself is reactive towards the excess electrons. Dissociative electron capture by the polymer

matrix competes effectively with all electron transport processes, and no electron drift from the generation region can be observed. No motion of holes is detected in the undoped PMMA because of the presence of structural traps (T), which capture holes according to the scheme

$$T + p^{+\cdot} \longrightarrow T^{+\cdot}.$$

The drift of holes begins at temperatures above 50 °C and 80 °C in the presence of TPA and CA respectively, but it is observed at room temperature in the simultaneous presence of TPA and CA. The formation of donor–acceptor complexes was not detected even at the maximum concentration of the dopants, which corresponded to an average intermolecular distance of ~20 Å. It was therefore concluded that the effect of the dopants on the drift of the holes was additive. It was suggested[139] that the drift of holes takes place by a hopping mechanism (between TPA molecules):

$$TPA^{+\cdot} + TPA \longrightarrow TPA + TPA^{+\cdot}.$$



Under these conditions the structural traps terminate the transfer by the scheme

$$TPA^{+\cdot} + T \longrightarrow TPA + T^{+\cdot}.$$

Chloranil interacts with defects of the hole trap type, lowering their concentration and thus increasing the drift mobility of the holes:

$$CA + T \longrightarrow CA^{-\cdot} + T^{+\cdot}.$$

The donor *N,N'*-bis(*m*-tolyl)-*N,N'*-diphenyl-1,1'-biphenyl-4,4'-diamine (TPD, see Fig. 1) was used to provide transport centres for p-type carriers in a single-layer EL diode based on PMMA, and the aluminium complex of tris(8-hydroxyquinoline) (Alq_3) was used as the acceptor:[112]

In systems based on two evaporated layers (a donor and an acceptor) the EL spectrum is shifted towards lower energies with respect to the PL spectrum of the individual component as a result of the formation of a charge transfer complex (responsible for the emission) or of an exciplex.[140] In a system consisting of a PMMA matrix containing TPD and Alq_3 the EL spectrum coincides with the PL spectrum of the complex of Alq_3 in PMMA and has a maximum at 510 nm (2.44 eV). Steric hindrance to the formation of an exciplex with the donor (TPD)[112] may be created by the octahedral configuration of the metal in the Alq_3.

The following jump model of the bipolar transport of charge carriers in this composition, involving the oxidation–reduction reaction

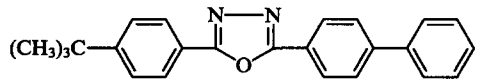
$$TPD^{+\cdot} + TPD \longrightarrow TPD + TPD^{+\cdot}$$
$$Alq_3^{-\cdot} + Alq_3 \longrightarrow Alq_3 + Alq_3^{-\cdot},$$

has been proposed, followed by the recombination

$$TPD^{+\cdot} + Alq_3^{-\cdot} \longrightarrow Alq_3^{*} + TPD$$
$$Alq_3^{*} \longrightarrow Alq_3 + h\nu^{fl}.$$

The luminescence of Alq_3 has been detected in the photoexcitation of the TPD in this composition, and therefore the possibility of the following reaction cannot be excluded:

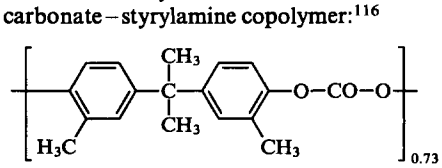
$$TPD^{+\cdot} + Alq_3^{-\cdot} \longrightarrow Alq_3 + TPD^{*}$$
$$Alq_3 + TPD^{*} \longrightarrow TPD + Alq_3^{*}.$$



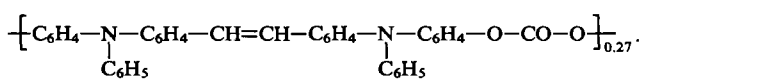
The diode current and the EL brightness are shown below for different TPD : Alq_3 ratios (by weight) in a diode based on ITO/TPD : Alq_3 : PMMA (1000 Å)/Mg with an applied voltage of 17 V and a ratio by weight of (TPD + Alq_3) : PMMA = 0.5.

TPD : Alq_3	0.43	0.67	1.0
i/mA cm^{-2}	60	170	90
EL/cd m^{-2}	180	920	430

7. Systems with separate transport layers



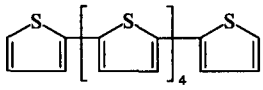
In order to minimise the direct discharge of the mobile current carriers on the electrodes, diodes consisting of two polymer layers (one providing electron transport, the other, hole transport) have been fabricated. We shall discuss them below, together with the characteristics of structures consisting of a polymer layer and an evaporated layer of a low-molecular compound. In these diodes the radiative recombination of injected charges is shifted from the cathode region to the region close to the boundary of the two polymer layers[96,103–105,107] (see Fig. 12*c*).



Brown et al.[104] have described the main characteristics of an EL diode consisting of PPV in contact with an electron transporting layer: 2-(4-biphenyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD)

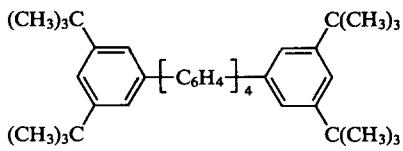
molecularly dispersed in PMMA. The EL spectrum of the structure ITO/PPV (3500 Å)/PBD in PMMA (300 Å)/Ca is identical to the EL spectrum of the PPV polymer. Hence the PPV layer is responsible for the emission of light in this two-layer system. The upper edge of the filled band in PPV lies ~1.5 eV above the highest occupied level of PBD, and the injected holes accumulate and contribute to reaction (30a) in the PPV layer near the PPV/PBD boundary (Fig. 12*c*). The accumulated holes create a large space charge which strengthens the electric field in the electron transport layer. This effect produces an increase in the number of injected electrons, and consequently an increased EL brightness. The quantum efficiencies of the two-layer and the single-layer structures (in the absence of PMMA containing PBD) for a current density of 1 mA cm^{-2} are, respectively, 1.1% and 0.07%, and at a current density of 15 mA cm^{-2} they are 0.8% and 0.1%. In the two-layer structure the ratio of luminescence brightness to current density is 0.85–0.6 cd A^{-1} over a wide range of current densities. In the one-layer structure this ratio is 0.017 cd A^{-1}, increasing to 0.034 cd A^{-1} when the current density is increased to 15 mA cm^{-2}.

The two-layer structures include a system based on a carbonate–styrylamine copolymer:[116]



The self-repeating styrylamine segment is responsible for the transport of holes and the emission of light. An electron-transport layer of PBD was evaporated onto the polymer.[116] ITO and Mg were used as electron and hole injecting electrodes respectively. The electroluminescence was characterised by λ_{max} = 460 nm (2.7 eV), the brightness was 130 cd m^{-2} for a current of 80 mA cm^{-2} and an applied voltage of 11 V. The conversion of electric energy into light energy was 0.05 lm W^{-1} at 11 V.[116]

The evaporated electron-transport layer of PBD was studied[115] in conjunction with polymethylphenylsilane (PMPS, see Fig. 1) doped with a europium complex, tris(phenyltrifluoroacetonato)europium, responsible for the transport of holes and the electroluminescence. ITO and Mg were used as the anode and the cathode respectively. A weak EL was observed in the red region, the luminescence being brightest (0.3 cd m^{-2}) at 18 V: it was attributed to the fact that effective nonradiative recombination of charge carriers can take place in europium complexes.



In the absence of additives the polymer PMPS is a p-type organic semiconductor, with a drift mobility of holes of 10^{-4} cm^2 V^{-1} s^{-1} at 20 °C. The ITO/PMPS (350 Å)/Alq_3 (1000 Å)/Mg system, in which a layer of Alq_3 had been evaporated onto the PMPS layer, produced EL with a maximum at 520 nm:[114] an applied voltage of 18 V produces a diode current density of 150 mA cm^{-2}, and the brightness of the electroluminescence rises to 1500 cd m^{-2}. Decreasing the thickness of the Alq_3 film to 600 Å lowered the brightness to 400 cd m^{-2}. Increasing the thickness of the PMPS layer from 350 to 460 Å did not affect the brightness, but decreasing it from 350 to 220 Å lowered the brightness approximately five-fold.

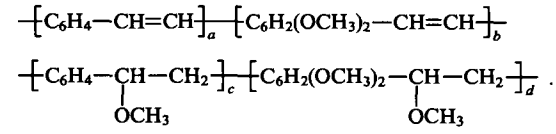
Studies of systems prepared from PMPS (350 Å) and Alq_3 (1000 Å) revealed a serious shortcoming of two-layer structures: the heating produced by high current densities through the device induces crystallisation of the evaporated film, which rapidly degrades the diode by disrupting the contact between the layers. It was established that at high enough voltages (20 V) the EL is irreversibly quenched in a period of a few seconds.

Alq_3 emission was observed[99] in cells having the structure ITO/T6 (200 Å)/TBP/Alq_3 (600 Å)/Mg, where T6 is the oligothiophen

(I_π = 5.2 eV, E_π = 2.9 eV), TBP is the tetrabutyl derivative of the six-ring polyphenyl

(I_π = 5.7 eV, E_π = 2.9 eV); EL was observed in the region of 450–700 nm with a maximum at 510 nm, due to the emission from Alq_3.[99] A linear dependence of the EL brightness on the device current density (i) and a superlinear increase of the current density with the applied voltage V were discovered: for $V > 4$ V, $i \propto V^n$, where $n > 9$. At voltages of 9 and 13 V the following characteristics were obtained for the EL cell with and without a TBP layer (300 Å thick).

	Without TBP	With TBP	
V/V	9	9	13
i/mA cm^{-2}	93	93	313
EL/cd m^{-2}	290	700	2300



At V = 9 V the conversion of electric energy into light energy is 0.1 lm W^{-1} in the cell without a TBP layer and 0.32 lm W^{-1} when the TBP has been included. The large increase in brightness of the EL as a result of the insertion of a TBP interlayer is ascribed[99] to the suppression by the TBP of the penetration of electrons, which inhibits the transfer of energy from the emitter to the semiconductor polymer.

The brightest EL was obtained in a two-layer system, in which a film of Alq_3 was deposited by vacuum evaporation on a polymer layer of PMMA or polycarbonate (PC) doped with TPD (see Kido et al.[117]). An increase in EL brightness upon increasing the dopant concentration was observed in the diode based on ITO/TPD:PMMA (400 Å)/Alq_3 (500 Å)/Mg. At an applied voltage of 16 V the following dependences of the diode current density and of the EL brightness on the ratio by weight of TPD:PMMA were obtained:

TPD:PMMA	0.3	0.5	0.8
i/mA cm^{-2}	100	180	420
EL/cd m^{-2}	1400	2300	7400.

Comparing these characteristics with those given above for the ITO/TPD:Alq_3:PMMA/Mg system shows that the change from a one-layer to a two-layer structure increases the brightness of the EL by almost an order of magnitude. A further increase in brightness was obtained by using a matrix of PC: for a component ratio of TPD:PC of 0.5 and an applied voltage of 14 V the diode current density reaches 420 mA cm^{-2}, and the EL brightness reaches 7700 cd m^{-2} (see Kido et al.[117]). It has been suggested that the improvement in the EL characteristics on replacing PMMA by PC is associated with the corresponding increase in the rate of hopping transport, resulting from the higher glass transition temperature and greater aromaticity of the PC. In the light of the results obtained with evaporated layers of low-molecular-mass compounds,[141] we can expect further improvements in the EL brightness by replacing the Alq_3 by other metal complexes, for example bis(10-hydroxybenzo-[h]quinoline)beryllium.

Electroluminescent diodes containing several mutually insoluble polymer layers are of considerable interest:[106] for example, MEG–PPV, or PPV and a copolymer having the structure

Structures of four types were studied:

A. ITO/copolymer/PPV (2300 Å)/MEG–PPV/Ca;
B. ITO/MEG–PPV/PPV (500 Å)/copolymer/Ca;
C. ITO/copolymer/MEG–PPV/PPV (1500 Å)/copolymer/Ca;
D. ITO/copolymer/PPV (300 Å)/copolymer/Ca.

In all the structures the thicknesses of the copolymer and of the MEG–PPV layers were 200 and 500 Å respectively. The quantum efficiency of reaction (30) was measured for light intensities of 5 cd m^{-2}: it was found to be η = 0.3%, 0.22%, 0.26%, and 0.16% (photons per injected electron) for the structures A, B, C, and D respectively. It was found that the structure A is the sole one for which only the (MEG–PPV) layer contributes to the EL spectrum (the characteristics of this spectrum are quoted above). Polyphenylenevinylene and the copolymer are responsible only for the transport of holes. Neither the electrons nor the excited states formed by reaction (30) extend beyond the (MEG–PPV) layer. The structure B is characterised by a broad emission spectrum, lying at 1.62–2.5 eV with a maximum at 2.13 eV. The intensity of the

radiation of light quanta with an energy of 1.75 eV is 15% of the maximum value (I_{max}). In this spectral region the MEG–PPV is the only luminescent component, and neither the copolymer nor the PPV emit radiation. At the same time the intensity of the emission of light quanta with an energy of 2.35 eV reaches 30% of I_{max}. This emission lies beyond the limits of the emission spectrum of MEG–PPV, and is due to the formation of excited states in the PPV or in the copolymer. The emission spectrum of the structure C is identical to that obtained for the structure B, confirming that both the intermediate MEG–PPV layer and the PPV (or the copolymer) layer are contributing to the process. The emission spectrum of the cell D also contains contributions from the radiation of the PPV and of the copolymer. Thus by allowing for the thickness of the individual layers we may conclude that the emission zone of the structures B–D extends over more than 500 Å. According to calculations the distance travelled by the charge carriers before their encounter is 2600 Å. The distance to which a neutral excitation can diffuse is $(Dt)^{1/2} \approx 50$ Å [D is the diffusion coefficient ($D \simeq 10^{-3}$ cm^2 s^{-1})], t is the lifetime of the excited state ($t \simeq 0.25$ ns)]. It can be seen that this distance is 10 times smaller than the emission zone. Thus the mobile species responsible for the fairly extensive emission zone are the charge carriers and not the excited states. The preparation of structures from layers emitting light in different spectral regions may provide a path to the development of EL sources of white light.

We may conclude from the above arguments that the best characteristics obtained from different structures are the following: quantum efficiency of the conversion, 1%;[118] brightness, $\sim 10^4$ cd m^{-2} (see Kido et al.[117]); stability of the parameters of the light-emitting polymer diode, 16 h.[118] The wide practical exploitation of EL layers now depends on the prospects of combining all these favourable characteristics into a single layer and of greatly increasing its operating and storage life.

V. Injection of charges into polymer transport layers

Our discussion has shown that in EP and EL systems the charge carriers can surmount various phase separation barriers: metal–polymer, inorganic semiconductor–polymer, and molecularly doped polymer–polymer with conjugated bonds.

In the EP layers light absorption in the generation layer produces charge carriers which are then injected into the transport layer. The properties of the contact (layer of molecules with developed regions of conjugated bonds)/(molecularly doped polymer layer), often used in EP and EL systems, have been extensively reviewed by Kanemitsu and Imamura[142] in the specific case of a polyester (PC), and of doped DEH/phthalocyanine. Like PPV, polythiophen (PT), and PAn, phthalocyanine contains a system of conjugated bonds which produces photosensitivity. This allows a given concentration of charge carriers to be generated in the material, providing quantitative data on the injection coefficient.[142] The sensitivity of the photoreceptor is defined as the ratio of the number of charges passing through the transport layer to the number of photons absorbed in the generation layer; for a given value of the electric field the injection coefficient of the carriers $\eta(F)$ is calculated as the ratio of the number of charge carriers (determined by electrophotographic or time of flight methods) passing through the molecularly doped transport layer to the number of photogenerated carriers which abandon the generation layer through its interface with the transport layer (photoacoustic method); the photoinjection coefficient η_f is the ratio of the number of carriers crossing the transport layer to the number of photogenerated free charge carriers.

Clearly, $\eta(F)$ is determined by the competition between the transport of charge carriers and their capture by deep traps at the interface, and it can be measured only by using pulse kinetic methods, whereas η_f depends on the rate of recombination of the photogenerated charges in the generation layer and on the rate of injection through the boundary. Since the ionisation potentials of DEH and phthalocyanine are almost identical (5.5 and 5.4 eV respectively) an interfacial barrier is not formed at the contact between the layers.

The parameter $\eta(F)$ increases markedly when F is increased: in a field of 10^5 V cm^{-1} $\eta(F)$ is 0.1, but it increases to 0.7 in a field of 10^6 V cm^{-1}. This effect is associated with the fact that the mobility of holes increases exponentially with F, as was shown in Section II, and their time of flight through the boundary and of capture by traps decreases correspondingly. It is interesting to note that increasing the concentration of the hydrazone DEH in the transport layer lowers $\eta(F)$ slightly. This effect is determined by the capture of holes at the interface by traps of an unspecified type, associated with the method of establishing the interface, of forming the charge transfer complexes between the hydrazone and the phthalocyanine, etc. Similar results were obtained in studies of the injection of positive charges from PPV into a transport layer consisting of polycarbonate molecularly doped with diaryldiamine (TPD).[134] In this case the injection coefficient in a field of 4×10^5 V cm^{-1} is equal to or greater than 0.25, and only a small trapping of carriers is observed at the interface of the two polymer layers at large F values.

These results suggest that in relatively high fields the interface between two polymer layers of different nature is permeable to the transfer of positive charge. However, in lower fields we must allow for the trapping of holes at the layer interface, leading to the formation of a barrier as a result of the passage of a sufficiently high electric current. Under stationary conditions $\eta(F) = 1$, and the barrier affects the value of η_f and the electric characteristics of the EP and EL devices. The interface between SeTeAs and a transport layer consisting of PVK or PC doped with pyrazoline derivatives has been examined in depth.[143–145] Under stationary conditions the following relationship is obeyed:[145]

$$\eta_f = a\left[(1 + 2\eta_c/a)^{1/2} - 1\right], \tag{33}$$

where $a = [k_i(F)]^2/2J_0k_r$ (k_i is the injection rate constant, k_r is the rate constant of the recombination in the bulk of the generation layer), η_c is the quantum yield of the photogeneration of free charge carriers. In large fields with $(2\eta_c/a) \ll 1$ it follows from Eqn (33) that $\eta_f \simeq \eta_c$, i.e. that all the generated charges are injected into the transport layer, and η_f is determined exclusively by η_c and is independent of the nature of the transport layer. In moderately large fields, when $(2\eta_c/a) \gg 1$, $\eta_f = (2a\eta_c)^{1/2}$ and η_f is determined, among other factors, by the function k_i, which depends on the height of the barrier formed at the interface as a result of the capture of holes by deep traps. It was found[145] that for a constant generation layer, and with a transport layer consisting of pyrazoline with $N(C_2H_5)$, OCH_3, and H as substituents, and also PVK, η_f decreases: for example an η_f value of 0.15 is reached in this series of compounds for $F = 1.7 \times 10^4$, 4×10^4, 1.2×10^5, and 2.5×10^5 V cm^{-1} respectively. In very strong fields ($F > 5 \times 10^5$) the differences between the field dependences for different layers disappear, and η_f becomes equal to 1. Thus in strong fields all the photogenerated charge carriers are injected into the transport layer, but in weak fields η_f depends on the nature of the transport layer, and in particular on the ionisation potential of the transport centres.

In multilayer EL systems the application of a potential difference introduces dark charge carriers into the luminescent layer, unlike the EP systems, in which photogenerated carriers are introduced into the transport layer. In EL diodes the energy efficiency of the conversion of electric current into light is strongly dependent (as it is in EP photoreceptors) on the

injection mechanism of charge carriers into the EL layer, but it should be noted that in this case dark charges are injected and the injecting layer should be transparent to the emitted light. In practice this means that ITO is used as a hole-injecting transparent and conducting layer. Let us examine in detail a typical ITO/PPV/Ca structure,[106] whose energy diagram is shown in Figs 12*a* and 12*b* . To make the discussion simpler and more meaningful we shall assume that the contacts between layers are neutral, i.e. that the PPV region, in direct contact with the interfaces, does not contain space charges.[146] In this case a potential difference $V_{1,2} = \phi_1 - \phi_2 = \varphi_1^e - \varphi_2^e$ is generated in the semiconductor: this impedes the access of electrons from the Ca and of holes from the ITO to the PPV layer, and the electric field is uniform in this layer ($F = V_{1,2}/L$). The barriers for electrons are given by the expression $\varphi_i = \phi_i - E_\pi$, and for $E_\pi = 2.5$ eV they take the values $\varphi_1^e = 1.6$ and $\varphi_2^e = 0.5$ eV (Fig. 12*a*). The application of a large external potential V (with its negative polarity on the electrode with the lower work function) produces a relative shift of the Fermi levels: ($E_{F1} - E_{F2} = eV$), and as can be seen from Fig. 12*b* the electrons and holes can easily overcome the barriers φ_2^e and φ_1^H. Since in PPV the holes are mobile but the electrons are captured by traps in the polymer near the metallic electrode, recombination takes place at the surface of the metal layer in parallel with the discharge of holes at the cathode.

The inclusion of an additional PBD electron transport layer between the Ca and the PPV (see Fig. 12*c*) creates a barrier to the motion of holes at the PPV/PBD boundary (φ_3^H), where the holes accumulate and recombine with the electrons drifting towards this barrier, with emission of luminescence. As was shown in the previous section, the PBD layer greatly improves the efficiency of the EL. Additional layers are added not only to create barriers opposing the escape of charges from the EL layer but also, conversely, to lower the barrier at the boundary of the EL layer. Thus, as was shown above, the insertion of oligothiophen[99] or PAn[97] between the EL layer and the metallic anode greatly increases the hole current because the edge of the valence band of the conjugated polymers lies only slightly above the Fermi level in the ITO. Evidently, neutral contacts are actually formed, in most cases, at the interface between polymer layers. A more complex state of affairs is found at the metal/polymer interface. The simple model of neutral contacts, though qualitatively consistent (in general) with experimental results, fails to explain many important observations. Since the work functions of Ca and Al differ by almost 1 eV we would not expect significant current flows at the PPV/Al interface because of the height of the φ_2^e barrier. Nevertheless, replacing the Ca by Al lowers the current (for the same bias) by only 1–2 orders of magnitude. Furthermore the neutral contact gives a linear current–voltage characteristic for both positive and negative bias.[145] In reality a rectification effect is observed at the metal/polymer boundary, and with forward bias the current is exponentially dependent on the potential, which is characteristic of a Schottky barrier.[147, 148] In this case a space charge is formed near the electrode in the polymer, and the applied potential is dropped mainly in the space charge region.

A Schottky barrier or an ohmic injecting contact can be formed at the contact between the metal and the polymer (doped with conjugated molecules or containing conjugated double bonds in the main chain), depending on the work function ratio of the metal and of the polymer. Metals with the lowest possible work function are chosen to inject electrons into an EL layer. A Schottky barrier is formed at the contact with In or Al, because these metals have a relatively high work function: $\phi = 4.2$ and 3.8 eV respectively. Changing to Ca ($\phi = 3$ eV) increases the EL by more than an order of magnitude. Nevertheless even in this case a barrier to electrons is formed. This is an important feature. A study of the metal/PPV interface by X-ray emission spectroscopy showed[119] that the bending of the bands in the PPV gradually increases, starting with an Al layer approximately 1 Å thick (monolayer), and reaching a constant value for an evaporated thickness of about 5 Å. No chemical interaction between the Al and the PPV is observed under these conditions. Conversely, when calcium is evaporated as an electrode the bands in the PPV begin to bend only when the thickness of the Ca layer reaches 8 Å, and at 15 Å the process goes to completion and the energy of the bond falls by 0.4 eV. As in the case of Al no interaction takes place between the Ca and the PPV. The behaviour can be explained by the presence on the surface of oxygen as hydroxyl groups and of sulfur as sulfide groups, formed during the synthesis of the polymer. These impurities protect the PPV macromolecules from attack by the calcium. Thus the real metal/polymer contact is a multilayer structure including metal oxides and other compounds.

Studies of polyacetylene, PAn, and other polymers with p-type conductivity have shown that a Schottky barrier is formed at the contact with metals having a work function $\varphi_M < 4.5$ eV. Because of the low charge mobility in polymers the electrons are transmitted through the barrier by a diffusion mechanism rather than by thermionic emission (as in extrinsic inorganic semiconductors).[147, 148]

For a sufficiently high potential difference the current is exponentially dependent on the temperature:

$$J_d = J_{0d}\left[\exp\left(\frac{eV}{nkT}\right) - 1\right], \tag{34}$$

where

$$J_{0d} = e\mu N_c F_g \exp\left(-\frac{e\varphi}{kT}\right),$$

and n is the ideality factor (in our case, close to 1), N_c is the effective density of states in the polymer, F_g is the electric field at the barrier, and φ is the height of the barrier at the metal/polymer contact, equal to the difference between the corresponding work functions.[147] The upper limit of the injection current is set by the resistance of the polymer layer, and therefore the smaller the thickness of the EL layer, the greater is the injected current, and the greater the energy efficiency of the transformation. The temperature dependence of the current through the aluminium/poly(3-octylthiophen) interface was used to establish[149] that an over-barrier transition takes place at temperatures above 340 K. At low temperatures the injected currents are greater than the values expected for a diffusion mechanism: this suggests a tunnel effect.

At the boundary between a metal with a high work function and a p-type semiconductor polymer, such as Au ($\phi = 5.2$ eV)/PPV, we find an ohmic contact[150] which efficiently injects holes into the transport layer. We should note that studies of the mechanisms of carrier injection from solid electrodes into polymer layers are much less widespread than the studies of transport and of electroluminescence: this state of affairs is inconsistent with the important role of injection in the processes which we have considered.

* * *

Our discussion has shown that the problems of electron transport in disordered dielectric layers are closely associated with a number of fundamental questions: the mechanism of electron transfer between identical centres in an organic medium, the effect of the physicochemical characteristics of the medium on the transfer, the formation of excited light-emitting recombination states, and the need to optimise the electric and the light-emission parameters of the organic layers used in newly developed and widely used optoelectronic devices. Studies in these directions should help the achievement of interesting new results and should assist the further progress of the problem as a whole.

This study was carried out with financial support from the Russian fund for fundamental research (project 93-03-5703) and from the American Physical Society (Sloan Foundation Grant).

Reactions of hydrocarbons with electrophilic transition metal complexes in trifluoroacetic acid

N F Gol'dshleger, A P Moravskii

Contents

I. Introduction 125
II. Trifluoroacetic acid and transition metal carboxylates as components of catalytic systems 125
III. Reactions of hydrocarbons with participation of electrophilic metal complexes in trifluoroacetic acid 126

Abstract. The results of studies on the catalytic and stoichiometric activation of C–H and C=C bonds in hydrocarbons by electrophilic metal complexes in trifluoroacetic acid are surveyed. Reactions involving the dehydrogenation of cycloalkanes, carboxylation and oxidative carbonylation of alkanes and aromatic compounds, oxidative coupling of aromatic hydrocarbons, oligomerisation of norbornadiene with participation of transition metal trifluoroacetates, and certain others are examined. Much attention is devoted to the conditions for the generation of active species and their nature. The bibliography includes 185 references.

I. Introduction

The reactions of alkanes with participation of transition metal complexes have aroused much interest in connection with the possibility of devising new selective catalytic procedures for the processing of hydrocarbons. Metal complex activation of alkanes was discovered in relation to platinum(II) complexes in 1969.[1] The wide scale study of this process made it possible to elucidate the factors affecting the reactivity of C–H bonds in alkanes and the mechanism of the activation of saturated hydrocarbons by transition metal complexes,[2–5] to extend the range of metal complexes capable of activating alkanes,[6–11] and to discover new reactions of alkanes, including methane.[12–16]

The role of electrophilic metal-containing centres in the catalytic and stoichiometric activation of C=C and C–H bonds in hydrocarbons is discussed in the present review and other reactions, the occurrence of which is favoured by an increase in the electron-accepting capacity of the metal centre, are considered. Data on the functionalisation of alkanes, alkenes, and aromatic compounds in the presence of transition metal complexes in trifluoroacetic acid are summarised. Questions concerning the oxidation of alkyl-substituted aromatic compounds by variable valence metal ions and thallium(III) trifluoroacetate have been dealt with in other reviews,[17,18] the oxidation of other substrates has been examined in a book,[19] and studies on the selective substitution of hydrogen attached to a saturated carbon atom, mainly a tertiary carbon atom, have been surveyed by Boguslavskaya et al.[20]

II. Trifluoroacetic acid and transition metal carboxylates as components of catalytic systems

Trifluoroacetic acid (TFA) is usually obtained by the electrolytic fluorination of acetyl chloride or fluoride; the acidity of its aqueous solutions is comparable to that of aqueous solutions of inorganic acids. It is a mild dehydrating but not oxidising agent.

Acid	pK_a	ε
CF_3COOH	0.2	8.4
CH_3COOH	4.76	9.55
HCOOH	3.7	62.0

The low dielectric constant shows that TFA is a poor ionising solvent—ions are solvated in CF_3COOH much less effectively than in water. However, TFA is a convenient solvent for the nitration of aromatic compounds with nitric acid,[21] the bromination of toluene,[22] the synthesis of adamantanol,[23] the hydroxylation of alkanes,[24] and a number of other reactions, and also for the investigation of the kinetics of electrophilic substitution processes. Solutions of mixtures of alkali metal nitrates and chlorides in aqueous TFA can be used for the selective halogenation of aromatic compounds.[25] A series of new oxidation reactions involving H_2O_2 in trifluoroacetic acid,[26,27] including perfluorinated aromatic and olefin compounds, have been discovered.

Metal trifluoroacetates are obtained by the reactions of the corresponding oxides, hydroxides, carbonates, sulfates, and amalgamated metals (in the case of aluminium and magnesium) with TFA,[28] via the oxidative addition of TFA to low-valence complexes,[29] and also by the reactions of metal chlorides (or organometallic compounds) with a solution of CF_3COOAg in organic solvents (nitromethane, acetone).[28,30] A widely used method of synthesis of metal trifluoroacetate complexes involves carboxylate exchange.[28,31,32]

$$Rh_2(O_2CCH_3)_4 + 4\,CF_3COOH \xrightarrow{k_i} \longrightarrow Rh_2(O_2CCF_3)_i(O_2CCH_3)_{4-i} + i\,CH_3COOH\ .$$

It has been shown for this reaction that the substitution of the acetate anion by the trifluoroacetate anion is a stepwise process, the ratios of the rate constants for the successive reactions being $k_1 : k_2 : k_3 : k_4 = 1 : 2.0 : 0.1 : 0.025$.

It is known from the totality of the physicochemical properties of carboxylates that the stability of the RCOO–M bond as a rule decreases as the electron-accepting properties of the group R become more marked.[33]

$CH_3 > CH_2Cl > CH_2F$,

$CH_3 > CH_2F > CHF_2 > CF_3$,

$CH_3 >$ Nic > *iso*-Nic,

where Nic = nicotine.

The principal feature of the carboxy-group is the multiplicity of its structural functions; it can play the role of a monodentate, cyclic bidentate, bridging bidentate, tridentate, and even tetradentate ligand with different (*syn* or *anti*) orientations of the bonds with the metal.[33] Monodentate and bridged coordinations are most characteristic of the trifluoroacetate group.[28] Comparatively numerous structural investigations of the carboxylates of 3*d* elements have been carried out hitherto and have made it possible to discover an extremely wide and varied spectrum of structures of these substances and the functional possibilities of the carboxylate ligands.[33,34]

The crystal and molecular structures of palladium acetate, the interest in which is due to its catalytic properties, have been investigated.[35] This substance is a symmetrical trimer $Pd_3(O_2CCH_3)_6$ with double *syn, syn*-bridges between each pair of palladium atoms, which was demonstrated by X-ray diffraction study of its solvates.[35–37] The oxygen atoms surrounding each palladium atom in this compound are arranged approximately in the same plane and give rise to the square configurations usual for d^8 metals. The compound differs sharply from the trimeric carboxylates of d^3-d^6 elements,[33] which must be stabilised by a μ_3-ligand (usually a μ_3-O atom located at the centre of an isosceles triangle comprising three M atoms), and also from platinum acetate, which is a tetramer[38] with strong covalent metal–metal bonds. X-Ray diffraction study of volatile trinuclear palladium(II) carboxylates—$Pd_3(O_2CBu^t)_6$ and $Pd_3(O_2CCF_3)_6$—showed[39] that both complexes are trimers like palladium acetate, but palladium trifluoroacetate has this structure in solution in benzene only at temperatures below 37 °C. The molecular geometries of the complexes are also extremely similar. The observed Pd...Pd distances (3.1–3.2 Å) exceed greatly the usual lengths of palladium–palladium bonds and indicate the absence of valence interactions. The replacement of an electron-donating substituent (CH_3) in the carboxylate ligand by an electron-accepting substituent (CF_3) leads to an increase in the Pd...Pd distance.

Monodentate coordination of the CF_3COO^- anion has been demonstrated by X-ray diffraction for different complexes, including $Pd_2(dppm)_2(O_2CCF_3)_2$[40] and $Pd(dppm)(O_2CCF_3)_2$,[41] where dppm = bis(diphenylphosphinomethane), $M(O_2CCF_3)_2 \cdot (NO)(PPh_3)_2$, where M = Rh or Ir,[42] and $Rh(CO)(O_2CCF_3) \cdot (PPh_3)_2$.[43] Both the monodentate and bridged coordinations of the trifluoroacetate groups have been found in the complex $Pr(O_2CCF_3)_3(H_2O)_3$,[44] which is a centrosymmetrical dimer in the solid state, and in the dimer $[Ru(C_6H_9)P(C_6H_{11})_2]_2 \cdot (\mu\text{-}CF_3CO_2)_2(CF_3CO_2)_2(\mu\text{-}OH_2)_2$.[45]

Vibrational spectroscopic data, determinations of the molecular mass, and the ready oxidisability of the complexes led to the hypothesis of the η^2-coordination of the trifluoroacetate group in complexes of the type $H_2IrL_2(O_2CCF_3)$ (L = PAr_3)[46] and $[Rh(PPh_3)_2(O_2CCF_3)]_2$.[47] The electrical conductivity found for the complex $Ir(NO)(O_2CCF_3)_2(PPh_3)_2$ permitted the conclusion that it is partly ionised in polar solvents, which confirmed the lability of the M–$OCOCF_3$ bond. Its treatment with sodium tetraphenylborate leads to the complex $[Ir(O_2CCF_3)(NO) \cdot (PPh_3)_2]^+BPh_4^-$ with an anomalously low ν_{OCO}^{as} frequency at 1572 cm^{-1}, which may indicate a bidentate cyclic coordination of the CF_3COO group in this compound.[34,42]

Since TFA is a strong acid, its conjugate base CF_3COO^- is relatively weak and the M–$OCOCF_3$ bond is labile, which, together with the thermal stability of the complexes and the ability of the trifluoroacetate anion to behave as a η^1- and η^2-ligand as well as the chemical resistance of the trifluoroacetate anion to oxidation, makes it attractive to employ TFA in catalytic metal complex systems. The introduction of CF_3COO^- groups into the coordination environment of the central metal atom enhances the electrophilic properties of the complexes, which as a rule ensures the possibility of the occurrence of the reaction at a lower temperature.

III. Reactions of hydrocarbons with participation of electrophilic metal complexes in trifluoroacetic acid

1. Activation of the C–H bond by metal complexes

Analysis of the literature data on the reactions of alkanes in solutions of metal complexes shows that a whole series of possible mechanisms of the primary interaction between the components exist.[2,3] The complexity of the problem of the activation of alkanes arises from their chemical inertness. In most of the known reactions leading to the formation of stable molecular products, one of the strong covalent C–H or C–C bonds in alkanes must be ultimately broken. In this respect, the problem of the activation of a C–H σ-bond of a paraffin is similar to that of the activation of the hydrogen molecule.[2,48]

Alkanes are very weak electron donors and poor electron acceptors.[2] However, the occurrence of intramolecular interactions between a nonactivated C–H sp^3-bond of the ligand and the transition metal atom surrounded by ligands has been noted in a series of structural studies.[49,50] The term 'agostic' bond has been proposed for this interaction;[51] data on complexes with such bonds have been summarised in two communications.[52,53] It has been shown that the electron deficiency of the metal is a necessary but not sufficient condition for the formation of the agostic bond. The metal must also possess fairly strong acid properties. Thus the replacement of π-acceptor ligands in the complex by π-donor ligands weakens the agostic bond.[54]

The low reactivity of saturated hydrocarbons is associated with the absence of low-lying unoccupied orbitals in the latter (the first band in the electronic absorption spectra of alkanes is located in the region above 10 eV). The transition state in reactions of such compounds frequently involves the excitation of electrons to antibonding orbitals. The reactivity of alkanes should accordingly be highest relative to species having low-lying unoccupied orbitals, i.e. electrophiles. The reactions of methane in superacids[55] and of its homologues in organic superacids[15] are well known. A high oxidation state of the central transition metal ion also favours the formation of its complexes with alkanes, which follows, in particular, from the similarity between these reactions and those of alkanes in superacids, which proceed with formation of carbenium ions.[55]

$$RH + H^+ \rightleftharpoons RH_2^+$$

Analysis[56] carried out for different types of interaction of C–H bonds with transition metals permits the following conclusions:

1. One-electron transfer reactions on treatment with oxidants which are stable in aqueous solutions are thermodynamically impossible for alkanes (the equilibrium oxidation–reduction potentials of the RH^+/RH pairs are 3.4–4.1 V).

$$L_nM + RH \longrightarrow L_n\bar{M} + RH^+$$

On the other hand, strong oxidants can abstract an electron from aromatic compounds (the corresponding oxidation–reduction potentials are in the range 1.6–2.0 V).

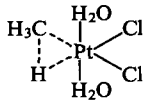
2. The mechanism of the reactions of alkanes with metal complexes involving the formation of free radicals with the simultaneous abstraction and solvation of a proton can be regarded as probable in the case of strong oxidants such as Co(III), Cr(VI), and Mn(VII), particularly in solutions of strong acids in which the oxidation-reduction potential of the $M^{(n+1)+}/M^{n+}$ pairs is a maximum.

$$L_nM + RH \longrightarrow L_n\bar{M} + \dot{R} + H^+$$

3. The formation of a M–R bond, coupled with the liberation and formation of H^+, diminishes the requirements as regards the strength of the oxidant. For the electrophilic substitution reaction

$$L_nM + RH \longrightarrow L + L_{n-1}\bar{M}R + H^+,$$

the energy expenditure on the creation of a coordination vacancy (E) is given by [56]



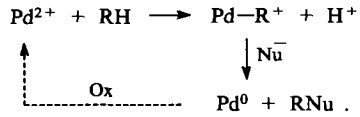
$$E = E(M-L) - Q_s(L) - Q_s(ML_{n-1}) + Q_s(ML_n),$$

where Q_s are the heats of formation of the system components.

Thus substitution is promoted by a low bond energy E(M–L) and high enthalpy of solvation of the ligand Q_s(L).

The substitution of H^+ by a metal ion M^+ as a result of the interaction of hydrocarbons with metal complexes is characteristic of aromatic compounds (mercuration and thallation reactions). For a high strength of the M–C bond, such a step becomes possible also for alkanes, but it differs from classical electrophilic substitution. For example, the interaction of platinum(II) complexes with alkanes [1] apparently begins with the oxidative addition of a C–H bond, which leads to the formation of an alkylplatinum(IV) hydride complex and terminates with the synchronous formation of a Pt(II)–C bond and the elimination of a proton. The proton may be bound by a water molecule, which is a stronger base than the Pt centre. [2, 56]

The results of a quantum-chemical study [57] of the model reaction of methane with the complex *trans*-$PtCl_2(H_2O)_2$ have shown that, in the initial stage of the interaction before the attainment of the transition state, the C–H bond is polarised with a significant intensification of the acidity of the hydrogen atom without change of the charge on the platinum.



In the presence of a base stronger than the platinum(II) complex, the transfer of H^+ to a molecule of the base is easier than the continuation of the oxidative addition process after the loosening and polarisation of the C–H bond [as a result of the initial stage of the interaction of CH_4 with Pt(II)]. The binding of the leaving group to the base is the driving force of the electrophilic substitution reaction. [48] The addition of methane with participation of zirconium complexes, [58] for example $(RNH)_2Zr$ = NR, where R = $SiBu^t_3$, may serve as an example of such interaction.

The study of the cyclometallation reactions has shown that cyclopalladation is predominantly electrophilic in character, whilst the interaction of a C–H bond of a coordinated ligand with platinum(II) is more likely to proceed via an oxidative addition mechanism. [59] The type of mechanism depends on the nature of the metal and the substrate or, which appears more likely, the balance between the steric and electronic factors determines the final product in each case. For example, the rate of the cyclometallation reaction increases in the sequence Cl < Br < I for PdX_2L_2 (L = hindered phosphine; X = Cl, Br, I), whilst the reverse sequence obtains for phosphite complexes. [59]

2. Reactions of hydrocarbons with participation of palladium complexes

Palladium occupies a special place in the series of oxidants. It is a good electrophile, [60] a typical two-electron oxidant, and can be reoxidised by fairly mild oxidants, which permits its use in catalysis. [61–63]

Scheme 1

a. Palladium(II) trifluoroacetate

Palladium(II) trifluoroacetate and acetate are trimeric in the crystalline state, but in benzene at 37 °C the trifluoroacetate is monomeric, in contrast to the acetate. [32, 35, 39] According to X-ray photoelectron studies, the influence of the ligands in palladium(II) compounds affects strongly the position of the Pd($3d_{5/2}$) level, the range of variation of the binding energy E_b amounting to 2 eV depending on the ligands. The binding energies of the internal electrons of the palladium atoms in complexes with ligands having pronounced π-acceptor properties are especially high (Table 1); the closest approximation to E_b [Pd($3d_{5/2}$)] for palladium(IV) is observed in the case of $Pd(O_2CCF_3)_2$, which agrees with the pronounced electron-accepting properties of palladium in this compound.

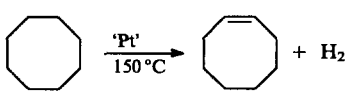
Table 1. The Pd($3d_{5/2}$) binding energies in palladium complexes.

Complex	E/eV	Ref.
Pd (metal)	335.8	64
$PdCl_2$	338.0	65
K_2PdCl_4	338.4	65
$Pd(O_2CCH_3)_2$	338.8	64
$Pd(CH_3CN)_4(PF_6)_2$	339.5	66
$Pd(CN)_2$	339.6	65
$Pd(O_2CCF_3)_2$	339.7	67
K_2PdCl_6	340.3	65

b. Alkanes and cycloalkanes

Palladium differs from platinum by the lower stability of the d^6 state of palladium(IV) and the smaller strength of the Pd–C bond. Oxidative addition via the C–H bonds of alkanes is therefore less probable for palladium(II) complexes than for platinum(II) complexes. On the other hand, it has been found that electrophilic substitution reactions at a carbon atom with participation of the palladium(II) centre proceed extremely effectively. The absorption of alkanes and benzenes, accompanied by the formation of metallic palladium, was observed in 1973–1974 in the $PdSO_4$–H_2SO_4 and $Pd(O_2CCF_3)_2$–anhydrous CF_3COOH systems. [68, 69]

Hydrocarbons (hexane, cyclohexane, benzene) reduced $Pd(O_2CCH_3)_2$ or $Pd(O_2CCF_3)_2$ in CF_3COOH at 92 °C. [69] For the ratio $Pd(O_2CCF_3)_2 : CF_3COOH$ = 1 : 10, palladium trifluoroacetate forms a stable homogeneous solution and dehydrogenates cyclohexane in accordance with the stoichiometric equation



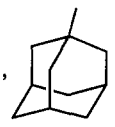
$$3\,Pd(O_2CCF_3)_2 + C_6H_{12} \longrightarrow 3\,Pd^0 + C_6H_6 + 6\,CF_3COOH.$$

Together with benzene, the products of its further reaction—biphenyl and phenyl trifluoroacetate—were detected. The absence of an induction period and autoacceleration as well as direct control experiments ruled out the possibility that the reaction takes place on the surface of precipitated metallic palladium. The reactivity of the hydrocarbons in the reaction with palladium trifluoroacetate decreases in the sequence benzene > cyclohexane > hexane.

Cyclohexane and methylcyclohexane are also dehydrogenated in the presence of the so called platinum(III) complexes [mixed-valence platinum(II) and platinum(IV) dimers] to benzene and toluene respectively.[70] It is noteworthy that palladium and platinum acetates are inert in CH_3COOH to hydrocarbons. The dehydrogenation of cycloalkanes apparently proceeds stepwise like the dehydrogenation of hydrocarbons in the presence of palladium(II) in solution in H_2SO_4.[71] This is confirmed by the detection of small amounts of cyclohexene in the dehydrogenation of cyclohexene with participation of platinum(III) complexes and by the rapid disproportionation of cyclohexene[72] to cyclohexane and benzene in the presence of palladium trifluoroacetate.

In contrast to platinum complexes, deuterium exchange is not observed in saturated hydrocarbons in solution in CF_3COOD following the addition of $Pd(O_2CCF_3)_2$, which is caused by the lower stability of palladium alkyls (see Scheme 1) compared with platinum alkyls. Indeed the reactions of the organomercury compounds RHgBr (R = CH_3, C_2H_5) with $Pd(O_2CCF_3)_2$ in CF_3COOD lead to ethane in the first case and to ethylene in the second, neither compound containing deuterium.[68] The decrease in the multiple exchange parameter M (the average number of deuterium atoms incorporated in the product molecule during one step of the interaction) to 1.34 in the H–D exchange in cyclohexane in the presence of $Pt(O_2CCF_3)_2$ in CF_3COOD compared with platinum(II) chloride complexes (M = 1.8) also indicates a decrease in the stability of the Pt–C bond with enhancement of the electron-accepting capacity of the ligand.[73] It is noteworthy that, on alkylation of $Pt(O_2CCF_3)_2$ with ethylmercury bromide in the gas phase, a significant increase in the fraction of ethylene, formed as a result of the β-elimination of hydrogen (ethylene : ethane = 9 : 1), is observed compared with the alkylation of $PtCl_2(H_2O)_2$ (ethylene : ethane = 1 : 3).

It has been shown[74,75] that the replacement of a chloride ion in platinum(II) complexes by the strong π-acceptor ligand $SnCl_3^-$ makes it possible to carry out reactions in organic media and favours dehydrogenation and hydrogen transfer for cyclohexene and cyclohexa-1,3-diene but not cyclohexane. Metallic platinum separated in the course of the reaction, but, as in the case of the H–D exchange in the presence of $PtCl_4^{2-}$,[1] it did not exhibit a catalytic effect. It was later found that a neutral complex of the pentacoordinated platinum(II) with π-acceptor ligands, namely $Pt(SnCl_3)_2[P(OR)_3]_3$ (R = CH_3, C_2H_5), which possesses electrophilic properties, dehydrogenates cycloalkanes with liberation of molecular hydrogen.[76] The authors believe that the active species is the coordinatively unsaturated d^8-ML_4 (a 16-electron complex).



Thus the π-acceptor properties of the ligands are decisive in preventing the reduction of Pt(II) to Pt(0) during the reaction. The strong σ-donor properties of $SnCl_3^-$, which should promote the transition Pt(II) → Pt(0), are evidently of secondary importance. This is the first example of a reaction of this type for platinum complexes. It had been shown earlier that linear cyclic alkanes are dehydrogenated both thermally and photochemically to the corresponding alkenes in the presence of the complex $IrH_2(OCOCF_3)[P(FC_6H_4)_3]_2$.[46] *tert*-Butylethylene is used as a hydrogen acceptor in the thermal dehydrogenation reaction, but in the photochemical process it is not required. The activity of the above iridium complex is determined by the ability of the CF_3COO^- group to behave both as a η^1- and η^2-ligand, which ensures the occurrence of β-elimination in the intermediate alkyliridium hydride complex $Ir(H)(R)(\eta^2\text{-}OCOCF_3)(PR_3)_2$. The iridium complex with the acetate anion is inactive in the dehydrogenation of alkanes. The thermocatalytic formation of molecular hydrogen and cyclooctene from cyclooctane in the presence of rhodium complexes has also been described.[77] A negative test with metallic mercury showed that the colloidal metal, formed apparently at temperatures in the range 150–180 °C, does not participate in the reaction of the substrate.

As already noted,[72] rapid disproportionation of cyclic olefins is observed in the presence of palladium trifluoroacetate at room temperature. When maleic acid is introduced as a hydrogen acceptor, they are dehydrogenated to substituted benzenes, the rate of formation of the aromatic compound in the presence of $Pd(O_2CCF_3)_2$ being appreciably higher than the rate of reaction with participation of $Pd(O_2CCH_3)_2$.

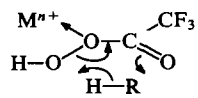
Later studies extended the range of hydrocarbons which can react with palladium(II) in TFA. The reaction of adamantane or methane with palladium acetate in TFA at 80 °C affords adamantyl trifluoroacetate and methyl trifluoroacetate respectively in 60% yield.

$$RH + Pd(O_2CCH_3)_2 \xrightarrow{CF_3COOH} CF_3CO_2R + Pd^0 + H^+;$$

R = CH_3,

.

The significant role of the quality of palladium acetate, especially in the oxidation of methane, was indicated. When the reaction was carried out with $Pd(O_2CCD_3)_2$, deuterium was not detected in the reaction product, which indicates, in the authors' view, the stability of the acetate group under the reaction conditions. Oxygen does not affect the reaction, which demonstrates the absence of radical stages. The test with metallic mercury for the heterogeneity of the reaction gave a negative result.[79] Since it has been stated in a number of investigations[80,81] that the high yields of the methane oxidation products are not reproducible in the presence of $Pd(O_2CCH_3)_2$ in TFA, the source of the differences is probably the acetate ion present in the study of Gretz and coworkers.[78,79]



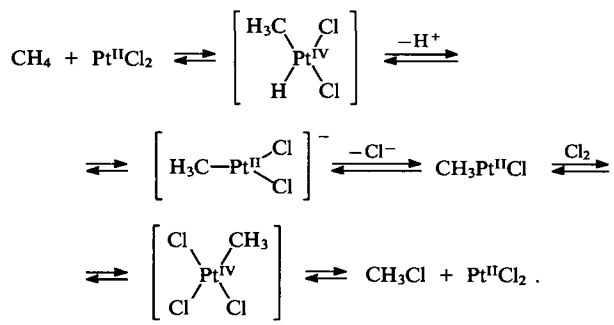
Pronounced electrophilic properties are retained even in the palladium(II) centre surrounded by phosphine ligands when aromatic C–H bonds are attacked. The alkylation of aromatic compounds by alkylpalladium complexes, in particular $(PhCH_2)ClPd(PPh_3)_2$, has been investigated. Experiments using a 1 : 1 C_6H_6–$CH_3OC_6H_5$ mixture showed[82] that the rate of alkylation of anisole is three times higher than that of benzene, which confirms the electrophilic character of the RPd^+ species.

Platinum and rhodium trifluoroacetates also interact with ethane at 80–150 °C and a pressure of 10–15 MPa with formation of methyl trifluoroacetate (0.5%–5.0%), the metal black, CO_2, and fluoroform.[81] The presence of CF_3H among the products indicates the instability of TFA under the reaction conditions and the possible involvement of the trifluoromethyl radical or cation in the C–H bond dissociation processes in methane. The presence of the acetate ion, which is even less stable in relation to decarboxylation, may lead, with a high degree of probability, to the formation of analogous intermediates in systems based on palladium acetate.[78,79] These intermediates can be the cause of the high yield of methyl trifluoroacetate, which is not reproduced in systems based on $Pd(O_2CCF_3)_2$.

Hydrogen peroxide has been used as the oxidant in the reactions of methane with $Pd(O_2CR)_2$ (R = CH_3, C_2H_5) in trifluoroacetic anhydride [90 °C, $p(CH_4)$ = 9 MPa].[83] It has been shown that the yield of $CF_3CO_2CH_3$ passes through a maximum as a function of time. In view of the hydrolysis of $CF_3CO_2CH_3$, the methane oxidation reaction can be represented by the equation

$$CH_4 + H_2O_2 \xrightarrow[(CF_3CO)_2O]{Pd(O_2CR)_2,\ 90\,^\circ C} CH_3OH + H_2O\,.$$

Excess of trifluoroacetic anhydride (TFAN) binds the water evolved during the reaction, preventing hydrolysis of the esters. In this system, palladium(II) can either oxidise ethane, being converted into a zerovalent palladium compound which is then oxidised by CF_3COOOH completing the catalytic cycle, or it can provide electrophilic cooperation in the reaction of the CF_3COOOH molecule with CH_4 by coordination to the oxygen of the peroxy-group in a transition state of the type [84]

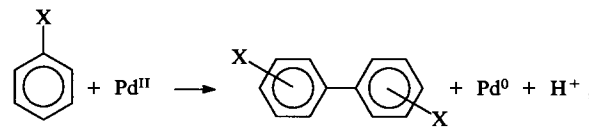


It has been stated that, under the reaction conditions, the acetate group is oxidised with formation of methyl trifluoroacetate. Similar data on the oxidation of CH_3COO^- in the presence of MnO_4^- with formation of $CF_3CO_2CH_3$ have been published. [81]

It has been observed that one of the methane oxidation products is methyl trifluoroacetate in the $V^V-H_2O_2-RCOOH$ system, where R is CH_3 or CF_3, under mild conditions [$p(CH_4)$ = 3–3.5 MPa, 20 °C]. [85]

Irradiation with light of a solution of adamantane and $Pd(O_2CCF_3)_2$ or $Cu(O_2CCF_3)_2$ in CH_3CN leads to the oxidation of the hydrocarbon mainly at the tertiary C–H bond. [86] Alkyl(aryl) trifluoroacetates are formed on irradiation with light of solutions of alkanes(arenes) in TFA in the presence of vanadate ions. [87]

In the presence of a deposited highly electrophilic rhodium(III) complex, methane is chlorinated with formation mainly of methyl chloride. [88] The authors of the above study postulated that the coordinatively unsaturated rhodium(III) attacks a C–H bond of the hydrocarbon. A proton then migrates to the ligand in the coordination sphere of rhodium. A more detailed study of the possible formation in this system of the catalytically active [SiO]–Rh(η^3-C_3H_5)(H) showed [89] that the activation of the C–H bond is apparently a result of the classical mechanism of the dissociation of a C–H bond in an alkane on the surface of a metal and is not caused by the electrophilic cleavage in the presence of rhodium(III).



A platinum(II)-modified heterogeneous catalyst for the oxidative chlorination of methane, namely $CuCl_2$ + Pt^{II}/Al_2O_3, has been obtained. [90] It is more active as a result of the appearance of a new reaction pathway involving the formation of methylplatinum(II) complexes. Methylplatinum(II) is subsequently oxidised by molecular chlorine with liberation of CH_3Cl. On the basis of earlier data, [2,90] Olah [55] demonstrated that the heterogeneous-catalytic technology for the synthesis of methanol and olefins via methyl halides is promising.

A new selective low-temperature (200–400 °C) catalyst, namely [$PdCl_2-H_9(PV_6Mo_6O_{40})$]/$SiO_2$, for the oxidative chlorination of methane with formation of methyl chloride has been discovered. [91] The absence of polychloromethanes and molecular chlorine from the reaction products may indicate the electrophilic properties of the system, which agrees with the behaviour of palladium in other reactions. It has been noted [92,93] that the selectivity of the oxidation of hydrocarbons in the presence of the heterogeneous analogue ($PdSO_4-H_2SO_4$)/SiO_2 (220 °C) is lower than for the homogeneous system. [3] One of the functions of H_2SO_4 as a strong Brønsted acid is to increase the oxidising capacity of palladium(II) and to enhance its electrophilicity.

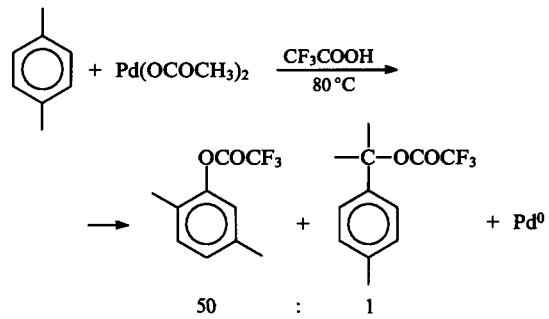
c. Aromatic compounds

The oxidative coupling of arenes on treatment with palladium(II) compounds was discovered in 1965. [94] These reactions take place in organic and, more rarely, in aqueous solutions at a temperature not exceeding 120 °C.

X = H, Alk, Hal, Ar, OR, O_2CR, OH, etc.

In the general case, a mixture of all possible isomers of biaryls is formed, their ratios being determined by the nature of the substituent X.

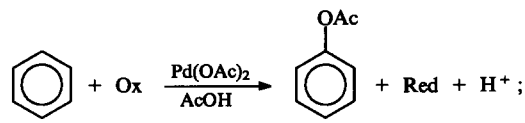
When $Pd(O_2CCH_3)_2$ is used instead of the complex $PdCl_2$–CH_3COONa, acetoxylation in the ring and, in the case of methylbenzenes, in the alkyl group takes place together with oxidative dimerisation. Perchloric acid inhibits the acetoxylation reaction, while the introduction of sodium acetate increases the yield of the product acetoxylated in the methyl group. [61,62,95,96]



The reactions of palladium with aromatic compounds in TFA occupy a special place. Benzene and its derivatives containing electron-accepting groups reduce palladium trifluoroacetate mainly with formation of oxidative dimerisation products [67] and also of small amounts of trifluoroacetoxylated derivatives under conditions where palladium acetate is inert to aromatic compounds. The preferential formation of oxidative coupling products has been attributed to the decrease in the basicity of the ligand on passing from acetate to trifluoroacetate.

Organopalladium compounds have been isolated in the reaction of benzene and naphthalene with palladium trifluoroacetate in TFA. On the basis of chemical reactions and IR and NMR spectra, Azzoumanidis and Rauch [97] considered these compounds as π-arene complexes in which there is a Pd–C bond. Palladium(II) acetate reacts with benzene in the presence of dialkyl sulfides at 70 °C with formation of a new diphenyltripalladium(II) complex, $(R^1SR^2)PhPd(\mu\text{-}CH_3CO_2)_2Pd(\mu\text{-}CH_3CO_2)_2$. .$PdPh(R^1SR^2)$, where $R^1 = R^2$ = Bu^t, Bu^i, Pr^i, Et, or CH_2Bu^t. [98] The study of these complexes demonstrated the presence in their structures of two phenyl groups and four bridging acetate groups.

As already mentioned above, [67] benzene and mono-, di-, and poly-substituted benzenes reduce palladium(II) in TFA. Benzene, *m*-xylene, and 1,2,3-trimethylbenzene then form mainly biaryls. The reactions of toluene and *p*-xylene involve the appearance of a new pathway, which leads to diarylmethanes. It becomes the main pathway for aromatic compounds with a low ionisation potential. [99]



Studies on the interaction of palladium trifluoroacetate with benzene, *p*-dimethoxybenzene, *p*-xylene, and toluene confirmed the electrophilic nature of the process, [79] because the C–H benzyl bonds were hardly attacked by palladium, as in Henry's study. [100] The increase in the rates of oxidation of benzenes containing electron-donating groups in the sequence *p*-dimethoxybenzene (1), *p*-xylene (0.1), toluene (0.02), benzene (0) (the rates are indicated in brackets) is consistent with the electrophilic attack by palladium on the C–H bond, while the primary kinetic isotope effect (k_H/k_D) for the oxidation of toluene and toluene-d_8 is 5.0, which is characteristic of analogous electrophilic systems. [61,62]

It is noteworthy that, in their analysis of the reactivity of aromatic compounds, Sen et al. [79] take into account only the acetoxylation reaction and ignore the oxidative coupling reaction.

d. The effect of the oxidant

The reactions of aromatic compounds with participation of palladium can be carried out under catalytic conditions using fairly mild oxidants. However, the oxidant not only participates in the reoxidation of palladium but is also capable of altering the mode of reaction. [100] In the absence of the oxidant, only oxidative coupling is observed, while in its presence the acetoxylation reaction occurs.

Ox = Cr(IV), $Pb(OAc)_4$, $NaClO_3$, $KMnO_4$, $NaNO_3$, $NaNO_2$.

In addition, there is a possibility of substitution in the aromatic ring by an external nucleophile Nu = N_3^-, Cl^-, NO_2^-, Br^-, CN^-, or SCN^-. Eberson and Jönsson [101] investigated in detail the ring acetoxylation reaction. They showed that the use of a bipyridylpalladium complex and $K_2S_2O_8$ as the oxidant makes it possible to carry out the acetoxylation reaction with formation of a smaller proportion of the *m*-isomer. [101] Potassium persulfate has also been used to oxidise the palladium formed as a result of the interaction of naphthalene with $Pd(O_2CCH_3)_2$ in solution in TFA. [78] The use of oxygen as the oxidant for zerovalent palladium [102] in reactions of aromatic compounds with palladium(II) leads, in contrast to other oxidants, to the formation of oxidative coupling products. [100] Biaryls are formed in high yields in the presence of oxygen also in systems based on palladium salts and heteropolyacids. [103] The oxidation of toluene by oxygen in the $Pd(OAc)_2-Sn(OAc)_2-KOAc-AcOH$ system takes place with formation of benzyl acetate, which indicates the influence of the components of the system on the nature of the processes occurring in it. [104] In particular, the oxidation of divalent tin salts involves the formation of active intermediates (for example, the OH radical), [105] which can in fact be responsible for the attack on the methyl group in the system mentioned above.

Attempts have been made to dehydrogenate cyclohexane with palladium trifluoroacetate in TFA under palladium reoxidation conditions. It was found that TFA attacks oxidants such as chromium(VI) and manganese(VII), enhancing their electron-accepting properties such that they are able to oxidise hydrocarbons rapidly without the participation of palladium. [70,81] However, aromatic compounds are formed only in the presence of palladium(II). Analogous results have been obtained by Sen and coworkers [106] for a wide range of cyclohexane derivatives.

e. The mechanism of the interaction of hydrocarbons with palladium

The mechanism adopted for the oxidation of arenes by palladium(II) includes the formation of an organopalladium intermediate and its reactions without the participation of free radicals. [61,62]

$$ArH + Pd^{2+} \longrightarrow ArPd^+ + H^+$$
$$2\,ArPd^+ \longrightarrow Ar_2Pd + Pd^{2+}$$
$$Ar_2Pd \longrightarrow Ar_2 + Pd^0$$

It has been shown by Kozhevnikov et al. [107] in a study of the oxidation of *o*- and *p*-xylenes by palladium(II) trifluoroacetate in TFA that the formation of diarylmethanes in a strongly acid medium can be explained by one-electron transfer with participation of aromatic radical-cations as intermediates, similar to the oxidation by cobalt(III) and lead(IV) salts. [17] The mechanism of the oxidation of methylbenzenes by palladium(II) (palladation or electron transfer) depends on the type of arene and the acidity of the medium.

$$Pd^{II} + ArH \longrightarrow (\pi\text{-}ArH)Pd^{II} \begin{cases} \longrightarrow ArPd^{II} + H^+ \\ \longrightarrow ArH^{+\cdot} + Pd^{I} \end{cases}$$

In relation to the reactions of toluene, palladation has been compared [108] with other aromatic substitution reactions in terms of the ratio of Brown's selectivities $\lg f_n = a \lg (f_n/f_m)$ (for toluene, $a = 1.31$), which characterises the relation between the substrate

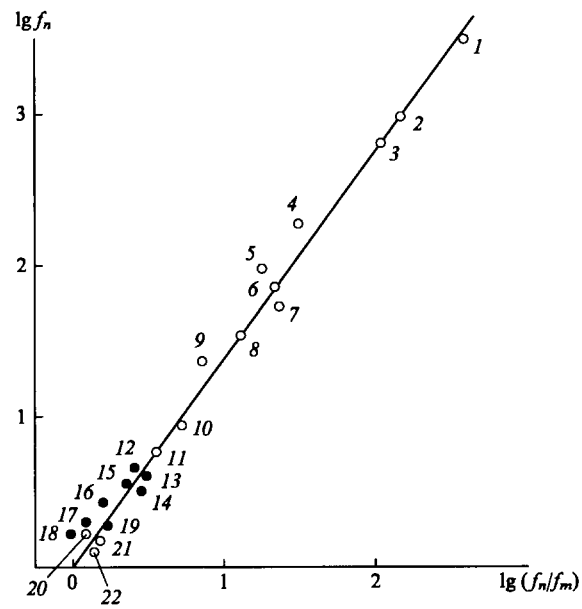


Figure 1. The ratios of selectivities for substitution in the toluene ring. [108] Filled circles — reactions with palladium(II). Bromination: (*1*) Br_2, 85% AcOH, 25 °C; chlorination: (*2*) Cl_2, AcOH, 25 °C; benzoylation: (*3*) PhCOCl in $PhNO_2$, 25 °C; thallation: (*4*) $Tl(O_2CCF_3)_3$, CF_3COOH, 10 °C; (*5*) 73 °C; nitration: (*6*) HNO_3, 90% AcOH, 45 °C; thallation: (*7*) $Tl(OAc)_3 + H_2SO_4$, AcOH, 70 °C; mercuration: (*8*) $Hg(OAc)_2 + HClO_4$, AcOH, 50 °C; (*9*) $Hg(OAc)_2$, AcOH, 50 °C; sulfonation: (*10*) $MeSO_2Cl + AlCl_3$, 100 °C; isopropylation: (*11*) *iso*-$C_3H_7Br + Ga_2Br_2$, 25 °C; palladation: (*12*) $Pd(OAc)_2 + H_2SO_4$, AcOH, 95 °C; (*13*) $Pd(OAc)_2 + HClO_4$, AcOH, 55 °C; (*14*) 95 °C; (*15*) $PdCl_2 +$ NaOAc, AcOH, 90 °C; (*16*) $Pd(OAc)_2 + CF_3COOH$, AcOH, 95 °C; (*17*) $Pd(OAc)_2$ + NaOAc, AcOH, 95 °C; (*18*) $Pd(OAc)_2$ in AcOH, 95 °C; catalytic coupling: (*19*) $Pd(OAc)_2$ in ArH, $p(O_2)$ = 2.5 MPa, 150 °C; radical arylation: (*20*) attacking radical *p*-$NO_2C_6H_4$, 20 °C; (*21*) *p*-$MeC_6H_4^{\cdot}$; (*22*) $\dot{P}h$.

(f_n) and positional (f_n/f_m) selectivities (the positional selectivity characterises the selectivity of the attack on different positions in the ring) of the substitution in the ArH ring. Fig. 1 shows that palladation is the least selective reaction in the series of electrophilic substitution processes, its selectivity approaching that of radical substitution, which is similar to the statistical selectivity with respect to the *meta*- and *para*-isomers.

Table 2 presents the electron affinities and electron excitation energies for a series of electrophiles—transition metals and traditional Lewis acids.[60] Evidently the electron affinity of palladium(II) is comparable to those of zinc(II) and mercury(II). However, palladium(II) has a much lower excitation energy. This leads to a strong donor–acceptor interaction with alkenes and aromatic compounds in the case of palladium (palladium is a soft acid in terms of Pearson's theory of hard and soft acids and bases), which results in the compensation of the influence of the polar (electronic) effects of the substituents in the ArH ring on the reaction centre. A similar result was obtained in a study of the H–D exchange and the oxidation of substituted benzenes in the presence of 'soft' acids—platinum(II) complexes.[109] With increase in the 'hardness' of the ligand environment of palladium(II) (transition from CH_3COO^- to the electron-accepting CF_3COO^- and ClO_4^-), the effectiveness of the compensation falls as a consequence of the weakening of the dative bond. Both the selectivity of the palladation reaction and its rate increase under these conditions. The electrophilic character of the metallation of arenes increases in the sequence Pd(II) < Hg(II) < Tl(III) and the values of ρ are –2.2,[110] –5.3,[111] and –7.5[108] respectively.

Table 2. The excitation energies [$nd^x \rightarrow nd^{x-1}(n+1)p^1$] and electron affinities for a series of metal ions.

Ion	Excitation energy/eV	Electron affinity/eV
Rh(I)	1.6[a]	7.31
Ir(I)	2.4[a]	7.95
Pt(II)	3.05[a]	18.56
Pd(II)	3.39[a]	19.42
Cu(I)	8.25	7.72
Ag(I)	9.94	7.59
Zn(II)	17.1	17.96
Cd(II)	16.6	16.90
Hg(II)	12.8	18.75
Tl(III)	18.3	29.80

[a] The values for Rh^0, Ir^0, Pd^I and Pt^I are presented.

By analogy with the existence of a common intermediate in the H–D exchange and oxidative chlorination of alkanes in the presence of platinum(II) and platinum(IV) complexes, which was postulated and demonstrated by kinetic methods,[2,112,113] in the case of palladation reactions there should also be a common intermediate, which affords the oxidative coupling products in the absence of an added oxidant and ring acetoxylation products in its presence. The primary isotope effect and the dependence of the rate of reaction on the concentration of the acid oxidant have been interpreted within the framework of ideas postulating that arylpalladium(II) and arylpalladium(IV) are intermediates leading to biaryls and aryl acetates respectively.[19,114]

$$Ph_2Pd^{II} \xleftarrow{C_6H_6} PhPd^{II}(OAc) \xrightarrow{Ox} PhPd^{IV}(OAc)_3$$

$$\downarrow \qquad\qquad\qquad\qquad \downarrow$$

$$Pd^0 + Ph_2 \qquad\qquad PhOAc + Pd^{II}(OAc)_2 .$$

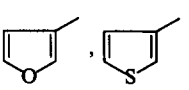
3. Carboxylation and oxidation of hydrocarbons with participation of palladium(II)

The formation of reactive organopalladium compounds in the reaction of hydrocarbons with palladium(II) made it possible to achieve the acetoxylation and oxidative coupling of arenes, the arylation of olefins, and also the direct oxidation and carboxylation of aromatic compounds and alkanes.

The stoichiometric carboxylation of arenes with carbon monoxide in the presence of palladium acetate has been carried out.[115] It was found that the reactivity of monosubstituted benzenes diminishes in accordance with the electrophilic character of the reaction in the following series of substituents: $OCH_3 > CH_3 > H > Cl$. The achievement of a single-stage synthesis of aromatic acid anhydrides from compounds such as benzene, toluene, anisole, chlorobenzene, thiophene, and furan, which are carbonylated in the β-position, has been reported.[116] A significant difference between the reaction conditions and those described by Fujiwara et al.[115] is the presence of 1,2-dibromoethane, the role of which is believed by the authors[116] to be the reoxidation of the metallic palladium formed in the reaction. Other polyhalo-compounds diminished the yield of the anhydrides.

$$ArH \xrightarrow[p(CO) = 1.5\ MPa]{Pd^{II}} (ArCO)_2O .$$

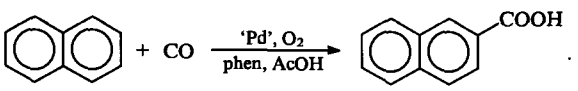
In the presence of *tert*-butyl hydroperoxide, the synthesis of aromatic acids with participation of palladium(II) in solution in acetic acid, which permits the use of a low carbon monoxide pressure, becomes catalytic.[117,118]



$$ArH \xrightarrow[Ox]{Cat} ArCOOH ;$$

Cat = $Pd(OAc)_2$;
Ox = Bu^nOOH, $CH_2{=}CHCl$, AcOH; $p(CO)$ = 0.1 MPa.

It is of interest to note that certain oxidants—H_2O_2, *m*-ClC_6H_4COOOH, $O{=}C_6H_4{=}O$, $CuCl_2$, $Pb(OAc)_4$, $FeCl_3$, and $K_2S_2O_8$—lower the yield of the oxidative carbonylation products.



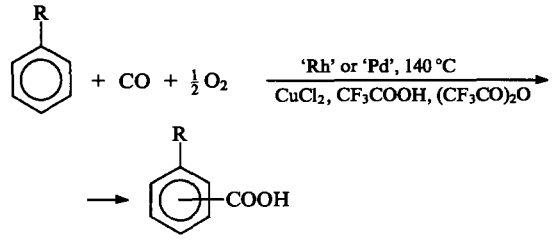
The insertion of CO_2 in the Pd–C bond of an organopalladium compound leads to the formation of acids, but the reaction selectivity is low,[119] the reactivity of CO_2 amounting to approximately 0.01 of the reactivity of CO. The joint employment of palladium(II) and Bu^tOOH increases the yield of aromatic acids in this case too.

$$ArH + CO_2 \xrightarrow{Pd(OAc)_2,\ Pd(NO_3)_2} ArCOOH ;$$

Ar = Ph, ClC_6H_4, $CH_3OC_6H_4$,  .

The proportions of the isomers of substituted benzenes are consistent with their proportions obtained on electrophilic substitution in an aromatic compound.

β-Naphthoic acid can be obtained with a selectivity in excess of 80% by the single-stage carboxylation of naphthalene with carbon monoxide in the presence of palladium(II) under mild conditions.[120]

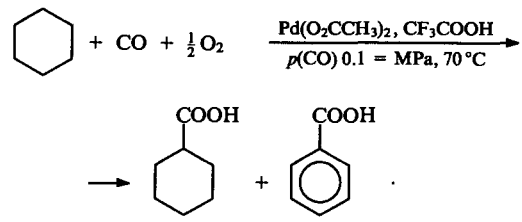


It is significant that the maximum yield of β-naphthoic acid is attained in the simultaneous presence of acetic acid, oxygen, and *o*-phenanthroline (phen), the last compound regulating the reaction selectivity. Palladium on charcoal or palladium black catalyse, like palladium(II) acetate, the carboxylation of naphthalene. The reaction apparently proceeds via a stage involving the formation of a σ-arylpalladium(II) complex via the electrophilic substitution of hydrogen in the aromatic compound in the case of palladium(II) or the oxidative addition of naphthalene in the case of zero-valent palladium. It may be that large palladium clusters, which are in fact the carboxylation catalysts, are formed during the reaction. [121]

The palladium-catalysed carboxylation of aromatic C–H bonds by carbon monoxide takes place with high yields and under mild conditions [p(CO) = 0.1 MPa, 20–50 °C] in TFA in the presence of sodium acetate as the cocatalyst. [122] The yield of the products corresponds to the stoichiometric consumption of palladium, but the reaction can be carried out under catalytic conditions with participation of $NaNO_3$, $Tl(O_2CCF_3)_3$, and $Hg(O_2CCF_3)_2$ like the carboxylation phenylmercury chloride in the presence of palladium(II). [123] The reaction with substituted aromatic compounds, such as anisole and toluene, is a typical electrophilic substitution process. The electrophilic character of the reaction agrees with the positive effect exerted by the addition of strong acids (CF_3COOH). Since in the presence of an oxidant the regioselectivity of the process increases compared with the stoichiometric reaction, thallium(III) and mercury(II) compounds probably not only oxidise the zerovalent palladium formed but also play the role of *ortho*- and *para*-directing agents. The role of sodium acetate is less clear. On the one hand, its presence can weaken the electrophilic properties of palladium (compared with trifluoroacetate) and, on the other, it should stabilise the catalytic system in relation to the reduction of palladium by carbon monoxide. These postulates require the existence of an optimum Pd : NaOAc ratio.

The palladium-catalysed carboxylation of the C–H bonds of thiophene and furan by carbon monoxide proceeds in acetic acid (both compounds are unstable in TFA) with participation of mercury(II) and thallium(III) carboxylates under mild conditions [p(CO) = 0.1 MPa, 20–50 °C]. [124]

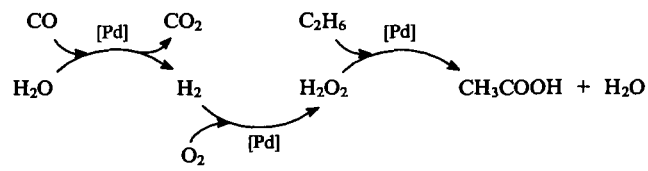
The oxidative carbonylation of benzene and its derivatives in the presence of rhodium(III) trifluoroacetate as well as palladium and copper compounds has been investigated. [125]



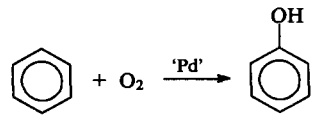
R = H, CH_3, CH_3O, Cl.

We may note that the replacement of rhodium in the form of $Rh(O_2CCF_3)_3$ by $Pd(O_2CCF_3)_2$ leads to a significant increase in the overall yield of toluic acids. It has been shown that, in conformity with the data of Gol'dshleger et al., [126] rhodium(III) trifluoroacetate is an electrophile which directs the carboxy-group predominantly to the *para*-position. We may also note that the system components—the copper(II) compounds CuX_2 (X = CH_3COO, CF_3COO, ClO_4)—themselves effectively catalyse the carboxylation of aromatic compounds.

The Rh^{3+}/nafion catalyst reacts as a strong electrophile: [127] *p*-toluic acid is formed under these conditions with a selectivity of 94%.



The first study on the carboxylation of cycloalkanes by carbon monoxide without irradiation in the presence of palladium(II) was carried out by Japanese investigators. [128]



Cyclohexanecarboxylic and benzoic acids are obtained in molar proportions of 1 : 3. Potassium peroxydisulfate proved to be a convenient oxidant in this case also. [129–131] The introduction of methanol and the increase in the reaction time and temperature appreciably increased the yield of cyclohexanecarboxylic acid. [129] The reactivity of the C–H bonds of cycloalkanes diminishes on passing from tertiary to primary bonds. [130] In the case of hexane, the 1-, 2-, and 3-carboxylic acids are obtained in molar proportions of 2 : 29 : 20, [129] which differ appreciably from the photochemical alkane carbonylation reactions in the presence of $RhCl(CO)[P(CH_3)_3]_2$. [9] In this connection, the results obtained in the oxidation and oxidative carbonylation of methane in the presence of potassium persulfate in aqueous solution are of interest. [132] It was shown that the $SO_4^{-\bullet}$ radical-anion, generated from $S_2O_8^{2-}$, abstracts a hydrogen atom from methane and ethane at 105–115 °C with formation of an alkyl radical, which can subsequently effectively interact with carbon monoxide, affording an acyl radical, the latter being converted in the final stages into carboxylic acids, CH_3COOH and C_2H_5COOH respectively, in high yields. It may be that this reaction makes an appreciable contribution to the oxidative carbonylation of cycloalkanes in the presence of the Pd(II)–$K_2S_2O_8$ system [the yield of carboxylic acid relative to the palladium(II) taken for the reaction reached 19 000%]. [131]

The carbonylation of methane by carbon monoxide in solution in TFA in the presence of $K_2S_2O_8$ as the oxidant is possible with participation of copper complexes, which presupposes a reaction mechanism different from the mechanism of the carboxylation of cyclohexane with participation of a σ-organopalladium compound. [133]

A highly effective system for the direct oxidation of lower alkanes by oxygen in aqueous solution has been proposed. [134] Pd/C serves as the catalyst of the low-temperature synthesis of carboxylic acids.

The direct hydroxylation of benzene by molecular oxygen or H_2O with formation of phenol, which proceeds via a stage with C–H bond activation by palladium(II) compounds, has been achieved. The reaction temperature is appreciably higher than the temperature necessary for the carboxylation of aromatic compounds by CO or for the oxidative coupling reaction. The selective synthesis of phenol requires the presence of carbon monoxide, phenanthroline, and oxygen. [135]

The effect of CO on the selectivity of the hydroxylation of aromatic compounds in the presence of palladium(II) is associated with the possibility of the acceptance of one oxygen atom with formation of CO_2, while the other is inserted in the Pd–C bond. A decrease in the concentration of palladium increases the yield of phenol. In the absence of CO, biphenyl is formed in addition to phenol. [136]

4. Reactions of aromatic compounds with participation of platinum(IV)

The interaction of platinum(II) and platinum(IV) complexes with aromatic hydrocarbons has been investigated. [137] The degree of reduction of platinum(IV) in the oxidative coupling of toluene in the $Hg(OAc)_2-H_2PtCl_6-AcOH$ system depends on the acidity of the medium: in a weakly acid medium, the reduction proceeds as far as platinum(II), while in a strongly acid medium it continues to zerovalent platinum with formation in the latter case of two moles of bitolyl per mole of platinum(IV). As in the case of palladium(II), the introduction of perchloric acid apparently increases the electrophilicity of platinum(II), which has been confirmed by data [138] indicating a greater activity of platinum(II) complexes with a low chlorine content — $PtCl(H_2O)_3^+$ and $Pt(H_2O)_4^{2+}$ — in the oxidation of benzene.

Evidence for the formation of relatively stable intermediate acyl and phenyl derivatives of platinum(IV) in the oxidation of methane and benzene in the platinum(II)–platinum(IV) system has been obtained by ^1H and ^{13}C NMR spectroscopy. [12,139]

Further studies demonstrated that σ-arylplatinum(IV) complexes can be obtained in yields up to 95% on heating the aromatic compound ArH with H_2PtCl_6 in CH_3COOH or a $CF_3COOH-H_2O$ mixture. [140,141]

$$ArH + H_2PtCl_6 \xrightarrow[2.\ SiO_2,\ NH_3]{1.\ CF_3COOH-H_2O} NH_4^+\left[(\sigma\text{-}Ar)PtCl_4NH_3\right]^-$$

Naphthalene and *o*-nitrotoluene complexes have been characterised by X-ray diffraction. [140,142] It has been established by the method of competing reactions [143,144] that the relative rates of reaction involving PhX, indicated below in brackets, decrease in the following sequence of X: OH (16), OCH_3 (8.5), CH_3 (3.0), C_2H_5 (2.7), OC_2H_5 (2.0), $CH(CH_3)_2$ (1.9), H (1.0), Ph (0.9), F (0.9), $COCH_3$ (0.1), COOH (0.09), Cl (0.08), NO_2 (0.04). The logarithms of the rates are correlated with Hammett's σ constant and Brown's σ^+ constants (the parameters ρ and ρ^+ are –3.0 and –1.5 respectively). On the basis of the data obtained, a mechanism is proposed for electrophilic substitution in the aromatic ring with participation of platinum(IV) complexes. [145] The behaviour of platinum(IV) in arene metallation reactions resembles that of palladium(II) complexes (ρ ad ρ^+ are –3.0 and –2.2 respectively). [110,144]

It is of interest that the interaction of mesitylene with $PtCl_6^{2-}$ in TFA with formation of (2,4,6,3′,5′-pentamethyl)diphenylmethane in the first stage apparently includes electron transfer from the arene to the platinum(IV) complex. Thus the behaviour of platinum(IV) is similar to that of palladium(II) in TFA. [146]

5. Oxidation of hydrocarbons by cobalt(III), manganese(III), lead(IV), and silver(II) carboxylates

Cobalt(III), manganese(III), and lead(IV) carboxylates are used to oxidise alkyl-substituted aromatic hydrocarbons. [17,19] Whereas cobalt(III) acetate is stable in acetic acid even at a high temperature, manganese(III) acetate decomposes even on slight heating with formation of radicals, which participate in further reactions.

$$\dot{C}H_2COOH \longrightarrow \dot{C}H_3 + CO_2.$$

This mechanism is characteristic of aromatic compounds with an ionisation potential above 8 eV. In the presence of more readily oxidised compounds, $Mn(O_2CCH_3)_3$ reacts via an electron-transfer mechanism with formation of the radical-cation of the aromatic compound. After the addition of a strong acid, this pathway becomes the only one. [147] The introduction of a strong acid such as CF_3COOH plays a decisive role in the interaction of these oxidants with benzene, toluene, and unsaturated hydrocarbons. [148–152] The effect of TFA may be attributed to the formation of a cationic species which renders cobalt(III) a stronger electrophile. [147]

$$Co(O_2CCF_3)_3 \longrightarrow Co(O_2CCF_3)_2^+(CF_3COO)^- \xrightarrow{H^+} \longrightarrow Co(O_2CCF_3)_2^+ + CF_3COOH$$

As a result, the oxidation of alkanes by cobalt(III) acetate in TFA becomes possible at low temperatures. Under an inert atmosphere, the reaction products are esters while in the presence of oxygen ketones are formed. When CCl_3COOH was used as the activator, alkyl chlorides, primarily secondary alkyl chlorides, were obtained under an inert atmosphere. Cobalt(III) trifluoroacetate was quantitatively reduced in TFA by cyclooctane and 2,3-dimethylbutane in 2 and 3 h respectively, but the esters were formed in a low yield. Cyclohexyl trifluoroacetate was obtained in a yield of 35% under similar conditions, which indicates its subsequent transformation under the reaction conditions (for example, the splitting off of TFA and subsequent reactions of cyclohexene). However, benzene was oxidised quantitatively to phenyl acetate with participation of $Co(O_2CCF_3)_3$ at room temperature. [151]

The interaction of manganese(III), iron(III), cobalt(III), copper(II), and lead(IV) trifluoroacetates with methane in solution in TFA at 100–200 °C and a methane pressure of 1–4 MPa has been investigated. The activity of the metal trifluoroacetates diminishes in the sequence Co(III) > Mn(III) > Pb(IV) ≫ Cu(II) > Pd(II); $Fe(O_2CCF_3)_3$ was inactive. The degree of formation of methyl trifluoroacetate reaches 90% in the case of cobalt(III) and takes place in conformity with the following equation: [80,153]

$$CH_4 + 2Co(O_2CCF_3)_3 \longrightarrow \longrightarrow CF_3CO_2CH_3 + 2Co(O_2CCF_3)_2 + CF_3COOH.$$

Further study of this system showed that the addition of oxygen (0.1–0.5 MPa) to methane leads to the catalytic synthesis of $CF_3CO_2CH_3$ from methane. The same yields of methyl trifluoroacetate were attained in the $Co(III)-O_2-CH_4$ and $Co(II)-O_2-CH_4$ systems. [80]

$$CH_4 + \tfrac{1}{2}O_2 + CF_3COOH \xrightarrow{\text{'Co'}} CF_3CO_2CH_3$$

It has been found [154] that ethane and propane also react with $Co(O_2CCF_3)_3$ under similar conditions in solution in TFA with formation of alkyl trifluoroacetates as the main products.

$$C_2H_6 + 2Co(O_2CCF_3)_3 \longrightarrow \longrightarrow CF_3CO_2C_2H_5 + 2Co(O_2CCF_3)_2 + CF_3COOH$$

$$C_3H_8 + 2Co(O_2OCF_3)_3 \longrightarrow \longrightarrow \textit{iso}\text{-}C_3H_7O_2CCF_3 + 2Co(O_2CCF_3)_2 + CF_3COOH$$

As in the case of methane, this interaction is accompanied by the decarboxylation of TFA, catalysed by cobalt salts, with formation of CO_2 and CF_3H. The oxidation of ethane and propane is a less selective process than the oxidation of methane. A reaction mechanism has been proposed. It involves direct electron transfer from the alkane RH molecule to Co(III) with formation of the radical-cation $RH^{+\bullet}$ in the first stage, as in the oxidation of alkanes in the presence of $Co(O_2CCH_3)_3$.

It has been found that bis(bipyridyl)silver(II) peroxydisulfate oxidises aromatic compounds in acetic acid at room temperature. The system becomes catalytic with respect to silver when an excess of potassium persulfate is used. [155]

Adamantane and other cyclic compounds are oxidised with a satisfactory yield to adamantyl and cycloalkyl trifluoroacetates [156] by the silver 'peroxide' $Ag(I)Ag(III)O_2$, which generates an active Ag(III) complex in the TFA–TFAN mixture.

6. Oxidation of hydrocarbons by manganese(VII), chromium(VI), and ruthenium(IV) in acetic acid

The oxidation of alkanes, cycloalkanes, and aromatic compounds by potassium permanganate $KMnO_4$ in aqueous trifluoroacetic acid has been investigated. It was found that the oxidising capacity of manganese(VII) increases with increasing acid concentration. The rate of oxidation of alkanes by manganese(VII) is sensitive to the structural differences in the substrate, in particular to the branching of the chain. A series of specific rates have been observed in terms of the selectivity of the oxidation of primary, secondary, and tertiary C–H bonds: 1, 60, and 2100 respectively. The rate of oxidation increases with increase in chain length; the methylene group is more reactive than the methyl group. After the introduction of electron-accepting substituents in the carbon chain, the rate of reaction falls. The primary isotope effect, determined for $C_6H_{12}-C_6D_{12}$ as 4.3, confirms that the rate-determining stage of the reaction is the cleavage of a C–H bond. It has been suggested [157] that the active species is the permanganyl cation MnO_3^+ in the free form or as the ester $MnO_3(O_2CCF_3)$.

The rate constants and the substrate selectivities for the first stage of the oxidation of RH (C_2-C_8 alkanes, benzene, toluene) by permanganate in TFA–H_2O solutions have been determined from the consumption of the substrate. [158] These data differ significantly from the results of the study of Stewart and Spitzer [157] obtained by a standard method from the consumption of the oxidant. Arguments have been put forward in support of the hypothesis that the reactants in solutions in TFA are MnO_4^-, $HMnO_4$, and $MnO_3(O_2CCF_3)$, the contribution of the last species becoming significant at a TFA concentration in excess of 50 mass%.

In the presence of manganese(VII), toluene in TFA is oxidised to CO_2, but, with increase in the concentration of water, the yield of benzoic acid increases; [159] rapid degradation of the aromatic compound, which follows the electrophilic attack by MnO_3^+, was also noted. [157]

Solutions of $KMnO_4$ in the TFA–TFAN mixture are capable of oxidising selectively methane to the product of its two-electron oxidation — methyl trifluoroacetate. [160–161] Methyl trifluoroacetate and methyl formate are formed in solution in the course of several hours at 60 °C and $p(CH_4)$ = 20 MPa, their overall yield reaching 90% relative to the unused oxidation equivalents of manganese(VII), converted during the reaction into manganese(IV) and manganese(III), in proportions of 3 : 1, which are inactive with respect to methane and sparingly soluble. Dimethyl formal $(CH_3O)_2CH_2$ is also formed (2%–4%). Fluoroform and carbon dioxide were detected in the reaction products, their amount corresponding to the consumption of ~10% of the oxidation equivalents of manganese(VII) on decarboxylation of TFA. The addition of small amounts of water reduces sharply the yield of the partial oxidation products as a result of the hydrolysis of the esters to methanol, which is relatively rapidly oxidised by potassium permanganate to CO_2. The use of methane enriched in $^{13}CH_4$ affords products containing the corresponding amount of the ^{13}C isotope. Manganese(VII) participates in the primary interaction with a methane molecule in the form of the cation MnO_3^+ or the ester $MnO_3(O_2CCF_3)$, the rate constants for this interaction amounting to 4×10^{-5} litre mol^{-1} s^{-1} at 70 °C and 1.5×10^{-5} litre mol^{-1} s^{-1} at 60 °C, which is higher than the corresponding constant for the $HMnO_4$ species determined in sulfuric acid solutions (10^{-5} litre mol^{-1} s^{-1} at 70 °C) and exceeds by three orders of magnitude the rate constant for the MnO_4^- species determined in neutral aqueous solutions. [160] Thus the rate constant for the reaction of methane with the manganese(VII) species increases sharply with increase in their electrophilicity.

In the presence of a large excess of sodium periodate, capable of oxidising in acid media the final product of the stoichiometric reaction [manganese(IV) and manganese(III) compounds] to permanganate, the process becomes catalytic with respect to the initial manganese both in aqueous acid media (10 cycles) and in TFA (2–3 cycles). [161] A simplified mechanism of the interaction for the TFA solutions is as follows:

$$\tfrac{2}{3}Mn^{VII} + CH_4 \xrightarrow[70\,^\circ C]{CF_3COOH} CF_3CO_2CH_3 + \tfrac{2}{3}Mn^{IV} + H_2O\,.$$

$$\tfrac{2}{3}Mn^{IV} \xrightarrow{NaIO_4} \tfrac{2}{3}Mn^{VII}$$

We may note that, in the absence of permanganate, the periodate exhibits an intrinsic activity in the oxidation of methane, which, however, is 20–30 times lower than the activity of permanganate. This apparently indicates unusual properties of oxo-complexes of metals in the C–H bond activation reaction and the fact that a higher standard two-electron redox potential of the periodate/iodate couple is insufficient for a more effective oxidation of the C–H bond.

A similar set of products [$CF_3CO_2CH_3$, CH_3CO_2H, $(CH_3O)_2CH_2$, CO_2, and CF_3H] was also found in the oxidation of methane in TFA by chromium(VI) compounds. [161]

A solution of potassium dichromate in TFA at room temperature oxidises n-pentane to the trifluoroacetic acid esters of 2-pentanol and 3-pentanol in molar proportions of 2 : 1 respectively. [162] Apart from these esters, the formation of small amounts of acetic and propionic acid was observed. Kinetic and spectrophotometric study of the reaction showed that the mononuclear chromium(VI) complexes are inactive and that the two-electron oxidation of a C–H bond of the methylene group of the alkane is effected by the dimeric complexes [$Cr^{VI}\cdots Cr^{VI}$]. The role of the second chromium ion in the complex apparently reduces to the enhancement of the electron-accepting properties of the oxo-groups of the first ion, [3] which serve as the active centre for the electrophilic interaction with a C–H bond of the alkane.

Extremely pronounced oxidising properties are characteristic of chromyl trifluoroacetate: in its presence, hydrocarbons reacted at temperatures in the range –20 to 25 °C in solvents without a C–H bond such as CCl_4 and $F_2ClC-CF_2Cl$. [163]

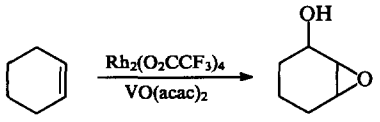
$$RH + CrO_2(OCOCF_3)_2 \longrightarrow$$

$$\longrightarrow \left[CF_3CO_2\overset{\displaystyle HO\quad R}{\overset{|\quad /}{Cr}}O_2CCF_3\right] \longrightarrow ROH\ (RO_2CCF_3)\,.$$

Ruthenium(IV) trifluoroacetate was used for the first time in the study of Lardais et al. [164] for the oxidative coupling reaction. The yield of the products of the oxidative dimerisation of phenylalkylisoquinolines in its presence was higher than in the case where $Tl(OCOCF_3)_3$ had been used.

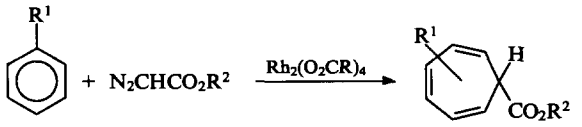
7. Reactions of olefinic hydrocarbons with transition metal carboxylates

The oxidation, dehydrogenation, oxidative coupling, acetoxylation, and carboxylation reactions of saturated and aromatic hydrocarbons, which take place effectively when acted upon by metal complexes with electron-accepting ligands, were examined above. Reactions such as the oxidation of olefins, conversion into cyclopropane derivatives, and cyclodimerisation of strained hydrocarbons are also sensitive to the electron-accepting properties of the carboxylate ligand. Several examples are presented below.



tert-Butyl peroxide complexes of palladium(II) ($RCO_2PdOO.Bu^t)_4$ have been synthesised. They are highly effective reagents for the selective stoichiometric oxidation of terminal olefins at the usual temperatures.[165] In the presence of an excess of *tert*-butyl peroxide, the oxidation reaction is catalytic.

$$Bu^tOOH + R'CH{=}CH_2 \xrightarrow{Pd(OCOR)_2} \longrightarrow Bu^tOH + R'{-}\overset{O}{\overset{\|}{C}}{-}CH_3$$

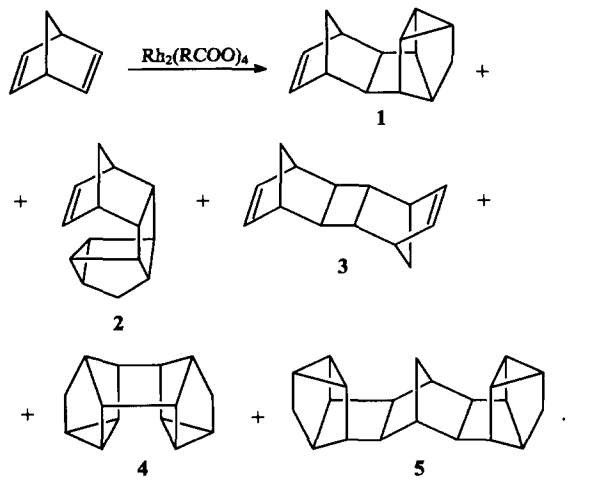


It was found that the rate of formation (indicated in brackets below) of, for example, 2-hexanone increases by two orders of magnitude on passing from the acetate to the trifluoroacetate in the following series of R: CF_3 (130), C_5H_{11} (80), CCl_3 (60), CH_3 (1).

The interaction of palladium complexes such as $Pd(OAc)_2$, $Pd(OPr)_2$, $Pd(O_2CCF_3)_2$, and $Pd(PPh_3)_4$ with H_2O_2 or K_2O_4 leads to the formation of superoxo-complexes of two types differing in the mode of coordination of the molecular oxygen radical-anion to the metal (η^1- or η^2-type of coordination) and hence in the reactivity with respect to olefins and carbon monoxide.[166]

Dirhodium(II) tetracarboxylate exhibits a catalytic activity in olefin oxidation reactions and in the conversion of the latter into cyclopropane derivatives.[167] The presence of the trifluoroacetate group ensures a high selectivity in the formation of epoxycyclohexanol in the oxidation of cyclohexene.

The addition of a carbenoid species to an aromatic compound is controlled by electronic factors. The effectiveness of the catalyst depends greatly on the electron-accepting capacity of the carboxylate ligand.[168]

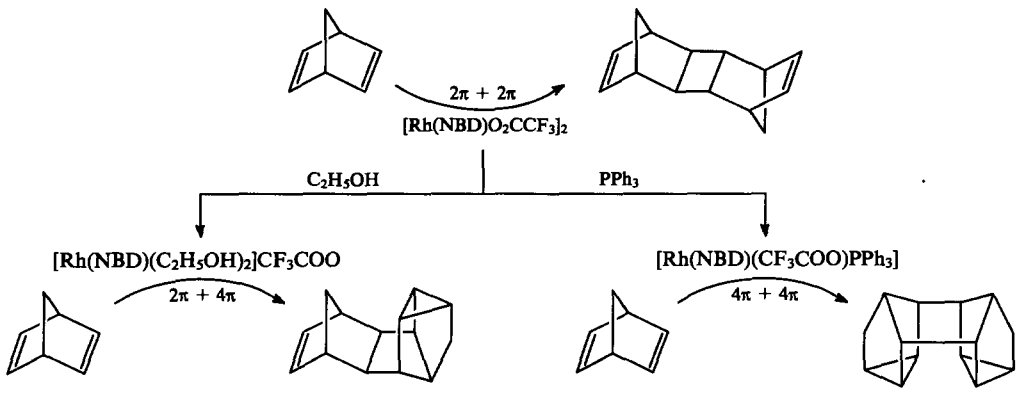


For example, the data for benzene are as follows:

Acid	pK_a	Yield (%)
CF_3COOH	0.23	100
C_6H_5COOH	1.48	89
CH_3OCH_2COOH	3.57	30
CH_3COOH	4.76	7
HCOOH	5.03	5

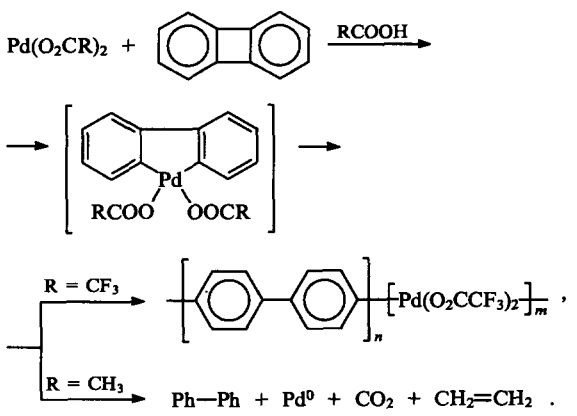
Dirhodium(II) tetracarboxylates $Rh_2(CO_2R)_4$ (R = CH_3, CCl_3, CF_3) have been investigated as catalysts for the cyclodimerisation of norbornadiene. It was found that in their presence the reaction proceeds with the preferential formation of *exo,endo*- and *endo,endo*-hexacyclo[9.2.1.$0^{2,10}$.$0^{3,7}$.$0^{4,9}$.$0^{6,8}$]-tetradec-12-enes (compounds **1** and **2**), but, depending on the reaction conditions, the pentacyclic dimers **3**, binor S **4**, and the norbornadiene trimer *endo,exo,endo*-decacyclo-[9.9.1.$0^{2,10}$.$0^{3,8}$.$0^{4,6}$.$0^{5,9}$.$0^{12,20}$.$0^{13,19}$.$0^{14,16}$.$0^{15,19}$]heneicosane **5** may be formed (Scheme 2).[30] The catalytic activity of the complexes increases with enhancement of the electron-accepting properties of the ligand in the sequence $Rh_2(O_2CCH_3)_4$ < $Rh_2(O_2CCCl_3)_4$ < $Rh_2(O_2CCF_3)_4$.

Scheme 2



The cyclodimerisation reaction was investigated in detail in the presence of $Rh_2(O_2CCF_3)_4$. It was shown that di(μ-trifluoroacetato)bis(norbornadiene)dirhodium(I), formed on reduction of $Rh_2(O_2CCF_3)_4$ by norbornadiene, is catalytically active.[169] A similar reaction was not observed for other olefins and dienes. The interaction of $Rh_2(O_2CCF_3)_4$ with olefins and dienes[170,171] also leads, like the interaction with norbornene,[172] to the rapid and reversible formation of axial monoadducts, the structure of one of which has been investigated.[173]

The interaction of rhodium(II) with norbornadiene (NBD) has been investigated spectrophotometrically and it has been shown that the reduction of $Rh_2(O_2CCF_3)_4$ proceeds via the intermediate formation of rhodium complexes of norbornadiene of the type $Rh_2(O_2CCF_3)_4$.NBD differing in the coordination of norbornadiene.[169] For the ratio $Rh_2(O_2CCF_3)_4$: NBD = 1 : 1, an adduct is formed in which the Rh—Rh bond is retained, which was demonstrated by the formation of the familiar complex $Rh_2(O_2CCF_3)_4.2PPh_3$ via the reaction of the adduct with PPh_3. On treatment with an excess of norbornadiene or polar agents such as alcohol and acetone, rhodium(II) is reduced in the adduct to rhodium(I) with formation of $[Rh(O_2CCF_3)NBD]_2$. The observed rate constants for the reduction of $Rh_2(O_2CCF_3)_4$ and $Rh_2(O_2CCH_3)_4$ by norbornadiene, measured at 90 °C, amounted to 9.26×10^{-3} and 0.31×10^{-3} litre $mol^{-1}s^{-1}$ respectively, which agrees with the results of the electrochemical reduction of rhodium(II) carboxylates.[174] The selectivity in the formation of cyclic norbornadiene dimers in the presence of $[Rh(O_2CCF_3)NBD]_2$ is determined by the ligand environment of the rhodium atom (Scheme 3).[175]



It may be that the rhodium(II) dimer disproportionates when acted upon by norbornadiene with formation of the intermediate $(NBD)Rh^I\cdots Rh^{III}$. The reduction of rhodium(III) by norbornadiene to a rhodium(I) complex, namely $[Rh(O_2CCF_3).NBD]$, confirms this pathway in the reaction of rhodium(II) on treatment with norbornadiene.[176] Rhodium(III) trifluoroacetate interacts in alcohol with $PRPh_2$ (R = Ph, *m*-$C_6H_4SO_3Na$) to form $Rh(O_2CCF_3)(PRPh_2)_3$ and $Rh(O_2CCF_3)(CO)(PPh_3)_2$.[43]

The study of the reactions of biphenylene, a tricyclic aromatic hydrocarbon, is of interest in view of the possibility of obtaining highly conducting polymers from it.[177] It has been found that the interaction of biphenylene in solutions in carboxylic acids with palladium(II) carboxylates takes place in accordance with Scheme 4.[178]

Scheme 3

Scheme 4

This reaction pathway differs significantly from the familiar reactions of biphenylene with mercury(II) carboxylates.[179,180]

* * *

The possibility of the selective functionalisation of alkanes and aromatic compounds with participation of electrophilic metal-containing centres in trifluoroacetic acid has been demonstrated in the present review in relation to dehydrogenation, carbonylation, carboxylation, and a number of other reactions. The problem of the activation of a C—H bond in alkanes still continues to engage the attention of investigators. For example, problems of the mechanism of the electrophilic activation of hydrocarbons in solutions in protic superacids have been discussed.[181] A new effective $CBr_4 \cdot n AlBr_3$ system has been proposed for the low-temperature reactions of alkanes and cycloalkanes.[182] Alkanes and cycloalkanes have been dehydrogenated with participation of low-valence rhodium complexes.[183,184] New evidence has been presented for the intermediate formation of alkylplatinum(IV) hydride in the activation of alkanes by platinum(II) complexes.[185]

Photochemistry of 2-dialkylamino-1,4-naphthoquinones

R P Shishkina, V N Berezhnaya

Contents

I. Introduction	139
II. Photochemical reactions of 2-dialkyl (1, ω-alkylene) amino-1,4-naphthoquinones	139
III. *ortho*-Substituted 2-dialkyl (1, ω-alkylene) amino-1, 4-naphthoquinones	143
IV. Conclusion	146

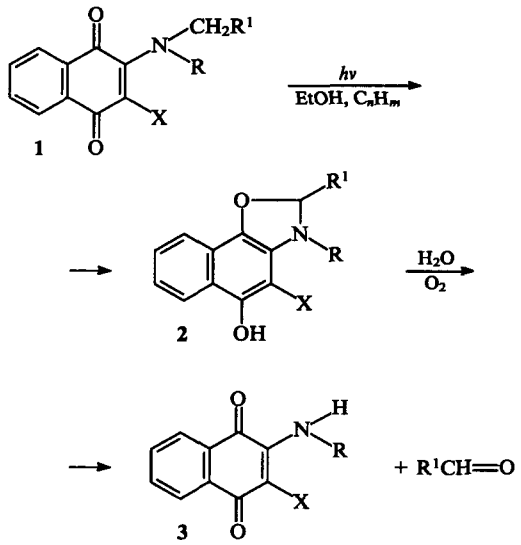
Abstract. The review surveys the results of studies on the photolysis of 1,4-naphthoquinones with 2-dialkylamino- and heterocyclic amino-groups. New data on the structures of the primary photolysis products and the mechanisms of their subsequent dark reactions are presented in relation to the reaction conditions and structure. The bibliography includes 53 references.

I. Introduction

Derivatives of 1,4-naphthoquinone are highly reactive and have a wide variety of valuable properties. Among naphthoquinones, dyes, vitamins, antibiotics, and pesticides are known. The ease of their excitation by light has led to the use of naphthoquinone derivatives as sensitisers and photoreducing agents in photographic materials of various types. Quinones with an internal source of hydrogen are most favoured. 2-Dialkylamino-1,4-naphthoquinones occupy a special place among them. They have found applications as photosensitive components in nonsilver photographic materials,[1–5] in particular in materials with physical development[1,2] and also in photoresist compositions.[4] Furthermore, the photochemical reactions of 2-dialkyl (1, ω-alkylene) amino-1, 4-naphthoquinones make it possible to obtain relatively easily derivatives of heterocyclic compounds which are either difficult or impossible to obtain by other procedures.[6–8] Much attention has therefore been devoted in recent years to the development of methods for the synthesis and study of the properties of 2-dialkylaminonaphthoquinones with various physicochemical characteristics.[9–21]

The wide variety of photochemical reactions of quinones has been most fully presented in the reviews by El'tsov et al.[22] and Maruyama and Osuka,[23] which cover the studies up to 1984. The present review is devoted to the photolysis of only 2-dialkyl (1, ω-alkylene) amino-1, 4-naphthoquinones, a characteristic feature of which is the intramolecular photochemical reduction reaction involving the abstraction of a hydrogen atom from the 2-position in the side chain via a readily formed six-membered transition state.[24] This determines the structure of the radicals formed — the primary photolysis products — and also the nature of the products formed when they are stabilised in secondary processes. The stabilisation can become, in the first place both intramolecular and intermolecular, i.e. with participation of the solvent.[22] The secondary intramolecular photochemical reduction reactions of 2-dialkylamino-1,4-naphthoquinones are primarily considered in the present review. In speaking of the primary photolysis products, we have in mind the primary products formed as a result of the stabilisation of the radicals.

The knowledge of the structure of the primary products and of the mechanism of the photolysis of photosensitive quinones makes it possible to determine the influence of various factors both on the process itself and on the stability of the primary photolysis products, which makes it possible to control the photochemical behaviour of the photosensitive component and the subsequent reactions of its photoinduced form in solutions and in polymer films.



Recently published studies on the photolysis of 2-dialkyl-(1, ω-alkylene) amino-1, 4-naphthoquinones, using NMR spectroscopy as the main research method, made it possible not only to establish the structures of the primary photolysis products but also to distinguish the photochemical and thermal processes, which enables one to explain the formation of a wide variety of photolysis products. The data dealt with in the present review have been divided into two parts: studies concerning mainly the results of the photolysis of 2-dialkylamino-1, 4-naphthoquinones, without a substituent in the quinone ring or having a substituent not involved in the photolysis, and subsequent reactions are discussed in the first part; the second part deals with studies on the photolysis of 2-dialkylamino-1, 4-naphthoquinones with a substituent in the 3-position which participates in the formation of the photolysis product.

II. Photochemical reactions of 2-dialkyl (1, ω-alkylene) amino-1, 4-naphthoquinones

1, 4-Naphthoquinones **1**, having a dialkyl- or an alkylarylamino-group in the 2-position, enter into an intramolecular photochemical reduction reaction on exposure to light with formation of relatively unstable naphtho [2, 1-*d*]-2, 3-dihydrooxazoles **2**,[25] which afford on decomposition the products **3** of the dealkylation of the initial quinones.[25–28]

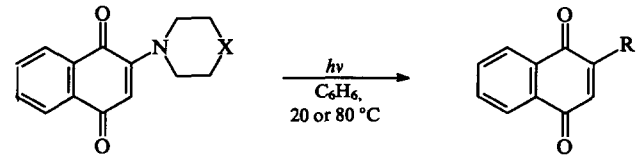
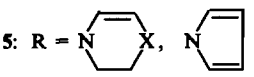
Uspekhi Khimii 63 (2) 145 – 153 (1994); translated by A K Grzybowski

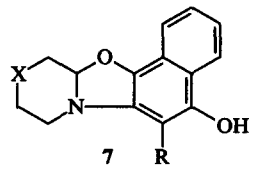


R = Me, Et, Ph; R^1 = H, Me; X = H, Cl.



In contrast to 2-dialkylaminonaphthoquinones **1**, 1,4-naphthoquinones **4**, having a heterocyclic amino-group in the 2-position, give rise to dehydrogenation products **5**[29–31] and the products of the degradation of the heterocyclic ring **6**[30,31] on photolysis.

The study of the photolysis of 2-dialkylamino-1,4-naphthoquinones **1** (R = Me; R^1 = H, Me; X = H, Cl) and 2-morpholino-1,4-naphthoquinone **4** by measuring the optical spectra[32] showed that the primary photochemical stages of their photolysis are the same, so that also in the presence of a heterocyclic amino-group the primary photolysis products have the structure of naphthodihydrooxazole **7**, which was subsequently demonstrated by ^{1}H and ^{13}C NMR spectroscopy.[33,34]



The conjunction of the amino-group with the π-system of the quinone is highly characteristic of 2-dialkylamino-1,4-naphthoquinones, which makes it possible to transfer the charge from the nitrogen atom to the oxygen atom directly during the

X = bond, CH_2, O.

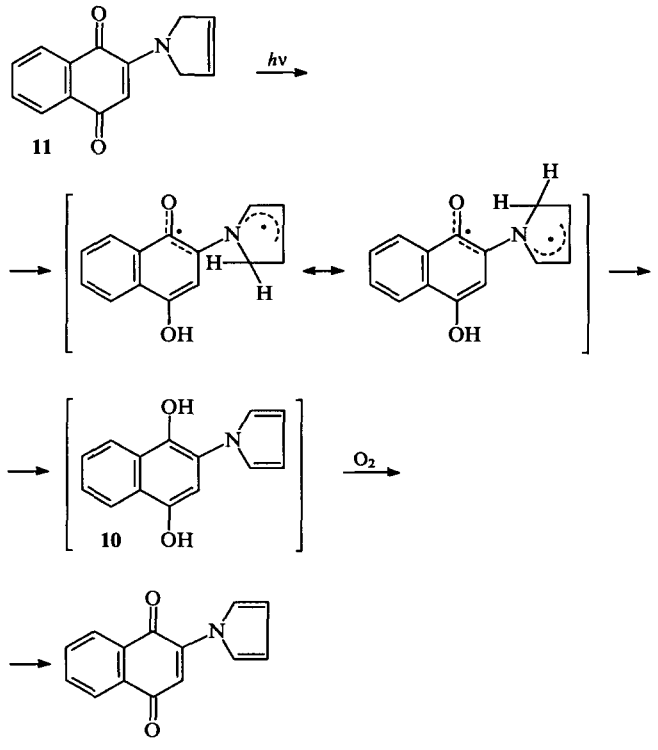
7: R = H, Me, OAlk; X = CH_2, O.

excitation process.[35] Quantum-chemical calculations of the electronic structures of 2-dialkylamino-1,4-naphthoquinones in the ground and excited triplet and singlet states showed that, on excitation of 2-aminonaphthoquinones, the electron density on the nitrogen atom falls appreciably[36,37] and increases on virtually all the atoms of the quinone ring, the increase being most significant not on the oxygen atom O(1) of the nearest carbonyl group but on the O(4) atom, which may be responsible for the subsequent migration of a hydrogen atom to the latter and this leads to cyclic structures of types **2** and **7**.[36]

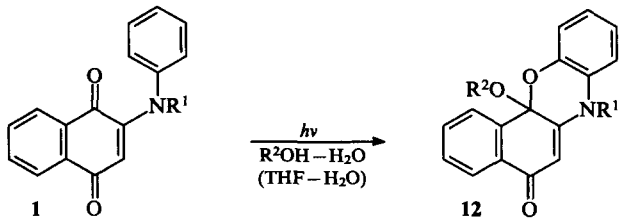
The study of the influence of various factors on the quantum yields of the formation reaction of naphthodihydrooxazoles **2** is of interest both from the standpoint of the elucidation of the details of the mechanism and of the selection of the optimum

Scheme 1



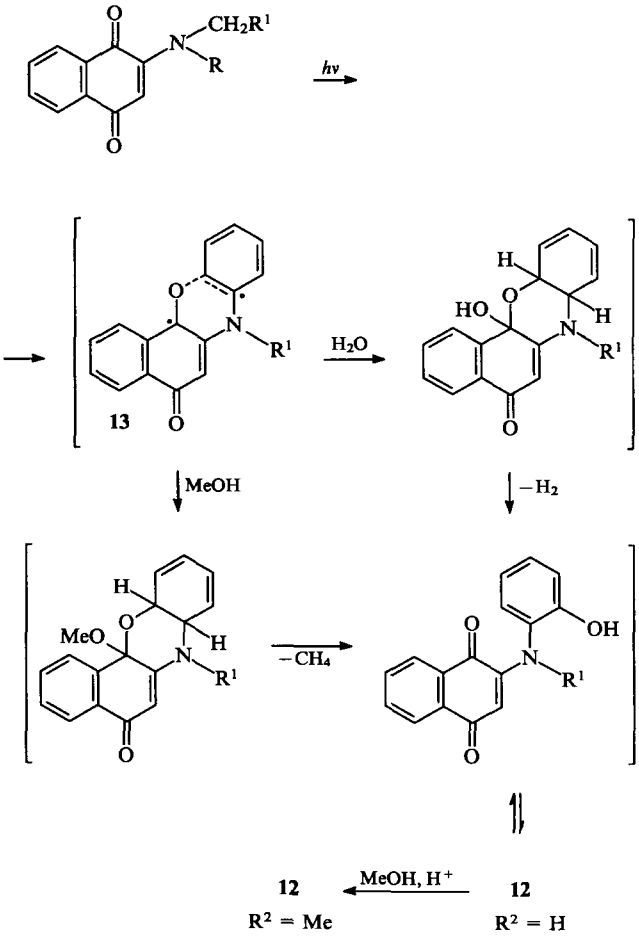
photolysis conditions. The nature of the solvent exerts a significant influence on the photolytic process. The photochemical reaction proceeds most effectively in nonpolar media such as hexane, benzene, and carbon tetrachloride; in alcohols, the effectiveness of the photolysis is appreciably lower owing to the formation of a hydrogen bond, which indicates the intramolecular abstraction of a hydrogen atom.[37] It has been established that this is a one-quantum and unimolecular process. A state of the $r_a\pi^*$ type is reactive, but the multiplet nature of the reactive state could not be established experimentally.[32,37] It has been shown that the nature of the photolysis product is independent of the irradiation wavelength (250–500 nm), the light intensity, and the concentration of the solutions ($0-2 \times 10^{-3}$ M). This permitted the assumption that the primary stage of the process is proton phototransfer and made it possible to put forward a hypothetical mechanism of the photolysis of 2-dialkylamino-1,4-naphthoquinones (Scheme 1).[32,35]

The multistage mechanism of the conversion of the photolysis products at 77 K into the product **2**, detected at room temperature, was put forward on the basis of low-temperature photolysis data. However, a biradical structure of type **8** could not be detected and its isomerisation to the zwitterion **9** was postulated.[35]



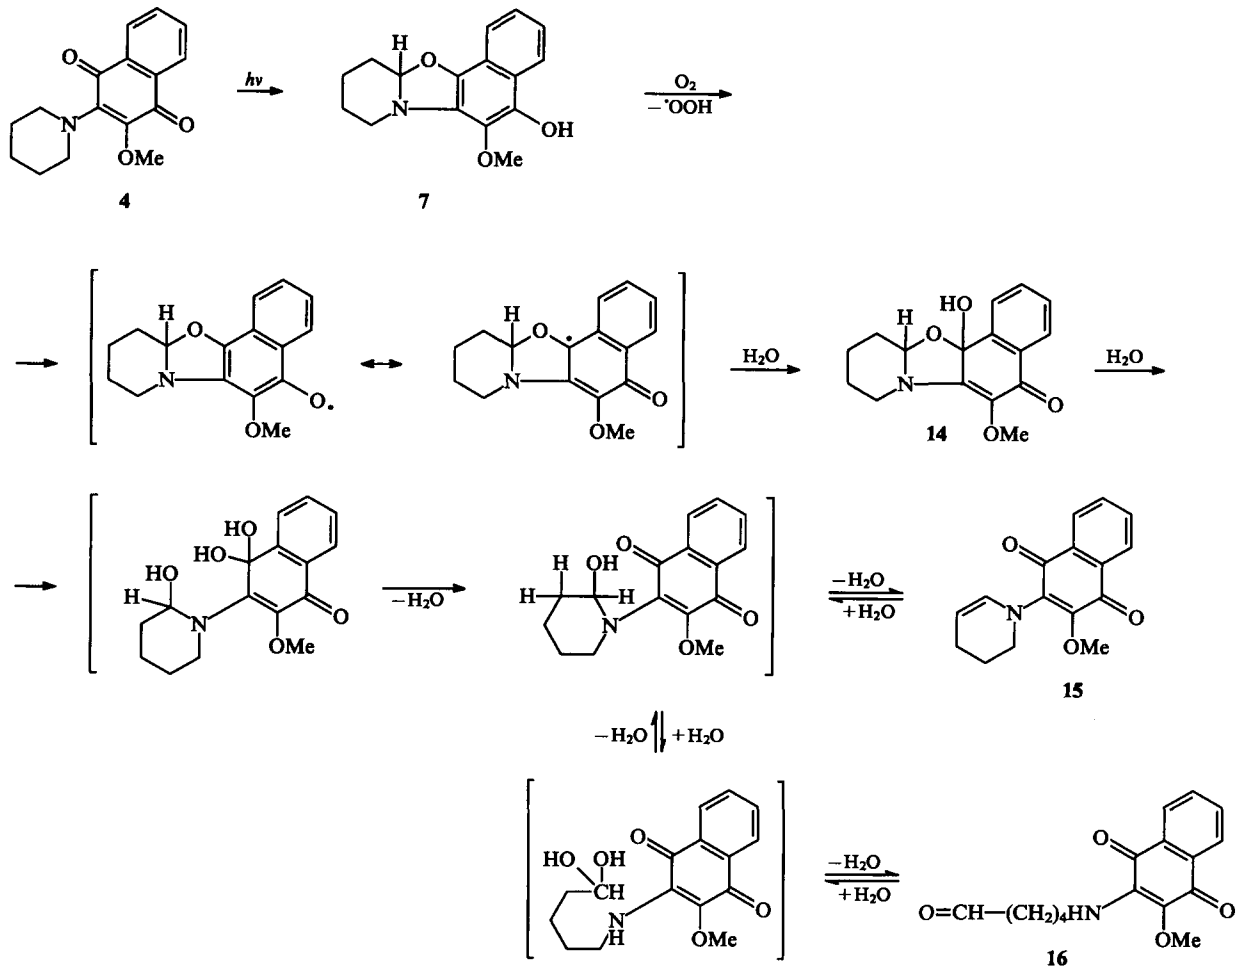
A somewhat different mechanism for the photolytic reaction—via the unstable 1,4-dihydroxy-2-(1-pyrrolyl)naphthalene **10**, which was detected as the diacetate—was proposed for the naphthoquinone **11** (Scheme 2).[30] The study of the photolysis of 2-(1-indolyl)-1,4-naphthoquinone in the presence of dienophiles may serve as its confirmation.[38]

Scheme 2



There are contradictory data as regards the products of the photolysis of 2-alkylphenylamino-1,4-naphthoquinones **1** (X = H, R = Ph). As already stated above, according to some data[25] irradiation results in the formation of naphthodihydrooxazoles **2**, whilst according to others[28] the products are benzophenoxazone derivatives **12**. It is noteworthy that the conditions of the photolysis in the above studies,[25,28] were different (water was present in the latter study[28]), which may partly alter the course of the reaction. It has been suggested[28] that the nonbonding orbital on the oxygen atom of the carbonyl group interacts in the excited state with the π electrons of the aromatic ring. There is then insufficient time for the occurrence of the intra- and intermolecular abstraction of a hydrogen atom by the biradical **13** formed and the latter is stabilised by combining with the solvent and cyclising (Scheme 3). Nevertheless, together with benzo[*c*]phenoxazone derivatives, dealkylation products (in some cases a product of this kind was the main one) were obtained with the preferential elimination of the alkyl residue compared with the aryl residue. This type of dealkylation is the result of the hydrolysis of the relatively unstable naphthodihydrooxazoles of type **2**.[25]

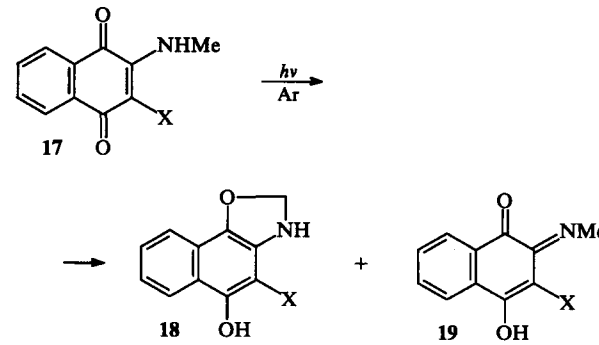
Scheme 3



R^1 = H, Me, Et, CH_2CH_2OH.
R^2 = H, Me.

According to the results of Gritsan and Bazhin,[32] the primary stage in the dark reactions of the naphthodihydrooxazoles **2** and **7** is the hydrolysis of the C–O bond, while according to Maruyama et al.[30] oxygen exerts the primary effect. The study of the properties of compounds **7** (R = Me, OMe, OPr^i; X = CH_2) showed that they are stable

Scheme 4

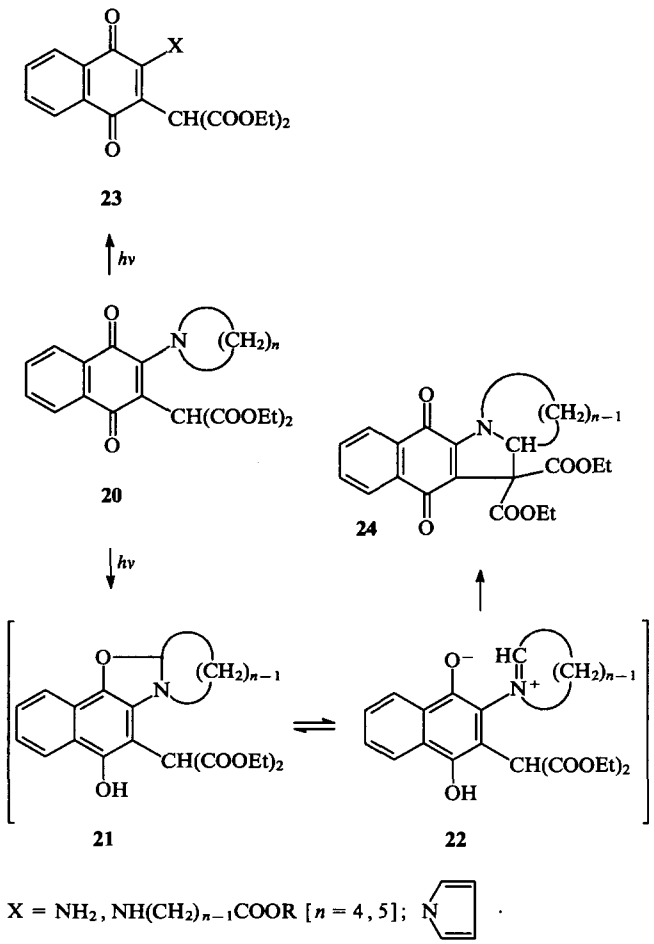


in the absence of oxygen for a long time at temperatures in the range from −70 to +23 °C.[33,39] The smallest traces of oxygen lead to the decomposition of the photolysis products; 6-methoxy-9,10,11,11*a*-tetrahydro-8*H*-naphtho[2′,1′:4,5]oxazolo-[3,2-*a*]pyridin-5-ol **7** gives rise to a mixture of compounds — the enaminoquinone **15**, the aminoaldehyde **16**, and compounds in which the oxazole ring is retained, namely 12*a*-hydroxy-6-methoxytetrahydroxazolopyridin-5-one **14**. The formation of compound **14** and the study of its properties enabled Shishkina et al.[33] to propose a mechanism of the dark reactions of the primary products of the photolysis of naphthodihydrooxazoles **7** including oxidation as the first stage (Scheme 4).

The methoxy-group as well as the more bulky isopropoxy-group[39] in the 3-position of 2-dialkylamino-1,4-naphthoquinones do not participate in photolysis on irradiation with light at $\lambda > 400$ nm,[33] although there are data showing that 2-alkoxy-1,4-naphthoquinones unsubstituted in the 3-position undergo photochemical reactions under more severe conditions.[40]

The methyl group is retained on irradiation of 2-dialkyl-(1,ω-alkylene)amino-3-methyl-1,4-naphthoquinones,[34] but its presence exerts a significant influence on the effectiveness of the photolysis: the quantum yields are 2–6 times higher than for 2-dialkylaminonaphthoquinones without a methyl group in the 3-position.[34,41,42] The greater effectiveness of the photochemical reaction of 2-dialkylamino-3-methyl-1,4-naphthoquinones made it possible to observe photochemical dealkylation also in the case of 2-monoalkylamino-1,4-naphthoquinones — a reaction which had not been known previously.

It has been found[45] that, on irradiation ($\lambda > 400$ nm) in organic solvents and under an inert atmosphere, compounds **17** are converted into naphthodihydrooxazoles **18** and 1,2-naphthoquinone 2-imines **19**. In the series of 1,4-benzoquinones, the stability of monoalkylamino-derivatives on irradiation has been explained by the presence of an intramolecular hydrogen bond between the NH and CO groups of the quinone.[43,44]

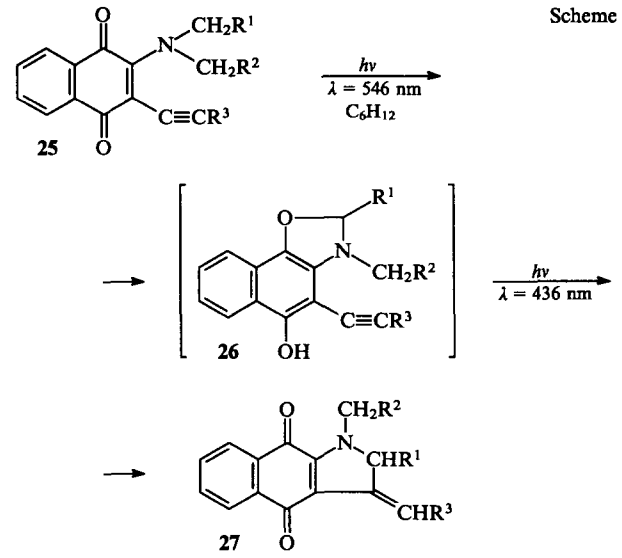


X = Me, OMe.

Since the methyl group gives rise to approximately the same bathochromic shift as the chlorine atom and the methoxy-group in the electronic absorption spectra of the corresponding 2-dialkylamino-1,4-naphthoquinones,[34] its activating effect is apparently not determined solely by the electronic effect of the substituent. It may be that the enhanced effectiveness of the photolysis of 2-dialkylamino-3-methyl-1,4-naphthoquinones is associated with their ability to form the quinone methide structure similar to that described by Serdobov.[46] However, one cannot rule out the additional involvement of the methyl group in the stabilisation of biradicals of type **8** as a result of the delocalisation of one of the unpaired electrons.[42]

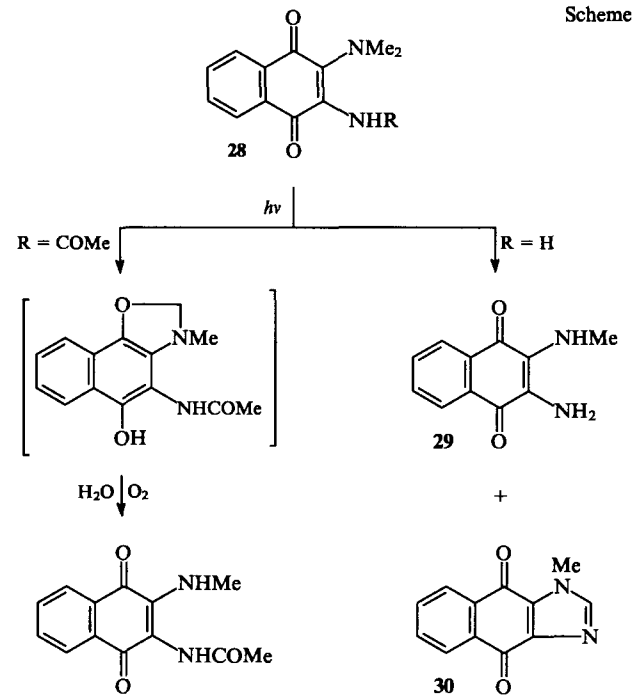
III. *ortho*-Substituted 2-dialkyl(1,ω-alkylene)-amino-1,4-naphthoquinones

The results of the photochemical reactions of 2-dialkyl-(1,ω-alkylene)amino-1,4-naphthoquinones without substituents in the *ortho*-position or with substituents such as a halogen, an alkoxy-group, or a methyl group, which do not affect the nature of the photolysis products, were discussed in the previous section. At the same time, there have been studies indicating the possible involvement of the *ortho*-substituent in the overall photolytic process.



Thus irradiation of 2-piperidino- and 2-pyrrolidino-1,4-naphthoquinones **20**, having an active methylene group in the 3-position, leads both to the products **23** of the dehydrogenation and degradation of the heterocyclic ring (a situation similar to that indicated by the results of Fokin and Detsina[29] and Maruyama et al.[30]) and to the indoloquinones **24**, the yield of the latter increasing in polar solvents.[7] It has been suggested that the intermediate oxazole **21** is converted into the indoloquinone **24** via the zwitterionic intermediate **22** in a polar medium.

There exists an example of the photochemical activity of the naphthodihydrooxazoles **26** formed on photolysis of 2-dialkylamino-3-alkynyl-1,4-naphthoquinones **25**, but the mechanism of the formation of the indole derivatives **27** has not been discussed.[47] This fact merits special attention, since it had been shown earlier[38] that naphthodihydrooxazoles without a substituent in the 3-position are stable on irradiation with light at $\lambda > 300$ nm (Scheme 5).

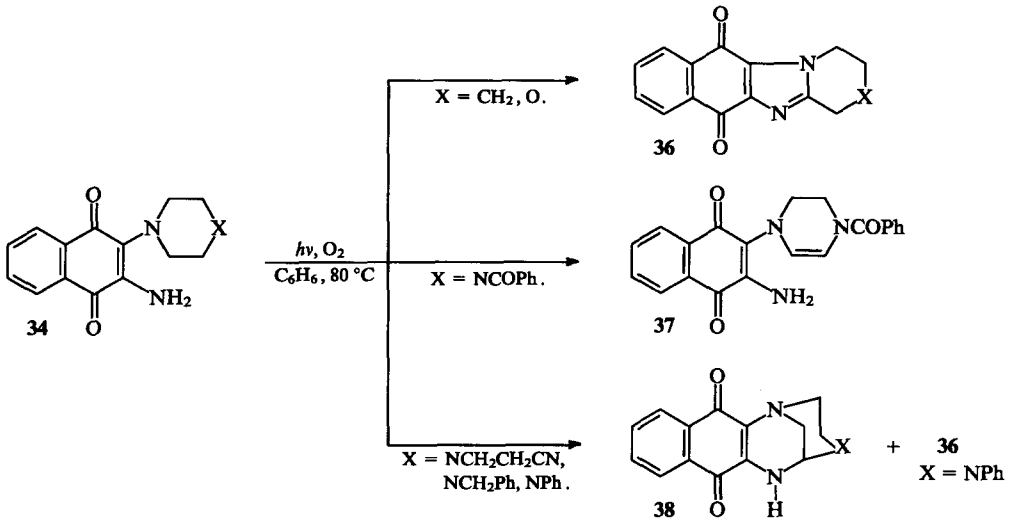


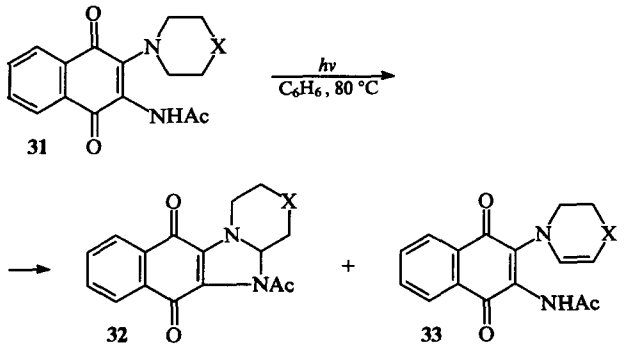
The products of the photolysis of 3-amino-2-dialkylamino-1,4-naphthoquinones are distinguished by the greatest variety. Thus irradiation of 3-amino-2-dimethylamino-1,4-naphthoquinone **28** (R = H) afforded, together with the dealkylation

Scheme 5

R¹ = H, Me; R² = Me, Et; R³ = H, Ph, CH_2OPh, CH_2OCOMe.

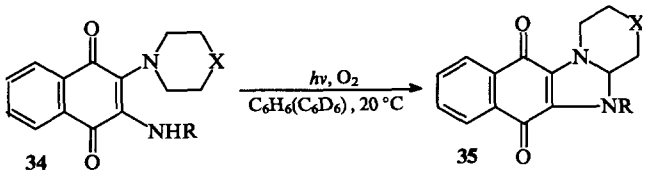
Scheme 6





product **29**, 1-methylnaphtho[2,3-*d*]imidazole-4,9-dione **30**, whereas only the dealkylation product is formed on photolysis of the 3-acetamido-derivatives **28** (R = COMe) (Scheme 6).[48]

When the 2-dialkylamino-group is replaced by a heterocyclic group, 3-acetamidonaphthoquinones **31** form on irradiation the dihydroimidazole derivatives **32** as well as the ring dehydrogenation products **33**.[49]



For the 3-aminonaphthoquinones with a cyclic alkylamino-group in the 2-position, the nature of the photolysis product is determined not only by the structure of the initial quinone but also by the reaction temperature. Thus the products of the photolysis of 2-cycloalkylamino-1,4-naphthoquinones with both primary[48,49] and secondary (alkyl,[39,50] and aryl[50,51]) amino-groups in the 3-position in the quinone at 20 °C are exclusively the unstable naphthodihydroimidazolediones **35**. Compounds **35** (R = Et) can be detected only spectroscopically,[39,51] since they are dealkylated with formation of naphthoimidazolediones **36** and, according to the data of Rubashko et al.,[50] the process takes place only under the influence of light. Depending on the

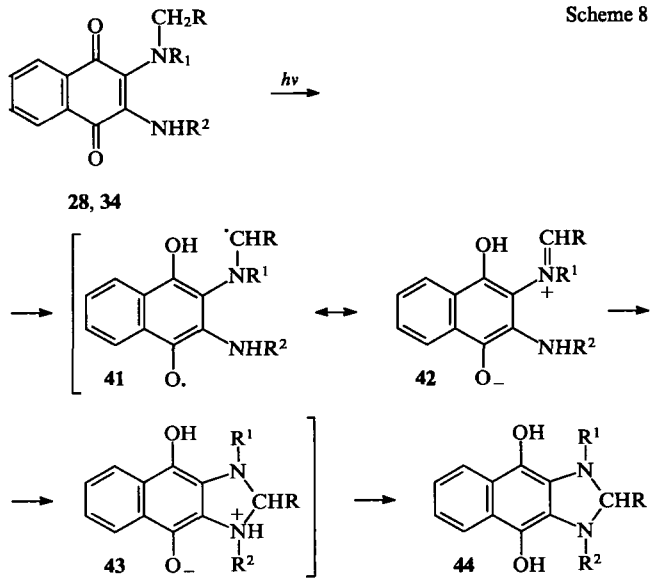
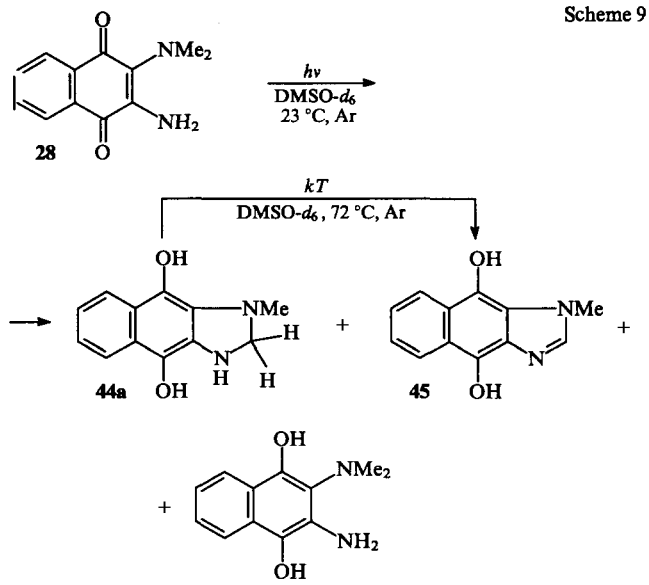
nature of the cyclic alkylamino-group, naphthoimidazole derivatives **36**,[49] enaminoquinones **33**,[49,51] as well as 1,2,3,4-tetrahydro-13-alkylphenyl)-3,1-(iminoethano)benzo[*g*]quinoxaline-5,10-diones **38** [51–53] are formed at 80 °C (Scheme 7).



Tetrahydrobenzo[*g*]quinoxalinediones of type **38** are also the main products of the photolysis of 2-(4-alkylpiperazino)-1,4-naphthoquinones with a secondary amino-group in the 3-position; compound **34** (R^1 = C_6H_4Me-*p*), having a phenyl group in the 4-position in the piperazine ring, gives rise to the enaminoquinone **40** and the corresponding naphthoimidazoledione **36** (X = NPh) in addition to benzoquinoxalinedione **39**.[51–53]

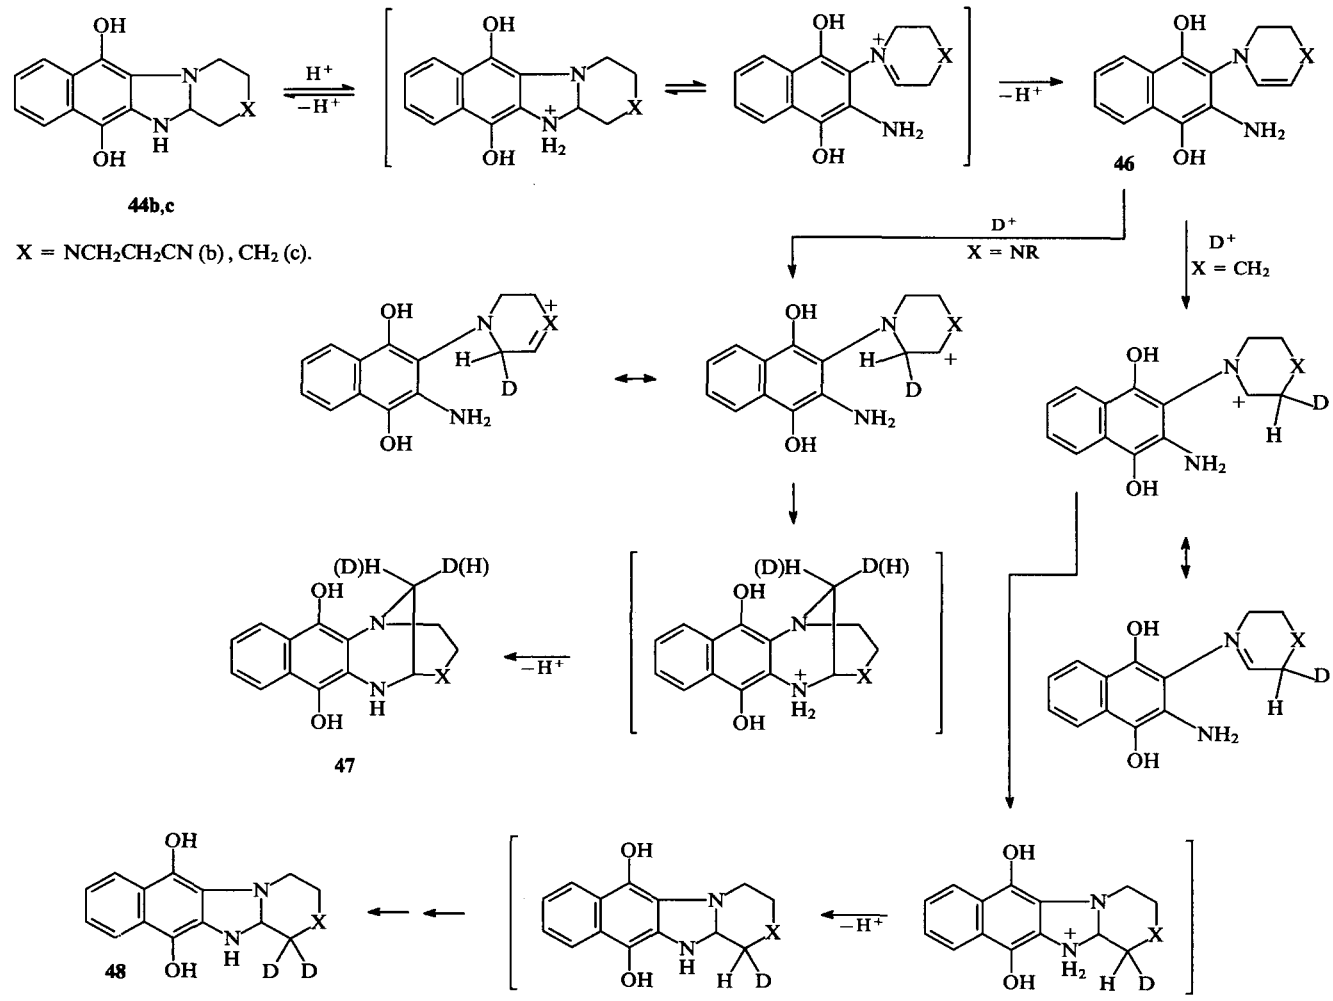
The wide variety of the data obtained is due to the increased sensitivity of the primary photolysis product to atmospheric oxygen and heating. It has been established by NMR spectroscopy that this product has the structure of naphthodihydroimidazolediol **44**. In contrast to a polar medium where the spectrum is recorded directly, in a nonpolar medium the spectrum of the photolysis product cannot be recorded; it has been suggested that the photolysis stops at the stage involving the formation of the zwitterion **43**. This enabled the authors[39] to conclude that the *ortho*-amino-group participates in the reactions of the biradicals **41** arising in the intramolecular photochemical reduction process (Scheme 8).



The naphthodihydroimidazolediols **44** are relatively unstable. In order to elucidate the pathway leading to the formation of a wide variety of final photolysis products from them (of the type of compounds **30** and **35**–**38**), a study was made of the influence of various factors (temperature, atmospheric oxygen, and the structure of the compounds) on their further reactions.[39,51,52] It was shown that naphthodihydroimidazolediols **44a**, which are unsubstituted in the 2-position, are oxidised under an inert atmosphere at a temperature in excess of 20 °C to the corresponding naphthoimidazolediols **45**, with the initial quinone or the solvent serving as the hydrogen acceptor.[39] In contrast to dihydroimidazolediol **44a**, which has no substituent in the 2-position in the imidazoline ring (Scheme 9), solutions of the products of the photolysis of 3-amino-2-piperidino-1,4-naphthoquinones **44** [R, R^1 = $(CH_2)_4$, R^2 = H, Et, *p*-MeC_6H_4] are stable at ~20 °C under an inert atmosphere. On exposure to atmospheric oxygen, they give rise to the products of the oxidation of the imidazoline and naphthalene rings of type **35** and **36**.[39,51]

A significant influence of the structure of naphthodihydroimidazolediols on their subsequent thermal reactions has been observed for compounds **44b**, c in which the imidazoline ring has a [2-*a*]-junction with a piperidine or 4-substituted piperazine ring. It was found that heating of compound **44b** — the product

Scheme 8



Scheme 9

of the photolysis of 2-[4-(2-cyanoethyl)piperazino]-1,4-naphthoquinone — leads to recylisation with formation of 1,2,3,4-tetrahydro-13-(2-cyanoethyl)-3,1-(iminoethano)benzo[*g*]quinoxaline-5,10-diol **47**, which is oxidised to the corresponding dione **38**. In the case of the [1,2-*a*]-junction between the imidazoline ring of naphthodihydroimidazolediol and a piperidine (compound **44c**) or piperazine ring having an electron-accepting substituent in the 4-position (compound **44b**), the thermolysis product has the structure of naphthodihydroimidazolediol **48**, i.e. the rearrangement is degenerate in character. On the basis of deuterium exchange data, a mechanism was proposed for the recyclisation of naphthodihydroimidazolediols, including the intermediate formation of the reduced form **46** of the enaminoquinone (Scheme 10).[51,52]

Scheme 10

Thus it has been shown[39,51,52] that, in the photolysis of 3-amino-2-dialkylamino-1,4-naphthoquinones, the *ortho*-substituent participates in the formation of the structure of the primary stable photolysis product—naphthodihydroimidazolediol, the subsequent reactions of which are determined by its structure and the photolysis conditions.

IV. Conclusion

It follows from the few available data on the mechanism of the photolysis of 2-dialkyl(1,ω-alkylene)amino-1,4-naphthoquinones that, regardless of the presence of other substituents in the naphthoquinone, the primary stage of the process is the phototransfer of a proton from the carbon atom in the α-position in the dialkylamino-group to the oxygen atom of the carbonyl group. The postulate that biradical structures of type **8** are formed and isomerise to the zwitterions **9**,[37] the subsequent cyclisation of which proceeds, depending on the structure, either with participation of the oxygen atom (formation of naphthodihydrooxazoles)[25, 33,34] or with participation of the *ortho*-substituent,[7,39,47–52] is entirely logical. The structure of the final photolysis product depends both on the irradiation conditions (temperature, the presence of atmospheric oxygen and water) and on the structure of the initial quinone.

NMR spectroscopy proved to be useful for the establishment of the mechanism of the photolysis of various 2-dialkylamino-1,4-naphthoquinones. It makes it possible to determine reliably the structure of the primary photolysis products and the structure of the compounds formed as a result of further dark reactions.

The questions concerning the structure of the primary photolysis products when 2-dialkyl(cycloalkyl)amino-1,4-naphthoquinones contain in the 3-position substituents other than a hydrogen or halogen atom and alkyl, alkoxy- and amino-groups and their influence on the subsequent reactions remain obscure. The problem of the behaviour of the primary photolysis products on further irradiation requires resolution.

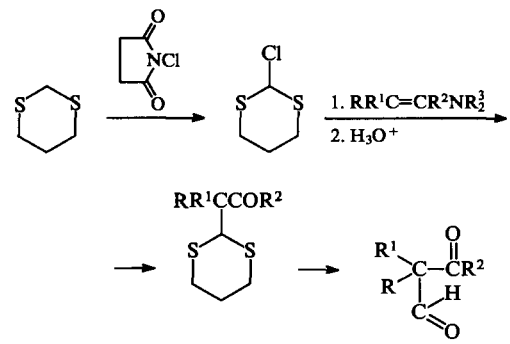
Abstract. The results of studies on the use of sulfides as synthons in organic synthesis are treated systematically and surveyed. The practical applications of sulfides are examined. The bibliography includes 187 references.

I. Introduction

The application of sulfides as synthons in fine organic synthesis is based on the characteristics of their reactivity manifested in the polarisation and low strength of the C–S bond, as a result of which it is relatively easily cleaved by both nucleophiles and electrophiles. The high lability of this bond makes it possible to eliminate, when required, the sulfide functional group, which thus fulfills its purpose. The use of sulfides for the protection of various functional groups and also as synthons for alkyl halides, acid chlorides, etc. is based on this fact. For example, methyl methylthiomethyl sulfide is a synthon for the non-existent formyl nucleophile,[1] because the conversion of RX into RCHO can be achieved with its aid.

$$(MeS)_2CH_2 \xrightarrow{BuLi} (MeS)_2CHLi \xrightarrow{RX} (MeS)_2CHR \xrightarrow{HgCl_2(H_2O)} RCHO$$



Bearing in mind the final results of the use of 2-chloro-1,3-dithiane in the synthesis (Scheme 1), it can be regarded as a synthon for the formyl cation.[2]

It is noteworthy that the strength of the C–S bond in sulfides is greatly influenced by the presence in the α-position of other heteroatoms (Cl, Br, N, O) and functional groups (C=O, C=C, C≡C, OH, SR, SO_2R, etc.). Therefore the introduction of heteroatoms and groups in the α-position relative to the sulfur atom makes it possible to regulate the lability of the C–S bond in sulfides.

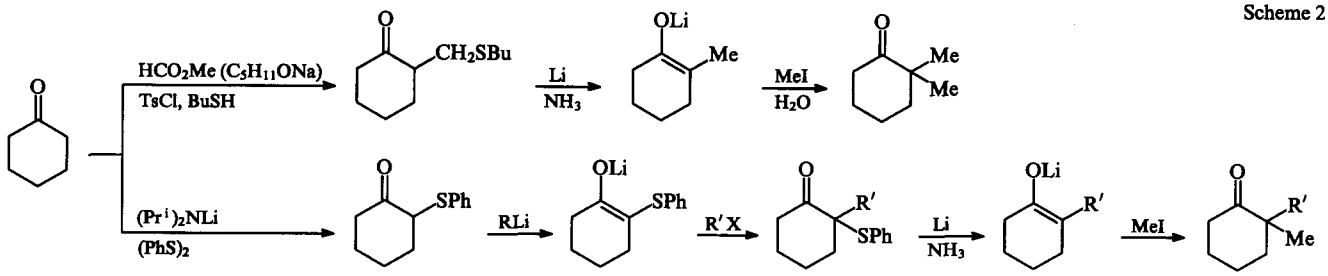
Scheme 1

Yet another feature of sulfides used in organic synthesis is the high susceptibility of the sulfur atom to attack by nucleophiles with formation of relatively stable and at the same time highly reactive intermediates (sulfonium salts, ylides, carbenes, etc.) participating in the transfer of alkylidene and other groups and also in a wide variety of rearrangements with formation of various products.

The ability of the sulfur atom in sulfides to pass fairly readily from one valence state to another and also to stabilise the α-carbanionic centre is frequently used in organic synthesis, for example, for the formation of saturated and unsaturated carbon–carbon bonds.



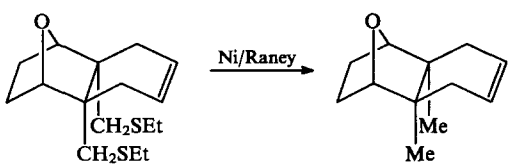
The primary products of the reactions of sulfides such as sulfoxides, sulfonium salts, sulfur ylides, sulfilimines, etc. have found extensive application in organic synthesis. Therefore a whole series of syntheses based on sulfides involve the conversion of the sulfide group into these products with subsequent transformation of the latter without their isolation from the reaction mixture.

Apart from fine organic synthesis, sulfides are widely used in agriculture, in the industrial manufacture of polymers, in the pharmaceutical industry, and in other fields of human activity. This is also reflected in the present review.

II. Cleavage of the C–S bond

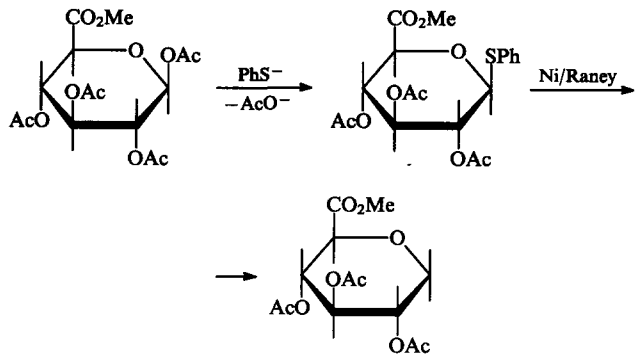
The application of sulfides in organic synthesis, based on the cleavage of the C–S bond, has been known for a relatively long time.[1] For example, chlorolysis of the C–S bond in sulfides serves as a basis of a series of preparative methods of synthesis of sulfenyl chlorides. The reductive cleavage of the C–S bond is

Scheme 2



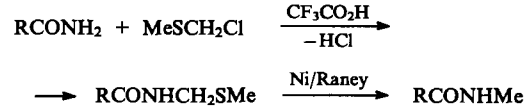
used in the synthesis of certain thiols and, in particular, toluenethiol and 2-propene-1-thiol. The thermal disproportionation of dialkyl sulfides and carboxylic acid esters is a useful alternative esterification procedure. By virtue of the high lability of the C–S bond, benzyl methyl sulfide $PhCH_2SMe$ is used as a source of the benzylcarbonium ion $PhCH_2^+$, the interaction of which with activated arenes in the presence of $ZnCl_2$ or $CuCl_2$ results in the formation of *ortho*- and *para*-substituted derivatives. The use of sulfides for the interconversion of functional groups in complex multistage organic syntheses began to be used only in the last 10–15 years, which can be explained by the lack of effective methods for the generation and removal of the sulfide functional group. Some of these reactions can be achieved also by other procedures, but the reactions using sulfides are as a rule distinguished by a higher selectivity.[1] A series of effective methods based on the use of thiols,[1,3] sulfenyl chlorides,[4–10] α-chlorosulfides,[1,11–13] unsaturated sulfides,[14,15] α-chlorocarbonyl sulfides,[16] α-chloroimide sulfides,[17] and organometallic compounds[18] have been developed in recent years for the introduction of the sulfide functional group into the molecules of organic substances. Depending on the nature of the reaction, a whole series of chemical, electrochemical, thermal, photolytic, and other methods have been developed for the removal or transformation of the sulfide functional group.

1. Hydrogenolysis of the C–S bond

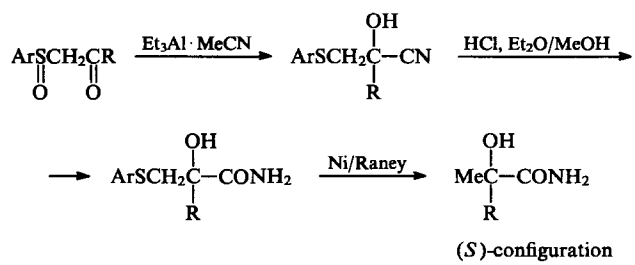


The hydrogenolysis and reductive cleavage of the C–S bond take place in the presence of reagents such as lithium in ethylamine, sodium in liquid ammonia, lithium tetrahydroaluminate, Raney nickel in boiling ethanol, and sodium tetrahydroborate in isopropyl alcohol. The electrochemical reductive cleavage of the C–S bond has come to be used increasingly in recent years.[1]

One of the first examples which demonstrated the advantage of the generation of the sulfide functional group with its subsequent removal by reductive cleavage has been Stork's synthesis of cantharidin, in the last stages of which the reductive cleavage of the C–S bond with the aid of Raney nickel was used to convert the ethylthiomethyl group into the methyl group.



The replacement of the acetoxy-group by the phenylthio-group with subsequent reductive cleavage of the C–S bond is used for the selective elimination of the acetoxy-group and the conversion of a D-glucuronic acid derivative into the deoxy-analogue.[19]



The introduction of the sulfide functional group with subsequent hydrogenolysis of the C–S bond (Scheme 2) has found extensive applications for the synthesis of alkyl-substituted cyclic ketones.[1]

The application of chloromethyl methyl sulfide in the synthesis of *N*-methyl-substituted carboxylic acid amides has been described.[20] The reductive cleavage of the C–S bond is used to eliminate the methylthio-group in the last stage of this synthesis.

The hydrogenolysis of the C–S bond has been used increasingly in recent years in stereospecific syntheses.[21–23] For example, the asymmetric synthesis of α-hydroxyacid amides from chiral β-oxosulfoxides[23] includes stages involving the reduction of the sulfoxide group to the sulfide group and the hydrogenolysis of the C–S bond with the aid of Raney nickel.

(*S*)-configuration

2. Hydrolysis of the C–S bond

Aqueous solutions of mercury acetate and inorganic acids, hydrogen chloride and bromide in acetic acid, divalent mercury salts in an acid medium, etc. are used for the hydrolytic cleavage of the C–S bond.[1]

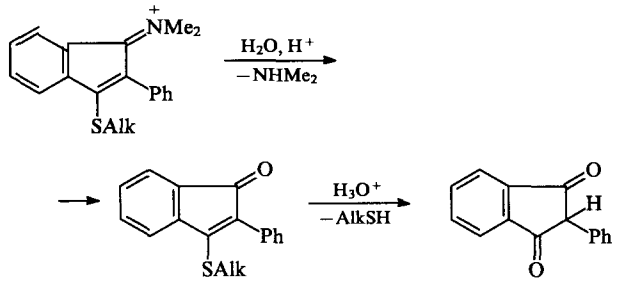
In contrast to unsaturated sulfides, the hydrolysis of which proceeds under severe conditions, unsaturated sulfides are relatively easily hydrolysed with formation of unsaturated alcohols which rearrange to carbonyl compounds. This is frequently used to synthesise aldehydes and ketones. For example,

the conversion of phosphorus ylides into ketones[24,25] includes stages where the sulfide functional group is introduced and the C–S bond is subjected to hydrolytic cleavage.

$$Ph_3P{=}CHR \xrightarrow[-HCl]{R^1SCl} Ph_3P{=}C(R)SR^1 \xrightarrow[-Ph_3PO]{R^2CHO} R^2CH{=}C(R)SR^1 \xrightarrow[-R^1SH]{H_2O} R^2CH_2COR$$

R = H, Me, COOEt, CN, COPh, 2-$NO_2C_6H_4$;
$R^1 = R^2$ = Alk, Ar.

A similar synthetic procedure has been used in the preparative synthesis of α-alkylthioketones.[26]



$$(EtO)_2P(O)CH{=}CH_2 \xrightarrow{MeSCl} (EtO)_2P(O)CH(SMe)CH_2Cl \xrightarrow{Et_3N} (EtO)_2P(O)C(SMe){=}CH_2 \xrightarrow[EtONa]{RSH} (EtO)_2P(O)CH(SMe)CH_2SR \xrightarrow{ArCHO} ArCH{=}C(SMe)CH_2SR \xrightarrow{H_3O^+} ArCH_2C(=O)CH_2SR$$

A new method of synthesis of ketones from organotin compounds[27] also includes a stage involving the hydrolytic cleavage of the C–S bond.

$$RCH{=}C(SPh)SnBu_3 \xrightarrow[CH_2Cl_2]{SnCl_4} RCH{=}C(SPh)SnCl_3 \xrightarrow{ArH\ (AlCl_3)} RCH{=}C(SPh)Ar \xrightarrow{HCl\ (AcOH)} RCH_2C(=O)Ar$$

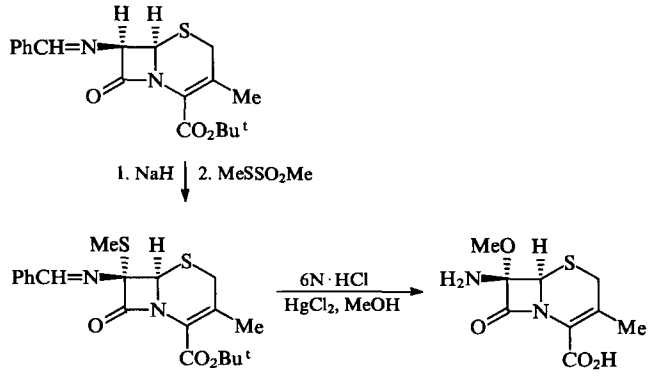
R = Pr, Pr^i, Bu^i; Ar = Ph, *p*-MeC_6H_4.

In the synthesis of cyclic 1,3-diketones from 3-alkylthio-2-phenyl-1-indenyl-*N*,*N*-dimethyliminium salts,[28] one of the keto-groups is formed as a result of the hydrolytic cleavage of the C–S bond.

A new method of synthesis of conjugated dienals, consisting of the stepwise introduction of the aldehyde group as a result of hydrolytic cleavage of the C–S bond and the introduction of a double bond as a result of the elimination of the tosyl group, has been described.[29]

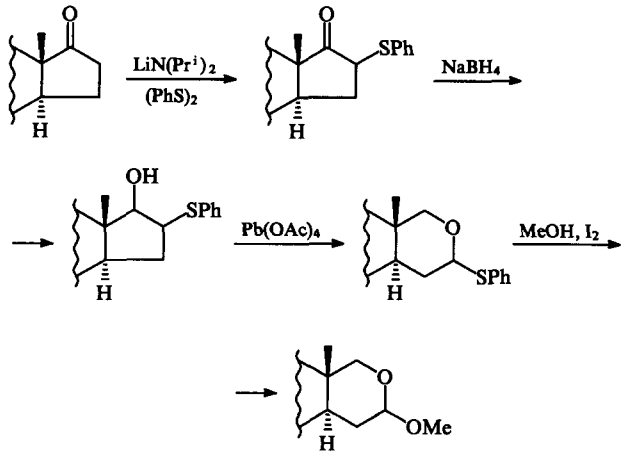
$$TsCH_2CH{=}CH{-}CH{=}CHSMe \xrightarrow[2.\ RBr]{1.\ BuLi,\ THF} TsCH(R)CH{=}CH{-}CH{=}CHSMe \xrightarrow{HCl\ (H_2O,\ MeCN)} TsCH(R)CH_2CH{=}CH{-}C(=O)H \xrightarrow[80\ ^\circ C]{MeCN} RCH{=}CH{-}CH{=}CH{-}C(=O)H$$

$$TsCH_2CH{=}CH{-}CH{=}CHSMe \xrightarrow[2.\ 2\,RBr]{1.\ NaH,\ THF} TsC(R)_2{-}CH{=}CH{-}CH{=}CHSMe \xrightarrow[MeCN,\ 80\ ^\circ C]{HCl} R_2C{=}CH{-}CH{=}CH{-}C(=O)H$$



R = $PhCH_2$.

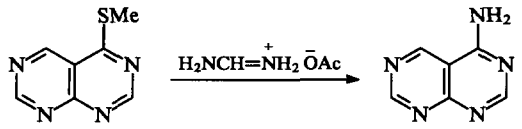
$$TsCH_2CH{=}CH{-}CH{=}CHSMe \xrightarrow[2.\ KH\ (THF,\ TMDA)]{1.\ Br(CH_2)_4CH(Br)Et} \text{Ts-substituted cyclohexene} \xrightarrow{HCl\ (MeCN)} \text{cyclohexene-CH=CH-CH=CH-C(=O)H}$$



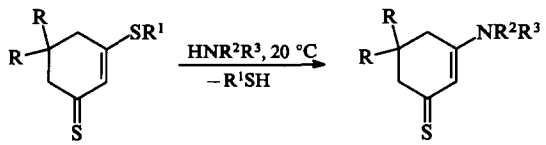
TMDA = tetramethylenediamine.

3. Alcoholysis of the C–S bond

The reaction involving the substitution of the sulfide group by an alkoxy group is used in rare instances, which is evidently due to the lack of effective methods for carrying out this process. As a rule, the alcoholysis of the C–S bond proceeds on treatment with alcohols in the presence of mercury dichloride, iodine, and other inorganic reagents. For example, methanol in the presence of mercury dichloride is used to substitute the methylthio-group by the methoxy-group in the synthesis of a derivative of cephalosporin.[1]

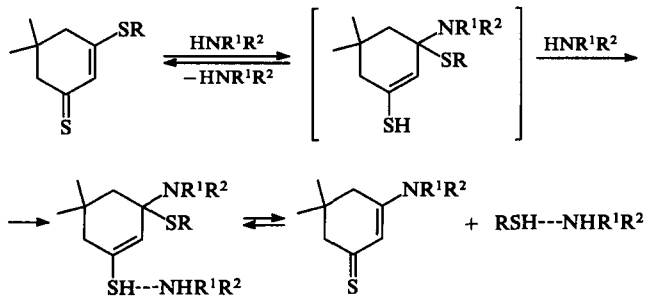


In the synthesis of acetals from cyclic ketones,[30] methanol in the presence of iodine is used to substitute the phenylthio-group by the methoxy-group.

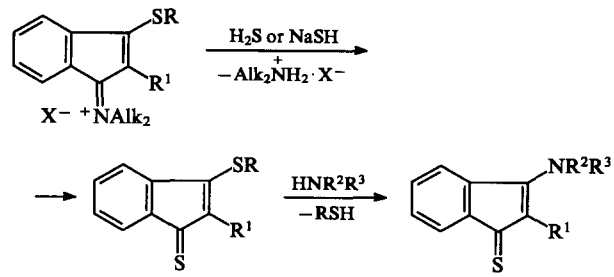


4. Aminolysis of the C–S bond

The replacement of an alkylthio-group with a saturated carbon atom by the amino-group or a substituted amino-group takes place when sulfides are treated with ammonia, amines, amidines, and other nitrogen-containing compounds. For example, azaheterocyclic sulfides undergo aminolysis fairly readily on treatment with formamidine [formamidinium? (Translator)] acetate—a process which is used in subsequent reactions of these heterocyclic compounds. [1]

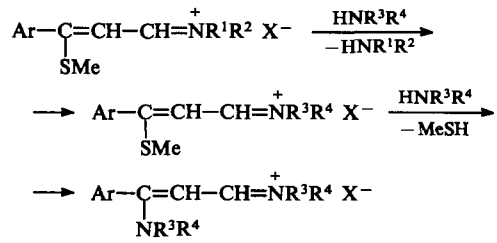


As a synthetic procedure, the aminolysis of the C–S bond has been used in recent years to modify groups such as $RSC=CR^1-CR^2=S$ and $RSC=CH-CH=NR^1$ in thiones and enamines. It has been noted, [31] for example, that 3-alkylthiocyclohex-2-ene-1-thiones react readily with ammonia and primary and secondary amines at 20 °C in benzene, chloroform, and alcohols, and dimethylformamide (DMF), affording 3-aminocyclohex-2-ene-1-thiones:



R = Me; R^1 = Me, Et; R^2 = Me; R^3 = Alk.

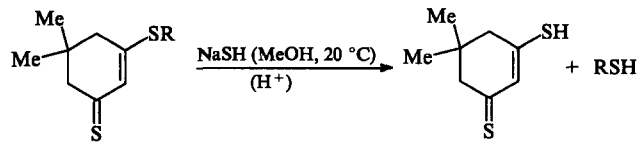
Detailed study of this reaction showed [32] that the aminolysis proceeds via a stage involving the formation of a stable intermediate in mobile equilibrium with the final product and that the aminolysis process itself can be described as 1,4-addition–elimination.



N,N-Disubstituted indenyliminium salts are converted into 3-amino-2-arylindene-1-thiones via a stage in which the intermediate 3-alkylthio-2-arylindene-1-thiones are subjected to aminolysis. [32]

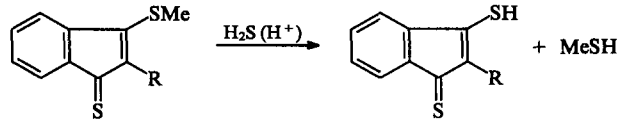
R = Me, Et; R^1 = Ph; R^2 = Ph, Me; R^3 = Me; X = BF_4, I.

It has been noted [33] that, in the reaction of 3-alkylthiopropenyliminium salts with alkyl- and aryl-amines, transamination is accompanied by the aminolysis of the C–S bond, which results in the formation of salts of enaminoimines containing identical substituents at the nitrogen atom.



Ar = Ph, 4-$MeOC_6H_4$;
R^1 = R^2 = Alk; R^3 = Alk, H; R^4 = Alk, Ar;
X = ClO_4, I.

The exchange of the alkylthio-group for the amino-group proceeds in an acid medium. In the case of X = ClO_4, the yield of the final product is 80%, while for X = I it is only 38%.

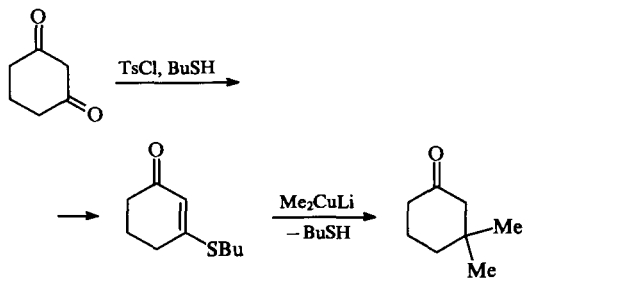


5. Hydrothiolysis of the C–S bond

The replacement of the alkylthio-group by the mercapto-group at an unsaturated carbon atom takes place in the reaction of unsaturated sulfides with sodium hydrogen sulfide in methanol, which is used in the synthesis of 5,5-dialkyl-3-mercaptocyclohex-2-ene-1-thiones. [34]

R = Me, Et.

A similar replacement occurs in the reaction of unsaturated sulfides with hydrogen sulfide in an acid medium. This property is used in the synthesis of 3-mercaptoindene-1-thiones. [32,36]



R = H, Et, Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4.

6. Cleavage of the C–S bond by organometallic compounds

When sulfides are acted upon by organometallic compounds, the sulfide group may be replaced by an alkyl group. The presence in the α-position in sulfides of groups such as C=O, C=C, C≡C, etc. promotes this reaction. For example, ketones are formed in high yields in the reactions of α-oxoalkyl sulfides with R_2CuLi; the formation of tertiary alcohols due to the competing attack on the carbonyl group is not observed under these conditions.[1,36] One of the stages of the synthesis of the pheromone of the German cockroach [3,11-dimethyl-2-nonacosanone (Translator)] involves the cleavage of the C–S bond by treat-ment with similar reagents.[37]

The replacement of the sulfide group by alkyl groups with the aid of organometallic compounds is used also in the synthesis of cyclic ketones[38,39] and acetylenes.[40]

$$MeSC{\equiv}C{-}C{\equiv}CEt + PrLi \xrightarrow[-MeSLi]{} PrC{\equiv}C{-}C{\equiv}CEt$$

7. Desulfurisation of sulfides

Sulfides containing other heteroatoms and functional groups in the α-position tend as a rule to undergo sulfur displacement reactions. The desulfurisation of such sulfides proceeds in the presence of alkali metal hydrides or trivalent phosphorus compounds. Thiirans are then formed at an intermediate stage.[1]

$$ArCH_2SCH(Cl)Ar \xrightarrow{Ph_3P,\ Bu^tOK} \left[\begin{array}{c} ArCH-CHAr \\ \quad\ \backslash / \\ \quad\ S \end{array}\right] \xrightarrow[-H_2S]{} ArCH{=}CHAr$$

The desulfurisation of sulfides is used as a synthetic procedure in the synthesis of sterically hindered alkenes[41] and also in the synthesis of corrins in order to form a C=C bond.[1]

$$RN{=}CR^1SCH_2COAr \xrightarrow{(EtO)_3P} RNHC(R^1){=}CHCOAr$$

8. Thermolysis of the C–S bond

The cleavage of the C–S bond in sulfides at high temperatures leads to the formation of thiyl and alkyl (or aryl) radicals.[42–45] The radicals undergo further reactions under the thermolysis conditions with formation of the final products, the composition of which is determined both by the structure of the initial sulfide and by the thermolysis conditions. For example, the thermolysis of diethyl sulfide results in the formation in the gas phase of a mixture, the main components of which are hydrogen sulfide and ethylene.[42,45]

$$(C_2H_5)_2S \xrightarrow{\Delta} C_2H_5\dot{S} + \dot{C}_2H_5 \longrightarrow C_2H_5SH + CH_2{=}CH_2$$

$$C_2H_5SH \longrightarrow C_2\dot{H}_5 + S\dot{H}$$

$$C_2H_5SH + \dot{S}H \longrightarrow Me\dot{C}HSH + H_2S$$

$$C_2H_5SH + \dot{C}_2H_5 \longrightarrow Me\dot{C}HSH + C_2H_5H$$

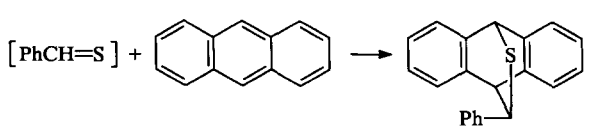
The thermolysis of dimethyl sulfide at 600–650 °C leads to the formation of thiophene.[46,47]

$$Me_2S \xrightarrow[-H_2]{600-650\ ^\circ C} \left[\begin{array}{c} CH_2-CH_2 \\ \quad\ \backslash / \\ \quad\ S \end{array}\right] \longrightarrow \left[CH_2{=}CHSH\right] \longrightarrow \text{thiophene}$$

At 450–500 °C in the presence of phenylacetylene, the same sulfide gives rise to 3-phenylthiophene and benzo[*b*]thiophene.[48]

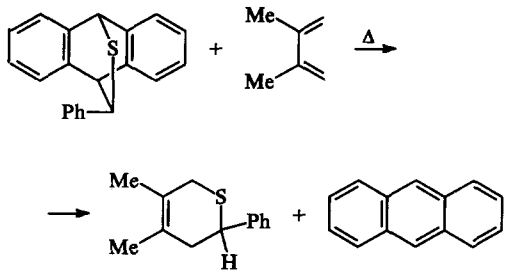
$$Me_2S \xrightarrow{450-500\ ^\circ C} \left[CH_2{=}CH\dot{S}\right] \xrightarrow{PhC{\equiv}CH} \left[\begin{array}{c} C{=}C\dot{H} \\ \quad\ | \\ \quad\ S \\ \quad\ | \\ H_2C{=}CH \end{array}\right] \xrightarrow[-[\dot{H}]]{-[CH_2{=}\dot{C}H]} \text{benzo[b]thiophene},\ \text{3-phenylthiophene}$$

The thermolysis of certain disulfides results in the formation of extremely rare and synthetically valuable intermediates. For example, the vacuum thermolysis of dipropargyl sulfide has been used as a selective path to the synthesis of the unstable thiopropynal.[49]



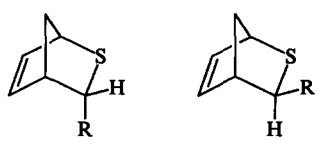
$$(CH{\equiv}CCH_2)_2S \xrightarrow[-MeC{\equiv}CH]{750-850\ ^\circ C,\ 10^{-3}\ Torr} \left[CH{\equiv}C{-}CH{=}S\right]$$

The flash thermolysis of diallyl sulfide and allyl benzyl sulfide leads to the formation of thioacrolein and thiobenzaldehyde respectively.[50–53]



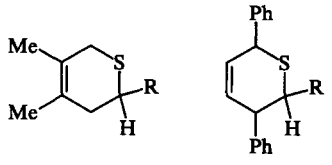
$$(H_2C{=}CH{-}CH_2)_2S \xrightarrow[-MeCH{=}CH_2]{550\ ^\circ C,\ 10-50\ Torr} \left[CH_2{=}CH{-}CH{=}S\right]$$

$$PhCH_2SCH_2CH{=}CH_2 \xrightarrow[-MeCH{=}CH_2]{500-600\ ^\circ C,\ 10-50\ Torr} \left[PhCH{=}S\right]$$

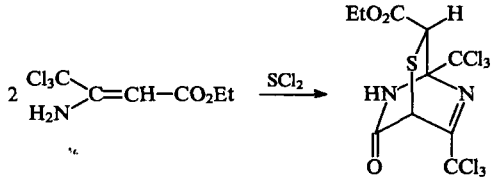


The thermolysis of these sulfides is usually carried out in the presence of dienes or anthracene, which serve as 'trapping agents' for the thioaldehyde formed. For example, anthracene reacts with thiobenzaldehyde to form an adduct which is itself a source of thiobenzaldehyde.[54,55]

When this adduct is heated with 2,3-dimethylbutadiene in a sealed tube, the corresponding 2*H*-dihydrothiane and anthracene are formed.

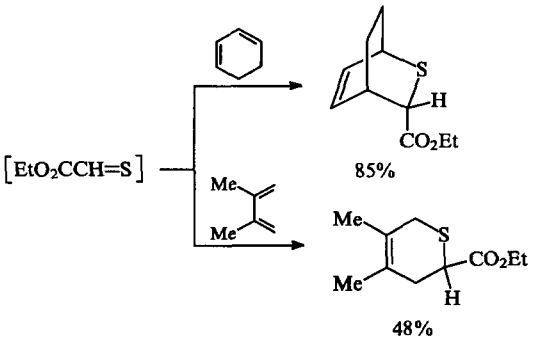


The α-sulfonyldisulfides $RCH_2SSCH(Ts)R$ (R = EtOCO) are excellent substrates for the synthesis of alkoxycarbonylthioformaldehydes.[56] The interaction of these disulfides with triethylamine in the presence of cyclopentadiene affords a mixture of *endo*- and *exo*-adducts, which are extremely valuable for preparative purposes.

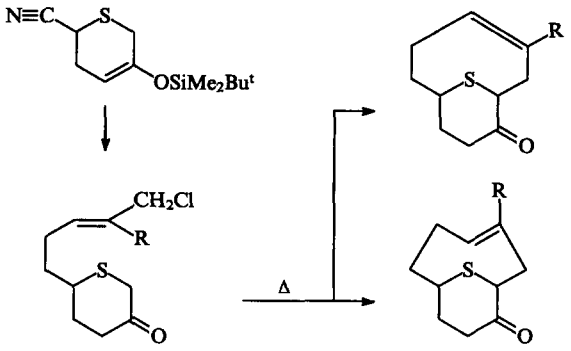


R = EtOCO.

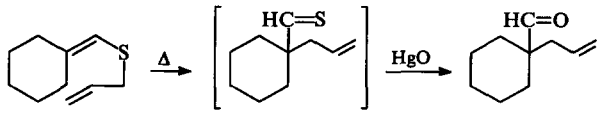
Ethoxycarbonylthioformaldehyde may be generated from these adducts and made to react with other conjugated dienes. For example, when it is heated with 2,3-dimethylbuta-1,3-diene and 1,4-diphenylbuta-1,3-diene, the following adducts are formed:



R = EtOCO.

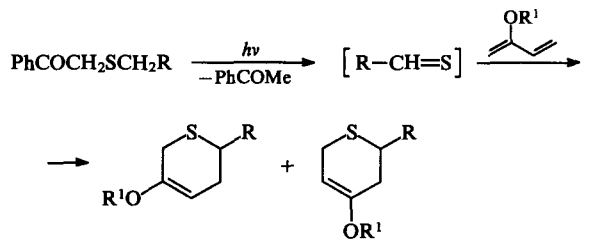


It has been suggested also that a derivative of diazathiabicyclooctane, formed in 34% yield in the reaction of ethyl 3-amino-4,4,4-trichlorocrotonate with sulfur dichloride, be used as a source of alkoxycarbonylthioformaldehydes.[57]



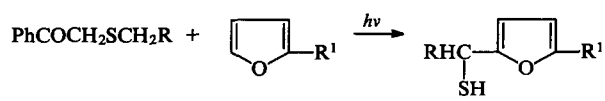
Heating of a solution of this compound in chlorobenzene at 80 °C induces the Diels-Alder retro-reaction and the formation, together with other products, of ethoxycarbonylthioformaldehyde, which reacts with cyclohexa-1,3-diene and also with 2,3-dimethylbuta-1,3-diene.[58]

The synthesis of 11-thiabicyclo[5.3.1]undecenes, which are otherwise difficult to obtain, from the adduct of cyanothioformaldehyde with 2-(*tert*-butyldimethylsiloxy)-buta-1,3-diene has been developed.[59,60]

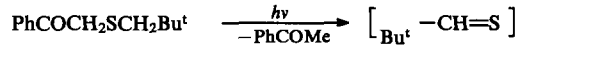


The thermolysis of certain sulfides in the presence of oxidants is of interest for preparative synthesis. For example, whereas the thermolysis of a cyclic sulfide at 160–180 °C leads to polymeric products, in the presence of mercury(II) oxide an aldehyde is formed in 82% yield.[58]

9. Photolysis of the C–S bond

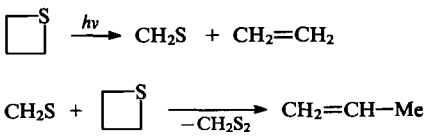


There are so far few examples of the photolytic cleavage of the C–S bond in sulfides and it has not found extensive application as a synthetic procedure for the transformation of the sulfide group. A simple method for the generation of dienophile thioaldehydes by the irradiation of a mixture of organyl phenacyl sulfides with a diene at 0 °C has been described.[58,61]

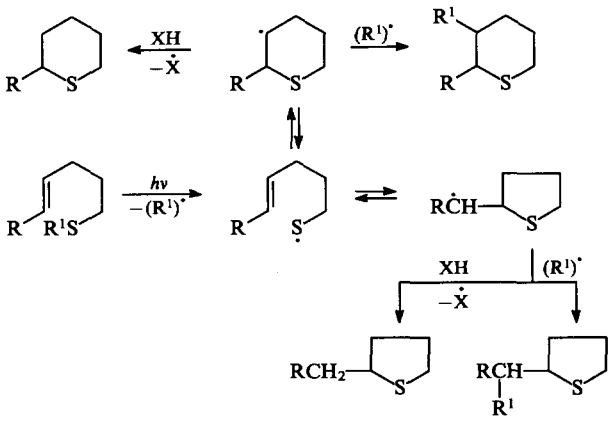


R = H, Ph, MeCO, PhCO, CN, AlkOCO, Ph_2PO, $PhSO_2$;
R^1 = $SiMe_2Bu^t$.

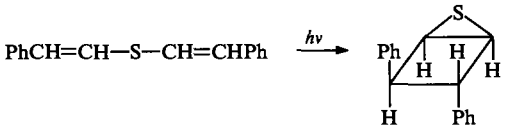
The use of the most reactive dienes in this process makes it possible to 'trap' even thioformyl sulfone $PhSO_2CH=S$ and thioformylphosphine oxide $Ph_2P(O)CH=S$, the oxygen analogues of which are unknown.



The photolysis of organyl phenacyl sulfides in the presence of furan proved to be a convenient and effective method of synthesis of mercaptoalkylfurans.[62]



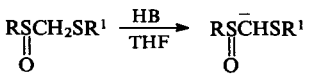
The photochemical decomposition of neopentyl phenacylsulfide is one of the most important methods of synthesis of the relatively stable 2,2-dimethylpropanethial.[63]



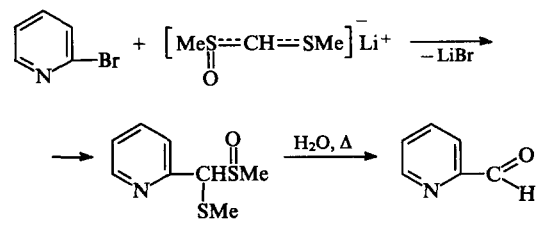
When thietane is irradiated with UV light at wavelengths of 254 and 313 nm in the temperature range 20–200 °C, ethylene and thioformaldehyde are formed. The latter reacts with a molecule of thietane to form an intermediate biradical, the subsequent decomposition of which leads to propene. [64]

The primary stage of the photolysis of alkenyl sulfides is again the cleavage of the C–S bond. The thiyl radicals produced in this process undergo subsequent intramolecular cyclisation with formation of cyclic products. [64]

UV irradiation of bis(2-phenylvinyl) sulfide leads to *trans*-2,3-diphenyl-5-thiabicyclo[2.1.0]pentane. [64]

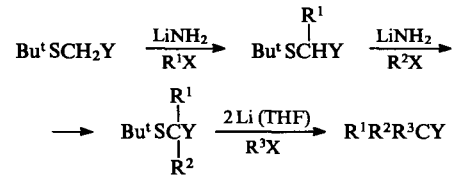


III. Generation of α-sulfenylcarbanions



The stabilisation of the α-carbanionic centre by a divalent sulfur atom is used to generate α-sulfenylcarbanions, which are widely used in organic synthesis to produce both single and double carbon–carbon bonds. Together with alkyl(aryl)thio-groups, other functional groups such as C=O, [6,66] CN, [7,66] EtOCO, [8,66] RSO, [67] NO_2, [68,69] $SiMe_3$, [70,71] RSO_2, [72] etc. can participate in the stabilisation of the carbanionic centre. Carbon–carbon bonds are formed as a result of the alkylation or acylation of α-sulfenylcarbanions and also as a result of the addition of the carbanionic centre to the sp^2-hybridised carbon atom in the C=O and C=C bonds. These synthetic procedures are widely used in the preparation of various compounds together with the elimination of the sulfide group.

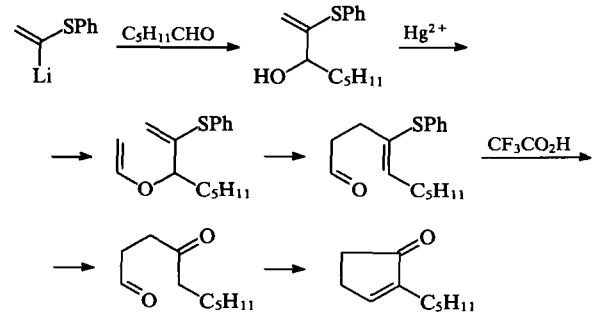
1. Synthesis of carbonyl compounds



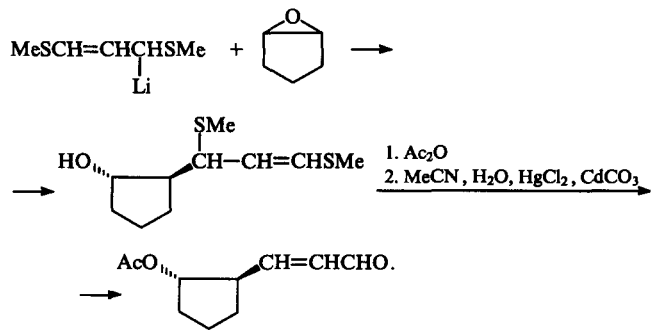
Carbanions containing functional groups other than the alkylthio- or arylthio-groups are frequently employed in the syntheses of carbonyl compounds. For example, the carbanions generated from ethyl methylthiomethyl or ethylthiomethyl methyl sulfoxide by treatment with NaH, BuLi, or Pr^i_2NLi in tetrahydrofuran are used successfully as synthons for acyl anions.

In the form of sodium or lithium salts, these carbanions react readily with primary alkyl halides or tosylates, affording aldehydes after hydrolysis. The interaction of the carbanion MeS(O)$\bar{C}$HSMe with 2-bromopyridine leads to an intermediate, which affords pyridine-2-aldehyde on distillation. [67]

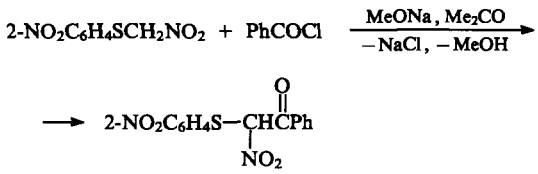
α-(*tert*-Butyl)thio-derivatives of carboxylic acid esters, nitriles, and ketones undergo stepwise alkylation via α-carbanions. The subsequent removal of the *tert*-butylthio-group by lithium in tetrahydrofuran with added naphthalene or trimesitylborane at 20 °C leads to alkyl-substituted carbonyl compounds. [64]



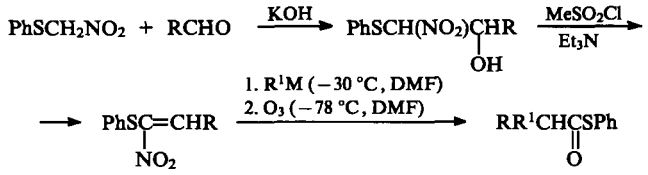
Y = CO_2Me, CO_2Bu^t, CN, COMe.



Phenylthiotrimethylsilylcarbanions are used to convert alkyl halides into aldehydes via alkylation, oxidation of the alkylation products to the sulfoxide, and rearrangement of the sulfoxide to α-trimethylsiloxysulfide, the hydrolysis of which leads to an aldehyde. [73]

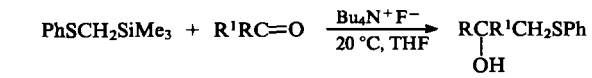


The α-carbanions obtained from vinyl sulfides can be regarded as acyl-anionic synthons, since they are capable of hydrolysing with formation of a carbonyl group, which in fact determines their use in organic synthesis. The synthesis of an unsaturated cyclic ketone by the addition of the carbanion of phenyl vinyl sulfide to hexanal has been described. [64] The alcohol formed is converted by transacetalisation with vinyl ether in the presence of divalent mercury salts into [a substituted?, Translator] vinyl ether, which is converted at 120 °C into an aldehyde. The hydrolysis of the aldehyde in the presence of trifluoroacetic acid leads to a ketoaldehyde, which cyclises to 2-pentylcyclo-penten-2-one.

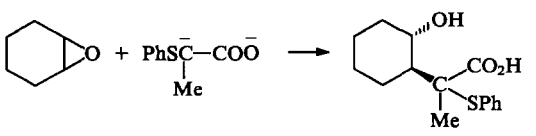


1,3-Bis(methylthio)allyllithium, which is a synthetic equivalent of the anion $\bar{C}H=CH-CH=O$, has found extensive application in the synthesis of *trans*-α,β-unsaturated aldehydes. One of the examples of such synthesis is presented in the scheme below: [64]

It has been shown in relation to the carbanion of 2-nitrophenylthionitromethane [68,69] that α-sulfenylcarbanions are relatively easily acylated by carboxylic acid chlorides with formation of α-arylthioketones.

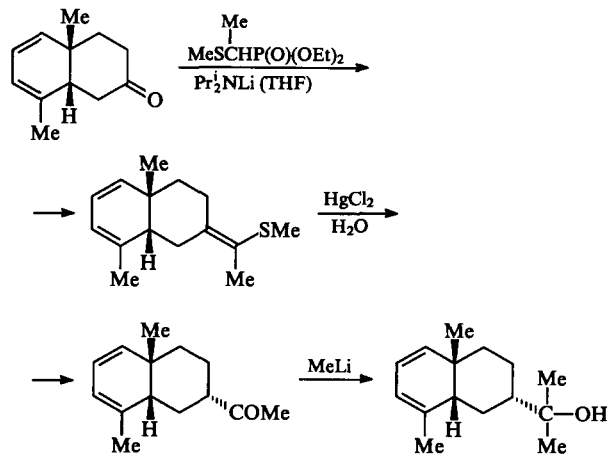


In view of the possibility of the subsequent removal of the sulfide group, one can regard this method as one of the alternative procedures for the synthesis of ketones.



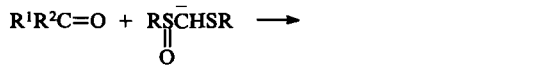
The addition of the anion of phenylthionitromethane to the carbonyl group of aldehydes with subsequent dehydration and ozonisation is used in the synthesis of thioloesters of carboxylic acids. [74]

2. Synthesis of alcohols

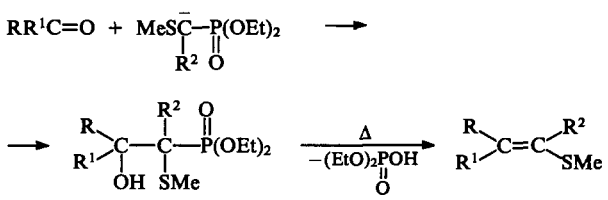


A hydroxy-group may be formed either as a result of the addition of α-sulfenylcarbanions to the sp^2-hybridised carbon atom of the carbonyl group or as a result of the opening of the oxirane ring. For example, the synthesis of secondary alcohols containing the phenylthio-group in the α-position from phenylthio(trimethylsilyl)methane and ketones with subsequent elimination of the trimethylsilyl group has been described. [75]

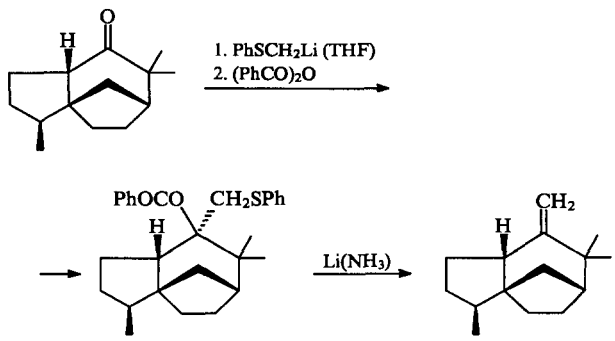
The opening of the oxirane ring by treatment with the dianion of 1-carboxyethyl phenyl sulfide is used in the synthesis of α-derivatives of cyclohexanol. [65]



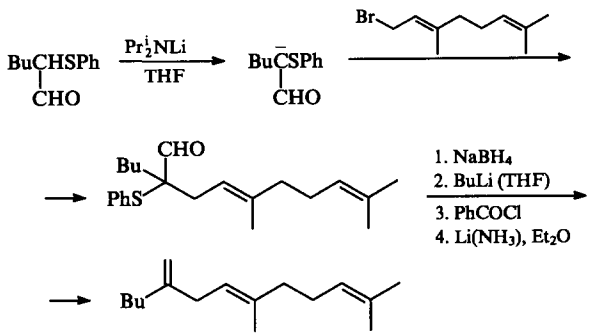
A multistage synthesis of tertiary alcohols has been described in the literature. [76] It is based on the addition of methyl α-diethoxyphosphonoethyl sulfide to the carbonyl group of a cyclic ketone, the subsequent stepwise elimination of the diethyl phosphonate and of the methylthio-group, and the addition of methyllithium to the carbonyl group.



3. Synthesis of unsaturated compounds

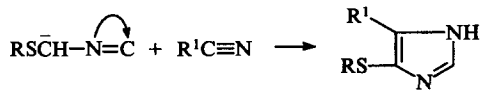


The use of α-sulfenylcarbanions for the formation of new C=C bonds under mild conditions is very important. The addition of α-sulfenylcarbanions to the carbonyl group of ketones leads to β-hydroxysulfides, which are converted into unsaturated sulfides after the elimination of the hydroxy-group. [1]

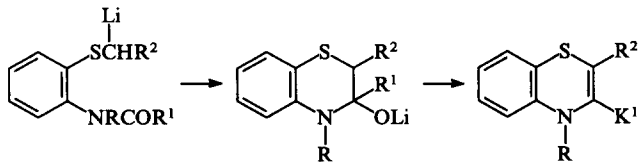


R = Me, Et; $R^1 = R^2 = Me$.

Several methods for the methylenation of ketones involving the use of α-sulfenylcarbanions have been developed. [64] One of them consists in the addition of α-sulfenylcarbanions to ketones with formation of β-hydroxysulfides, which are converted into methylene derivatives after acylation and reductive elimination of the phenylthio-group. The sesquiterpene zizaene has been obtained in this way.

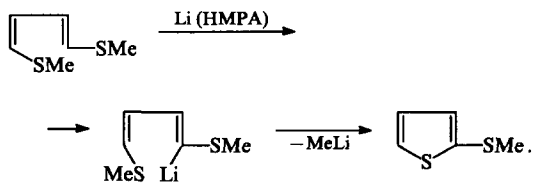


Alkylation of the carbanion $Bu\bar{C}(CHO)-SPh$ followed by the reductive cleavage of the C–S bond is used in the synthesis of 2-butyl-5,9-dimethyldeca-1,4,8-triene. [1]

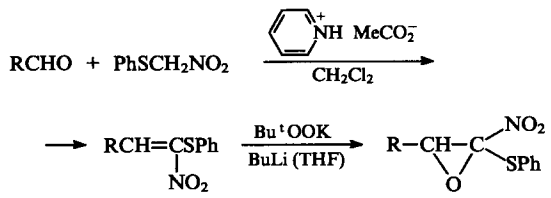


4. Synthesis of heterocyclic compounds

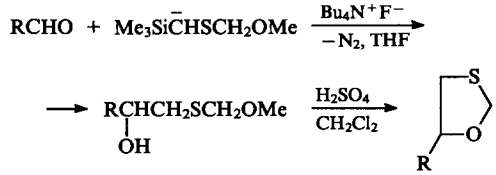
α-Sulfenylcarbanions with functional group substituents are frequently used in the synthesis of heterocyclic compounds. For example, the interaction of the α-isocyano-α-sulfenylcarbanion with nitriles leads to the formation of imidazoles. [64]



The synthesis of 4*H*-1,4-benzothiazines in accordance with the scheme



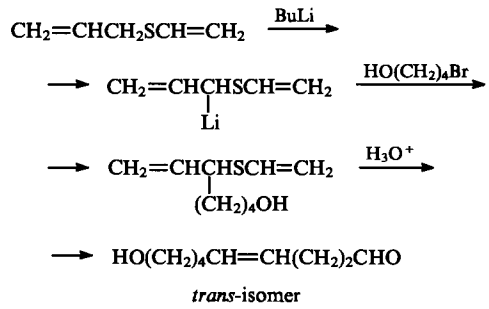
has also been described. [71]



It has been noted [64] that the metallation of a 1,4-bis(alkylthio)alkadiene with lithium in the presence of hexamethylphosphoramide (HMPA) is accompanied by cyclisation with formation of alkylthio-derivatives of thiophene, for example:

The addition of the phenylthionitromethane anion to the carbonyl group in aldehydes with subsequent dehydration and selective oxidation of the ethylene bond constitutes the basis of the synthesis of oxiranes containing the phenylthio-group. [78, 79]

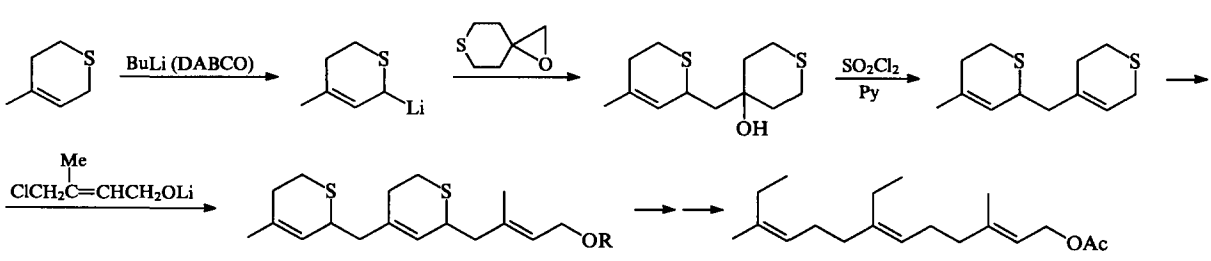
Functionalised β-hydroxysulfides, formed as a result of the addition of α-sulfenylcarbanions to the carbonyl group of aldehydes, can cyclise with participation of the hydroxy-group and other functional groups, which is used in the synthesis of 1,3-oxathiolanes. [80]



R = Ph, 4-MeOC$_6$H$_4$, 4-ClC$_6$H$_4$.

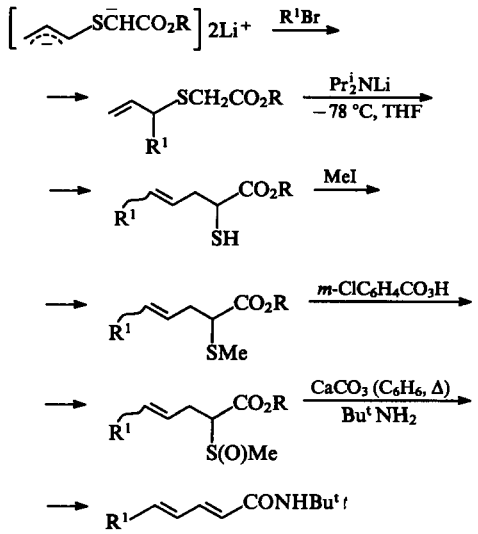
The synthesis of thiiranes [80] and other heterocyclic compounds [81] from α-sulfenylcarbanions has also been described.

5. Synthesis of natural products



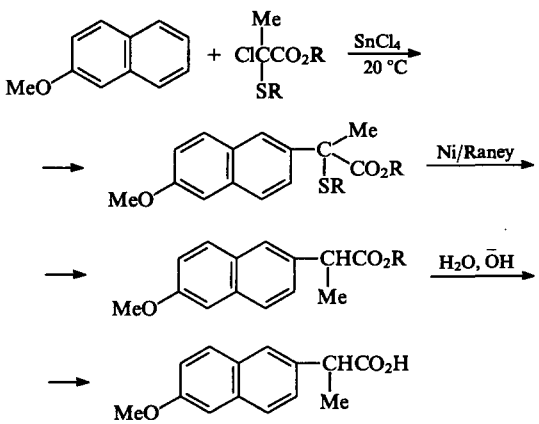
Apart from the synthesis of the sesquiterpene zizaene described above, α-sulfenyl carbanions with functional group substituents have found extensive application also in the syntheses of other natural products. For example, allyl carbanions are most important intermediates in the synthesis of juvenile hormones — cembranolides (Scheme 3). [64]

The hydroxyaldehyde which is a key compound in the synthesis of the pheromone propylure has been obtained by metallating allyl vinyl sulfide and subsequent alkylation and thio-Claisen rearrangement. [64]

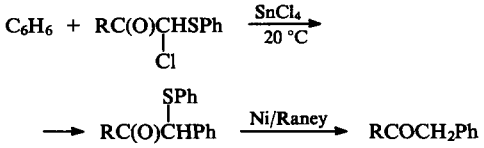


The dianion of allylthioacetic ester is a convenient reagent for the stereoselective synthesis of derivatives of (2*E*,4*E*)-dienoic acids, for example the precursor of the insecticide pellitorine. [82, 83]

Scheme 3

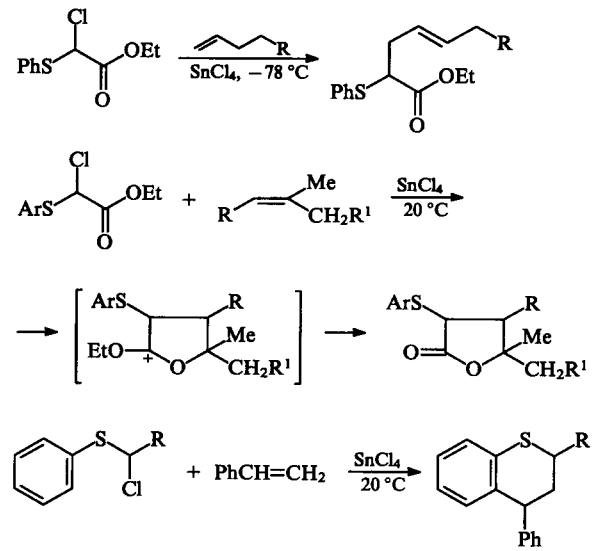


DABCO = diazabicyclo[2.2.2]octane

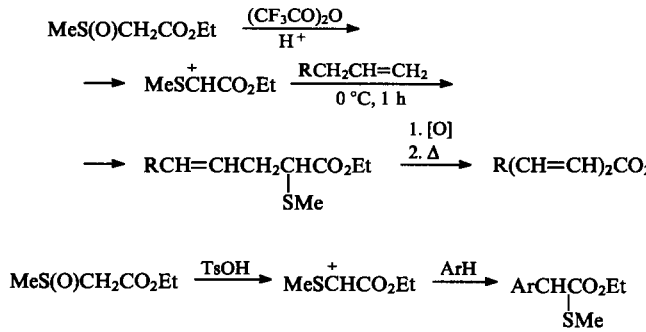


IV. Generation of α-sulfenylcarbonium ions

The sources of α-sulfenylcarbonium ions are as a rule α-chlorosulfides, on the basis of which a series of methods have been developed for the introduction of the sulfide group into aromatic compounds. This synthetic procedure is used in multistage organic syntheses, in particular in the syntheses of various carbonyl compounds. For example, the synthesis of α-(6-methoxy-2-naphthyl) propionic acid includes stages in which β-methoxynaphthalene is alkylated by the α-alkylthio-α-chloropropionic acid ester with subsequent elimination of the alkyl group and hydrolysis of the ester group.[84]



A series of alkyl(aryl) benzyl ketones have been obtained by alkylating benzene with acylchloromethyl phenyl sulfide in the presence of tin tetrachloride and subsequent reductive elimination of the phenylthio-group.[85]

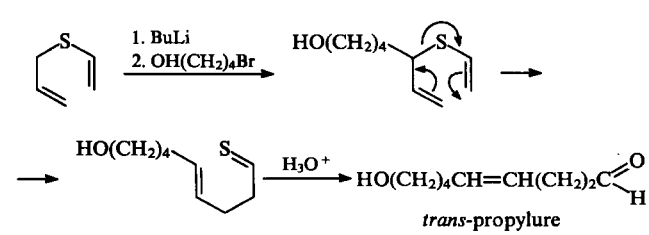


R = Me, Ph, CH_2Ph, $(CH_2)_2Ph$.

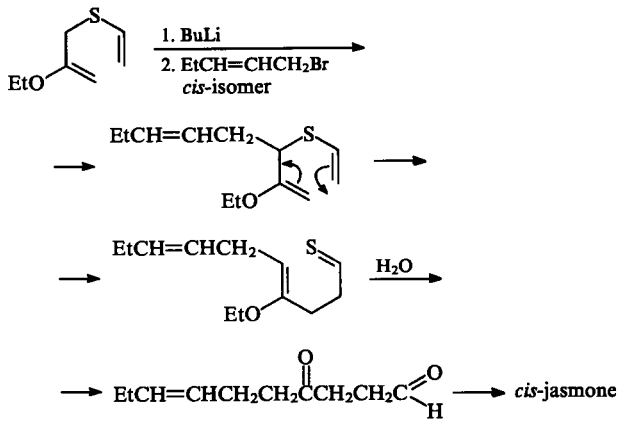
Another aspect of the use of α-sulfenylcarbonium ions in multistage organic syntheses involves their ene-type interaction with terminal alkenes,[86] which is sometimes used to obtain certain heterocyclic compounds.

R = CO_2Et, $CONMe_2$; R^1 = Alk.

Certain sulfoxides are also used as sources of α-sulfenylcarbonium ions. They generate α-sulfenylcarbonium ions under the conditions of the Pummerer rearrangement. For example, it has been noted[64] that the carbonium ion $MeS\overset{+}{C}HCO_2Et$, obtained by the Pummerer rearrangement from the sulfoxide $MeS(O)CH2CO_2Et$, reacts with terminal alkenes via the ene pathway (it is used in the synthesis of dienoic acids) and also enters into alkylation reactions of aromatic hydrocarbons.[87]

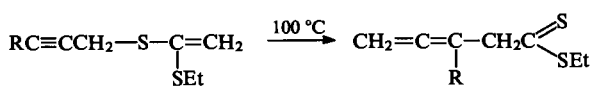


Ar = Ph, C_6H_4Me, C_6H_4Cl.

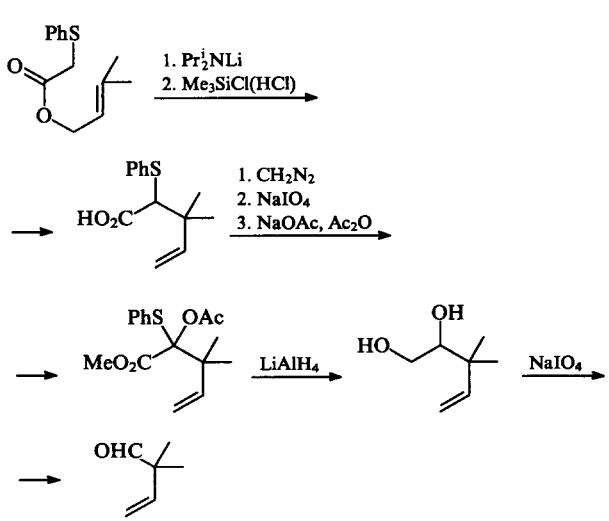


V. Reactions involving the rearrangement of sulfides

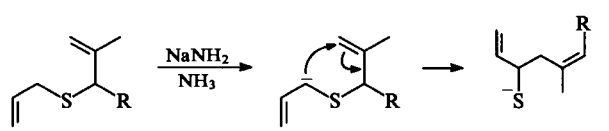
Among the known rearrangements of sulfides, the thio-Claisen rearrangement and also various sigmatropic migrations of alkylthio- and arylthio-groups have found most extensive application. Rearrangements involving the migration of other functional groups and hydrogen atoms are also used.



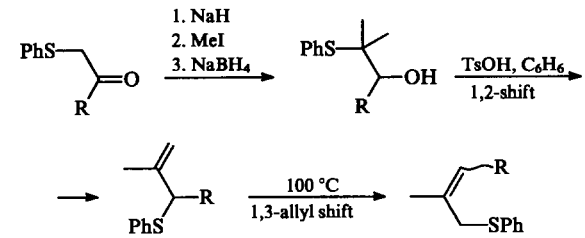
The thio-Claisen rearrangement of carbanions derived from allyl sulfides with subsequent alkylation and cleavage of the $C_{All}-S$ bond (or its hydrolysis) constitutes a convenient method of synthesis of certain aliphatic natural products.[1]



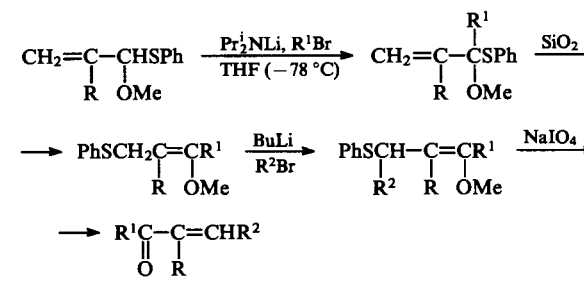
trans-propylure



The thio-Claisen rearrangement of 1-alkylthio-1-propargylthioalkenes[1] to the alkyl esters of dienedithiocarboxylic acids, which are otherwise difficult to obtain and for which other methods of synthesis have not yet been developed, is of special interest.

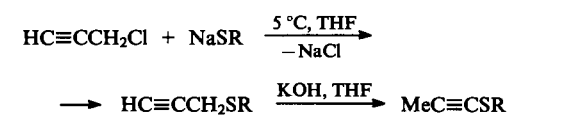


The Claisen rearrangement of allyl α-phenylthioacetates leads to α-phenyl-substituted thiocarboxylic acids, which can be converted further into β,γ-unsaturated aldehydes and the relatively difficult to obtain (*Z*)-diene-2-carboxylic acids.[88]



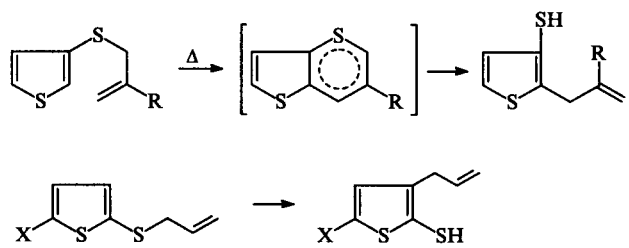
In the synthesis of unsaturated thiolates from allyl sulfides, the [2,3]-sigmatropic rearrangement of the carbanion derived from the allyl sulfide takes place.[89]

A large number of the rearrangements of sulfides involve the migration of the alkylthio- or arylthio-groups.[90–95] For example, the synthesis of unsaturated sulfides from β-oxoalkyl sulfides includes rearrangements involving 1,2- and 1,3-shifts, which make it possible to move the phenylthio-group by one carbon atom along the chain.[90]



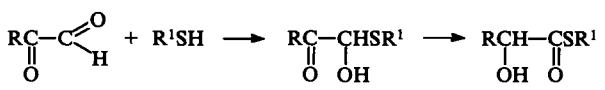
The synthesis of unsaturated ketones from β-methoxysulfides[91] includes a stage involving a rearrangement with migration of the phenylthio-group of the 1,3-shift type.

R = H, Me; $R^1 = R^2$ = Me, Et.



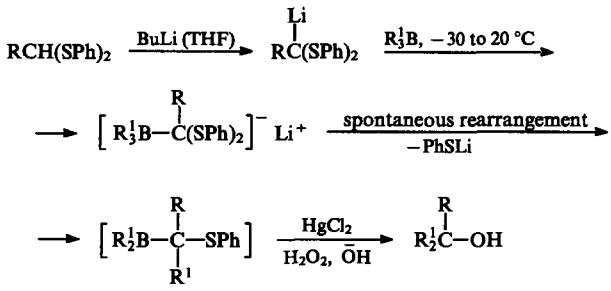
The rearrangement of alkyl propargyl sulfides with the 1,3-shift of the alkylthio-group constitutes the basis of the synthesis of alkylthiopropynes, which are used to obtain polymers.[93]

R = Me, Et, Bu, C_6H_{13}, C_8H_{17}, $C_{10}H_{21}$.



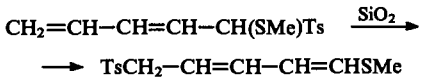
The migration of the alkylthio-group in indole from the 3-position to the 2-position, occurring under the influence of trifluoroacetic acid,[95] is extremely important for the synthesis of alkyl 2-indolyl sulfides, since the sulfenylation of indole by sulfenyl chlorides takes place as a rule in the 3-position.[96,97]

The [3,3]-sigmatropic rearrangement of allyl 2-thienyl and allyl 3-thienyl sulfides, which proceeds via a six-membered transition state, is very important from the standpoint of the synthesis of 2- and 3-allylthiophenethiols.[89]

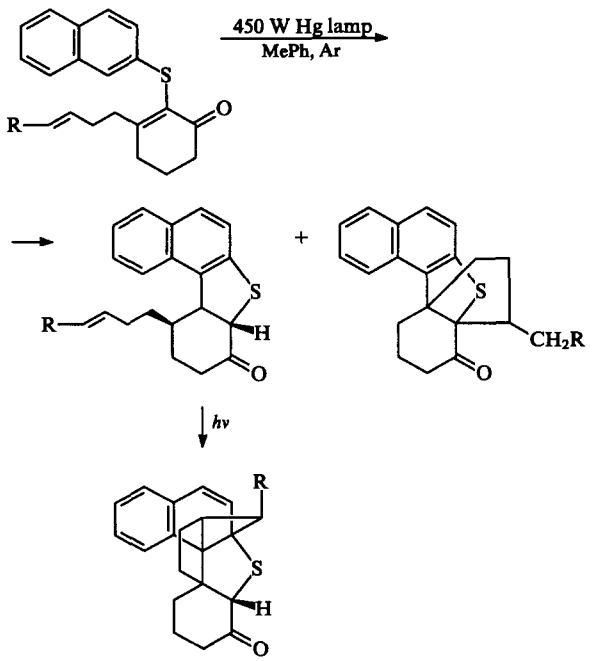


X = H, Me, MeO, MeS, Cl, Br.

Together with the syntheses presented above, a whole series of syntheses based on rearrangements involving the migration of hydrogen atoms and alkyl, arenesulfonyl, and other functional groups have been developed. For example, the synthesis of α-hydroxy-substituted thiocarboxylic acids from α-oxoaldehydes and thiols is based on the rearrangement of the intemediate α-hydroxy-β-oxoalkyl sulfides, which proceeds with migration of a hydrogen atom.



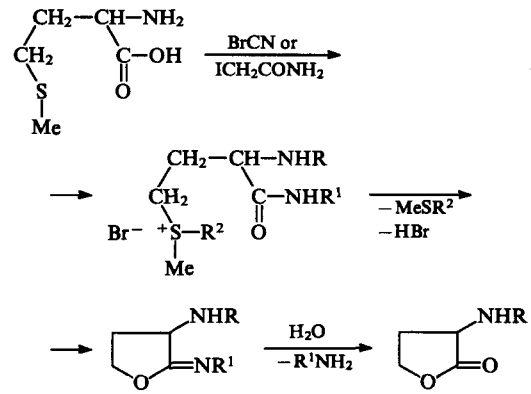
R = Me, Et, Pr; R^1 = Et, Bu.



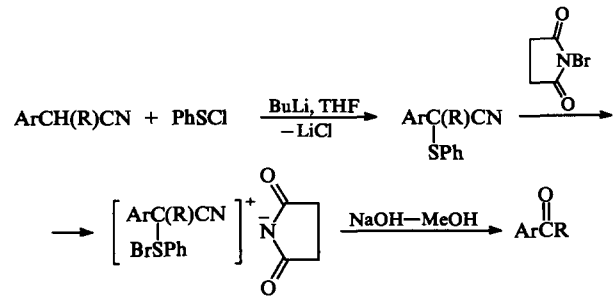
The migration of an alkyl group is especially characteristic of sulfides containing boralkyl groups, which are used in the synthesis of tertiary alcohols from thioacetals. [98]

The rearrangement with migration of the arenesulfonyl group is characteristic of sulfides containing arenesulfonyl and alkyl(aryl)thio-groups at the allylic carbon atom. [99,100] For example, the synthesis of 1-methylthio-5-tosylpenta-1,3-diene is based on the rearrangement of 1-methylthio-1-tosylpenta-2,4-diene.

The synthesis of cyclic sulfides based on the photoinduced intramolecular cycloaddition reactions of arylthiocyclohexenones [101] and phenylthiocyclohexanones has been described. [102]

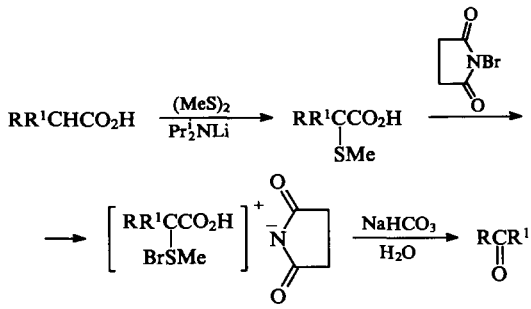


VI. Syntheses based on the primary products of the reactions of sulfides

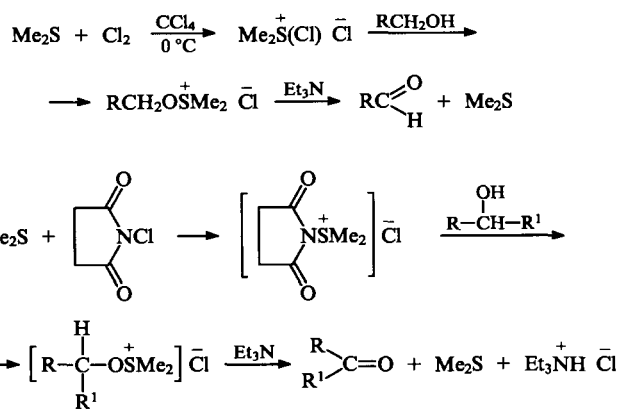


The conversion of the sulfide group into the sulfonium, ylide, sulfoxide, sulfilimine, and other groups with their subsequent transformation is widely used in multistage organic syntheses. The products of the primary reactions of sulfides are then formed as a rule in high yields and are frequently employed without isolation from the reaction mixture.

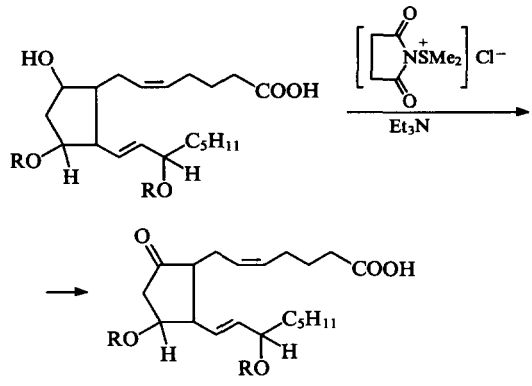
1. Syntheses via sulfonium salts



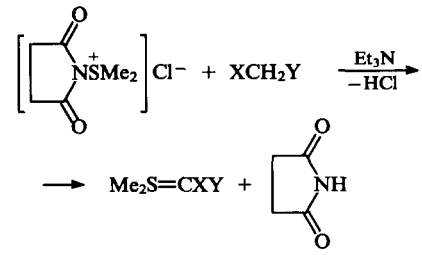
The conversion of the sulfide group into the sulfonium group is one of the most important synthetic procedures widely used in multistage organic syntheses. For example, the protection of the carboxy-group by means of the formation of alkylthiomethyl esters $RCO_2CH_2SR^1$ affords derivatives resistant to the action of alkalis and reductants, which has found applications in the peptide and phosphatide syntheses. [1] In order to remove the alkylthiomethyl group by treatment with methyl iodide, the former is converted into the sulfonium group, which is then cleaved by a solution of alkali, i.e. the conversion of the sulfide group into the sulfonium group with subsequent cleavage is one of the methods for the elimination of the former. A method for the specific cleavage of peptides at the methionine linkages with intramolecular substitution of the oxygen atom of a neighbouring amide group has been developed on the basis of the formation reaction of sulfonium salts. [1]



The synthesis of ketones from nitriles ArCHRCN (R = alkyl, aryl) consists in the phenylsulfenylation of the nitrile, the conversion of the sulfide group into the sulfonium group, and the cleavage of the latter with the aqueous NaOH solution–MeCN system.

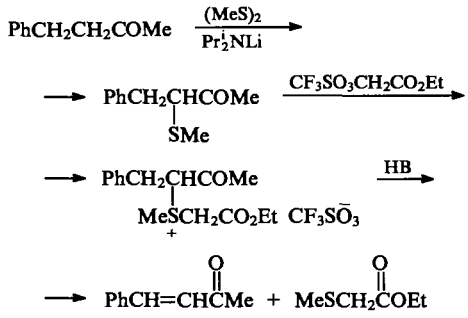


A similar synthetic procedure has been used in the oxidative decarboxylation of carboxylic acids, where *N*-bromosuccinimide served as the oxidant. [1]

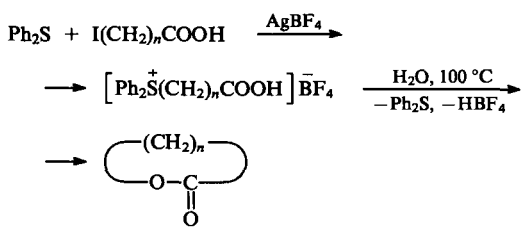


The complexes of dimethyl sulfide with chlorine and *N*-chlorosuccinimide (the Corey–Kim reagent) are widely used in the oxidation of primary and secondary alcohols to carbonyl compounds in synthetic organic chemistry. The carbonyl compound is formed in this case as a result of the cleavage of the intermediate alkoxysulfonium salt. [103]

In the improved synthesis of prostaglandins described by Fieser and Fieser,[103] the Corey–Kim reagent is used to convert the hydroxy-group into the keto-group.

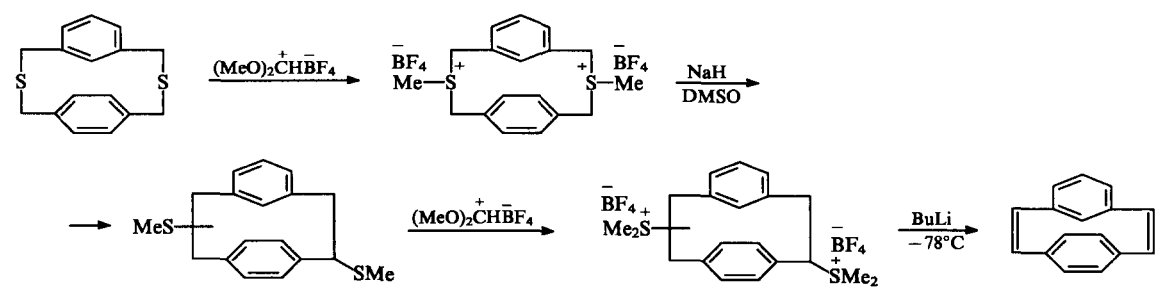


It has been shown [104] that the interaction of the above reagent with CH acids in the presence of triethylamine leads to the formation of sulfur ylides.

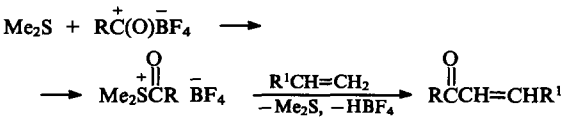


X = Br, Ac, CN; Y = Br, Ac, CO_2Et, CO_2Me, Ph.

The sulfonium centre attacks the β-hydrogen atoms, while the eliminated sulfonium group can function as the leaving nucleophile in E_2 reactions. The conversion of the sulfide group into a sulfonium group with subsequent removal of the latter is used as a method for the introduction of a carbon–carbon double bond, for example in the synthesis of unsaturated ketones from saturated ones. [105]

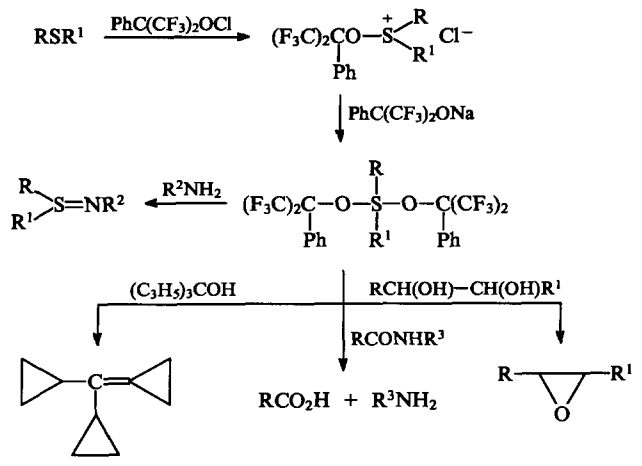


A similar synthetic procedure has been used to convert macrocyclic sulfides into unsaturated hydrocarbons. [103] For example, the key stage in the synthesis of *m,p*-[2,2]cyclophane-1,9-diene is the replacement of the sulfide group by a carbon–carbon double bond, which is achieved as a result of the Stevens rearrangement of the intermediate ylide with subsequent elimination of the sulfonium group (Scheme 4).



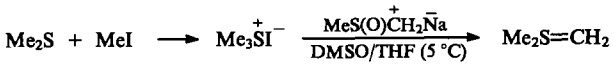
The high lability of the C–S bond in sulfonium salts makes it possible to employ them as alkyl and acyl group transferring agents, which has found applications in biological methylation reactions [106] and also in the syntheses of alkanecarboxylic acid lactones [107] and unsaturated ketones. [108, 109]

n = 3–7

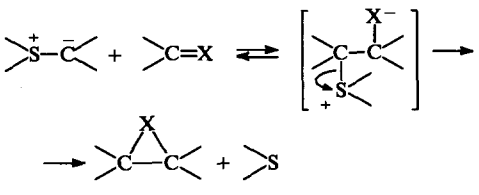


Scheme 4

R = Me, Bu^t; R^1 = Ph.



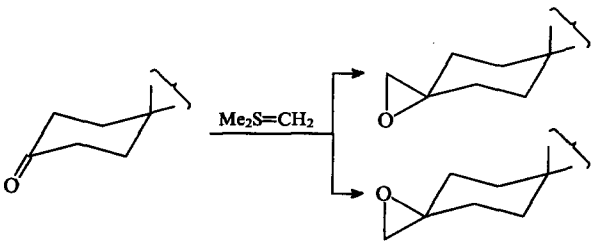
Alkyl sulfonium salts, formed in the reactions of sulfides with alkyl hypochlorites, are readily converted in the presence of alkoxides into highly reactive and relatively stable dialkoxysulfuranes, on the basis of which a whole series of syntheses of sulfilimines, oxiranes, carboxylic acids, and unsaturated hydrocarbons have been developed. [110]



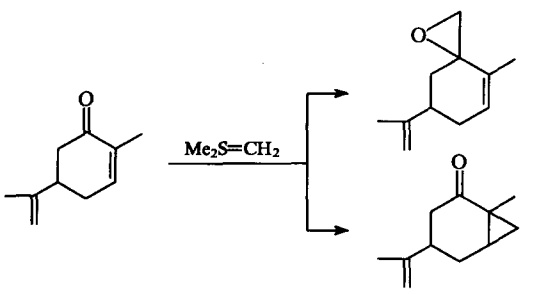
2. Formation of sulfur ylides

a. Transfer of alkylidene groups

The conversion of sulfides into sulfur ylides in multistage organic syntheses is determined primarily by the fact that the latter, being nucleophiles, can participate in the transfer of alkylidene groups to the electrophilic double bond with formation of a three-membered ring, which is frequently used in the syntheses of cyclopropanes, oxiranes, and other cyclic compounds. In view of the ready availability of aldehydes and ketones, the conversion of sulfides into sulfur ylides followed by their condensation with aldehydes and ketones is an important synthetic method for the preparation of oxiranes with a wide variety of structures. [1, 103, 111, 112] Dimethylsulfonium methylide, formed as a result of the reaction of dimethyl sulfide with methyl iodide and subsequent dehydrogenation of the resulting sulfonium salt, is widely used in preparative organic chemistry as a methylene group transferring agent. [1, 66]

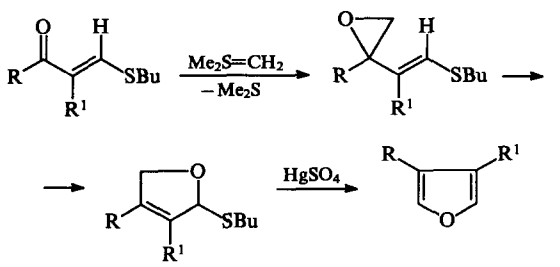


The overall mechanism of the transfer of the alkylidene group with the aid of ylides is presented below. [1] The inter-mediate betaine cyclises via direct substitution at a carbon atom.

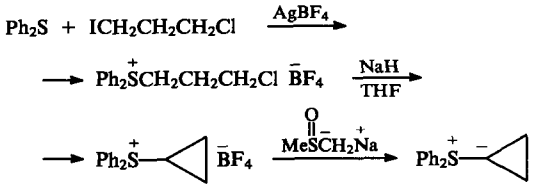


X = O, C.

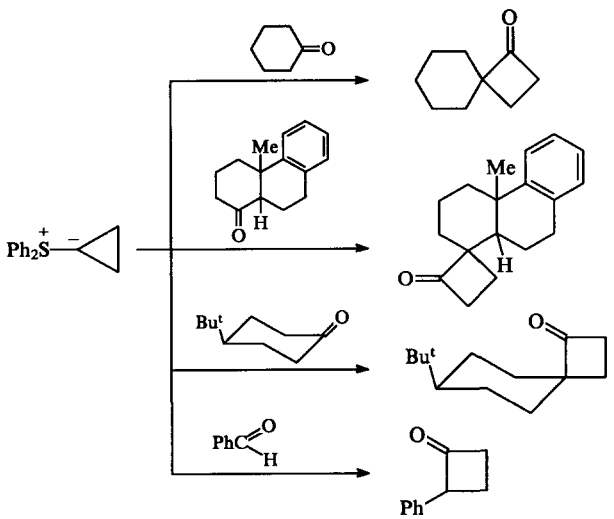
Depending on the structure of the ylide and the substrate, their addition to one another can lead to the formation of diastereoisomeric or structurally isomeric betaines. The decomposition of such betaines affords various products. For example, the addition of dimethylsulfonium methylide to cholestan-3-one leads to the formation of two structurally isomeric products with oxirane rings.



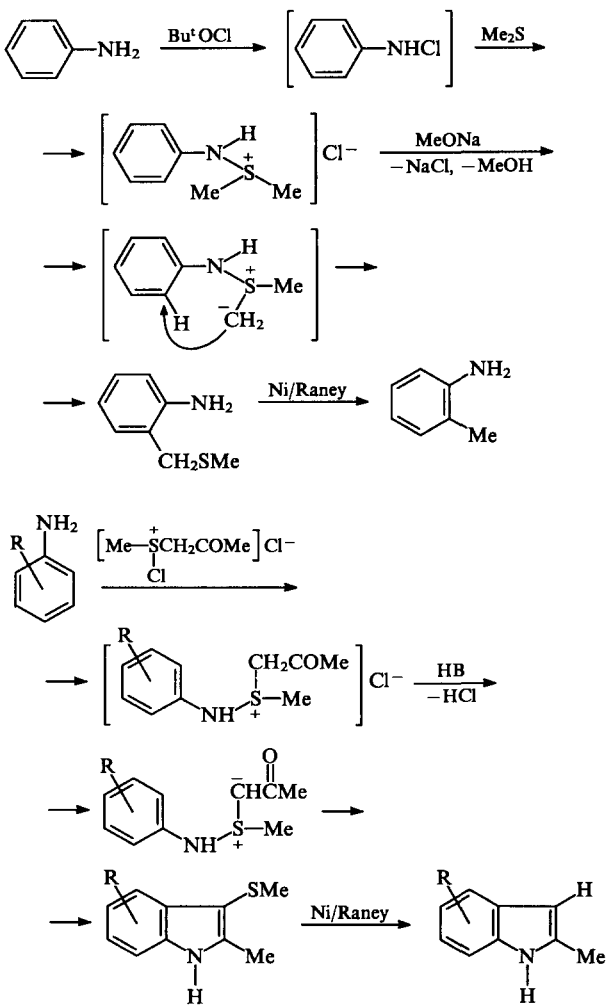
main product



The addition of the same ylide to carvone leads to two different products containing the oxirane and cyclopropane rings with the former predominating.

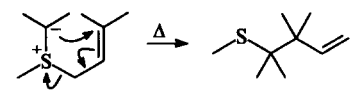


When the substrate molecule contains a mobile hydrogen atom, the oxirane ring formed may be opened with subsequent formation of a five-membered ring, which is used in the synthesis of furans from dimethylsulfonium methylide and unsaturated ketones. [103]

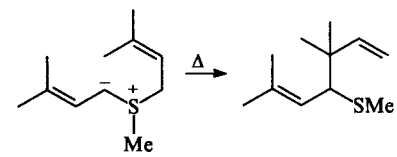


Diphenylsulfonium cyclopropylide, formed in the reaction of diphenyl sulfide with 3-chloro-1-iodopropane in the presence of silver tetrafluoroborate, is used in preparative organic chemistry for the transfer of the trimethylene fragment. [103]

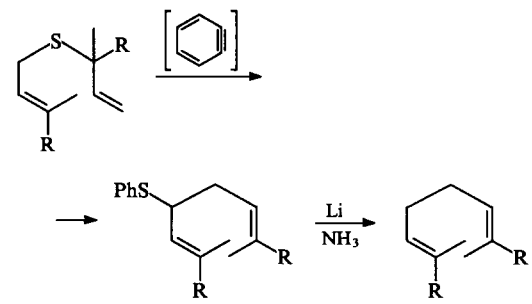
The transfer of the trimethylene fragment to the electrophilic double bond with the aid of diphenylsulfonium cyclopropylide is one of the alternative methods of synthesis of spirocycloalkanones and cyclic ketones. [103]



The intramolecular transfer of alkylthiomethylene groups in sulfur ylides is used for the *ortho*-methylation of anilines [113] and in the synthesis of indoles. [114]

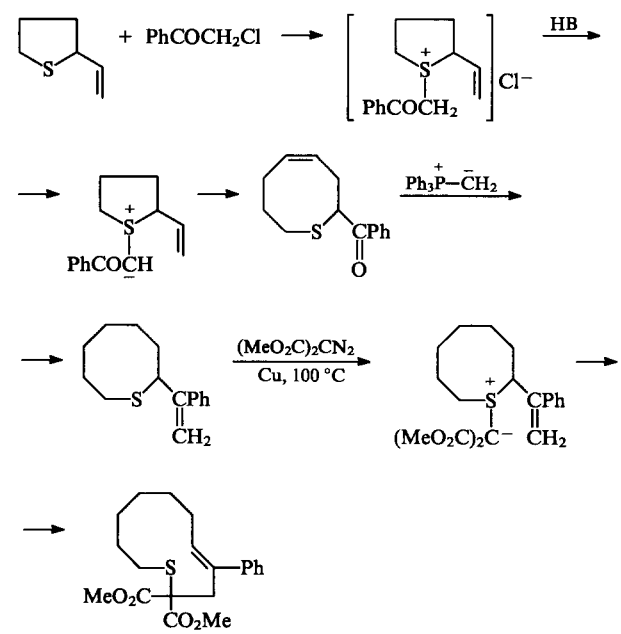


b. Rearrangements of ylides

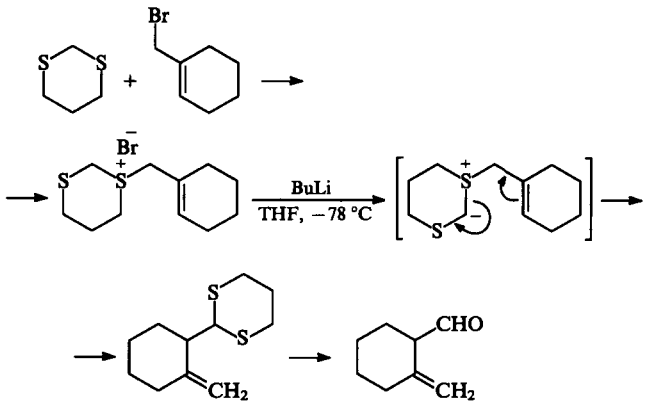


A second aspect of the use of sulfur ylides in organic synthesis is the formation of products as a result of their rearrangement. These rearrangements usually occur fairly readily with formation of a new carbon–carbon bond. For example, the [2,3]-sigmatropic rearrangement of allylsulfonium alkylides leads to but-3-enyl sulfides. [1]

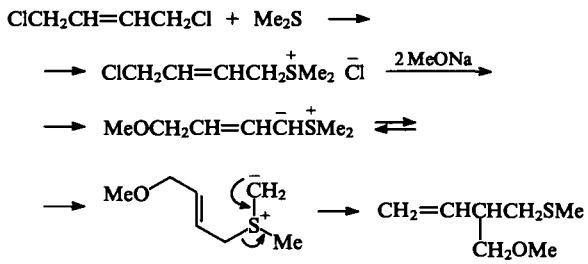
As a rule, this rearrangement takes place with inversion of the allyl group and can be used for the transfer of chirality from the sulfur to a carbon atom. [115]



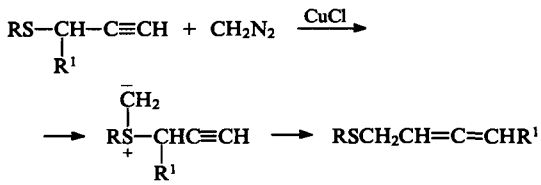
The [2,3]-sigmatropic rearrangement of allylsulfonium alkylides has been used in the synthesis of squalene. [116]

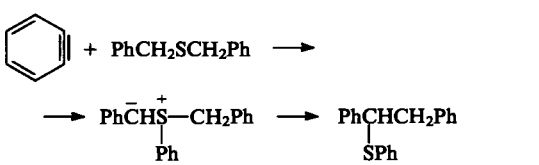


R = $Me_2C{=}CH(CH_2)_2C(Me){=}CH(CH_2)_2$.

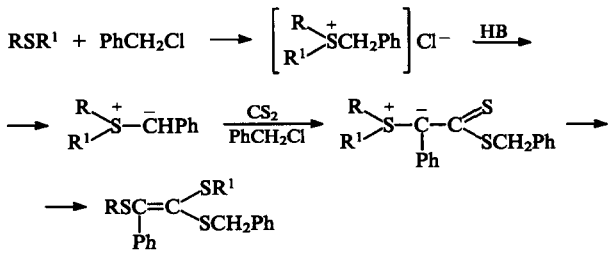


A similar rearrangement is used in the method involving successive ring expansion in cyclic sulfides described by Vedejs and Hagen. [117].

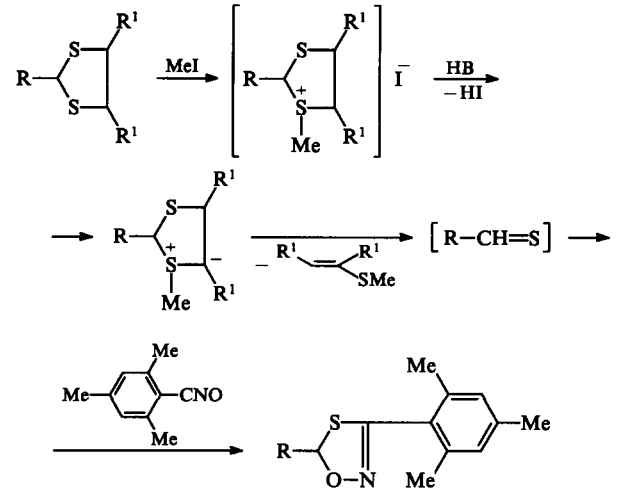




One of the stages in the synthesis of β,γ-unsaturated aldehydes from 1,3-dithiane [103] involves the [2,3]-sigmatropic rearrangement of an intermediate ylide.

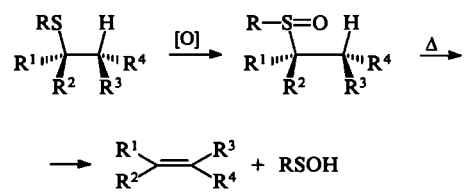


A series of methods of synthesis of polyfunctional sulfides have been developed on the basis of the rearrangement of the corresponding sulfur ylides via a 1,2-shift.[1,118]

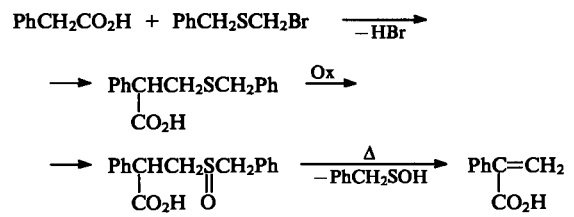


Examples of the use of other rearrangements of sulfur ylides in syntheses of sulfides have been described. For example, the synthesis of 1,1,2-tris(alkylthio)alkenes from dialkyl sulfides includes the rearrangement of ylides stabilised by the introduction of the thiocarbonyl group.[118]

c. Fragmentation of sulfur ylides

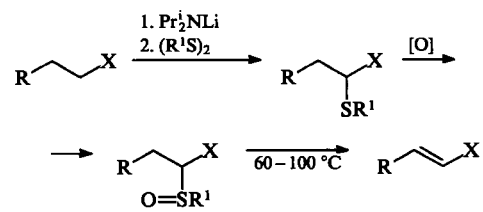


The conversion of 1,3-dithiolanes into thioaldehydes is based on the fragmentation of the intermediate ylide.[119] Mesitonitrile *N*-oxide is used to trap the thioaldehyde. It reacts with the thioaldehyde to form stable 1,4,2-oxathiazoles. In the absence of a 'trapping agent', polymers or trimers are formed.



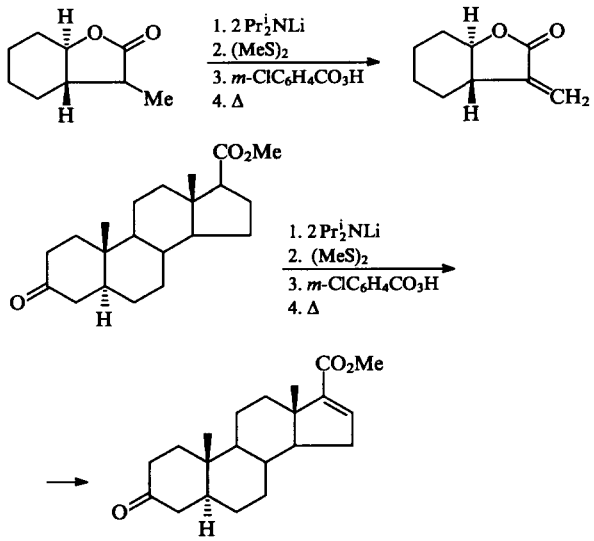
By virtue of the fragmentation reaction of sulfur ylides, 1,3-dithiolanes are convenient reagents for the synthesis of various thioaldehydes.

3. Syntheses of sulfoxides

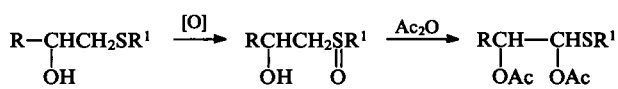


Another approach to the problem of the cleavage of the C–S bond in sulfides is based on the tendency of sulfoxides to undergo thermal *cis*-elimination, which results in the formation of a carbon–carbon double bond.[1]

An important factor for this reaction is the availability of effective selective methods for the oxidation of sulfides, the search for which has been prosecuted vigorously in recent years.[120–126] The presence of powerful electron-accepting groups in the sulfoxide molecule promotes the thermal *cis*-elimination. A clear example of this is provided by the synthesis of α-phenylacrylic acid.[127]

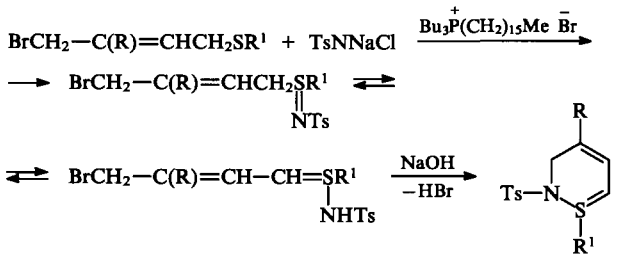


The method for the introduction of a carbon–carbon double bond with the (*E*)-configuration has been investigated in greater detail by Trost et al.[128] The essential feature of the method is the introduction of the phenylthio- or methylthio-group into the α-position relative to the electron-accepting group, the oxidation of the sulfide group to the sulfoxide group, and thermal elimination of the latter.

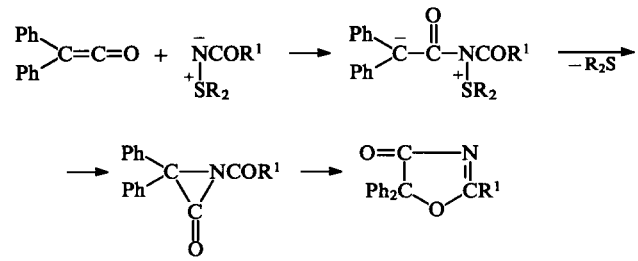


X = COR, CO_2R, CN; R = Alk, Ar; R^1 = Ph, Me.

The elimination of benzenesulfenic acid takes place very readily on refluxing in benzene or carbon tetrachloride, whereas heating in toluene is necessary to split off methanesulfenic acid. A similar chain of reactions is used in the synthesis of α-methylene-3-lactones and also for the selective introduction of a double bond in the α,β-position relative to the ester group in steroids. [129]



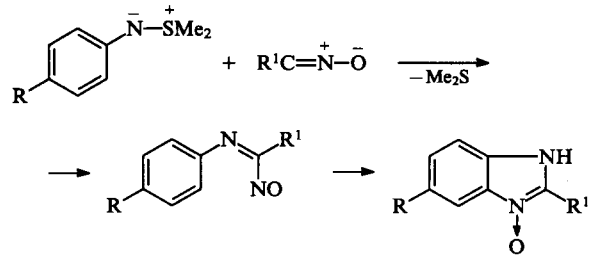
Another aspect of the use of sulfoxides in organic synthesis is their rearrangement in the presence of acetic anhydride (the Pummerer rearrangement). This rearrangement is used widely to convert one sulfide into another. [1,130]



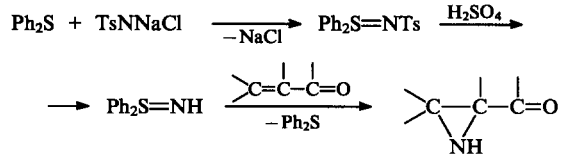
4. Reactions accompanied by the formation of sulfilimines

a. Cyclisation and cycloaddition reactions

The conversion of sulfides into sulfilimines with their subsequent cyclisation or cycloaddition to compounds containing double or triple bonds is used in syntheses of heterocyclic compounds. For example, the preparation of nitrogen-containing heterocyclic compounds from alkyl allyl sulfides, involving a stage with oxidative imination of the sulfide by the sodium salt of the chloramide of toluene-*p*-sulfonic acid and subsequent cyclisation of the resulting sulfilimine, has been described. [131]

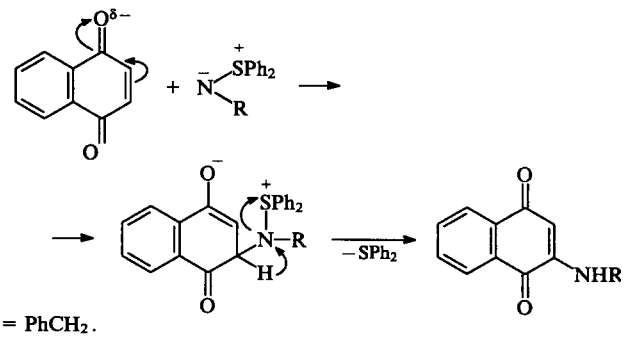


N-Acylsulfilimines, formed as a result of the reaction of sulfides with the *N*-chloramides of carboxylic acids, enter relatively readily into a cycloaddition reaction with diphenylketene, which is used in the synthesis of 1,3-oxazol-4-ones. [132]

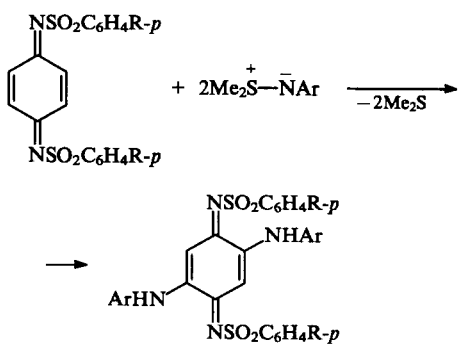


In essence, the reaction represents the transfer of the acylamino-group to the electrophilic double bond.

The cycloaddition of *N*-arylsulfilimines to nitrile oxides is used to obtain benzimidazole *N*-oxides. [133]

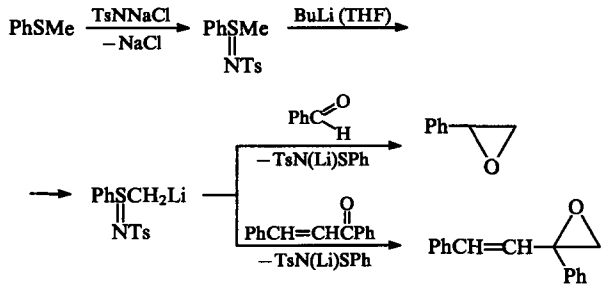


The synthesis of aziridines from sulfides is based on the cycloaddition of diphenylsulfilimines to the double bond in α,β-unsaturated ketones. [134,135]

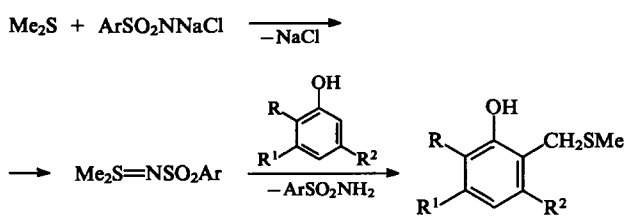


b. Transfer of arylamino-groups

Apart from the cycloaddition reactions, the transfer of the imine fragment of sulfilimines to the electrophilic double bond is used also to introduce arylamino-groups into the quinonoid rings of quinones [136] and quinone imines. [137]

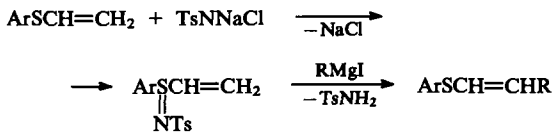


R = PhCH$_2$.



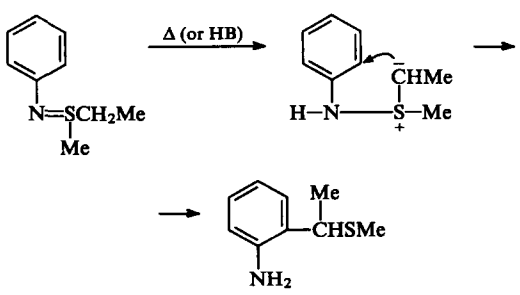
R = H, Me; Ar = Ph, *p*-MeC$_6$H$_4$, *p*-ClC$_6$H$_4$, *p*-NO$_2$C$_6$H$_4$.

c. Transfer of alkylidene groups

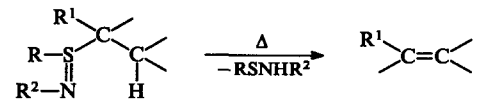


The strong electron-accepting influence of the arenesulfonylimino-group in *N*-arenesulfonylsulfilimines increases the acidity of the α-hydrogen atoms in the *S*-alkyl groups, which promotes their substitution by an alkali metal atom. Such organo-metallic compounds are used as nucleophiles which transfer alkylidene groups to an electrophilic double bond (for example, C=O) with formation of a three-membered ring.[138,139] The stable anion of *N*-arenesulfonylsulfenamide is the leaving group, the elimination of which leads to the formation of a three-membered ring, which also promotes the occurrence of this process.

The introduction of the methylthiomethyl group into the ring of phenols with the aid of *N*-arenesulfonyl-*S*,*S*-dimethylsulfilimines is used in the synthesis of benzylmethyl sulfides.[139,140]

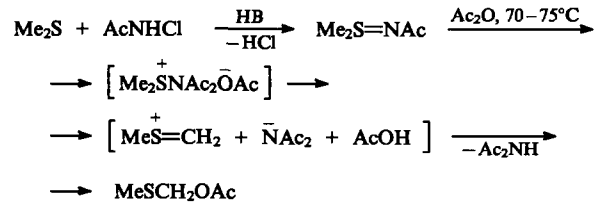


The conversion of the vinyl sulfide $ArSCH=CH_2$ into $ArSCH=CHR$ via the corresponding sulfilimine by means of a Michael type reaction using organomagnesium compounds has been described.[141]



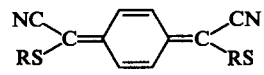
d. Rearrangements of sulfilimines

On heating and also on treatment with bases, certain *N*-arylsulfilimines undergo a Sommelet type rearrangement, which is used to introduce alkylthiomethyl groups into the *ortho*-position in anilines.[139]



S-Alkylsulfilimines containing β-hydrogen atoms undergo on heating a rearrangement with formation of alkenes,[142] which can serve as one of the methods for the elimination of the sulfide group.

R^1 = H, Me; R^2 = Ar, MeCO.



The Pummerer rearrangement of *N*-acylsulfilimines is used to convert dimethyl sulfide into acetoxymethyl methyl sulfide.[1]

VII. Practical applications of sulfides

1. Sulfides in macromolecular chemistry

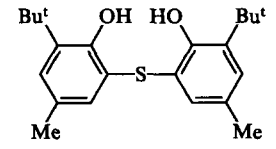
Sulfides are used in macromolecular chemistry in several ways. One of these involves the employment of sulfides as monomers. As a rule, in this case sulfides contain, apart from the sulfide group, unsaturated bonds or other functional groups which participate directly in the formation of the polymer chain as a result of polymerisation or polycondensation reactions.[143] Thus a series of homopolymers and copolymers containing sulfur atoms in the main chain have been obtained from divinyl sulfide.[144] The synthesis of 7,8-bis[alkyl(aryl)thio]-7,8-dicyanoquinodimethanes having the general formula

R = Et, Bu^t, Ph,

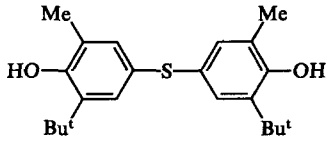
has been described and their reactions have been investigated.[145] For R = Et, the polymerisation proceeds via radical, anionic, and cationic mechanisms with formation of a polymer having an ethylthio-group in the side chain, for R = Ph it proceeds via radical and anionic mechanisms, and for R = Bu^t the monomer does not polymerise, which the authors believe[145] to be due to a steric effect.

The synthesis of poly(phenylene sulfide) via the polycondensation of *o*- and *m*-di(chlorophenyl) sulfides with sodium sulfide in an organic solvent has been described in the patent literature.[146,147] Aromatic polythioesteramideimides with effective mechanical properties, a high heat resistance, and a high plasticity have been obtained by the polycondensation of the disulfide $NH_2C_6H_4SC_6H_4SC_6H_4NH_2$ with the monochloride of trimellitic acid and subsequent cyclisation of the polyamido-acid.[148] The synthesis of aromatic polyketones containing sulfur atoms in the main chain is based on the polycondensation of diphenyl sulfide and phosgene.[149] A new type of sulfide-formaldehyde polymer, capable of being cross-linked, has been obtained by the polycondensation of di(2-hydroxyphenyl) sulfide and formaldehyde.[150]

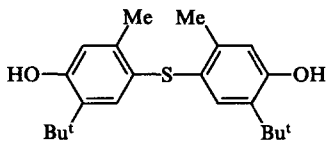
A second application of sulfides in macromolecular chemistry involves their participation in the regulation of polymer formation processes. It has been noted,[151] for example, that the sulfides $PhCH_2SR$ and $C_6H_4(CH_2SR)_2$ are inifers of the radical polymerisation of styrene. The principle of the action of such



inifers consists in the initiation of the radical polymerisation and transfer of the polymer chain in the concluding stage of the polymerisation reaction, which leads ultimately to a linear dependence of the number-average molecular weight of the polymer on the polymerisation time. The influence of sulfides on the cationic polymerisation of vinyl ethers initiated by UV light and sulfonium salts,[152] the rate of which diminishes with increase in the nucleophilicity of the sulfide, has also been noted.

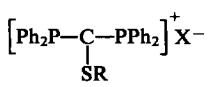


2-Benzothiazolyl 2,4-dinitrophenyl sulfide has found extensive application in the manufacture of white and light-coloured rubbers as a vulcanisation accelerator which does not induce additional vulcanisation.[153]

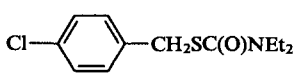


The third application of sulfides in macromolecular chemistry is the stabilisation and protection of polymeric materials against the negative influence of various factors (light, heat, oxygen, etc.) For example, dialkyl sulfides decompose the peroxides formed in the oxidative degradation of polymers without the formation of free radicals, which is very important for the arrest of oxidative degradation.[154,155] These compounds are very effective in mixtures with other stabilisers, in particular stabilisers of the phenolic or amine types.

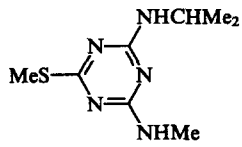
The mutual intensification of the protecting effect can be explained by the fact that one of the stabilisers terminates the degradation process, giving up hydrogen to the peroxyl radicals, while the other decomposes hydroperoxides. Dialkyl and diaryl sulfides mixed with other substances are effective stabilisers of vinyl polymers, polyolefins, and poly(vinyl acetals).



Diaryl sulfides containing hydroxy- and alkyl groups in the aromatic rings have found an application as stabilisers of rubber, protecting it against the effects of oxygen and heat.[156]

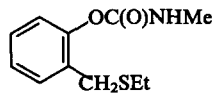


Phosphorus-containing sulfides are effective antipyrenes, which protect polymeric materials against combustion.[25]



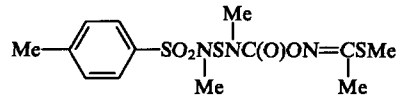
X = SO_4, BF_4, $AlCl_4$.

2. Biological activity of sulfides



A whole series of compounds containing the sulfide group are used in agriculture as effective pesticidal preparations.[157] For example, 2-chlorobenzyl-2-chlorophenyl sulfide, known under the commercial name chlorbenzid or chlorocid, is used as an effective acaricidal preparation against plant ticks on fruit. Benthiocarb

and desmetryn

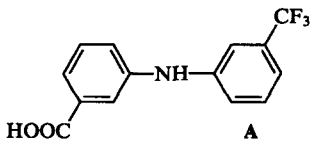


are used as herbicidal preparations to combat oat-like weeds. Ethiofencarb

is used as an insecticide against aphids. 2-Benzothiazolyl butyl sulfide is employed as a defoliant of the thin-fibre cotton plant.

Studies on the biological activity of sulfides have been directed in recent years both to the search for new and the modification of already known pesticides in order to reduce their toxicity to warm-blooded animals. For example, methomyl MeNHCOON=C(Me)–SMe and aldicarb MeNHCOON=CH–$(CH_2)_2$–SMe possess outstanding insecticidal and acaricidal properties, but are toxic to warm-blooded animals.[158]

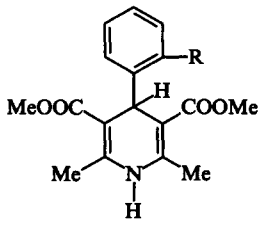
It has been established for carbamates[159] that the substitution of a hydrogen atom at the nitrogen atom by an amino- or amidosulfenyl group lowers sharply their toxicity to warm-blooded animals whilst retaining and in certain cases actually intensifying their pesticidal activity. Several groups of investigators therefore undertook studies on the synthesis of aminosulfenylated derivatives of methomyl, aldicarb, and ethiofencarb.[159–167] Apart from *N*-amino(amido)sulfenylated derivatives of methomyl,[168–173] aldicarb,[174] ethiofencarb,[25] and their analogues, these studies led to the synthesis also of a whole series of *N*,*N*′-dicarbamoyl sulfides[175–178] and *N*-sulfenylated 2-(alkylthiomethyl)phenyl-*N*-alkylcarbamates[179] with insecticidal activity. The above studies also made it possible to obtain an insectoacaricidal preparation with systemic activity, a better phytotoxicity than methomyl, and an effectively long duration of activity.[180]



A series of biologically active sulfides which are potential pesticides have been synthesised in recent years. For example, it has been noted[69] that the sulfides 2-$NO_2C_6H_4SCH_2NO_2$ and (2-$NO_2C_6H_4S)_2CHNO_2$ exhibit a relatively high nematocidal activity and an insectoacaricidal activity against the beetroot aphid. The sulfides 4-$NO_2C_6H_4SCH(CN)_2$, 2,4-$(NO_2)_2C_6H_3SCH(CN)_2$, and 2-$NO_2C_6H_4SCH(COMe)_2$ possess a relatively high insectoacaricidal activity in relation to the rice snout-beetle and the arachnoid tick.[68]

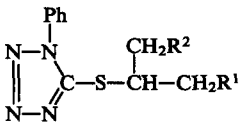
3. Sulfides as pharmaceutical preparations

One of the important properties of medicinal preparations is solubility in lipids, its increase enhancing their effectiveness (by facilitating their transport in the organism and their permeation through membranes and by increasing their concentration in lipid regions).[181,182] The solubility of medicinal preparations can be increased by introducing into their molecules lipophilic groups, the relative lipophilicity of which is characterised by Hantzch's π constants. According to literature data,[183,184] these constants for certain groups have the following values: 1.44 (SCF_3), 1.28 (SCF_2Br), 1.23 (C_2F_5), 1.04 (OCF_3), 1.01 (OCF_2Br), 0.88 (CF_3), 0.68 (SCF_2H), 0.61 (SMe), 0.58 (OCF_2H), 0.56 (Me), 0.55 (SO_2CF_3).

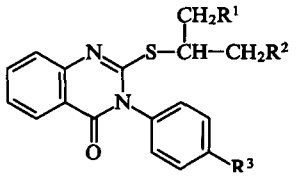


As can be seen from these data, the trifluoromethylthio-group exhibits a fairly high lipophilicity and its introduction into the molecules of medicinal preparations should evidently increase their effectiveness.

This hypothesis has been to some extent confirmed by the introduction of the trifluoromethylthio-group and other lipophilic groups in various positions in the benzene ring A of flufenamic acid.[182]

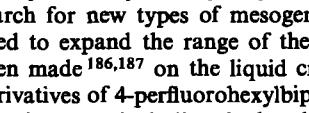


A



It was found that the sulfide formed as a result of the introduction of the trifluoromethylthio-group has a lower anti-inflammatory activity than flufenamic acid, but is superior to the latter in its antiproteinase activity. The antiproteinase activity of derivatives of flufenamic acid increases in the following sequence of substituents $HF_2CO < CHF_2SO_2 < CF_3 < SCF_3$, which corresponds approximately to the increase in their lipophilicity. Especially interesting results have been obtained following the introduction of the above substituents in the *ortho*-position in the benzene ring of 4-phenyl-1,4-dihydropyridine.

Such preparations exert a powerful effect on the cardiovascular system and are antagonists of calcium ions.[182]



Certain sulfides, in particular those containing the tetrazole and pyrimidine rings, have radioprotecting properties.[185]

4. The liquid crystal properties of sulfides

Organic compounds forming liquid crystals have found extensive applications in the reproduction and recording of information in various branches of science and engineering. Such compounds have the ability to generate, on heating and cooling in the range between the liquid crystal state and the isotropic liquid melt, intermediate smectic and nematic mesophases which differ in the degree of molecular order.[182] Derivatives of various classes of organic compounds, the molecules of which have a linear shape and have largely a structure of the same type, possess the properties of liquid crystals. These compounds (mesogens) contain a central rigid fragment, consisting of a conjugated aromatic or bridged system, and also end groups of different nature (alkyl, alkoxy-, alkoxycarbonyl, cyano-, nitro-groups, etc.). In the search for new types of mesogens and in connection with the need to expand the range of their characteristics, studies have been made[186,187] on the liquid crystal properties of a series of derivatives of 4-perfluorohexylbiphenyl containing various functional groups, including the butylthio-group in the *para*-position in the second benzene ring.

X = H, CN, NHBu, SBu.

It has been established that the introduction of the strong electron-donating butylamino-group ($\sigma_n = -0.60$) leads to the appearance of a liquid crystal phase of the more ordered smectic type with an increased thermal stability. When the butylamino-group is replaced by the less electron-donating butoxy-group ($\sigma_n = -0.32$), the formation of a liquid crystal phase of the smectic type is nevertheless still ensured. On further weakening of the electron-donating properties of the substituents and, in particular, following the introduction of the butyl group ($\sigma_n = -0.16$) and the butylthio-group ($\sigma_n = 0.03$), the mesogenic property vanishes.

* * *

It is seen from the present review that the use of sulfides as synthons in fine organic synthesis has undergone in recent years considerable expansion based on the characteristic features of the reactivity of sulfides — the high lability of the C–S bond. The sulfide group can be replaced by a hydrogen atom and hydroxy-, alkyl, alkoxy-, thiyl, and other functional groups. The thermal and photolytic cleavage of the C–S bond leads to the formation of highly reactive intermediates, which are used in the synthesis of various cyclic adducts. A characteristic feature of the reactivity of sulfides, which is of great synthetic importance, is their tendency to form α-sulfenylcarbanions, which are used widely in multistage organic syntheses for the formation of carbon–carbon bonds. The ease of the conversion of sulfides into sulfonium, ylide, sulfoxide, and sulfilimine intermediates is also used widely in multistage organic syntheses for the transfer of various groups to an electrophilic double bond, for the formation of a carbon–carbon double bond, and for other transformations.

The practical applications of sulfides in macromolecular chemistry, in agriculture, in pharmaceutical industry, and in other fields of human activity are no less important and this too has been reflected in the present review.

V. Regioselective and enantioselective hydrogenation of the Δ^2-bond in α-functionalised isoprenoids	181

Abstract. The chemical and microbiological methods developed for the synthesis of polyprenols and dolichols are examined. These methods involve the construction of regular functionalised (*Z*)-isoprenoids accompanied by the creation of new C—C and/or (*Z*)-trisubstituted C=C bonds. Also considered are the highly regioselective and enantioselective procedures for the conversion of α-functionalised isoprenoids into their 2,3-dihydro-derivatives. The bibliography includes 87 references.

I. Introduction

Polyprenols **1** and dolichols **2** occupy an important place in the series of biologically active isoprenoids.

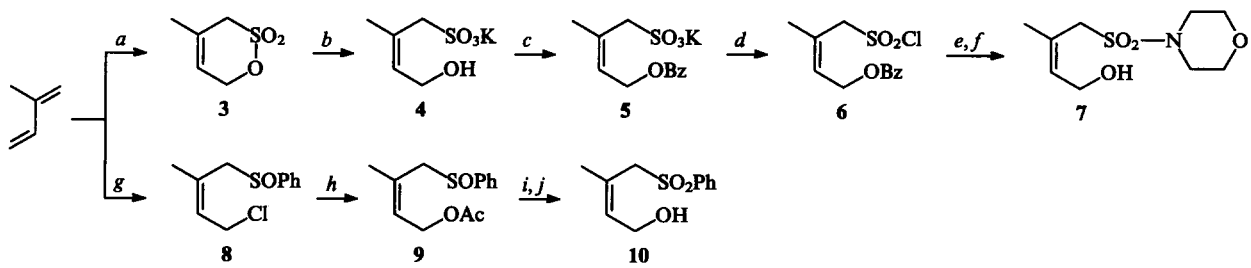
1, 2

1: $l = 3, 4$; $m > 3$; $n = 0$.
2: $l = 3$; $m = 8 \div 20$; $n = 1$.

It has now been reliably established that these regular polyisoprenoid alcohols are low-molecular-mass bioregulators of the coenzyme type, ensuring the transport of monosaccharides through cell membranes and their subsequent inclusion in the biosynthesis of carbohydrate-containing biopolymers of the cell wall in prokaryotes and eukaryotes.[1—3] The problem of the total synthesis of the individual polyprenols, dolichols, and their modified analogues, which arose in connection with the study of the mechanism of this process, required for its solution the development of methods for the stereoselective construction of a fairly long (*Z*)-isoprenoid chain—the principal structural element of the molecules of compounds **1** and **2**. In the course of studies carried out on these lines during the last twenty years, general methods have been devised for the construction of (*Z*)-disubstituted methylolefins, a special case of which is the construction of the (*Z*)-isoprene unit, and procedures have been developed for the regioselective and enantioselective transformation of compounds **1** into compounds **2**. These methods have expanded the range of procedures available in synthetic chemistry and can be used for the construction of new natural and biologically active products. The Laboratory of Polyunsaturated Compounds of the Institute of Organic Chemistry of Russian Academy of Sciences, headed by A M Moiseenkov, a Corresponding Member of the Russian Academy of Sciences, has made an appreciable contribution to the development of the above methods. This review has been written in honour of the memory of A M Moiseenkov.

II. Construction of the (*Z*)-isoprenoid chain with formation of a C—C bond

1. Biogenetic-like conversion of isoprenoids into higher (*Z*)-C_5-homologues



Moiseenkov and coworkers[4—7] showed that the δ-sultone **3**, which can be readily obtained from isoprene, dissociates at the S—O bond during controlled hydrolysis with the exclusive formation of the (*Z*)-sulfonate **4**, which affords the hydroxysulfonamide **7** via the benzoate **5** and sulfonyl chloride **6** stages with complete retention of the configuration (Scheme 1). The hydroxysulfonamide was used as the key block-synthon for the biogenetic-like (*Z*)-C_5 growth of the isoprenoid chain in the construction of the polyprenyl molecule. As shown in Scheme 2, this operation is carried out in three stages. Thus the conversion of (*E,E*)-farnesol **11** into the corresponding bromide **12**, alkylation by the latter of the dilithio-derivative **13** of the hydroxysulfonamide **7**, and finally the reductive desulfurisation of the resulting hydroxysulfonamide **14** to (*Z,E,E*)-geranylgeraniol **15** illustrate the conversion of the sesquiterpenoid skeleton into a diterpenoid skeleton. The repetition of the above transformations starting with compound **15** leads, via the hydroxysulfonamide **16** stage, to the (*Z,Z,E,E*)-sesterterpenol **17**, which is similarly converted, via the hydroxysulfonamide **18**, to a (*Z,Z,Z,E,E*)-triterpenol—the hexaprenol WT_2C_3OH† **19**.

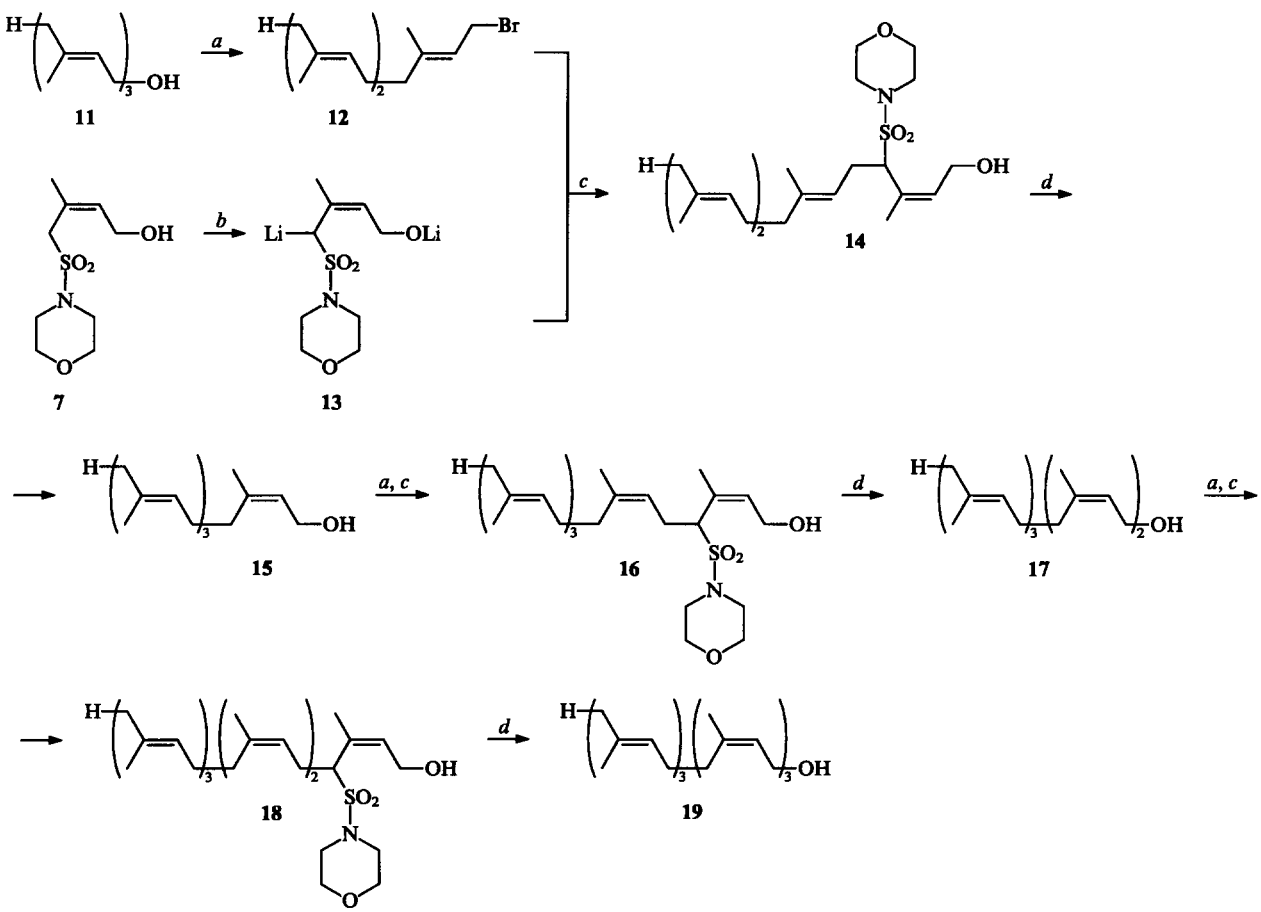
Uspekhi Khimii **63** (2) 177—191 (1994); translated by A K Grzybowski

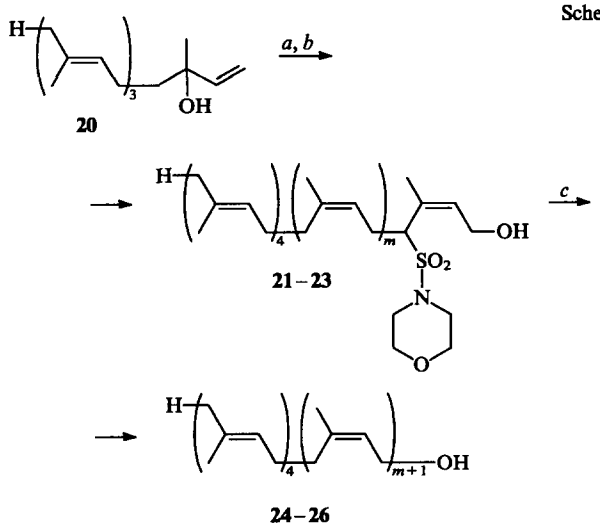


† Here and henceforth the following abbreviations recommended by IUPAC[9] are used to designate the configurations of polyprenols: W is the terminal unit, T and C are the inner (*E*)- and (*Z*)-isoprene units, and S is the 2,3-dihydroisoprene unit.

Scheme 1

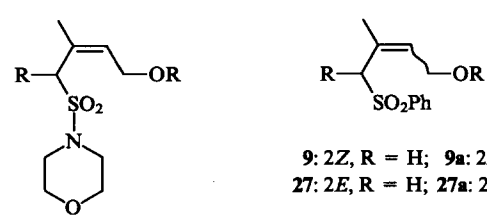
Bz = benzoyl;
(*a*) SO_3; (*b*) aq. KOH (pH 7 – 8); (*c*) BzCl/Py; (*d*) $POCl_3$; (*e*) HN⟨O⟩; (*f*) $LiAlH_4$;
(*g*) PhSOCl, 5 kbar; (*h*) AcOK/AcOH; (*i*) *m*-$ClC_6H_4CO_3H/CH_2Cl_2$; (*j*) H_3O^+.

Scheme 2



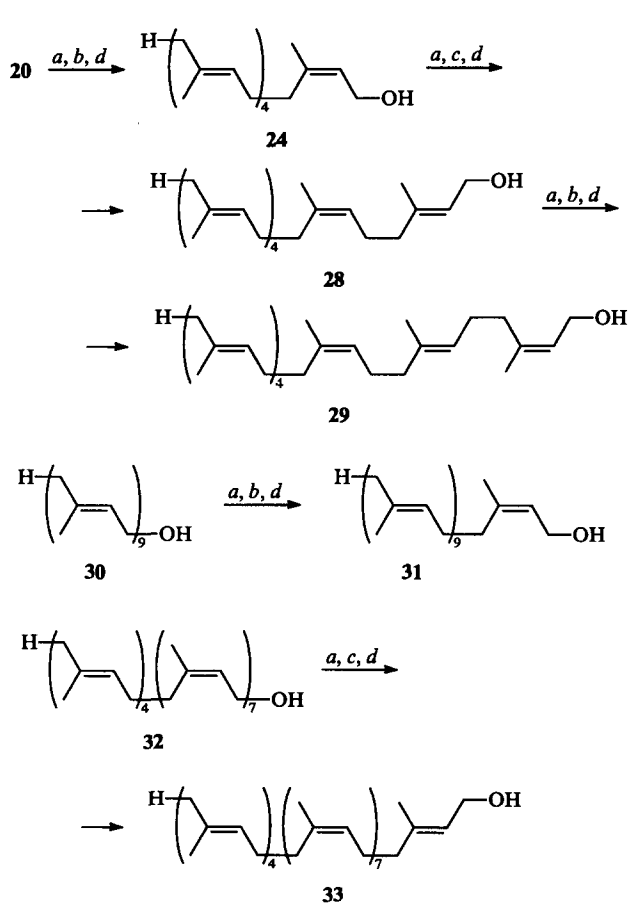
(*a*) PBr_3/Py; (*b*) Bu^nLi; (*c*) **13**/THF, −70 °C; (*d*) $Na/NH_3-C_6H_{14}-Et_2O$, DB18C6
(DB18C6 = dibenzo-18-crown-6).

The reactions presented in Scheme 2 constituted the first reliably documented total synthesis of polyprenols.[8]



The pentaprenol WT_3COH **24**, hexaprenol WT_3C_2OH **25**, and heptaprenol WT_3C_3OH **26** were obtained similarly in succession from geranyllinalool **20** (Scheme 3) via stages involving the sulfonamides **21**–**23** respectively.[10] Compounds **25** and **26** were subsequently isolated from the leaves of the palm *Serenoa repans*.[11]

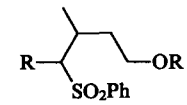
Scheme 3



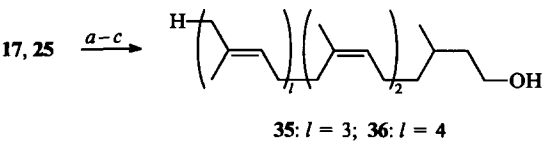
21, 24: $m = 0$; **22, 25**: $m = 1$; **23, 26**: $m = 2$.
(*a*) PBr_3/Py; (*b*) **13**/THF, −50 °C; (*c*) $Na/NH_3-C_6H_{14}-Et_2O$, DB18C6.

Scheme 4

9: 2*Z*, R = H; **9a**: 2*Z*, R = Li.
27: 2*E*, R = H; **27a**: 2*E*, R = Li.



7: R = H.
13: R = Li.

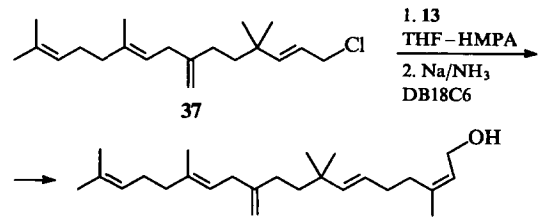


(*a*) PBr_3/Py; (*b*) **13**; (*c*) **27a**; (*d*) $Na/NH_3-C_6H_{14}-Et_2O$, DB18C6.

The approach considered proved to be extremely fruitful in the synthesis of modified polyprenols with a specified nonnatural sequence of the (*Z*)- and (*E*)-isoprene units in the molecule as well as dolichol-like structures. A more readily available block-synthon — the hydroxysulfone **10** — was used successfully together with compound **7** for the formation of (*Z*)-C_5-homologues. Compound **10** was obtained from the acetate **9** via the (*Z*)-chlorosulfoxide **8** (Scheme 1), which is formed smoothly in its turn from isoprene and benzenesulfinyl chloride at a high pressure.[12,13] Accordingly, the (*E*)-hydroxysulfone **27** in the form of its dilithio-derivative **27a** was used as the (*E*)-C_5-block.[14] The heptaprenol WT_3CTCOH **29** was synthesised by the (*Z*)/(*E*)-C_5-homologue formation method from geranylinalool **20** via the pentaprenol **24** and hexaprenol WT_3CTOH **28** stages using the block-synthons **7** and **27**, while the decaprenol WT_8COH **31**[16] and the dodecaprenol WT_3C_7TOH **33**[16] were obtained from the readily available natural products solanesol **30** and moraprenol **32**[15] respectively (Scheme 4).

The use of the saturated block-synthon **34** in the form of its dilithio-derivative **34a** in the concluding stage of the C_5-homologue formation reaction made it possible to obtain the racemates of the dolichol-like hexaprenol WT_2C_2SOH **35**[18] and the heptaprenol WT_3C_2SOH **36**[17] from the pentaprenol **17** and hexaprenol **25** respectively, while the use of the chiral (3*R*)-form of the block-synthon **34** led to the above compounds with the natural (*S*)-configuration of the α-isoprene unit.[19]

34: R = H; **34a**: R = Li.

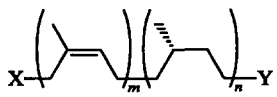


35: $l = 3$; **36**: $l = 4$

(*a*) PBr_3/Py; (*b*) **34a**; (*c*) $Na/NH_3-C_6H_{14}-Et_2O$, DB18C6.

A partial synthesis of a combined preparation of (*S*)-dolichols **2** ($l = 2$, $m = 11-19$, $n = 1$) and their (*R*)-analogues from a mixture of the polyprenols **1** ($l = 2$, $m = 11-19$, $n = 0$), isolated from the leaves of *Ginkgo biloba*, has also been achieved with the aid of the (*R*)- and (*S*)-forms of compound **34**.[20]

The C_5 isoprene chain C_5-homologue formation method, developed for the synthesis of polyprenyl structures, was used successfully subsequently in the synthesis of the (*Z*)-isoprene section of the non-regular sesterterpenol moenocinol **38** from the chloride **37**.[21]

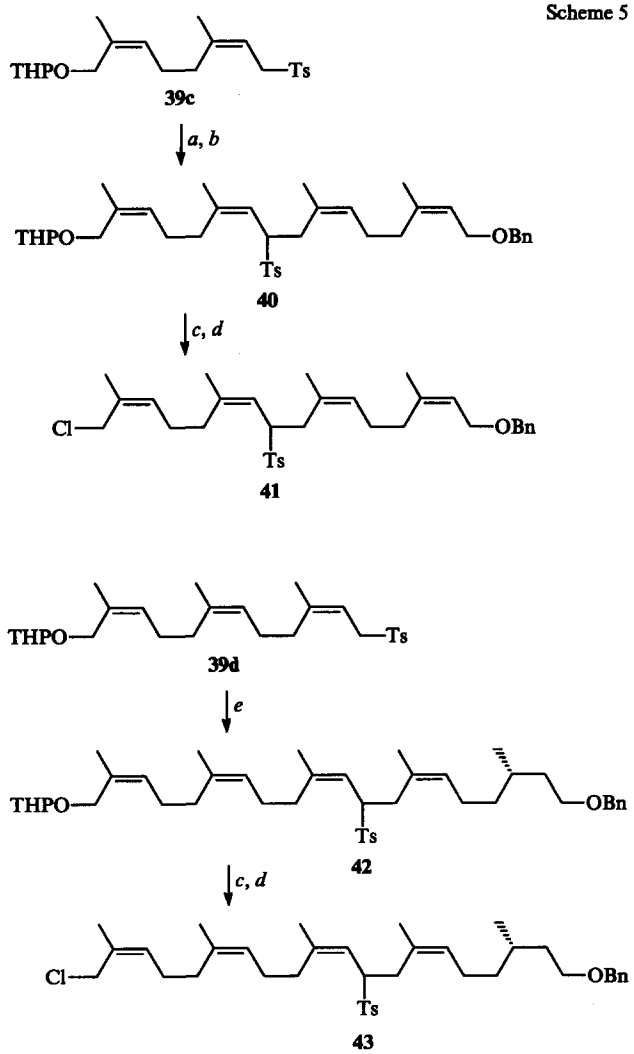


37

38

THF = tetrahydrofuran, HMPA = hexamethylphosphoramide.

2. A block method for the construction of the isoprenoid chain

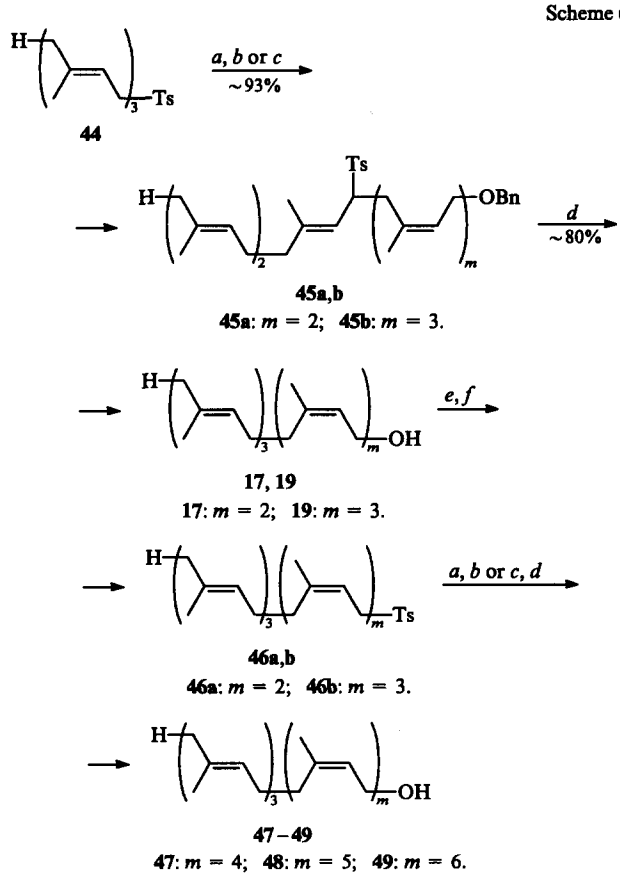


During approximately the same years, Sato et al.[22] proposed that the (*Z*)-isoprenoid chain be constructed by 'cross-linking', via the C–C bonds, block-synthons of type **39** containing two or more (*Z*)-isoprenoid units. Such compounds became available after the observation by the authors of the high (*Z*)-stereoselectivity of the Wittig reaction with participation of hydroxyacetone derivatives.[23] This question is considered in detail in Section III.1. Here one should only note that the key (*Z*)-C_{10} and (*Z*)-C_{15}-bifunctional building blocks of type **39** were obtained precisely from the benzyl ethers of nerol, (*Z,Z*)-farnesol, and (*S*)-citronellol.[22,24,25]

39a–e

39a: $m = 2$, $n = 0$, X = Cl, Y = OBn.
39b: $m = 3$, $n = 0$, X = Cl, Y = OBn.
39c: $m = 2$, $n = 0$, X = OTHP, Y = Ts.
39d: $m = 3$, $n = 0$, X = OTHP, Y = Ts.
39e: $m = 1$, $n = 1$, X = Cl, Y = OBn.
(Bn = benzyl, THP = Tetrahydropyranyl, Ts = toluene-*p*-sulfonyl).

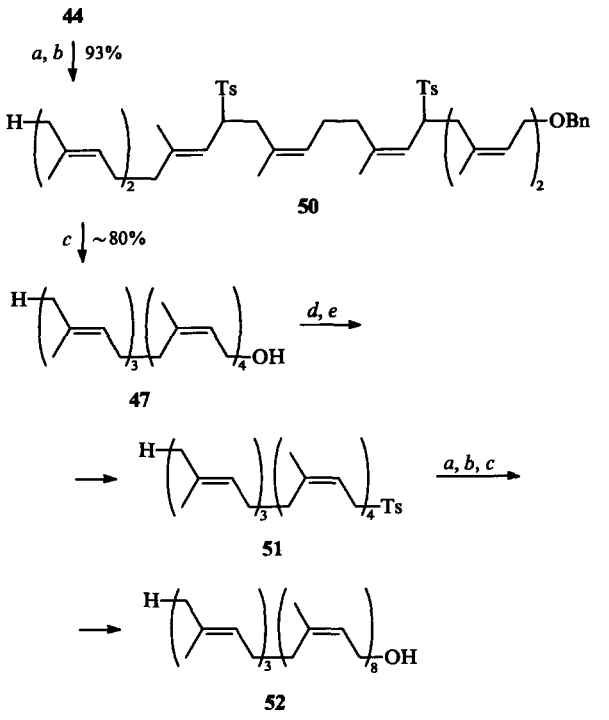
Scheme 5



(*a*) Bu^nLi/THF–HMPA, –78 °C; (*b*) **39a**; (*c*) H_3O^+; (*d*) MsCl, LiCl, *sym*-collidine, DMF; (*e*) **39e**, Bu^n_4NBr/50% NaOH, 20 °C (Ms = methanesulfonyl).

In order to construct the (*Z*)-isoprenoid chain with the aid of these blocks, Sato's group[25] used one of the modern versions of the Wurtz reaction, first proposed by Biellmann[26] and then developed in detail by Altman[27] and Masaki[28] for the construction of the regular (*E*)-polyisoprenoid chain. This method includes the alkylation of the carbanions (stabilised by sulfur-containing functional groups) with the aid of allyl halides and the subsequent Birch reductive cleavage of the C–S bond in the reaction products. Thus the alkylation of the tolyl sulfone **39c** with the aid of the chloride **39a** affords the tolyl sulfone **40** containing four (*Z*)-isoprene units. The latter is converted by a standard method into the chloride **41**, used for the subsequent increase in the length of the (*Z*)-isoprenoid chain (Scheme 5). The tolyl sulfone **42** with a (3*S*)-α-isopentane unit, which is smoothly converted into the chloride **43**, was obtained similarly from the block-synthons **39d** and **39e**.

Having at their disposal (*Z*)-C_{10}-, (*Z*)-C_{15}-, and (*Z*)-C_{20}-block-synthons (compounds **39a**, **39b**, and **41** respectively), Sato's group[24,29] achieved the effective syntheses of pentaprenol (WT_2C_2OH, **17**), hexaprenol (WT_2C_3OH, **19**), heptaprenol (WT_2C_4OH, **47**), octaprenol (WT_2C_5OH, **48**), nonaprenol (WT_2C_6OH, **49**) (Scheme 6), and undecaprenol (WT_2C_8OH, **52**) (Scheme 7). (*E,E*)-Farnesyl tolyl sulfone **44** was used to introduce the transoid fragment into the target compound.

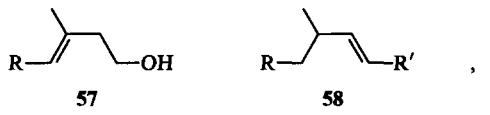


Scheme 6

(*a*) Bu^nLi/THF–HMPA, –78 °C; (*b*) **39a**; (*c*) **39b**; (*d*) Li/$EtNH_2$; (*e*) MsCl, LiCl, *sym*-collidine/DMF; (*f*) TsNa/DMF.

As shown in Scheme 6, the alkenylation by the chlorides **39a, b** of the (*E*)-tolyl sulfone **44** deprotonated by treatment with Bu^nLi affords the tolyl sulfones **45a, b**, the reductive desulfurisation of which is accompanied by the removal of the benzyl protecting groups and leads to pentaprenol **17** and hexaprenol **19** respectively. The latter are smoothly converted by a standard method into the tolyl sulfones **46a, b**, the introduction of which into the sequence of reactions described above gives rise to heptaprenol **47**, octaprenol **48**, and nonaprenol **49** respectively.

Scheme 7

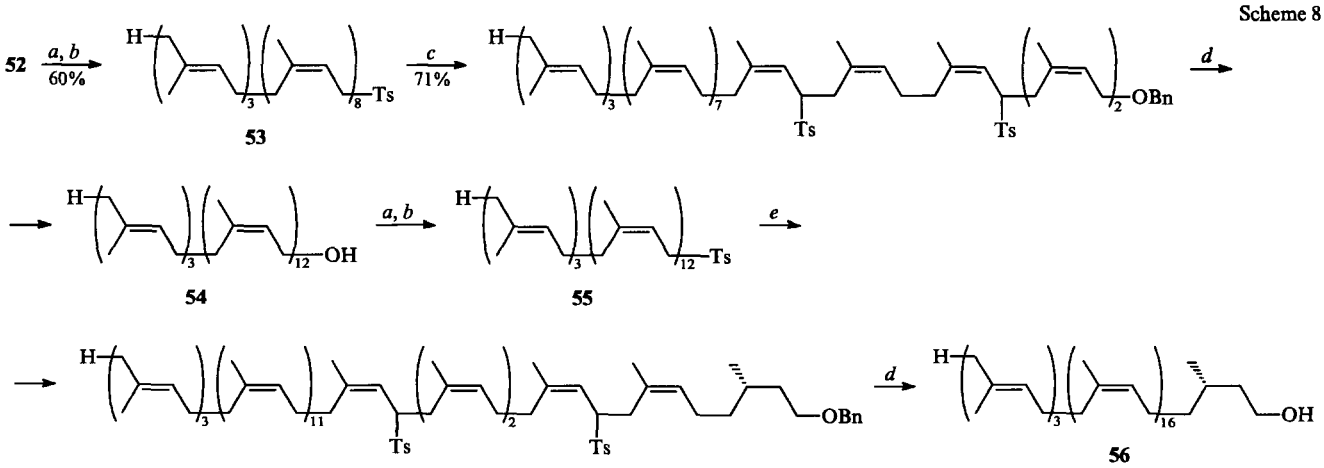


(*a*) Bu^nLi/THF–HMPA, −78 °C; (*b*) **41**; (*c*) $Li/EtNH_2$; (*d*) MsCl, LiCl, *sym*-collidine/DMF; (*e*) TsNa/DMF.

The use of the block-synthon **41** proved to be extremely convenient for the synthesis of higher polyprenols. Thus alkylation of the deprotonated tolyl sulfone **44** by the chloride **41** leads to the tolyl sulfone **50** in 93% yield. The latter loses simultaneously the tosyl and benzyl groups on treatment with lithium in $EtNH_2$ and is converted into heptaprenol **47**. The tolyl sulfone **51** obtained from heptaprenol **47** was transformed similarly into undecaprenol **52**.[29]

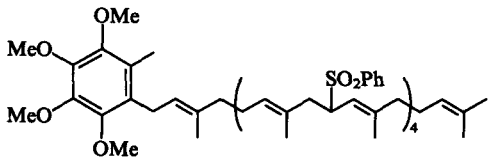
Undecaprenol **52** served in its turn as the starting material for the total synthesis of (*S*)-dolichol (20-eicosaprenol, WT_2C_{16}. .SOH, **56**), achieved with record speed in the chemistry of prenols by Sato and coworkers[25] via a stage involving the synthesis of pentadecaprenol **54** (Scheme 8) by using the C_{20}-block **41** and the (3*S*)-C_{25}-block **43** to increase the length of the (*Z*)-isoprenoid chain.

It is noteworthy that, as in the synthesis of the C_{25}-block **43**, in this synthesis the authors use successfully the effective and technologically convenient method for the alkylation of the toluene sulfones **39d**, **53**, and **55** under phase transfer catalytic conditions.



The version of the Wurtz reaction examined in Section II can be used successfully for the construction of the (*Z*)-isoprenoid chain. However, despite all its advantages, the method suffers from a significant disadvantage, which was noted by the authors of the studies quoted above. In the reductive cleavage of the C–S bond in sulfones of type **21**–**23** and in tolyl sulfones of type **45a, b**, the formation of the target products is accompanied by the formation of their regioisomers, which can be explained by the migration of the C=C bond in the carbanionic intermediate: in the case of the C_5-homologue formation reaction, these are the homoallyl alcohols **57**, while in Sato's block syntheses they are products of type **58**:

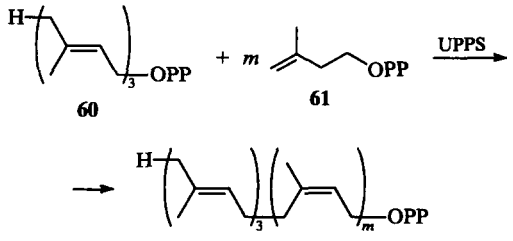
where R and R′ are the corresponding polyprenyl groups.



Systematic study of the desulfurisation conditions in relation to the tolyl sulfones **21**–**23**, undertaken to overcome this disadvantage, showed[10,18,30] that, when the reaction is carried out with the aid of sodium in the 4:4:1 ammonia–hexane–ether emulsion in the presence of 10 mol.% of DB18C6 at −50 °C, it is possible to reduce to 5%–10% the admixture of the isomer **57** and also to suppress completely the hydrogenolysis of the allylic C–O bond. The residual homoallyl alcohol **57** either decomposes in the conversion of the corresponding isoprenols (for example, compounds **15** and **17**) into the corresponding bromides[10,31] or can be removed (as well as an admixture of type **58**) with the aid of precision chromatography on silica gel impregnated with $AgNO_3$.[22,24,29]

Scheme 8

(*a*) MsCl, LiCl, *sym*-collidine/DMF; (*b*) TsNa/DMF; (*c*) **41**, Bu^n_4NBr/50% NaOH, 20 °C; (*d*) $Li/EtNH_2$; (*e*) **43**, Bu^n_4NBr/50% NaOH, 20 °C.

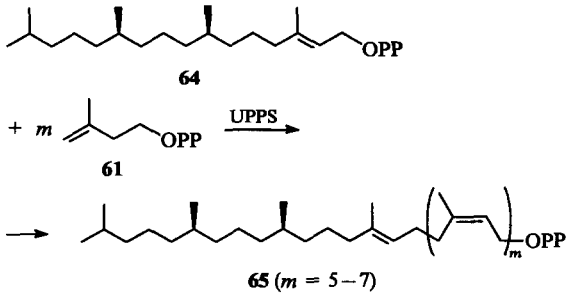


In this connection, one should note an interesting procedure for the selective reduction of allyl sulfones,[32] which was used by the authors of one of the specific syntheses of ubiquinone (10),[33] who showed that all four $PhSO_2$ groups can be removed from the sulfone **59** (without shift of the C=C bond) by means of $LiBHEt_3$ in the presence of catalytic amounts of 1,3-bis-(diphenylphosphino)propanopalladium dichloride.

59

3. Construction of the chain with the aid of enzyme catalysis

Studies in recent years on the biosynthesis of polyprenols have led to the isolation and characterisation of the enzyme responsible for the construction of the (*Z*)-isoprenoid section of the molecule of compound **1**, which has been called undecaprenyl pyrophosphate synthetase (UPPS).[34] Preparations of this enzyme, obtained from various bacterial sources,[34–37] exhibited *in vitro* a high and virtually identical activity in the successive (*Z*)-C_5-homologue formation reactions of the phosphates of isoprenols[38] using isopentenyl pyrophosphate **61** as the source of the (*Z*)-C_5-unit. Thus pyrophosphates of decaprenol (WT_2C_7OH, **62**) and undecaprenol (WT_2C_8OH, **63**) have been synthesised from (*E,E*)-farnesyl pyrophosphate **60**, which is the primary substrate of UPPS *in vivo*.



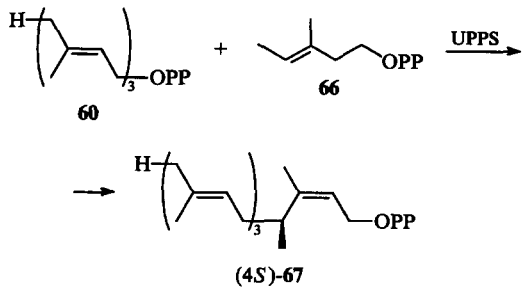
60 **61**

62, 63

62: m = 7; **63**: m = 8.

OPP = pyrophosphate.

The enzyme UPPS does not exhibit a high substrate specificity in relation to the primary substrate and can 'work' with allyl alcohols having different structures.[34–36] For example, the C_{45}–C_{55} glycinoprenols **65**, detected recently in the leaves of the soya bean *Glycine max Merrill*,[40] have been obtained from phytyl pyrophosphate **64** with the aid of the UPPS preparation isolated from *Escherichia coli*.[39]



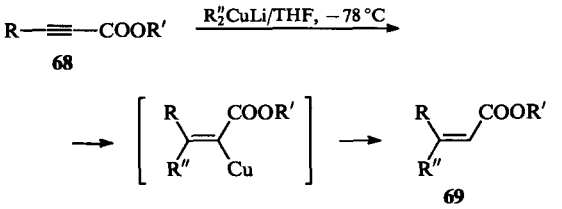
64

61

65 (m = 5–7)

The requirements of UPPS as regards the structure of the homoallyl substrate are more definite. The enzyme exhibits an adequate activity in relation to only one non-natural homoallyl substrate—the pyrophosphate **66**. The presence of the methyl group at the C(4) atom in compound **66** completely alters the nature of the reaction: regardless of the chain length of the allyl substrate, the enzyme catalyses only its conversion into the C_6-homologue, forming 4-methylpolyprenol with the (*S*)-configuration of the C_4 centre, which is illustrated by the conversion of farnesyl pyrophosphate **60** into the phosphate (4*S*)-**67** (Scheme 9).[41]

Scheme 9



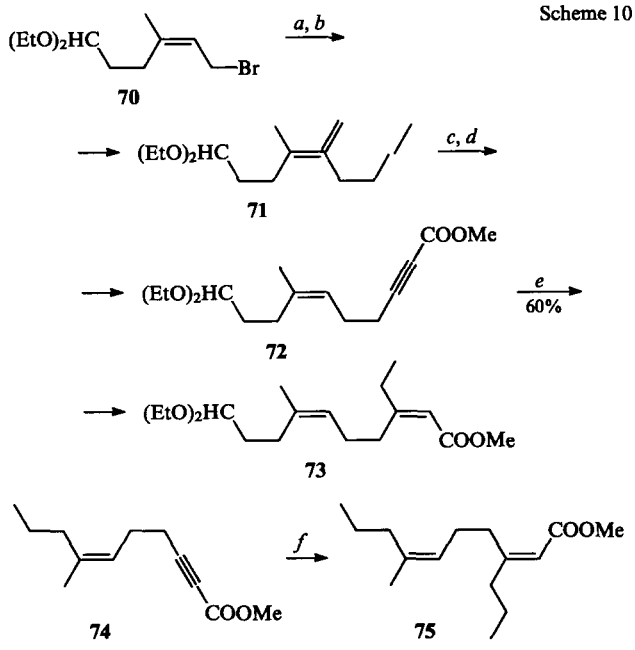
60

(4*S*)-**67**

It may be hoped that the high stereo- and enantio-selectivity of this reaction will find further practical application, as has been shown in relation to farnesyl pyrophosphate synthetase, with the aid of which, the syntheses of faranal and 4-methyl-substituted juvenile hormones have been achieved.[42–44] Thus studies on the biosynthesis of polyprenols provided chemists engaged in organic synthesis with a new valuable reagent for the construction of the (*Z*)-isoprenoid chain.

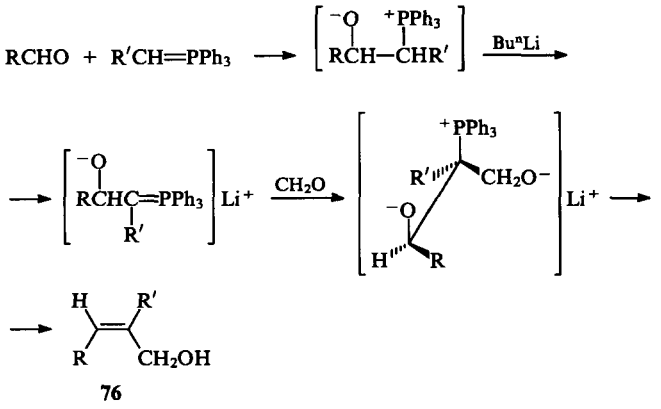
III. Construction of the isoprenoid chain with formation of a new (*Z*)-trisubstituted C=C bond

The elucidation of the biological functions of (*E*)-isoprenoids, in the first place the acyclic steroid precursor squalene, and insect juvenile hormones aroused at the end of the 1960s and the beginning of the 1970s an explosion of interest by chemists concerned with organic synthesis in the development of stereoselective methods for the construction of the (*E*)-trisubstituted C=C bond.[45,46] On the other hand, the methods for the synthesis of (*Z*)-trisubstituted olefins in general and (*Z*)-isoprenoids in particular did not develop adequately before the start of systematic studies on the synthesis of polyprenols. Nevertheless, towards the beginning of the 1970s several methods were described in the literature for the stereoselective construction of (*Z*)-trisubstituted olefin systems. Thus Corey and Katzenellenbogen[47] showed that the addition of dialkyl cuprates to α,β-acetylenic acids and their esters in THF at low temperatures proceeds exclusively as a *cis*-process[47] and they suggested that it be used, in particular, for the conversion of esters of β-alkyl- and β-alkenyl-propiolic acids **68** into esters of type **69**.



68

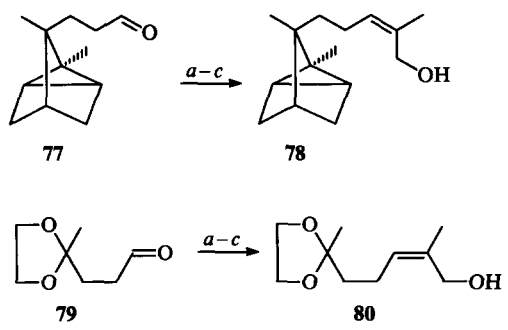
69



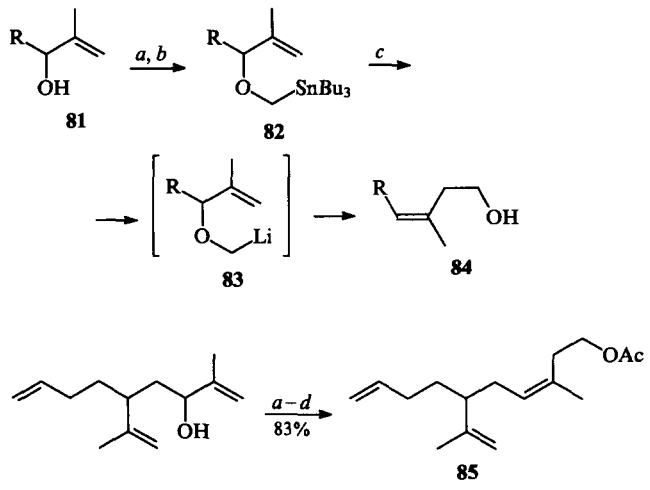
R = Me, Et, Bu^n, Ph; R′ = Me, Et, Bu^s; R″ = Me, Et.

The application of the method is illustrated in Scheme 10. The allyl bromide **70** is synthesised and converted via the enyne **71** and ester **72** stages into the ester **73**—the key block-synthon in the synthesis of the natural ionophore monensin,[48] while the ester **74** is converted into the pheromone of the lesser apple-worm *Laspeyresia pomonella L.* **75**.[49]

Scheme 10

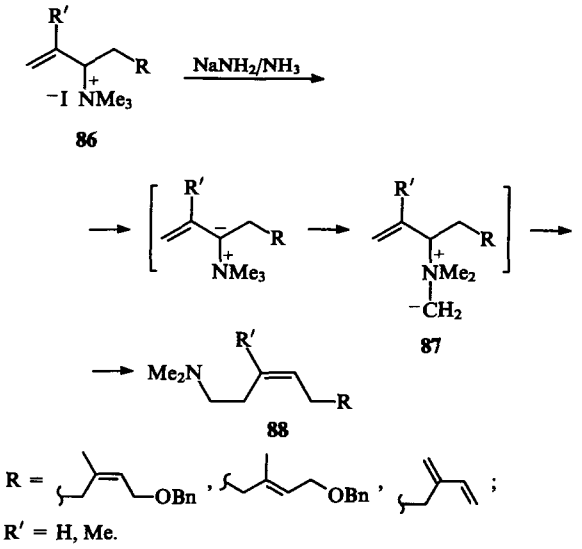


(*a*) $LiCH_2C{\equiv}CSiMe_3$; (*b*) $AgNO_3$, NaCN; (*c*) Bu^nLi; (*d*) $ClCO_2Me$; (*e*) Et_2CuLi/THF, −70 °C; (*f*) Pr^n_2CuLi/THF, −70 °C.



A highly stereoselective method for the construction of allyl alcohols **76** with the aid of two consecutive Wittig reactions achieved in one reactor (using formaldehyde as the carbonyl component in the second reaction) was developed simultaneously in Corey's laboratory.[50]

For R′ = Me, this sequence of reactions makes it possible to construct the terminal (*Z*)-isoprene unit, as shown for the conversion of the aldehyde **77** into α-santalol **78**[50] and of the aldehyde **79** into the ketal alcohol **80**. The latter is a key block-synthon for the synthesis of (±)-trisporal B and (±)-trisporic acid.[51]

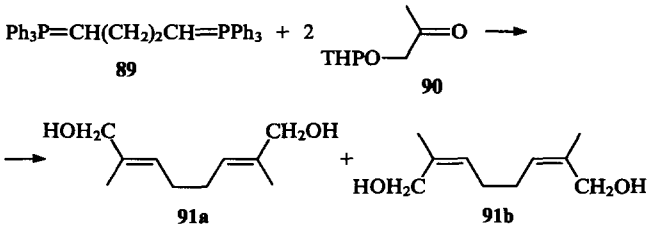


(*a*) $MeCH{=}PPh_3$; (*b*) Bu^nLi; (*c*) CH_2O.

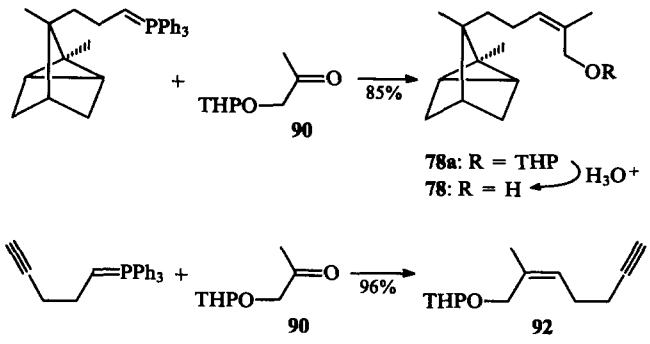
An effective method of synthesis of (*Z*)-homoallyl alcohols **84** is also noteworthy. It was developed by Still and Mitra[54] on the basis of the stereochemically unusual [2,3]-sigmatropic rearrangement (cf. Masaki et al.[52] and Inoue et al.[53]) of the methylallyloxymethyllithio-derivatives of compound **83**, which they observed. The rearrangement takes place *in situ* on treatment of the tributylstannylmethyl ethers of the methylallyl alcohols **82** with Bu^nLi.[54] The method has been used successfully in the synthesis of the component **85** of the pheromone of the red San Jose scale.[54]

(*a*) KH; (*b*) Bu_3SnCH_2I; (*c*) Bu^nLi; (*d*) Ac_2O–Py.

Yet another example of the [2,3]-sigmatropic rearrangement, leading to the highly stereoselective synthesis of di- and tri-substituted (*Z*)-olefins, appeared later in the literature. It was discovered by Sato's group[55] in relation to the ylides **87**, which are converted into the amines **88** on treatment with $NaNH_2$ in NH_3 at the instant of formation from the quaternary ammonium salts **86**.[55] The amines **88** can be readily transformed by standard methods into the corresponding (*Z*)-homoallylic aldehydes or alcohols.



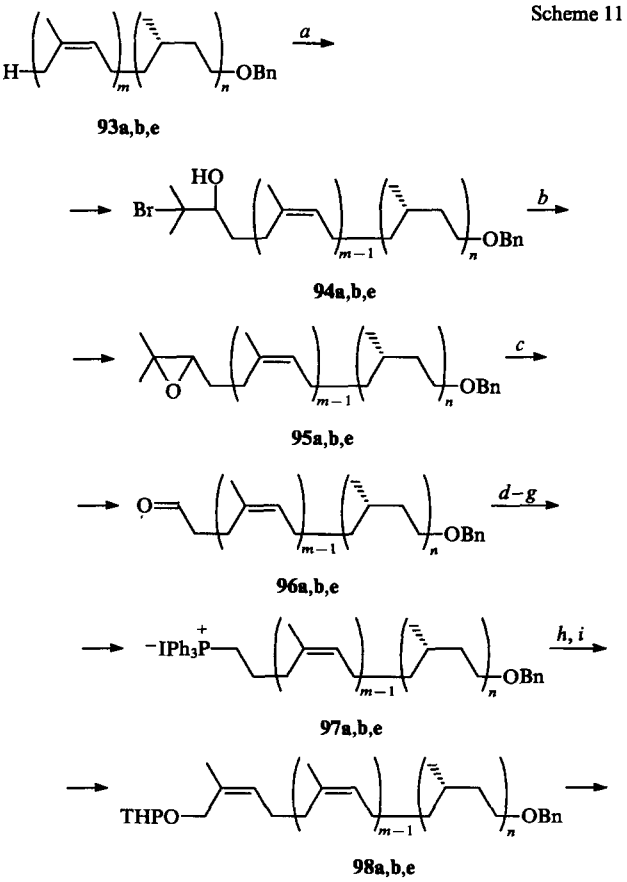
All the methods considered above yield satisfactory results in the synthesis of the terminal (*Z*)-isoprene unit (for example, in the alcohol **76** for R' = Me or in compound **84**), but they are fundamentally unsuitable for the synthesis of the disubstituted (*Z*)-methylalkene fragment in the middle of the chain. The attempt to construct a fairly long (*Z*)-isoprenoid chain from them by the multistage growth of the (*Z*)-C_5-units was also relatively ineffective because the construction of each succeeding unit requires a multistage preparatory step involving the preparation of the necessary starting materials. These disadvantages were overcome in the method of synthesis of (*Z*)-trisubstituted olefins examined below, which were developed for the synthesis of polyprenols.



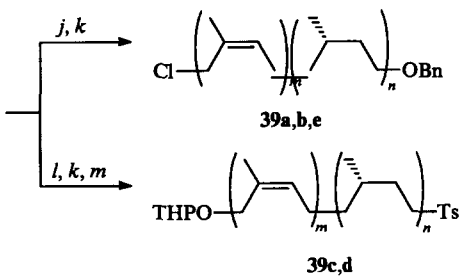
1. Conversion of derivatives of hydroxyacetone into olefins by the Wittig reaction

As already mentioned in Section II. 2, Sato and coworkers [22, 24, 25] suggested that fairly large (*Z*)-(C_{20}–C_{25})-isoprenoid blocks, obtained by alkylating (*Z*)-tolyl sulfones **39c, d** by the chlorides **39a, b, e** be used for the synthesis of polyprenols and dolichols. On the other hand, the authors used the Wittig reaction between unstabilised phosphonium ylides and derivatives of hydroxyacetone, for example its THP-derivative **90**, in order to synthesise the ω-functionalised (*Z*)-block-synthons of type **39**, which are otherwise difficult to obtain.

The considerable predominance of the (*Z*)-isomer in products of this reaction was first noted by Bhalerao and Rapoport [56] in the conversion of the ketone **90** into an olefin by treatment with the bisylide **89**, which led to a mixture of the diols **91a** and **91b** in proportions of 1 : 4.

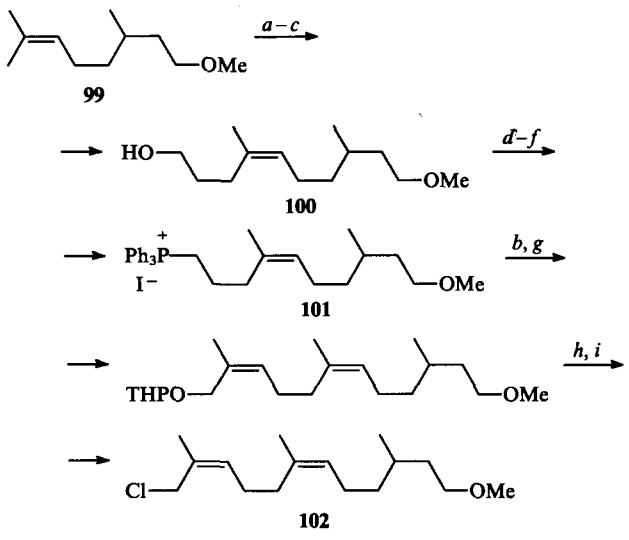


Systematic study of the influence of the reaction conditions on reaction stereochemistry, carried out simultaneously by Sato's [57] and Still's [58] groups, made it possible to increase the (*Z*)-stereoselectivity of the process to 95%–99% with virtually quantitative yields of the product. Still's group synthesised α-santalol **78** with precisely such stereochemical purity, [58] while Sato's group obtained the enyne **92** — a key block-synthon in the total synthesis of (*Z*,*Z*)-farnesylacetone — with the same stereochemical purity. [57]



On the basis of the above results, Sato's group [22, 24, 25] achieved the stereoselective synthesis of the block-synthons **39**, having obtained by a standard procedure the phosphonium salts **97a, b, e** required for this purpose from the aldehydes **96a, b, e**, which were prepared in their turn by transforming, by means of the van Tammelen method, the benzyl ethers of nerol (**93a**), (*Z*,*Z*)-farnesol (**93b**), and (3*S*)-citronellol (**93e**) via stages involving the formation of the bromohydrins **94a, b, e** and the epoxides **95a, b, e** (Scheme 11). The condensation of the ylides generated from the phosphonium salts **97** with the THP-derivatives of hydroxyacetone **90** affords the (*Z*)-isoprenoids **98** containing hydroxy-groups in different positions — the α- and ω-positions. As a result of this, the blocks **98a, b, e** can be selectively converted by standard methods both into the chlorides **39a, b, e**, modelling the 'tail' (OH-containing) fragment of polyprenols of types **1** and **2**, and into the tolyl sulfones **39c, d** containing the central (*Z*)-fragment of these compounds.

Scheme 11



Scheme 11 (continued)

a,**c**: $m = 2, n = 0$; **b**,**d**: $m = 3, n = 0$; **e**: $m = n = 1$.

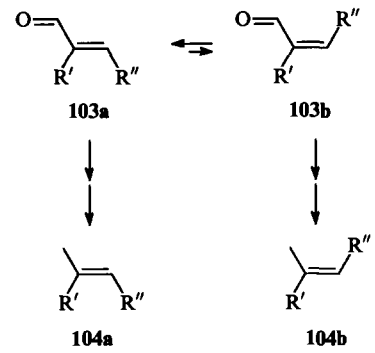
The same authors[59] recently patented yet another method for the (*Z*)-functionalisation of isoprenol ethers. It consists in the successive treatment of the methyl ether of the corresponding isoprenol, for example citronellol **99**, with strong bases and epoxyethane. This affords the (*Z*)-bishomoallyl alcohol **100**, which can be readily converted into the phosphonium salt **101** and the latter is subsequently transformed, as shown above for the phosphonium salt **97**, into the chloride **102** (Scheme 12).

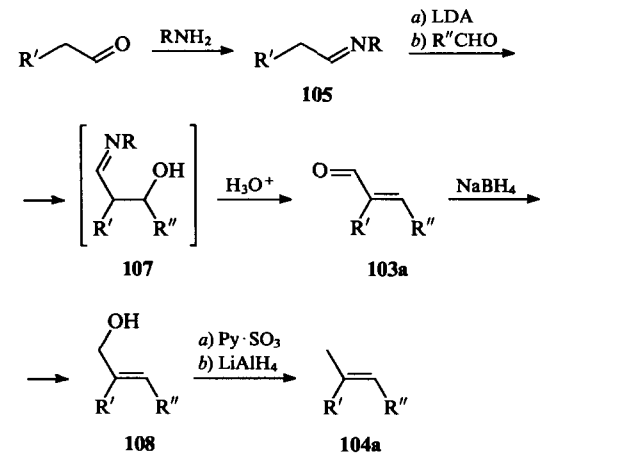
Scheme 12



(*a*) Bu^tOK; (*b*) Bu^nLi; (*c*)  ; (*d*) TsCl; (*e*) NaI; (*f*) Ph_3P; (*g*) **90**; (*h*) H_3O^+; (*i*) MsCl, LiCl.

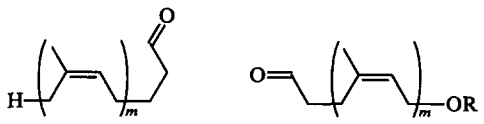
It was demonstrated in Section II, 2 how polyprenols **1** and **2**, containing up to 16 (*Z*)-isoprene units, were synthesised with the aid of the sulfones **39c**,**d** and the chlorides **39a**,**b**,**e**, **41**, and **43**.

2. A general method for the construction of the (*Z*)-trisubstituted C=C bond by specific aldol condensation



Another approach to the construction of (*Z*)-trisubstituted olefins has been developed in the Laboratory of the Chemistry of Polyunsaturated Compounds of the Institute of Organic Chemistry of Russian Academy of Sciences. It is based on the fact, observed by Grigor'eva et al.,[60] that α,β-disubstituted (*E*)-acroleins **103a** are thermodynamically preferable to their (*Z*)-isomers **103b**, which ensures the presence of more than 95% of the (*E*)-isomer **103a** in the equilibrium mixture (^1H NMR data).[61] This rule is general in the case of acroleins **103** without a branched chain at the allylic carbon atom.[60]

Since the acroleins **103** can be converted by Corey's method[62] into the methylalkenes **104** with complete retention of the configuration, the observed ability of the CHO group to fix the configuration of compound **103a** opened a highly stereoselective path to the construction of the disubstituted (*Z*)-methylalkenes **104a** (involving the synthesis of compound **103a**) and their subsequent stereospecific reductive transformation.

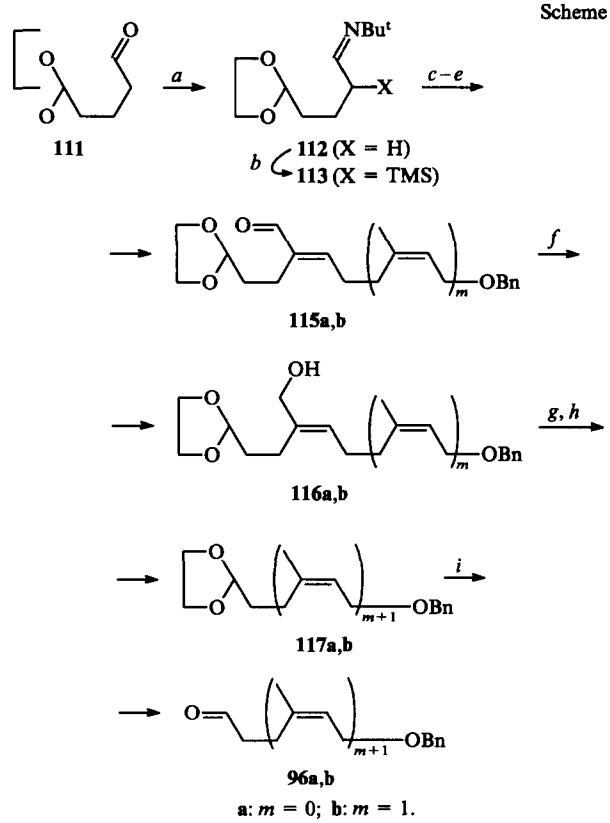


In order to obtain the key (*E*)-acroleins **103a**, the authors applied a version of the cross-condensation of aldehydes, one of which is in the form of the aldimine **105** (Scheme 13). In the literature, this reaction is known as the specific Wittig condensation.[63] The interaction of aldimines **105** deprotonated by means of lithium diisopropylamide (LDA) with the aldehyde **106** leads, after mild acid hydrolysis of the intermediate β-hydroxyimines **107**, to the (*E*)-acroleins **103a**, the stereochemical purity of which in all the cases investigated exceeds 95%.[64] The subsequent reductive transformation of compound **103a** via the stage of the allyl alcohols **108** and the corresponding sulfoesters by the method of Corey and Ahiwa[62] affords the (*Z*)-methylalkenes **104a**.

Scheme 13

R = *tert*-C_4H_9, *cyclo*-C_6H_{11}; R′ = C_2H_5, n-C_4H_9, n-C_6H_{13}, n-C_7H_{15}; R″ = n-C_5H_{11}, n-C_6H_{13}, n-C_7H_{15}, $(CH_2)_nOTHP$ (n = 5, 8), $(CH_2)_nOAc$ (n = 8).

α-Trishomoisoprenals of type **109** and ω-bisnorisoprenals of type **110** are necessary for the construction of the (*Z*)-isoprenoid chain with the aid of this method.

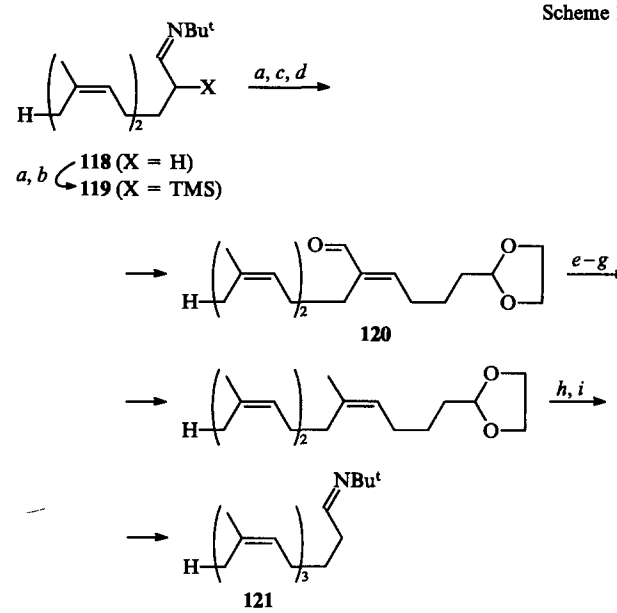


109 **110**

Compounds **109** and **110** can be obtained by the transformation of natural (*Z*)-isoprenoids, as shown above for the aldehydes **96a, b, e** (Scheme 11) or aldehydes which can be readily obtained by oxidising the alcohols **100** (Scheme 12). The method of synthesis of disubstituted (*Z*)-methylalkenes considered leads to the possibility of synthesising aldehydes of types **109** and **110** from non-isoprenoid compounds. The monoacetal of glutaraldehyde **111** and the corresponding *tert*-butylimine **112** are convenient starting materials for this purpose. Block synthons of both types indicated have been synthesised from them.[65]

Thus the synthesis of the aldehyde **96b** from the α-TMS-derivative of *tert*-butylimine **113** is illustrated in Scheme 14.[66] The process includes the condensation of the TMS-derivative of compound **113**, deprotonated by means of LDA, with benzyloxyacetaldehyde **114**, which leads to the (*E*)-acrolein **115a** in a preparative yield and with a stereoselectivity in excess of 95%. On reductive transformation via stages involving the formation of the allyl alcohol **116a** and the corresponding sulfoester, the acrolein **115a** is converted into the acetal **117a** in an overall yield of 25%. When the aldehyde **96a**, formed on hydrolysis of the acetal **117a** via the (*E*)-acrolein **115b** ($E \geqslant 95\%$), the alcohol **116b**, and the acetal **117b** stages, was introduced into the sequence of reactions described, the target aldehyde **96b** was obtained. By repeating the above chain of reactions, it is possible, in principle, to continue the growth of the (*Z*)-isoprenoid chain still further from its α-unit to its ω-unit.

Scheme 14



111 **112** (X = H), **113** (X = TMS) **115a,b** **116a,b** **117a,b** **96a,b**

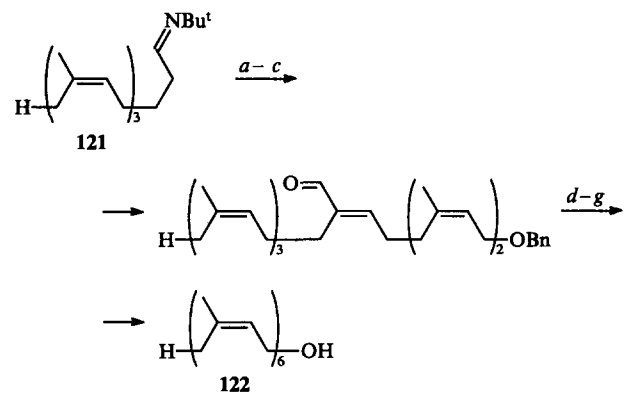
The conversion of the aldehydes **96a, b** into olefins by the Wittig method[67] affords the stereochemically pure nerol and (*Z,Z*)-farnesol. The latter were used to synthesise with the aid of the monoacetal **111** the imines of trishomoprenals of type **109**, which is illustrated (Scheme 15) by the conversion of the α-TMS-derivative of the aldimine **119**, prepared in six stages from nerol,[68] into the aldimine **121** via the key (*E*)-acrolein **120** stage in an overall yield of ~10%.

Scheme 15

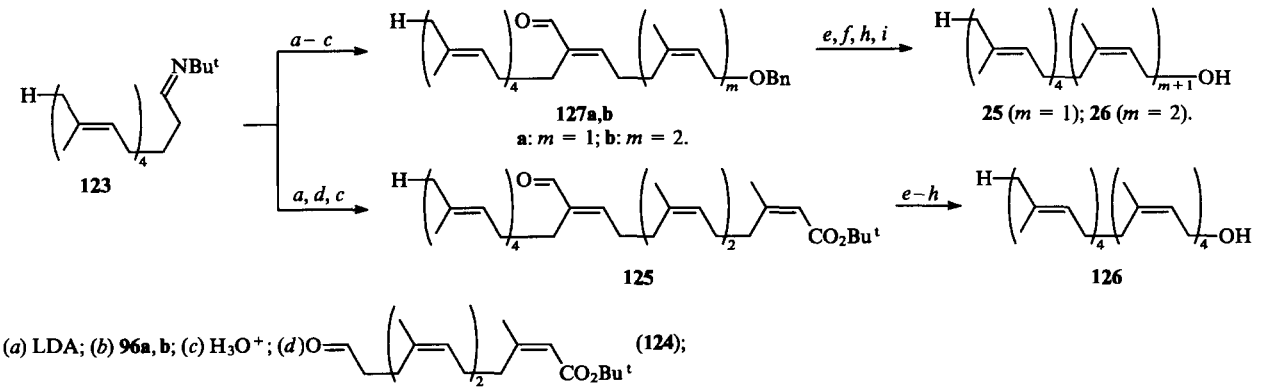


118 (X = H), **119** (X = TMS) **120** **121**

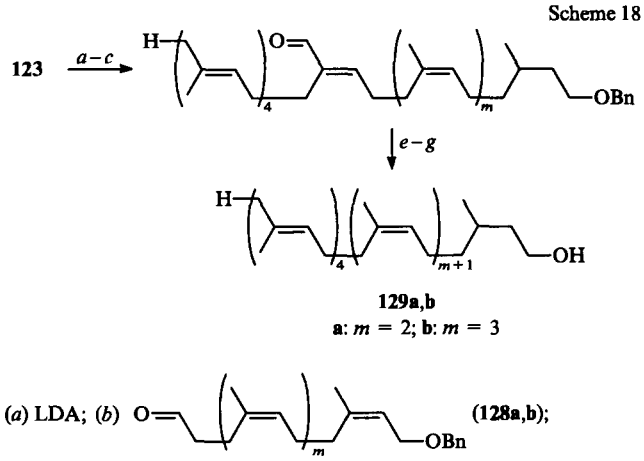
(*a*) LDA; (*b*) Me_3SiCl; (*c*) **111**; (*d*) H_3O^+ (pH 4); (*e*) $NaBH_4$; (*f*) Py·SO_3; (*g*) $LiAlH_4$; (*h*) H_3O^+; (*i*) Bu^tNH_2.

The aldimine **121** and the aldehyde **96b** obtained in this way were used to construct the (*Z*)-isoprenoid chain in the synthesis of the fully cisoid hexaprenol WC_5OH **122** with a nonnatural configuration of the ω-section of the chain (Scheme 16).[66]

Scheme 16

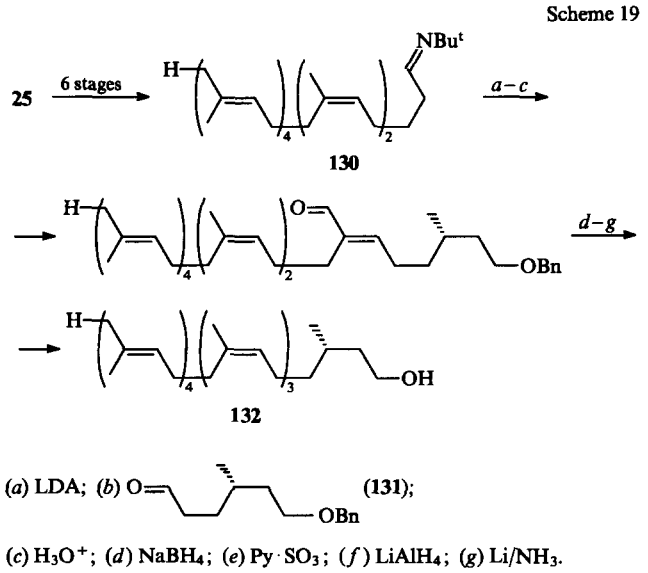


121 **122**



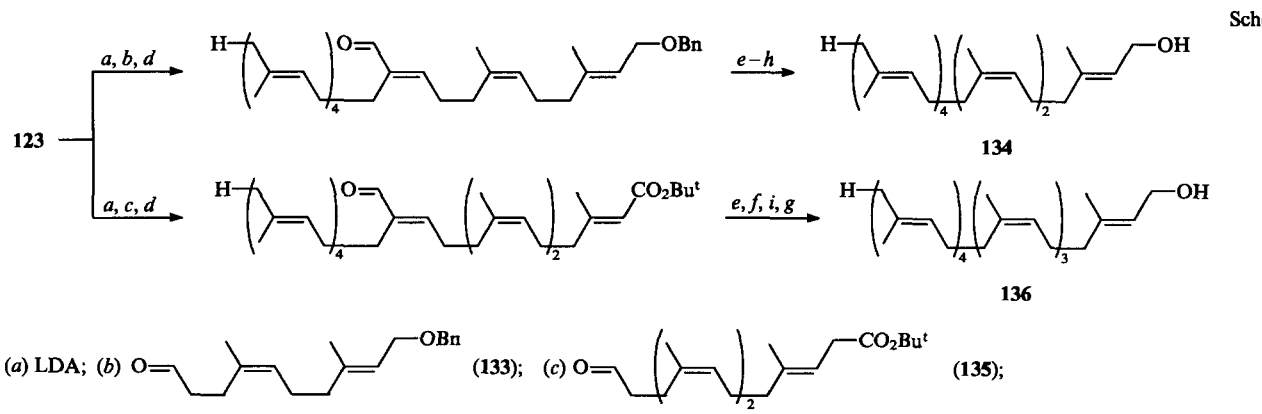
(*a*) LDA; (*b*) **96b**; (*c*) H_3O^+; (*d*) $NaBH_4$; (*e*) Py·SO_3; (*f*) $LiAlH_4$; (*g*) Li/NH_3.

The approach considered proved to be extremely effective also in the construction of natural polyprenols, as shown in relation to hexaprenol (WT_3C_2OH, **25**),[69] heptaprenol (WT_3C_3.OH, **26**),[10] and octaprenol (WT_3C_4OH, **126**)[70] isolated from the juice of the palm *Serenoa repens* (Scheme 17).[11] They were synthesised with participation of the aldimine **123**, containing a ω-transoid fragment of the above polyprenols and prepared from geranyllinalool,[71] and the aldehydes **96a, b** and **124** respectively[70] via key stages involving the formation of the (*E*)-acroleins **127a, b** and **125**.

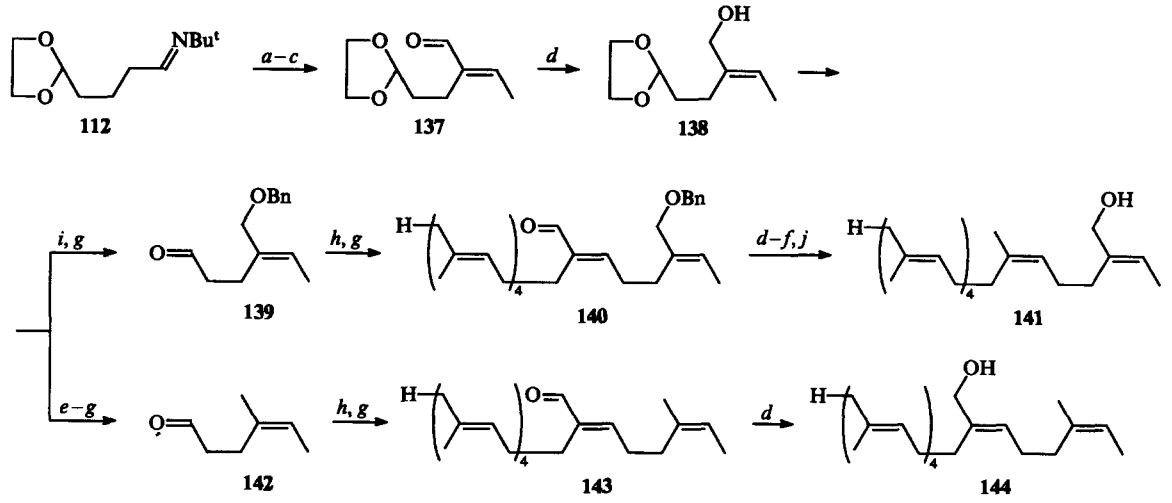


Scheme 17

Scheme 18

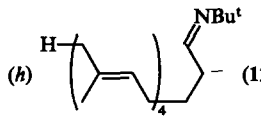


Scheme 19



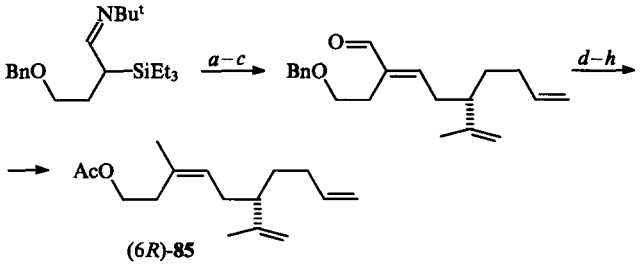
By means of the same methodology,[72] the racemic octaprenol (WT_3C_3SOH, **129a**) and nonaprenol (WT_3C_4SOH, **129b**), related to dolichols, were obtained from the aldimine **123** and the aldehydes **128a, b** (Scheme 18), while the dolichol-like octaprenol WT_3C_3SOH **132**,[69] with the natural (*S*)-configuration of the α-unit, was synthesised from the aldimine **130** prepared from the hexaprenol **25** described above and the chiral aldehyde **131** (Scheme 19).

The method has also found a successful application in the synthesis of modified polyprenols necessary for biochemical research. Thus the polyprenols **134**[71] and **136**,[70] with the non-natural (*E*)-configuration of the α-unit, have been obtained with its aid using the aldimine **123** block and the aldehyde **133** and **135** blocks (Scheme 20).

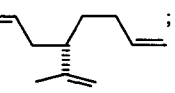


Scheme 20

Scheme 21



(*a*) LDA; (*b*) CH_3CHO; (*c*) H_3O^+ (pH 4); (*d*) $NaBH_4$; (*e*) Py·SO_3; (*f*) $LiAlH_4$; (*g*) H_3O^+;



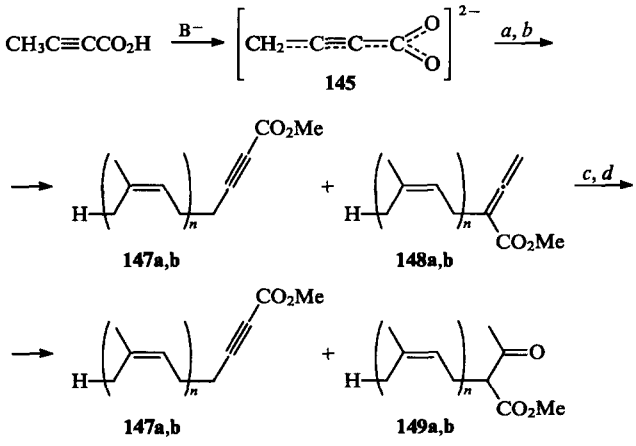
(*h*) (**123a**); (*i*) BnCl/NaH; (*j*) Li/NH_3.

The modified hexaprenols **141** and **144**,[73] with a nonnatural disposition of the OH group, were synthesised similarly from the same aldimine **123** and the aldehydes **139** and **142**. We may note that the block-synthons **139** and **142** were also obtained with the aid of the method, considered here, for the construction of (*Z*)-isoprenoids from the common precursors **137** and **138** (Scheme 21).

French chemists showed recently[74] that the method under discussion is optimal for the synthesis of the (6*R*)-**85** component of the pheromone of red San Jose scale and that its stereoselectivity is superior to that of other procedures[54,75] proposed for the synthesis of this compound.

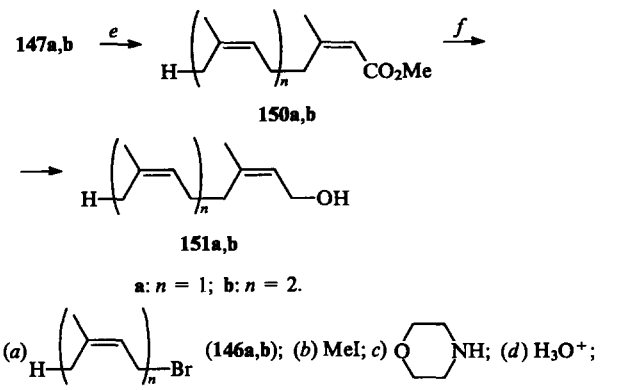
(6*R*)-**85**

(*a*) LDA; (*b*)  ; (*c*) H_3O^+; (*d*) $LiAlH_4/Et_2O$;



(*e*) Py SO_3; (*f*) $LiAlH_4$/THF; (*g*) Li/NH_3; (*h*) Ac_2O–Py.

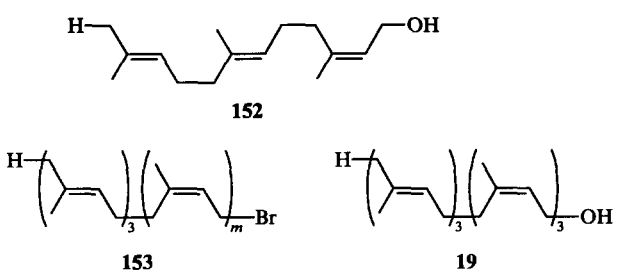
Thus the method for the construction of (*Z*)-trisubstituted olefins, based on the thermodynamic preference for α,β-disubstituted (*E*)-acroleins, leads to extensive possibilities for the synthesis of biologically active (*Z*)-isoprenoids.



IV. Synthesis of (*Z*)-isoprenoids with formation of new C–C and (*Z*)-trisubstituted C=C bonds

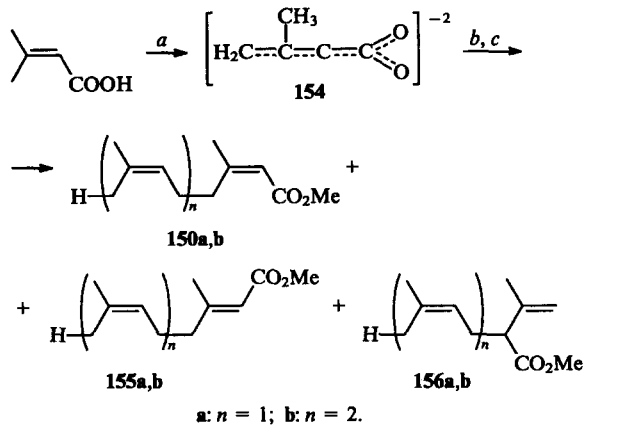
In 1975, Baran and coworkers[76,77] investigated the possibility of the specific γ-alkylation of α,β-unsaturated acids in order to use the above reaction in the synthesis of polyprenols. They showed that the alkylation of the dianion of 2-butynoic acid **145** by prenyl bromide **146a** or neryl bromide **146b** leads to mixtures of products of γ- and α-alkylation stabilised in the form of the methyl esters **147a, b** and **148a, b**, which can be readily separated chromatographically after the conversion of the allene esters **148a, b** into the ketoesters **149a, b** (Scheme 22). The regioisomers ratio **147** : **148** is to a large extent determined by the nature of the base used to generate the dianion **145** and amounts to 2 : 1 in the case of lithium tetramethylpiperidide[76] and 3 : 1 in the case of LDA.[77] The use of the Bu^nLi–TMEDA (TMEDA = tetramethylethylenediamine) system made it possible to obtain the target ester **147** virtually free of compound **148**.[78]

Scheme 22



Scheme 22 (continued)

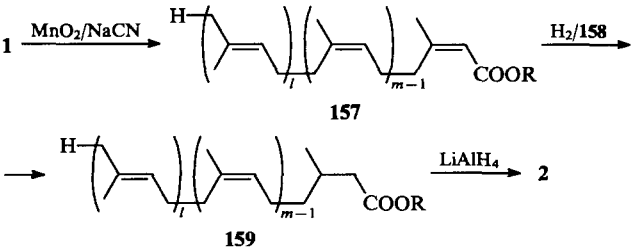
The stereoselective addition of dimethyl cuprate to the acetylenic fragment **147** by Corey's method[47] completes the formation of the new (*Z*)-isoprene unit and affords the esters **150** with an isomeric purity of about 98%, which can be smoothly reduced to the target (*Z*)-isoprenols **151**.



The involvement of geranyl bromide in the reaction chain presented in Scheme 22 led to (*Z,E*)-farnesol **152**[77] and the successive employment in these reactions of the isoprenoid bromides **153** (m = 0–2) enabled Baran et al.[79] to achieve the total synthesis of the hexaprenol WT_2C_3OH **19**, which they published without experimental details.

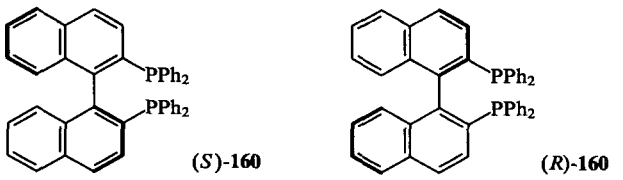
The version, investigated by the same authors,[77] of the synthesis of (*Z*)-isoprenols **151a,b** by alkylating the dianion of 3-methylcrotonic acid **154**, which is *a priori* more attractive than the γ-alkylation of 2-butynoic acid examined above since it makes it possible to construct in one stage the required isoprenoid skeleton (Scheme 23), proved to be less successful. Experimental tests showed that the interaction of the dianion of the acid **154** with prenyl bromide **146a** or neryl bromide **146b** affords, after methylation of the carboxy-group, a mixture of the products of γ-(*Z*)-alkylation (compound **150**), γ-(*E*)-alkylation (compound **155**), and α-alkylation (compound **156**) in proportions of 1 : 4 : 11. The γ : α product ratio can be increased[77] to ~4 : 1 and even to ~13 : 1 by using the cuprate complex.[154] This procedure has little effect on the stereochemistry of the reaction. The isomer ratio **150** : **155** in this reaction does not exceed ~5 : 3 and the isolation of the target product **150** requires repeated chromatography.

The data described in Section IV make it possible to conclude that, although the method involving the regioselective γ-alkylation of 2-butynoic acid developed for the synthesis of polyprenols is less effective than the alternative methods for the construction of the (*Z*)-isoprenoid systems examined in Sections II and III, nevertheless it can be used successfully for the synthesis of acetylenic esters of type **147**, which are convenient block-synthons in organic synthesis.



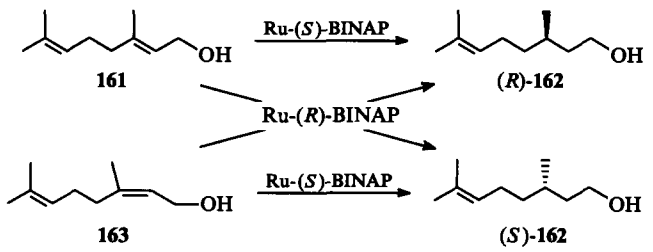
Scheme 23

V. Regioselective and enantioselective hydrogenation of the Δ^2-bond in α-functionalised isoprenoids



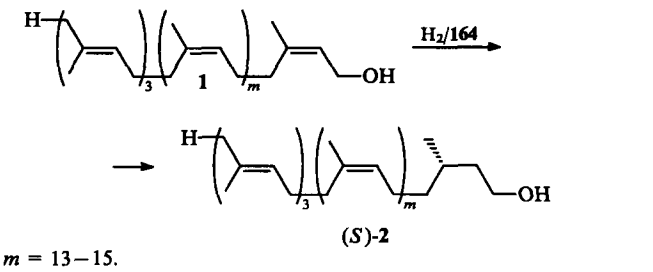
The methods for the construction of the (*Z*)-isoprenoid chain examined above made it possible to achieve the total syntheses of polyprenols **1**, dolichols **2**, and their modified analogues. At the same time, the possibility of the regioselective and enantioselective hydrogenation of the Δ^2-bond of polyprenols **1** is of significant interest for the partial synthesis of dolichols (which are a characteristic type of polyprenols in mammals) from much more readily available polyprenols of plant origin. The first attempt on these lines was by Polish biochemists[80] but did not yield the required results. Hydrogenation of the undecaprenol WT_2C_8OH **52** in alcohol over a platinum catalyst in the presence of $NaBH_4$, which they investigated, led to a mixture of the undecaprenols WT_2C_7SOH, WT_2C_6SCOH, $WT_2C_5SC_2OH$, and $WT_2C_4SC_3OH$.

The regioselective reduction of the α,β-unsaturated esters **157**, described in a patent,[81] proved more successful. The esters were obtained by standard methods from polyprenols **1** of plant origin with the aid of lithium in NH_3 or hydrogen in the presence of a metal complex catalyst — μ,μ'-dichlorobis-(cycloocta-1,5-diene)-rhodium/neopentyldiphenylphosphine **158**. The racemic esters **159** formed in this reaction are reduced smoothly by $LiAlH_4$ to the target dolichols **2**.



R = H, Alk; l = 2, m = 15.

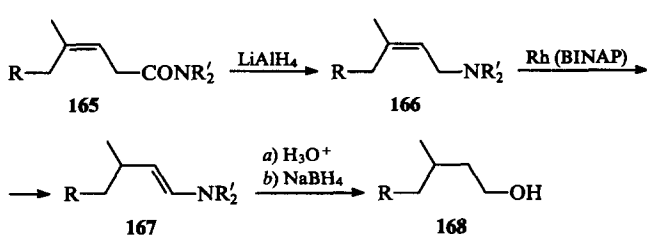
The introduction of metal complex catalysts with optically active ligands into practical organic synthesis made possible the single-stage conversion of polyprenols **1** into (*S*)- or (*R*)-dolichols. Ruthenium complexes of the (*S*)- or (*R*)-form of 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl (BINAP) **160** proved to be optimal for this process.[82]



It was shown in relation to the simplest isoprenols—geraniol **161** and nerol **163**—that there is a rigorous correlation between the olefinic geometry of the substrate, the configuration of the chiral ligand in the catalyst, and the configuration of the chiral centre in the reaction product. Thus hydrogenation of the alcohol **161** in the presence of a ruthenium dicarboxylate complex with (*S*)-BINAP ligands affords (*R*)-citronellol **162**, whilst in the presence of the analogous complex with (*R*)-BINAP ligands the product is (*S*)-citronellol **162**. On the other hand, hydrogenation of compound **163** in the presence of the complexes with (*S*)-BINAP and (*R*)-BINAP ligands leads to (*S*)-**162** and (*R*)-**162** respectively.[83]

The method involving hydrogenation using the above catalysts has all the qualities necessary to achieve total asymmetric synthesis: high yields and enantiomeric purity in excess of 96%, a high regioselectivity of the reaction, the absence of the migration of the C=C bond and of the *E*/*Z* isomerisation, a high substrate/catalyst molar ratio, and, ease of recovery and regeneration of the catalyst without loss of its activity and selectivity.

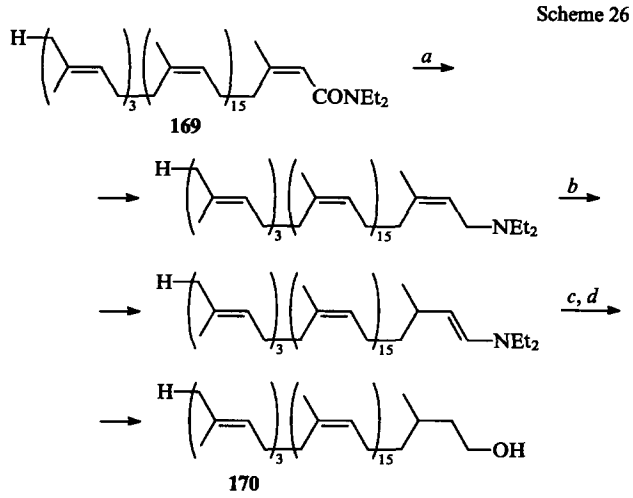
The asymmetric hydrogenation of the mixture of polyprenols **1** isolated from *Ginkgo biloba*, catalysed by Ru-(*S*)-BINAP bistrifluoroacetate **164** and carried out taking into account the above features, led to a mixture of the corresponding dolichols **2** in a high yield and with an enantiomeric purity in excess of 95%. The mixture contained less than 2% of the products involving the reduction of other C=C bonds (Scheme 24).[84]



Scheme 24

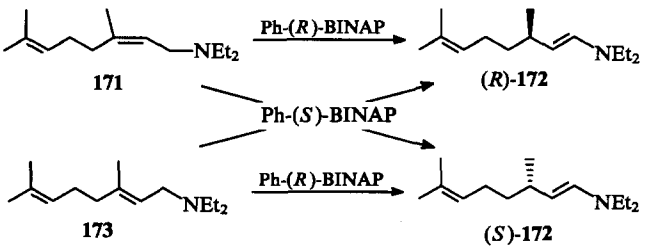
m = 13–15.

The synthesis of dolichols **2** with the aid of metal complex catalysis can also be achieved starting with derivatives of polyprenylcarboxylic acids isolated, together with polyprenols **1**, from plant raw material. Thus it has been found[85] that BINAP-containing rhodium catalysts exhibit a high activity in the isomerisation of tertiary allylamines **166**, formed smoothly on hydride reduction of the amides **165** (Scheme 25).



Scheme 25

R = Alk, ; R' = Alk, cycloalk, Ar.



The enamines **167** thus obtained can be readily converted by standard methods into the correpsonding 4-C-substituted isopentanols **168**. The method has been applied successfully in the synthesis of the racemic dolichol $WT_2C_{15}SOH$ **170** from the amide **169** (Scheme 26).[86]

Scheme 26

(*a*) $LiAlH_4$; (*b*) Rh[BINAP(COD)]ClO_4; (*c*) H_3O^+; (*d*) $NaBH_4$
COD = cycloocta-1,5-diene.

The successful use of the Rh-(*R*)- and Rh-(*S*)-BINAP catalysts for the conversion of *N*,*N*-diethylnerylamine **171** and *N*,*N*-diethylgeranylamine **173** respectively into the enamines (*R*)- and (*S*)-**172**, which are intermediates in the synthesis of (*R*)- and (*S*)-citronellol, permits the hope that it will be possible also to achieve the synthesis of chiral dolichols with the aid of these catalysts.

By virtue of its high effectiveness and enantioselectivity, the method for the asymmetric hydrogenation of polyprenols **1** examined above appears to be the best of the known procedures for the conversion of (*Z*)-isoprenols into their (*S*)- or (*R*)-2,3-dihydro-derivatives.[18,87]

* * *

The data described show that the synthetic studies on polyprenols and dolichols provided organic chemistry with a series of effective and highly stereoselective methods for the construction of disubstituted (*Z*)-methylalkene systems, as well as regioselective and enantioselective procedures for the conversion of α-functionalised isoprenoids into their 2,3-dihydro-derivatives, which have already found interesting applications in the synthesis of other biologically active compounds.

II. Models of the molecular weight distribution 185
III. Experimental molecular weight distributions 189
IV. The influence of the conditions in the Fischer–Tropsch synthesis on the molecular weight distribution 192

Abstract. The literature data on the principal types of experimental molecular-weight distributions in the products of the Fischer–Tropsch synthesis are examined and classified. The influence of the catalyst composition and the experimental conditions in the Fischer–Tropsch synthesis on the type of molecular weight distribution is considered. The possible mechanisms of the propagation and termination of the hydrocarbon chain in the Fischer–Tropsch synthesis are discussed using the available data on the molecular-weight distribution. The bibliography includes 94 references.

I. Introduction

The study of the molecular weight distribution (MWD) in the products obtained in the Fischer–Tropsch (FT) synthesis constitutes a rapidly developing field of research. Data on the MWD of the products obtained are quoted in virtually every study published after 1980 and devoted to the FT synthesis. These data are of great interest in understanding the mechanism of the FT synthesis and can serve as a basis for the regulation of the process selectivity — an important and complex problem. The increase in the number of publications on this aspect of research has been caused to some extent by the advances in the development of methods for the determination of the quantitative and qualitative compositions of multicomponent mixtures of organic compounds — in the first place high prerformance gas–liquid capillary chromatography and chromatograph-linked mass spectrometry.

Insufficient attention has been devoted to the molecular weight distribution in the monographs and reviews on the FT synthesis.[1–9] For example, the eighth chapter of the book 'Chemical Substances from Coal'[1] is wholly devoted to the FT synthesis but there are no MWD data. In the monographs,[10,11] the examination of the MWD is restricted to data obtained up to 1980 inclusive. It has therefore become necessary to survey theoretical and experimental studies on the MWD which have appeared in the literature during the last 15 years.

II. Models of the molecular weight distribution

The experimental molar distribution of the n-alkanes obtained in the FT synthesis as a function of the number of carbon atoms in the molecule was first formulated by Herington[12] [Table 1, Eqn (1)]. It follows from Eqn (1) that the ratio β_n of the mole fraction m_n of an n-alkane with n carbon atoms in the molecule to the sum of the mole fractions of n-alkanes containing between $n + 1$ and ∞ carbon atoms is constant.

On the basis of experimental MWD data for hydrocarbons produced by the FT synthesis, Anderson et al.[13] obtained Eqn (2), from which it follows that the ratio α of the mole fractions of n-alkanes containing $n + 1$ (m_{n+1}) and n (m_n) carbon atoms in the molecule is independent of n within the limits of experimental error. The parameter α of the distribution of the FT synthesis products is in the range $0 < \alpha < 1$. It is easy to show that, when β_n is independent of n, the parameters α and β are linked by the following relation:

$$\alpha = \frac{1}{1+\beta}.$$

Eqns (1) and (2) were obtained by analysing multicomponent† products which consisted mainly of a mixture of n-alkanes. An attempt has been made[14] to derive an equation for the distribution of the FT synthesis products, incorporating, apart from hydrocarbons, an appreciable amount of oxygen-containing compounds (mainly alcohols). Eqn (3), describing the MWD for alcohols, was obtained by combining the familiar formulae for the m_n term, i. e.

$$m_n = m_1^{n-1},$$

and the sum of n terms, i. e.

$$\sum_{n=1}^{\infty} m_n = \frac{m_1}{1-\alpha},$$

of an infinitely diminishing geometrical progression, where α is the denominator of the progression. Shuikin et al.[14] understood by $\sum m_n$ the sum of the numbers of moles (or quantities proportional to them) of the oxygen-containing compounds formed in the FT synthesis. The experimental data on the composition of the oxygen-containing compounds were treated in terms of Eqn (3′) — the logarithmic form of Eqn (3). The dependence of MWD on n for n-alkanols, expressed by a plot of $\lg m_n$ against n,

† The components of the FT synthesis products are understood as organic compounds of one class (n-alkanes, n-alkanols, etc.).

Table 1. Equations describing the molecular weight distribution for the FT synthesis products.

Equation	Number of equation	Author(s) of equation	FT synthesis products to which the equation was first applied	Ref.
$m_n = \beta_n \sum_{n=1}^{\infty} m_{ni}$	(1)	Herington	n-Alkanes	12
$m_n = m_{ni}\alpha^{n-1}$	(2)	Anderson, Friedel, and Storch	"	13
$m_n = (1-\alpha)\sum_{n=1}^{\infty} m_{ni}\alpha^{n-1}$	(3)	Shuikin, Kryukov, and Bashkirov	n-Alkanols	14
$\lg m_n = \lg\left[(1-\alpha)\sum_{n=1}^{\infty} m_{ni}\right] + (n-1)\lg\alpha$	(3′)	"	"	
$g_n = (\ln^2\alpha)\, n\alpha^n$	(4)	Schulz	n-Alkane, n-alkanols, and n-alkylamines	15, 18
$\lg(g_n/n) = \lg(\ln^2\alpha) + n\lg\alpha$	(4′)	"	"	
$m_n = (1\alpha)\alpha^{n-1}$	(5)	Flory	n-Alkanes, alkenes, and alkanols	19
$\lg m_n = \lg[(1\alpha)/\alpha] + n\lg\alpha$	(5′)	"	"	
$\lg m_n = \lg(1\alpha) + (n-1)\lg\alpha$	(5″)	"	"	
$g_n = (1\alpha)^2 n\alpha^{n-1}$	(5‴)	Madon	n-Alkanes	20

Note. m_n and g_n are respectively the mole and weight fractions of the components of the FT synthesis products with n carbon atoms in the molecule.

has the form of a straight line, which shows that this equation is applicable to the description of the MWD for the oxygen-containing FT synthesis products.

1. The Anderson–Schulz–Flory distribution

Until the publication of the study of Henrici-Olive and Olive,[15] the analysis of the MWD for the FT synthesis products was not systematic. The authors of this and a series of subsequent studies, surveyed in a monograph,[11] applied to the description of the MWD for the FT synthesis products the Schulz[16] [Eqn (4)] and Flory[17] [Eqn (5)] equations familiar in polymer chemistry. These equations were derived for the analysis of the MWD for polymers obtained respectively by radical polymerisation and linear polycondensation. The MWD calculated by Eqns (4) and (5) are similar for $\alpha > 0.5$,[11,15] so that both equations can be applied with equal success. The logarithmic forms of the Schulz equation [Eqn (4′)] and the Flory equation [Eqns (5′) and (5″)] are more convenient for analysis. As an illustration, Fig. 1 presents the theoretical MWD for a monofunctional product calculated by Eqn (5‴) for $\alpha = 0.9$. Here one may note that there exists an internal check of the agreement between the distribution and Eqns (4′) and (5′) or (5″) based on the equality of the values of α calculated by two independent methods — from the slope of the straight line (α_{sl}) and from the intercept on the ordinate axis (α_{int}). The possibility of describing the MWD for the products with the aid of the Schulz and Flory equations confirms the idea that the polycondensation and polymerisation processes and the mechanism of the formation of C–C bonds in the FT synthesis are all related. By analogy with the polycondensation and polymerisation processes, the parameter α for the FT synthesis occurring under stationary conditions can then be defined by the relation

$$\alpha = \frac{r_p}{r_p + r_t},$$

where r_p and r_t are the rates of propagation and termination of the carbon chain respectively. Here it is assumed that α is independent of chain length.

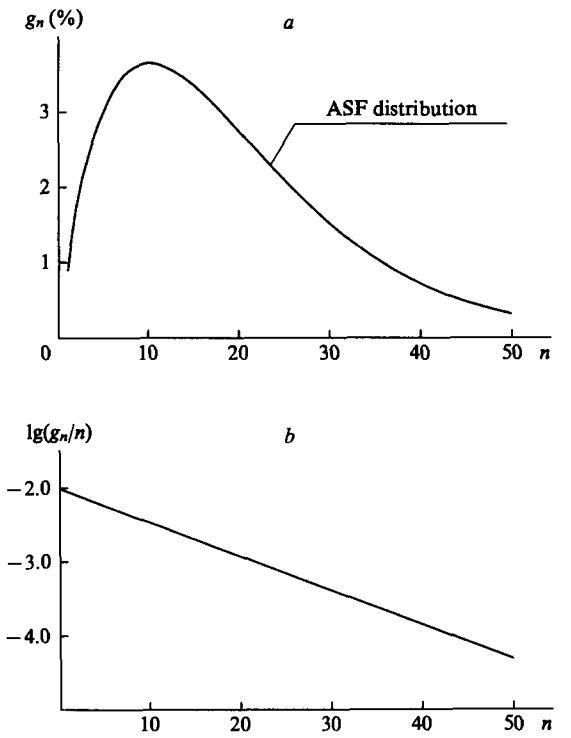

Figure 1. The Anderson–Schulz–Flory normal distribution for the FT synthesis product with $\alpha = 0.9$.[25] (*a*) $g_n - n$ plot; (*b*) semilogarithmic $\lg(g_n/n) - n$ plot.

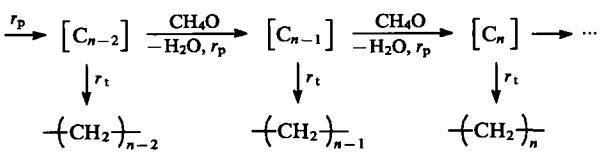


Evidently, the Schulz and Flory equations are applicable to the MWD for the products of the FT synthesis proceeding in accordance with Scheme 1 and the formal Scheme 2 when a polymer having the composition C_nH_{2n} is formed from n hypothetical monomers having the empirical formula CH_4O. Strictly speaking, only alkenes correspond to the polymer in the product.

Scheme 1

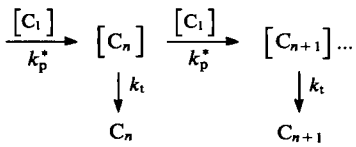
$$n(CO+2H_2) \longrightarrow \text{-}(CH_2)_n\text{-} + nH_2O$$

monomer polymer

Scheme 2

Here C_{n-2}, C_{n-1}, and C_n are intermediates with $n-2$, $n-1$, and n carbon atoms respectively.

In the general case, a multicomponent product is formed in the FT synthesis. It consists mainly of alkanes, alkenes, alkanols, and alkanals with a normal structure and contains from 1 to 100 or more carbon atoms.[21,22] The attempts to apply Eqns (4′) and (5′) or (5″) to the description of the MWD for the real products were unsuccessful because of the failure of the internal check of the MWD in terms of α. This difficulty can be partially obviated by applying Eqns (4′) and (5′) or (5″) separately to each component of the FT synthesis product (alkanes, alkanols, etc.). It is noteworthy that Eqn (3′) is transformed into Eqn (5″) if the sum of the moles of the components is unity:



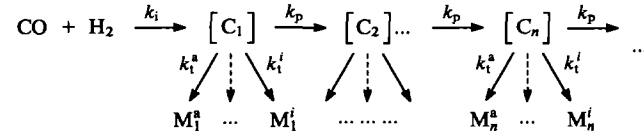
$$\sum_{n=1}^{\infty} m_n = 1.$$

Following Henrici-Olive and Olive,[15] other investigators also began to refer to the molecular weight distributions obeying Eqns (4′) and (5″) as the Schulz–Flory (SF) distributions. At the present time the term Anderson–Schulz–Flory (ASF) distribution is more often employed in the literature.

2. Special problems of the Anderson–Schulz–Flory distribution

A number of problems arise when the ASF distribution is applied to the analysis of real multicomponent FT synthesis products obtained under stationary and nonstationary conditions complicated by the occurrence of secondary reactions, various types of termination of the hydrocarbon chain, and other factors. Before proceeding to their discussion, it is appropriate to return yet again to the consideration of the classical model on the basis of which Eqns (4) and (5) may be obtained. Consider Scheme 3.

Scheme 3



Here $[C_1]$, $[C_n]$, and $[C_{n+1}]$ are the concentrations of intermediates with 1, n, and $n+1$ carbon atoms on the surface of the catalyst, and k_p^* and k_t are the hydrocarbon chain propagation and termination constants respectively.

By use of Scheme 3, the above equations can be derived on the basis of the following postulates: the propagation of the carbon chain takes place as a result of the addition of the C_1 intermediate; chain termination is the result of simple desorption; k_p^* and k_t are independent of the length of the carbon chain. It is then evident that for stationary FT synthesis we have $[\dot{C}_n] = 0$ and, when $k_p = k_p^*[C_1]$ and $\alpha = k_p/(k_p = k_t)$, it is easy to obtain, for example, Eqn (5). In this case, the state involving the formation of the $[C_1]$- intermediate from CO and H_2 (the initiation stage) is unimportant for the derivation of the equation.

Multicomponent products of the FT synthesis. The attempts to apply Eqns (4) and (5) to the analysis of the MWD for real multicomponent FT products, which were unsuccessful because of the failure of the internal check of the MWD in terms of α, were already mentioned above. Eqn (5″) has been derived[23] for the multicomponent FT synthesis products on the basis of the following model (Scheme 4):

Scheme 4

Here $[C_1]$, $[C_2]$, and $[C_n]$ are the concentrations of the intermediates with 1, 2, and n carbon atoms on the catalyst surface, k_i and k_p are the initiation and carbon chain propagation rate constants, k_t^a and k_t^i are the carbon chain termination rate constants for the formation of an alkanol and the ith component of the FT synthesis product, and M_1^a, M_n^a, M_1^i, and M_n^i are the alkanols and the ith components of the product with 1, ..., n carbon atoms respectively.

The derivation of the MWD equation for a multicomponent FT synthesis product involves an increase in the number of postulates from three to five. A further two postulates are added to those described above for the classical model of the ASF distribution: the product components with the same number of carbon atoms n are formed from the C_n intermediate via parallel pathways; the constants for the termination of the carbon chain of the alkanol and the ith components are independent of chain length.

In the stationary state, the rate of initiation r_i is equal to the sum of the rates of termination, i. e.

$$r_i = \sum^{i} r_t^i = \sum^{i} k_t^i \sum_{n=1}^{\infty}[C_n], \tag{6}$$

$$[\dot{C}_1] = \sum^{i} k_t^i \left(\sum_{n=1}^{\infty}[C_n] - k_p[C_1] - \sum^{i} k_t^i[C_1] \right) = 0,$$

$$[\dot{C}_2] = k_p[C_1] - k_p[C_2] - \sum^{i} k_t^i[C_2] = 0, \tag{7}$$

.....

$$[\dot{C}_n] = k_p[C_{n-1}] - k_p[C_n] - \sum^{i} k_t^i[C_n] = 0.$$

Simultaneous solution of Eqn (6) and Eqns (7), taking into account

$$k_p \Big/ \left(k_p + \sum^{i} k_t^i \right) = \alpha,$$

makes it possible to obtain the Flory equation for the intermediates:

$$[C_n] \Big/ \sum_{n=1}^{\infty}[C_n] = (1-\alpha)\alpha^{n-1}. \tag{8}$$

It is seen that $[C_n]/[C_{n-1}] = \alpha$ and, since $[M_n^i] = k_t^i[C_n]$ and $[M_{n-1}^i] = k_t^i[C_{n-1}]$, we have

$$\frac{[M_n]}{[M_{n-1}]} = \alpha . \tag{9}$$

It follows from Eqn (9) that, when the propagation of the carbon chains of the components of the FT synthesis products takes place in accordance with Scheme 4, then the data for the composition of such products, expressed in terms of the semilogarithmic variables of the Flory equation, should fit on straight lines with the same slope. Having solved the equations

$$\begin{aligned} \sum^i [\dot{M}_1^i] &= \sum^i k_t^i[C_1] , \\ \sum^i [\dot{M}_2^i] &= \sum^i k_t^i[C_2] , \\ &\cdots\cdots\cdots\cdots \\ \sum^i [\dot{M}_n^i] &= \sum^i k_t^i[C_n] , \end{aligned} \tag{10}$$

we obtain, after integrating the expression for the mole fraction of the ith components of the products,

$$\sum^i m_n^i = \sum^i [M_n^i] \Big/ \sum_{n=1}^{\infty} \left(\sum^i [M_n^i] \right) = (1-\alpha)\alpha^{n-1} , \tag{11}$$

$$\sum^i g_n^i = n(\ln^2 \alpha)\alpha^n . \tag{11'}$$

Eqns (11) and (11') represent the Flory [Eqn (5)] and Schulz [Eqn (4)] equations for a multicomponent product. The differences between Eqns (11) and (5) and between Eqn (11') and Eqn (4) consists in the fact that the left-hand side of Eqn (11) contains the sum of the mole fractions, while in Eqn (11') it contains the sum of the mass fractions of the ith components of the product with the same number of carbon atoms. An equation analogous to Eqn (11) for the special case of the formation of n-alkanes and n-alkanols has also been obtained by O'Young and Buchwalter.[24]

Chain propagation with two intermediates. In contrast to the classical model of the ASF distribution, the propagation of the carbon chain of a multicomponent product with participation of two intermediates, C_1 and C_2, has been examined.[25] In this case, the rate of formation of the C_n intermediate in the stationary state with $n \geqslant 3$ is described by the equation

$$\begin{aligned} [\dot{C}_n] &= k_p[C_{n-1}] - k_p[C_n] - k_t[C_n] + k_p^*[C_{n-2}] - k_p^*[C_n] \\ &= 0 \end{aligned} \tag{12}$$

Here the MWD parameter α^* is defined by the relation

$$\alpha^* = \frac{k_p}{k_p + k_t + k_p^*} = \frac{\alpha}{1 + y\alpha} , \tag{13}$$

where $y = k_p^*/k_p$.

An analytical solution of Eqn (12) has been described.[25] Fig. 2 presents the calculated MWD curves for two values of y. Evidently, the curves have an oscillatory form.

The dual nature of chain termination. A more involved version of the termination of the carbon chain, determined by the possibility that part of the monocomponent product with n carbon atoms is formed as a result of the interaction of the intermediates with $n - m$ and m carbon atoms in the molecule,

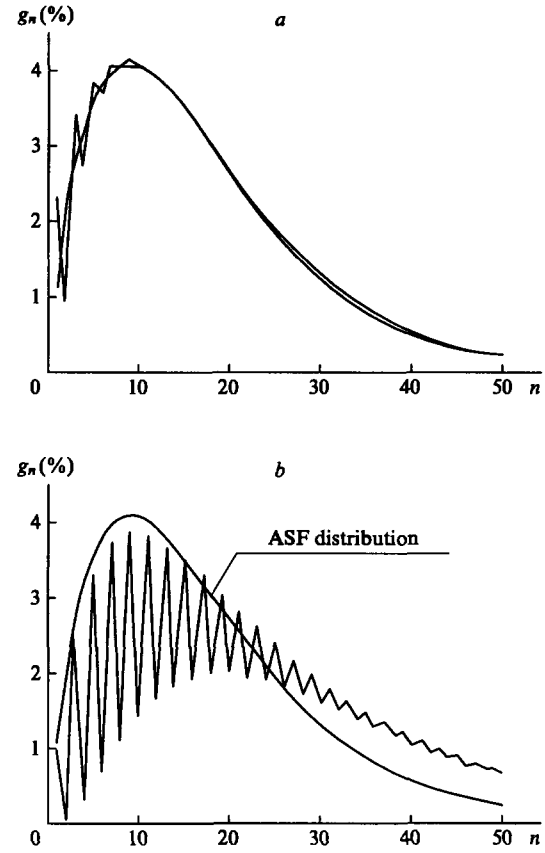


Figure 2. Molecular weight distribution for the FT synthesis products in the case where the carbon chain is propagated with participation of C_1 and C_2 intermediates for different values of y: (*a*) 1; (*b*) 10.[25]

has been analysed.[25] In this case, the rate of formation of the C_n intermediate in the stationary state is described by Eqn (14), such termination being taken into account by the term $k_t'[C_n]$:

$$[\dot{C}_n] = k_p[C_{n-1}] - (k_p + k_t + k_t')[C_n] = 0 . \tag{14}$$

The MWD parameter α' for this case is defined by the relation

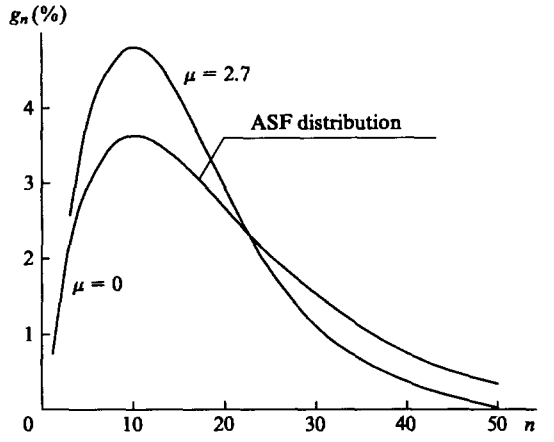
$$\alpha' = \frac{k_p}{k_p + k_t + k_t'} = \frac{\alpha}{1 + \mu(1-\alpha)} , \tag{15}$$

where $\mu = k_t'/k_t$.

The exact solution of Eqn (14) has been published.[25] Fig. 3 presents as an illustration the calculated MWD curve for $\mu = 2.7$. It is seen that the selectivity with respect to C_{10} under the conditions of the dual type of termination of the carbon chain is higher than the selectivity for the ASF distribution.

MWD taking into account the propagation of the carbon chain with participation of the products formed as well as the possibility of the cracking of these products have also been examined.[25,26] However, such MWD are so far of purely theoretical importance because under real conditions the contribution by such reactions of the FT synthesis products is extremely low.[27]

Molecular weight distribution for branched FT synthesis products. Depending on the conditions of the FT synthesis, its products may contain different (sometimes appreciable—up to 10%) amounts of alkanes with a branched carbon skeleton—mainly 2- and 3-monomethyl-substituted isomers. The MWD for such hydrocarbons were first examined by Anderson and



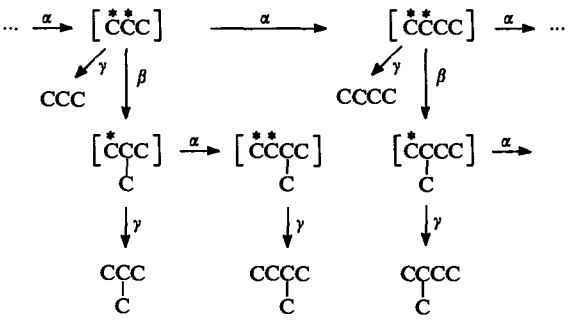


Figure 3. Molecular weight distribution for the FT synthesis product under the conditions of mutual termination of the carbon chain.[25]

coworkers.[28–31] There exist several models of the propagation of the carbon chain of isoalkanes differing from one another by the number of limitations and the extent to which the isomeric composition of the alkanes is taken into account.[10,28–35] In the most complete form, these models have been described by Wojciechowski.[35] We shall confine ourselves to the consideration of Anderson's model.[10]

Evidently the problem associated with the estimation of the proportions of isoalkanes arises in the case of a carbon chain containing four carbon atoms in the molecule. It is then postulated that there is no isomerisation of the normal carbon chain. In this connection, we shall consider a fragment of the model of the propagation of an isomeric alkyl chain (Scheme 5).

Scheme 5

Here $[\overset{**}{C}CC]$, $[\overset{**}{C}CCC]$, $[\overset{*}{C}(C)C]$, $[\overset{*}{C}(C)CC]$ are the concentrations of the intermediates with the normal and isomeric carbon chains on the surface of the catalyst; the asterisks denote the carbon atoms to which the addition of the intermediate $[C_1]$ is postulated, α and β are the propagation rate constants for the normal and isomeric carbon iso-chains respectively, and γ is the rate constant for the termination of the carbon chain in the n-alkanes and isoalkanes.

In the stationary state two equations can be written for the intermediate containing four carbon atoms: for the isomers with the normal $[C_4]$ and branched [*iso*-C_4] chains:

$$\dot{[C_4]} = \alpha[C_3] - \alpha[C_4] - \gamma[C_4] - \beta[C_4] = 0, \quad (16)$$

$$\dot{[iso\text{-}C_4]} = \beta[C_3] - \gamma[iso\text{-}C_4] - \alpha[iso\text{-}C_4] = 0. \quad (17)$$

The following relations can be obtained readily from Eqns (16) and (17):

$$\frac{[C_4]}{[C_3]} = \frac{\alpha}{\alpha + \gamma + \beta} = a,$$

$$\frac{[iso\text{-}C_4]}{[C_3]} = \frac{\beta}{\alpha + \gamma} = b.$$

If the notation $b/a = f$ is used, then the concentration of isobutane relative to that of n-butane depends only on f.

Anderson[10] obtained the following MWD equation for isomeric alkanes — the products of FT synthesis:

$$g_n = \frac{g_3 n F_{(n)} a^{n-3}}{3} \quad \text{for } n \geqslant 4, \quad (18)$$

where

$$F_{(n)} = 1 + (n-3)f + \frac{(n-4)(n-5)f^2}{2} + \ldots .$$

Data on the compositions of the isomeric and normal alkanes are usually expressed in a tabular form.

The special problems of the ASF distribution are not exhausted by the examples examined. Thus the kinetic parameters of the FT synthesis have been determined from MWD data.[35,36] A method has been proposed for the calculation of α as a function of the ratio H_2/CO.[37,38] Using the method of chemical potentials, an equation has been derived for the description of the ASF distribution.[39]

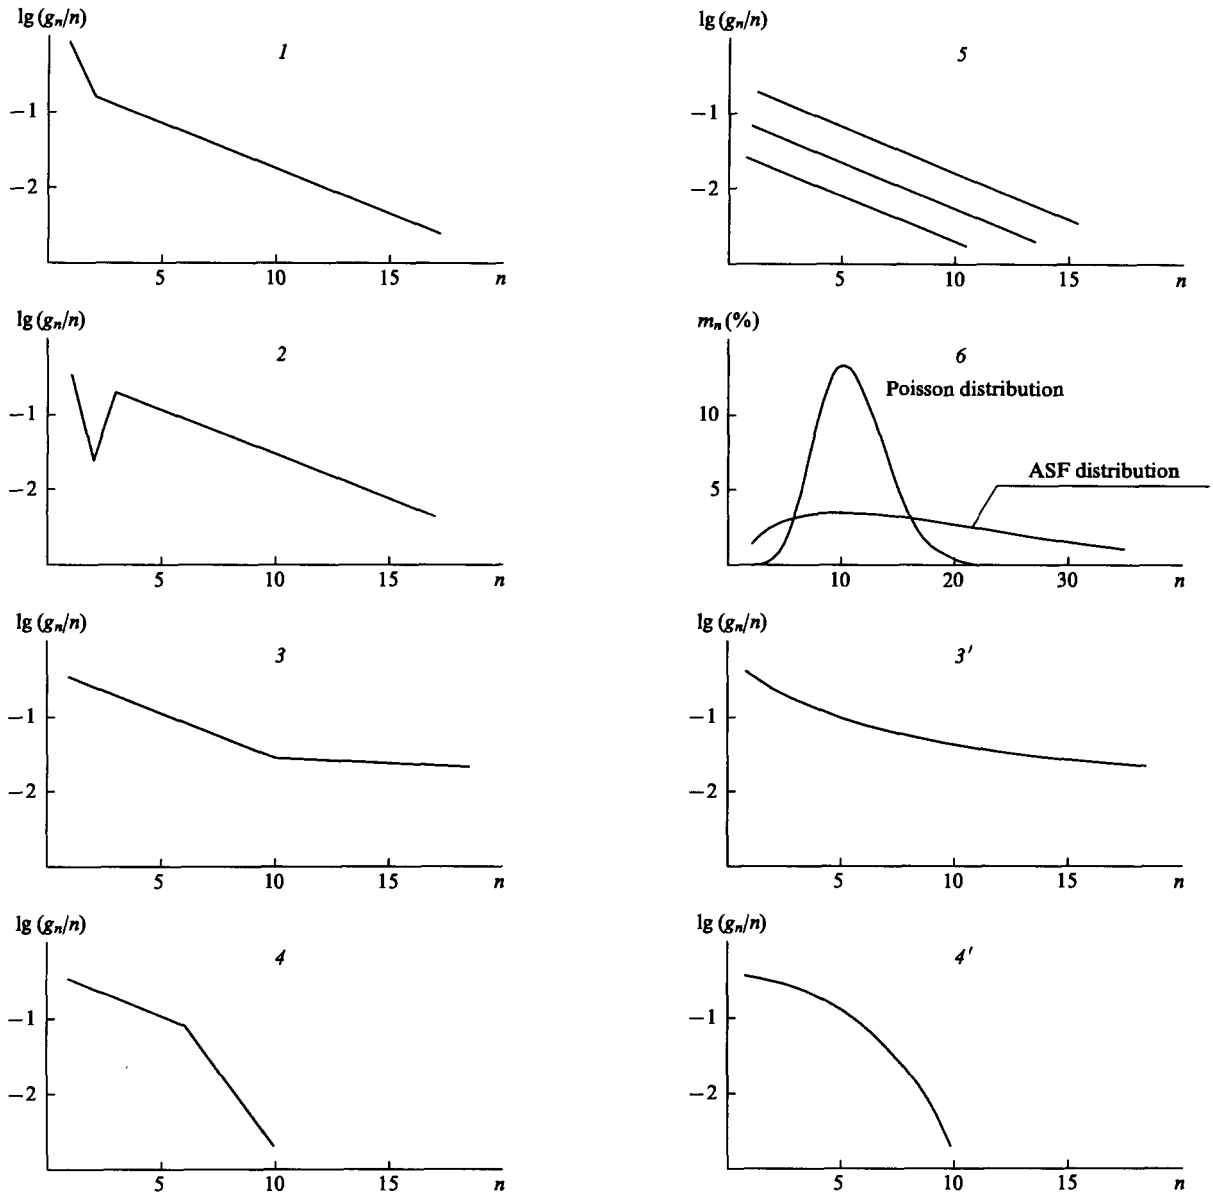
III. Experimental molecular weight distributions

Very many publications have been devoted to the experimental study of the MWD for monocomponent and multicomponent FT synthesis products. In most cases, the experimental MWD obey satisfactorily the ASF distribution (Fig. 1*b*), i.e. are assumed to be normal MWD.[11,15,19,40–47] At the same time, there is a large number of MWD characterised by deviations from the normal ASF distribution. In terms of the semilogarithmic variables of the Schulz and Flory equations, these deviations are manifested either by the curvature of the MWD or are associated with the appearance of different kinds of breaks on the linear MWD plots. However, in such cases the possibility, in principle, of describing part of the experimental MWD by the Flory and Schulz equations remains.

We shall examine the types of experimental MWD most frequently encountered (Fig. 4).

1. The molecular weight distribution characteristic of hydrocarbon FT synthesis products with an enhanced content of methane.[11,15,48,49] The composition of the hydrocarbons, with the exception of the C_1 product, corresponds to the ASF distribution. The maximum of the distribution, corresponding to the C_1 product is probably associated with the existence of an additional path to its formation, either via the $[C_1^*]$ intermediate, different from the $[C_1]$ intermediate, with the participation of which other hydrocarbons are obtained, or via the $[C_1]$ intermediate, which is converted into the C_1 product on other active centres of the catalyst, or, finally, via the intermediate $[C_1^*]$, which is in addition transformed on other active centres of the catalyst.

2. The molecular weight distribution characteristic of hydrocarbon FT synthesis products with a reduced content of C_2 products.[11,15,50–56] The reduced content of ethane and ethylene compared with the normal ASF distribution can be due to several causes in such cases: the propagation and termination of the carbon chain with participation not only of the $[C_1]$ intermediate but also the $[C_2]$ intermediate and secondary reactions involving C_2 products, for example the hydroformylation of ethylene.[57] Sometimes the breaks on the



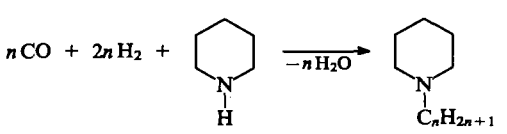


Figure 4. Different types of experimental MWD for the FT synthesis products: (*1*)–(*6*) see text.

linear distribution plots correspond to the C_3-C_4 products[11] which is probably due to the same causes as for the C_2 products. More complex cases, representing a combination of versions *1* and *2*, are encountered.[11,58,59]

3. The molecular weight distribution characteristic of the case where α increases with increase in n. This type of MWD is encountered for alkanes,[34,53,58–73] alkanols,[74] and alkylamines.[75,76] The last can be obtained, for example, in the piperidine-modified FT synthesis in accordance with Scheme 6.

Scheme 6

The break on the MWD curves for alkanes, alkanols, and alkylamines is usually observed at $n = 5-13$, the parameter α for low-molecular-weight products (α_1) being smaller than for high-molecular-weight products (α_2). If the degree of nonlinearity of the MWD is determined in terms of $\Delta\alpha = \alpha_2 - \alpha_1$, then it amounts to 0.12–0.20 for alkanes,[60,66] 0.26 for alkanols,[74] and 0.20 for alkylamines.[75,76] In some cases, there is no break on the MWD curves. Such MWD constitutes type *3'*. The appearance of MWD of types *3* and *3'* can arise from the following causes: the nonstationary nature of the FT synthesis, as a result of which α increases significantly during the period necessary for the collection of the FT synthesis products for analysis; the presence on the catalyst surface of two or more types of active centres on which products with different values of α are obtained;[7,60] the increase in the probability of the propagation of the carbon chain, which is proportional to the number of carbon atoms in the molecule. Several equations have been proposed for the description of MWD of types *3* and *3'*.[60,76,77] The simplest of these is based on the Flory equation [Eqn (5)] and has the following form:

$$m_n = x(1-\alpha_1)\alpha_1^{n-1} + (1-x)(1-\alpha_2)\alpha_2^{n-1}, \qquad (19)$$

where x and $1-x$ are the fractions of the products having the molecular weight distribution parameters α_1 and α_2 respectively.

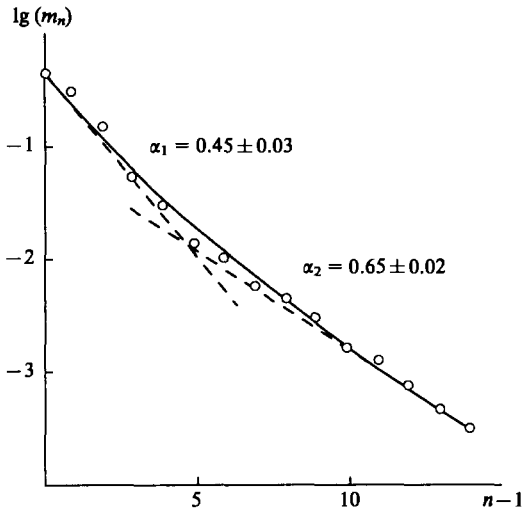

Figure 5. Molecular weight distribution for *N*-(n-alkyl)piperidines obtained in synthesis from CO, H_2, and piperidine on a reduced fused iron catalyst promoted with 5% V_2O_5:[75] circles—experimental data; curve—calculation by Eqn (19) for $x = 0.36$.

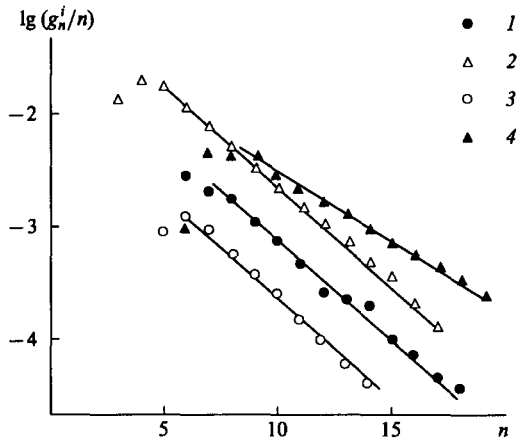

Figure 6. Molecular weight distribution for the liquid fraction of the multicomponent product of synthesis from CO and H_2 (for the conditions of the synthesis, see Table 4):[82] (*1*) α-alkenes; (*2*) n-alkanols; (*3*) n-alkyl methyl ketones; (*4*) n-alkanes; $\alpha = 0.66 \pm 0.02$ (*1–3*) and 0.77 ± 0.02 (*4*).

Evidently the change in the MWD parameters from α_1 to α_2 with increase in n from 1 to ∞ takes place continuously. The chemical significance of such continuity is associated with the simultaneous formation of the FT product independent of n, part of which is characterised by α_1 and is obtained on centres of one type, while another part is characterised by α_2 and is formed on other active centres. Eqn (19) describes MWD of type *3'* with a smaller error. As an illustration, Fig. 5 presents the MWD for *N*-n-alkylpiperidines obtained in accordance with Scheme 6 on a reduced fused iron catalyst containing 5% V_2O_5 as the promoting agent.[75] The experimental molecular weight distribution can be fitted either by two straight lines intersecting at $n = 6$, each of which is described by the Flory equation [Eqn (5)] with $\alpha_1 = 0.45 \pm 0.03$ or $\alpha_2 = 0.65 \pm 0.02$ ($\Delta = 0.20$), or by a curve corresponding to the equation

$$\lg m_n = \lg [0.36\,(0.45)^{n-1} + 0.64\,(0.65)^{n-1}].$$

The maximum standard deviation when the above equation is used for $n = 6$ is 55%, while in the range $1 < n < 15$ it is only 14%. The large error of the description of the experimental MWD by Eqn (19) in the vicinity of the break point may indicate the lack of validity of the approach used by Huff and Satterfield[60] and the inadequacy of Eqn (19) for such sections of the MWD. It is entirely likely that the type of the FT synthesis products obtained depends on n: FT products with only α_1 or α_2 are formed for $1 < n < 6$ and $n > 6$ respectively. The appearance of a break can then be associated with, for example, the steric control of the FT synthesis occurring with participation of two types of active centres of the catalyst.

4. The molecular weight distribution characteristic of cases where the parameter α diminishes with increase in n. Such MWD are also encountered in the study of hydrocarbon FT synthesis products.[21,48,51,78–80] Sometimes there is no break and the MWD reduces to type *4'*. The MWD of types *4* and *4'* arise under nonstationary conditions of the FT synthesis (in the presence of temperature and concentration gradients)[78] or for large losses in the stages involving the collection and/or analysis of low- and high-molecular-weight products.[79]

5. The molecular weight distribution in the form of several, often parallel, straight lines occurs in the study of real multicomponent FT products containing (a) only hydrocarbon components (n-alkanes, isoalkanes, α-alkenes, *cis*- and *trans*-alkenes),[53,63,64] (b) hydrocarbons and oxygen-containing compounds (n-alkanes, alkenes, alkanols, alkanals),[61,65,81] and (c) hydrocarbons and oxygen- and nitrogen-containing compounds in the case of the FT synthesis products modified by the addition of ammonia or dimethylamine (Fig. 6).[82–84] Different equations are used to describe the MWD. Some of them were examined above. Fig. 6 presents the MWD for the part of the product obtained from CO, H_2, and Me_2NH on a reduced, promoted, and fused iron catalyst (RPFIC).[82,84] It is seen from these data that Eqn (11') describes satisfactorily the experimental results.

6. The molecular weight distribution differing from the ASF distribution and not described by the Schulz or Flory equation.[2,11,20,85–89] Successful attempts to consider such MWD with the aid of the Poisson equation[90] are described in the literature:[11,88]

$$m_n = \frac{e^{-v} v^{n-1}}{(n-1)!}, \tag{20}$$

$$g_n = \frac{e^{-v} v^{n-1} n}{(n-1)!\,\bar{n}}, \tag{21}$$

where m_n and g_n are the mole and weight fractions of the FT synthesis product with n carbon atoms, v is the average number of chain propagation stages, and $\bar{n} = v + 1$ is the average degree of polymerisation.

Products obtained from CO and H_2 on Ru, Co, or Fe catalysts deposited on carriers with a high specific surface (of the order of 100 $m^2\,g^{-1}$ and above) have a type *6* distribution. The position of the maximum on the distribution curve depends on the carrier surface,[85] the maximum shifting towards low-molecular-weight synthesis products with its increase. The most probable causes of the MWD of this type are a high degree of dispersion of the catalyst particles,[87] the internal diffusion control of the chain propagation by the carrier ('the cage effect'),[87] and the nonstationary nature of the FT synthesis.

IV. The influence of the conditions in the Fischer–Tropsch synthesis on the molecular weight distribution

The catalyst as well as the conditions in the Fischer–Tropsch synthesis are known to influence the composition of the products, in particular the ratio of the hydrocarbon and oxygen-containing components.[10,11] In this section, attention is concentrated on studies which consider the influence of the conditions in the FT synthesis on the MWD. Only those investigations are analysed in which there were no effects due to the nonstationary nature of the FT synthesis, as well as those in which the parameter α was determined taking into account the experimental error, including cases where the data presented in the original papers made it possible to estimate the accuracy of the calculation of α. The temperature, pressure, the composition of the synthesis of gas and its space velocity, the type of reactor and the catalyst, the duration of the synthesis, and the addition of a third component to the mixture of CO and H_2 (modified FT synthesis) represent a list of factors (regime parameters), the effect of which on the MWD for the products will be examined below.

Temperature. The influence of temperature on the MWD has been investigated for products obtained on iron-containing heterogeneous catalysts in the gas phase in a reactor with a stationary catalyst bed[19,23] and in the liquid phase in a reactor with a stirrer and a suspended catalyst.[65,66,73] The temperature was varied from 159 to 285 °C. In all cases, α remained constant regardless of the temperature of the FT synthesis within the limits of the error of the determination. For example, in the study of Glebov et al.[23] the 'productivity' of the FT synthesis with respect to the products (hydrocarbons + oxygen-containing compounds) increased by a factor of 3.1 with increase in temperature from 159 to 180 °C, whereas the parameter α remained constant at 0.5 ± 0.1.

Table 2 presents the values of the MWD parameter α for the FT synthesis product obtained at different temperatures on iron catalysts of different composition. It is seen from the tabulated data that, when the temperature is varied in the range of ~ 50 °C, the MWD parameter hardly changes.

Space velocity. The influence of the space velocity of the synthesis gas on the MWD for the FT synthesis products has been frequently investigated.[19,60,65,74] It has been noted that the degree of conversion of CO changes significantly (by tens of percentage points) but the parameter α hardly varies. For example, when the space velocity of the synthesis gas ($H_2/CO = 1.3$) changes from 88 to 424 h^{-1} in FT synthesis at 269 °C in the liquid phase on a RPFIC, the degree of conversion of CO diminishes from 96% to 76%, while the MWD parameter α remains at the level of 0.67 ± 0.02.[73]

Table 2. The molecular weight distribution parameters α for the FT synthesis products at different temperatures.[65,66]

Catalyst[a]	T/°C	α	$\bar{\alpha}$
100% Fe_3O_4	285	0.61	
+ (2–3)% Al_2O_3	273	0.59	
+ (0.7–1.2)% CaO	262	0.61	0.60 ± 0.01
+ (0.5–0.8)% K_2O	251	0.60	
+ 0.4% SiO_2	239	0.60	
	231	0.62	
100% Fe_2O_3	241	0.59	
	223	0.63	
	214	0.60	0.63 ± 0.04
	199	0.64	
	188	0.68	
100% Fe_2O_3	261	0.66	
+ 0.6% K_2O	251	0.66	0.67 ± 0.01
	224	0.69	
	211	0.68	

[a] The composition of the catalyst is quoted for a nonreduced specimen.

Pressure and the H_2/CO ratio. Data concerning the influence of pressure on the MWD for the FT synthesis products have been published[8,51,67] and are contradictory. Thus, on a cobalt catalyst at 250 °C and for $H_2/CO = 3$, an increase in pressure from 1 to 7.8 atm led to a slight increase in α. However a further increase in the overall pressure to 14 atm no longer affected the MWD parameter.[51]

Ambiguous data are available also for the influence of the composition of the synthesis gas on the MWD for the FT synthesis products.[40,65,66,71] For example, when polycrystalline iron foil was used as the catalyst at 287 °C and an overall pressure of 1 atm for the ratio $H_2/O = 100$, $\alpha = 0.13$ was obtained while in the case where $H_2/CO = 4$ it amounted to 0.30.[40]

Table 3 presents the MWD parameters α for different H_2/CO ratios, different catalysts, and a degree of conversion of CO of 5%.[65,66] It is seen from the data presented that the simultaneous change in the H_2/CO ratio from 0.5 to 5 and in the overall pressure from 3 to 13 atm hardly affects the parameter α. However, we may note that the simultaneous alteration of two inde-pendent factors (H_2/CO and P_{tot}) does not permit the estimation of the influence of the H_2/CO ratio on the MWD in a pure form.

Duration of the FT synthesis. Data concerning the influence of the duration of the FT synthesis on the MWD for the products obtained have also been published.[8,23,79] It has been shown that the parameter α increases by 0.1–0.2 with increase in the synthesis time. For example, in the study of Glebov et al.[23] α

Table 3. The molecular weight distribution parameters α for the FT synthesis products corresponding to different H_2/CO ratios.

Catalyst	T/°C	P_{tot}/atm	H_2/CO	α	$\bar{\alpha}$

reached 0.5 ± 0.1 in the gas-phase FT synthesis in a flow reactor with a stationary RPFIC bed after 100 h, whereas after 1000 h it amounted to 0.7 ± 0.1.

Type of reactor. The results of studies on FT synthesis by different groups of investigators using a flow reactor (stationary RPFIC bed)[14,23] and a reactor with a stirrer (a suspension of RPFIC in a solvent)[19,60,65,66] demonstrated with acceptable accuracy that the type of reactor hardly affects the parameter α, which varies in the range 0.6 ± 0.1. There has been one study,[91] specially devoted to this question, in which it was shown that the values of α for the FT synthesis products obtained on the same RPFIC and under the same conditions but in reactors of two different types are similar.

Reduction of the catalyst. Reduced heterogeneous catalysts are usually employed in FT synthesis because the reduction (or activation) operation is accompanied by an increase in the rate of the FT synthesis and ultimately leads to an increase in its productivity. The influence of the RPFIC reduction time on the MWD for the FT synthesis product has been investigated.[65] As expected, the rate of the FT synthesis increases by a factor of 20 with increase in the reduction time from 0 to 92 h, while the molecular weight distribution parameter α hardly changes.

Composition of the catalysts for the FT synthesis. Heterogeneous catalysts exhibit the greatest effectiveness in the FT synthesis. Their composition exerts the greatest influence on the MWD for the FT synthesis products.[42,43,45,47,49,55,66] It is sometimes sufficient to introduce a small amount (several per cent only) of promoting additives in order to observe a change in the MWD. We shall consider such additives in greater detail.

The addition of alkali metal compounds in the form of carbonates or oxides to the prepared catalysts or in the course of their preparation frequently increases the average molecular weight of the product.[8,40,51] However, when FeB is used as the catalyst (250–270 °C), its promotion with 1%–2% of Na_2O does not affect α.[45]

Promotion of the Ru/SiO_2 catalyst with copper diminishes α. For example, the addition of 15% of copper reduces the MWD parameter from 0.55 to 0.44.[55]

The results of the study of the influence of lanthanide metals on the MWD for the FT synthesis products have been published.[43,49] When nickel catalysts are used, the addition of 1%–1.5% of lanthanum or cerium expands the range of hydrocarbon fractions obtained from C_1–C_4 to C_1–C_8, its alteration being accompanied by a significant increase in α.[49]

FT synthesis on the (5%Fe + 2%Cu)/SiO_2 catalyst at 350 °C, at a pressure of 100 atm, and for the H_2/CO = 1 ratio results in the formation of hydrocarbons and alkanols, characterised by the same value of α = 0.37. The promotion of this catalyst with 10% La under the same conditions leads to the retention of α = 0.37 in the case of alcohols, whereas in the case of hydrocarbons α increases to 0.52.[43]

So far only one instance of the influence on α of the addition of MoS_2 to catalysts based on molybdenum carbide is known.[47] For alkanols, the addition of molybdenum sulfide diminishes α from 0.31 to 0.14.

Carriers. The carrier can also affect the MWD for the FT synthesis products. A study has been made[42] of the catalyst 5%Ru + 5%Mo + 1.25%Na_2O deposited on different carriers: activated charcoal (AC), SiO_2, and Al_2O_3. It was found that the parameters α for the products obtained at 255 °C, at a pressure of 86 atm, and for the H_2/CO = 2 ratio are different on the above carriers and increase from 0.26 to 0.39 in the sequence AC < SiO_2 < Al_2O_3.

The influence of the regime parameters and the catalyst on the break on the MWD curves. As already mentioned, breaks may appear on the MWD curves for the FT synthesis products plotted in terms of the semilogarithmic variables of the Schulz or Flory equation. The question of the stability of the breaks as a function of time and of the influence on the latter of the regime parameters (temperature, pressure, etc.) arises in this connection. There are literature data concerning exclusively the type *3* MWD characterised by two values of the distribution parameter: α_1 and α_2 with $\alpha_1 < \alpha_2$ (Fig. 4).

The stability as a function of time of the break on the MWD curves obtained on a commercial (produced by the Ruhrchemie Company) deposited catalyst having the composition 100Fe : 4.3Cu : 4.1K : 25SiO_2 at 250–265 °C, at a pressure of 15 atm, and for H_2/CO = 1 over a period of 700 h has been investigated.[73] The results of tests in both a flow reactor with a stationary catalyst bed and in a stirred reactor proved to be similar. Thus, in the flow reactor, α_1 and α_2 were respectively 0.58 and 0.94 after 71 h and 0.60 and 0.88 after 427 h. In the stirred reactor, α_1 and α_2 were found to be respectively 0.57 and 0.92 after 95 h and 0.60 and 0.85 after 619 h.

Data on the MWD for the FT synthesis products, obtained using commercial catalysts produced by various companies, have been analysed[69] and in all the instances investigated the break on the MWD curve persisted throughout the period of the tests. Similar results have been published in another communication.[70]

The influence of the composition of iron-containing catalysts on the breaks on the MWD curves has been examined.[62,68]

The following catalysts were investigated: RPFIC having the composition Fe(30%–37%) + Fe_2O_3 (59%–65%) + Al_2O_3 (3%–4%) + CaO (1%–1.3%) + K_2O (0.7%–0.9%), a 10% Fe/SiO_2 deposited catalyst (the specific surface of SiO_2 was about 700 $m^2 g^{-1}$), and a 6% ThO_2/Fe_2O_3 deposited catalyst.[68] It was established that the initial value of the distribution parameter was α = 0.61 ± 0.02 for all the products. However, after a certain time had elapsed (after 56, 30, and 14 days for the first, second, and third catalysts respectively), breaks appeared on the MWD curve at n = 11. In the range n = 1–11, we have $\alpha_1 = \alpha$, while under conditions where $n > 11$ the parameter α_2 is different for all the catalysts, reaching, for example, 0.8 for the first catalyst.

The pressure and space velocity influence the MWD with break points.[60,67] Without altering the position of the break point, their increase leads to some increase in α_2.

Modification of FT syntheses with ammonia and amines. The MWD for the FT synthesis products under conditions where a third component was added to CO and H_2 has been investigated.[44,75,76,82–84] The third component employed was NH_3,[83] Me_2NH,[82] Et_2NH,[44] and piperidine.[75,76,84] All the results were obtained on iron-containing catalysts under the conditions of gas-phase synthesis in a reactor with a stationary catalyst bed.

Thus, in the presence of the 20.4% Fe_2O_3/SiO_2 catalyst at 220 °C at a pressure of 1–10 atm and for the H_2/CO = 2–3.6 ratios, the addition of Et_2NH to the synthesis gas hardly resulted in the formation of the corresponding alkyl(diethyl)amines, the synthesis products being the usual mixture of hydrocarbons and alcohols. The molecular weight distribution parameter α for the products remained virtually constant and amounted to 0.72 for n-alkanes (0.70 in the absence of the additive) and 0.32 for n-alkanols (0.25 without the additive).[44]

Results different from those presented above were obtained in the presence of the RPFIC.[75,76,82–84] As an illustration, we shall consider in greater detail the MWD and the overall composition for the products obtained via the CO + H_2 + Me_2NH reaction (Table 4, Fig. 7).

Table 4. Composition of the products of the synthesis on a reduced, promoted, and fused iron catalyst (RPFIC).[84]

Composition of products (%)	$CO + H_2$	$CO + H_2 + Me_2NH$
n-Alkanes	26	29
α-Alkenes	9	8
n-Alkyl methyl ketones	3	3
n-Alkanols	51	18
n-Alkyl(dimethyl)amines	–	26
Unidentified components	12	16

Note. The composition of the RPFIC was 100% Fe_3O_4 + 1% V_2O_5 + 0.75% BaO for a nonreduced specimen; the Me_2NH concentration in the synthesis gas was 7 vol.%; the content of n-alkanals was less than 1%; conditions of synthesis: T = 172 °C, P_{tot} = 120 atm, H_2/CO = 4, space velocity 10^3 h^{-1}.

The data presented in Table 4 show that the addition of Me_2NH to a mixture of CO and H_2 induces the formation of n-alkyl(dimethyl)amines having the general formula $C_nH_{2n+1}Me_2N$, where $n \leqslant 17$. On the other hand, it is seen from Fig. 6 that, in terms of the semilogarithmic variables of the Schulz equation [Eqn (4′)], the linear MWD plots for alkenes, n-alkanols, and n-alkyl methyl ketones are parallel, while the distribution parameter α, calculated from the slope of the straight line, is the same for these components, amounting to 0.66 ± 0.02. However, the n-alkanes synthesised from CO and H_2 have the parameter $\alpha = 0.77 \pm 0.02$.

After the addition of Me_2NH to the synthesis gas (Fig. 7), the MWD parameters for alkenes, n-alkanols, and n-alkyl methyl ketones remain the same. Furthermore, the n-alkyl(dimethyl)amines formed in the presence of the above components have the same $\alpha = 0.66 \pm 0.02$. The MWD parameter α for n-alkanes (0.73 ± 0.02) is again different from those for the other components. The reader is referred to other communications[82–84] for a detailed analysis of the MWD for the products of the modified FT synthesis and the mechanism of their formation and here we shall only note that the introduction of Me_2NH does not affect the nature of the MWD for all the components of the product with the exception of a slight influence on the MWD for n-alkanes (α diminished from 0.77 to 0.73).

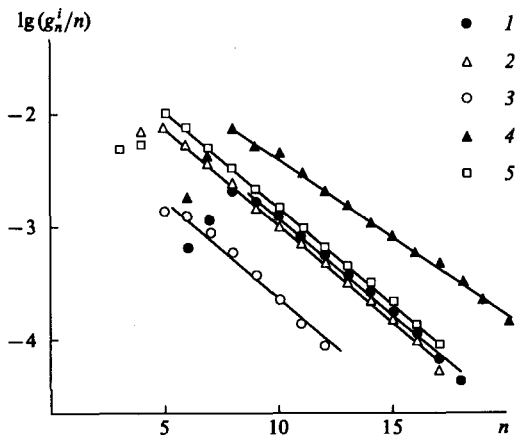

Figure 7. Molecular weight distribution for the liquid fraction of the multicomponent product of synthesis from CO, H_2, and dimethylamine (for the conditions of the synthesis, see Table 4):[82] (*1*)–(*4*) see Fig. 6; (*5*) n-alkyl(dimethyl)amines.

Zeolite-containing catalysts. New data on the MWD for the synthesis products have been obtained as a result of the study of zeolite-containing catalysts.[92,93]

Thus the catalyst having the composition 10% Fe_2O_3 + 15% MnO + 39% HY was used in the synthesis from CO and H_2 at 300–370 °C and P_{tot} = 21 atm, for a space velocity of 230 h^{-1}, and for the ratio H_2/CO = 3. The synthesis products contained C_6–C_{11} aromatic hydrocarbons which did not obey the ASF distribution. The introduction of the HY zeolite into the catalyst induced (apart from the appearance of aromatic hydrocarbons among the synthesis products) a change in the MWD for the alkanes, expressed by a shift of the break point on the MWD curve for the alkanes from n = 12 to n = 10 and was accompanied by a decrease $\Delta\alpha$ in the distribution parameter.[92] Failure of the aromatic hydrocarbons obtained in the synthesis from CO and H_2 to obey the ASF distribution was noted also in another study,[93] where the 14.7% Co/SiO_2 + ZSM-5 catalyst was used.

The deviation of the MWD for aromatic hydrocarbons from the ASF distribution has been observed also by Savel'ev et al.[94] The synthesis from CO and H_2 on an iron-containing catalyst having the composition (8.3% Fe + 4.5% K)/Al_2O_3 at 380–420 °C and P_{tot} = 1 atm, for a space velocity of 75–150 h^{-1}, and for H_2/CO = 2 yielded a product containing up to 20% of C_6–C_9 aromatic hydrocarbons apart from C_1–C_6 aliphatic hydrocarbons. On the basis of data for the MWD for the synthesis products, the authors[94] concluded that the paths leading to the formation of aliphatic and aromatic hydrocarbons are independent.

* * *

Thus the study of the MWD for the real synthetic products obtained in the FT synthesis or its modifications constitutes a vigorously developing field of research. Answers to a number of questions associated with the mechanisms of these syntheses and with the occurrence of side reactions have been obtained with the aid of the MWD. Attention has been turned to the possible hydrocondensation and hydropolymerisation character of the FT syntheses. For example, it has been possible to demonstrate that the paths leading to the formation of the main components of the product from the common intermediate in FT synthesis on the RPFIC are parallel and it has been established that the paths leading to the formation of aliphatic and aromatic hydrocarbons are independent. There is also no doubt that further improvement of highly effective analytical methods will promote the development and progress in the studies on the MWD for the products. One may claim that the study of the MWD for the FT synthesis products occupies a special place among modern methods for the investigation of the FT synthesis, such as the kinetic and isotopic methods under stationary and non-stationary conditions, spectroscopic methods applied in situ, and methods involving the organometallic analogues of the reactions of CO and H_2. The MWD method helps to obtain more complete experimental data in this interesting and promising and hitherto not fully investigated field of the synthesis of organic compounds.

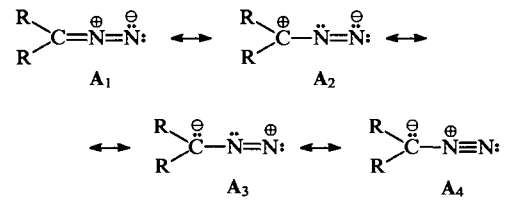
III. Complexes with the ligand coordinated through a carbon atom	206
IV. Reactions of diazoalkane complexes	210
V. Conclusion	215

Abstract. The results of studies on the interaction of diazoalkanes with transition metal complexes are presented and the successive transformations of the diazoalkane complexes formed are traced. The reactions have been classified in terms of the proposed mechanism and the structure of the products. The principal structural parameters of the diazo-ligands are presented. The bibliography includes 145 references.

I. Introduction

The reactions of diazoalkanes with transition metal complexes have become the subject of intensive study during the last 20 years. The products of these reactions are important both theoretically (for example, diazoalkanes coordinated to a metal are possible intermediates in the insertion of molecular nitrogen into organic compounds[1,2]) and synthetically (the reactions with diazoalkanes constitute the most convenient method of synthesis of bridged carbene complexes of transition metals[3,4]).



Generally speaking, several review articles have been devoted to the reactions of diazoalkanes with transition metal complexes.[5–8] In the present review, an attempt has been made to classify the available data in terms of the type of reactions or the structure of the complexes formed, mainly the interactions of diazoalkanes with mono- and bi-metallic complexes of transition metals being considered. On the other hand, the reactions of polynuclear (trinuclear and more highly condensed species) complexes are presented only in those cases where they strongly resemble the reactions of the mono- and di-nuclear complexes in terms of the mechanism or the structure of the complexes formed.

It is essential to note that a systematic approach to the consideration of the mechanisms of the processes occurring is difficult since the available literature data about them are usually restricted to the description of the structures of the complexes obtained. One should also recall that the information about the structure of the complexes can be frequently unreliable if it is based solely on data obtained by individual spectroscopic methods and not the results of X-ray diffraction studies.

The electronic structure of diazoalkanes may be represented by the following canonical structures:[3,6]

On the basis of these structures, one can postulate that diazoalkanes enter into reactions (including those with transition metal complexes) as 1,3-dipoles (A_2, A_3), N-nucleophiles (A_1, A_2), or C-nucleophiles (A_3, A_4). Furthermore, bearing in mind the unsaturated nature of the diazoalkanes, one may also expect the formation of complexes of the π-type.

Naturally the result of the interaction of transition metal complexes with diazoalkanes depends on the nature and reactivity of the complexes. Fig. 1 presents the principal structural types of the products obtained as a result of such interaction.

It is essential to note that the simultaneous formation of several complexes of different types has been repeatedly observed in one reaction. Furthermore, the same initial complex can afford different products in reactions with different diazoalkanes and, conversely, the same diazoalkane can lead to the formation of products of a completely different type in reactions with different complexes. For example, the interaction of diazocyclopentadienes substituted in different ways with transition metal compounds afforded six types of complexes:

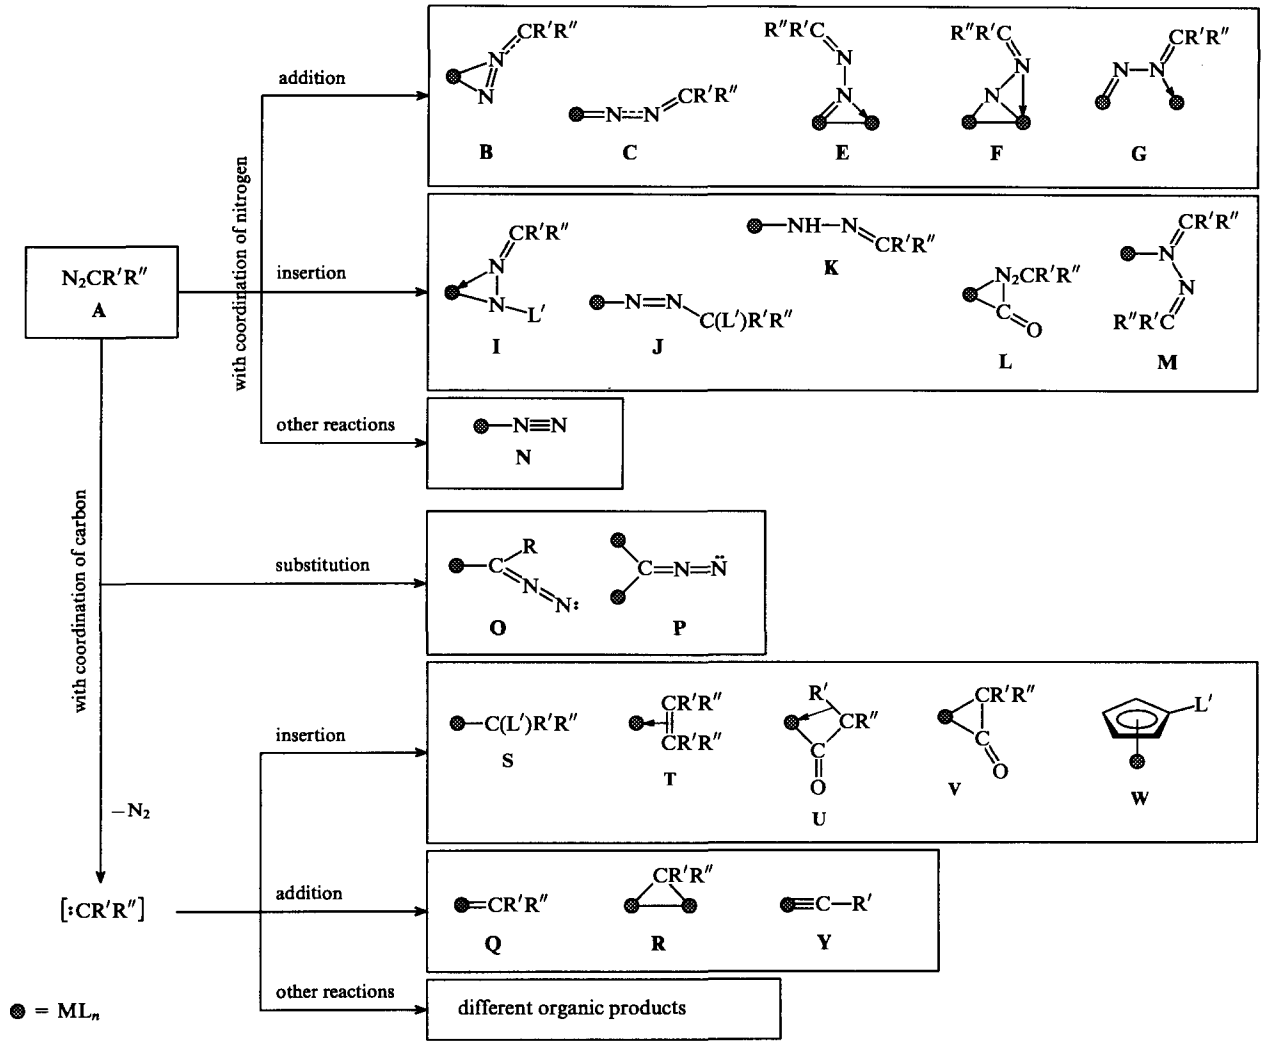

Figure 1. The principal structural types of the products of the interaction of transition metal complexes with diazoalkanes.

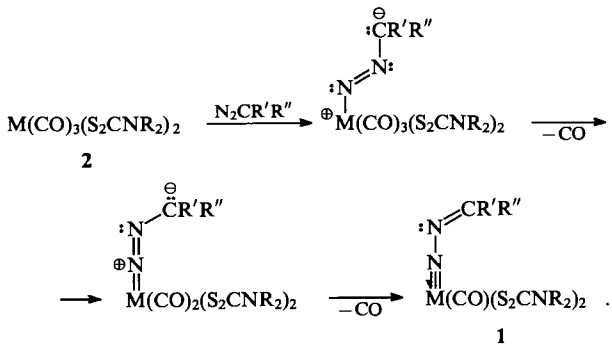
It follows from the wide variety of the products that the classification of reactions of diazoalkanes with transition metal complexes is by no means a trivial task. We have classified these reactions in terms of the structure of the products taking into account as far as possible the proposed reaction mechanism and the type of complex entering into the reaction.

II. Complexes with the ligand coordinated through a nitrogen atom

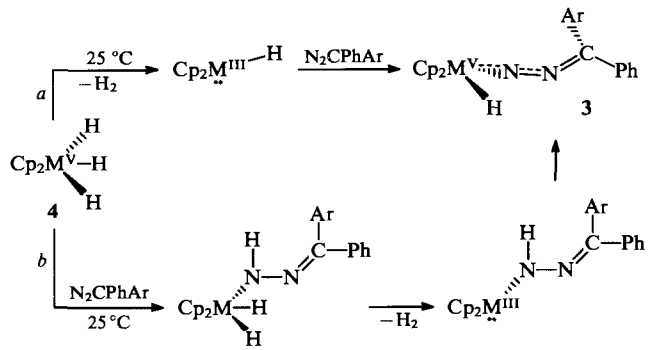
1. Addition reactions with formation of η^1-*N*- and η^2-*N*, *N'*-diazoalkane complexes

Coordinatively unsaturated transition metal complexes (ML_n)[9–19] or their precursors (ML_nY), containing only readily eliminated ligands Y such as hydrogen,[20–23] nitrogen,[24–29] carbon monoxide,[30–32] phosphine,[31–33] tetrahydrofuran,[34–36] or an alkene,[9,10,29,32,37] can enter into oxidative addition (or ligand exchange) reactions, which lead to the formation of η^2-*N*, *N'*-diazoalkane complexes (**B**) or η^1-*N*-diazoalkane complexes (**C**).



$$N_2CR'R'' \xrightarrow[(\text{or } ML_nY)]{ML_n} \longrightarrow L_nM\langle N{=}N{=}CR'R'' \quad \text{or} \quad L_nM{=}N{=}N{=}CR'R''$$

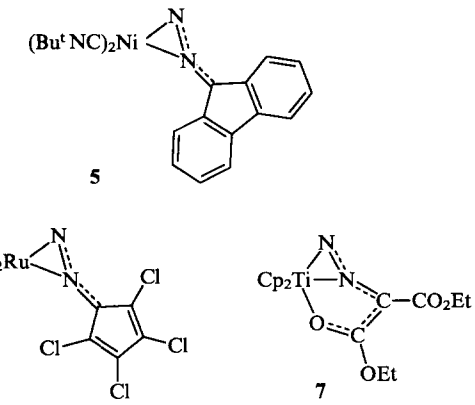
B **C**



Y = H_2, N_2, CO, PR_3, THF, alkene.

In the presence of an excess of the diazoalkane, the elimination of the phosphine ligand may be accompanied by the formation of the phosphazine $R_3PN_2CR'R''$.[32]

The mechanism of the replacement of the ligand Y can be both associative and dissociative—depending on the coordination capacity of the metal atoms and the ability of the other ligands to undergo a change in their electron-donating properties. Thus it has been suggested[17] that molybdenum and tungsten complexes of the type $M(CO)(S_2CNR_2)_2(\eta^1\text{-}N_2CR'R'')$ (M = Mo, W) **1** are formed from $M(CO)_2(S_2CNR_2)_2$ **2** and $N_2CR'R''$ in several stages, in which the diazoalkane $N_2CR'R''$ is consecutively a 0-, 2-, and 4-electron-donating ligand (the process is accompanied by the elimination of two CO molecules in successive stages:



A mechanism differing from the usual one for the formation of η^1-*N*-diazoalkane complexes has been proposed for the formation of diaryldiazomethane complexes of niobocene and tantalocene $Cp_2M(H)(N_2CPh_2)$ (M = Nb, Ta) **3** [21,22] by the reaction of the corresponding metallocene trihydride **4** with the diazoalkane. Since the rate of elimination of hydrogen from Cp_2MH_3 (pathway *a*) is appreciably lower than the rate of formation of compound **3**, pathway *b*, involving the insertion of the diazoalkane in a M – H bond and only then the elimination of hydrogen, is more likely.

In the first communications [9,10,24] (up to 1975) in which the synthesis of stable monometallic diazoalkane complexes was reported, the question of the type of coordination of the diazoalkane usually remained open. The hypothesis, put forward in 1966,[38] that diphenyldiazomethane is coordinated to cyclododeca-1,5,9-trienenickel exclusively via the carbon atom can hardly be regarded as realistic in the light of present day knowledge.

The results of X-ray diffraction studies on the complexes $Ni(CNBu^t)_2(N_2Fld)$ (N_2Fld = 9-diazofluorene) **5** [14] and $Ru(CO)_2(PPh_3)_2(N_2C_5Cl_4)$ **6** [11] indicate that diazoalkanes are involved in η^2-*N,N'*-coordination (type **B**) in both complexes. The above complexes with the η^2-*N,N'*-coordination of the diazoalkane are regarded as π-type complexes. A similar type of coordination has been demonstrated by X-ray diffraction for the complex $Cp_2Ti[\eta^3$-*N,N',O*-$N_2C(CO_2Et)_2]$ **7**, [12] in which the metal atom is additionally coordinated to an oxygen atom of the carboxy-group. The displacement of the ν_{CNN} vibration band from 2050–2150 cm^{-1} for the free diazoalkanes to 1400–1600 cm^{-1} for the complexes has been observed in the spectra of the complexes. On this basis, it has been suggested that this type of coordination of the diazoalkane occurs also in many other complexes, in particular in $Cp_2V(N_2CR_2)$ (R = Ph, CO_2Et),[12,13] $Cp_2M(H)(N_2CPh_2)$ (M = Nb, Ta) **3**,[20] and $Cp_2Mo(N_2Fld)$,[23] and in certain complexes of the type $L_2M(N_2CR_2)$ (L = $CNBu^t$, PR_3; M = Ni, Pd; CR_2 = CPh_2, $C(CN)_2$, Fld, C_5X_4; X = H, Cl, Br).[9–11,14]

Complexes with the η^1-*N*-coordination of the diazoalkane ligand were obtained later — for example, $IrCl(N_2C_5Cl_4)(PPh_3)_2$ **8a**.[33] It was then also suggested [11] that the η^2-*N,N'*-coordination of the diazoalkane is more probable in those cases where the electron-accepting nature of the nonterminal nitrogen atom becomes enhanced under the influence of the electron-deficient CR_2 of the diazoalkane and when the *d* orbitals of the transition metal are filled to a greater extent.

Numerous data are already available on complexes for which the η^1-*N*-coordination of the diazoalkane has been postulated with a high degree of probability or reliably established:

$MClL_2(N_2CR'R'')$ — $Cp_2Ti(PMe_3)(N_2CPh_2)$ [31]

8 — **9**

$Cp_2M(X)(N_2CPhAr)$ [21,22,39] — M = Nb, Ta; X = H, Cl, Br.

3, 10

$M(CO)(S_2CNR_2)_2(N_2CR'R'')$ [15,30] — M = Mo, W.

1

$MX_2(N_2CR'R'')L(PMe_2Ph)_2$ [40,41] — M = Mo, W; X = Hal, OR; L = PMe_2Ph, π-ligands.

11

$[MX(N_2CR'R'')(dppe)_2]^+Y^-$ [42–48]

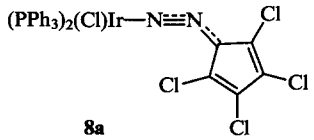
12

M = Mo, W; X = Hal; dppe = $PPh_2(CH_2)_2PPh_2$; Y = Br, BF_4, PF_6.

$X_2W(\mu\text{-}CSiMe_3)_2WX_2(N_2CPh_2)$ [16] — X = CH_2SiMe_3, OPr^i.

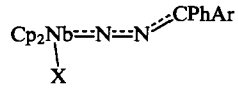
13

$Mo(OBu^t)_4(N_2CAr_2)$ [18]

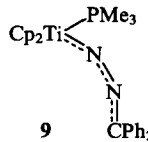


14

$Cp'Mn(CO)_2[N_2C(CO_2R')_2]$ [34,35] — Cp' = C_5H_5, C_5H_4Me.



15



$MCl_{3-x}H_xL_2(N_2CR'R'')$ [26,27,29,37] — M = Ir, Rh; x = 1, 2; L = CO, PR_3.

It was observed that the absorption band for the ν_{CNN} vibration in the spectra of these complexes is in the same range as for the complexes with η^2-*N,N'*-coordination of the diazoalkane, i.e. in the region 1400–1600 cm^{-1}.

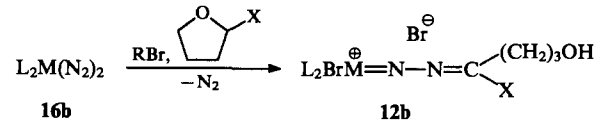
14a

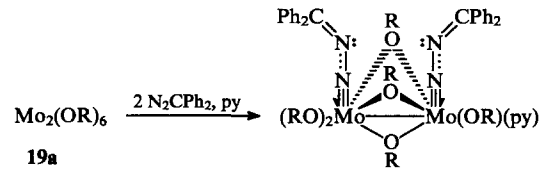
15a



Apart from the reactions involving the addition of diazoalkanes to the coordinatively unsaturated complex or the substitution of another ligand by the diazoalkane, other methods of synthesis of η^1-*N*-diazoalkane complexes have also been discovered. Among the molybdenum and tungsten complexes $M(N_2)_2L_n$ **16** containing coordinated molecular nitrogen, the diazoalkane complexes **11** and **12** have been obtained in two ways: (*a*) by reaction with geminal dibromocompounds;[46–48] (*b*) by the protonation of the nitrogen with formation of hydrazinate(2-) complexes and subsequent condensation with aldehydes or methyl ketones.[40–46]

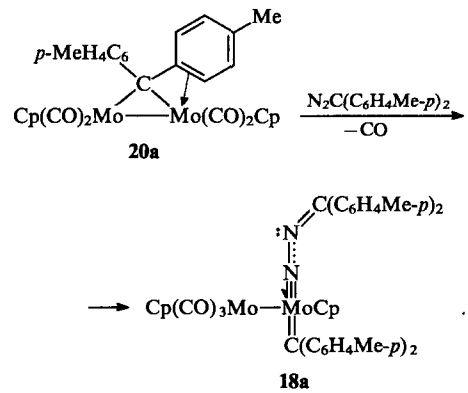
11, 12

M = Mo, W;
X = F, Cl, Br, I, BF_4, PF_6;
L = PMe_2Ph, dppe;
R′ = H, Me; R″ = H, R, COR, Ar.



The tungsten complex of diazobutanol **12b** and the related complexes $[MBr(N_2C(X)CH_2CH_2CH_2OH)(dppe)_2]^+$ (M = Mo, W; X = H, Me)[48–50] have been obtained by the reaction of $M(N_2)_2(dppe)_2$ **16b** with 2-X-substituted tetrahydrofuran (THF) in the presence of alkyl bromides.

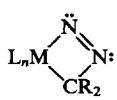
16b **12b**



M = Mo, W; L = dppe; R = Alk; X = H, Me.

The molybdenum complexes $Mo(OBu^t)_4(N_2CAr_2)$ **14**,[18] $(RO)_2(N_2CAr_2)Mo(\mu\text{-}OR)_3Mo(OR)(N_2CAr_2)(py)$ **17**, where R = Pr^i or CH_2Bu^t,[18,51] and $Cp(CO)_3MoMoCp(CAr_2)\cdot(N_2CAr_2)$ **18**[52,53] with η^1-*N*-coordination of the diazoalkanes have been obtained from the complexes $Mo_2(OR)_6$ **19** and $Cp(CO)_2Mo(\mu\text{-}CAr_2)Mo(CO)_2Cp$ **20**. The addition of the diazoalkane molecule takes place as a result of the transformation of the coordination sphere in the initial complexes, for example:

19a **17a**



R = Pr^i.

20a **18a**

The diazoalkanes in complexes with η^1-*N*-coordination can be formally regarded as neutral diazoalkane or nitrene ligands or as hydroazonate(2-) ligands. However, the nature of the bonds in them, particularly that of the N–N bonds, differs from those in hydrazones. The N–N bond length in these complexes is close to that in a double bond, while the M–N–N angle tends to 180°. The principal structural parameters of diazoalkane and related complexes are presented in Table 1 and the average C–C and C–N bond lengths in organic molecules are shown for comparison in Table 2. On the basis of the structural data for the diazoalkane complexes, one can postulate the *sp* hybridisation of the terminal nitrogen atom. The M–N bond length is also close to that of a double bond, so that the diazoalkane ligand can be regarded as a 2-electron donor (in complexes **3**, **8**, **9**, **10**, and **15**) and a 4-electron donor (in complexes **11**–**14**, **17**, **18**) depending on the coordination capacity of the metal atom.

The formation of metallocyclobutane complexes of type **D** with 1,3-*N*,*C*-coordination of the diazoalkane has been postulated only as intermediates in the catalytic decomposition of diazoalkanes, leading to carbenes and hence to the products of the reactions of carbenes.

D

[a] The length of a single bond conjugated with a double bond.

2. Addition (insertion) reactions with formation of bridged diazoalkane complexes

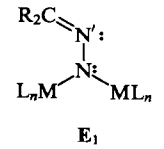
Bridged diazoalkane complexes have been obtained in several ways: (a) by addition (insertion) to multiple (Mo≡Mo, W≡W[63–69] and Os=Os[70]) or single (Zr–Zr[71] and Ru–Ru[72]) metal–metal bonds; (b) by the dimerisation of coordinatively unsaturated metal complexes (Ti,[19,36] Zr,[17] Nb,[73,74] Mn, Co[75]); (c) by the substitution of other bridging ligands (Rh[76]):

(a) $L_nM{\equiv}ML_n + N_2CR_2 \longrightarrow (L_nM)_2(\mu\text{-}N_2CR_2)$ (M–M)

$L_nM{=}ML_n + N_2CR_2 \longrightarrow (L_nM)_2(\mu\text{-}N_2CR_2)$ (M–M)

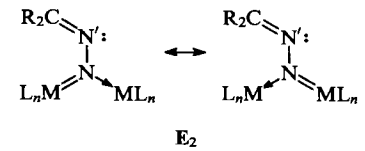
$L_nM{-}ML_n + N_2CR_2 \longrightarrow (L_nM)_2(\mu\text{-}N_2CR_2)$

(b) $2\left[L_nM{=}\ddot{N}{-}\ddot{N}{=}CR_2\right] \longrightarrow (L_nM)_2(\mu\text{-}N_2CR_2)_2$



$2\,L_nM + N_2CR_2 \longrightarrow (L_nM)_2(\mu\text{-}N_2CR_2)$

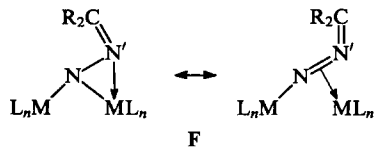
(c) $(L_nM)_2(\mu\text{-}Y)_2 + N_2CR_2 \xrightarrow[-Y_2]{} (L_nM)_2(\mu\text{-}N_2CR_2)$



Y = H.

One can postulate at least four types of coordination of bridging diazoalkanes to a bimetallic centre (regardless of whether the direct valence metal–metal interaction is then retained):[7]

(a) A symmetrical bridge with the coordination of only the terminal nitrogen atom — with $\mu\text{-}\eta^1:\eta^1$-*N*-coordination of the diazoalkane, the diazoalkane being capable of functioning both as a 2-electron donating (E_1) or a 4-electron-donating (E_2) ligand.



E_1

E_2

(b) An asymmetric bridge with additional coordination of the nonterminal N' atom to one metal atom (type **F**) — with μ-η^1 : η^2-*N,N,N'*- or μ-σ,π-coordination of the diazoalkane.

F

(c) A bridge where each nitrogen atom is coordinated to only one specific metal atom — with μ-η^1 : η^1-*N,N'*-coordination of the diazoalkane (type **G**).

(d) A bridge the terminal nitrogen atom of which is coordinated to one metal atom while the carbon atom is coordinated to the second metal atom — with μ-η^1 : η^1-*N,C*-coordination of the diazoalkane (type **H**).

G **H**

In bimetallic complexes, the asymmetric type **F** coordination of the diazoalkane is most often encountered. Such coordination has been established (or postulated) for the following complexes:

$CpClTi(N_2CPh_2)_2TiClCp$ [19,36]

21

$CpClZr(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_{10}H_8)(N_2CPh_2)ZrClCp$ [71]

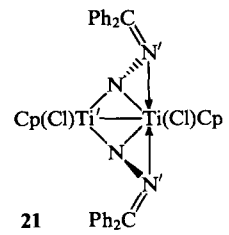
22

$Cp'(CO)_2Mo(\mu\text{-}CO)(N_2CR'R'')Mo(CO)Cp'$ [63-65]

23

$Cp' = C_5H_5, C_5H_4Me, C_5Me_5$; $R' = R'' = Me$; $R' = H$, $R'' = CO_2Et$

$C_5Me_5(CO)_2Mo(\mu\text{-}CH_2)(N_2CH_2)Mo(CO)_2C_5Me_5$. [66]



24

It has been observed (Table 3) that the N–N' bond in these complexes is intermediate between a double and single bond, while N'–C is very close to a double bond.

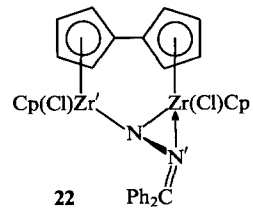


Table 3. Selected structural parameters of diazoalkane and related complexes.

No.	Complex	Bond lengths/Å		Bond angles/deg			Ref.
		N–N'	N'–C	M–N–M'	M–N–N' (M'–N–N')	N–N'–C

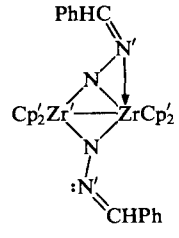
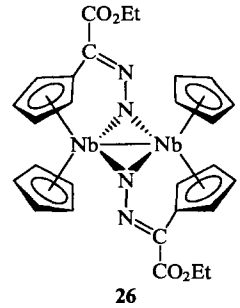
21

22



23a

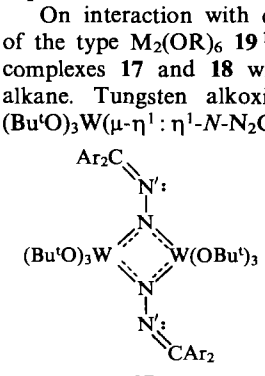


23b

Cp* = C_5Me_5.

Dimerisation of the coordinatively unsaturated complexes [$Cp'_2Zr{=}NN{=}CHAr$] generated afforded the interesting complexes $Cp'_2Zr(\mu\text{-}\eta^1:\eta^1\text{-}N\text{-}N_2CHAr)(\mu\text{-}\eta^1:\eta^2\text{-}N,N,N'\text{-}N_2CHAr).ZrCp'_2$ **25** (Cp′ = C_5H_5, C_5H_4Me),[17,76] in which the symmetrical (**E**) and asymmetric (**F**) coordination of the diazoalkane has been established. The titanium and zirconium diphenylhydrazinate(2-) complexes $CpXM(\mu\text{-}\eta^1:\eta^1\text{-}N\text{-}N_2Ph_2)(\mu\text{-}\eta^1:\eta^2\text{-}N,N,N'\text{-}N_2Ph_2).MXCp$ (M = Ti; X = Cl; M = Zr; X = Cp), similar to complexes **25**, have also been synthesised.[76,77]

25a

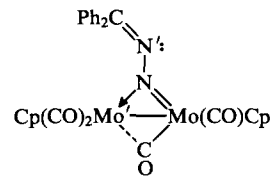


Cp′ = C_5H_4Me. 26

The interaction of the complex Cp_2NbH_3 **4a** with diazoacetate afforded the unique bimetallic complex [$CpNb\text{-}\eta^5\text{-}C_5H_4C.(CO_2Et){=}N\text{-}\mu\text{-}\eta^1:\eta^1\text{-}N]_2$ **26** containing a diazoalkane ligand coordinated to the metal atom and simultaneously bound to one of the ligands.[73] The substitution of the Cp ligand in the metallocene complexes of the early transition metals is encountered extremely rarely. It has been suggested that the formation of complex **26** also includes a stage in which coordinatively unsaturated monometallic intermediates dimerise (see Section IV.1).

A bridged diazoalkane complex $[Cp_2Nb(\mu\text{-}N_2CPh_2)]_2$ [74] has been obtained from $Cp_2(Br)Nb(\eta^1\text{-}N\text{-}N_2CPh_2)$ **10c** and sodium naphthalide.

On interaction with diazoalkanes, molybdenum alkoxides of the type $M_2(OR)_6$ **19** [18] give rise to mono- and bi-metallic complexes **17** and **18** with η^1-*N*-coordination of the diazoalkane. Tungsten alkoxides afford the bridged complexes $(Bu^tO)_3W(\mu\text{-}\eta^1:\eta^1\text{-}N\text{-}N_2CAr_2)_2W(OBu^t)_3$ **27** in this reaction.



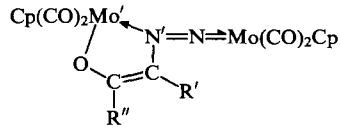
27a

Ar = C_6H_4Me-*p*.

The complexes $Rh_2(\mu\text{-}N_2CRCO_2Et)(CO)_2(dppm)_2$, where R = H or CO_2Et and dppm = $PPh_2CH_2PPh_2$,[76] have been obtained by replacing the bridging hydride atoms in $Rh_2(\mu\text{-}H)_2.(CO)_2(dppm)_2$ by the diazoalkane.

Coordination to the terminal nitrogen atom of the diazoalkane (related to type **E**) has been observed in the clusters $Os_3(CO)_9(\mu_3\text{-}PhC{=}CPh)(\mu_2\text{-}N\text{-}N_2CH_2)$,[70] $Fe_3(CO)_9(\mu_3\text{-}N\text{-}N_2.CPh_2)$,[80] $Co_4(CO)Cp_4(\mu_3\text{-}N\text{-}N_2CPh_2)$,[75] and $Ru_5(CO)_{12}(\mu_4\text{-}C{\equiv}CPh)(\mu_4\text{-}N\text{-}N_2CPh_2)(\mu\text{-}PPh_2)$,[72] the N—N′ bond being somewhat lengthened compared with that in the type **E** bimetallic complexes (Table 3).

The $\mu\text{-}\eta^1:\eta^1$-N-coordination of the diazoalkane (type **E**) has been observed in bimetallic molybdenum complexes in those cases where the groups R′ and R″ in this diazoalkane molecule are bulky and can prevent the additional coordination of the N′ atom as a consequence of steric hindrance. A coordination of this type has been observed in the complexes $Cp(CO)_2Mo(\mu\text{-}CO)(N_2CAr_2).Mo(CO)_2Cp$ **28** (Ar = Ph, C_6H_4Me-*p*).[65,66] According to spectroscopic data, at room temperature the diazoalkane bridge in complex **28** is fully symmetrical, but X-ray diffraction study of complex **28a** demonstrated some deviation from total symmetry.

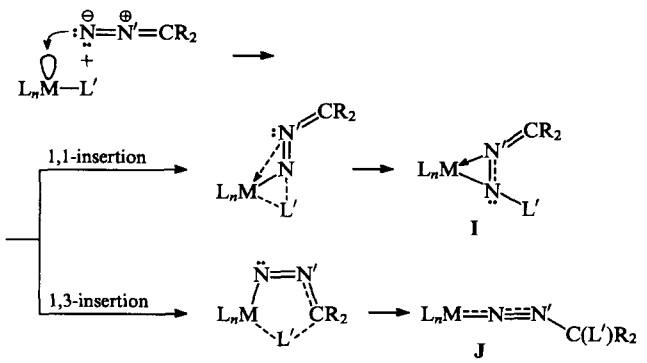


28a

It was shown later[64,65] that the ^1H NMR spectra of the complexes $Cp'(CO)_2Mo(\mu\text{-}CO)(N_2CR'R'')Mo(CO)Cp'$ **23** (Cp′ = C_5H_5, C_5H_4Me, C_5Me_5; R′ = R″ = Me; R′ = H, R″ = CO_2Et)[63,65] are only partly consistent with the structure established. In the case of the diazopropane derivative (R′ = R″ = Me), a slow isomerisation of two structures, **F** ⇄ **E**, was observed at room temperature on the basis of NMR spectroscopic data.[64] It has been suggested for the diazoacetic acid ester derivative **23b** (R′ = H, R″ = CO_2Et) [65] that thermodynamic equilibrium is established at room temperature between the complexes in which the N′ nitrogen atom is involved in type **F** coordination to one or several metal atoms.

It has been postulated that bridged type **E** and **F** complexes are formed as intermediates also in the reaction of diazoalkanes with other bimetallic complexes containing a multiple metal—metal bond. For example, in the interaction of complexes of the type $[Cp'(CO)_2W]_2$ with diazoalkanes at negative [below 0 °C (Ed.)] temperatures, the formation of type **E** and **F** complexes was observed, but only the products of the subsequent interactions, analogous to those obtained on heating the corresponding molybdenum analogues (see Section IV.1), were isolated.[81]

In the interaction of α-diazoketones with the molybdenum complex $Cp'(CO)_2Mo{\equiv}Mo(CO)_2Cp'$ **30** (Cp′ = C_5H_5, C_5Me_5), the Mo≡Mo bond is fully cleaved and type **G** complexes are formed with additional coordination of the oxygen atom of the oxo-group to one metal atom. The complexes $Cp'(CO)_2Mo(\mu\text{-}\eta^1:\eta^2\text{-}N,N',O\text{-}N_2C(R'){=}C(R'')OMo'(CO)_2Cp'$ **29** [Cp′ = C_5H_5, C_5Me_5; R′ = R″ = Ph; R′ = CO_2Et, R″ = OEt; R′—R″ = $C(O)CH_2CMe_2CH_2$] have been obtained in the same way.[64,65,69]

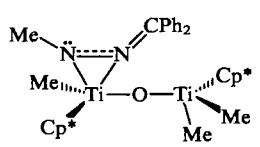


29a,b

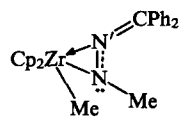
29a: R′ = R″ = Ph.
29b: R′ = CO_2Et; R″ = OEt.

Type **H** complexes have not been isolated but it has been suggested that they are intermediates in the formation of carbenes from diazoalkanes [3,4,7] catalysed by bimetallic transition metal complexes.

3. Reactions involving insertion in the M–L bond with formation of hydrazonate, alkyldiazene, and ketazine complexes

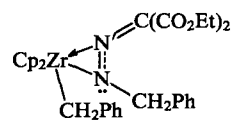


Diazoalkanes are capable of being inserted in highly reactive metal–ligand bonds (in the first place in M–H and M–C bonds) and the reaction can proceed as 1,1- or 1,3-insertion of the diazoalkanes. The η^2-*N,N'*-hydrazonate complexes **I** and alkyldiazene complexes **J** have been obtained in this way.

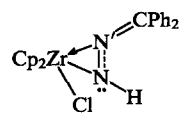


I **J**

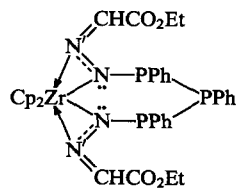
The 1,1-insertion reactions proceed as a rule more readily in those cases where the initial metal complex is coordinatively unsaturated and preliminary coordination of the diazoalkane promotes its subsequent insertion. However, the insertion product must be coordinatively unsaturated and stabilised as a result of the additional coordination of the nonterminal nitrogen atom (type **I** complex). The nonterminal nitrogen atom is not coordinated in insertion reactions with bridged complexes **K**.



The reaction involving the insertion of N_2CPh_2 in the Ti–CH_3 bonds of the dinuclear and trinuclear titanium oxides $[Cp^*Me_2Ti]_2(\mu\text{-}O)$ and $[Cp^*MeTi(\mu\text{-}O)]_3$ ($Cp^* = C_5Me_5$) leads to the formation of hydrazonate complexes with η^2-*N,N'*-coordination (type **I**).[82] The reaction products are the following titanium complexes: $Cp^*Me_2Ti(\mu\text{-}O)TiMe(\eta^2\text{-}N,N'\text{-}NMe\text{–}N'=CPh_2)Cp^*$ **31** and $(Cp^*MeTi)_2(\mu\text{-}O)_3Ti(\eta^2\text{-}N,N'\text{-}NMe\text{–}N'=CPh_2)Cp^*$. Complex **31** can interact with another N_2CPh_2 molecule to form $(\mu\text{-}O)[TiMe(\eta^2\text{-}N,N'\text{-}NMe-N'=CPh_2)Cp^*]_2$. It has also been observed that diazoalkanes are inserted in the Zr–H, Zr–C, and Zr–P bonds of the corresponding zirconocene derivatives. The complexes $Cp_2ZrR(\eta^2\text{-}N,N'\text{-}NRN'=CR'_2)$ **32** (R = Me, CH_2Ph; R' = Ph, CO_2Et),[83,84] $Cp_2ZrCl(\eta^2\text{-}N,N'\text{-}NHN'=CPhAr)$ **33** (Ar = Ph, *o*-C_6H_4Br),[83–85] and $Cp_2Zr.[(\eta^2\text{-}N,N'\text{-}NR'N'PPh)_2PPh]$ **34** (R' = $CHCO_2Et$)[86] have been obtained similarly. Complex **33** has been synthesised also by the reaction of Cp_2ZrCl_2 with $LiHNN=CPh_2$, although the authors[17,77] assumed that only the η^1-*N*-coordination of the hydrazonate ligand takes place in it. It has been shown for complexes **32** and **33**[83–85] that only the *exo*-isomers are formed. An azametallocyclobutene derivative—the complex $Cp_2^*Zr.(\eta^2\text{-}N,C\text{-}CPh=CPh-NN'=CPh_2)$—has been obtained by inserting N_2CPh_2 in the acetylene complex $Cp_2^*Zr(C_2Ph_2)$.[87]

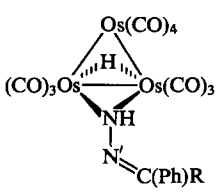


31



32a

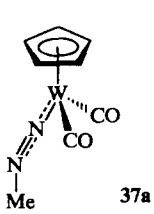
32b



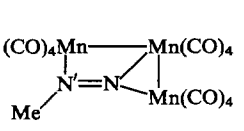
33a

34

Although the bridging hydride atoms in the rhodium complex $[Rh_2(\mu\text{-}H)_2(CO)_2(dppm)_2]$ are substituted in the reaction with diazoalkanes,[76] in the osmium cluster $(\mu\text{-}H)_2.Os_3(CO)_{10}$ the diazoalkane is inserted with formation of the complex $(\mu\text{-}H)Os_3(CO)_{10}(\mu\text{-}NH-N=CR'R'')$ **35** (R', R'' = H, Me, Ph).[88,89] The analogous ruthenium complexes $(\mu\text{-}H)Ru_3.(CO)_{10}(\mu_2\text{-}N\text{-}NH-N=CR'R'')$ have been obtained in the reaction of hydrazones with $Ru_3(CO)_{12}$;[90,91] when yet another CO molecule is lost, the complex $(\mu\text{-}H)Ru_3(CO)_9(\mu_3\text{-}N,N,N'\text{-}NH-N=CR'R'')$, with the μ_3-*N,N,N'*-coordination of the hydrazonate ligand, is formed.



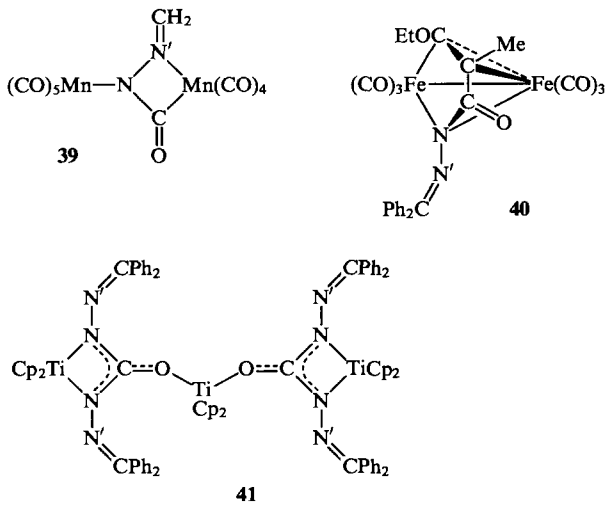
35a,b



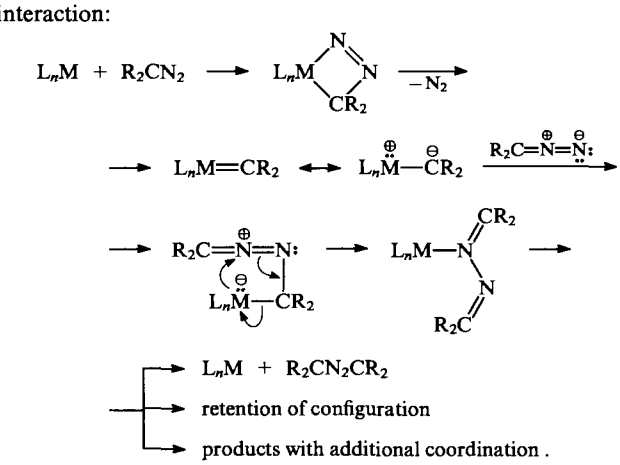
35a: R = Ph.
35b: R = Me.

1,3-Insertion has been observed only for metal hydride complexes. This is probably due to the great mobility of the H atom. The 1,3-insertion products are derivatives of alkyldiazenes $HN=N-CHR_2$, which are tautomeric forms of diazoalkanes (hydrazones) $H_2N-N=CR_2$. According to quantum-chemical calculations,[92] either one or other tautomeric form is more convenient (depending on R) for the simplest alkyl substituents R; the energy difference between them does not exceed 5 kcal mol^{-1}.

It has been found that the alkyldiazene complexes $CpM.(CO)_2(\eta^1\text{-}N\text{-}N=N-CHR'R'')$ **37** are formed as the main products in the reactions of $CpM(CO)_3H$ **36** (M = Mo, W) with the diazo-compounds $N_2CR'R''$ (R', R'' = H, Me, CO_2Et).[93–96] Under analogous conditions, the reaction of the manganese hydride $(CO)_5MnH$ with N_2CH_2 gives rise to a mixture of products,[54,97,98] from which the product of the insertion of diazomethane in the Mn–H bond, namely $(\mu_3\text{-}N,N,N'\text{-}N_2CH_3)[Mn(CO)_4]_3$ **38**, was obtained in ~10% yield.



37a



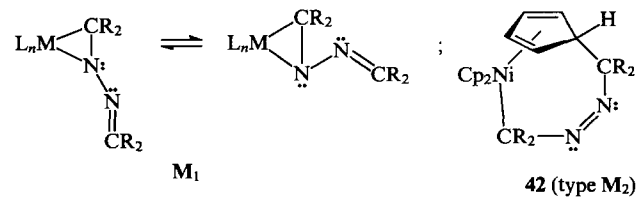
38

The products of the insertion of N_2CH_2 in the M–CO multiple bond, i.e. the manganese carbohydrazonate complex $(CO)_5Mn(\mu\text{-}N,N',C\text{-}C(O)-NN'=CH_2)Mn(CO)_4$ **39**, is formed in the same reaction in 25%–30% yield.[54,98,99] The dinuclear

complex $Fe_2(CO)_6[Ph_2C=N'NC(O)C(Me)C(OEt)]$ **40**, also containing the carbohydrazonate fragment, has been obtained in the reaction of the cluster $Fe_3(CO)_9(\mu_3\text{-CMe})(\mu_3\text{-COEt})$ with N_2CPh_2.[100] The double insertion of a diazoalkane in a M—CO bond has been observed in the interaction of $Cp_2Ti(CO)_2$ with N_2CPh_2. The product also contains a ligand of the carbohydrazonate type $(Cp_2Ti)_3[Ph_2CN_2C(O)N_2CPh_2]_2$ **41**.[9] On the other hand, the reaction of $Cp_2Ti(PMe_3)_{2-x}(CO)_x$ ($x = 0.1$) with N_2CPh_2 afforded a product with the η^1-*N*-coordination of the diazoalkane ligand—$Cp_2Ti(PMe_3)(N_2CPh_2)$ **9**.[31]

Diazoalkanes are capable of being inserted not only in a multiple M—CO bond in carbonyl complexes but also in a M=C double bond in carbene complexes. The products are then either ketazine complexes or a free ketazine (depending on the coordination capacity of the metal atom). The products of the interaction of diazoalkanes with transition metal complexes can also be carbene complexes (see Section III, 2). Generalising these results, a number of workers,[101—104] who observed the formation of ketazine complexes and the decomposition of diazoalkanes into a ketazine and nitrogen in the interaction of the diazoalkanes with transition metal complexes, proposed the following mechanism of this interaction:

Ketazine complexes have also been obtained by the direct interaction of ketazines with transition metal complexes, usually at elevated temperatures.[105]



$[(\mu\text{-OAc})_2\overline{Pd(\eta^2\text{-}N,C\text{-}Ar'_2CN'NC(Ar')\text{-}2\text{-}C_6H_3(4\text{-}OR))}]_2$

Ar′ = *p*-C_6H_4OR; R = Alk.

The decomposition reactions of diazoalkanes, catalysed by transition metal complexes [for example, $Pd(OAc)_4$ [106] and $Ni(C_{12}H_{18})$ [38]] and proceeding with evolution of nitrogen, are encountered fairly often and correspond to the very simple mechanism

$$2\,N_2CR_2 \xrightarrow{ML_n} N_2 + R_2CN_2CR_2.$$

There are several ways in which ketazines may be coordinated in transition metal complexes. The π-(η^2-*N*,*C*)-coordination (type M_1) of one of the C=N bonds of the ketazine has been proposed in studies at the beginning of the 1970s [24,101] for the complexes $L_2M(R'_2C=NN=CR'_2)$ (M = Pt, Pd, Ni; L = RNC, PR_3; R′ = CF_3). The interaction of nickelocene with $N_2C(CF_3)_2$ afforded the compound $Cp_2Ni(C_6F_{12}N_2)$ **42**.[102] It is suggested that complex **42** has the structure M_2. It is essential to note that the structures M_1 and M_2 presented have not been elucidated by objective methods.

It has been established that in ketazine complexes whose structure has been determined [these are in all cases the derivatives $N_2C(C_6H_4R\text{-}p)_2$, where R = H or Me] the transition metal atom is always coordinated solely to one nitrogen atom of the ketazine ligand. Three types of structures have been found:

(a) with η^1-*N*-coordination (type M_3)

$Ar_2Pt(CO)(\eta^1\text{-}N\text{-}Ph_2CN_2CPh_2)$ (Ar = C_6F_5)[103];

(b) with η^2-*N*,*C*-coordination (type M_4)

$(CO)_2(PPh_3)\overline{OsH[\eta^2\text{-}N,C\text{-}Ar'_2CN'NC(Ar')\text{-}2\text{-}C_6H_3(4\text{-}Me)]}$

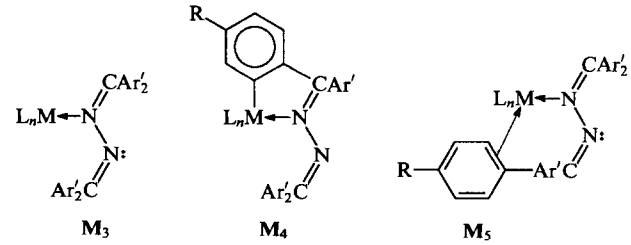
Ar′ = C_6H_4Me-*p*[104]

$Ar\overline{Pt(CO)(\eta^2\text{-}N,C\text{-}Ph_2CN'NC(Ph)-C_6H_4\text{-}o)}$

Ar = C_6F_5[103]

$[(\mu\text{-OAc})_2\overline{Pd(\eta^2\text{-}N,C\text{-}Ar'_2CN'NC(Ar')\text{-}2\text{-}C_6H_3(4\text{-}OR))}]_2$

Ar′ = C_6H_4OR-*p*; R = Alk.[105]



A case has also been described where the ketazine *ortho*-metallated at the benzene ring behaves as a bridging ligand, i.e. $(\mu\text{-}OAc_2)_4.Pd_3[\mu\text{-}\eta^2:\eta^2\text{-}(\text{-}NC(Ph)\text{-}C_6H_4\text{-}o)_2]$:[106]

(c) with η^2-π-coordination (type M_5)

$Ar_2Pt(Ph_2C\text{-}\eta^1\text{-}NNC(Ph)\text{-}\eta^2\text{-}C_6H_5)$

Ar = C_6F_5.[103]

Thermolysis of the latter afforded the platinum complex $Ar_2Pt.[\eta^1\text{-}(C_6H_4\text{-}o)\text{-}C(Ph)\text{-}\eta^1\text{-}NNC(Ph)\text{-}\eta^2\text{-}C_6H_5)$,[103] for which both types of coordination were found simultaneously—M_4 and M_5.

The structural parameters of a series of hydrazonate, alkyldiazene, carbohydrazonate, and ketazine complexes are presented in Table 4.

Table 4. Selected structural parameters of the hydrazonate, alkyldiazene, and ketazine complexes.

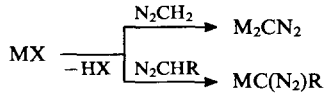
4. Reactions with formation of other complexes

It was shown above that the diazoalkane complexes can be obtained from complexes containing coordinated molecular nitrogen.[40–50] However, there have also been cases where the opposite process — the cleavage of the diazoalkane in the coordination sphere of the metal and the coordination of the nitrogen thus produced (type **N**) — was observed in the interaction of diazoalkanes with transition metal complexes.[107,108]



$$(ON^*)Os(Cl)(PPh_3)_3 + IC(N_2)CO_2Et \longrightarrow$$

$$\longrightarrow EtO_2CCH{=}N^*{-}Os(N_2)(Cl)_2(PPh_3)_2$$
$$\quad\quad\quad

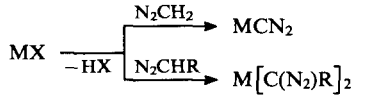


Table 5. Structural parameters of α-metallated diazoalkane complexes and free diazoalkanes.

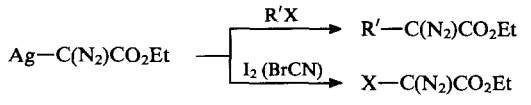
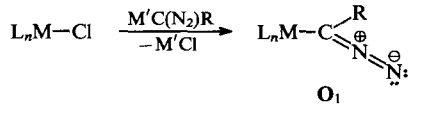
Complex	Bond lengths/Å		Bond angles/deg		Ref.
	N–N′	N′–C	M–N–N′	N–N′–C	
Free diazoalkanes	1.12–1.13	1.28–1.32	–	–	61, 62
$(PMe_3)_3MeIRh[C(N_2)SiMe_3]$	1.09	1.30	119	175	114
$(PPh_3)_2ClPd[C(N_2)CO_2Et]$	1.16	1.28	122	177	112, 113
$(PBu_3)_2Pd[C(N_2)CO_2Et]_2$	1.13	1.28	120	176	113



α-*C*-metallated diazoalkane derivatives of Group IB and IIB elements—silver,[109] mercury,[110,111] zinc, and cadmium[111]—have been fairly widely investigated. They have been synthesised directly from the corresponding inorganic compounds of the above metals and diazoalkanes. The compounds obtained can be used in the synthesis of substituted diazoalkanes.

M = Ag; X = $\frac{1}{2}$O.
M = RHg; X = NR_2, OR.

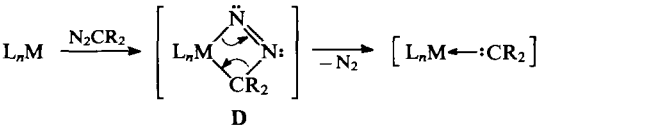


M = Hg; X = NR_2, $\frac{1}{2}$O, OR.
M = Zn, Cd; X = NR_2.

X = I, Br.

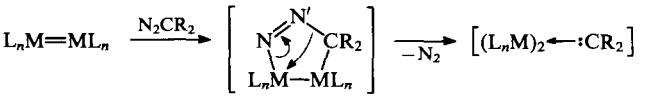
α-Metallated diazoalkane complexes of palladium,[112,113] rhodium,[114,115] yttrium, lutetium, and ytterbium[116] (type $\mathbf{O_1}$) are also known. They were obtained via a transmetallation reaction:

$\mathbf{O_1}$



L_nM = Pd(Hal)$(PR'_3)_2$; M′ = Li, $\frac{1}{2}$Hg; R = CO_2Et, COMe, Ph.
L_nM = $Rh(PMe_3)_4$; M′ = Li; R = $SiMe_3$, $P(NR_2)S$, $P(NR_2)_2$.
L_nM = YCp^*_2, $LuCp^*_2$, $YbCp^*_2$; M′ = Li; R = $SiMe_3$.

Type $\mathbf{O_2}$ palladium complexes $(PR'_3)_2Pd[C(N_2)R]_2$ have been synthesised in a similar way.[113] Owing to the hindered rotation about the Pd–C bond in this complex, the conformational *anti*- and *syn*-isomers $\mathbf{O'_2}$ and $\mathbf{O''_2}$ were found to be present.

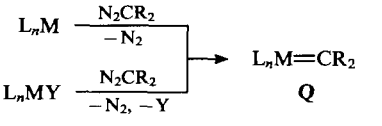


The IR spectra of the α-metallated diazoalkane complexes show a bathochromic shift of the absorption band due to the ν_{CNN} vibrations by 0–100 cm^{-1} relative to its position in the spectra of the free diazoalkanes. This finding is consistent with the observed lengthening of the N–N bond (Table 5). On the other hand, the C–N bond in α-metallated diazoalkane complexes is shorter than in the free diazoalkanes.

2. Reactions with evolution of nitrogen and the formation of carbene complexes

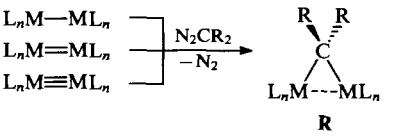
Apart from the coordination of the diazoalkane, the mono- and bi-metallic transition metal complexes can promote the cleavage of the diazoalkane with evolution of nitrogen and the formation of a carbene as an intermediate. It has been suggested that this stage of the interaction of the diazoalkane with the transition metal complex proceeds via a four-membered (type **D**) metallocycle in the case of monometallic complexes and a five-membered (type **H**) metallocycle in the case of bimetallic complexes.

D



H

The intermediate coordinated carbene enters into subsequent reactions. The structure of the final product depends both on the nature of the diazoalkane itself and on the coordination capacities of the 'carbene' complexes mentioned above, on the presence in the latter of other highly reactive bonds, and also on the presence of other reactive substrates in the reaction mixture.

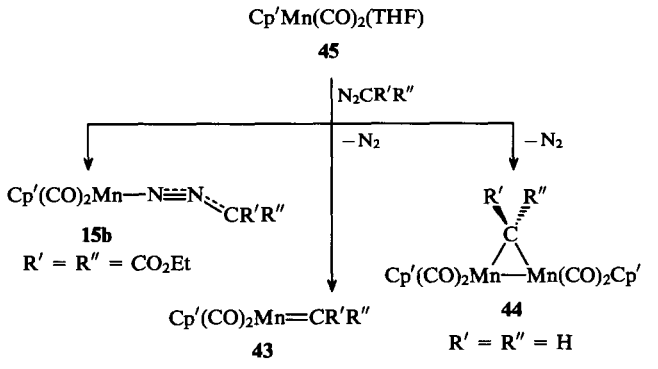


The reactions of transition metal complexes with the carbenes formed as a result of the interaction of the complexes with diazoalkanes will be examined here only to an extent sufficient to emphasise the principal features of these reactions. Since there are excellent reviews on this topic,[3,4,7] embracing the literature up to 1983, only specific studies carried out mainly since 1983 will be referred to.

a. The addition of the carbene to transition metal complexes

The simplest version of the reaction between transition metal complexes and the carbenes generated involves the addition of the latter either to a coordinatively unsaturated monometallic complex [or the substitution of another readily eliminated ligand Y with formation of carbene complexes (type **Q**)] or its addition to the metal–metal bond of a dinuclear complex with formation of methylene or other bridged complexes (Type **R**).

Q

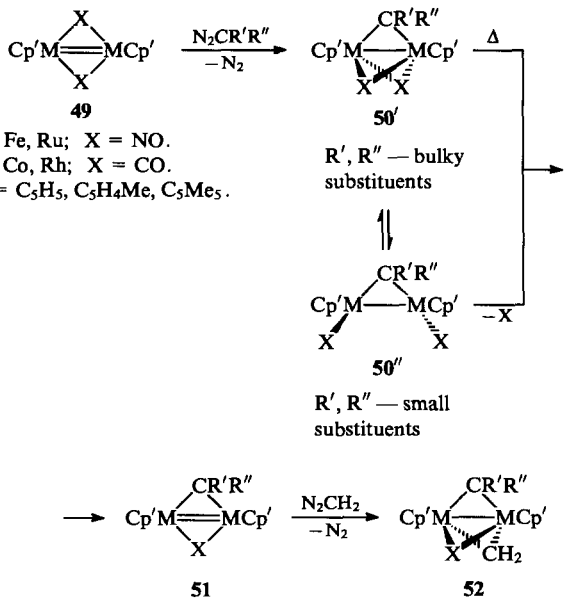


R

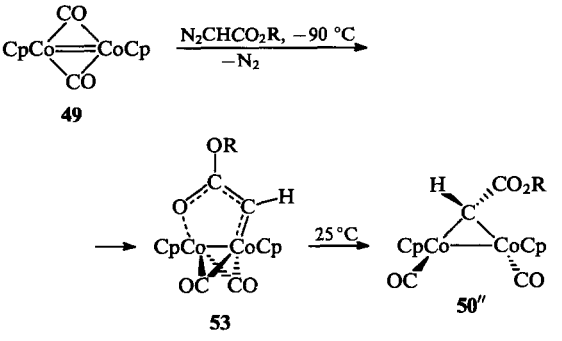
For example, the complex $(PPh_3)_3(NO)ClOs(=CH_2)$ has been obtained by the reaction of $(PPh_3)_3(NO)ClOs$ with N_2CH_2,[117] while the interaction of the molybdenum and tungsten complexes $M(N_2)_2(dppe)_2$ **16b** with N_2CH_2[25] leads to

the formation of $M(CH_2)_2(dppe)_2$. The products **15b**, **43**, and **44** have been synthesised by the reaction of $Cp'Mn(CO)_2(THF)$ **45** ($Cp' = C_5H_5$, C_5H_4Me) with diazoalkanes (Scheme 1).[3, 34, 118]

Scheme 1

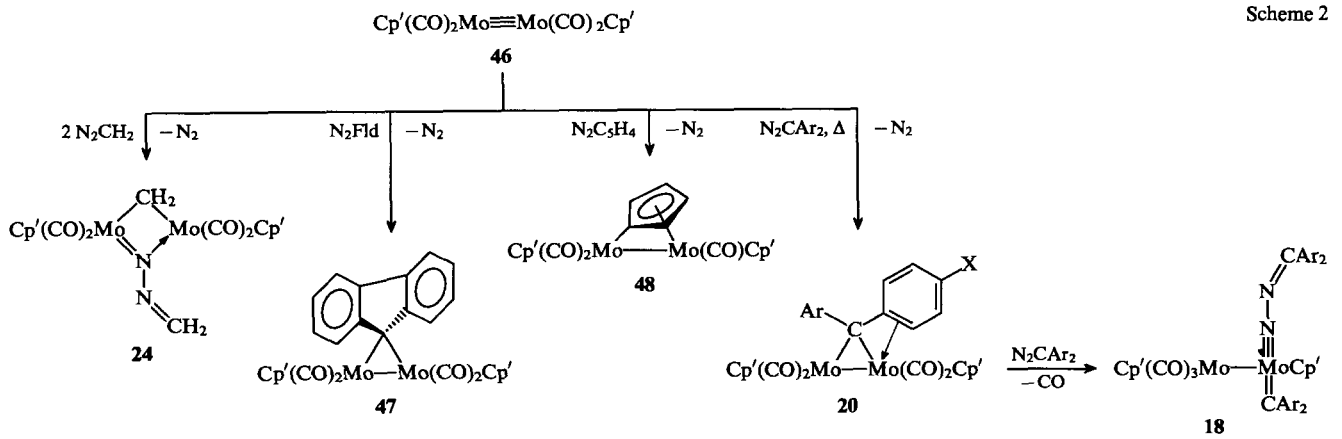


R′ = Ar; R″ = various groups.

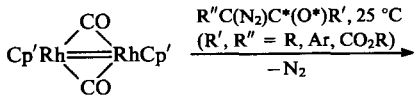


A multiplicity of various compounds have been obtained by the reaction of $Cp'_2Mo_2(CO)_4$ **46** ($Cp' = C_5H_5$, C_5H_4Me, C_5Me_5) with diazoalkanes.[65] The carbene complex **18**, the methylene-bridged complexes **24** and **47**, and the σ,π-bridged complexes **20** and **48** have been synthesised apart from the μ-η¹ : η¹-*N,N*-bridged diazoalkane complexes **18**, **24**, and **28**, the μ-η¹ : η²-*N,N,N'*-bridged diazoalkane complex **23**, and the μ-η¹ : η²-*N,N',O*-bridged diazoalkane complex **30** [Sic. Ed. possibly **29** is intended] (Scheme 2).

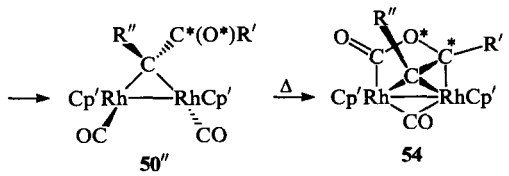
It is seen from Schemes 1 and 2 that the cleavage of the diazoalkane into nitrogen and a carbene is more likely when the carbon atom of the diazoalkane is more accessible (N_2CH_2) or when the substituents R′ and R″ in $N_2CR'R''$ are capable of stabilising the intermediate carbene.



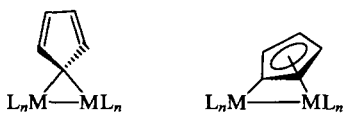
The cleavage of the diazoalkane and the formation of new bridging ligands are almost always observed in the interaction of diazoalkanes with dinuclear complexes of Group VIII transition metals ($Cp'MX)_2$ **49** (M = Fe, Ru, Co, Rh, Ni)[3, 4, 7, 66, 119–125] containing a metal–metal double bond. If the substituents R′ and R″ are relatively bulky (for example Ar), then complex **50′** with three bridging ligands obtained initially is usually the final product. If the groups R′ and R″ are small (H, n-alkyl), then the isomer **50″**, in which the ligands X (NO, CO) are terminal, is more stable. Thermodynamic equilibrium is observed between the two isomers. On heating they can both lose one molecule of X, affording complex **51**, which can react with yet another equivalent of N_2CH_2, forming thereby complex **52** with two methylene bridging ligands.



If the diazoacetic acid esters are used in the given reaction with cobalt complexes,[3] then at a reduced temperature it is possible to obtain complexes **53** with the bridging μ-η¹ : η¹-*C,O*-coordination of the carbene and, when α-diazoketones are introduced into the reaction with rhodium complexes, then more complex products **54** are formed at an elevated temperature.[3, 121]



Scheme 2



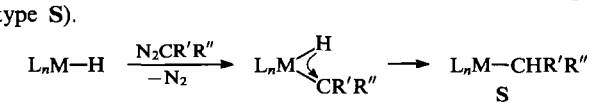
49

50″ 54

Certain carbene ligands may be coordinated in different ways in bimetallic complexes. For example, both μ-η¹: η¹- coordination (type $\mathbf{R}_{\sigma,\sigma}$) in $[CpFe(\mu\text{-}NO)]_2(\mu\text{-}C_5H_4)$, $[Cp^*Co(\mu\text{-}CO)]_2 \cdot (\mu\text{-}C_5Cl_4)$ and in all the fluorene complexes and μ-η¹: η⁵-coordination (type $\mathbf{R}_{\sigma,\pi}$) in the dimeric complexes $Cp_2(CO)_3Mo_2(\mu\text{-}C_5H_4)$ and $[Cp^*Co(\mu\text{-}CO)]_2(\mu\text{-}C_5H_4)$ have been found for the cyclopentadienylidene ligand.[3,126,127]

$\mathbf{R}_{\sigma,\sigma}$ $\mathbf{R}_{\sigma,\pi}$

It has been found that certain carbene complexes obtained from α-diazoketones may rearrange with formation of π-ketene complexes.[3]

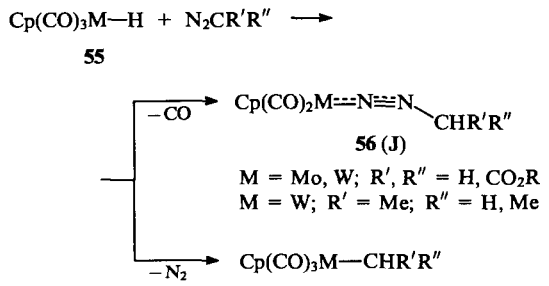


Instead of diazoalkanes, their precursors — hydrazones (in the presence of MnO_2) or *N*-alkyl-*N*-nitrosoureas — have been used successfully in the synthesis of carbene and related complexes.[3,124]

Bridged methylene complexes have also been synthesised by inserting diazoalkanes in the Pt–Pt bond in a platinum complex[128] or by substituting the bridging groups NCMe in an osmium complex[129] and CO in a palladium complex.[130]

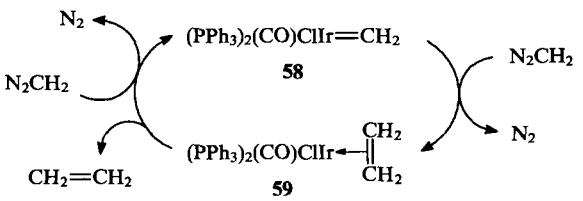
b. Insertion of the carbene in the metal–ligand bond

Another version of the interaction of transition metal complexes with carbenes generated from diazoalkanes involves the insertion of the carbenes in metal–ligand bonds. These reactions usually take place at reduced temperatures — under conditions where the diazoalkanes themselves are stable. However, certain reactions require either elevated temperatures or UV irradiation, i.e. conditions under which the diazoalkanes themselves decompose, forming carbenes initially.[131] It is at present impossible to draw a clear-cut boundary between the thermal or photolytic decomposition of diazoalkanes and their decomposition on interaction with transition metal complexes.



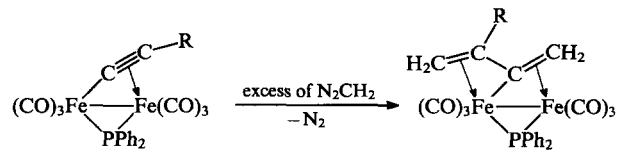
Since the M – H bond belongs to the class of the most reactive M – L bonds, it is to be expected that the carbene may be inserted in this bond too. This results in the formation of alkyl complexes (type S).

S



Thus the reactions of $Cp_2Zr(H)Cl$ with N_2CH_2[73] and of $(CO)_5MnH$ and $Cl(PEt_3)_2PtH$ with $N_2C(CF_3)_2$[132,133] afforded the corresponding alkyl complexes. One of the complexes of this type, namely $Fp-CH(CF_3)_2$, where Fp = $Cp(CO)_2Fe$, has been synthesised quite unexpectedly in the reaction of Fp_2 with $N_2C(CF_3)_2$ in THF.[34] The solvent served as the source of hydrogen in this process.

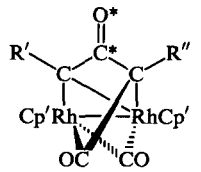
The interaction of molybdenum and tungsten hydride complexes $Cp(CO)_3MH$ **55** with diazoalkanes[95] leads to a mixture of products of the insertion of the diazoalkanes (compounds **56**) and carbenes (compounds **57**) in M–H bonds. The ratio of the alkyldiazene complex **56** (type **J**) and the alkyl complex **57** (type **S**) depends on the nature of the substituents R′ and R″ in the diazoalkane.



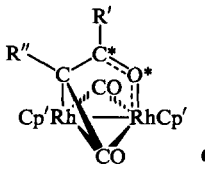
M = Mo, W; R′ = H; R″ = H, Ar.
M = W; R′ = Me; R″ = H, Me.

The insertion of the carbene has been observed also in metal–carbon multiple bonds. For example, the carbene complex of iridium **58** gives rise to the ethylene complex **59** (type **T**) on interaction with diazomethane.[134] When an excess of N_2CH_2 is used, the process proceeds as catalytic decomposition of the latter into nitrogen and ethylene.

Diazomethane diluted with an inert gas decomposes similarly on the surfaces of transition metals (Ni, Pd, Fe, Co, Ru, Cu),[136] which results in the formation of ethylene and nitrogen, while its reaction in a mixture with hydrogen affords a mixture of alkanes. A reaction mechanism involving the formation of carbenes coordinated on the surfaces of metals has been proposed[135] and the reaction has been compared with the Fischer–Tropsch reaction.

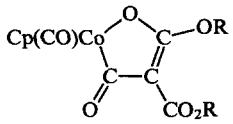


The interaction of the dinuclear iron complex **60**,[136] containing a π-bound alkyne, with diazomethane leads to the butadiene complex **61**.



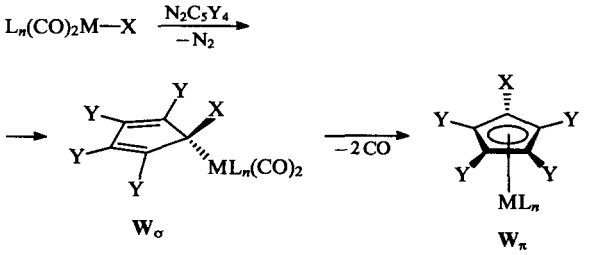
60 **61**

A similar reaction has been described also for a trinuclear ruthenium complex.[137]



If the reaction of the rhodium complex $[Cp'Rh(\mu\text{-}CO)]_2$ (Rh = Rh) **49** (Cp′ = C_5Me_5) described above is carried out with diazodimedone $(R'C^*(O^*)C(N_2)R''$, where R′ = R″ = Ph or R′–R″ = $-CH_2CMe_2CH_2CO-$)[3,121] or benzoylphenyldiazomethane, it is possible to obtain more involved complexes **62** and **63**, which are the products of the insertion of the carbene in the Rh–CO bond. The insertion of the carbene formed from diazomalonate in the Co–CO bond of the monomeric analogue of complex **49**,[3,7] leading to complex **64** (type **U**) with additional coordination of the oxygen atom of the carboxy-group, has also been described.

62 R′ = R″ = Ph.



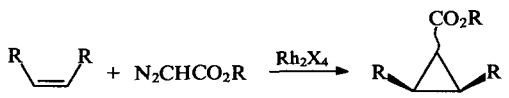
63 R′–R″ = $C(O)CH_2CMe_2CH_2$.

64 R = Me, Et.

The synthesis of the η^2-*C*,*C*-ketene complex $Cp'Mn(CO)_2.[C(O)-CR_2]$ (CR_2 = 9-anthron-10-ylidene) (type **V**) from $Cp'Mn(CO)_3$ and N_2CR_2 catalysed by the complex $CpMn.(CO)_3(THF)$ can serve as the next example of the reaction involving the insertion of the carbene in the M–CO bond.[3]

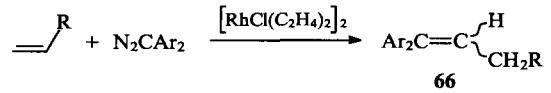
The insertion of the carbene generated from $N_2C(CF_3)_2$ in metal–halogen bonds has been described[24] for the platinum and palladium complexes $(PhCN)_2MCl_2$. The complex $(PhCN)_2.M[C(CF_3)_2Cl]_2$ (type **W**) is then formed. The carbenes obtained from substituted diazocyclopentadienes are readily inserted in metal–halogen bonds. The reaction leads to the formation of halo-substituted 5-cyclopentadienyl complexes ($\mathbf{W}_\sigma$).[3] The reactions proceed tentatively via the formation of η^1-cyclopentadienyl complexes ($\mathbf{W}_\pi$), which were successfully detected in some cases [ML_n = $Mn(CO)_3$; X = Cl, Br; Y = Cl].

ML_n = $Mn(CO)_3$, $Re(CO)_3$, $Fe(CO)_2X$, RhL_2;
X = Cl, Br, I; C_5Y_4 = C_5H_4, C_5X_4, indenyl.



The insertion of carbenes obtained from various diazoalkanes in the Co–S and Rh–S bonds has also been observed.[138]

c. Reactions of the carbenes with other reactive substrates



The carbenes generated from diazoalkanes can react with other reactive substrates in the reaction mixture. In such cases, the transition metal complexes behave as catalysts of the reactions.

There is in fact a large amount of information in the literature about reactions of this kind and reviews on this topic have appeared regularly (for example those of Hegedus[139] and Shapiro et al.[140]) and they will therefore not be described in this review.

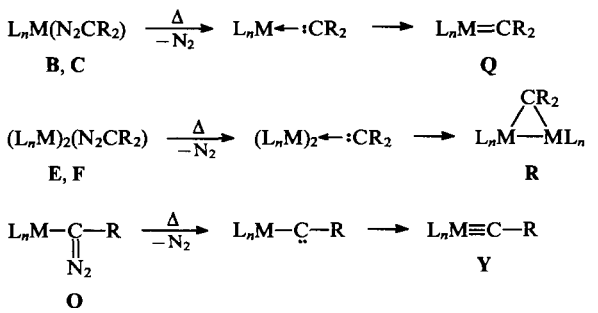
We shall only note that among these processes the greatest importance attaches to the reactions of diazoalkanes with alkenes catalysed by transition metal complexes, which lead to the formation of cyclopropanes **65**[139] or substituted alkenes **66**.[29,37]

65

66

IV. Reactions of diazoalkane complexes

Diazoalkane complexes, i.e. complexes with coordinated diazoalkanes of types **B**, **C**, **E**, **F**, and **O**, are of undoubted theoretical interest as an individual class of compounds. In this sense, they have been thoroughly characterised structurally: their parameters differ from those of the free diazoalkanes. However, in order to obtain exhaustive information about such complexes, it is essential to know to what extent the coordination to the transition metal atom promotes a change in the electron density and polarity of the bonds and hence a change in the reactivity of the coordinated diazoalkane ligands compared with the free diazoalkanes.



There have been few studies on the reactions of diazoalkane complexes of transition metals and they have almost all been carried out during the last decade. The diazoalkane complexes obtained were usually introduced into other reactions. Hitherto there have been no systematic studies on the reactions of diazoalkane complexes.

The available information about the reactions of diazoalkane complexes can be divided into two groups: studies involving the investigation of the products of the thermolysis of diazoalkane complexes and studies on the interaction of diazoalkane complexes with different classes of reagents.

1. Thermolysis of diazoalkane complexes

The majority of diazoalkane complexes have a limited thermal stability. When they are heated, nitrogen is usually evolved and it has been assumed tentatively that a carbene is formed and interacts with the initial complex. In principle, these are the products which have been obtained by the reaction of diazoalkanes with transition metal complexes (see Section III.2). The difference is insignificant and in essence consists only in the fact that some diazoalkane complexes decompose even below room temperature, whilst others are stable under these conditions. When the product of the reaction of the carbene with the initial complex is formed directly (sometimes at reduced temperatures), it is possible to detect diazo-complexes, which are converted into more stable products on slight heating.[6]

The thermolysis of diazoalkane complexes proceeds mainly in three ways. In the first, simplest version of the thermolysis, the evolution of nitrogen and the formation of carbene (type **Q**) or bridged methylene (type **R**) complexes is observed, while in the case of α-metallated diazoalkane complexes (type **O**) carbyne complexes are obtained (type **Y**).

For example, the carbene complex $[Cp(CO)_2Mo]_2(\mu\text{-}CPh_2)$ **20** has been synthesised from $[Cp(CO)_2Mo]_2(\mu\text{-}N_2CPh_2)$ **28a**,[65] while the complex $(PEt_3)_2Pd(CCO_2Et)_2$ has been obtained from $(PEt_3)_2Pd[C(N_2)CO_2Et]_2$.[113]

Together with the hydrazone $H_2NN=CPh_2$, the complex $Cp_2(Cl)Zr(\eta^2\text{-}NH-N=CPh_2)$ **33a**[73] gave rise to its disproportionation products—molecular nitrogen, Cp_2ZrCl_2, and the carbene complex $[Cp_2Zr(\mu\text{-}CPh_2)]_2$.

The second type of thermolysis occurs when the initial transition metal complex is insufficiently reactive in relation to the carbene or it does not form a sufficiently strong bond with the lattice. The formation of the corresponding ketazine is then observed. Ketazines are the main products of the thermolysis[104]

and photolysis[131] of the diazoalkanes themselves. In the case of α-metallated diazoalkane type **O** complexes, quantitative evolution of nitrogen is observed and the corresponding acetylenes are formed. Alkenes and alkanes may be obtained as side products in the first reaction and alkenes in the second.

$$L_nM(N_2CR_2) \xrightarrow[-N_2]{\Delta} L_nM{\leftarrow}{:}CR_2 \xrightarrow{L_nM(N_2CR_2)}$$

B, C

$$\longrightarrow L_nM + R_2C{=}N{-}N{=}CR_2$$

$$(+ R_2C{=}CR_2 + R_2HC{-}CHR_2)$$

$$L_nM{-}\underset{\underset{N_2}{\|}}{C}{-}R \xrightarrow[-N_2]{\Delta} L_nM{-}\ddot{C}{-}R \xrightarrow[-N_2]{L_nM[C(N_2)R]}$$

O

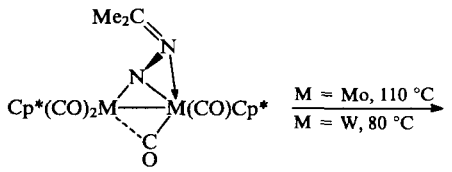
$$\longrightarrow L_nM + R{-}C{\equiv}C{-}R \ (+RHC{=}CHR)$$

For example, diphenylacetylene with an admixture of stilbene has been synthesised from the complex $(PEt_3)_2Pd[C(N_2)Ph]_2$,[113] while thermolysis of $(Bu^tNC)_2Ni(N_2Fld)$ **2** in the presence of phosphine[10] afforded fluorenone azine and $(Bu^tNC)_2Ni(PPh_3)_2$ as the main products. The formation of the products of the coupling of the carbenes to other reactive ligands is possible. For example, thermolysis of the nickel complexes $(Bu^tNC)_2.Ni(N_2CR_2)$ [CR_2 = Fld, CPh_2, $C(CN)_2$] without phosphine afforded a mixture of the corresponding azine and the ketene imine $(R_2C{=}C{=}N{-}Bu^t)$.[9,10] For CR_2 = CPh_2 or $C(CN)_2$, the latter gives rise to the complex $(Bu^tNC)_2Ni(\eta^2\text{-}N,C\text{-}(Bu^t).N{=}C{=}CR_2)$.

Ketazines have been obtained in the reaction of diazoalkane complexes **3**[21,22] and **33**[85] of the oxophilic early transition metals (Nb and Zr) with atmospheric oxygen. Oxidation of the niobium complexes **3** results in the formation also of the free diazoalkanes.

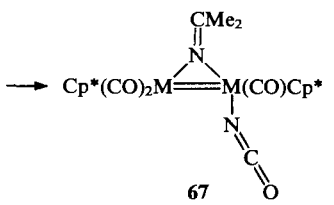
$$Cp_2Zr(Cl)(HNNCPhAr) \xrightarrow{O_2}$$

33



$$\longrightarrow [Cp_2ZrCl]_2O + N_2 + ArPhC{=}N{-}N{=}CPhAr$$

$$Cp_2Nb(H)(N_2CPhAr) \xrightarrow{O_2}$$

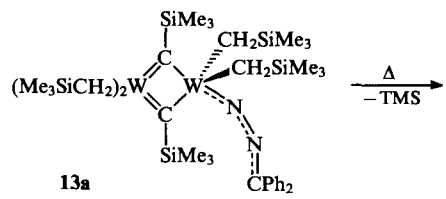


3

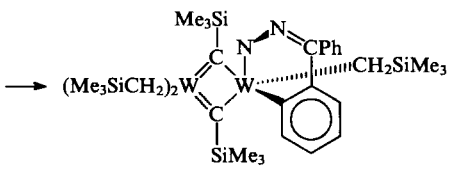
$$\longrightarrow (Cp_2NbO)_n + N_2 + ArPhC{=}N{-}N{=}CPhAr + N_2CPhAr$$

The third type of thermolysis comprises special cases where moderate heating can result in rearrangements or other structural changes in the molecules of the diazoalkane complexes. Thus the N–N bond is ruptured in the bridged diazopropane complexes **23a** of molybdenum[67] and tungsten[81] and in the μ-alkylideneaminometal isocyanate complex **67**.

23a



67



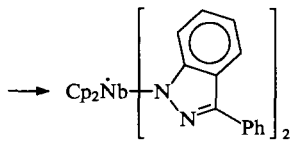
Cp* = C_5Me_5.

The same process has been described also for a tungsten complex of diazocyclopentadiene,[81] but it occurs already at −10 °C. The molybdenum bimetallic complex **67** $Cp^*(CO)_2Mo.(\mu\text{-}\eta^1:\eta^2\text{-}N_2CH_2)(\mu\text{-}CH_2)Mo(CO)_2Cp^*$ of a similar type loses one CO molecule on heating and isomerises to the complex $Cp^*(CO)_2Mo(\mu\text{-}\eta^1:\eta^1\text{-}N{=}CH_2)Mo(\eta^1\text{-}N{=}CH_2)(CO)_2Cp^*$ containing two different alkylideneamino-groups.

In a crystal the M–N–N fragments of the η^1-*N*-diazoalkane ligands (Table 1) are usually almost linear (the M–N–N and N–N–C angles are 153°–177° and 117°–151° respectively). However, reactions have been discovered in which the M–N–N–C fragment is distorted, which promotes the intramolecular interaction of the reactive bonds of the CR_2 group with metallic or other reaction centres in the molecule of the complex. For example, when the diphenyldiazomethane complex of tungsten **13a** is heated, the metal is inserted in a C–H bond of the benzene ring of the diazoalkane.[17] This reaction results in the formation of the product **68** containing a metalpyridazine ring.

13a

68



Whereas the interaction of Cp_2NbH_3 **4a** with $N_2C(Ph).(C_6H_4Br\text{-}o)$ at room temperature results in the formation of the η^1-*N*-diazoalkane complex **3b**, moderate heating of complex **4a** with an excess of the same diazoalkane afforded the bisindazole complex **69**.[22]

$$Cp_2NbH_3 \xrightarrow[25\,^\circ C]{N_2C(Ph)(o\text{-}C_6H_4Br)}$$

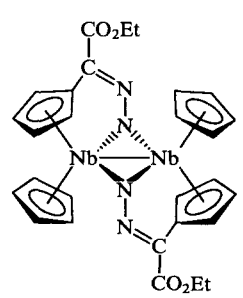
4a

$$\longrightarrow Cp_2Nb(H)NNC(Ph)(o\text{-}C_6H_4Br) \xrightarrow[50-60\,^\circ C]{N_2C(Ph)(o\text{-}C_6H_4Br)}$$

3b

69

In the interaction of compound **4a** with ethyl diazoacetate, the unstable η^1-*N*-diazoalkane complex **3c** is formed initially and is then slowly converted into complex **26** substituted in the Cp ring.[22,73]



Cp_2NbH_3

4a

$\downarrow N_2CHCO_2Et$

$Cp_2Nb(H)NNCHCO_2Et$ →

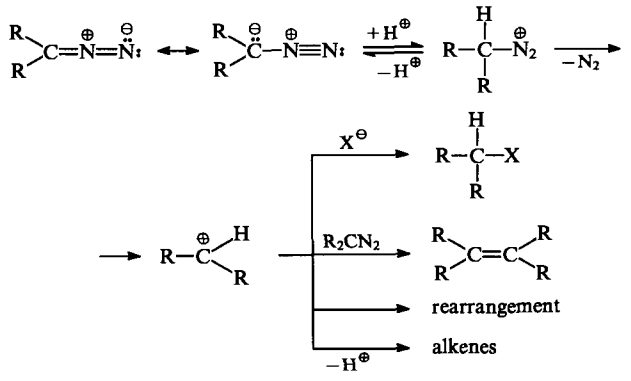
3c

26

Thermolysis of the complex $(PPh_3)_2ClIr[N_2C(COPh)_2]$ afforded[140] the products of the *ortho*-metallation of the benzene ring of both the dibenzoyldiazomethane ligand and the triphenylphosphine ligand.

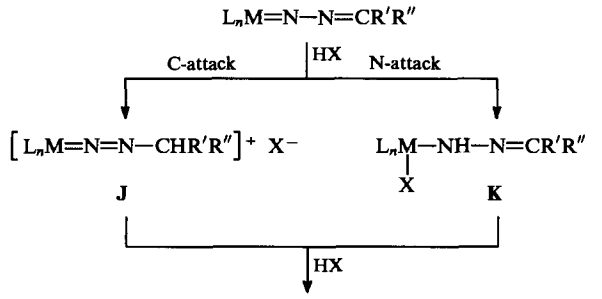
It has been found that, when the iridium complex $(PPr^i_3)_2.ClH_2Ir(N_2CPh_2)$ is heated,[29] a reaction which is the opposite of its formation reaction takes place—diphenyldiazomethane and the coordinatively unsaturated complex $IrH_2Cl(PPr^i_3)_2$ are formed.

When the hydrazonate complex $Os_3(\mu\text{-}H)(CO)_{10}(\mu\text{-}\eta^2\text{-}NH\text{-}N=CMe_2)$ obtained from $Os_3(\mu\text{-}H)_2(CO)_{10}$ and diazopropane is heated, it loses nitrogen and the 'carbene', reforming the cluster $Os_3(\mu\text{-}H)_2(CO)_{10}$.[89]



Photolytic reactions can sometimes lead to products related to the thermolysis product. As already stated above, diazoalkanes themselves usually afford ketazines in both these reactions. Unfortunately, special studies of the effect of UV radiation have been scarcely performed.

So far as we are aware, only one case of photolytic decomposition has been described in the literature, namely that of the diazoalkane complex[30] $(PPr^i_3)_2MeIr(N_2CPh_2)$, the product of which is the complex $(PPr^i_3)_2MeIr(N_2)$ with coordinated molecular nitrogen (structural type **N**).



2. Interaction of diazoalkane complexes with electrophiles

In order to account for the reactions of diazoalkanes coordinated to transition metal atoms with other reagents, it is necessary to analyse the distribution of electron density in this diazo-ligand. Schwartz and coworkers,[17,77,142] claim, on the basis of reactions with the 'metalloazine' complexes of zirconium, that these compounds are exceptionally easily subjected to electrophilic attack on the carbon atom, i.e. a characteristic feature of the diazoalkane fragment in relation to this carbon atom is the repolarisation ('umpolung') of the quasi-carbonyl group of which it is a derivative.

As a consequence of the attack by a proton on the carbon atom of the diazo-group, the diazoalkanes themselves lose nitrogen in the reaction with protic acids[143] and give rise to a carbonium ion, which may be stabilised as a result of reactions with a nucleophile X and a diazoalkane, rearrangement, or deprotonation. Thus the decomposition of diazoalkanes in an acid medium can afford different products depending on the nature of the substituents R in the diazoalkane and the nucleophile present.

The protonation of the coordinated diazoalkanes can be directed both to the carbon atom and to the terminal nitrogen atom, while on treatment with a stoichiometric amount of acid the protonation products obtained initially (products of type **J** and **K**) are usually stable. Only on interaction with an excess of acid does the diazoalkane ligand decompose with formation of organic compounds.

products of the dissociation of the M – N(N – C) bonds

The above hypothesis concerning the direction of electrophilic attack on a carbon atom of the coordinated diazoalkane in the reaction with acids was confirmed directly in only one case—in the reaction of $[Rh_2(\mu\text{-}N_2CHCO_2Et)(CO)_2(dppm)_2]$ with HBF_4,[76] which leads to the formation of the cationic alkyldiazene complex $[Rh_2(\mu\text{-}N_2CH_2CO_2Et)(CO)_2(dppm)_2]BF_4$. The reaction is reversible—the initial diazoacetate complex was obtained on interaction with EtONa.

The interaction with HBF_4 resulted in the conversion of the related diazomalonate complex $[Rh_2(\mu\text{-}N_2C(CO_2Et)_2)(CO)_2.(dppm)_2]$ into $[Rh_2(\mu\text{-}H)(CO)_2(dppm)_2]BF_4$.[76]

In the remaining cases described, the site of attack by the proton is not a carbon atom but the terminal nitrogen atom of the diazo-group. The diazoalkane then undergoes a formal transformation from a hydrazonato(2-)-ligand (type **C**) into a hydroazonato(1-)-ligand (type **K**). Overall, the reaction with one equivalent of hydrogen halide proceeds as addition of HX to the metal–nitrogen bond. For example, the diazoalkanetungsten complex **11c** reacts with one equivalent of HBr via this mechanism.[42]

$$[(PMe_2Ph)_3Br_2W{=}N{-}N{=}CMe_2] \xrightarrow{1\ \text{equiv. HBr}}$$

11c

$$\longrightarrow [(PMe_2Ph)_3Br_3W{-}NH{-}N{=}CMe_2]$$

A mixture of products containing $WBr_4(PMe_2Ph)_2$ (65%), hydrazine, and acetone ketazine (25%–30%) was obtained by reaction with HBr. The cationic complex $[WBr(N_2CH_2).(dppe)_2]^+Br^-$ does not react with HBr at all.[47] The interaction of another tungsten complex **1a** with an excess of HBr afforded[30] the product of the addition of two HBr molecules (compound **70**), which slowly decomposed with formation of a hydrazone.

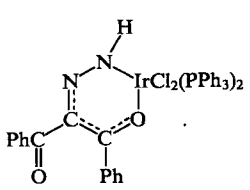
$$(Me_2NCS_2)_2(CO)W(=N{-}N{=}CHAr) \xrightarrow[-CO]{\text{excess of HBr}}$$

1a

$$\longrightarrow (Me_2NCS)_2Br_2W(N_2H_2CHAr) \longrightarrow$$

70

$$\longrightarrow (Me_2NCS)_2WBr_2 + ArCH{=}NNH_2$$



Ar = C_6H_4Me-*p*.

In the interaction of the iridium complex **8b** with HCl, the oxidative addition of hydrogen chloride takes place initially and is followed by a shift of the proton with a rearrangement of the coordination sphere.[26]

$$(PPh_3)_2ClIr[N_2C(COPh)_2] \xrightarrow{HCl}$$

8b

$$\longrightarrow (PPh_3)_2Cl_2HIr[N_2C(COPh)_2] \longrightarrow$$

The complete decomposition of the diazoalkane coordinated to a transition metal atom has been described[13] for diazoalkane complexes **71** of vanadocene.

$$Cp_2V(N_2CR'R'') \xrightarrow[-N_2]{\text{excess of HCl}} Cp_2VCl_2 + R''R'CHCl + R''R'CH{-}CHR'R''$$

71

The interaction of the dinuclear diazoalkane complex **25b** with $Et_3O^+BF_4^-$ (or EtI),[77] which resulted in the formation of a *N*-alkylated hydrazone **72** and a *N*- and *C*-alkylated hydrazone **73** (in approximately equal amounts), is an example of the reactions of diazoalkane complexes with aprotic electrophiles.

$$[Cp_2Zr(\mu\text{-}N_2CHPh)]_2 \xrightarrow[or\ EtI]{Et_3O^+BF_4^-} \underset{\mathbf{72}}{Ph(H)C{=}N{-}N(H)Et} + \underset{\mathbf{73}}{Ph(Et)C{=}N{-}N(H)Et}$$

25b

Free diazoalkanes are known to decompose on treatment with the halogens,[143] producing nitrogen and geminal dihaloalkanes. On the other hand, the interaction of the molybdenum and tungsten complexes $(R_2NCS_2)_2(CO)M(N_2CHAr)$ (**1a**) (Ar = C_6H_4Me-*p*) with an equimolar amount of chlorine or bromine[30] entails the exchange of CO for halogen atoms and the formation of the complex $(R_2NCS_2)_2X_2M(N_2CHAr)$.

Among other electrophiles, carbonyl compounds have been investigated in the reactions with diazoalkane complexes. Their interaction with the free diazoalkanes usually leads to the formation of the product of the insertion of the carbene,[140] obtained from the diazoalkane, in the C–CO bond or the products of the addition of the carbene to the C=O bond. The diazoalkane fragment in the zirconium complex **25b** behaves as both a N- and a C-nucleophile in reactions with various aldehydes and ketones,[17,77,142] which results in the formation of a mixture of the alkene **74** and the ketazine **75** in a nearly equimolar ratio.

$$[Cp_2Zr(\mu\text{-}N_2CHPh)]_2 \xrightarrow{R'(R)C{=}O} \underset{\mathbf{74}}{Ph(H)C{=}C(R)R'} + N_2 + \underset{\mathbf{75}}{Ph(H)C{=}N{-}N{=}C(R)R'} + \text{'}Cp_2ZrO\text{'}$$

25b

It has been observed that the enhanced electron-accepting nature of the carbonyl compounds promotes the formation of alkenes, whilst the use of substituted derivatives (steric factor) promotes the formation of ketazines. If the benzene ring in the diazoalkane fragment in complex **25b** is substituted, the rate of the second-order reaction increases with enhancement of the electron-donating nature of the substituent in the *para*-position in the benzene ring. Two mechanisms have been proposed[17,77,142] for the formation of alkenes and ketazines. They both involve the formation of an intermediate as a result of the coordination of the oxygen atom of the carbonyl compound to the oxophilic zirconium atom and the formation of a bond between the carbonyl carbon atom and the diazoalkane (with either a C- or N-nucleophile). This reaction is an analogue of the Wittig reaction and is synthetically valuable because the diazoalkane complex has also been obtained from a carbonyl compound.

In contrast to the free diazoalkanes, the diazo-ligands are resistant to the action of mild electrophiles such as alkyl halides. For example, the interaction of the niobium complex $Cp_2Nb(H).(N_2CPhAr)$ **3** with various alkyl and aryl halides involves only the substitution of the hydride atom by the halogen, which leads to the formation of the complexes $Cp_2Nb(X)(N_2CPhAr)$ **10** (X = Cl, Br, I).

3. Interaction of diazoalkane complexes with nucleophiles

Although free diazoalkanes are relatively stable in a neutral or alkaline medium, the diazoalkane complexes are appreciably more sensitive to the action of bases and nucleophiles. The attack by the nucleophile in such a reaction is usually directed to a carbon atom of the coordinated diazoalkane and leads to the formation of alkyldiazene complexes (type **J**).[46]

$$L_nM{\equiv}N{=}N{=}CR'R'' + \ddot{X} \longrightarrow \underset{\mathbf{J}}{L_nM{\equiv}N{\equiv}N{-}CXR'R''}$$

Reactions of this type have been observed for 4-electron-donating diazoalkane complexes of tungsten and molybdenum.[2,40,42,46,47,49,144] The polarisation of the carbon atom of the diazoalkane fragment in such a reaction must be the opposite to that observed in reactions with electrophiles. On this basis, one may postulate that either the reactivities of 2- and 4-electron-donating diazoalkane ligands differ very greatly or that the diazoalkane fragment in the diazo-complexes is not markedly polar and is capable of becoming adjusted to the reagent introduced.

The neutral methyldiazene complex **76a**, the ethyldiazene complex **76b**, and the benzyldiazene complex **76c** have been obtained from the cationic diazomethanetungsten complex **12d** by its reaction with the corresponding nucleophiles.[47,49]

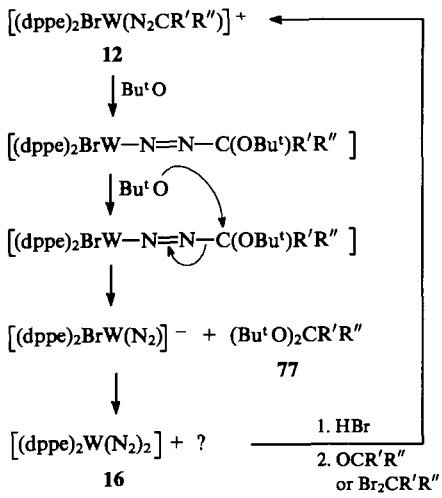
$$\underset{\mathbf{12d}}{[(dppe)_2BrW(N_2CH_2)]^+} \xrightarrow{LiAlH_4} \underset{\mathbf{76a}}{[(dppe)_2BrW(N_2CH_3)]}$$

$$\xrightarrow{MeLi} \underset{\mathbf{76b}}{[(dppe)_2BrW(N_2CH_2CH_3)]}$$

$$\xrightarrow{PhLi} \underset{\mathbf{76c}}{[(dppe)_2BrW(N_2CH_2Ph)]}$$

The analogous diazopropanetungsten complex **12a**[46] and diazobutanoltungsten complex **12b**[49] $[(dppe)_2BrW(N_2CR'R'')]^+$ [R' = R'' = Me; R' = H, R'' = $(CH_2)_3OH$] react with $LiAlH_4$ to form the alkyldiazene complexes $[(dppe)_2BrW(N_2CHR'R'')]$.

On treatment with $LiAlH_4$, the neutral diazoalkane complexes $[(PMe_2Ph)_3Br_2W(N_2CR'R'')]$ **11c,d** [R' = R'' = Me; R'–R'' = $(CH_2)_5$] decompose quantitatively to the corresponding amine R'R''CHNH$_2$ and ammonia.[42]



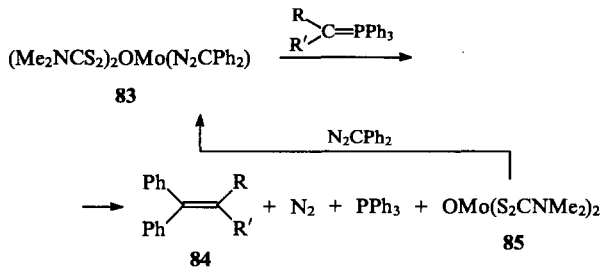
The interaction of the dinuclear rhodium complex $[Rh_2.(\mu\text{-}N_2CHCO_2Et)(CO)_2(dppm)_2]$ with $NaBH_4$ involves the substitution of the bridging dialkyl ligand by hydride atoms with formation of $[Rh_2(\mu\text{-}H)_2(CO)_2(dppm)_2]$.[76]

The attack by the nucleophile can be directed also to other highly reactive bonds of the diazoalkane complex. Thus the reaction of $Cp_2Nb(Br)(N_2CPh_2)$ **10c** with MeLi leads to the formation of the complex $Cp_2Nb(Me)(N_2CPh_2)$, while the reaction of $Cp_2Nb(H)(N_2CPh_2)$ **3a** with BuLi affords the salt $[Cp_2Nb(N_2CPh_2)]^-Li^+$.[39]

The reactions of diazoalkane complexes with oxygen-containing nucleophiles usually proceed with dissociation of metal–nitrogen or nitrogen–carbon bonds. Thus the interaction of complexes of the type $(RO)_2W(N_2CR'R'')$ with alcohols[40] led to the formation of the corresponding hydrazones $H_2NN{=}CR'R''$. On hydrolysis in air,[30] the diazoalkane complexes of molybdenum and tungsten $(Me_2NCS_2)_2(CO)M.(N_2CHC_6H_4Me\text{-}p)$ **1a** decompose, forming the hydrazone

($H_2NN=CHC_6H_4Me$-*p*), CO, and $(Me_2NCS_2)_2MO$. The complexes $Cp_2Nb(H)(N_2CPhAr)$ **3** [39] and $Cp_2Zr(Cl)(N_2CPhAr)$ **33** [85] also hydrolyse readily to the corresponding hydrazone and oxo-complex (especially in an alkaline medium).

The interaction of the cationic tungsten complexes **12** with an excess of Bu^tOK leads to the formation [46] of the initial nitrogen complex **16** (from which complex **15** was obtained) and the geminal diether **77**. It is of interest that the analogous reaction proceeds differently with MeONa.



R′, R″ = H, Me.

The interaction of cationic diazoalkane complexes of molybdenum and tungsten **12** with strong bases [145] entails the deprotonation of the diazoalkane ligand, leading to the alkenyldiazenide complexes **78**. Certain reactions of the alkenyldiazenide complexes, resulting in the formation of the coupling product **79** and the alkylation product **80** and in the nucleophilic addition of the α-carbon atom of the diazo-group and of H^+ to the C=N bond (compound **81**) and the C=O bond (compound **82**) (Scheme 3), have been investigated.

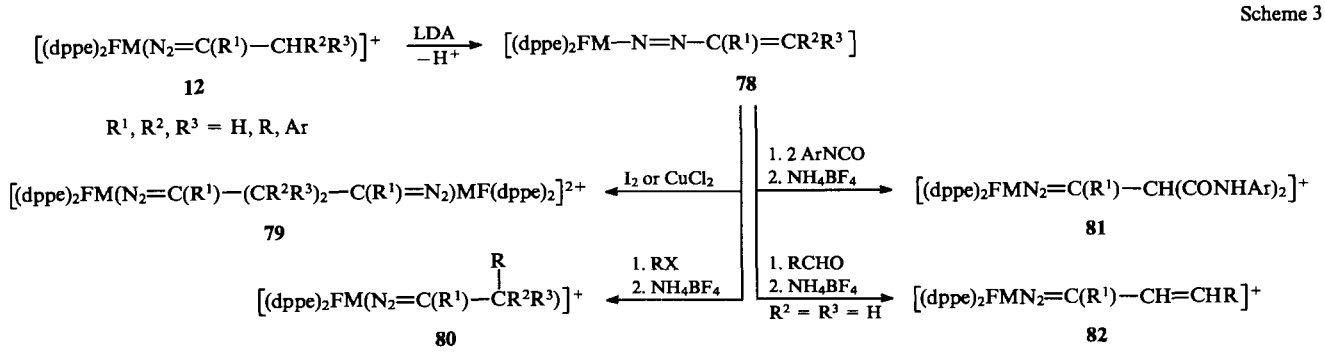
Schwartz and coworkers [15,17] have described another reaction of the diazoalkane complexes that is analogous to the Wittig reaction. The diazoalkanes coordinated to a molybdenum atom behave in this process as C-electrophiles, which is the opposite of the behaviour found for the diazoalkanezirconium complexes.

The interaction of the diazoalkane complex **83** with various alkylidenephosphines afforded the corresponding alkenes **84**. Nitrogen and the free phosphine are then evolved and the molybdenum complex **85** is formed. The initial diazoalkane complex **83** can be synthesised from it.

The olefins obtained are identical with those formed in the reaction of benzophenone with alkylidenephosphines. In the case of the analogous complex of phenylmethyldiazomethane with asymmetrically substituted alkylidenephosphines, the (*Z*)- and (*E*)-alkenes are formed in approximately the same proportions as in the classical Wittig reaction [the (*Z*)-isomer predominates]. However, in contrast to the classical Wittig reaction, the authors suggest that this reaction be regarded as an oxidation-reduction process.

The reactions of diazoalkane complexes with alkenes are in principle similar to the reactions of the carbenes (obtained from the diazoalkanes) with alkenes (Section III.2.b). The difference consists solely in the thermal stability of the diazoalkane complexes. On heating, diazoalkane complexes usually lose nitrogen and the carbene (the electrophile) formed thereby adds to the C=C double bond; the main reaction product is then a substituted cyclopropane. For example, the diazofluorene complexes $(Bu^tNC)_2M(N_2Fld)$ **5** (M = Ni, Pd) react in this way. The reactions of these complexes with dialkyl maleate afforded a mixture of the *cis*- and *trans*-isomers of the cyclopropane derivative produced thereby.[14]

Another type of reaction involves the interaction of the diphenyldiazomethane complexes of iridium and rhodium **8**, in which the diazoalkane ligand is displaced.[29,37]



M = Ir; X = Me.
M = Ph; X = Cl.

The replacement of the diazoalkane ligand by another one has been described also in the reaction of $[Rh_2(\mu\text{-}N_2CRCO_2Et).(CO)_2(dppm)_2]$ (R = H, CO_2Et) with CO.[76]

Numerous exchange reactions of other ligands (not diazoalkanes) in the diazoalkane complexes of transition metals have also been described in the literature. However, the description of these reactions is outside the scope of the present review.

Scheme 3

V. Conclusion

The review presents and surveys the results of studies of the interaction of diazoalkanes with transition metal complexes and the reactions of the diazoalkane complexes obtained.

The results of these reactions are varied — both as regards the class of ligands formed from the diazoalkanes and as regards the type of coordination of the latter. The structure of the product depends both on the nature of the transition metal and its valence state and on the nature of the diazoalkane itself.

The interaction of a diazoalkane with a transition metal complex is usually accompanied either by the addition or insertion of the diazoalkane itself or of the carbene formed from it.

Apart from the principal structural parameters of the MN_2C fragment, the diazo-complexes have been characterised by their chemical behaviour — thermal reactions and interaction with various reagents. The principal differences between the structures and properties of the diazo-ligands and the free diazoalkanes have been elucidated.

However, it is essential to note that, as a consequence of the complexity and great variety of the reactions of diazoalkanes with transition metal complexes and the reactions of the products obtained, the studies in this field have been unsystematic and the results presented are not always sufficiently reliable.

The above reactions can serve as convenient methods of synthesis of valuable classes of complexes, in the first place hydrazonate, alkyldiazene, carbene, and alkyl complexes.

III. Experimental study of the interaction between adsorption layers of polymers	235
IV. Conclusions	240

Abstract. Modern theories of the steric stabilisation of dispersions containing polymers and experimental results of studies of the interaction between adsorption layers of polymers in microscopic liquid films are critically reviewed. The bibliography includes 109 references.

I. Introduction

Polymeric adsorption layers (AL) formed on the surface of particles of a dispersed phase in disperse systems containing polymers control the stability and the structural and mechanical properties of these systems.

Adsorption layers have thicknesses of the order of the size of the macromolecules in the bulk of the solution (a few nanometres). They hinder the approach to the surfaces of particles, and they limit it to the distances at which the forces of intermolecular attraction (van der Waals) lead to an irreversible thinning of the microscopic liquid films (MLF) formed in the contact region between the particles, i.e. to the coagulation or coalescence of the particles.

Thus, since the energy of molecular interaction of the interfaces in disperse systems containing a polymer becomes negligibly small owing to the relatively large thickness of the MLF, and furthermore since the ionic–electrostatic interaction between the electric double layers vanishes at high enough electrolyte concentrations in the system, the main contribution to the energetics of the contact interactions in these systems is provided by the interaction between the AL of macromolecules and by the energy properties of these AL.

The interaction between polymeric AL takes place when the segments of macromolecules are in direct ('steric') contact, and is determined by short-range forces such as hydrogen bonds, hydrophobic interaction, and Born repulsion, and also by the Coulomb interaction between the ionised functional groups in the case of polyelectrolytes and (to a smaller extent) by the molecular forces between the macromolecules themselves in the adsorption layers.

If the energy of the steric interaction between two AL in a liquid film is small (for example, a few kT, where k is Boltzmann's constant and T is the absolute temperature) the disperse system becomes stable by aggregation. In this case the stabilisation of the disperse system is said to be steric.[1,2] Detailed reviews of the theory and of the experimental foundations of the steric stabilisation in these systems have been published.[3–7]

The aim of the present review is to analyse theoretical and experimental studies of the interaction between adsorption layers of macromolecules in microscopic liquid films whilst allowing for nonequilibrium effects in the thermodynamic description of the steric stabilisation of dispersions.

II. Theories of the steric stabilisation of liquid films

Some procedural difficulties are met in the thermodynamic description of the steric interaction between adsorption layers of macromolecules in microscopic liquid films.

One of the problems is the lack of an unambiguous definition of the specific interfacial free energy (interfacial tension) of the phase boundary in the presence of a polymeric adsorption layer whose thickness usually exceeds the radius of action of the molecular forces. In the modern theories of the adsorption of polymers and of interacting adsorption layers of polymers in liquid films[11–23] the interfacial tension σ is expressed as the sum of two components,

$$\sigma = \sigma_s(\varphi_s) + I(\varphi_s, \varphi_b), \quad (1)$$

where φ_b and φ_s are the densities of the polymer in the bulk of the solution and at the contact with the interfacial surface respectively.

The $\sigma_s(\varphi_s)$ component allows for the interfacial tension at distances of the order of the molecular size, and is often expressed as[18,24]

$$\sigma_s(\varphi_s) = \sigma_{s0} + \sigma_1\varphi_s + \sigma_2\varphi_s^2 + \ldots, \quad (2)$$

where σ_1 and σ_2 are the virial coefficients of the expansion, which allow for the interaction between the monomers and the surface, and also between the segments of the macromolecules in the adsorption layer closest to the surface.

The component $I(\varphi_s, \varphi_b)$ describes the contribution to the surface tension of effects associated with a change in the density profile $\varphi(z)$ of the segments close to the interfacial surface. Thus, in order to describe the thermodynamic properties of interfaces (and, even more, their interactions in liquid films) we require information on the density profile of the segments $[\varphi(z)]$ in the adsorption layer, which is a new element, not previously

considered in the thermodynamics of interfaces and films stabilised by low-molecular surface-active substances (SAS).[25,26]

Hence we should expect the properties of interfaces in liquid films stabilised by polymers to depend on factors such as the molecular mass, the degree of ionisation of the macroions, the hydrophilic–lipophilic balance (HLB) of the molecules, the rigidity of the macromolecular network, and also on the physicochemical factors (pH and ionic strength of the solution, bulk concentration of the polymers, temperature, nature of the solvent, etc.) which affect both the energy of the intermolecular interactions and the conformation of the macromolecules in the adsorption layer.

We should note that tensometry (the main experimental method of determining the energy properties of interfaces stabilised by low-molecular SAS) can no longer characterise unambiguously the energy properties of interfaces when these are stabilised by polymeric AL. Indeed, the measured values of the interfacial tension do not allow for or include the interaction between the segments of the macromolecules in the AL separated from the physical interface by a distance greater than the action radius of the molecular forces. This problem is not found in the measurements of interfacial tension of surfaces stabilised by low-molecular SAS, because the molecules of these SAS are localised within the force field of the interface.

Another problem in the thermodynamic description of liquid films stabilised by polymeric adsorbed layers arises from the indefiniteness of the concept of thermodynamic equilibrium in a system of interacting adsorption layers of macromolecules when interfacial surfaces are brought closer together in a solution of the polymer.

Whereas in the adsorption of low-molecular SAS the equilibrium between the bulk concentration and the concentration in the film is established rapidly, at the contact of adsorption layers of high-molecular SAS the 'true' equilibrium may never be reached (at least, under the conditions of the experiment). de Gennes[19] understood the problem, and suggested that the steric interaction should be calculated for two extreme cases: (1) ideal equilibrium, corresponding to the possibility of reversible adsorption of the macromolecules during the interaction of polymeric adsorption layers, and (2) a limited equilibrium, corresponding to a condition of constant adsorption, reached when the two AL are placed in contact and unchanged thereafter.

However, as will be shown below, the conclusions of the theory of the aggregation stability of a disperse system are strongly influenced by the subjective choice of a hypothesis concerning the type of equilibrium. As was pointed out by de Gennes,[19] with a thermodynamically good solvent, and assuming ideal equilbrium, we must conclude that an attraction exists between polymeric AL, whereas under conditions of limited equilibrium, mutual repulsion between the layers becomes possible. Thus we are faced with the problem of defining and assigning the type of equilibrium in the interaction of AL of macromolecules.

This problem is closely associated with that of determining the extent of the mutual penetration of the AL, when the film thickness is increased, in order to calculate the relative contribution of the entropic and the osmotic effect to the total free energy of interaction of the polymeric AL. This problem could not be solved by using the 'early' theories of the interaction of adsorption layers of macromolecules, such as the Hesselink–Vrij–Overbeek (HVO) theory,[27] because the solution requires a knowledge of the exact form of the density distribution function of the segments of the macromolecule with respect to the distance to the interfacial surface.

At present the most widely used approaches to the construction of a thermodynamic theory of adsorption and of the interaction between adsorption layers of polymers are those developed by Scheutjens and Fleer,[11–17] de Gennes,[18,19] and Klein and coworkers.[20–23]

1. The Scheutjens–Fleer theory

The statistical theory of the adsorption of polymer proposed by Scheutjens and Fleer allows for the effect on the structure of the polymeric AL of interactions between the segments of polymeric molecules and also for those of the interactions between the macromolecules, the solvent molecules, and the interfacial surface. The physical basis of this theory is the postulate that under equilibrium conditions (assuming that the adsorption of polymers is reversible under equilibrium conditions) [17] the conformation of the adsorbed macromolecule is unambiguously determined by the energy of the interaction between the segments of the macromolecules χ and between a macromolecule and the surface χ_s, and also by the length (degree of polymerisation) of the molecule N.

The special feature of this approach is that its authors exploit the concept of the conformational probability of the macromolecule p_c, which is determined in the framework of the quasi-crystalline lattice model by the distribution of segments over the layers of the lattice, by the orientation in space of the bonds between the segments, and by the parameters χ and χ_s (Fig. 1).

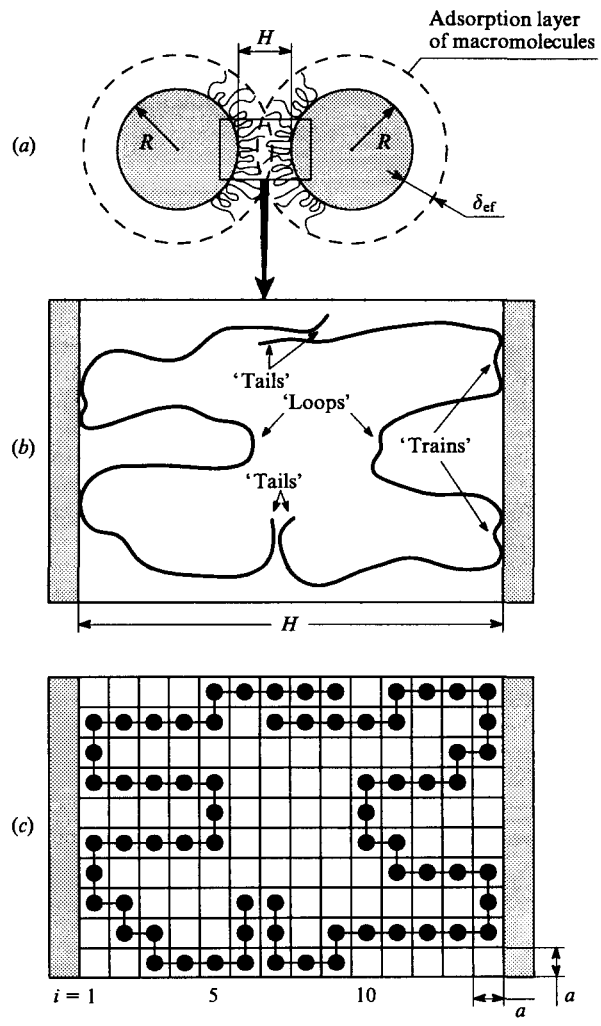

Figure 1. Calculation of the energy of the interaction between adsorption layers of macromolecules in a liquid film. (*a*) Contact of two particles of the disperse phase, of radius R, coated with adsorption layers of the polymer having an effective thickness δ_{ef}; direct steric contact between the two AL takes place in the gap thickness H within the liquid microscopic film; (*b*) the conformation of the interacting adsorbed macromolecules is characterised by 'tails', 'loops', and 'trains'; (*c*) schematic representation of interacting macromolecular chains between two planes in the lattice model used by Scheutjens and Fleer.[13,14]

Assuming that all the states of a segment in a layer of the lattice parallel to the surface are energetically equivalent the authors determined the density profile $\varphi_i = \varphi(z)$ of the segments of the AL in the ith layer of the lattice ($i \approx z/a$, where a is the lattice constant) as the mean probability (weighted over all the conformational states of the macromolecule) of finding the segment in the ith layer of the lattice, i.e.

$$\varphi_i = \varphi_b \sum_c r_{i,c} p_c , \tag{3}$$

where φ_b is the density of the segments in the bulk of the solution and $r_{i,c}$ is the number of segments in the ith layer of the lattice for the given conformation c. The conformational probability p_c of the macromolecule, characterised by the number of segments r_i in the ith lattice layer ($\Sigma r_i = r$), is expressed as

$$p_c = \lambda_0^q \lambda_1^{r-1-q} \sum_{i=1} p_i^{r_i} , \tag{4}$$

where λ_0 is the relative coordination number of the cell in a layer parallel to the surface ($\lambda_0 = 2/3$ for a cubic lattice), λ_1 is the relative coordination number of the cell in contact with the neighbouring layers ($\lambda_1 = 1/6$ for a cubic lattice), q and $(r - 1 - q)$ are the numbers of steps parallel and perpendicular to the surface, and p_i is a weighting factor determined by the configurational entropy and by the parameters χ and χ_s (expressed in units of kT), so that

$$p_i = \frac{\varphi_i^0}{\varphi_b^0} \left\{ \exp\left[-2\chi \left(\langle \varphi_i^0 \rangle - \langle \varphi_b^0 \rangle \right) \right] \right\} \exp(\chi_s - \lambda_1 \chi) \delta_{i,1} , \tag{5}$$

where

$$\langle \varphi_i^0 \rangle = \lambda_i \varphi_{i-1}^0 + \lambda_0 \varphi_i^0 + \lambda_1 \varphi_{i+1}^0 , \tag{6}$$

φ_i^0 is the density of solvent molecules in the ith layer, φ_b^0 is the same density in the equilibrium solution, and $\delta_{i,1}$ is the Kronecker delta function ($\delta_{i,1} = 1$, if $i = 1$; $\delta_{i,1} = 0$, if $i \neq 1$).

A matrix formalism was developed[28] to solve the system of equations (3) and (4): it was based on a calculation of the density profile $\varphi(z)$ of the segments in the vicinity of the surface for noninteracting segments, i.e. when $p_i = 1$ for $i > 1$ and $p_1 = \exp \chi$. In Scheutjens and Fleer's modified matrix formalism[13,14] allowance is made for the effect of interactions between the polymer and the solvent by including in p_i the parameter χ [see Eqn (5)], thus allowing the density profile $\varphi(z)$ of the segments to be calculated as a function of the thermodynamic quality of the solvent.

The new theory offers an additional advantage: it allows the individual contributions to the overall density of the layers of polymer near the interface from its various components to be calculated, i.e. it expresses the density of segments in the form

$$\varphi(z) = \varphi_f + \varphi_t + \varphi_l + \varphi_{tr} ,$$

where φ_f, φ_t, φ_l, and φ_{tr} are the densities of free (nonadsorbed) macromolecules, and the densities of 'tails', 'loops', and 'trains' respectively. This is achieved by introducing a formal calculation procedure which involves using a new method of calculating the probability p_c in Eqn (3):[29-31]

$$\sum_c r_{i,c} p_c = \frac{1}{r p_i} \sum_{s=1}^{r} p(i,s)\, p(i, r - s + 1) , \tag{7}$$

where p_i is given by Eqn (5); $p(i,s)$ and $p(i, r-s+1)$ are the probabilities of finding the sth segment in the ith layer, and the first and subsequent segments of the macrochain occupy all the positions allowed for the given conformation of the macromolecule. Then all the conformations for which neither both chain ends nor one of the intermediate segments are found (even once) in the first layer will correspond to a 'free' (not adsorbed) macromolecule. The corresponding contribution φ_f to the density of the segments can be allowed for by using Eqn (3). The contribution from 'tails' and 'loops' is determined by allowing for the conformations having only one or two contacts with the surface respectively.

The authors carried out numerical calculations of the density profile $\varphi(z)$ and of its components for different values of r (up to 10^4), for several values of the parameter χ (0 for an athermal solvent, 0.5 for a θ-solvent, and 0.7 for a poor solvent), and also for different values of the bulk density of the segments in solution φ_b (Fig. 2). The authors also considered the case of adsorbed ($\chi_s = 1$) and nonadsorbed ($\chi_s = 0$) polymers.

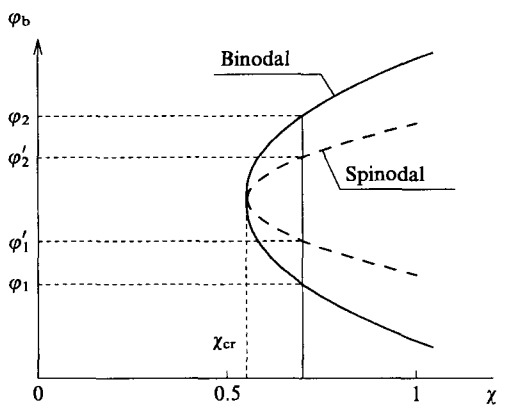

Figure 2. Phase diagram $\varphi_b(\chi)$ for the polymer solution.

For an adsorbable polymer at low coverages φ_s of the surface by adsorbate in a good solvent the proposed theory predicts a 'prone' conformation of the macromolecules on the surfaces, and a density profile $\varphi(z)$ decreasing exponentially with increasing distance from the surface, as expected from the early theories of adsorption known as the 'isolated chain' theories.[32-37] For finite values of φ_b (even quite small, of the order of 10^{-6}) the density profile $\varphi(z)$ takes a specific form, characterised by the presence of a fairly extensive region where the density φ_b is low (Fig. 3). In the layer nearest to the surface the density profile $\varphi(z)$ is determined mainly by the energy of

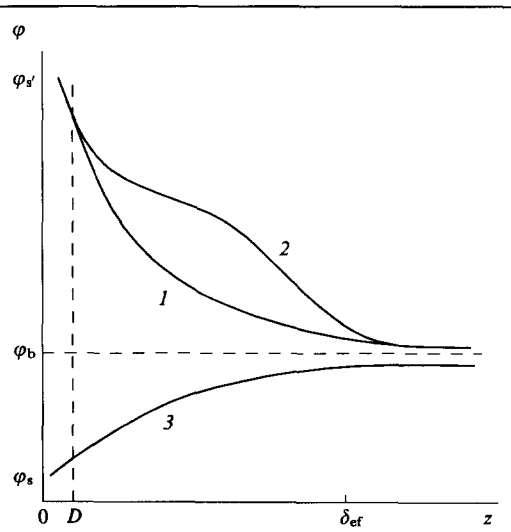

Figure 3. Density profiles of the polymer segments $\varphi(z)$ as a function of the distance to the interfacial surface in a thermodynamically good (*1*, *3*) or bad solvent (*2*) for adsorbed (*1*, *2*) and for nonadsorbed polymers (*3*).

adhesion χ_s, and as the chain length r of the macromolecule is increased the dependence on φ_b is effectively suppressed and replaced by an exponential decrease with increasing distance from the surface. In the more remote layers the density profile is determined essentially by the 'tails'. This is a new element, not considered in the 'isolated chain' theories. It was shown that the root-mean-square thickness δ_{ef} of the adsorption layer in a good solvent is proportional to $M^{0.5}$ (where M is the molecular mass of the polymer). At high adsorptions of the polymer the thickness δ_{ef} becomes comparable with the size of the macromolecular cluster in the bulk of the solution.

A calculation of the density profile of the segments for a thermodynamically poor solvent[16] is of special relevance to the attempt to reconcile the Scheutjens–Fleer theory with other theories (in particular, that of de Gennes[18]). The authors considered the cases of $\chi = 0.7$ ($r = 100$) and $\chi = 0.56$ ($r = 1000$) for $\varphi_b = 10^{-6}$. The problem was that in the transition region of the AL (i.e. in the region between the first layer, with a relatively high density, and the solution, with a relatively low density) the density corresponds to the liquid–liquid phase separation region in the Flory–Huggins diagram (see Fig. 2), i.e. $\varphi_1 < \varphi < \varphi_2$, if the parameter χ exceeds the critical χ_{cr}. For example, for the case of $\chi = 0.7$ ($\varphi_b = 10^{-4}$ and $r = 100$) the binodal concentrations are $\varphi_1 = 1.5 \times 10^{-4}$ and $\varphi_2 = 0.37$; under these conditions the spinodal concentrations are $\varphi_1' = 2.7 \times 10^{-2}$ and $\varphi_2' = 0.27$ respectively, and $\chi_{cr} = 0.605$, i.e. in the transition region of the adsorption layer the condition mentioned above ($\varphi_1 < \varphi < \varphi_2$) is realised. The authors did not observe any anomalous deviations of the density profile $\varphi(z)$ from the corresponding density profile for a thermodynamically good solvent [but we note that for the latter type of solvent the de Gennes theory predicts[20–22] the formation of a plateau in the $\varphi(z)$ profile].

In the case of a nonadsorbable polymer Scheutjens and Fleer[14] determined the density profile $\varphi(z)$ and used it to calculate the energy of the interaction between the surfaces (see Fig. 3).

The interaction energy Δg (referred to one cell of area a^2) is defined as follows in the lattice models for an 'ideal'[19] (or 'full'[13]) equilibrium:

$$\Delta g = kT\left[\left(1-\frac{1}{r}\right)\Gamma + \sum_i \ln\frac{\varphi_i^0}{\varphi_b^0} + \chi\sum_i(\varphi\langle\varphi_i\rangle - \varphi_b^2)\right], \quad (8)$$

where

$$\Gamma = \sum_i(\varphi_i - \varphi_b)$$

is the adsorption of the polymer.

In the case of a 'limited' equilibrium the expression for Δg becomes[13,19]

$$\Delta g = kT\left(\frac{\Gamma_t}{r}\ln\frac{\Gamma_t}{\sum p_c} + \sum_i \ln\varphi_i^0 + \chi\sum_i \varphi_i\langle\varphi_i\rangle\right), \quad (9)$$

where $\Gamma_t = \Sigma\,\varphi_i$.

In the present quasicrystalline lattice model the term containing the parameter χ in the expressions (8) and (9) allows for the interaction between the ith segment and its nearest neighbours. An exact determination of the density profile of the polymer and of the solvent, involving the solution of Eqns (3)–(7), allows for the entropy factor associated with the volume limitation effects.

Most of the calculations were carried out for thermodynamically 'good' solvents under conditions of 'limited' equilibrium, i.e. on the assumption that in the case of adsorbable polymers the macromolecules are not desorbed when the two surfaces come close together. In this case the energy of adsorption associated with one segment is fairly large (1 kT, which corresponds to $\chi_s = 1$). The above results lead to the following conclusions.

In an 'ideal' equilibrium we find attraction between the adsorbed layers for both good and poor solvents, and at all coverages of the surface by polymeric molecules. The authors assume[14,16] that this case is a bad representation of the real state of affairs, and they confine all further discussions to the case of a 'limited' equilibrium.

In a limited equilibrium in poor solvents the close approach of the AL produces attraction, which is replaced by repulsion as the film is additionally thinned. In good solvents attraction occurs at low coverages, but at high coverages only repulsion can be observed. It is pointed out that in the case of a good solvent the attraction is created by 'bridge formation', in which the macromolecule is adsorbed at its end segments on the surfaces of different particles. In a poor solvent a negative osmotic pressure is induced in addition to bridge formation, and leads to attraction between the particles (whereas positive osmotic pressure causes repulsion of the particles stabilised by polymeric adsorption layers).

In the theory of Scheutjens and Fleer great importance is attached to the formation of long 'tails' on the outer side of the adsorption layer at high coverages of the surface by adsorbed molecules. This feature distinguishes the theory from the early theories of steric stabilisation. In spite of the depletion of the outer part of the AL the concentration of the 'tails' is sufficient to produce repulsion when the interfacial layers in the film are brought closer together. The frequently observed film thicknesses substantially greater than double the diameter of the average cluster of macromolecules in solution are attributed to this effect.

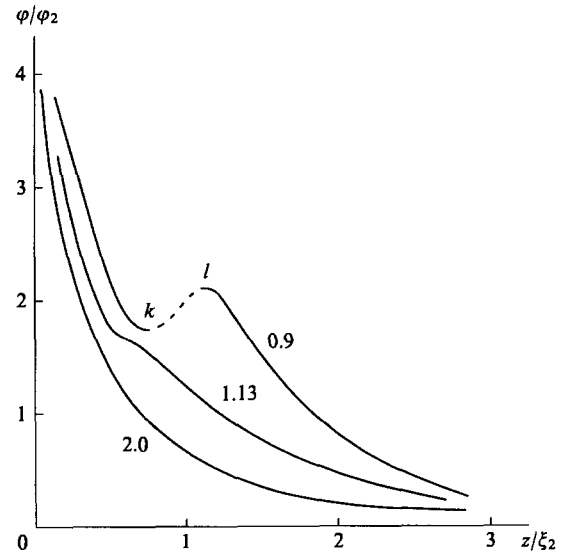

Figure 4. Density profiles of adsorbed layers of polymer in a thermodynamically poor solvent calculated by Eqn (19) for several fixed values of the parameter β^2.

As was pointed out above, in the case of nonadsorbable polymers the local concentration $\varphi(z)$ of segments close to the surface is much lower than the bulk concentration φ_b (Fig. 4). In dilute solutions this 'depletion zone' leads to the development of attraction between the surfaces. However, with a large bulk concentration of the polymer in solution the dislodgment of the macromolecules from the gap between the plates can be hindered, because when the plates are brought closer together the dislodgment should be accompanied by an increase in the free energy of the system (since the macromolecule is being transferred from a region of low bulk concentration of polymer

to a region of high concentration). This produces a coagulation barrier at distances of the order of the size of the macromolecule in solution, similar in shape to the coagulation barrier produced by the electrostatic interaction between electric double layers in the Deryagin–Landau–Overbeek theory. However, in this case the development of a barrier is associated with a decrease in the entropy of the system upon the mutual approach of the surfaces, i.e. the coagulation barrier has an entropic nature.

2. The de Gennes theory

In the theory of the adsorption of polymers proposed[18] by de Gennes the density profile $\varphi(z)$ of segments in the AL is described in terms of the average field approximation in conjunction with the ideas on the theory of polymer solutions developed by Flory and Huggins.[38] For a monodispersed polymer solution having a degree of polymerisation N, described by the Flory–Huggins model with a constant a and a coordination number λ, the free energy of the solution F_0 referred to the volume of one cell of the lattice model can be written as

$$F_0 = kT\left[\frac{\varphi}{N}\ln\varphi - \frac{1}{2}\upsilon\varphi^2 + \frac{1}{6}w\varphi^3 + \ldots\right], \tag{10}$$

where υ and w are the second and the third virial coefficient of the expansion respectively, the first term of the expansion corresponding to the usual Flory–Huggins combinatorial entropy, whereas the second and the third term characterise the interaction between the monomers in solution. The free energy of the system is expressed[39] as

$$F = F_0 + \frac{kT}{24\varphi(z)}\left[a\nabla\varphi(z)\right]^2. \tag{11}$$

The specific interfacial free energy σ is written[18]

$$\sigma = \sigma_s(\varphi_s) + \int_0^\infty \left(\frac{F}{a^3} - \mu_0\varphi + \pi_0\right)dz, \tag{12}$$

where $\sigma_s(\varphi_s)$ is the specific energy of the contact (the energy of adhesion of the first layer of the lattice to the interface), and μ_0 and π_0 are the standard values of the chemical potential and of the osmotic pressure respectively. The integrand expression is the excess of the free energy [referred to unit volume of a solution of density $\varphi(z)$] over a solution having the parameters μ_0 and π_0.

According to Cahn[24] the expression $\sigma_s(\varphi_s)$ in a dilute solution at low coverage of the interfacial surface can be written in the form of Eqn (2) with $\sigma_2 \approx 0$ (since $\varphi_s \ll 1$). Furthermore a weak link between the monomer and the surface is postulated, i.e. it is assumed that $\sigma_1 < kT/a^2$. According to de Gennes[18] this postulate is not inconsistent with the condition of positive adsorption if allowance is made for the multitude of contacts between the polymer and the surface. Thus, in spite of the smallness of the ratio $|\sigma_1|a^2/kT$ in the expression

$$p = A\exp\left[-\theta N\frac{|\sigma_1|a^2}{kT}\right] \tag{13}$$

for the distribution coefficient of the macromolecule units, the large value of N in Eqn (13) ensures a substantial adsorption. (θ is the coverage and A is the preexponential factor introduced by allowing for the increase in entropy produced by the desorption of the macromolecules).

These relationships can be analysed further by determining the density profile of the segments $\varphi(z)$ in the AL [by minimising the interfacial energy σ given by Eqn (12)].[18] The main postulate of the theory is the assumption that the profile $\varphi(z)$ is fully determined by the term $(d\varphi/dz)^2$ in the expression (11). By combining the equality $\varphi(z) = \psi^2(z)$ with expressions (2) and (11), Eqn (12) can be rewritten

$$\sigma - \sigma_{s0} = \sigma_1|\psi_s|^2 + \int_0^\infty \left[\frac{1}{2}L\left(\frac{\psi}{z}\right)^2 + G(\psi^2)\right]dz, \tag{14}$$

where ψ_s is the density of segments in contact with the surface, $L = kT/3a$, $G(\psi^2)$ is a function of the parameter ψ^2, and $\psi_s = \varphi_s^{0.5}$.

Cahn[24] published a detailed analysis of the problem of minimising the functional (14). He showed that the function of state ψ obeys a linear second-order differential equation whose first integral is

$$\frac{1}{2}L\left(\frac{d\psi}{dz}\right)^2 = G(|\psi|^2) - G(|\psi_b|^2), \tag{15}$$

where $\psi_b = \varphi_b^{0.5}$ corresponds to the density of segments in the solution.

The boundary condition on the surface is found by minimising the functional (14), with $\psi = \psi_s$ for $z \to 0$ (see Cahn[24]):

$$2\sigma_s|\psi_s| - L\frac{d\psi}{dz}\bigg|_0 = 0. \tag{16}$$

Expressing (16) as

$$\frac{1}{\psi}\frac{d\psi}{dz}\bigg|_0 = 2\frac{\sigma_1}{L} = \frac{1}{D},$$

we obtain (allowing for $L = kT/3a$)

$$D = \frac{kT}{6a\sigma_1}. \tag{17}$$

Here D is the characteristic thickness of the AL near the surface, where the interaction between the monomer and the wall is substantial.

According to de Gennes's theory of adsorption[18] the structure of the adsorption layer is defined by three regions (see Fig. 3): (1) a near region of thickness D [see Eqn (17)] inversely proportional to the energy of the monomer–surface interaction σ_1; (2) an intermediate region $D < z < \zeta_b$, where the upper limit is the correlation length for the polymer solution; (3) a far region $z > \zeta_b$, in which the density of segments $\varphi(z)$ tends exponentially towards φ_b.

It has been shown[39] that $\zeta_b = a\varphi^{-3/4}$, $\mu_b \sim kT\varphi^{5/4}$, and $\pi_b \sim kTa^{-3}\varphi^{3/4}$. Furthermore, for good solvents in the intermediate region we can write[18]

$$\varphi(z) = \left(\frac{a}{z}\right)^{4/3}.$$

Since the main contribution to $\varphi(z)$ is provided by the 'loops' the effective thickness δ_{ef} of the adsorption layer can be significantly greater than D, and it can approach the thermodynamic radius R_F of the statistical macromolecular cluster. This latter feature is of special interest because it can be checked experimentally. Equally interesting is the expression obtained[18] for the adsorption of the polymer:

$$\Gamma \sim a^{-2}\left(\frac{a}{D}\right)^{1/3},$$

according to which Γ is independent of the degree of polymerisation, i.e. of the molecular mass of the polymer.

The concepts of the de Gennes theory, which had been developed for a good solvent, were extended to thermodynamically poor solvents by Klein et al.[20,22] On the assumption of monomolecular adsorption they determined the profile $\varphi(z)$ of

the adsorption layer of macromolecules by minimising the functional (14) while allowing for the negative sign of the second virial coefficient in Eqn (10).

These authors postulated a small ($\sigma_1 a^2/kT \ll 1$) and irreversible adsorption [$N \gg 1$, see Eqn (13)]. As a result of the adsorption the local concentration of the polymer in the AL exceeds its bulk value in the solution, and it can also exceed the value φ_1 corresponding to the metastable concentration of the polymer on the Flory–Huggins phase diagram (see Fig. 2), and therefore the profile $\varphi(z)$ in the transition region should differ from the profile obtained by de Gennes [18] for a good solvent. In their calculations the authors assumed that the binodal curves (determined from the condition of equality of the chemical potentials in the different phases) and the spinodal curves [determined from the condition of zero osmotic compressibility $a^{-3}\varphi(\partial^2 F/\partial\varphi^2) = 0$] are indistinguishable, and they used the phase curve (spinodal) equation

$$\upsilon(\varphi) = \frac{1}{N\varphi} + w\varphi \,. \tag{18}$$

The region $\varphi_1 < \varphi < \varphi_2$, which includes dilute and semidilute states of the solution, corresponds to phase separation of the system (see Fig. 2). From this standpoint the critical concentration φ_{cr} is given (in terms of N and w) by the expression

$$\varphi_{cr} = (Nw)^{-0.5} \,,$$

where the critical temperature T_{cr} exceeds the temperature of the given state of the system. By using the correlation length $\zeta = a(3\upsilon\varphi/2)^{-0.5}$ (see Klein and coworkers [21,23]), or $\zeta = a\varphi^{0.75}$ (see Babak [7]), and also the new coordinates $y = (\varphi/\varphi_2)^{0.5}$ and $x = z/\zeta_2$, we can minimise the functional σ in Eqn (14) and obtain the expression

$$\left(\frac{dy}{dx}\right)^2 = \alpha y^6 - \gamma y^4 + \beta^2 y^2 + b \,. \tag{19}$$

Here $\alpha = 1$ (Refs 18 and 20) or $\alpha = w\varphi_2^{0.5}$ (Ref. 7), $\gamma = 2$ (Refs 21 and 23) or $\gamma = 3\upsilon/\varphi_2^{0.5}$ (Ref. 7), $\beta^2 \simeq 2\gamma(\ln\varphi_b)/(\ln\varphi_1)$, b is a constant adjustable parameter [chosen by using the condition $y \to y_s \gg 1$ for $x \to 0$, where $y_s = (\varphi_s/\varphi_2)^{0.5}$].

By using the numerical values $\varphi_1 \simeq 2 \times 10^{-4}$ and $\varphi_2 \simeq 0.2$, reported by Klein,[40–42] and also $w \simeq 0.2$ and $\upsilon = w\varphi_2 \simeq 0.04$, and $\gamma \simeq 0.3$, it is easy to prove [7] the existence of a critical value of the parameter β_{cr}^2 [$\beta_{cr}^2 = 1.125$ for the numerical values used above, below which Eqn (19) has no real solution]. For $\beta_{cr} > \beta$ the calculated density profiles tend to become S-shaped when β decreases (Fig. 4). For $\beta = \beta_{cr}$ the $\varphi(z)$ curve has a point where $d\varphi/dz = 0$. For $\beta < \beta_{cr}$ we find a region (the part of the curve between the points k and l) for which Eqn (19) has no real solution. This region can be interpreted as a region of 'condensation' of the polymeric molecules,[7] where the molecules are spontaneously densified from a thickness z_l to z_k. If this interpretation is legitimate we may conclude that in a poor solvent a bulk concentration $\varphi_{cr\,b}$ can be defined above which direct 'condensation' of the macromolecules can take place, producing a continuous increase in the adsorption of the polymer with time.

The critical value of the bulk concentration of the polymer $\varphi_{cr\,b}$, corresponding to the instability region of the AL, is related to the concentrations φ_1 by the expression [40]

$$\varphi_{cr\,b} \simeq \varphi_1^{\upsilon} \,,$$

where $\upsilon \simeq \beta_{cr}^2/2\gamma$. It follows that at polymer concentrations above $\varphi_{cr\,b} \approx 10^{-7}$ multimolecular adsorption can be expected. Thus, in real system there is no equilibrium between the AL and the solution in the case of poor solvents, though phase separation in the bulk may not take place if $\varphi_b < \varphi_1$.

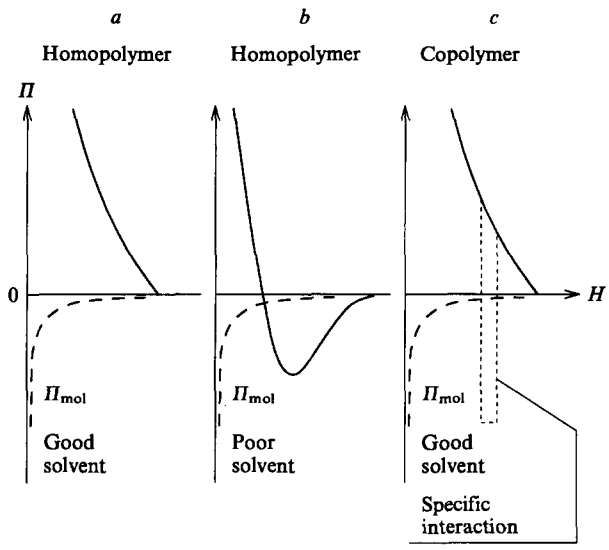

Figure 5. $\Pi(H)$ disjoining pressure isotherms for a plane-parallel liquid film stabilised by adsorption layers of a homopolymer in a good (*a*) and in a poor solvent (*b*), and for a copolymer in a good solvent (*c*).

de Gennes [19] studied the contact between two parallel surfaces in a solution of a polymer in a good solvent and determined the dependence of the disjoining pressure $\Pi(H)$ on the width of the gap (H) between the plates. To this end he used Eqn (14), and expressed its first integral as

$$\frac{1}{2}L\left(\frac{\partial\psi}{\partial z}\right) = G(|\psi|^2) - \tilde{G}(|\psi_{H/2}|^2) \,, \tag{20}$$

where $\tilde{G}(|\psi_{H/2}|^2)$ is an integration constant chosen from the condition $d\psi/dz|_{H/2} = 0$. By using the boundary condition (16) he determined unambiguously the distribution function of the equilibrium profile $\varphi(z)$, and also the function $\sigma(z)$, from which the disjoining pressure was calculated;

$$\Pi = -\frac{\partial\sigma}{\partial z} \,.$$

The main conclusions of the theory of de Gennes [19] relating to thermodynamically good solvents can be formulated as follows: (1) in the case of an 'ideal' equilibrium (i.e. when the adsorption is reversible) a force of attraction is observed beween the surfaces; (2) in the case of a 'limited' equilibrium (i.e. for a constant adsorption of the polymer) a force of repulsion between the surfaces is observed for all values of the distance H. Thus, in relation to these topics the conclusions of the theories of de Gennes [19] and of Scheutjens and Fleer [13,14] are fully consistent.

When applying the results of theoretical studies of adsorption and of the interaction between adsorbed layers of polymers to real dispersions containing polymers the difference in interacting conditions between parallel platelets and spherical particles should not be forgotten.[19] Whereas in the approach of infinite parallel surfaces the desorption of macromolecules from the surfaces is hindered, leading to mutual repulsion of the surfaces, at the contact between spherical particles the macromolecules can migrate away from the region of increased pressure at the centre of the contact and move towards the periphery of the contact region. In the latter case the local adsorption Γ at the centre of the contact zone can decrease, thus inducing mutual attraction between the particles. Similarly, at the contact between liquid interfaces, for which the lateral mobility of the macromolecules is greater than on solid surfaces, we may find that other conditions being equal emulsion particles experience attraction whereas the solid particles of sols experience repulsion.

Furthermore, the brief contacts of particles in Brownian motion may generate mutual repulsion, whereas in the deposits from suspensions or emulsions the desorption of the macromolecules is more likely, leading to mutual attraction of the particles.

Thus the problem of the aggregation stability of dispersions stabilised by polymeric AL in thermodynamically good solvents in still unsolved. It is directly related to a more complex problem: how can the degree of equilibration (or the reversibility of the adsorption) be estimated under actual experimental or technological conditions?

The interaction between platelets in a solution of a polymer in a thermodynamically poor solvent was studied by Klein and coworkers,[20-22] who used the computation schemes proposed by de Gennes[19] supplemented by an additional condition: a negative value of the second virial coefficient v in the expansion (10). In particular, it was shown[22] that the type of interaction between AL of macromolecules is determined by parameters which characterise the bulk properties of the polymer solution, for example by parameters of its phase separation diagram (see Fig. 2), and also by the unperturbed radius of the polymer cluster in solution and by the third virial coefficient w of the expansion (10). One of the consequences of this conclusion is that, in the range of parameters corresponding to mutual attraction between two AL in contact, the adsorption of macromolecules at the boundary with the bulk solution should increase indefinitely with time, and the thicknesses of the AL should also increase indefinitely.[7] We note that Scheutjens and Fleer[14-16] criticised the suggestion[22] that the phase separation diagram of polymers can be used to describe the interaction between AL of macromolecules in a polymer solution.

3. Interaction between adsorption layers of polyelectrolytes

Lyklema et al.[17] have pointed out that the adsorption theories developed to explain the steric stabilisation of dispersions by nonionic macromolecules with flexible chains can be extended (in principle) to copolymers and polyelectrolytes by adding to Eqn (5) the term: $\exp(y_i - y)$ (where $y = e\phi/kT$, and ϕ is the electrostatic potential in the solution), in order to allow for the specific (electrostatic) interaction. However, a statistical theory of the adsorption of polyelectrolytes has not yet been developed.

Hesselink's theory of the adsorption of polyelectrolytes[43,44] is often quoted in the discussion of experimental results. It is an approximate theory, because the exponential dependence of the density of segments upon distance from the surface $\varphi(z)$ is postulated rather than established. Furthermore the theory makes the following assumptions: low concentration of polyelectrolytes in solution (which allows the intermolecular interactions in solution to be neglected), and high ionic strength of the solution [which allows the effect of ionic electrostatic forces between charged functional groups upon the distribution $\varphi(z)$ to be neglected]. This theory establishes the interrelation between the parameters of the adsorption layer of polyelectrolyte (layer thickness, extent of adsorption, density of charges on the interfacial surface) and the physicochemical parameters (degree of dissociation of the macroion, ionic strength of the solution, concentration of the polyelectrolyte, molecular mass, surface charge density, etc.).

The conclusion of Hesselink's theory, that the adsorption of a polyelectrolyte decreases as the degree of dissociation of the macroion is increased, is attributed to a decrease in the electrostatic component of the energy of adsorption. The effect is also explained by an increase in the hydrodynamic radius of the polymer cluster with increasing charge. According to Hesselink's theory a lowering of the Debye screening length (for example, by increasing the ionic strength of the solution) should result in an increased adsorption of the polyelectrolytes (PE): this prediction is confirmed experimentally by a study[46,47] of the effect of pH and of the concentration of sodium chloride on the surface activity of poly(acrylic acid) (PAA) at the solution–air interface. In particular it has been shown that for ionisation levels of the macroion $\alpha \geqslant 0.2$ (i.e. at pH $\geqslant 4$) the PAA becomes surface-inactive because of the increase in solubility of the polyacid with increase in α.

Hydrophobic interactions play an important role in the conformation of polyelectrolytes and in their adsorption at the oil–water inteface.[2,48-52] Hydrophobic binding favours the formation of a more convoluted and rigid conformation of the macroion. The interaction between the hydrophobic (residual acetate) functional groups of poly(vinyl alcohol) and the water–oil interface increases the surface activity of the macromolecule by lowering the free energy in response to the accumulation of hydrophobic groups in the oil phase.[50,51] Increasing the content of acetate groups in the copolymers of acrylic acid and vinyl acetate leads to the formation of gel-like layers at the interface, and therefore also to an increase in the stability of the emulsion films towards rupture (coalescence).[8,9,52-57] The effect of hydrophobic and of electrostatic interactions on the conformation of natural PE (proteins, polysaccharides, etc.) under given physicochemical conditions can be used to explain (at least, qualitatively) the special aspects of their adsorption at phase boundaries.[58-60]

A working theory of the steric stabilisation of dispersions of polyelectrolytes has not yet been developed, in spite of the wide technological use of these materials as stabilisers (especially in mixtures with nonionic polymers).[56,61,62] The difficulty of describing the specific interactions in terms of statistical theories is responsible for this state of affairs, as well as the long-standing interest of researchers in this area in the opposite effect of PE on disperse systems (i.e. in aggregative destabilisation effects such as flocculation and coagulation). However, studies of stabilisation based on the work of La Mer[63,64] and Gregory[65,66], now form a substantial part of the work of Baran,[67] Audebert and coworkers,[68-71] and others.

III. Experimental study of the interaction between adsorption layers of polymers

The most serious problem in the interpretation of experimental results on the properties of AL of polymers and on the interaction between AL is the lack of a criterion for recognising and controlling the thermodynamic equilibrium in disperse systems containing polymers. Because of the finite diffusion time of the macromolecules from the solution to the surface, and of the slowness of the conformational rearrangements of an adsorbed molecule (in particular, at relatively high bulk concentrations of the polymer in solution) we can define a time beyond which the rate of the transition processes falls to zero (i.e. ceases to be an experimentally determinable quantity). This time is of the order of hours or days. The probability of reaching what has been called the 'equilibrium' state of these systems decreases still further if structure formation processes can take place in the AL as a result of the specific interactions between the macromolecules.

Another difficulty met in the experimental study of the properties of AL is the correct choice of a model substance (both for the polymer and for the surface) for difference studies of the effect of physicochemical factors on the adsorption of polymers. In particular, uncontrolled polydisperseness of the polymer samples is reported[67,72] to introduce serious distortions into the results of adsorption measurements, because of the difference in surface activity between macromolecules with small and with large molecular masses. Most probably the adsorption of macromolecules on immobile surfaces (vessel walls, mica laminae, or quartz surfaces in the modelling of contact interactions)[20-23,41,42,52,73-85] or on colloidal deposits[67] is markedly different from their adsorption on the particles of sols undergoing Brownian motion, partly because of the difference in the accessibility of the surface to the molecules and partly because of the hydrodynamic effects produced by the motion of the particles. The effect of the method of measuring adsorption on the result of the measurement has been examined in depth.[67]

1. Measurement of the thickness and of the density profile of adsorption layers of polymers

As was pointed out above, modern theories of the steric stabilisation of disperse systems by polymer layers[11-13] attach great importance to the structure of the AL of macromolecules in their outer side (oriented towards the solution). The layer, formed by 'tails' (and to a smaller extent by 'loops'), makes a relatively minor contribution to the density profile $\varphi(z)$ of the adsorption layer, but its role in the stabilisation of the disperse phase is dominant. The stabilising power of this layer is associated with the mutual repulsion of 'tails' and 'loops' at their steric contact (see Fig. 1*a*).

Unfortunately, only a small number of experimental methods of determining the density profile or the thickness of the outer part of the AL is available at present. Among the methods most recently reported we should include the low-angle neutron diffraction method,[86] and also the measurement of contact interactions between molecularly smooth mica surfaces[20,74,83] or between liquid interfacial surfaces (air bubbles or oil drops approximately 1 mm in diameter) in aqueous solutions of polymers.[84] However, other indirect methods have also been a valuable source of information on the structure of AL. Detailed analyses of all these methods have been published.[5,7,67]

Many systematic studies of the effect of various physico-chemical factors on the thickness of AL of polymers have been reported.[41,42,52,53,74,79-84,87-95] All these works concluded that the effective thickness of the AL is substantially greater than the root-mean-square distance between the ends of the statistical macromolecular cluster ($2R_F$), or than double the hydrodynamic radius R_h of the macromolecule, in keeping with the ideas proposed in the steric stabilisation theories[11-23] on the structure of the AL (i.e. on the mutual repulsion between 'tails' and 'loops' of the macromolecular chains in the liquid film).

The experimental determination of the dependence of the effective thickness of the AL on the molecular mass of the polymer is of great importance because its results can be compared with calculations based on the steric stabilisation theories.

In particular, the following dependence was obtained[88] for AL of poly(vinyl alcohol) (PVA) on particles of polystyrene latex:

$$\delta_{ef} = M^{\beta},$$

where $\beta = 1.14$ in the range $8000 < M < 67000$. On the other hand, a study of aqueous emulsion layers stabilised by PVA gave[93] $\beta \simeq 0.2$. This suggests a weak dependence of δ_{ef} on M. It was also stated[93] that the thickness of an adsorption layer of poly(ethylene oxide) on a solid surface, measured ellipsometrically, corresponds to a value of the β coefficient of 0.4, which differs from the value (0.5) predicted by the theories of Hoeve[29] and of Scheutjens and Fleer.[11,14] Kawaguchi et al.[93] interpret this result on the basis of the de Gennes theory,[18] developed for thermodynamically good solvents, by assuming that the size of the 'tails' is comparable with the size of the macromolecule R_F in the bulk of the solution, and that the density profile is described by the function $\varphi(z) \sim z^{-4/3}$, which is valid for the bulk of the solution. By determining δ_{ef} by the expression

$$\delta_{ef} = \int_0^{R_F} z\varphi(z)\mathrm{d}z$$

and putting $R_F \sim M^{0.6}$ (see de Gennes[18]) they obtained the value of 0.4 for β quoted above.

It should be noted that according to de Gennes[18] the adsorption Γ should be independent of the molecular mass M of the polymer. In this respect the reported[93] $\delta_{ef}(M)$ dependence [which is effectively a $\Gamma(M)$ dependence, having been measured ellipsometrically] is incompatible with the de Gennes theory for good solvents.[18] Therefore it is relevant to note the comment[18] that an increase in the adsorption Γ with M can be expected if the adsorbent surface has a mosaic structure with extended 'active' centres (such as dislocations) which can bond to the segments of the macromolecule with a relatively large energy.

The effective thickness of AL of poly(ethylene oxide) on a mica surface in a thermodynamically good solvent (an aqueous 0.1 mol dm^{-3} KNO_3 solution and toluene) was measured by Klein and Luckham[23] by the contact interactions method. The result ($\beta = 0.43 \pm 0.02$) differed from de Gennes' prediction of $\beta = 0.6$, but allowing for the experimental error it is consistent with the theory of Scheutjens and Fleer.[11,14] It has been reported[23] that the agreement with the de Gennes theory[18] is improved by making a correction for the rigidity of the dynamometer used to detect the instant of contact between the two AL. Klein et al.[22] showed that in a thermodynamically poor solvent (polystyrene in cyclohexane) $\beta \leqslant 0.5$. In particular, when calculating the dependence of the thickness δ_{ef} of the adsorption layer on the molecular mass of the polymer in the limit of $f_a^* \to 0$ (where f_a^* is the maximum force, leading to the dislodgment of a particle) these workers obtained the relationship $\delta_{ef} \sim M^{0.5}$ whereas for a finite value of the adhesion force the relationship was $\delta_{ef} \sim M^{0.3}$, which is not inconsistent with any of the adsorption theories.

As regards the effect of the quality of the solvent on the adsorption and on the thickness of the adsorption layer it is usually found that worsening the solvent increases the adsorption of nonionic polymers from aqueous solutions on hydrophobic surfaces.[70] This is attributed to the decrease in size of the macromolecules, to their aggregation, and to the increase in the adsorption energy. In particular, an increase in the adsorption of polymers on hydrophobic surfaces (PVA on polystyrene, and polyvinylpyrrolidone on silica) has been observed upon worsening the quality of the solvent.[90,92,97] The same workers noted a decrease in the thickness of AL of the polymers δ_{ef} when a worse solvent was used, which contradicted Klein's experimental data[22] on the adsorption of poly(ethylene oxide).

In a study[52] of the contact interactions between mica sheets and drops of heptane ($\sim$1 mm in diameter) in aqueous solutions of polymers it was found that although the thickness of the undeformed AL of macromolecules [poly(acrylic acid) (PAA) and copolymers of acrylic acid and vinyl acetate with different contents of acetate groups] exceeded the size of the average macromolecular cluster in the bulk of the solution it increased monotonically with R_F (for example, upon increasing the pH or decreasing the ionic strength of the solution).

A special study[83] by the contact interactions method of the effect of the time of formation of adsorption layers of PVA on a molecularly smooth mica surface in aqueous solutions upon the thickness δ_{ef} of undeformed AL showed that this thickness increases with time at a rate of $\sim 10^{-4}$ nm s^{-1} (the δ_{ef} value doubling in approximately 48 h). Under these conditions structuring effects (gel formation processes) develop within the AL, as shown by the increase in the effective viscosity of the layers (a decrease in their rate of thinning).[8]

Structural changes in the adsorption layers of PVA, dependent on time and leading to an increase in the refractive index of the thin liquid layers, were observed[97] at the contact of a silicone sphere and a solid surface in a solution of PVA, but the authors were unable to draw any firm conclusions as to the nature of this phenomenon. In the experiments of Sonntag and coworkers,[76,85] and of Rabinovich et al.,[73,98] who studied the contact interactions between crossed filaments in solutions of PVA, the change in thickness of the AL could not be determined because the method can measure the absolute deformation of the AL but not their thickness.[47] A study[2,91,99] of foam and emulsion films stabilised by adsorption layers of PVA, and in particular of the dependence of their thickness on the difference in hydrostatic pressure ΔP, allowed the disjoining pressure (or its

steric component) to be expressed as a function of the film thickness, thus making it possible to calculate the thickness of the undeformed adsorption layers of PVA in the limit of $\Delta P \to 0$. The time-changes in the properties of the films observed in these experiments were interpreted as a consequence of the failure of the transition processes to go to completion, which complicated the experiment and compelled the hold time of the interfaces prior to film formation (i.e. the time of formation of the adsorption layers of polymer) to be fixed arbitrarily between 0.5 and 2 h. Thus in these experiments no attempt was made to study the effect of the formation time of the adsorption layers of PVA on their thickness or on the adsorption. Estimates of the thickness of AL of polymers formed on the surface of particles in sols and suspensions have a much lower precision than the direct measurements.[5,67] In particular, even an integral characteristic such as the adsorption of the polymer depends on the chosen measurement method (rate of displacement, method of precipitation of the dispersion, etc.).[67]

Thus our analysis of experimental studies aimed at measuring the thickness of the adsorption layers of polymers or their density profile has shown that the conclusions of the steric stabilisation theories of Scheutjens and Fleer[11-17] and of de Gennes[18,19] on the structure of AL of polymers (the presence of 'tails' and 'loops' in the outer part of the AL, oriented towards the solution, and making an important contribution to the steric stabilisation of the dispersions) is essentially confirmed both for nonionic polymers and for polyelectrolytes. However, we should stress the fact that experimental tests of the dependences predicted by these theories (for example, of the dependence of the thickness of the AL on the molecular mass of the polymer) have given contradictory results. There is very little information on the properties of AL of polymers in thermodynamically poor solvents, and no experimental approaches towards solving this problem have so far been developed. In particular it has been shown[83] that the thickness of adsorption layers of PVA on a molecularly smooth mica surface increases monotonically with time, in spite of the fact that aqueous solutions of electrolytes are moderately good for this polymer ($\chi = 0.45-0.48$).[5] Evidently, in polymers with thermodynamically poor solvents the increase in the thickness of the AL should be even more marked. Therefore experimental methods of studying the properties of AL of polymers should allow for possible time-changes of the parameters of the AL (thickness, rheological properties, etc.), and they should be designed to measure these changes.[52]

2. Steric repulsion between adsorption layers of polymers

According to the thermodynamic theories of steric stabilisation[11-23] an increase in the thickness of liquid films stabilised by AL of polymers produces an increase in the free energy of the repulsion between these AL (Fig. 6). The direct determination of this energy as a function of the film thickness H is a difficult problem. This accounts for the small number of publications on this topic. We shall consider only the experimental methods which allow the pressure P to be measured as a function of the contact pressure force (in the case of a contact between solid surfaces), or of the difference in hydrostatic pressure ΔP (in the case of liquid films).

The first measurements of the repulsive force f_p between bent mica plates in a polymer solution [an aqueous solution of poly(ethylene oxide), PEO, with a molecular mass of the order of 150 000] as a function of the width of the gap between the plates (H) were reported by Israelachvili et al.[74] These workers found that after a 2 h exposure to the solution the thickness of the film (double the thickness of the undeformed AL) reached 300 nm, and that in this region the force of repulsion increased exponentially as H was decreased. In the 10–150 nm region the force f_p depended on the rate of compression of the plates, and showed hysteresis phenomena (the thickness of the AL after loading was not restored to its initial value). Lastly, in the region < 5 nm a steep increase in the repulsive force was observed: it was accompanied by removal of the polymer from the gap and the appearance of a cohesive force as a result of 'bridge formation'.

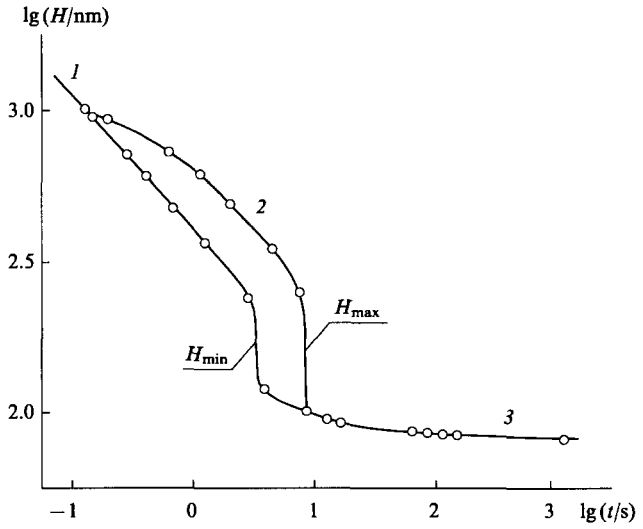

Figure 6. Kinetic curve for the thinning of a water film stabilised by a copolymer of acrylic acid and vinyl acetate containing 74% of acetate groups.[53]

The main conclusions from the work of Israelachvili et al.[74] can be formulated as follows: (1) the adsorption of PEO in a moderately good solvent (Flory–Huggins parameter $\chi = 0.45-0.48$)[100] is multimolecular, since a continuous increase in the thickness of the AL was observed; (2) a gel-like structure is formed in adsorption layers of PEO, with an elastic deformation time (after compression) exceeding the characteristic relaxation time of the sample, thus leading to hysteresis effects; (3) the achievement of film thicknesses $H < 5$ nm in the experiments indicates the absence of contaminants such as dust and microgel particles in the PEO solution.

Klein and Luckham,[41] using a similar apparatus, repeated the measurements of the deformation properties of AL of PEO in an aqueous solution of KNO_3 (0.1 mol dm^{-3}). The PEO samples had molecular masses of 4×10^4 and 1.6×10^5, and the formation time of the AL of polymers was 16 h (as opposed to 2 h, used by Israelachvili et al.[74]). Their main conclusions[41] were: (1) the adsorption of PEO on a mica surface is monomolecular; (2) the adsorption of PEO is irreversible, i.e. the so-called 'limited' equilibrium is established between the polymer solution and the AL (whereas Israelachvili[74] stipulated a 'full' equilibrium since macromolecules are removed from the gap when its thickness is reduced to < 5 nm); (3) the possibility of forming a gel-like structure in the AL is denied; (4) though mica plates were compressed as far as $H \simeq 6$ nm no adhesion between the AL of the polymer was detected (in contrast to the report[74] of the development of a cohesive force between the adsorbed layers of PEO at gap thicknesses < 5 nm).

Klein and Luckham[41] noted the good agreement between the results of measurements of the interaction energy of AL of polymers and those given by the steric stabilisation theory developed by de Gennes[19] for thermodynamically good solvents. The specific free energy of repulsion as a function of the film thickness $\Delta F(H)$ was found by the expression $\Delta F(H) \sim f_p/R$, where R is the radius of curvature of the surface. On the assumption that in the region of weak overlapping of the AL ($H \approx 80$ nm) the mutual repulsion effect between the AL is associated with an increase in the osmotic pressure in the contact region, with $\Delta F(H) \sim V\pi$, where $V = 2\delta - H$ (δ is the thickness of the undeformed AL, π is the excess osmotic pressure), the authors expressed π in terms of the density profile

$\varphi(H)$ of the segments in the contact region [stated[19] to obey the expression $\varphi(H) \sim \exp(-H/2\zeta)$, where ζ is the correlation length], and

$$\pi \sim v\varphi^2(H) \sim \exp\left(\frac{-H}{\xi}\right).$$

Then,

$$\Delta F(H) \sim (2\delta - H)\exp\left(\frac{-H}{\xi}\right),$$

and the parameter $\Delta = \partial[\lg \Delta F(H)]/\partial(\lg H) = -H/(2\delta - H) - H/\zeta$. In the region of slight overlapping of the AL the inequality $H \leqslant 2\delta$ applies, and the parameter Δ is negative, with $\Delta \to -\infty$ for $H \to 2\delta$. Exactly this law for the changes in Δ was observed[41] for a good solvent in the region of slight overlapping of the adsorption layers of PEO.

Conversely, in the region of strong overlapping of the AL, i.e. for $H < 10$ nm, the following dependence is observed (on the assumption of a constant adsorption of the polymer):[19]

$$\varphi(H) \sim H^{-1},$$

whence we find

$$\pi \sim \varphi^2 \sim H^{-2},$$

which leads to the expression

$$\Delta F(H) \sim H^{-1},$$

which was formulated experimentally.

Klein and Luckham[41] also discovered a hysteresis on the $\Delta F(H)$ curve during a heating–cooling cycle, the parameter $\Delta F(H)$ being smaller during unloading than during loading and remaining always positive (i.e. adhesion between the AL was not observed).

The present writer has reported[83] measurements of the time-dependence curves $H(t)$ of films of aqueous soutions of PVA while compressing mica sheets with gradually increasing forces (f_p). A sudden increase in f_p produces a thinning of the film at a measurable rate even after 10^3 s of observation, though the deformation is mostly completed in 100–200 s after the application of the constant force f_p. After a sudden decrease in the force f_p to a new constant value the thickness of the film relaxes to the previous value in a period of $\sim 10^3$ s in the case of adsorption layers of PVA formed over a time $t_f > 10^5$ s. No relaxation was seen for $t_f < 10^3$ s. As has been pointed out,[52] the experimental $\Delta F(H)$ dependences are not well correlated with the theoretical dependences $\Delta F(H) \sim (2\delta - H)\exp(-H/\zeta)$ and $\Delta F(H) \sim H^{-1}$ for a weak and a strong overlapping of the adsorption layers respectively in a thermodynamically good solvent.[19] The best concurrence is found for AL formed in times $t_f > 10^4$ s, with weak overlapping of the AL, by formally choosing the parameters $\delta = 80$ nm and $\zeta = 7$ nm. We note that the value $\delta = 80$ nm greatly exceeds the value $\delta = 35$ nm, which corresponds to the contact interaction force $f_p \simeq 10^{-8}$ N, i.e. to the precision of the measurement of force in these experiments.

It was also pointed out[52,83] that for an extent of overlapping corresponding to a film thickness $H > 40$ nm (and $t_f \sim 10^4$ s) the $\Delta F(H)$ curves are satisfactorily described on the basis of the HVO theory † (see Ref. 27). Those papers also discuss an attempt to describe the deformation of adsorption layers of PVA by rheological methods based on a simplified solution of the Hertz contact problem[101,102]

$$\frac{f_p}{R} = 0.75E\left(\delta - \frac{H}{2}\right)^{5/2}(R+\delta)^{1/2}, \qquad (21)$$

† More exactly, on the basis of a variant of the HVO theory which assumes an exponential distribution of the density of segments with increasing distance from the surface.

where E is the effective elastic compression modulus of the AL of polymer.

It has been shown that none of the theoretical curves drawn by using Eqn (21) describes the experimental dependence over the whole region of overlap of the adsorption layers. However, by formally assuming that the layer is not uniformly thick the appropriate elastic modulus can be calculated by Eqn (21) for each value of the thickness δ. The following values of E/Pa were obtained for adsorption layers of PVA having $c_{PVA} = 0.1\%$, $c_{KCl} = 10^{-2}$ mol dm^{-3}, and $t_f \geqslant 2.2 \times 10^4$ s: 4.2×10^3, 2.0×10^5, 2.5×10^6 for δ values of 50, 30, and 20 nm respectively.

Thus we have to consider a gradient of the elastic properties of AL of polymers, probably generated by the density gradient of the the polymer segments near the surface or by the gradient in the bulk density of the number of contacts between the segments, responsible for the formation of a gel-like structure within the AL.

The studies by Klein and Luckham,[20,41] of the polystyrene–cyclohexane system were aimed at the interactions between AL of polymers in thermodynamically poor solvents. They stress the presence of an equilibrium minimum on the $\Delta F(H)$ curve [or the $\Pi(H)$ curve, see Fig. 5*b*], having a depth of 10^{-3} J m^{-2}. A strong repulsion arises between the AL when mica sheets are squeezed together.

A group of experimental papers[89,91,99] describes studies of the steric interaction between AL of polymers in free emulsion and foam films. In this work the thickness of the films H was determined interferometrically as a function of the difference in hydrostatic pressure ΔP (which is equal, under equilibrium conditions, to the disjoining pressure in the film). In particular, it was found[91] that the dependence of the disjoining pressure Π on the deformation is linear up to values of $\Delta H/H \simeq 0.3$ when the film is compressed under hydrostatic presure, which is markedly different from the dependence $\Pi \sim \exp(-H/\zeta)$ predicted for good solvents at low coverages by the AL.[19]

The steric interaction between adsorption layers of polymers in microscopic foam or emulsion films (about 100 μm in size) located between air bubbles or liquid droplets in a solution of the polymer has been widely discussed[52,53,96,103]. In particular, it has been shown that when a load is suddenly applied as a constant compressive force f_p between two liquid or gaseous particles with a radius of ~ 1 mm three characteristic regions can be distinguished on the curve which describes the thinning of the liquid film [$H(t)$] between the particles (see Fig. 6). In the first region ($H \sim 1$ μm) the form of the approaching surfaces remains spherical (as shown by the interference image of the film in reflected light), and the thinning of the film can be described by Taylor's equation for the flow of a medium of constant velocity η out of the gap between two undeformed spheres of radius R (see Ref. 52).

$$-\frac{dH}{dt} = \frac{4f_p H}{3\pi R^2 \eta}. \qquad (22)$$

The parameter η calculated by formula (22) is satisfactorily consistent with the bulk viscosity of the polymer solutions.[52,53]

In the second region ($H < 1$ μm) we observe a compression of the spherical surface of the drops and the formation of lenticular thickenings ('dimples') at the centre of the circular films, from which the polymer solution flows through a gap of thickness H_{min} towards the periphery of the film.

Lastly, when the compression of the 'dimple' is almost complete we come to the third stage of thinning of the film, taking place against a background of steric interactions between AL of macromolecules with a variable effective viscosity and a velocity of the order of 10^{-2}–10^{-1} nm s^{-1} (see Refs 52 and 53). The deformation of the element of the flat film has been described by using the rheological model of Kelvin, consisting of elastic (E_K) and viscous elements (η_K) connected in parallel,

according to which

$$\Delta P = E_K \varepsilon + \eta_K \frac{d\varepsilon}{dt}, \quad (23)$$

where $\varepsilon = (H_0 - H)/H_0$ is the relative deformation of the film, H is its thickness, and H_0 is the effective thickness of the undeformed film, i.e. the thickness of the film for $\Delta P = 0$. By solving Eqn (23) we obtain the expression

$$H(t) = H_0\left[1 - \frac{\Delta P}{\eta_K}\tau\left(1 - \exp\frac{-t}{\tau}\right)\right], \quad (24)$$

in which $\tau = \eta_K/E_K$. In spite of the fact that Eqn (24) does not describe the experimental curves for the third stage of thinning of the film $H(t)$ a formal application of this equation to the separate parts of the $H(t)$ curve can determine the rheological parameters E_K and η_K as a function of the film thickness.

It has been shown[52,53] that the elastic modulus of the adsorption layers of PVA can vary between 100 and 500 Pa, suggesting a relatively low value of the density of segments for film thicknesses between 90 and 75 nm. According to the steric stabilisation theories[11-23] relatively low values of the elastic modulus (and therefore also of the free energy of mutual repulsion between the AL of macromolecules) are typical of a bulk density of segments not much greater than the bulk density of the polymer in solution, and may be attributed to the entropic component of the disjoining pressure associated with the limitation imposed on the volume of the macromolecules (in terms of the HVO theory[27]).

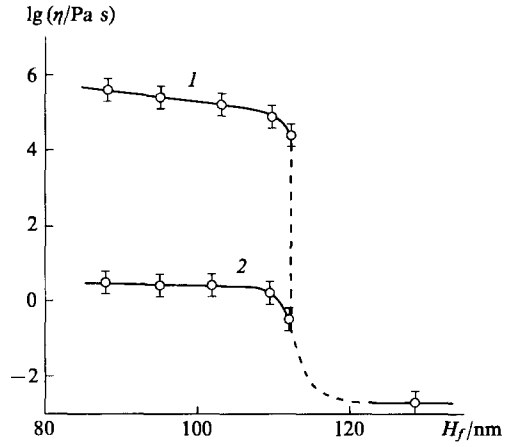

Figure 7. Dependences of η_K (*1*) and η_0 (*2*) for a water film stabilised by PVA upon its thickness H_f.

A characteristic feature of the dependence of the viscosity η_K upon the thickness H of the film is the sudden increase in η_K over a relatively narrow range of film thickness (Fig. 7). The H_0 value can be interpreted as the thickness of the film formed by almost undeformed adsorption layers of the polymer. The effective value of the viscosity η_0 calculated by the expresssion

$$\eta_K = \frac{3}{2}\frac{r_0^2 H_0}{H^3}\eta_0,$$

which corresponds to the plane-parallel disc model, also increases in this range of film thickness but only by 2-3 orders of magnitude (see Fig. 7). Unfortunately, the estimated value of η_0 thus obtained does not justify any unambiguous conclusions on the structure of the steric contact region between AL of macromolecules. For example, the above estimate of η_0 can be obtained by assuming the presence in the central region of the film of a layer of dispersion medium ~ 10 nm thick flowing almost freely.[52] By assuming 'tails' and 'loops' of the macromolecules (which impart a positive disjoining pressure to the film) can penetrate into this layer we are compelled to allow for the hydrodynamic resistance of the segments to the outflow of the liquid medium, i.e. to postulate that the thickness of the layer in which the flow of the liquid is fast can be much greater than 10 nm.

Babak and Monissova[53,96] reported the first attempt to determine the specific free energy of the interaction $\Delta F(H_f)$ in a film of thickness H_f stabilised by polymers. They used the expression

$$\Delta F(H_f) \simeq \Delta P(H_{\min} - H_f), \quad (25)$$

where H_{min} is the minimum thickness of the idealised profile, which can be obtained by extrapolating the profile of the surface of constant average curvature to the region of the bulk meniscus on the intermediate region of the film.[26] It was shown that the positive quantity $\Delta H_{\min} - H_f$ is not greater than 4-6 nm, which sets the following upper limits for $\Delta F(H_f)$: 4×10^{-7} J m^{-2} for PVA [96] and 1.5×10^{-7} J m^{-2} for PAA.[53] The values thus obtained for $\Delta F(H_f)$ are consistent with those predicted by the steric stabilisation theory for the interaction between AL of polymers in liquid films.

3. Adhesion between adsorption layers of polymers in liquid films

The development of adhesion between AL of macromolecules in thermodynamically poor solvents is predicted by all the steric stabilisation theories[11-19] and is confirmed by direct measurements of the cohesive forces between the mica plates in polymer solutions.[20-23]

In the case of thermodynamically good solvents the steric stabilisation theories predict mutual repulsion between AL of polymers at high coverages and on the assumption of a limited thermodynamic equilibrium (constant adsorption of the polymer in the region of steric contact between the two AL in the film, i.e. no desorption of macromolecules upon compressing two AL). Under full thermodynamic equilibrium these theories predict mutual attraction between AL in good solvents.

Direct measurements of the attachment forces between AL of polymers in good solvents are inconsistent. As was pointed out above, Klein and Luckham[41] failed to detect any cohesive forces between adsorption layers of PEO. On the other hand Israelachvili et al.[74] observed large adhesion forces for AL of the same polymer upon bringing mica surfaces within 5 nm of each other. Rabinovich and coworkers[73,85,98] reported the absence of adhesion between adsorption layers of PVA formed on the molecularly smooth surfaces of quartz fibres. Large adhesion forces were detected between adsorption layers of PVA on a mica surface,[8,52,78,83] and also on other solid or liquid interfaces.[104,105] Some of these studies[8,52,57,106] included a systematic examination of the effect of different physicochemical factors on the force of adhesion between two air bubbles or heptane drops in aqueous solutions of PVA.

Concentrated emulsions of oil (heptane) in water, stabilised by PVA, acquire a finite plastic shear strength P_s (see Refs 8, 9, 52, 57) after sedimentation in a centrifuge. We shall assume that the plastic strength can be calculated from the expression

$$P_s \simeq n\bar{f}_a^*. \quad (26)$$

Here n is the surface density of broken contacts in the shear plane, equal to $\approx 1/\bar{R}^2$ ($\bar{R}$ is the average radius of the emulsion drops), $\bar{f}_a^*$ is the average adhesion force between drops of emulsion, given (according to the theory of adhesion of liquid particles[107]) by the expression

$$\bar{f}_a^* = \pi v_a R \Delta F_a, \quad (27)$$

where ν_a is a parameter dependent on the capillary pressure and on the shape of the profile of the disjoining pressure, varying between 0.5 and 1, and $\Delta F_a = \Delta F(H_f)$ is the specific free energy of adhesion in a liquid emulsion film of thickness H_f, formed between emulsion drops. Using Eqns (26) and (27) gives the expression [8,9]

$$P_s \simeq \frac{\Delta F_a}{\bar{R}}. \tag{28}$$

Calculations of ΔF_a by means of Eqn (27) from measured values of the plastic strength of concentrated emulsions give values of the order of (-10^{-5}) to (-10^{-4}) J m^{-2} (see Refs 8–10, 52, 57).

It should be noted that the plastic strength of very concentrated emulsions is measured at a small but finite relative shear velocity. Under these conditions the breaking of the adhesion contacts between the emulsion drops and the formation of new contacts take place in a finite time. Thus the adhesion force f_a^* calculated by Eqn (26) cannot be assumed to be an equilibrium adhesion force, just as the ΔF_a value calculated by Eqn (28) is not an equilibrium value of the specific free energy of adhesion. We can expect (as is found in practice) [52,78,83] a decrease in the cohesive force between emulsion drops on lowering the shear rate, i.e. on lowering the velocity of the breaking load applied to the drops

$$f_a = \frac{df_a}{dt}.$$

On the rheological curve this region corresponds to creep. The creep phenomenon itself is characteristic not only of disperse systems stabilised by AL of polymers (interacting through short-range forces, including hydrophobic interactions produced by hydrogen bonds), but also of very concentrated dispersions with contacts of the coagulation type between particles, interacting through molecular and electric forces.

When the size of the particles is decreased, i.e. when the potential energy of the interaction between particles is lowered to a level comparable with kT, the breaking of the adhesion force between particles is caused by thermal fluctuations and becomes controlled by probability laws.[108] The same is true of the breaking of the adhesion contact between two AL of macromolecules, when the discrete bonds between 'active' functional groups are not broken simultaneously upon the application of a disjoining pressure. Under these conditions we can expect the force of adhesion between particles coated with AL of polymers to depend on the rate of application of the disjoining pressure P_a, decreasing as dP_a/dt is decreased.

The effect was discovered in measurements of the cohesive force between two mica sheets in a solution of PVA while increasing the disjoining load at a controlled rate to the value

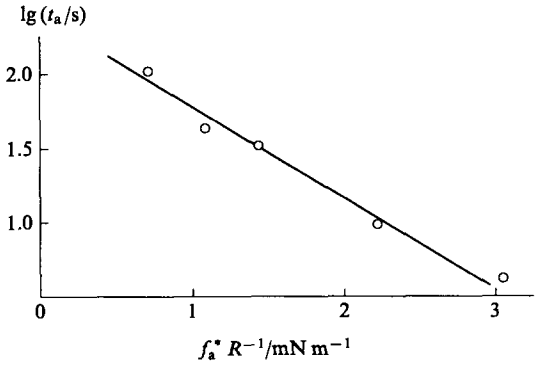

Figure 8. Dependence of the breaking time t_a of the contact between mica sheets in an aqueous solution of PVA upon the pull force f_a^*/R (see Babak [83]).

$f_a^* \leqslant 10^{-5}$ N s^{-1} (see Refs 52, 78, 83). Furthermore, in these experiments the authors measured the time t_a needed to break down the adhesion contact after the application of a constant pulling force to the particles, and they noted that t_a decreases as f_a^* increases (Fig. 8). The following expression was used [108,109] to describe the dependence $t_a(f_a)$ on the assumption that a thermal fluctuation mechanism is applicable to the breaking of the adhesion contact between the surfaces:

$$t_a = t_0 \exp\left[\frac{E_a - \gamma P_a}{kT}\right], \tag{29}$$

where t_0 is a constant parameter, E_a is the activation energy for bond breaking, γ is the activation volume of the bond breaking, and $P_a = f_a/A$ is the detachment pressure (A is the area of contact).

The value thus obtained ($\gamma \simeq 500$ nm^3) has been interpreted [52,78,83] as the volume assigned to one acetate group in the macromolecule of PVA (the content of residual acetate groups in the sample of PVA used in this work was $\sim 1\%$).

It has been pointed out that the volume γ is smaller by a factor of 100 than the volume of one molecule, and approximately 100 times greater than the volume assigned to one hydroxyl group. We also note that the activation energy E_a obtained from the temperature dependence of the force of adhesion f_a^* between adsorption layers of PVA is $(0.1-0.4) \times 10^{-20}$ J (see Refs 8, 52), i.e. it is a quantity of the order of kT, which is in keeping with the suggested thermal fluctuation character of the breaking of the adhesion bond between AL of the polymer.

There have been repeated references [9,52,57] to the practical problems met in the measurement and in the determination of the specific free energy of the interaction $\Delta F(H_f)$ between the AL of polymers resulting from the short-range forces between the bonds which are not broken simultaneously, and also from the long-range elastic compression forces between the AL during compression. In particular, during the compression of two AL in the film the corresponding work of elastic compression of the macromolecules can be arbitrarily assigned to the dividing surface of the liquid film, and it can be assumed that the interfacial tension σ_0 is increased by an amount $\Delta F(H_f)$, which can be found for the profile of the film by using Eqn (25). A positive sign of $\Delta F(H_f)$ corresponds to long-range forces of mutual repulsion between the phase boundary surfaces in the film, containing elastically compressed AL. Under these conditions if specific interactions between the AL of macromolecules (hydrophobic interactions, hydrogen bond formation, electrostatic interaction between oppositely charged functional groups) are taking place in the region of steric contact, leading to a decrease in the free energy, the shape of the film profile can be almost unaffected by this decrease in the free energy because of the short-range influence of these interactions. In experiments aimed at the direct measurement of the contact interaction forces in the compression cycle of mica plates [41,74,83] or of quartz fibres [73,85,98] the decrease in free energy could not be detected against the background of long-range repulsive forces between the elastically compressed AL of macromolecules.

However, dilution of the samples produces an elastic expansion of the macromolecules in the AL as a result of the short-range specific interactions, which formally converts these interactions into 'long-range' interactions since the deformed macromolecules in the AL produce a deformation of the interfacial surface and give the characteristic 'neck' shape to the film profile: in other words, a finite contact angle is created. The formal application of formula (25) in this case leads to negative values of $\Delta F(H_f)$. However, the magnitude of this effect, i.e. the value of the negative energy $\Delta F(H_f)$, will depend on the relationship between the rate of change of the external interaction and the rate of the relaxation processes in the AL of polymers. Since the specific interactions are short-range forces

and cannot be assigned to the dividing surfaces of the film their contribution is arbitrarily shown as a broken line[8,9,52] on the disjoining pressure isotherm (Fig. 5*c*).

IV. Conclusions

The new ideas[8-10,52,57] on the mechanism of the interaction between AL of macromolecules clearly point to the need to devote proper attention to the kinetic factors in experimental studies of the steric interaction between the AL of polymers: these factors include the ageing time of the AL (i.e. the time of formation of the AL), the time of formation of the steric contact between two AL, the rate of application of the pull force when breaking the adhesion contact between the AL, etc. This state of affairs arises because in the stabilisation theories[11-19] the problem of choosing between a 'limited' and a 'full' equilibrium in a system of two interacting AL (see Introduction) is solved arbitrarily, since there are no rational criteria for choosing the type of equilibrium which best describes the steric interaction between AL of polymers. However, the conclusions suggested by the theory as to the stability of sterically stabilised dispersions are strongly affected by the type of equilibrium, since (as was pointed out above) in the case of thermodynamically good solvents these theories predict the formation of adhesive forces between AL of polymers on the assumption of a 'full' equilibrium but not on the assumption of a 'limited' equilibrium.

Evidently the best approach in these circumstances is to assume that, when the time of formation or of steric contact between AL of polymers is increased, a 'limited' equilibrium will tend towards a 'full' equilibrium, thus creating adhesion forces between the particles coated with AL and suppressing the aggregative stability of the dispersions. Similarly, lowering the rate of application of the pull force creates conditions favouring a 'full' equilibrium between the interacting AL of macromolecules, and the adhesive force between particles will be lowest when the equilibrium is most evident. In the limit of a 'full' equilibrium the force of adhesion between polymer particles coated with AL in a thermodynamically good solvent will vanish, as predicted by the steric stabilisation theories.[11-19]

The above concepts were used as a foundation for the interpretation of the results of measurements of the rheological properties of very concentrated emulsions stabilised by adsorption layers of PVA. The development of plastic strength in the emulsions stabilised by this polymer, for which aqueous solutions of electrolytes are thermodynamically good solvents, and also the increase of this strength with time of centrifuging,[9,57] can only be explained by allowing for the finite time needed for the transition of the system from a 'limited' to a 'full' equilibrium. Allowing (in terms of the steric stabilisation theories) for the kinetic factor which characterises the achievement of a 'full' equilibrium by a system of two interacting AL of macromolecules, which can be determined experimentally, should bring the steric stabilisation theories closer to the description of actual nonequilibrium processes in disperse systems containing polymers.

Abstract. The aggregation of cyanine dyes on the surfaces of AgHal microcrystals is examined. It is shown that the photochemical activity of the aggregates in processes involving the spectral sensitisation of photographic materials is determined to a large extent by the occurrence of secondary dark reactions in which photoelectrons recombine with dye holes—the so called type II dye self-desensitisation processes. The inhibition of the self-desensitisation of dyes increases the effectiveness of the spectral sensitisation, i.e. leads to supersensitisation. The principal mechanisms of the supersensitisation of photographic emulsions are discussed. The bibliography includes 149 references.

I. Introduction

The history of more than a century of the development of the spectral sensitisation of silver halides (AgHal) has led to a definite selection of the cyanine dyes used to sensitise AgHal in the visible and infrared ranges of the spectrum. *J*-Aggregating dyes, which make it possible to attain the highest level of additional photosensitivity, are nowadays as a rule generally used for the spectral sensitisation of colour and black and white photographic materials. The phenomenon of the aggregation of cyanine dyes is a striking example of the self-organisation of matter. It was discovered by Jelley[1] and Scheiber,[2] although the first observations apparently date back to an earlier period.[3] They showed that an increase in the concentration of solutions of the dyes displaces the absorption maximum towards shorter wavelengths (*H*-aggregation) or shifts it sharply towards longer wavelengths (*J*-aggregation). The anomalously large (up to 90–100 nm) bathochromic shift of the absorption and sensitisation of certain dyes adsorbed on silver halides, which are characteristic of thiacarbocyanines with substituents in the *meso*-position in the chain, were classified in 1939 by Schwarz as sensitisation of the second kind.[4] Numerous communications and reviews (see, for example, Refs 3–7) have been devoted to the phenomenon of the aggregation of dyes and the influence on the latter by the substrate, by the structure of the dyes, and by a series of emulsion factors and also to problems of the structure and properties of the aggregates themselves.

The *J*-aggregation of dyes on the surface of microcrystals of silver halides is by itself a necessary but not a sufficient condition for their high photographic effectiveness. Many satisfactory *J*-aggregating dyes are relatively ineffective under certain emulsion conditions. Here a characteristic feature is that there is no unambiguous relation between the energy levels of the dyes forming part of the aggregate and the sensitising effect of the *J*-states. This is illustrated in Fig. 1 (see over), which presents the absorption and spectral sensitivity distribution curves for photolayers sensitised by four cyanine dyes forming *J*-aggregates with close absorption maxima of the *J*-bands. The convention adopted in the literature[7] is that the energy levels of the dyes (Dy) are characterised by the polarographic half-wave oxidation and reduction potentials. The potential $E_{1/2}^{Ox}$ represents the energy of the highest occupied electronic level of the dye (ε_{ho}), while $E_{1/2}^{Red}$ reflects the energy of the lowest unoccupied (ε_{lu}) level from which the photoelectron is transferred to AgHal. It is assumed that for effective spectral sensitisers the ε_{lu} level of the dye should be higher than or close to the bottom of the conductivity band of AgHal.[7] On the electrochemical scale, the potential at the bottom of the conductivity band (E_{cb}^{0}) of silver bromide is -1.1 V [relative to the normal hydrogen electrode (rel. n.h.e.)] or -1.34 V [relative to the normal calomel electrode (rel. n.c.e.)].[8] The potential of the top of the valence band (E_{vb}^{0}) = 1.5 V (rel. n.h.e.) or 1.26 V (rel. n.c.e.).[8]

It follows from Fig. 1 (curves *2* and *3*, Fig. 1*b*) that the photographic effectiveness, characterised by the logarithm of the spectral sensitivity (lg S_λ) is significantly different for the two imidacarbocyanines of similar structure. Whereas 2-[3-(5-chloro-1,3-diethyl-2,3-dihydrobenzimidazol-2-ylidene)prop-1-enyl]-5-chloro-1,3-diethylbenzimidazolium iodide **1** ($E_{1/2}^{Ox}$ = 0.55 V and $E_{1/2}^{Red}$ = -1.73 V rel. n.c.e. in methanol) is relatively ineffective, 2-[3-(5,6-dichloro-1,3-diethyl-2,3-dihydrobenzimidazol-2-ylidene)prop-1-enyl]-5,6-dichloro-1,3-diethylbenzimidazolium iodide **2** ($E_{1/2}^{Ox}$ = 0.60 V, $E_{1/2}^{Red}$ = -1.58 V) is highly effective, although the difference between the potentials is comparatively small ($\Delta E_{1/2}^{Ox}$ = 0.05 V, $\Delta E_{1/2}^{Red}$ = 0.15 V). The ε_{lu} levels lie above the bottom of the conductivity band (-1.34 V) for both dyes. The sharply reduced activity of the *J*-aggregate of 2-(1-ethyl-1,2-dihydroquinolin-2-ylidenemethyl)-1-ethylquinolinium iodide **3** (curve *1*, Fig. 1*b*) might seemingly be attributed to the deeper location of the ε_{ho} and ε_{lu} levels ($E_{1/2}^{Ox}$ = 0.99 V, $E_{1/2}^{Red}$ = -1.04 V) relative to the levels of compound **2** and primarily to the higher value of $E_{1/2}^{Ox}$ ($\Delta E_{1/2}^{Ox}$ = 0.39 V). However, 2-[3-(3-ethyl-5-phenyl-2,3-dihydrobenzoxazol-2-ylidene)-2-ethylprop-1-enyl]-3-ethyl-5-

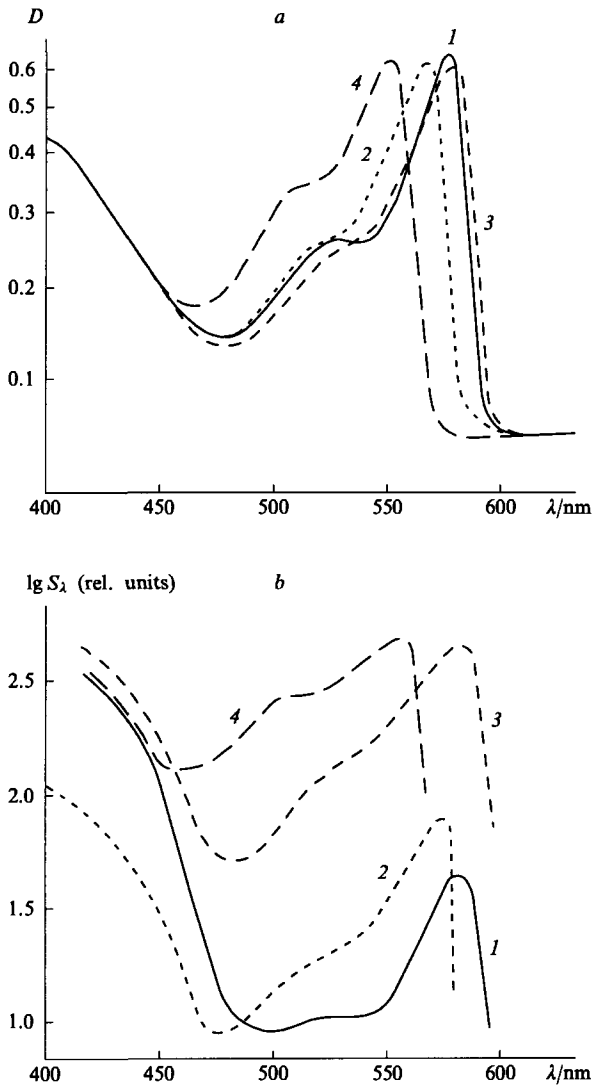

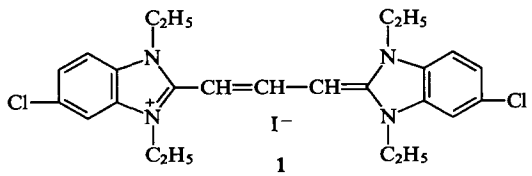

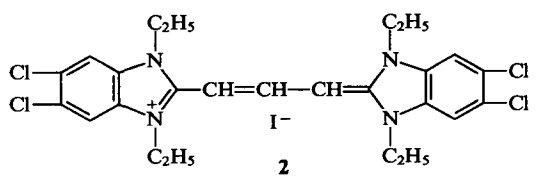

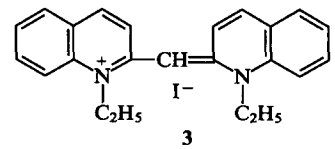

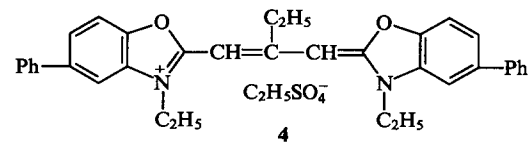

Figure 1. Reflection spectra (*a*) and spectral sensitivity curves (*b*) for the AgBr emulsion [cubic crystals, l = 0.17 μm, (S + Au)-sensitisation] sensitised by dyes **3** (curve *1*), **1** (curve *2*), **2** (curve *3*), and **4** (curve *4*); concentration of dyes — 2 × 10^{-4} mol (mol AgBr)$^{-1}$.

phenylbenzoxazolium ethyl sulfate **4** with $E_{1/2}^{Ox}$ = 0.93 V, which is close to the potential of compound **3**, and with $E_{1/2}^{Red}$ = −1.33 V, which is less negative than for compound **2**, is just as highly effective as compound **2** (curve *4*, Fig. 1*b*). On these grounds, one may conclude that the energetics of the molecules forming part of the *J*-aggregate is not the principal limiting factor.

The absence of a correlation between the photographic activity of cyanine dyes and the positions of their energy levels is apparently due to the following cause. The spectral sensitisation process takes place on the surface of the AgHal microcrystal where the dye is adsorbed. Impurity centres (IC), formed during the chemical sensitisation of the photographic emulsion, are located on the same surface. They play an extremely important role in the separation of the photogenerated charges — photoelectrons and photoholes. The capture of photoelectrons by the impurity centres is in essence the first stage of the formation of the latent photographic image. However, when problems of spectral sensitisation are discussed, as a rule processes in the dye–AgHal binary systems are considered. On the other hand, the real processes include a third important component of the system — the impurity centres which can accept both photoelectrons and holes. The interaction of dyes with impurity centres may be the cause of the secondary reactions which diminish the photographic sensitivity — the so called AgHal desensitisation processes. Methods for the supersensitisation of photographic materials are used to suppress these processes.

The influence of additionally introduced organic compounds — the supersensitisers (S) — on the photographic process in the region where the dye *J*-aggregates absorb is well known (see the relevant reviews [7–13]). The use of supersensitisers has made it possible to increase sharply the photographic activity of a series of *J*-aggregating dyes, frequently without change in the absorption bands of the sensitisers. As will be shown below, because of this the effectiveness of dyes **1**–**4** considered may be made virtually identical. The first publications on supersensitisation date back to 1920 when Bloch and Renwick [14] demonstrated the appreciable supersensitising effect of auramine on layers sensitised by different cyanines. More detailed studies, which led to the formulation of a series of supersensitisation mechanisms, were carried out by West and Carroll, [15] Scheibe and coworkers, [16,17] Bird, Rosenoff, Zuckerman, et al., [18–21] Riester, [22,23] Gilman, [10,24] and other investigators. [10–13] West and Carroll [15] noted that the role of the supersensitiser consists in creating a trap for the exciton formed on photoexcitation of the *J*-aggregate and moving towards the latter at a high rate. The capture of the exciton results in an increase in the probability of its decomposition and of the transfer of a photoelectron to AgHal. According to the ideas of Brunner and coworkers, [16,17] in the supersensitisation step the excitation energy is transferred from the dye to the supersensitiser, the longer lifetime of the excited (triplet) state of which is in fact responsible for the greater probability of the energy transfer to AgHal. Zuckerman and coworkers [18–21] examined the hypothesis that the dye aggregates are broken up with the aid of the supersensitiser molecules, as a result of which the antisensitiser, incorporated in the *J*-aggregate and diminishing the effectiveness of the dye, is localised in small regions of the aggregate and its deactivating effect on the photoexcited state of the entire dye *J*-aggregate (Dy_J^*) is reduced thereby. The separation of the dye from AgHal with the aid of the supersensitiser constitutes the basis of Riester's adsorption model. [22,23] The formation of a layer of supersensitiser (potentiator) molecules between the dye and AgHal promotes, according to Riester, [22,23]

a more effective energy or electron transfer from the photoexcited dye Dy* to AgHal, particularly as a result of the decrease in the contribution by recombination processes.

According to Gilman,[10,24] the supersensitiser, which is a more readily oxidisable compound, captures from the dye a hole formed on photoexcitation of the *J*-aggregate and on photo-transfer of an electron from Dy* to AgHal. There is then a possibility of electron transfer from the supersensitiser to the Dy* molecule (to the ε_{ho} level of the dye liberated on photoexcitation), with formation of the radical-anion $Dy^{-\cdot}$, or to the radical-cation $Dy^{+\cdot}$ (arising after the transfer of an electron to AgHal) with regeneration of the dye. In the first case, the effectiveness of the spectral sensitisation increases by virtue of the higher level of the electron in $Dy^{-\cdot}$ compared with Dy* and in the second it increases as a result of the decrease in the probability of the recombination of electrons with the holes of the dye ($Dy^{+\cdot}$). The above mechanisms have been examined in greater detail in other reviews.[7-13]

It is striking that in the world literature there is no single approach to the supersensitisation processes and the mechanisms discussed are specific to the given case and sometimes contradictory and they are not always justified experimentally. Gilman's hole capture mechanism is most justified for *J*-aggregating dyes, but it is subject to a series of exceptions which will be discussed below. It is essential to note that studies involving the supersensitisation and desensitisation of silver halides by dyes were largely uncoordinated for a long time.

A generalised chemical concept concerning the spectral sensitisation processes has been described in a series of studies by the present author.[8,25,26] According to this concept, the effectiveness of the sensitisation is determined by secondary dark dye desensitisation reactions, whilst the supersensitisation of photographic materials inhibits these processes. The kinetics of the desensitisation processes, which depend on supersensitisers to a greater extent than the energetics of the sensitiser levels, limit the photographic activity of the dye. The main task of the present review is therefore to examine systematically the relation between the processes involving the desensitisation of silver halide emulsions by *J*-aggregates of dyes and the inhibition of these processes by organic compounds of different nature. New approaches to the problem of the effectiveness of spectral sensitisation are also considered.

II. Desensitising effect of *J*-aggregates

Desensitisation is understood as a decrease in the intrinsic (blue) photosensitivity of silver halides under the influence of the adsorbed dye. The desensitisation of AgHal is known to be induced by dyes with a low electron affinity ($E_{1/2}^{Red} < -1.0$ V).[7,27] The desensitisation by such dyes (type II desensitisation) takes place via a mechanism involving the capture of a hole from AgHal.[7,28-36] The dye radical-cations thus produced can serve as centres for recombination with photoelectrons, which are thereby prevented from creating a latent image. This process was first examined by Carroll[37] and Saunders et al.[38] The degree of desensitisation increases as a rule with increase in the dye concentration and is particularly characteristic of dyes adsorbed as polymolecular *J*-aggregates.[7] A hole from the dye moving through the aggregate can reach the electron capture centre and can recombine with a captured electron or even oxidise the silver in the latent image. The type II desensitisation may be represented schematically in the form of the following sequence of reactions:[27]

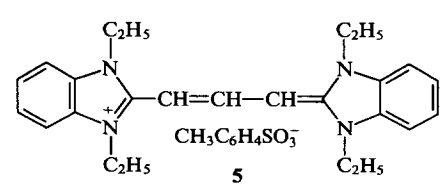
$$AgHal + h\nu_b \longrightarrow [AgHal]^* \quad (1)$$

$$[AgHal]^* + Dy \longrightarrow [AgHal]^- + Dy^{+\cdot} \quad (2)$$

$$[AgHal]^- + Ag^+ \longrightarrow [AgHal/Ag^0] \quad (3)$$

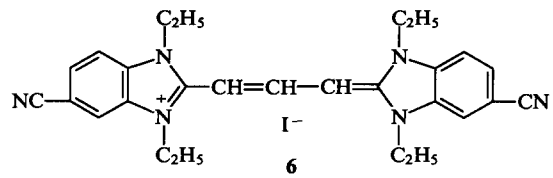
$$[AgHal]^- + Dy^{+\cdot} \longrightarrow [AgHal] + Dy \quad (4)$$

$$[AgHal/Ag^0] + Dy^{+\cdot} \longrightarrow [AgHal/Ag^+] + Dy. \quad (5)$$



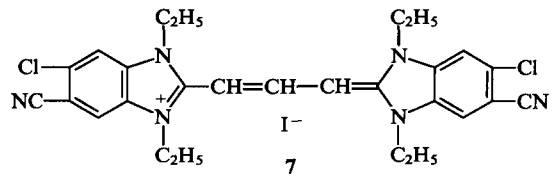
According to the above scheme, the silver halide photoexcited by a 'blue' light quantum ($h\nu_b$) oxidises the dye to the radical-cation $Dy^{+\cdot}$ (the convention that this is referred to as the dye hole may be adopted), which competes with silver ions for the capture of a photoelectron [stages (3) and (4)] or oxidises [stage (5)] the silver of the latent image formed in stage (3).

The desensitisation via the hole mechanism requires that the highest occupied electronic level of the dye ε_{ho} should lie above the top of the valence band (VB) of AgHal. Since the ε_{ho} level may be characterised by the polarographic potential $E_{1/2}^{Ox}$, it would seem that a relationship should be observed between the type II desensitisation and $E_{1/2}^{Ox}$ for dyes. Unfortunately, the dependence of the degree of desensitisation on $E_{1/2}^{Ox}$ for dyes has been investigated to a much lesser extent than its dependence on the reduction potentials $E_{1/2}^{Red}$. This is due to the fact that, for the *J*-aggregating dyes, which desensitise emulsions to the maximum extent (particularly monodisperse emulsions with sulfur sensitisation), the measured potentials $E_{1/2}^{Ox}$ (in solution in the molecular state) do not always characterise adequately the ε_{ho} level of the aggregate.



Leubner[39,40] showed that dyes having $E_{1/2}^{Ox} < 0.95$ V actually increase the intrinsic sensitivity of emulsions at low concentrations by accepting holes from AgHal. Only on raising the concentration of the dyes is desensitisation observed.[40] The increase in the sensitivity of fine-grain emulsions under the influence of dyes in the molecular state with $E_{1/2}^{Ox} \leqslant 0.76$ V (rel. n.c.e.) has also been demonstrated in other studies.[41,42] Tani[43] investigated the dependence of the desensitisation on the calculated value of ε_{ho} for a series of dyes. It was found that, with increase in the ε_{ho} level, the degree of desensitisation increases. It is striking that for dyes in which ε_{ho} lies 0.3 eV above the top of the valence band of AgHal not only is desensitisation observed but an EPR signal appears, which the author attributes to the dye radical-cation formed on excitation of AgHal [stage (2)]. These conclusions concerning the position of ε_{ho} relative to the AgHal valence band are not unambiguous because the dyes investigated were adsorbed in different states (in the molecular state *M* and in the aggregated states *H* and *J*), while the calculations of ε_{ho} were performed for molecular forms of the dyes. Another study by Tani was devoted to the exchange of holes between the dye and the valence band of AgHal.[44]

It is essential to note that the hole desensitisation is determined to a large extent by the topography of the centres formed on chemical sensitisation. For example, emulsions with bulk-phase chemical sensitisation[45,46] or emulsions containing Ir^{3+} ions in the bulk of the microcrystals[40] are desensitised by *J*-aggregating dyes to a lesser extent than by the surface sensitivity centres. The influence of oxygen on the type II desensitisation is not quite so unambiguous as for electron-accepting dyes.[7]



In order to determine the dependence of the type II desensitisation on the structure of the dyes and on their oxidation-reduction potentials (in the first place $E_{1/2}^{Ox}$), a systematic study has been made[47-49] of the influence on photosensitivity by four types of dyes with a low electron affinity ($E_{1/2}^{Red} < -1.0$ V): imidacarbocyanines, thiacarbocyanines, oxacarbocyanines, and quino-2-monomethinecyanines. Dyes **1**–**4** and **5**–**17**, the structures of which are presented below, were investigated.

The photographic effect of the dyes was studied on a monodisperse AgBr emulsion with cubic microcrystals subjected to sulfur–gold (S + Au) sensitisation.

Table 1 presents certain characteristics of the dyes investigated. Depending on their structure, the dyes have been divided into the following groups: imidacarbocyanines **1**, **2**, and **5**–**8**, thiacarbocyanines **9**–**15**, oxacarbocyanines **4** and **16**, and quino-2-monomethinecyanines **3** and **17**. The influence of sensitisers on the intrinsic sensitivity of AgBr emulsions (behind a UFS-1 light filter with a transmittance range of 240–400 nm) has been characterised by the degree of desensitisation (DD).

It follows from the data in Table 1 that all the dyes investigated desensitise the AgBr emulsion. The degree of desensitisation (DD) varies from 1.2 to 3.6. In the series of dyes, a lower degree of desensitisation is induced by dyes in the *M* state (compounds **8** and **13**). The *J*-aggregating dyes **1**, **5**, **6**, and **11** give rise to

Table 1. Desensitising activity of cyanine dyes and some of their characteristics.[49]

Dye	DD	$E_{1/2}^{Ox}$/V	$E_{1/2}^{Red}$/V	$\lambda_{C_2H_5OH}^{max}$/nm	λ_{AgBr}^{max}/nm	State

17	1.2	0.99	−1.14	530	575	*J*

Note. The concentration of the dyes was 2×10^{-4} mol mol^{-1} AgHal and the polarographic potentials in CH_3OH are expressed relative to the normal calomel electrode. The absorption maxima of the dye solutions refer to solutions in ethanol and in the AgBr emulsion; if the state of the dye adsorbed on AgBr is insufficiently clear-cut to determine the absorption band maximum, the latter is indicated in brackets. The degree of desensitisation (DD) was calculated on the basis of the criterion $D = 0.85 + D_0$; the colour temperature of the light source was 5000 K; developer — UP-2; development time — 8 min; layer contrast coefficient $\gamma \geqslant 4.0$.

[a] Two transitions.

the maximum desensitisation (DD $\geqslant 3.0$). However, an unambiguous relation between the tendency of the dyes to undergo *J*-aggregation and their desensitising activity has not been discovered. For example, dyes **1** and **2**, which have similar structures and absorptions and form aggregates, differ significantly as regards desensitisation. A similar behaviour has been observed also for dyes **6** and **7**. The quino-2-monomethinecyanines **3** and **17**, which give rise to *J*-aggregates, have a weak desensitising effect. Thus *J*-aggregation itself is not a necessary and sufficient condition for desensitisation.

It is noteworthy that the desensitisation is not associated in a definite manner with the charge on the dyes, since cationic and ionic dyes with the same chromophoric component of the molecule desensitise to approximately the same extent (cf. compounds **11** and **12** and compounds **3** and **17**). There is also no unambiguous relation between the degree of desensitisation and the potentials $E_{1/2}^{Ox}$ of the dyes. For example, dyes **1** and **2** as well as **6** and **7** with similar potentials $E_{1/2}^{Ox}$ differ by a factor of approximately two in terms of their desensitising activity. This is partly associated with the fact that, on aggregation of the dyes, their energetics may change and it is not altogether legitimate to characterise the aggregates by their polarographic potentials. It has been shown by luminescence and photographic methods in relation to quino-2,2′-monomethinecyanine **3**[48] that the energies of the levels of the dye do indeed change on *J*-aggregation. A change in the positions of the energy levels of a series of carbocyanines on *J*-aggregation has also been demonstrated by photoelectrochemical methods.[50,51] However, the main cause is different, namely the probability of desensitisation is determined not only by energy factors but also to a considerable extent by kinetic factors.[8,26]

A kinetic model of the electron transfer reactions in a photographic emulsion has been developed in the present author's studies[8,25–27,52,53] on the basis of the electrochemical potentials of the dyes and other components of the emulsion. Since the processes examined are typical oxidation-reduction reactions, the ideas of Marcus's theory, which describes electron transfer reactions in polar media, are applicable to them.[54–56] According to this theory, there is a linear relation between the change in the free energy of the transition state and the thermodynamic characteristics of the elementary oxidation-reduction step:

$$\Delta G^{\neq} = -RT \ln k \approx a\Delta G^0 + b \approx anF\Delta E^0 + b \ , \qquad (6)$$

where k is the reaction rate constant, ΔG^0 the change in the standard free energy of the reaction, a and b are constants for a particular class of reactions, n is the number of electrons involved in the reaction, F the Faraday, and ΔE^0 the difference between the standard potentials in volts.

In this case, the rates of electron transfer reactions between the components of the photographic layer — the Dy*, Dy, [AgHal]*, and AgHal molecules as well as those of other compounds — can be expressed in kinetic equations in which the activation energy is a function of the difference between the normal oxidation-reduction potentials of the systems participating in the electron transfers. The kinetics of the hole processes are determined by the rate of exchange of the hole between [AgHal]* and Dy, between Dy* and AgHal, and between $Dy^{+\cdot}$ and other components of the layer. The rate of capture of holes from the valence band of AgHal by the components of the emulsion and in the first place by the dye can be represented by the sum of the reaction rates:

$$\sum_i -\frac{dn_i(p)}{dt} = \sum_i k_i c_i n(p)$$

$$= \sum_i A_i \exp(-\alpha_i \Delta E_i^0/T) c_i n(p) \ , \qquad (7)$$

where $n_i(p)$ is the number of holes, c_i the concentration of the hole-acceptor form of the ith system, and ΔE_i^0 the difference between the normal potential of the ith system and the potential of the top of the valence band (E_{vb}^0). When a hole is captured by the dye, $\Delta E_i^0 = E_{1/2}^{Ox} - E_{vb}^0$. According to the data of Mikheeva et al.,[57] $E_{vb}^0 = 1.5$ V (or 1.26 V rel. n.c.e.) for AgBr. Thus the capture of holes from AgHal by the dye is in principle possible for dyes with $E_{1/2}^{Ox} < 1.26$ V, i.e. for all the dyes presented in Table 1.

However, the capture of holes from AgHal by the dye is only the beginning of the type II desensitisation process, which ultimately represents the recombination of the dye hole with the photoelectrons present in the traps, including the impurity centres (IC_e). Such impurity centres may be chemical sensitisation products (in the first place, the products of the sulfur or sulfur-gold sensitisation).[7] According to the kinetic model, the rate of recombination can be defined by an equation of type (7) in which ΔE_i^0 is the difference between the electrochemical potentials of the electron in the trap and the dye hole ($\Delta E_D^0 = E^0(IC_e) - E_{1/2}^{Ox}(Dy)$]. Consequently the desensitisation rate constant can be formulated as follows:[53]

$$k_D = A_D \exp(-\alpha_D \Delta E_D^0/T) \ . \qquad (8)$$

Since ΔE_D^0 is a function of $E_{1/2}^{Ox}$ (Dy), one would have to expect the existence of a relation between the degree of desensitisation, determined by k_D, and $E_{1/2}^{Ox}$(Dy). However, as mentioned above, such a relation does not exist. The question arises of the cause of such behaviour of the dyes.

According to Eqn. (8), the rate of desensitisation is determined not only by the exponential term but also by the pre-exponential term A_D. One may assume that in type II desensitisation processes the pre-exponential term plays an appreciable role. As a rule, for simple electron transfer processes, the rate of the oxidation-reduction reactions in nonorganised (stochastic) systems, particularly in solutions, depends significantly on the exponential term, i.e. on the activation energy, or, according to the Marcus theory, on ΔE^0. It is noteworthy that such a dependence on ΔE^0 has indeed been observed for type I desensitisation reactions proceeding via a mechanism involving electron capture by electron-accepting dyes in the ground state.[7,27,46,57–61] This is manifested by the steady increase in the degree of desensitisation with increase in the electron affinity of the dyes. However, in the case of organised systems, such as the *J*-aggregates of dyes on the surface of AgHal, the characteristic features of the rates of oxidation-reduction processes are different. Here the frequency factor A_D assumes a special importance. Type II desensitisation processes should depend significantly on the position in space of the *J*-aggregate (in which the hole is located) relative to the impurity centre (in which a photoelectron is captured), i.e. on the distance r between Dy and IC_e.[53,62] This is illustrated schematically in Fig. 2 (see over). On photoexcitation of AgHal, an electron (e) – hole (p) pair is formed. The electron is captured by the electron-acceptor centre IC_e, while the hole is captured either by the hole-acceptor centre IC_p or by the dye aggregate.

If the self-organisation of the dye molecules in the form of a *J*-aggregate is difficult, it begins on the surface defects of AgHal, which diminish the activation energy for the initiation of the aggregates.[63] Surface defects have in addition centres for the localisation of the impurity centres, including the photosensitivity centres formed during sulfur sensitisation.[7,64,65] As a result of the contact between the *J*-aggregate and the electron-acceptor impurity centre $IC_e(r \to 0)$, the frequency factor A_D and the rate of recombination increase, which is manifested by the appreciable desensitisation of the dye. The probability of contact between the *J*-aggregates and IC_e is high, since according to estimates[64] the number of Ag_2S centres is several thousand per μm^2, i.e. approximately per single AgHal microcrystal. On the other hand, the number of dye molecules on such a microcrystal reaches $10^5 - 10^6$, so that there are between several tens and several hundreds of dye molecules per Ag_2S centre.

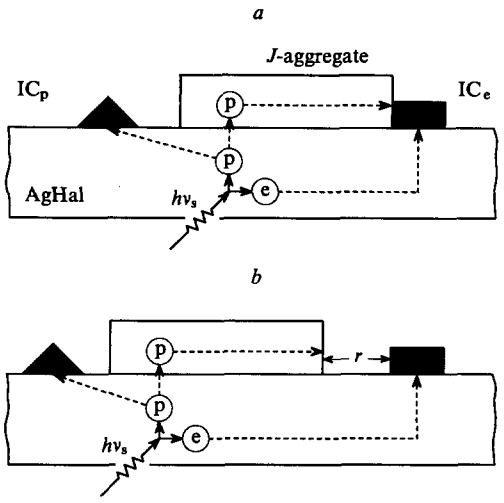

Figure 2. Schematic representation of the type (II) desensitisation processes via the hole mechanism: (*a*) *J*-aggregate in contact with the electron acceptor impurity centre (IC_e); (*b*) *J*-aggregate separated from the IC_e by a distance *r*; IC_p—hole acceptor impurity centre; $h\nu_s$—light quantum absorbed by AgHal; e = photoelectron; p = photohole.

On the other hand, if *J*-aggregation is achieved readily aggregates may be formed not only on AgHal defects but also at other sites, the probability of contact between the aggregate of IC_e falls, *r* increases (Fig. 2*b*), and hence the frequency factor A_D and the rate of recombination diminish.

If a hole is transferred from $Dy^{+\cdot}$ to IC_e via a tunnel mechanism, then the probability *W* of the transfer of the particle under the potential barrier per unit time is expressed by Gamow's classical formula, the simple version of which is

$$W = \nu \exp(-2r/a) , \qquad (9)$$

where ν is the frequency factor, *r* the distance corresponding to the width of the barrier, $a = \gamma h/[2m(U_{max}-E)]^{1/2}$ is the parameter characterising the attenuation of the wave function of the particle under the barrier, $\gamma \approx 1$ is a numerical coefficient which depends on the form of the barrier, *m* is the mass of the particle, U_{max} is the height of the barrier, and *E* is the energy of the particle. It follows from Eqn. (9) that the probability of the tunnel transition diminishes exponentially with the distance *r*. Thus $A_D = f[\exp(-2r/a)]$ and the type II desensitisation rate constant should therefore depend very greatly on *r*. This approach may serve as one of the explanations of the complex dependence of the hole desensitisation on the structure of the dyes.

The oxidising capacity of holes derived from all the dyes presented in Table 1 is apparently sufficient to accept electrons located on the impurity centres. According to the data of Berriman and Gilman,[59] the electrochemical potential corresponding to the oxidation of the silver film on the AgHal surface is 0.4 V (rel. Ag/AgCl electrode). Thus, even if account is taken of the possibility of a change in $E_{1/2}^{Ox}$ on aggregation of the dyes, all the sensitisers investigated are capable of oxidising the silver particles formed on the impurity centres. The observed difference between the desensitising properties [of the dyes] can be attributed to their different capacities for *J*-aggregation or the consequent different distances *r* between the *J*-aggregate and the IC_e.

Apart from the distance *r*, the frequency factor A_D can be determined by the velocity of the hole within the *J*-aggregate or by the mobility of the dye hole μ. The latter quantity must be related to the structure of the *J*-aggregate and in the first place to the interplanar distance between the dye molecules, their packing angle, and the molecular structure. For a low hole velocity in the aggregate, the probability of the decomposition of the latent image centre is naturally lower than for a high hole velocity. Therefore in a general form we have $A_D = f(r, \mu)$.[53]

III. Selective desensitisation and self-desensitisation of *J*-aggregates

The desensitisation processes should occur also on photoexcitation of dyes. In this case, one is dealing with selective desensitisation in the region of spectral sensitisation, the presence of which has been discussed.[35,66,67] Unfortunately the selective desensitisation of the spectral sensitiser itself, or, in terms of the nomenclature used by James[7] and Shapiro,[25] the self-desensitisation of the dye, cannot be measured directly, since it is impossible to achieve a controlled exposure of the photographic material at the same wavelength without the spectral sensitiser. At the present time, the degree of selective desensitisation is estimated by an indirect method from the influence of compounds introduced additionally on the intrinsic and spectral sensitivities of photographic emulsions. This method has been used to investigate selective type I desensitisation; electron-accepting compounds with a variable electron affinity were introduced into spectrally sensitised layers. It has been shown[57] that selective desensitisation can greatly exceed the intrinsic desensitisation.

One may postulate that experiments on the selective desensitisation of photographic emulsions via additionally introduced *J*-aggregating dyes, in which there is a possibility of the translation of a hole from the main spectral sensitiser, may serve as a definite test for type II self-desensitisation processes. Such a method has been used by the present author and his coworkers.[68]

Compositions comprising highly effective and weakly desensitising dyes combined with dyes which are weakly effective and induce an appreciable desensitisation via the hole mechanism were investigated. The highly effective dyes were compounds **4** and **14**, while the desensitising dyes were compounds **1** and **6** (Table 1). The dyes were introduced at equal concentrations and in a series of experiments the order of their introduction into the composition was varied. Fig. 3 presents spectral sensitivity and absorption curves for layers sensitised by dyes **4** and **1** individually and also by the **1** + **4** composition. According to the absorption spectrum (Fig. 3*a*), the use of a sensitiser composition has little effect on the positions of the absorption bands of the individual dyes (of curves *1*, *2*, and *3*). However, the introduction of the desensitising dye **1** leads to an appreciable suppression of the effectiveness of the spectral sensitisation at the sensitisation maximum of compound **4** (cf. curves *1* and *3*, Fig. 3*b*). The degree of desensitisation in the region of the AgHal absorption also increases under these conditions.

Fig. 4 illustrates the results for the **14** + **1** composition. Two absorption bands with λ_{max} = 518 and 590 nm are characteristic of 9-methylthiacarbocyanine **14**. Different assignments of these bands exist. They have been attributed either to the *H*- or *J*-aggregates respectively or to two spectral transitions in a single *J*-aggregate with a 'parquet' type of structure. According to Reich,[69] the splitting of excited dye levels into two components (S_1^1 and S_1^2) is observed for such molecular packing, where the structure cell contains two dye molecules at an angle close to 90°. Two spectral transitions, $S_0 \rightarrow S_1^1$ and $S_0 \rightarrow S_1^2$, of equal intensity then take place. The addition of dye **1** does not alter the positions of the absorption bands of dye **14** (cf. curves *1* and *3*, Fig. 4*a*), but it suppresses sharply the effectiveness of the sensitisation in bands with λ_{max} = 518 and 590 nm and approximately to the same extent for both bands (cf. curves *1* and *3*, Fig. 4*b*). It is noteworthy that similar results have been obtained for the reverse order of introduction of the dyes into the composition, i.e. **14** + **1** and **4** + **1**. The replacement of the desensitising dye **1** by compound **6** did not alter fundamentally the results—its introduction together with dye **14** diminished the photographic activity of the *J*-aggregates of dye **14**. Thus selective type II desensitisation does indeed take place.

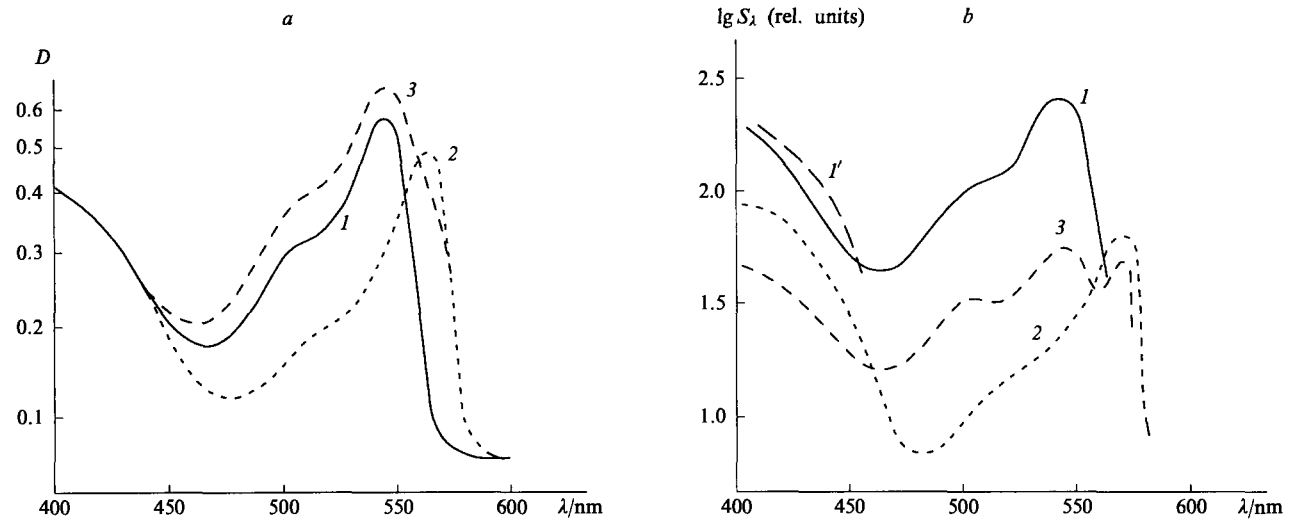

Figure 3. Reflection spectra (*a*) and spectral sensitivity curves (*b*) for AgBr emulsion layers sensitised by dyes **4** (curve *1*) and **1** (curve *2*) and by the **1** + **4** dye composition (curve *3*); (*1'*) layer without dye. AgBr emulsion—cubic crystals, $\bar{l} = 0.17$ μm, (S + Au)-sensitisation; concentration of dyes—2×10^{-4} mol (mol AgBr)$^{-1}$.

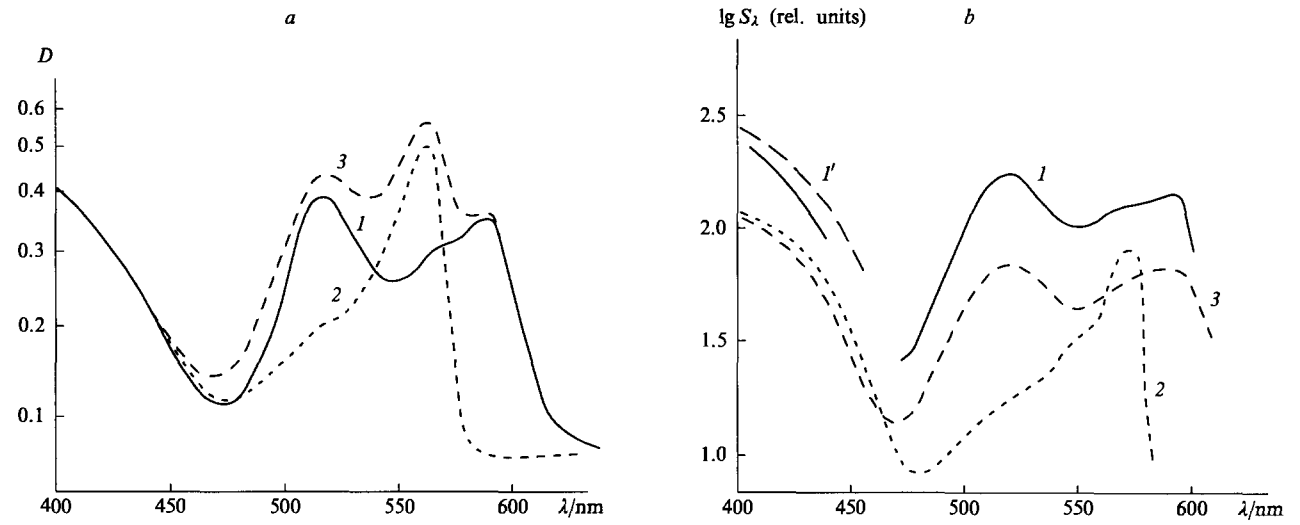

Figure 4. Reflection spectra (*a*) and spectral sensitivity curves (*b*) for AgBr emulsion layers sensitised by dyes **14** (curve *1*) and **1** (curve *2*) and by the **1** + **14** dye composition (curve *3*); (*1'*) layer without dye. Concentration of dyes—2×10^{-4} mol (mol AgBr)$^{-1}$.

The desensitising effect of dyes **1** and **6**, i.e. the decrease in the intrinsic sensitivity of AgHal, is apparently due to the capture of a hole from AgHal, its translation in the *J*-aggregate to the photoelectron capture centre (IC_e), and the recombination of the dye hole with the captured electron (Fig. 2*a*). The large desensitisation effects produced by these dyes (Table 1) may be due to two causes. Firstly, we have the energy-based cause. According to the data in Table 1, $E^{Ox}_{1/2}(\mathbf{1}) = 0.55$ V and $E^{Ox}_{1/2}(\mathbf{6}) = 0.67$ V, i.e. is appreciably lower than the potential corresponding to the upper limit of the AgBr valence band [estimated as 1.26 V on the same electrochemical potential scale (rel. n.c.e.)].[57] Thus the capture of a hole from AgBr by the dye is extremely likely (even when account is taken of the possible change in the energy levels on *J*-aggregation[48,50]). Secondly there is the kinetic cause. The probability of desensitisation may increase owing to contact between the *J*-aggregates of dyes **1** and **6** and the impurity centres—electron acceptors.[49] In the case of the effective dyes **4** and **14**, the lower desensitising effect is to some extent due to energy dependent causes [$E^{Ox}_{1/2}(\mathbf{4}) = 0.93$ V, $E^{Ox}_{1/2}(\mathbf{14}) = 0.77$ V (Table 1)], but it is determined to a large extent by kinetic causes—due to the lower probability of contact between the *J*-aggregates and the impurity centres.

We shall consider the effect of dye compositions. The decrease in the effectiveness of the spectral sensitisation by dyes **4** and **14** following the additional introduction of the desensitiser **1** or **6**, observed by Shapiro et al.,[68] may be a consequence of the decrease in the probability of processes involving the recombination of dye photoelectrons and holes. The use of the second dye is equivalent to a decrease in the distance *r* between the *J*-aggregate and the IC_e, which is illustrated schematically in Figs. 5*a* and 5*b* (see over). According to this scheme, the hole of the first dye (for example, compound **4**) is translocated to the second dye (compound **1**), as a result of which there is a sharp increase in the pre-exponential term A_D in Eqn. (8) and hence in the rate of desensitisation. The translocation of the holes of dyes **4** and **14** to dyes **1** and **6** is possible, since $E^{Ox}_{1/2}(\mathbf{4}, \mathbf{14}) > E^{Ox}_{1/2}(\mathbf{1}, \mathbf{6})$.

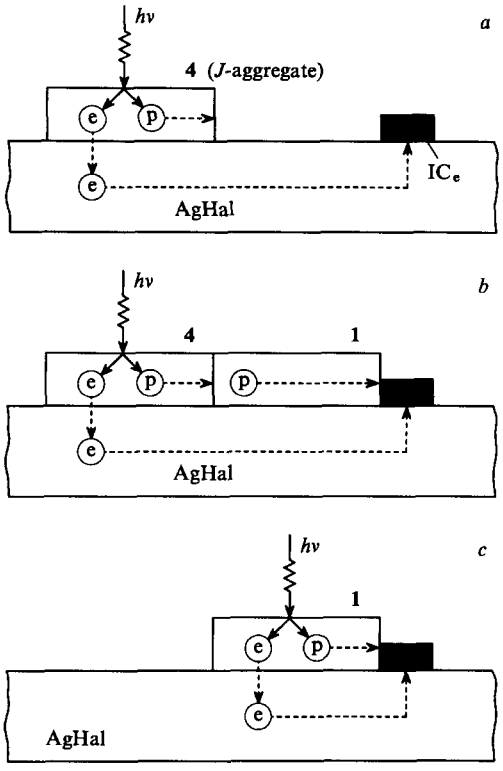

Figure 5. Schematic representation of the selective type (II) desensitisation (*a*, *b*) and self-desensitisation (*c*) of dyes.

According to Fig. 4*b*, the additional introduction of compound **1** has the same influence on the effectiveness of sensitisation in both absorption bands of dye **14** (cf. curves *1* and *3*, Fig. 4*b*), so that one can assume that they indeed belong to the same *J*-aggregate and, according to Reich,[69] both spectral transitions take place from the same ground level S_0. As a result of this, the holes generated under the conditions of both bands have the same energy. In essence, it is the same hole and its transfer through the *J*-aggregate of the second dye is equally probable regardless of the band used for its excitation.

It is essential to bear in mind that the translocation of a hole from one aggregate to another should not always be manifested as desensitisation. One can imagine a situation where, on photoexcitation of a desensitising dye in contact with the impurity centre, on the one hand, and with the *J*-aggregate of another dye, on the other, the hole of the first *J*-aggregate may be captured by the second. For this, it is necessary that Gilman's condition[10] $E_{1/2}^{Ox}(Dy'') < E_{1/2}^{Ox}(Dy')$ should hold. On the other hand, on photoexcitation of the second dye, the *J*-aggregate of the first as it were insulates the hole from IC_e. Thus there is a possibility of the mutual supersensitisation of the dyes. This case is apparently characteristic of the so called cation-anionic dyes containing in their structure two dyes one of which (cationic) has alkyl groups attached to the nitrogen atom of the heterocycle, while the other (anionic) has acid groups. As a rule individual sensitisers have different values of $E_{1/2}^{Ox}(Dy)$. Furthermore, the composition comprising such dyes frequently incorporates the desensitising quinomonomethinecyanine **3** as the orthochromatic sensitiser and one of the effective thiacarbocyanines as the panchromatic sensitiser. The cation-anionic dyes are known[70,71] to be highly effective and photochemically more active than a mixture of individual sensitisers. The explanation of this may be as follows. Since the charge on the individual cyanines is compensated by the counterion, on aggregation the *J*-aggregates of two different dyes need not necessarily be in contact. On the other hand, in the case of cation-anionic dyes contact between oppositely charged *J*-aggregates of the two dyes is more probable and hence there is also a greater probability of the supersensitising transfer of a hole from one aggregate to the other.

It is noteworthy that the processes involving the translocation of a hole from one dye to another should be manifested particularly clearly in direct positive materials. In such materials, the holes oxidise the silver fogging centres generated beforehand and the translation of holes between different dyes should lead not to the desensitisation of the photographic layers but actually to their supersensitisation. Indeed the supersensitisation of the photobleaching of the fogging centres by cyanine dye compositions has been observed.[72] The possibility of the translocation of holes from one dye to another with a lower value of $E_{1/2}^{Ox}$, leading to an increase in the effectiveness of the direct positive process, has been discussed.[73]

Thus the reality of selective type II desensitisation processes has been demonstrated.[68] This can be regarded as an argument in support of the existence of type II dye self-desensitisation processes via a hole mechanism. The probability of this process as well as the type II desensitisation process is determined by the distance *r* between the *J*-aggregate and the IC_e impurity centre of the electron-acceptor type. The self-sensitisation on photoexcitation of the dye (the spectral sensitiser) is particularly probable on contact between the *J*-aggregate and the IC_e (Fig. 5*c*).

It is essential to note that the type II desensitisation process consists of a greater number of stages than the self-desensitisation of the dyes. This condition is illustrated conventionally in Fig. 2 *a*. On photoexcitation of AgHal, some of the holes may be captured by the dye on the surface of the microcrystal with formation of dye holes, whilst others are captured by impurity centres—hole acceptors (IC_p). On the other hand, the type II self-desensitisation process is simpler, since a dye hole inevitably arises on spectral sensitisation, i.e. on transfer of electrons from the photoexcited dye to AgHal (Fig. 5*c*). Thus the number of dye holes may be larger. The probability of self-desensitisation can therefore be also greater than the probability of desensitisation and hence its influence on the spectral sensitivity may exceed that of desensitisation on the intrinsic photosensitivity of the emulsion. This apparently leads to the very pronounced difference between the effectiveness of the spectral sensitisation by dyes **1**—**4** illustrated in Fig. 1 despite the similar maxima and intensities of the absorption bands of the *J*-aggregates. Table 2 presents certain photographic characteristics of the layers sensitised by individual *J*-aggregating dyes.[68] The relative quantum yield of the spectral sensitisation was determined by means of the equation[74]

$$\varphi_r = \frac{A_{410}\, S_\lambda\, 410}{A_\lambda\, S_{410}\lambda}, \qquad (10)$$

where A_{410} and A_λ are the absorption coefficients of the emulsion layer at 410 nm and at the wavelength λ corresponding to the absorption maximum of the dye, while S_{410} and S_λ ($cm^2\,erg^{-1}$) are the photosensitivities of the layer at the corresponding wavelengths. The coefficient φ_r is the ratio of the number of quanta in the regions corresponding to absorption by AgHal (410 nm) and the dye (λ, nm) leading to the same photographic effect—in the given instance to the blackening density $D = 0.5$ over the fogging level.

According to the data in Table 2, dye **1**, which exhibits a desensitising effect, tends to decrease the intrinsic sensitivity of the emulsion (S_{410}). In contrast to dye **1**, dye **3** has little effect on S_{410}, which may be due to the difference between the potentials $E_{1/2}^{Ox}$ (Table 1). The highly effective dyes **2**, **4**, and **14** have virtually no desensitising effect [cf. the degrees of desensitisation (DD) in Table 2]. The quantum yields φ_r for the dyes are comparatively high—0.70 to 0.85, i.e. in order to induce the same effect as that of the 'blue' quantum 1.2—1.4 quanta absorbed by the dye are required. In the case of self-desensitising dyes **1** and **3**, the quantum yields φ_r are significantly smaller (0.40—0.08), i.e. 2.5—12 quanta are now required per 'blue' quantum.

Table 2. Photographic characteristics of layers based on the AgBr emulsion sensitised by individual *J*-aggregating dyes.[68]

Dye	λ_{max}^{sens}/nm	S_{410}^{a}/cm² erg⁻¹	S_{λ}/cm² erg⁻¹	DD	φ_r[a]
Without dye	–	1.2	–	–	–
1	568	0.5	0.4	2.4	0.40
2	577	1.1	1.6	1.1	0.85
3	575	1.1	0.2	1.1	0.08
4	545	1.1	1.6	1.1	0.85
14	518	1.1	0.9	1.1	0.70
	590		0.7		0.70

[a] Calculated on the basis of the criterion $D = 0.5 + D_0$.

Thus the effectiveness of the light quanta absorbed by the sensitiser is much smaller than that of the photons absorbed by the AgHal lattice, the latter being suppressed by desensitisation in the case of dye **1**.

The well known experimentally observed decrease in spectral sensitisation with increase in the concentration of *J*-aggregating dyes above the optimum value can also be accounted for within the framework of ideas concerning the self-desensitisation of dyes. By virtue of the increase in the coating of the surface of the AgHal microcrystals by the *J*-aggregates, the distance *r* between them and the IC_e should decrease and hence the rate of recombination process should increase.

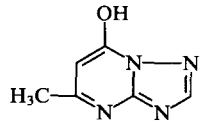
On the basis of the foregoing, one may conclude that the self-desensitisation processes can in essence determine the effectiveness of the spectral sensitisation itself. As a result of the examination of the role of the self-desensitisation processes in the spectral sensitivity of silver halide photographic materials, it has been concluded[25] that the spectral sensitisation of negative silver halide emulsions is determined not by the primary photoreaction but by the kinetics of secondary reactions, i.e. self-desensitisation reactions. The theory of the spectral sensitisation of such materials must therefore be in the first place a theory of the self-desensitisation of dyes. It is noteworthy that this postulate is valid only if desensitisation (and self-desensitisation) via the hole mechanism is included in the concept of desensitisation. Subsequent studies[8,26,47–49,57,68] only increased the author's certainty about the validity of this postulate.

IV. Supersensitisation of *J*-aggregating dyes as inhibition of their self-desensitisation

Within the framework of the mechanism of the spectral sensitisation of *J*-aggregating dyes under discussion, it is possible to consider at least three methods for increasing the effectiveness of the sensitisation, i.e. three supersensitisation methods. They all reduce to the inhibition of the self-desensitisation via the hole mechanism and hence to the inhibition of recombination processes. One of the supersensitisation methods mentioned in the introduction consists, according to Gilman's 'reductive' mechanism,[10,24] in the capture (reduction) of the dye holes by the more readily oxidised organic compound. Thus the supersensitisation conditions already mentioned may be expressed in the form[10]

$$E_{1/2}^{Ox}(S) < E_{1/2}^{Ox}(Dy) .$$

A hole of the *J*-aggregate is then translocated to the supersensitiser (S), loses its mobility, and no longer participates in the recombination processes. Since Gilman's supersensitisation mechanism has already become in essence classical and has been discussed in detail in a number of reviews,[7–13] it will not be considered separately in the present article.



The second supersensitisation method reduces to the insulation of the *J*-aggregates of the impurity centres, which prevents the recombination of the dye holes with the electrons captured by these centres. This 'insulation' mechanism of supersensitisation will be examined in detail below.

The generally acknowledged factors influencing the aggregation of dyes are their structure, the halide composition of the photographic emulsion, the type of faces of the AgHal microcrystals, the concentration of silver ions, the acidity of the medium, and the nature of various substances introduced into the emulsion.[7] Since the self-association of dyes is a process which takes place over a period of time, it is logical to postulate that some of the factors enumerated influence the kinetics of the formation of the ordered structures of the aggregates. On the other hand, the aggregation kinetics can undoubtedly determine the structure of the aggregate — primarily the packing angle of the dye molecules in the aggregate and their number and hence the topography on the surface of AgHal and in particular the distance *r* from the IC_e. The third supersensitisation method consists in the regulation of the *J*-aggregation of the dyes with the aid of organic substances, introduced additionally into the emulsion, which are either adsorbed or not adsorbed on AgHal.

1. The 'insulation' mechanism of supersensitisation

Towards the end of the 1970's, a considerable number of experimental data accumulated according to which the supersensitisation of photographic layers with *J*-aggregating dyes was induced by organic compounds oxidised with greater difficulty than the dyes. Since the principal condition for supersensitisation via Gilman's 'reductive' mechanism was infringed in such cases, it followed naturally that one could deal only with some other supersensitisation mechanisms.

The supersensitising effect of a familiar stabiliser — 4-hydroxy-6-methyl-1,3,3*a*,7-tetraazaindene **18** (the sta-salt) — has been described in greatest detail. It is manifested on emulsions with sulfur sensitisation.[3,9,75–79]

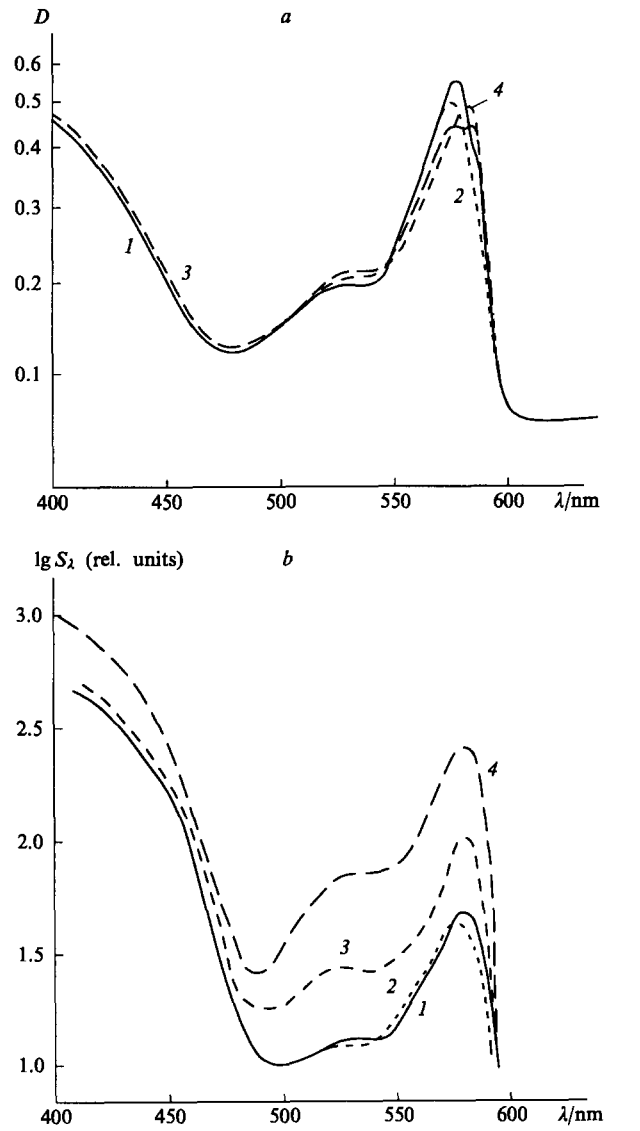
18

The increase in the additional sensitivity induced by certain *J*-aggregating dibenzothiacarbocyanines and unaccompanied by a change in the nature of the absorption centres has been explained[78,79] by the facilitation of the transfer of the energy absorbed by the dye to the AgHal lattice. The effect of various 2- and 5-alkyl derivatives of compound **18** has been investigated.[80] An increase in the intrinsic sensitivity and the preferential growth of the spectral sensitivity of the emulsion were noted. The influence of the compounds on the additional sensitivity is regarded by the authors as the sum of two effects: (1) the influence on the intrinsic sensitivity of the microcrystals because of the deactivation of a number of sensitivity centres following the chemisorption of compound **18** and its derivatives on the impurity centres as a result of which the latter cease to serve as the sites for the capture of electrons;[81] (2) the influence on the state of aggregation of the dye adsorbed on AgHal.

The photographic effect of compound **18** and other tetra- and penta-azaindenes has been investigated in a series of studies by Tani and coworkers.[82–86] It was shown[82] that compound **18** is primarily a chemical sensitiser of monodisperse emulsions with sulfur sensitisation. Various sulfur-containing anti-fogging substances exhibit an influence similar to that of compound **18**.[83] The mechanism of the action of the stabiliser **18** on the intrinsic sensitivity of AgHal is treated as an increase in the depth of the electron traps formed on sulfur sensitisation and a decrease in the number of fine traps on the surface of microcrystals acted upon by the adsorbed tetraazaindene.[85] It is not difficult to see in this interpretation a definite similarity with the concept proposed previously.[80,81] The preferential influence of compound **18** and other supersensitisers on the spectral sensitivity of emulsions with

sulfur sensitisation has been explained[84] by a decrease in the desensitising effect of dyes both due to the increase in the fraction of electrons captured by the sulfide-silver centres at greater depth and due to the decrease in the mobility of the dye holes in the aggregates. In addition, the increase in the rate of electron transfer on fragmentation of the *J*-aggregates by the supersensitiser,[87] similar to that described by West and Carroll,[15] has been considered.

The influence of compound **18** on various *J*-aggregating dyes has been considered in a series of studies by the present author.[8,26,47–49,68] In the first place, the influence of the sta-salt was considered in relation to the repeatedly investigated quino-2,2′-monomethinecyanine **3**. For a monodisperse AgBr emulsion (cubic crystals, $\bar{l} = 0.17$ μm) with sulfur-gold sensitisation it has been shown that a transformation of the *J*-band ($\lambda^{J}_{max} = 575$ nm) is observed under the influence of the sta-salt, namely its hypsochromic shift at low concentrations of compound **18** amounting to $(1-2) \times 10^{-3}$ mol (mol AgBr)$^{-1}$, the appearance of two absorption bands ($\lambda^{J_1}_{max} = 570$ nm, $\lambda^{J_2}_{max} = 581$ nm) with increase in the concentration of compound **18** to $(2-5) \times 10^{-3}$ mol (mol AgBr)$^{-1}$, and finally the appearance of one long-wavelength J_2 band at a concentration equal to or greater than $(8-10) \times 10^{-3}$ mol (mol AgBr)$^{-1}$ (Fig. 6). According to Fig. 6*b*, the content of compound **18** does not induce the growth of the photographic activity of the J_1-aggregates (cf. curves *1* and *2*, Fig. 6*b*) but it does supersensitise the J_2-aggregates. It is noteworthy that the nature of the aggregation and the effectiveness of the supersensitisation depend to a large extent on the order in which the supersensitiser and the dye are introduced. When compound **18** is introduced before the dye, the maximum supersensitisation effect and subsequent formation of the J_1- and J_2- aggregates are observed; when compound **18** is introduced after the dye, the effectiveness of the supersensitisation is reduced sharply and is accompanied by a slight transformation of the *J*-band.[47] The influence of the order in which compound **18** is introduced on the aggregation has been noted also in another study.[76]



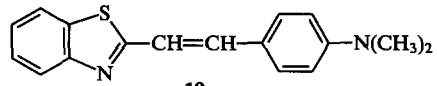


Figure 6. Reflection spectra (*a*) and spectral sensitivity curves (*b*) for AgBr emulsion layers sensitised by dye **3** [2×10^{-4} mol (mol AgBr)$^{-1}$] without a supersensitiser (curve *1*) and with the supersensitiser **18** at different concentrations [10^{-3} mol (mol AgBr)$^{-1}$]: (*2*) 1.0; (*3*) 4.0; (*4*) 8.0; emulsion with (S + Au)-sensitisation.

It has been shown[47] that the introduction of the supersensitiser 2-(*p*-dimethylaminostyryl)benzothiazole **19**, which is traditional for dye **3** and which operates via Gilman's 'reductive' mechanism, into spectrally sensitised layers containing various amounts of compound **18** does not alter the nature of the absorption spectra.

19

It is striking that the supersensitising effect of compound **19** on layers with J_1-aggregates is significantly smaller than the effect on the *J*-aggregates of dye **3** without compound **18** (cf. curves *5* and *6*, Fig. 7), while on layers with J_2-aggregates an additional supersensitisation effect was observed (cf. curves *3* and *7* and curves *4* and *8* in Fig. 7).

Table 3 presents the calculated relative quantum yields of the spectral sensitisation of the photographic layers investigated.[47] It follows from the data in Table 3 that, at low concentrations of compound **18**, whereupon J_1-aggregates are formed preferentially, there is virtually no supersensitising effect of compound **19**. On the other hand, at higher concentrations of compound **18**, in the region where J_2-aggregates are formed, a superadditive effect of compounds **18** and **19** is observed. In this case, $\Delta\lg S_\lambda^{18+19} \approx \Delta\lg S_\lambda^{18} + \Delta\lg S_\lambda^{19}$, and $\varphi_r^{18+19} > \varphi_r^{18} + \varphi_r^{19}$. These data led to the conclusion[47] that the superadditive effect may serve as definite evidence for the different mechanisms of the supersensitisation of the layers by compounds **18** and **19**.

Table 3. The influence of the supersensitisers **18** and **19** on the relative quantum yield of the spectral sensitisation of the photolayers sensitised by quino-2-monomethinecyanine **3** [2×10^{-4} mol (mol AgBr)$^{-1}$].[47]

Supersensitiser	$10^3 c$/mol (mol AgBr)$^{-1}$ [a]	φ_r [b]			Nature of *J*-aggregation[c]
		λ_{570}	λ_{575}	λ_{581}	
–	–	0.02	0.02	0.02	*J*
18	2.0	0.03	0.02	0.03	J_1
18	5.0	0.09	0.11	0.16	J_1+J_2
18	20.0	0.19	0.21	0.19	J_2
19	0.02	0.23	0.22	0.20	*J*
18+19	2.0+0.02	0.04	0.04	0.04	J_1
18+19	5.0+0.02	0.36	0.44	0.53	J_1+J_2
18+19	20.0+0.02	0.49	0.69	0.55	J_2

[a] *c* = supersensitiser concentration.
[b] Calculated on the basis of the criterion $D = 0.2 + D_0$.
[c] AgBr emulsion with (S + Au)-sensitisation.

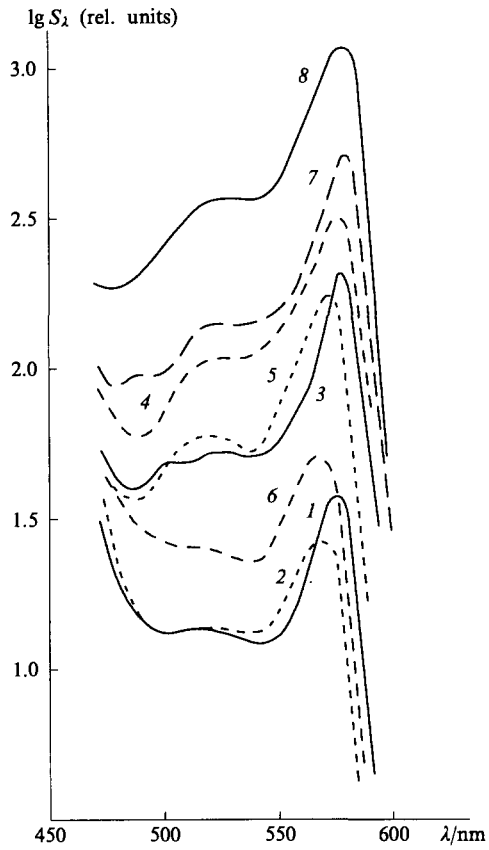

Figure 7. Spectral sensitivity distribution curves for AgBr emulsion layers sensitised by dye **3** [2 × 10^{-4} mol (mol AgBr)$^{-1}$] without a supersensitiser (curve *1*) and with the supersensitiser **18** at different concentrations [10^{-3} mol (mol AgBr)$^{-1}$]: (*2*) 2.0; (*3*) 5.0; (*4*) 20.0; emulsions sensitised by dye **19** at a concentration of 2 × 10^{-5} mol (mol AgBr)$^{-1}$ (curve *5*); emulsion sensitised by the **18** + **19** composition at different concentrations [mol (mol AgBr)$^{-1}$]: (*6*) 2 × 10^{-3} and 2 × 10^{-5}; (*7*) 5 × 10^{-3} and 2 × 10^{-5}; (*8*) 20 × 10^{-3} and 2 × 10^{-5}; emulsion with (S + Au)-sensitisation.

It is striking that the photographic effect of compound **18** on the same AgBr emulsion but without chemical sensitisation is completely different despite the similar influence of compound **18** on the transformation of the *J*-bands of aggregates of dye **3**. At low concentrations of compound **18** [$\leqslant$ 2 × 10^{-3} mol (mol AgBr)$^{-1}$], a slight increase in the photographic sensitivity of the layer is observed in the region of absorption by the J_1-aggregates, but, as the content of compound **18** rises and J_2-aggregates are formed, a decrease in the effectiveness of the dye is observed. This is illustrated in Fig. 8, from which it also follows that aminostyrylbenzothiazole **19** supersensitises the *J*-aggregates of dye **3** regardless of its chemical sensitisation (cf. curves *1* and *5*, Fig. 8*b*). Thus the photographic effect of compound **18** is due to at least three causes: (a) the adsorption of compound **18** on the AgBr surface before the adsorption of the dye, (b) the presence of the products of the sulfur-gold sensitisation, and (c) the type of the *J*-aggregate.

The effect of the sensitiser **18** has been investigated[49] for a series of *J*-aggregating dyes of different structure: imidacarbocyanines **1**, **2**, **6**, and **7**, thiacarbocyanines **9**, **11**, **12**, **14**, and **15**, and oxacarbocyanine **4**. It is striking that the greatest photographic effect of compound **18** is observed on photographic emulsions sensitised by aggregating dyes, which gives rise to appreciable desensitisation (compounds **1**, **6**, **9**, and **15**). For dyes similar to quinomonomethinecyanine **3**, after the introduction of compound **18** a hypsochromic shift of the absorption *J*-bands is observed initially, then their bathochromic shift, and finally, at concentrations [**18**] $\geqslant$ 10^{-2} mol (mol AgHal)$^{-1}$ (except for compound **15**) there is again a hypsochromic shift of the *J*-band. On formation of long-wavelength J_2-aggregates under the influence of compound **18**, there is an appreciable decrease in the degree of desensitisation and there is a sharp jump in the additional photosensitivity. For example, for dye **6**, the supersensitisation coefficient is K_s = 20. Under these conditions, K_s significantly exceeds the change in the degree of desensitisation. For the highly effective and less desensitising dyes **2**, **7**, **12**, **14**, and **4**, for which only a slight hypsochromic shift of the *J*-band under the influence of the stabiliser **18** is observed, the decrease in the degree of desensitisation leads to an increase in the additional sensitivity of similar magnitude. The significantly greater value of K_s relative to the change in the degree of desensitisation for dyes **1**, **6**, **9**, and **15** has

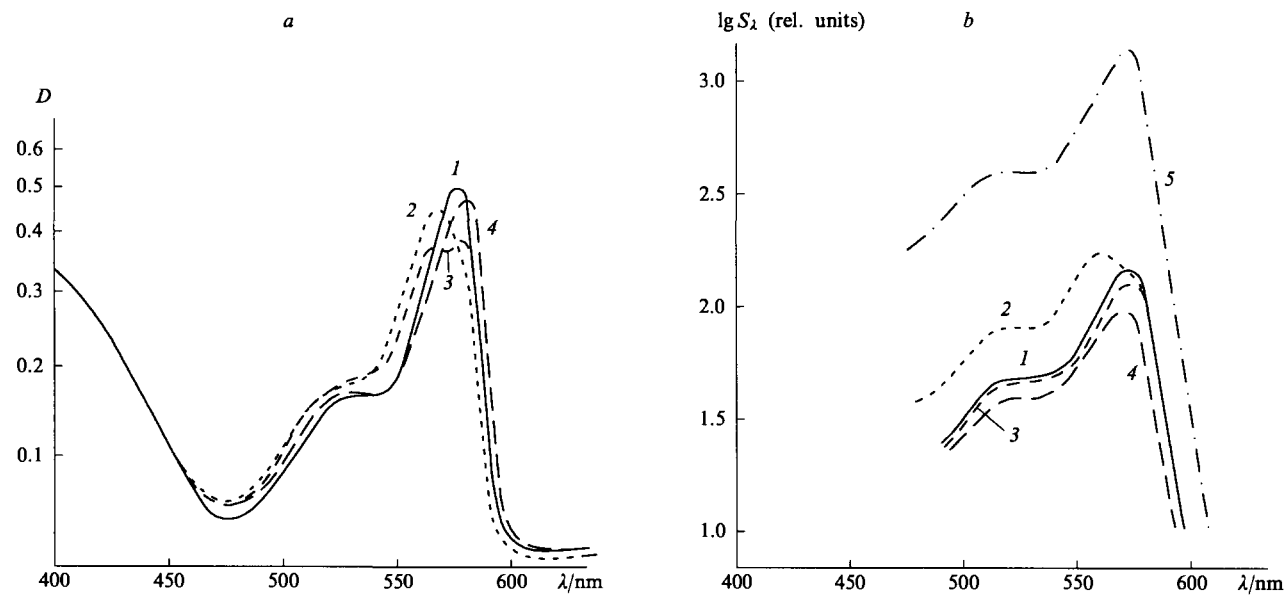

Figure 8. Reflection spectra (*a*) and spectral sensitivity curves (*b*) for AgBr emulsion layers sensitised by dye **3** [2 × 10^{-4} mol (mol AgBr)$^{-1}$] without a supersensitiser (curve *1*) and with the supersensitiser **18** at different concentrations [10^{-3} mol (mol AgBr)$^{-1}$]; (*2*) 1.0; (*3*) 5.0; (*4*) 20.0; with the supersensitiser **19** at a concentration of 2 × 10^{-5} mol (mol AgBr)$^{-1}$ (curve *5*); emulsion without chemical sensitisation.

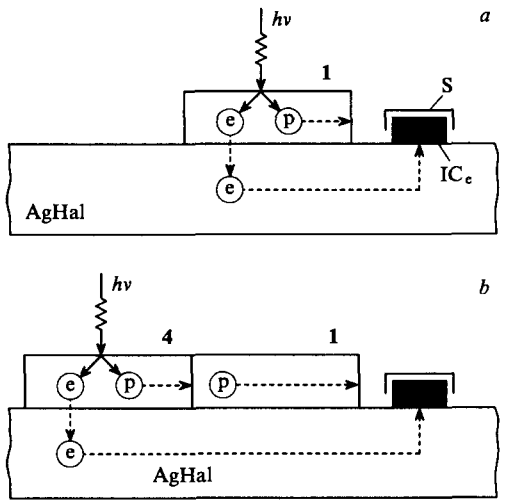
been considered[49] as additional evidence for the difference between the processes involving the desensitisation of AgHal by dyes and the self-desensitisation of the dyes. If this is so, then the inhibition of the self-desensitisation by compound **18** should affect the spectral sensitivity of the emulsion to a greater extent than its intrinsic sensitivity.

The effect of the stabiliser **18**, manifested on AgHal emulsions with chemical sensitisation, has been explained by the formation of an 'insulating' layer between the *J*-aggregates and the impurity centres (IC_e) — the products of the sulfur-gold sensitisation. This layer, comprising molecules of the supersensitiser (S), should prevent the recombination of the dye holes with the electrons captured by the IC_e, which is illustrated schematically in Fig. 9*a*. The formation of the layer between the products of the sulfur sensitisation and the dye should be promoted by the known preferential adsorption of compound **18** on Ag_2S compared with AgHal.[88] The formation of such a layer between the dye *J*-aggregates and the silver sulfide clusters has been demonstrated by the luminescence method.[89,90] It has been established[91–93] that the sulfur sensitisation of silver halide emulsions is accompanied by the appearance of a low-temperature luminescence in the near infrared. The sulfide-silver clusters of the type $(Ag_2S)_n$ or $(Ag_2S)_n.Ag_m$ generated during chemical sensitisation, are responsible for the above luminescence, the position of the luminescence band in the spectrum depending on the value of n.[93,94] Belous and Tolstobrov[95] observed that the absorption of light by the dye *J*-aggregate adsorbed on silver sulfide in the dye–Ag_2S cluster system diminishes the intensity of the luminescence of the Ag_2S cluster in the IR region of the spectrum.



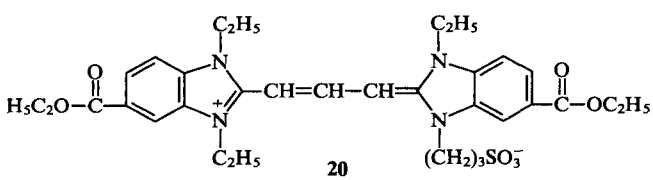


Figure 9. Schematic representation of the 'insulation' supersensitisation mechanism involving the inhibition of the type (II) self-desensitisation (*a*) and the selective desensitisation by compositions comprising *J*-aggregating dyes (*b*).

Fig. 10 presents the dependence of the luminescence intensity I of the silver sulfide clusters on the exciting light wavelengths λ_e.[90] The Ag_2S clusters were spectrally sensitised by dye **3** and 3-{2-[3-(5-ethoxycarbonyl-1,3-diethyl-2,3-dihydrobenzimidazol-2-ylidene)prop-1-enyl]-5-ethoxycarbonyl-1-ethylbenzimidazol-3-yl}propanesulfonate **20**.

20

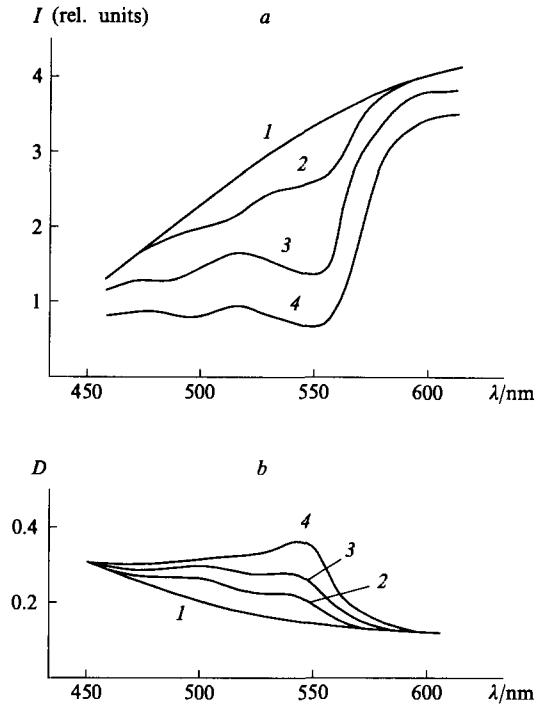

Figure 10. Dependence of the intensity of IR luminescence on the incident light wavelength (*a*) and the spectral distribution of the absorbances (*b*) of gelatine layers containing Ag_2S clusters and compound **18**. Dye concentration (10^{-4} M): (*1*) 0; (*2*) 0.1; (*3*) 0.25; (*4*) 0.5.

According to Fig. 10, as the *J*-aggregates of the dyes are formed, a decrease in I is observed. The decrease was explained by the Fano antiresonance effect[96] due to the interference of the excited state of the dye and Ag_2S, which may lead to the observation of a sharp decrease in the absorption coefficient within narrow spectral regions. A similar decrease in the luminescence intensity of the Ag_2S clusters (with λ_{max} = 800 nm), formed on sulfur sensitisation of monodisperse AgBr emulsions with cubic microcrystals, occurred on excitation by light corresponding to the absorption band of the *J*-aggregates of different dyes.[89,90] Fig. 11*a* illustrates the decrease in the intensity of the IR luminescence of Ag_2S clusters at the wavelength of the band due to the *J*-aggregate of dye **20**. A similar pattern has been observed also for other *J*-aggregating dyes.[90]

A necessary condition for the manifestation of the antiresonance, apart from the energy correspondence between the excited levels of the dye and the Ag_2S clusters, is also direct contact of the sensitiser with the impurity centre. The luminescence method therefore makes it possible to establish unambiguously the occurrence of the direct interaction of the dyes with the chemical sensitisation products. An increase in the distance between the cluster and the dye should entail a sharp decrease in the antiresonance and hence an increase in the intensity of the sensitised luminescence of the Ag_2S cluster. Experiments[89,90] have shown that the introduction of compound **18** weakens the decrease in I caused by the antiresonance (Fig. 11*b*) and, at concentrations exceeding 0.1 g per litre of the emulsion, a typical case of sensitised luminescence can be recorded. A similar pattern has been observed when the Ag_2S and dye aggregates were separated by AgBr shells grown on the AgBr microcrystal after sulfur sensitisation and before the introduction of the dye (Fig. 11*c*). Thus comparison of the data presented permits the conclusion that compound **18** does indeed ensure the spatial insulation of the dye from the Ag_2S clusters and the explanation of the photographic effect of this compound may be the inhibition by the above 'insulating' layer of the secondary reactions involving the oxidation of the photographically active centres by the dye

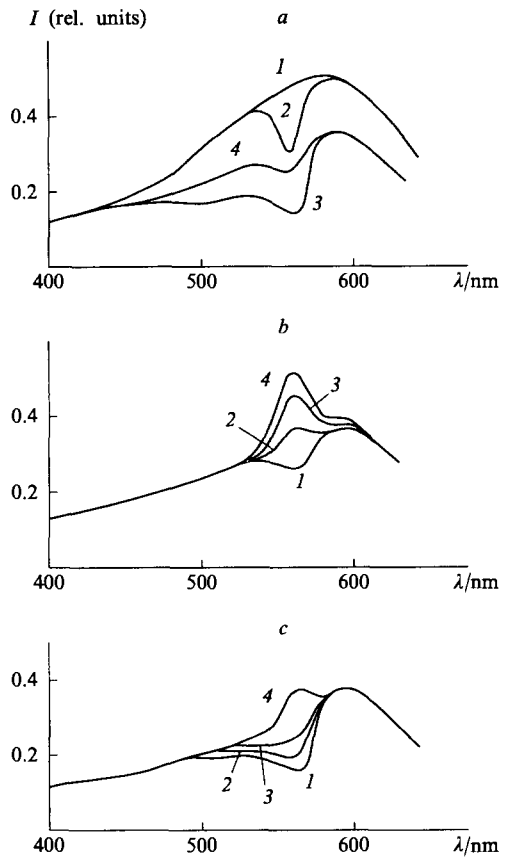

Figure 11. Dependence of the luminescence intensity of the sulfur-sensitised AgBr emulsion with λ_{max} = 800 nm on the wavelength of the light incident on layers sensitised by dye **20** [10^{-4} mol (mol AgBr)$^{-1}$]: (*a*) without a dye (curve *1*); with the dye at concentrations of 0.1 (curve *2*), 0.6 (curve *3*), and 1.0 mol (mol AgBr)$^{-1}$ (curve *4*): (*b*) with the dye and the supersensitiser **18** at concentrations of 0 (curve *1*), 0.1 (curve *2*), 0.3 (curve *3*), and 0.8 g litre^{-1} (curve *4*); (*c*) with the dye at a concentration of 6 × 10^{-5} mol (mol AgBr)$^{-1}$; thickness of the AgBr shell on the microcrystals (Å): (*1*) 0; (*2*) 10; (*3*) 15; (*4*) 30. holes (Fig. 9*a*). Evidence for the insulation of the dye from the impurity centres is provided by the experiments, mentioned above, designed to elucidate the influence of the order of the introduction of compound **18** into the emulsion on the photographic and spectral characteristics of the photolayers. When compound **18** is introduced before the dye, the adsorption of the supersensitiser on the Ag_2S centres and hence their insulation from the dye *J*-aggregates are more likely. When the dye is introduced first, the *J*-aggregates apparently come into contact with the Ag_2S centres and the subsequent addition of compound **18** now has little influence on the state of the dye and its photographic effect.

The question arises of the cause of the different photographic effects of compound **18** on the dye J_1- and J_2-aggregates and in particular on the *J*-aggregates of quinomonomethinecyanine **3**. When the light quanta absorbed by the *J*-aggregates of dye **3** are of similar magnitude ($\Delta h\nu$ = 0.04 eV), this difference may be a consequence of the different oxidising capacities of the holes, which are determined both by the positions of the highest occupied electronic levels of the aggregates ε_{ho} (the energy factor) and by the length of the associated dye species and their proximity to the impurity centres (the frequency factor). An attempt to determine the position of the energy levels of the *J*-aggregates of dye **3** has been undertaken [48] using photographic and luminescence methods for the purpose. The difference between the oxidising capacities of the J_1- and J_2-aggregates has been demonstrated in a study of the photochemical oxidation of the latent image centres generated by the preliminary exposure to light of the AgBr emulsion with sulfur-gold sensitisation. *N,N'*-Dimethyl-4,4'-bipyridylium dichloride (methylviologen) was used as the photoelectron acceptor. The J_1- and J_2-aggregates were formed by the procedures described above with the aid of the stabiliser **18**. Fig. 12 presents the corresponding spectrograms. The photochemical oxidation of the latent image is most effective in layers which do not contain or contain only small amounts of compound **18**, i.e. in the presence of J_1-aggregates (Figs 12*b* and 12*c*). Photobleaching is then most pronounced in the region of the absorption maximum of the J_1-aggregates at 570 nm. On raising the concentration of compound **18**, i.e. with increase in the amount of J_2-aggregates, the effectiveness of the photobleaching falls (Figs 12*d*, 12*e*, and 12*f*). It is striking that in the region of the absorption by the J_2-aggregate (λ = 581 nm) the extent of photobleaching diminishes sharply and then is not observed at all. Furthermore, a negative image is produced (Figs 12*d* and 12*e*). The formation of the J_2-aggregate is accompanied by a decrease in the extent of photobleaching by the light corresponding to the intrinsic absorption band of AgBr (λ < 400 nm, cf. Figs 12*a* and 12*c* and Figs 12*d*, 12*e*, and 12*f*). At concentrations of compound **18** greater than 10^{-2} mol mol^{-1} AgBr, at which new J_2'-aggregates are formed (λ = 578 nm), the effectiveness of the bleaching again increases (Figs 12*g* and 12*h*). Thus the oxidising capacity of the holes of the J_1-aggregate is greater than that of the holes of the J_2-aggregate; the J_2'-aggregate apparently occupies an intermediate position.

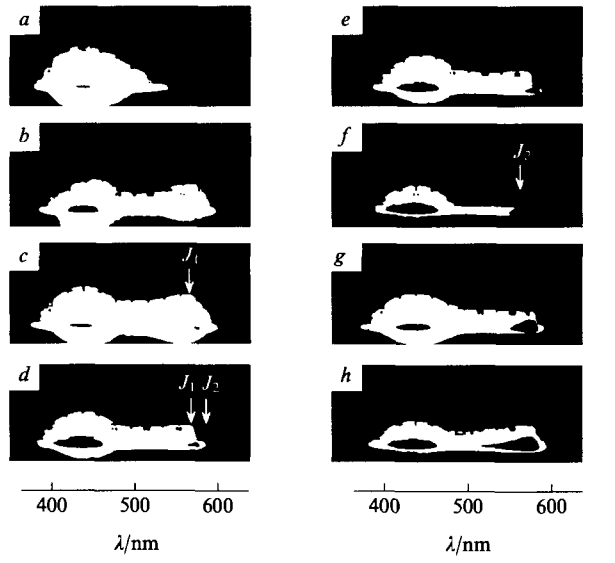

Figure 12. Photobleaching sensitisation spectra for AgBr emulsion layers without a dye (*a*), spectrally sensitised by dye **3** [2 × 10^{-4} mol (mol AgBr)$^{-1}$] without a supersensitiser (*b*), and with the supersensitiser **18** introduced before the dye at different concentrations [10^{-3} mol (mol AgBr)$^{-1}$]: (*c*) 2; (*d*) 4; (*e*) 5; (*f*) 9; (*g*) 10; (*h*) 20; emulsion with (S + Au)-sensitisation exposed beforehand to light until the attainment of a fogging level D_0 = 2.0; methylviologen concentration 7.5 × 10^{-4} mol (mol AgBr)$^{-1}$.

The question arises why the stabiliser **18** layer does not protect the latent image centres from the holes of the J_1- and J_2'-aggregates but prevents their oxidation by the holes of the J_2-aggregates. One of the explanations may be that the position of the ε_{ho} level of the J_1-aggregate is adequate for the injection of the hole directly into the silver halide, as a result of which the insulation of the J_1-aggregates from the impurity centres cannot significantly inhibit the recombination of the electrons captured by the traps in AgBr with the holes which have also been injected into AgBr. Experiments, using Gilman's method, [10] on the supersensitisation of these aggregates by the additionally introduced

carbocyanine dyes with different polarographic potentials $E_{1/2}^{Ox}$ varied in the range 0.54–0.98 V (in methanol, rel. n.c.e.) were carried out in order to characterise the disposition of the ε_{ho} levels of the J_1- and J_2-aggregates of dye **3** relative to one another and relative to the AgBr valence band. It was shown[48] that, in the case of the J_1-aggregates of dye **3**, the supersensitising dyes do not affect the spectral sensitivity over the entire range of $E_{1/2}^{Ox}$. For layers containing J_2-aggregates, a distinct supersensitisation effect is observed (Fig. 13). This is consistent with data[47] indicating the different supersensitising effects of the traditional supersensitiser 2-(*p*-dimethylaminostyryl)-benzothiazole **19** on the J_1- and J_2-aggregates of compound **3** (Table 3). For layers with J_2-aggregates over a certain range of $E_{1/2}^{Ox}(S)$, a nearly linear dependence of the logarithm of the supersensitisation coefficients lg K_s on $E_{1/2}^{Ox}(S)$ is observed (Fig. 13). For a potential $E_{1/2}^{Ox}(S) \geqslant 0.82$ V, there is no supersensitisation effect and this value was therefore chosen as a characteristic of the position of the ε_{ho} level of the J_2-aggregate. The conclusion that the ε_{ho} level of the J_1-aggregate is deeper (by 0.10–0.15 eV) than the ε_{ho} level of the J_2-aggregate was reached on the basis of experiments on the quenching of the fluorescence of the aggregates by the same supersensitising dyes.[48] The ε_{vb} level of the J_1-aggregates was estimated in terms of the potential $E_{1/2}^{Ox}(J_1) \approx 0.9-0.95$ V. If one assumes, in conformity with the data of Mikheeva et al.,[57] that the potential of the top of the valence band of AgBr is $E_{vb} = 1.26$ V (rel. n.c.e.), then, in conformity with the data of Shapiro et al.,[48] the time required for the injection of a hole from the J_1-aggregate into the valence band of AgBr is $\tau = 10^{-7}$ s. For the J_2-aggregate, this time is much longer ($\sim 10^{-4}$ s). Thus the injection of a hole from the J_1-aggregate of dye **3** into AgBr is entirely probable.

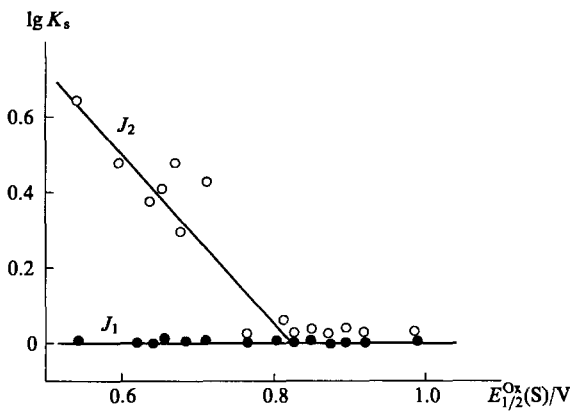

Figure 13. Dependence of the logarithm of the supersensitisation coefficient (lg K_s) for AgBr emulsion layers spectrally sensitised by dye **3** [2×10^{-4} mol (mol AgBr)$^{-1}$] in the J_1- and J_2-states on the potential $E_{1/2}^{Ox}$ of the supersensitiser dyes [4×10^{-6} mol (mol AgBr)$^{-1}$].

In view of the foregoing, it is important to revise the conditions for the supersensitisation via Gilman's 'reductive' mechanism. When rapid injection of holes from the *J*-aggregate into AgHal is possible, supersensitisers satisfying Gilman's condition $E_{1/2}^{Ox}(S) < E_{1/2}^{Ox}(Dy)$ may have insufficient time to capture a dye hole owing to kinetic limitations. The conditions for supersensitisation via the 'reductive' mechanism have been expressed[48] in the form 0.8 V $> E_{1/2}^{Ox}(S) < E_{1/2}^{Ox}(Dy)$.

Thus a dual influence on the spectral sensitisation processes is characteristic of the hydroxy-derivative of tetraazaindene **18**. This compound promotes the formation of *J*-aggregates of certain types. It has been noted[63] that the formation of the dye *J*-aggregates begins on defects and primarily on AgHal surface steps. The rate of formation of aggregates is then higher and their size is smaller (absorption at shorter wavelengths) on the more defective (111) surface than on the (100) surface. The influence of surface defects on the formation of *J*-aggregates has been fully accounted for from the standpoint of the initiation of a regular structure such as the *J*-aggregate.[7] Apparently the stage involving the initiation of aggregates, requiring a definite activation energy, determines to a large extent the aggregation process itself. Surface defects diminish its energy.

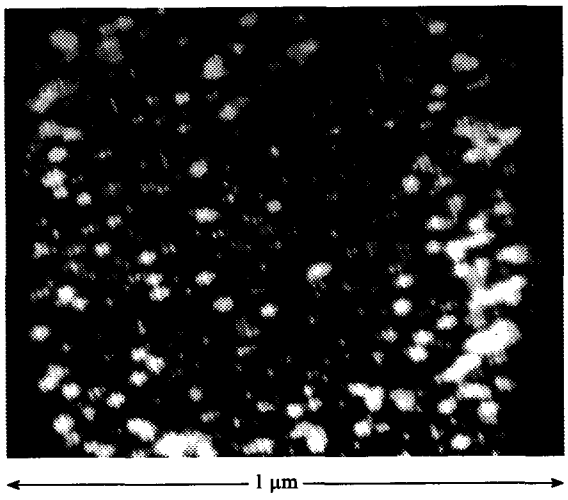
One should recall that surface defects are the sites at which impurity centres are located, including photosensitivity centres formed in the sulfur sensitisation process.[7] One may assume that the introduction of compound **18** at low concentrations leads to the insulation of a comparatively small number of 'deep' defects by the molecules of compound **18** adsorbed on them and that *J*-aggregates are formed on a large number of 'fine' surface defects, which leads to the formation of the smaller J_1-aggregates. We may note that without compound **18** *J*-aggregates are formed on both 'deep' and 'fine' defects, which is the reason for the appearance of a single band with $\lambda_{max} = 575$ nm, arising as a consequence of the superposition of the absorption bands due to at least two *J*-aggregates.

On further increase in the concentration of compound **18**, the tetraazaindene molecules are adsorbed also on finer defects as a result of which the number of these defects diminishes, which promotes the formation of the larger J_2-aggregates. Finally, for a still higher content of compound **18**, the defectiveness of the surface diminishes so much that new J_2'-aggregates are formed on a larger number of surface sites—defects of another type. Thus the stabiliser **18** is a regulator of the defectiveness of the AgHal surface and hence a regulator of the aggregation of the dye.

As a consequence of the causes discussed above, the stabiliser **18** influences the energy levels of the *J*-aggregates. The observed changes in the energy levels of the *J*-aggregates of the same dye either depend on the different numbers of molecules combined in the aggregate or may be determined by the angle of inclination of the molecules in the aggregate.[7] As a rule, an increase in the number of molecules and a decrease in the angle of inclination lead to a bathochromic shift of the absorption owing to the increased length of the delocalised π-system. If the main cause of the difference between the properties of the *J*-aggregates is the number of molecules in the aggregate, then this can be regarded as evidence for a small number of structural elements entering into the polymer, since only in this case should one expect a significant difference between the energetics of the aggregates on increase in their size. This agrees, in particular, with the conclusions reached in studies[97,98] in which *J*-aggregates comprising four dye molecules were considered. *J*-Aggregates consisting of tens or several tens of molecules have been considered in the literature.[7,99]

Fig. 14 presents a photomicrograph of luminescing *J*-aggregates of oxacarbocyanine on a real cubic 1 μm AgBr crystal.[100] It follows from the figure that, at the dye concentrations employed in practice, the *J*-aggregates are preferentially extended in one direction and their size is small.

The lower photographic effectiveness of the J_1-aggregates in the negative process compared with the J_2-aggregates[47] is determined by the deeper disposition of both the highest occupied level ε_{ho} and the lowest unoccupied level ε_{lu} (since the J_1- and J_2-aggregates absorb approximately the same energy). A consequence of the deepening of the ε_{ho} level is the injection of holes into the valence band of AgHal and an increase in the probability of secondary recombination processes, including, as shown by Shapiro and his coworkers,[48] the oxidation of the latent image centres. Owing to the high rate of injection of holes into AgHal, under these conditions the supersensitisers operating in accordance with Gilman's mechanism are apparently unable to capture a dye hole. According to luminescence data,[48,101] the ε_{lu} levels of the *J*-aggregates of dye **3** are located under the conduction band of AgBr. A decrease in the ε_{lu} level in the J_1-aggregate therefore reduces also the probability of the photochemical reduction of AgHal via electron transfer either to the conduction band or to the surface capture levels. Despite the absence of the direct injection of holes from the J_2-aggregate into



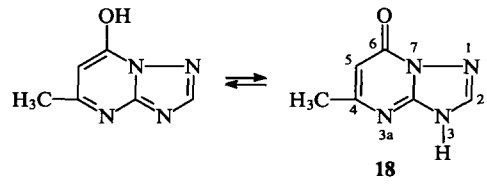


Figure 14. Photomicrograph of luminescing *J*-aggregates of oxacarbocyanine on a 1 μm cubic AgBr microcrystal.

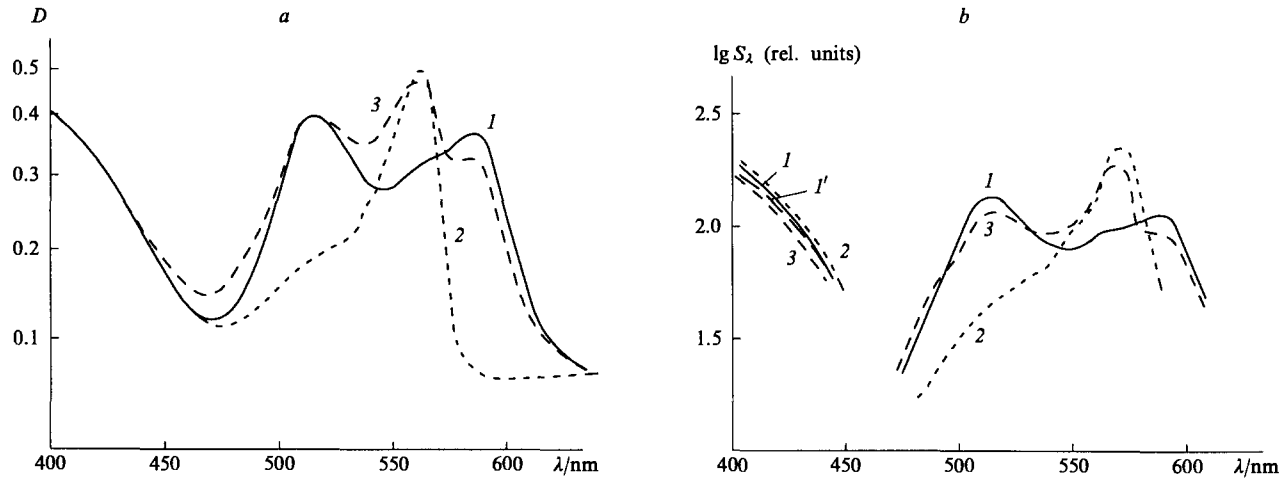
the valence band of AgBr and the higher location of ε_{lu}, the photographic effectiveness of these aggregates is also low in the absence of compound **18**.[47] This indicates the occurrence of secondary reactions involving the recombination of photoelectrons and holes without the participation of the valence band of AgBr. As already noted, the recombination reactions or dye self-desensitisation processes proceeding via a hole mechanism[8,25,26] are apparently determined to a large extent by the presence of direct contact between the *J*-aggregates and the impurity of sulfide-silver centres (Fig. 5*c*). This contact may be a consequence of the localisation of the impurity centres on the surface defects, i.e. the sites where *J*-aggregation begins. Another possible cause is increased adsorption of the dyes on the Ag_2S centres themselves.

Owing to the specific adsorption on Ag_2S, the stabiliser **18** insulates the J_2-aggregates from the impurity centres and hence inhibits the self-desensitisation reactions of the dyes in accordance with the scheme in Fig. 9*a*. Additional evidence in support of the 'insulation' mechanism has been obtained in experiments on the inhibition by compound **18** of the type II selective desensitisation caused by the use of compositions comprising two *J*-aggregating dyes,[68] which was considered in Section III (see Figs. 3 and 4). If the selective desensitisation is associated, in conformity with Fig. 5*b*, with the translation of a hole of the highly effective dye **4** through the *J*-aggregate of dye **1** in contact with the IC_e and hence with the increase in the probability of the recombination processes at the IC_e, then the insulation of the impurity centres in the *J*-aggregates should sharply diminish the selective desensitisation. Indeed it has been shown[68] that the introduction of the sta-salt before the introduction of the **1** + **4** and **1** + **14** dye compositions suppressed the selective desensitisation to a large extent at wavelengths corresponding to the absorption bands of dyes **4** and **14** (Fig. 15). It follows from a comparison of Figs. 4 and 15 that, in the presence of compound **18**, a sharp increase in sensitivity is observed at the wavelengths corresponding to both absorption bands of dye **14** (λ_{max} = 518 and 590 nm) despite the presence of dye **1** in the photographic layer (cf. curves *3* in Figs. 4*b* and 15*b*). This constitutes another piece of evidence indicating that these bands belong to the same dye *J*-aggregate. A similar picture has been observed for the **6** + **14** dye composition. It is striking that the supersensitisation effect at the wavelengths corresponding to the bands of dyes **14** and **4**, estimated in terms of K_s, is close to the selective desensitisations (SD_λ),[68] on the basis of which one may conclude that the supersensitisation is definitely associated with the inhibition of the selective desensitisation and in the general case with the self-desensitisation of the dye. Thus the translation of a hole of one dye through the *J*-aggregate of another becomes ineffective probably owing to the insulation of the *J*-aggregates from the impurity centres, which is illustrated schematically in Fig. 9*b*.

The question arises what determines the specific adsorption of compound **18** on the sulfide-silver centres which imparts unique properties to this stabiliser and supersensitiser. In order to discover the structural element in the molecule of compound **18** promoting the 'insulating' effect, model experiments were performed with heterocyclic compounds having structural elements in common with the sta-salt.[102] The structural formulae of some of them are presented below.

18



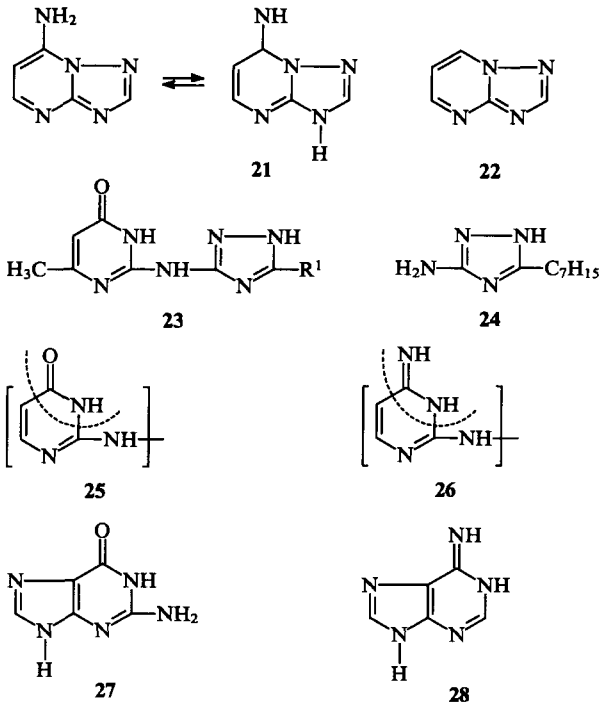


Figure 15. Reflection spectra (*a*) and spectral sensitivity distribution curves (*b*) for AgBr emulsion layers containing the supersensitiser **18** and sensitised by dyes **14** (curve *1*) and **1** (curve *2*) and the **1** + **14** dye composition (curve *3*); (*1'*) layer without dye. Concentration of compound **18**—8 × 10^{-3} mol (mol AgBr)$^{-1}$; concentration of dyes—2 × 10^{-4} mol (mol AgBr)$^{-1}$.

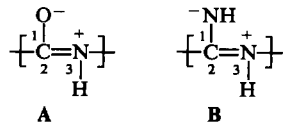
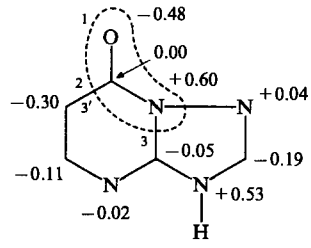
The structural formula with a carbonyl oxygen atom is best justified for compound **18**.[103,104] The study was carried out on fine-grain monodisperse AgBr emulsion [cubic crystals, $\bar{l}$ = 0.17 μm, (S + Au)-sensitisation spectrally sensitised by dye **1**; dye concentration 2 × 10^{-4} mol (mol AgBr)$^{-1}$]. According to the results presented above, the *J*-aggregates of this dye are appreciably supersensitised by compound **18**. The concentration of the substances introduced into the emulsion before the dye was varied over a wide range [from 10^{-4} to 10^{-2} mol (mol AgBr)$^{-1}$].



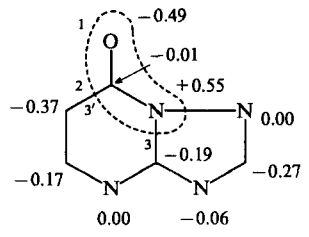
It has been shown that the replacement of the CH_3 group in the 6-position in compound **18** by hydrogen and also the introduction of alkyl groups (up to n-C_7H_{15}) in the 2- and 5-positions do not affect fundamentally the supersensitisation effect. The replacement of the hydroxy-group in the 4-position in compound **18** by an amino-group (compound **21**) also did not change significantly the results, which is illustrated by the supersensitisation coefficients presented in Table 4. On the other hand, compound **22** (without a hydroxy-group) was photographically inactive. Experiments with compound **23** (R^1 = H, CH_3, n-C_7H_{15}, C_6H_5) in which the triazole ring is not condensed with the rest of the molecule, demonstrated their photographic activity, although these compounds were in fact inferior to compound **18** as regards the supersensitising effect. 5-Amino-1,2,4-triazole **24**, which is a fragment of compound **23** (R^1 = C_7H_{15}), by itself had little effect in the concentration range investigated.

Table 4. Photographic effect of compounds **18**, **21**–**24**, **27**, and **28** on layers sensitised by imidacarbocyanine **1**.[102]

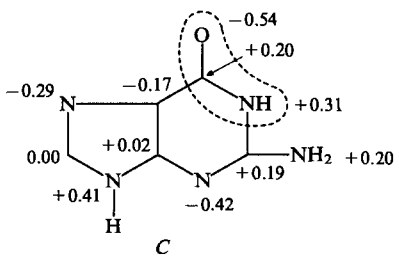


Compound	10^4c/mol (mol AgBr)$^{-1}$	K_s	D_0	λ_{max}^{sens}/nm
Control	–	1.0	0.10	568
18	60	8.0	0.20	571
21	60	7.0	0.26	571
22	60	0.8	0.16	568
23 (R^1 = n-C_7H_{15})	60	3.5	0.11	569
24	60	1.4	0.12	567
27	30	4.8	0.30	569
28	30	6.0	0.20	569

On the basis of the experiments presented, it proved possible to locate extremely approximately the photographically active group within the limits of fragments **25** and **26**. The results obtained with purine bases (guanine **27** and adenine **28**), the structure of which contains the fragments **25** and **26** mentioned above, served as indirect confirmation of this finding. According to the data presented in Table 4, these compounds also have a supersensitising effect on layers with dye **1**.



It has been postulated, with a certain amount of caution,[62] that the photographic activity of compounds containing the fragments **25** and **26** is associated with the presence of amide (**A**) or amidinium (**B**) 1,3-dipolar structures.

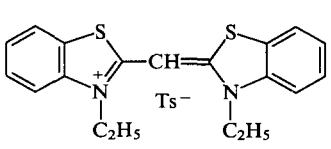


Molecular diagrams of the distribution of π-electron density in the molecule of compound **18** (*A*) and in its anion (*B*), calculated by the molecular orbital method in terms of the Hückel approximation (MOH), are presented below.[62] The parameters taken from Streitwieser[105] were adopted for the Coulombic and exchange integrals. The calculations for the anion of compound **18** were carried out because the anion has in fact been considered in the literature[104] as the photographically active form of compound **18**.

A

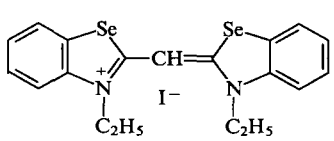
B

C



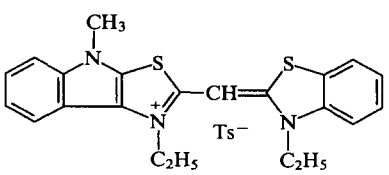
According to molecular diagrams, structures *A* and *B* both contain distinct 1,3-dipoles with a marked localisation of the charges on the oxygen and nitrogen. A characteristic feature of the structures examined is also the presence of a large negative charge on the C(3′) atom of the pyrimidine ring, i.e. a second 1,3-dipole incorporating N(3) and C(3′). A similar pattern in the distribution of π-electron density in guanine has been presented by Pullman and Pullman.[106] The diagram of the π-charges (*C*), calculated by the MOH method, also contains a 1,3-dipole.

The presence of 1,3-dipolar structures is apparently an essential but not a sufficient condition for the photographic activity of the compound. The inclusion of such groups (one or several) in the cyclic system probably promotes the manifestation of supersensitising properties associated with the specific adsorption on the Ag_2S centres.

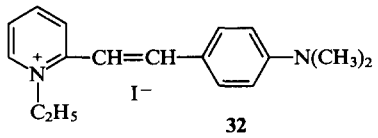


The stabiliser **18** is not the only compound oxidised with difficulty which exerts a supersensitising effect on the dye *J*-aggregates. For example, the application for supersensitisation of compounds, which are clearly oxidised with greater difficulty than the dyes which they supersensitise, has been described in a series of patents mentioned in Mudrovčič's review.[9] It was shown in the early studies by Scheibe and coworkers[17,107] that, together with the readily oxidisable bases of styryl dyes, thiamonomethinecyanine, the polarographic oxidation potential of which ($E_{1/2}^{Ox}$ = 1.20 V) exceeds significantly the potential of quinomonomethinecyanine **3** ($E_{1/2}^{Ox}$ = 0.99 V in CH_3OH rel. Ag/AgCl electrode), has a supersensitising effect on quinomonomethinecyanine **3** *J*-aggregates.[108] We confirmed that certain monomethinecyanines supersensitise the *J*-aggregates of dye **3**; under these conditions, a bathochromic shift of the absorption band maximum of the *J*-aggregate is observed, as for compound **18**.[109] It has been suggested that in this case the 'insulation' supersensitisation mechanism operates.[62,109] It is essential to note that the application of monomethinecyanines as well as quaternary salts of heterocyclic bases as substances increasing the spectral sensitivity of AgHal emulsions sensitised by cyanine dyes has been claimed in a series of patents in the 1970s–1980s (see, for example, Refs 110–113).

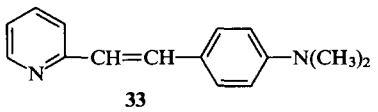
The photographic effect of such compounds has been studied in detail.[114] The experiments were performed on a monodisperse AgBr emulsion with cubic microcrystals ($\bar{l}$ = 0.17 μm) with sulfur-gold sensitisation. The principal studies were carried out on two *J*-aggregating dyes—quinomonomethinecyanine **3** and imidacarbocyanine **1**. The choice of these two particular dyes was determined by the following factors. Firstly, following adsorption on AgBr microcrystals, both dyes form *J*-aggregates with similar absorption maxima—λ_{max}(**3**) = 575 nm and λ_{max}(**1**) = 568 nm. Secondly, they have significantly different potentials $E_{1/2}^{Ox}$ ($\Delta E_{1/2}^{Ox}$ = 0.44 V), which should affect the type (II) hole self-desensitisation processes.



Numerous monomethinecyanines, merocyanines, and styryl dyes have been investigated as supersensitisers. However, the most detailed study has been made of the photographic effect of the four supersensitiser dyes (Dy-S) **29**–**32**. The polarographic potentials of these supersensitiser dyes are presented in Table 5.



29



30

32

33

Table 5. Characteristics of the dyes investigated[144] (potentials in acetonitrile rel. n.c.e.).

Compound	$E_{1/2}^{Ox}$/V	$-E_{1/2}^{Red}$/V
3	0.94	1.15
1	0.50	1.77
29	1.21	1.52
30	1.21	1.53
31	0.75	1.84
32	0.73	1.24
33	0.60	1.50
19	0.60	1.62

It follows from Table 5 that the supersensitiser dyes **29** and **30** are oxidised with greater difficulty than dye **3** and in addition all the supersensitisers **29**–**32** investigated are oxidised less effectively than dye **1**. The supersensitiser dyes were introduced into the emulsion over a wide range of concentrations [(0.5–8) × 10^{-4} mol (mol AgBr)$^{-1}$] before the *J*-aggregating dyes. Their effect was compared with that of compound **18** and also with the effect of readily oxidisable bases of the styryl dyes **19** and **33** (Table 5) acting on the layers containing dye **3** via Gilman's 'reductive' mechanism.[10]

The main result of the investigation[114] was that the supersensitiser dyes, also oxidised with greater difficulty than dyes **3** and **1**, gave rise to the supersensitisation effect in photographic layers with *J*-aggregates of both spectral sensitisers. It is striking that a definite analogy was observed between the spectral and photographic effects of these supersensitiser dyes and compound **18**. When thiamonomethinecyanine **29** is introduced into the emulsion, the same transformation of the spectra as that occurring after the addition of compound **18** is observed, namely at comparatively low concentrations of compound **29** the maximum of the main absorption band initially undergoes a hypsochromic shift, then, as the concentration is increased, two absorption bands due to two *J*-aggregates (J_1 and J_2) are observed simultaneously, and finally, after further rise in concentration, the longer-wavelength band of the J_2-aggregate is established. The appearance of J_2-aggregates is accompanied by an increase in the effectiveness of the spectral sensitisation by dye **3**. A similar pattern in the changes in the spectra of dye **3** has been observed on treatment with supersensitisers **30**–**32**.

The supersensitising effect is also characteristic of other short-wavelength dyes **30**–**32** investigated (Fig. 16), the maximum effect being obtained for compounds **31** and **32** (by a factor of 5–6). The observed effect of the monomethinecyanines **29** and **30** (in conformity with the potentials $E_{1/2}^{Ox}$), which are difficult to oxidise, cannot be accounted for within the framework of Gilman's 'reductive' mechanism. On the other hand, the capture of a hole from dye **3** is possible for the supersensitiser dyes **31** and **32** in conformity with the potentials $E_{1/2}^{Ox}$ listed in Table 5. However, one should note that, in contrast to the typical supersensitiser **19** (according to Gilman), these dyes induce a significant transformation of the *J*-bands already noted above.

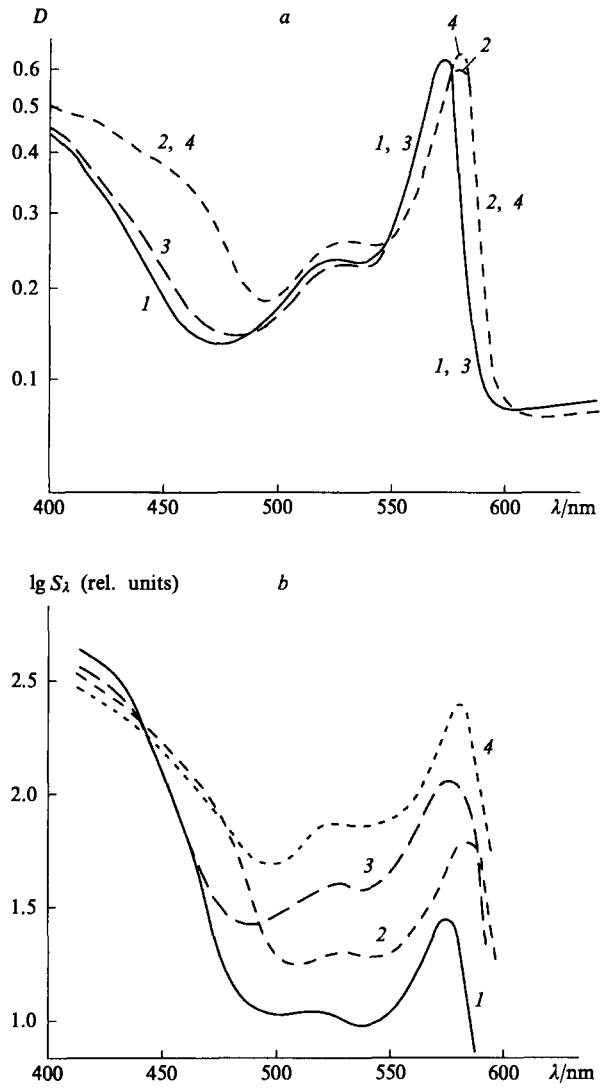

Figure 16. Reflection spectra (*a*) and spectral sensitivity curves (*b*) for AgBr emulsion layers spectrally sensitised by dye **3** [2 × 10^{-4} mol (mol AgBr)$^{-1}$] without a sensitiser (curve *1*) and in the presence of other dyes: (*2*) dye **30** at a concentration of 4 × 10^{-4} mol (mol AgBr)$^{-1}$; (*3*) dye **19** at a concentration of 0.5 × 10^{-4} mol (mol AgBr)$^{-1}$; (*4*) the **30** + **19** composition at concentrations of 4 × 10^{-4} and 0.5 × 10^{-4} mol (mol AgBr)$^{-1}$.

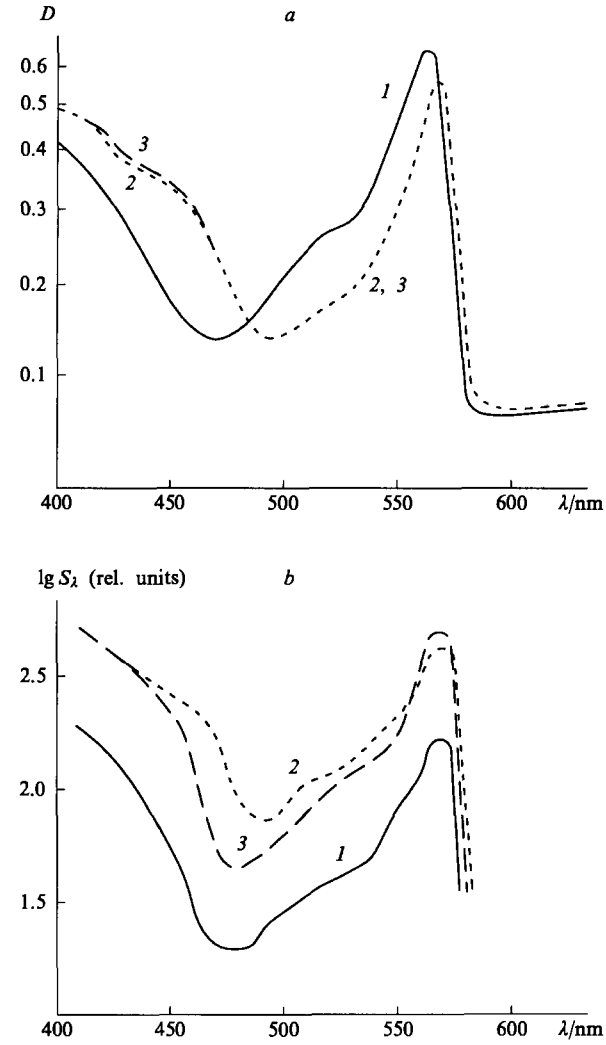
The results of experiments in which compositions of difficult to oxidise supersensitiser dyes with styryl bases **19** and **33** ($E_{1/2}^{Ox}$ = 0.60 V) were used to provide evidence for another mechanism of the influence of compounds **29** and **30** (a non-Gilman mechanism). As with compositions comprising compounds **18** and **19** in earlier studies[47] (Fig. 7 and Table 3), a supersensitisation effect greatly exceeding the effect of the individual substances was observed for the supersensitiser compositions under these conditions. One of the examples of such superadditive effect of compounds **30** and **19** is presented in Fig. 16 (cf. curves *1*–*4*, Fig. 16*b*). It is striking that, in contrast to selenamonomethinecyanine **30**, the styryl base **19** does not alter the position of the *J*-band of the dye (cf. curves *1*, *2*, and *3*, Figs 16*a* and 16*b*). A similar effect has been observed also for the styryl dye **32** and the corresponding base **33**.

The study of the photographic effect of compositions comprising the stabiliser **18** and the supersensitiser dyes **29** and **30** which are difficult to oxidise demonstrated the absence of an additive supersensitisation effect by the compositions, which can be regarded as evidence that the components of the compositions exert an influence of the same type.

The supersensitisation by compounds which are difficult to oxidise is manifested even more clearly on layers with imidacarbocyanine **1**. In this case, all the supersensitisers **29**–**33** were oxidised with greater difficulty than the *J*-aggregating dye **1** (cf. $E_{1/2}^{Ox}$ in Table 5). When compounds **29**–**32** as well as compound **18**[49] are introduced into the emulsion, a characteristic transformation of the *J*-band, analogous to that occurring under the influence of compound **18**, and an increase in the effectiveness of the spectral sensitisation (by a factor up to 5) are observed. Fig. 17 presents examples of the supersensitising effect of the monomethinecyanines **29** and **30**. The introduction of these dyes before the *J*-aggregating dye **1** leads to a bathochromic shift of the absorption bands and to an increase in the spectral sensitivity of the layers (cf. curves *1*–*3*, Figs 17*a* and 17*b*).



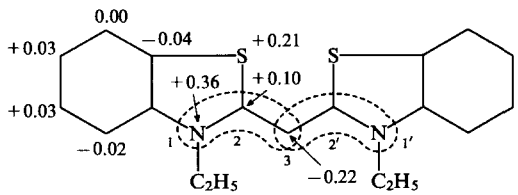


Figure 17. Reflection spectra (*a*) and spectral sensitivity curves (*b*) for AgBr emulsion layers spectrally sensitised by dye **1** [2 × 10^{-4} mol (mol AgBr)$^{-1}$] without a sensitiser (curve *1*) and in the presence of selenamonomethinecyanine **30** (curve *2*) and thiamonomethinecyanine **29** (curve *3*); concentration of the supersensitiser — 4 × 10^{-4} mol (mol AgBr)$^{-1}$.

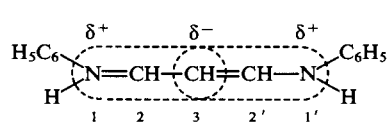
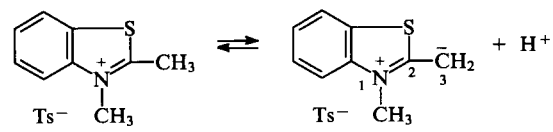
Since dye **1** is itself a readily oxidised compound ($E_{1/2}^{Ox}$ = 0.50 V), it is hardly subjected to a supersensitising influence by the typical supersensitiser **19** ($E_{1/2}^{Ox}$ = 0.60 V) described in the literature;[10] on the other hand, all the dyes investigated belonging to the classes of monomethinecyanines, merocyanines, and styryl dyes, which are known to be oxidised with greater difficulty than dye **1**, lead to an appreciable increase in the effectiveness of the sensitisation at the wavelength corresponding to the *J*-band of

imidacarbocyanine. It is quite natural that there is also no additive increase in the sensitivity for compositions of the supersensitiser dyes **29** and **30** with the styryl base **19**.



The change in the spectra and in the photographic effect of the difficult to oxidise dyes investigated, similar to the influence of compound **18**, permits the conclusion that the nature of their photographic effect is the same, namely that it entails a single 'insulation' supersensitisation mechanism. This is probably due to the preferential adsorption of dyes belonging to the classes of thia(selena)monomethinecyanines, styryl dyes, and merocyanines on the Ag_2S centres. The selective adsorption of dyes and of the sta-salt on the Ag_2S lattice may be associated with the significant difference between the parameters of this lattice and those of the AgHal lattice and also with the specific properties of the Ag_2S centres having a high concentration of mobile silver ions according to Van Doorselaer's hypothesis.[115] The superionic properties of Ag_2S were examined by Kartuzhalskii et al.[116]

It had been postulated earlier in relation to the sta-salt and its analogues[102] that the selective adsorption of the supersensitiser on the Ag_2S centre may be due to the presence of 1,3-dipolar structures. It is striking that distinct 1,3-dipolar fragments are present in the molecules of cyanines and in the first place monomethinecyanines. According to the molecular diagram for the distribution of π-electron density in thiamonomethinecyanine **29**,[62] calculated by the PPP method, there are several 1,3-dipoles in the supersensitiser dye, including the nitrogen and sulfur atoms of the heterocyclic nuclei and the methine carbon atom.



It is striking that the distance between the sulfur atom and the methine carbon atom (~2.6 Å) is close to the distance between the Ag^+ and S^{2-} ions in the Ag_2S clusters (2.58 Å on the AgBr surface).[117] It is significantly smaller than the distance between the Ag^+ and Br^- ions in the AgBr lattice (~2.9 Å). Thus the selective adsorption of organic compounds containing 1,3-dipoles may be due to the correspondence of the distance between the charge centres in the 1,3-dipoles and the distance between the Ag^+ and S^{2-} ions in the Ag_2S clusters.

Experiments with the simplest streptocarbocyanines, also containing 1,3-dipoles in their structure, showed that their introduction into an emulsion sensitised by dye **1** leads to a fourfold increase in additional sensitivity. The increase in sensitivity is accompanied by a bathochromic shift of the *J*-band. The alternation of the π-electron density in the most effective of these dyes is illustrated below.

The supersensitising effect of a quaternary benzothiazole salt (2-methylbenzothiazolium toluene-*p*-sulfonate **34**) has been noted,[114] although it is significantly lower than that of the supersensitiser dyes **29**—**32**. It is well known that the quaternary salts of thiazoles, exhibit, like compound **18**, antifogging and stabilising effects on photographic emulsions.[118] The supersensitisation by the quaternary salt of 2-methylbenzothiazole may be a consequence of the acid properties of the salt, in which a 1,3-dipole may arise after dissociation in accordance with the scheme below.

34

It was noted at the beginning of this review that the first publication by Bloch and Renwick on supersensitisation described the appreciable photographic effect of auramine on layers sensitised in the panchromatic region of the spectrum.[14] We confirmed the sensitising effect of auramine G on layers with the *J*-aggregating dye **1**. Like compound **18**, auramine induces a bathochromic shift of the band of the aggregate. According to the molecular π-electron distribution diagram, calculated by the MHO method, the molecule of auramine G contains 1,3-dipolar fragments and supersensitisation by this dye can therefore also be considered within the framework of the 'insulation' mechanism.

The special role of surface defects in the 'insulation' supersensitisation mechanism necessitated the development, as the next task, of a method which would make it possible to infer the interaction of spectral sensitisers and supersensitisers with the impurity centres formed on chemical sensitisation. The fogging effect of a phenothiazine dye—Methylene Blue (MB)—has been described.[119–121] Eggert and Reitstötter[119] as well as Steigman[120] attribute the fogging to the catalysis of electron transfer from the developer to AgHal involving the adsorbed MB^+ cation. Dähne[121] explains the fogging as a result of the formation of MB^+ dimers following their adsorption on AgHal. It has been noted[119,120] that other sulfur-containing dyes as well as the sulfur-free dye Janus Green also exhibit a fogging capacity.

Preliminary experiments carried out on a monodisperse AgBr emulsion containing cubic microcrystals with sulfur-gold sensitisation showed that the introduction of MB in an amount of $(1-5) \times 10^{-5}$ mol (mol AgBr)$^{-1}$ induces an intense increase in the fog density D_0, from 0.12 to 2.0—4.0, when unexposed emulsions are treated in UP-2 developer (development time 8 min). Naturally, an appreciable desensitisation is also observed under these conditions. It is striking that there was virtually no fogging at the same MB^+ concentrations on the same emulsion not subjected to the (S + Au)-sensitisation. However, in the course of chemical sensitisation, the fogging due to the MB steadily increased[122] with increase in sensitivity, the latter being attributed to the formation of electron-accepting Ag_2S sensitivity centres.[59]

Thus fogging is undoubtedly associated with the presence of Ag_2S centres, formed on sulfur and sulfur-gold sensitisation. One can therefore assume that the fogging effect of MB^+ is caused by its adsorption not on silver halides, as claimed by Eggert and Reitstötter,[119] but on impurity Ag_2S centres (IC_e). The adsorption of MB^+ can be associated with the presence of 1,3-dipoles in the structure of the phenothiazine dye. As a result of the specific adsorption of the electron-accepting MB^+ on the IC_e, there is a possibility of catalysis of the electron transfer from the developer to the Ag_2S centre and further to AgHal. This is illustrated schematically in Fig. 18 (see over), according to which direct electron transfer from the developer (Red) to the Ag_2S centre is kinetically hindered owing to the high energy barrier corresponding to the activation energy E_{act} (Fig. 18*a*). As a result of the specific adsorption of MB^+ on the Ag_2S centre, the electron transfer reaction is divided into two stages, the first of which is electron transfer from Red to MB^+. Owing to the lower activation energies for the two stages (E'_{act} and E''_{act}) compared with E_{act}, catalysis of the oxidation-reduction reaction, expressed by the fogging of the photolayers, is observed (Fig. 18*b*). According to the data of Eggert and Reitstötter,[119] the dye Janus Green also exhibits a fogging capacity. It has likewise been demonstrated that electron-accepting pyrylo- and thiapyrylo-monomethinecyanines are effective fogging agents.

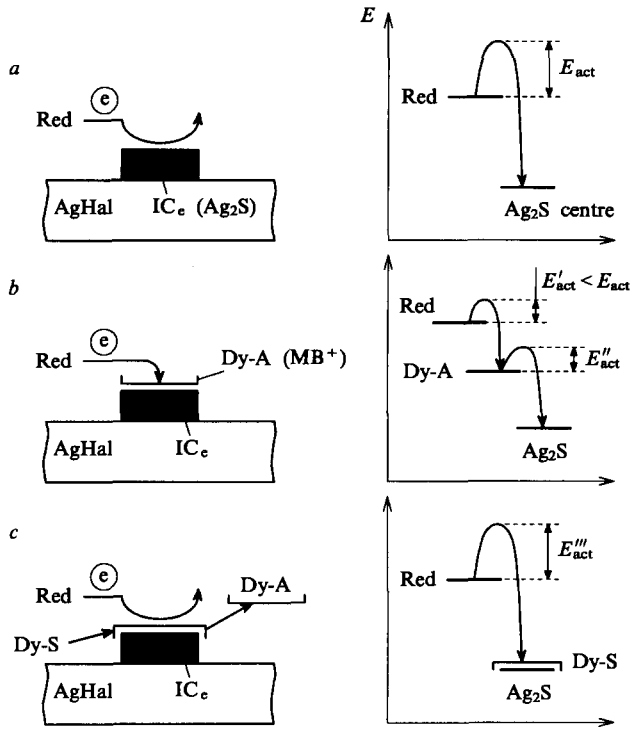


Figure 18. Schematic representation of the catalysis of electron transfer from the developer (Red) to the Ag_2S centre (IC_e) with the aid of an electron acceptor dye (Dy-A) and of the inhibition of the transport process by the supersensitiser dye (Dy-S).

By use of the specific adsorption of MB^+ and other electron-accepting dyes on the Ag_2S centres, manifested by the fogging of the AgBr and AgBr(I) photographic emulsions, experiments designed to investigate the influence of a series of supersensitisers, operating, in conformity with our ideas, via the 'insulation' mechanism, on the fog within the photolayers, have been carried out.[62,122] For the selective adsorption of the supersensitisers on the Ag_2S centres, one should expect the desorption of the fogging dyes from these centres and hence a decrease in fogging. Experimental methods involved the initial introduction of supersensitisers into the AgBr emulsion in amounts inducing the supersensitisation of the *J*-aggregating dyes, with subsequent addition of MB or another fogging dye at concentrations leading to a fog level $D_0 = 2.0-3.0$ within the layers. Supersensitiser dyes **29** and **30** have been studied in greatest detail.

Indeed the introduction of thia- and selena-monomethinecyanines **29** and **30** suppresses sharply the fogging in the photolayers due to MB. It is striking that it is not associated with the desorption of MB from AgBr because the desensitisation of the emulsion not only does not diminish under these conditions but sometimes actually increases. The influence of the stabiliser **18** on fogging is weaker than that of monomethinecyanines. Like monomethinecyanines, auramine G also suppresses the fogging induced by MB, i.e. its effect is similar to that of cyanines.

The explanation of the antifogging effect of supersensitisers can also be associated with the displacement of MB^+ from the impurity centres, with the increase in the activation energy for the redox reaction E''_{act}, and with the inhibition of the catalysis. This is illustrated schematically in Fig. 18*c*. Thus, on the basis of the experimental data obtained one may conclude that the supersensitisers are adsorbed selectively on the Ag_2S centres and hence that the 'insulation' supersensitisation mechanism really operates.

It is essential to note that, in the course of the development of methods designed to demonstrate the existence of the 'insulation' supersensitisation mechanism, the present author [122] observed in essence a new phenomenon—catalysis by dyes and reactions involving electron transfer from reductants to Ag_2S impurity centres. Whereas in the classical photographic negative process, the catalysis is effected by the Ag_n^+ silver species, formed on the Ag_2S centres following exposure, in the present instance the catalyst is the electron-accepting dye molecule having a specific affinity for the impurity centre. The possibility of the inhibition of the catalysis (negative catalysis) with the aid of substances competing with the acceptors for specific adsorption sites is no less important.

It must be emphasised that monomethinecyanines and other dyes can function not only as supersensitisers but also as stabilisers as well as antifogging agents in photographic emulsions as a consequence of their specific adsorption on the Ag_2S centres. The results obtained lead to the expectation that the stabilising capacity of cyanine dyes is higher than that of the traditional stabiliser **18**. According to modern ideas,[104] the stabilisation of emulsions is associated with the interaction of compound **18** with the Ag_2S centres. Thus the method developed may be useful for a rational selection of not only supersensitisers but also of stabilisers and antifogging agents.

The results obtained indicate the existence of at least two mechanisms of the supersensitisation of the *J*-aggregating dyes: the 'insulation' and Gilman's 'reductive' mechanisms. The difference between these two mechanisms is shown particularly clearly in the experiments, already examined, with compositions comprising readily oxidisable bases of the styryl dyes (compounds **19** and **33**) together with the supersensitisers **18**, **29**, and **30** which are difficult to oxidise. The observed superadditive supersensitisation effect (Figs 7 and 16, Table 3) can be explained by the hypothesis that supersensitisers of two types act on two consecutive stages in the inhibition of the hole-type self-desensitisation reactions. In this case, there is either initial hole capture from the dye by the readily oxidisable supersensitiser **19** (in accordance with Gilman's mechanism) and subsequent insulation of the remaining holes from the photographically active centres by compound **18**, which is difficult to oxidise, or the supersensitisers act in the opposite sequence. When the supersensitisers act consecutively, the probability of the entire recombination process is in fact determined by the product of the probabilities of the processes involving each of the individual substances, as a result of which the supersensitisation coefficient may approach the product of the coefficients for the individual supersensitisers, i.e. may be superadditive.[8,52]

The requirements which must be met by supersensitisers working in accordance with the above mechanisms are different: $0.8\ V > E_{1/2}^{Ox}(S) < E_{1/2}^{Ox}(Dy)$ for supersensitisers of the first kind working in accordance with the 'reductive' mechanism; $E_{1/2}^{Ox}(S) > E_{1/2}^{Ox}(Dy)$ for supersensitisers of the second kind working in accordance with the 'insulation' mechanism.[8,48] There is also a possibility of a variant where the supersensitiser dyes exhibiting a specific affinity for the Ag_2S centres and at the same time meeting the requirements of the 'reductive' mechanism may operate simultaneously via the two mechanisms. This case is in principle applicable to the supersensitiser dyes **31** and **32**, which were examined above and which are oxidised more readily than the quinomonomethinecyanine **3** supersensitised by them.

It is essential to note that the 'insulation' mechanism of the supersensitisation of the *J*-aggregating dyes differs significantly from Riester's mechanism.[23,24] Whereas the insulation of dye molecules from the AgHal surface and from one another is considered in Riester's model, the essence of the 'insulation' mechanism consists in the insulation of the sensitiser from the impurity centres alone. Furthermore, the introduction of Riester's potentiators leads to the decomposition of the dye *J*-aggregates and hence to the suppression of the spectral sensitivity.

The model involving the 'insulation' of the dye *J*-aggregates from the photographically active centres is apparently realised in emulsions with deep electron capture centres—in emulsions of the 'core–shell' type and in emulsions with Ir^{3+}.[45,123–127] As a consequence of the capture of photoelectrons, electron-hole

recombination processes are hindered in the bulk of the AgHal microcrystals, which makes it possible to diminish significantly type (II) self-desensitisation and hence to increase the effectiveness of the sensitiser.

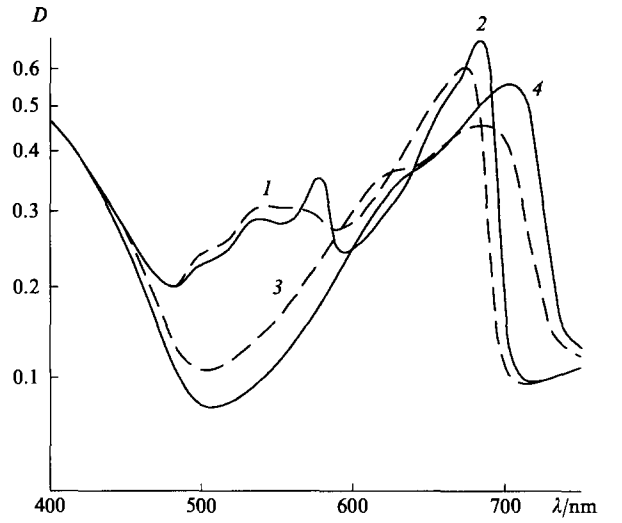
2. Regulation of the *J*-aggregation of dyes

The self-association of dyes into *J*-aggregates should apparently have a series of analogies with crystallisation processes and should therefore involve at least two stages — the nucleation stage and the stage involving the growth of the ordered structure. Cyanine dyes aggregate on the real, and hence defective surface of AgHal microcrystals. The nucleation stage should therefore be determined by, apart from the structure of the dye molecule, the number and type of surface defects as well as the degree of supersaturation of the dye solution. On the other hand the *J*-aggregate growth stage is determined mainly by the degree of supersaturation of the sensitiser solution. The defectiveness of the surface of microcrystals is linked directly to the type of faces of the microcrystals and to the type of chemical sensitisation during which new defects (impurity centres) are formed. An analysis of the factors influencing the *J*-aggregation may be found in a number of reviews.[3,7,66]

The organic or inorganic substances introduced into a photographic emulsion during the growth of microcrystals and chemical and spectral sensitisation are capable of influencing the *J*-aggregation either in the aggregate nucleation stage, by altering the defectiveness of the surface, or in the aggregate growth stage. The influence of the stabiliser **18**, some of its analogues, and cyanines on the *J*-aggregation as regulators of the defectiveness of the surface was examined in Section I. In the present section, we shall consider the effect of a number of other organic compounds on the *J*-aggregate growth stage.

It has already been noted that the influence of a series of photographically relatively inactive compounds (for example, ketones, nitriles, quinoline derivatives, etc.) on the *J*-aggregation of dyes has been described in the literature.[9] The photographic effect of phenol added to the emulsion together with dyes has been investigated.[128] Its strong influence on the position of the absorption *J*-bands and on the effectiveness of the spectral sensitisation was observed. At a phenol concentration of 0.5–1.0 mol (mol AgHal)$^{-1}$, a bathochromic shift of the *J*-band up to 20 nm occurs. This is illustrated in Fig. 19 for the cation-anionic dye **35** and the anionic dye **36** adsorbed on a monodisperse AgBr(I) emulsion (cubic crystals, $\bar{l} = 0.25$ μm).

According to Fig. 19, phenol induces a bathochromic shift of the bands of orthochromatic and panchromatic sensitisers incorporated in compound **35** (cf. curves *1* and *2*) and of the *J*-band of the panchromatic dye **36** (cf. curves *3* and *4*). The changes in the *J*-bands are accompanied by an increase in the effectiveness of the spectral sensitisation. The influence of phenol was observed also for a series of other cationic, anionic, and cation-anionic dyes.



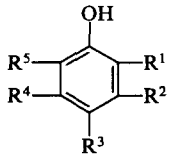


Figure 19. Reflection spectra of AgBr emulsion layers spectrally sensitised by dyes **35** (curves *1* and *2*) and **36** (curves *3* and *4*) individually (curves *1* and *3*) and in the presence of phenol (curves *2* and *4*). Concentration of dyes — 2 × 10^{-4} mol (mol AgBr)$^{-1}$; concentration of phenol — 0.5 mol (mol AgBr)$^{-1}$.

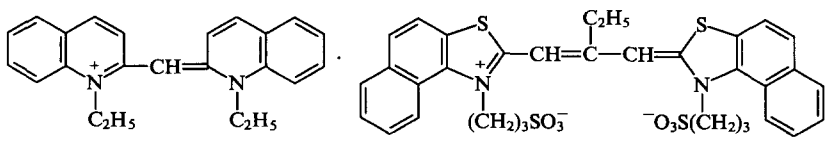
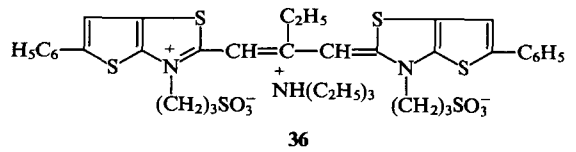


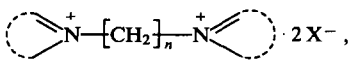
37



R^1–R^5 = H, Alk;

The influence of phenols having the general formula **37** has been investigated.[128] It was shown that cresol (R^3 = CH_3; R^1, R^2, R^4, R^5 = H) acts similarly to phenol. The introduction of longer alkyl groups in the *para*-position suppresses the *J*-aggregation. Dimethylphenols (1,2,4-, 1,3,4-, 1,3,5-, and 1,4,5-xylenols) have an effective influence on the *J*-aggregation at significantly lower concentrations [0.1–0.25 mol (mol AgHal)$^{-1}$] than phenol.

The bathochromic shift of the *J*-bands is usually attributed either to a decrease in the packing angle of the dyes or to an increase in the number of sensitiser molecules in the aggregate.[3,7] Both parameters should depend on the rate of aggregation. For fast aggregation, the random formation of many aggregates of different sizes should occur on the AgHal surface defects. It has



35

36

been shown[120] that the influence of the phenol persisted also when it was introduced into the emulsion after the formation of the *J*-aggregates. It was postulated that the 'recrystallisation' of the *J*-aggregates or, in the usual photographic terminology, the 'first ripening of the *J*-aggregates' takes place under the influence of phenols.[62,120] Phenols play the role of the medium (solvent) promoting the recrystallisation. One of the results of this may be the formation of more ordered structures of the *J*-aggregates (having bands which have undergone a bathochromic shift) remote from the impurity centres ($r > 0$, Fig. 2). The second result is the increase in the photographic activity of the *J*-aggregates. It is noteworthy that this may not in fact be a general rule because, for a sufficiently long ordered *J*-aggregate, contact between the latter and the IC_e can arise again with the consequent self-desensitisation of the dye. In this case the insulation of the *J*-aggregates from the IC_e with the aid of supersensitisers should be the main method for increasing the photographic activity of the long-wavelength *J*-aggregates.

Bisquaternary salts of heterocyclic bases having the general formula **38**,

38

exert an appreciable influence on the *J*-aggregation. Here

represents the quaternary salt of the nitrogen-containing base ($n > 2$).

Bisquaternary salts of a hydrogen-containing heterocycle have been used for a comparatively long time.[129–132] The influence of bisquaternary salts of benzimidazole has been studied in detail by Lifshits and coworkers,[133–135] while that of α-picoline has been investigated by the present author and Schelkina.[62,136] The introduction of bisquaternary salts into a photographic emulsion at concentrations comparable to that of the *J*-aggregating dye intensifies the tendency of the dye towards *J*-aggregation, gives rise to a bathochromic shift of the absorption band maximum, and increases the effectiveness of the spectral sensitisation. The effect of the bis-salts is manifested not only on AgHal but also on other semiconductors, in particular on WO_3.[50,51,137,138]

The influence of bisquaternary salts has been treated[62,136] from the standpoint of the facilitation of the *J*-aggregation of the dyes. This phenomenon has been designated as aggregation catalysis. Additional experiments using MB as a test for specific adsorption of the Ag_2S centres demonstrated that the bisquaternary salts do not exhibit an affinity for these centres and hence do not operate via the 'insulation' mechanism. Owing to the correspondence between the paired positive charges localised on the nitrogen atoms and the paired negative charges of the halide ions on the AgHal centre, a potential surface relief of a kind which facilitates the formation of *J*-aggregates not only on the defects but also on other surface sites and which favours the growth of the ordered structures of the aggregates is probably created in the adsorption of the bis-salts on the AgHal microcrystals. A consequence of this may be the absence of contact between the *J*-aggregate and the impurity centre IC_e, which is in its turn manifested by an increase in the photographic effectiveness of the dye. The formation of the ordered structures of the *J*-aggregates may influence the effectiveness of the spectral sensitisation as a consequence of the decrease in the probability of the dissipation of the excitation energy among different *J*-aggregates differing from one another by their sets of energy levels.

It has already been mentioned that the tendency of dyes towards *J*-aggregation is determined to a large extent by the molecular structure. The familiar fact that the replacement of alkyl groups at nitrogen atoms by sulfoalkyl groups, while the chromophoric part of the molecule of the cyanine dye remains unaltered, intensifies the tendency towards *J*-aggregation merits special attention.[7,137] The presence of dipolar betaine structures in anionic dyes can probably facilitate both the nucleation stage on the dipolar surface of the AgHal microcrystals (Ag^+ and Hal^- ions) and the growth of the aggregates themselves. According to Meyer's hypothesis,[140] the molecules of betaine dyes form more stable *J*-aggregates than the cations of the alkylates of carbocyanines.

The creation on the surface of AgHal microcrystals, before the introduction of the spectral sensitiser, of a multiplicity of new defects stimulating the growth of *J*-aggregates at sites not bound to the impurity centres should promote *J*-aggregation. Such numerous defects arise, for example, in the synthesis of AgHal microcrystals with a variable halide composition, particularly in the synthesis of AgBr(I) emulsions. *J*-Aggregation therefore is as a rule facilitated with increase, up to a certain limit, in the content of iodide ions in AgBr(I) emulsions. It has been shown[141] that the addition of iodide ions to a AgBr emulsion with cubic microcrystals leads to the formation on the vertices and edges of the microcrystals of silver iodide, on which *J*-aggregation is facilitated. The influence of thiocyanate and cyanide ions, forming sparingly soluble compounds with Ag^+ ions,[142] can be explained in the same way. There is apparently a possibility also of other methods of regulating the defectiveness of the surface of AgHal microcrystals.[136] In addition, mention should be made of the control of the *J*-aggregation by reducing the rate of introduction of the dye into the solution. This is achieved by introducing into the emulsion dyes sparingly soluble in water in the form of aqueous sols or, for example, by the readsorption of dyes from the surface of an inert substrate (SiO_2 etc.) on AgHal.[7,143] The three principal supersensitisation procedures, examined above, are summarised in Fig. 20.

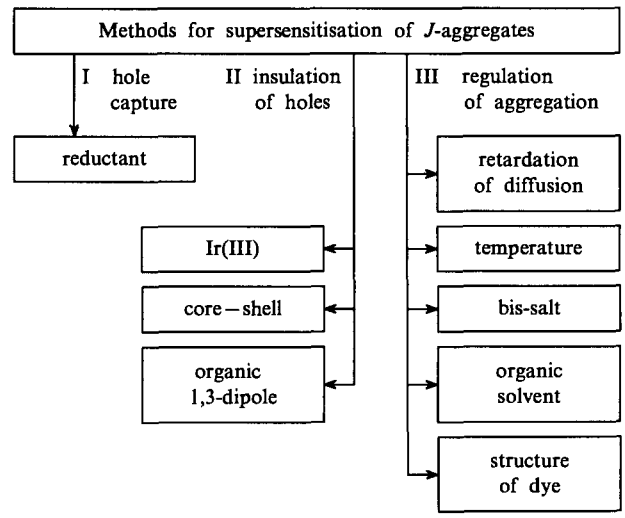


Figure 20. Principal methods for the supersensitisation of *J*-aggregating dyes.

V. Conclusion

The characteristics of the spectral sensitisation of silver halide photographic materials by *J*-aggregating dyes are determined primarily by the unusual structure of the aggregates, which consist of organised structures with delocalised π-electrons. This is reflected both in the spectra (λ_{max}, line widths, absorption coefficient, and the lifetime of the excited state) and in the photographic behaviour of cyanines. The system of delocalised π-electrons of the *J*-aggregate creates conditions for the transfer of

the photogenerated charge carriers (electrons and holes) over distances larger than the molecular size. The delocalisation of holes within the limits of the *J*-aggregates constitutes the basis of the desensitisation and the type (II) self-desensitisation examined above. The hole desensitisation is a typical example of the catalysis of recombination processes in which the *J*-aggregate plays the role of an intermediate species promoting the reaction.

The processes involving the transfer of holes and photoelectrons between aggregates of various dyes not only play a major role in the spectral sensitisation of photographic materials but are also of considerable interest for the future developments in molecular microelectronics.[144–148] Artificially organised systems on the basis of *J*-aggregates serve as electronic elements of molecular dimensions (switches, triodes, memory cells, etc.). Thus one is dealing with the organisation of photoinitiated electronic processes in the microsystems of the *J*-aggregates.

The uniqueness of the *J*-aggregates of cyanine dyes as spectral sensitisers, which has been responsible for their general application in the black and white and colour photographic materials is apparently determined by the effective primary separation of the photogenerated charges between the molecules in the system of the *J*-aggregate. Here one can trace a definite analogy between the spectral sensitisation process created artifically by man and the natural spectral sensitisation processes in photosynthesis, which in the course of many millions of years of evolution have been brought to perfection. The primary step of the spectral sensitisation in the photosynthesising reaction centre involves the separation of charges in the dimeric molecules of bacteriochlorophyll.[149] The effectiveness of the primary charge separation creates favourable conditions for the subsequent multistage processes involving the separation of the charges from one another. The primary charge separation in the *J*-aggregates promotes in exactly the same way the subsequent effective separation of electrons and holes in the dark stages with participation of silver halides. Nature has devoted much effort to the creation of a perfect mechanism of the 'dark' separation of charges in photosynthesis. This has been achieved exclusively by an exact spatial organisation of a transport system for electrons and holes in which electron and hole acceptors are located at rigorously defined distances from the reaction centre.[149] According to the results obtained, the disposition of the *J*-aggregates relative to electron and hole acceptors on the AgHal surface also determines to a significant extent the effectiveness of the charge separation in the photographic process and the spectral sensitivity associated with this. Consequently the topography of the *J*-aggregates on the real surface of AgHal microcrystals is extremely important and the specific regulation of the *J*-aggregation therefore in fact constitutes, in our view, the essential feature of the future developments in the spectral sensitisation of new photographic materials.

It is essential to note that the difficulties which many investigators encountered in their attempts to find a relation between the effectiveness of the spectral sensitisation of specific photographic emulsions and the structure of the *J*-aggregating dyes, which were mentioned in the Introduction, arose in the first place from the one-sided nature of the approach to the problem of spectral sensitisation. This was either a consequence of a one-sided study of the structure and energetics of the energy levels of the dyes incorporated in the *J*-aggregate without reference to the emulsion system (in the first place its impurity levels) or, conversely, a result of overestimating the role of the substrate without taking into account the structural characteristics of the dye. The hopes of the investigators are therefore frequently associated either with the search for a kind of 'golden' dye or with the preparation of a 'special' photographic emulsion showing a tendency towards supereffective spectral sensitisation. Naturally, because of its limitations, neither approach is able to solve this problem. Only the study of processes in a single system incorporating the dye, the AgHal surface, its defects, and, in the first place, the products of the sulfur sensitisation can help to find an answer to the question why a particular cyanine dye in one or other emulsion is either highly effective or, conversely, is photochemically inactive. This review represents an attempt at an integrated consideration of the problem of the effectiveness of the spectral sensitisation of *J*-aggregating dyes.

Attention should be drawn also to one, largely ideological, limitation of the approach adopted to the problem of the effectiveness of spectral sensitisation. Hitherto processes involving the supersensitisation of photographic layers with *J*-aggregating dyes have been considered from the standpoint of the prohibitive principle of the 'fight against holes'. Both the 'reductive' and 'insulation' supersensitisation mechanisms correspond to precisely this principle. However, practice has shown that another principle is more promising — the 'collaboration' principle, in the present instance the principle of collaboration with holes. This means that a desirable organisation of the spectral sensitisation process is one in which it would be useful to employ the energy of the holes, namely their oxidising capacity, which leads to the liberation of the chemical energy stored in the photographic system. One is dealing with the oxidation of certain organic substances — supersensitisers of a new type — as a result of which the oxidised molecule, depleted in bonding electrons, would react with decomposition of the initial cyclic skeleton. Ultimately another molecule would arise with a new cyclic skeleton, possessing reducing properties in relation to AgHal. This means that the chemical reactions of the oxidised form of the supersensitiser would result in the injection into the AgHal microcrystal of one (or more) electron capable of intensifying the latent photographic image. Consequently one is dealing with a latent image intensification process in which the relative quantum yield of the spectral sensitisation can be formally greater than unity. In fact, one would inject not one but several electrons into AgHal per quantum adsorbed by the *J*-aggregate — one electron from the photoexcited dye and the others from the products $Dy^{+\cdot}$ of the oxidation by the hole. The ability of the *J*-aggregate to effect the translation of the hole should in principle increase the probability of such a process. The process probability should increase to an even greater extent following the specific adsorption of a supersensitiser of the type considered on the impurity centre functioning as the electron acceptor. In this case, on capture of a hole by the supersensitiser and after the chemical reaction of the

$$Dy + h\nu \longrightarrow Dy^{*}; \quad (12)$$

$$Dy^{*} + AgHal \longrightarrow Dy^{+\cdot} + [AgHal]^{-}; \quad (13)$$

$$[AgHal]^{-} + Ag^{+} \longrightarrow [AgHal/Ag^{0}]; \quad (14)$$

$$Dy^{+\cdot} + BH \longrightarrow Dy + BH^{+\cdot}; \quad (15)$$

$$BH^{+\cdot} + R^{-} \longrightarrow B^{\cdot} + HR; \quad (16)$$

$$B^{\cdot} + [AgHal/Ag^{0}] \longrightarrow B^{+\cdot} + [AgHal/Ag^{0}]^{-}; \quad (17)$$

$$[AgHal/Ag^{0}]^{-} + Ag^{+} \longrightarrow [AgHal/Ag_{2}^{0}]; \quad (18)$$

$$B^{+\cdot} + \text{medium} \longrightarrow \text{products}; \quad (19)$$

oxidised supersensitiser molecule, a second electron would enter directly the IC_e. A hypothetical mechanism of the 2-electron process could be represented, for example, in the following form: where BH is the supersensitiser and R^- the base. According to this scheme, the supersensitiser BH is oxidised by a dye hole to the radical-cation $BH^{+\cdot}$, which interacts with the base R^- as a consequence of its acid properties, affording the radical $B^{\cdot}$. The latter can serve as a reductant in relation to the silver halide, i.e. it can inject a second electron into AgHal and intensify thereby the latent photographic image centre.

Abstract. The review surveys the reactions of aromatic diazonium salts with diene and monounsaturated compounds in the presence of nucleophiles. Certain further reactions of the reaction products and their applications are considered. The bibliography includes 63 references.

I. Introduction

The reaction of arenediazonium chloride with unsaturated compounds in the presence of copper salts (the Meerwein or Meerwein–Schuster reaction) was described in 1939[1] and immediately found extensive applications in synthetic organic chemistry for the preparation of aryl- and chloroaryl-substituted derivatives.[2–19]

The view that the reaction is catalysed solely by copper halides while diazonium sulfates and nitrates as well as other diazonium salts do not interact with unsaturated compounds was held for a long time. The explanation is that acid and not neutral diazonium salts plus divalent copper salts were used in the reaction, whereas it is univalent copper salts that are the catalysts of the decomposition of diazonium salts. Ethylene derivatives are known to be able to reduce divalent copper halides to the univalent state under certain conditions. However, divalent copper sulfates and nitrates are apparently difficult to reduce in an acid medium, since acids inhibit the reduction of divalent copper salts.[19] It was not until the beginning of the 1980s that conditions were found under which arenediazonium sulfates, nitrates, and tetrafluoroborates react with unsaturated compounds in the presence of external nucleophiles to form products of the addition of the aryl group and the anion to the double bond.[10–15] We suggested that this type of reaction be called anionarylation.[10,16] If sodium chloride is used as the anionoid reagent, then the Meerwein reaction becomes a special case of the anionarylation reaction.[14]

II. Factors determining the effectiveness of the reaction

The possibility of the anionarylation of dienes by diazonium sulfates and nitrates as well as other diazonium salts was discovered by Ganushchak et al.[10] The factors determining the effectiveness of the anionarylation reaction were elucidated later.

Diazonium salts. Among arenediazonium sulfates, nitrates, acetates, and tetrafluoroborates, arenediazonium tetrafluoroborates proved to be the most convenient in the anionarylation reaction. They are extremely stable compounds which can be stored for a long time.

It was noted that the highest yields of the products of the anionarylation reaction are obtained if there are no substituents at all in the aromatic ring or the substituents are in the *para*- or *ortho*-position regardless of their nature. *Meta*-substituted compounds afford significantly lower yields.[20]

Unsaturated compounds. Both monounsaturated and diene derivatives have been investigated in the anionarylation reaction. If the reaction system contains the same anionoid reagent, the yields of the anionarylation products (buta-1,3-diene, isoprene, and chloroprene) are comparable.[11–13]

The vinyl monomers $CH_2=CH-X$ and $CH_2=CX_2$, in which the double bond is activated by one or two electron-accepting groups (X = Cl, CN, Ar, COR, COOH, COOAlk, $P^V=O$, etc.) enter most readily into the anionarylation reaction.[20–22] Owing to the high capacity of copper or iron salts for the transfer of radical chains, such monomers do not produce high-molecular-mass compounds under the reaction conditions.

Catalysts. Various compounds, in particular copper acetate, thiocyanate, hydroxycarbonate [bicarbonate?], tetrafluoroborate, *O,O*-diethyl phosphorodithioate, and ethylxanthate as

well as the $CuSO_4 + FeSO_4$, $Cu(NO_3)_2 + Cu$, and $Cu(NO_3)_2 + Fe$ systems have been tested as catalysts of the anionarylation reaction. The optimum molar ratio of the diazo-salt to the catalyst is in the range from 0.1 to 0.01–0.025. It is essential to note that the anion of the copper salt hardly affects the reaction. Furthermore, under these conditions as exchange reaction takes place between the copper salts and the anionoid reagents with formation of CuA_2. In most cases, the presence of the catalyst—copper or iron salts—is an obligatory condition, but sometimes the anionarylation reaction can occur also in the absence of the catalyst.[17,18,20,22]

Anionoid reagents. Alkali metal or ammonium salts have been most often used as anionoid reagents. Anionoid reagents such as chlorides, bromides, iodides, fluorides, sulfides, nitrites, thiocyanates, *O,O*-diethyl phosphorodithioates, xanthates, *N,N*-diethyldithiocarbamates, and carboxylates have been investigated in the reaction. Apart from the salts, water, methyl, ethyl, isopropyl, n-butyl, isobutyl, *sec*-butyl, *tert*-butyl, and benzyl alcohols, ethylene glycol, and formic acid have been used successfully as the anionoid reagents.

Solvents. The anionarylation reaction has been carried out in various solvents: water, acetone, acetonitrile, diethyl ether, dimethyl sulfoxide, dimethylformamide, and alcohol. If the unsaturated compound dissolves in water, the reaction can be carried out in an aqueous medium,[23] but, in view of the fact that the majority of unsaturated compounds are insoluble in water, the reaction is usually carried out in an aqueous organic medium. The optimum reaction media are water–acetone or water–acetonitrile mixtures in 1:(1–4) proportions.[14,20–22] In many instances, the reaction takes place only in an organic solvent. When water–acetone or alcohol–acetone systems are used as the organic medium in the absence of other anionoid reagents, the alcohol or water functions as an external nucleophile, whereupon hydroxyarylation and alkoxyarylation reactions occur.

Acidity of the medium. The optimum pH of the reaction medium is in the range from 4 to 6; in order to maintain and regulate the necessary pH, the following additives are introduced: CH_3COONa, CaO, $Ca(OH)_2$, $NaHCO_3$.

Temperature conditions. The anionarylation reaction takes place at temperatures from −65 to +25 °C depending on the nucleophilicity of the anion introduced and the order in which the reagents are added. If the temperature is not regulated, the reaction becomes uncontrolled, the temperature rises rapidly, and nitrogen is evolved abundantly; in such cases, the process involving the substitution of the diazo-group by the anions present in the mixture predominates.

Reaction procedure. The following order of the introduction of reagents into the reaction mixture is optimal: catalyst, solvent, unsaturated compound, diazonium salt. If the anionoid reagent is introduced last, the reaction proceeds as a rule very rapidly, which is indicated by the vigorous evolution of nitrogen. When the last reagent is the diazonium salt, the reaction proceeds quietly even at a higher temperature. The most successful diazonium salt: unsaturated compound: anionoid reagent reactant ratios are 1:(1–1.5):(1.25–2).

III. Anionarylation of 1,3-dienes

The influence of the nature of the aromatic diazonium salt, the catalyst and its amount, and the pH of the medium on the yields of the final products of the hydroxyarylation of buta-1,3-diene (hydroxyarylbutenes) and on the ratio of the 1,2- and 1,4-adducts have been studied.[24] A more detailed investigation established[11] that arenediazonium sulfates and nitrates react with buta-1,3-diene in the presence of a catalyst in a water–acetone medium at pH 5–7 with vigorous evolution of nitrogen and the formation of hydroxyphenylbutenes.[11] The best yields of the products of the hydroxyphenylation of buta-1,3-diene are obtained when mixtures of copper and iron(II) sulfates and of copper nitrate and copper powder or iron filings are used as the catalyst. The hydroxyphenylation of buta-1,3-diene proceeds in both the 1,2- and 1,4-positions with the preferential formation of the 1,4-adduct. 4-Hydroxy-1-phenylbut-2-ene (28%) and 2-hydroxy-1-phenylbut-3-ene (7%) were isolated and their structures were confirmed by chemical reactions.

$$ArN_2X + CH_2{=}CH{-}CH{=}CH_2 + HOH \xrightarrow[Cu(NO_3)_2 + Cu(Fe)]{CuSO_4 + FeSO_4}$$
$$\rightarrow ArCH_2{-}CH{=}CH{-}CH_2OH$$
$$\rightarrow ArCH_2{-}\underset{OH}{CH}{-}CH{=}CH_2$$

Ar = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$, *p*-$NO_2C_6H_4$.
X = HSO_4, NO_3.

Under analogous conditions, arenediazonium tetrafluoroborates interact with buta-1,3-diene in the presence of copper acetate or bicarbonate to form hydroxyarylbutenes.

In the anionarylation of isoprene, the aryl group adds to the isoprene molecule in the 1-position while the hydroxy-group adds in the 2- and 4-positions of the diene chain (the yield of the corresponding products is 30%–42%).[13]

$$ArN_2X + CH_2{=}C(CH_3){-}CH{=}CH_2 + HOH \xrightarrow{Cat.}$$
$$\rightarrow ArCH_2{-}C(CH_3){=}CH{-}CH_2OH$$
$$\rightarrow ArCH_2{-}\underset{OH}{C}(CH_3){-}CH{=}CH_2$$

Treatment of 4-hydroxy-2-methyl-1-phenylbut-2-ene and 2-hydroxy-2-methyl-1-phenylbut-3-ene with thionyl chloride afforded in both cases only 4-chloro-2-methyl-1-phenylbut-2-ene.[25] γ-Benzyl-β-methylacrolein, identified by the melting point of the semicarbazone, was obtained by the reaction of 4-hydroxy-2-methyl-1-phenylbut-2-ene with oxygen in dimethyl sulfoxide (DMSO) and also by the reaction of 4-chloro-2-methyl-1-phenylbut-2-ene, obtained from 4-hydroxy-2-methyl-1-phenylbut-2-ene, with a secondary nitropropane in an alkaline medium.[26] Furthermore, treatment of 4-chloro-2-methyl-1-phenylbut-2-ene with potassium hydroxide in dioxane led to the synthesis of 2-methyl-1-phenylbuta-1,3-diene.[25]

$$C_6H_5CH_2{-}C(CH_3){=}CH{-}CH_2OH \xrightarrow{SO_2Cl} C_6H_5CH_2{-}C(CH_3){=}CH{-}CH_2Cl$$
$$C_6H_5CH_2{-}C(CH_3){=}CH{-}CH_2OH \xrightarrow[DMSO]{O_2} C_6H_5CH_2{-}C(CH_3){=}CH{-}CHO$$
$$C_6H_5CH_2{-}C(CH_3){=}CH{-}CHO \xleftarrow{CH_3CH(NO_2)CH_3} C_6H_5CH_2{-}C(CH_3){=}CH{-}CH_2Cl$$
$$C_6H_5CH_2{-}C(CH_3){=}CH{-}CH_2Cl \xrightarrow{KOH} C_6H_5CH{=}C(CH_3){-}CH{=}CH_2$$

The reactions of arenediazonium tetrafluoroborates with buta-1,3-diene and isoprene both in acetone and in a water–acetone mixture in the presence of copper fluoride or acetate and various added alcohols take place with evolution of nitrogen and the formation of 4-alkoxy-1-arylbut-2-enes.[27]

$$ArN_2X + CH_2{=}CR{-}CH{=}CH_2 + AlkOH \xrightarrow{-N_2}$$
$$\rightarrow ArCH_2{-}CR{=}CH{-}CH_2{-}OAlk$$

Ar = C_6H_5, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4.
X = BF_4, HSO_4, NO_3.
R = H, CH_3.

Similar products have been obtained by the interaction of arenediazonium sulfates and nitrates with dienes in the anionarylation reaction with the corresponding alcohols. Methyl, ethyl, isopropyl, n-butyl, isobutyl, *tert*-butyl, and benzyl alcohols as well

as ethylene glycol were used. In the presence of ethylene glycol, the alkoxyarylation takes place with participation of both hydroxy-groups.

$$2\,CH_2{=}CR{-}CH{=}CH_2 + 2\,ArN_2BF_4 \xrightarrow[-N_2]{HOCH_2CH_2OH} \longrightarrow [ArCH_2CR{=}CHCH_2OCH_2]_2$$

15%–20%

The best yields of the alkoxyarylation products are attained when primary alcohols are used (31%–57%). In the presence of secondary alcohols, the yields of the products fall (14%–23%), whilst tertiary alcohols do not react, which can probably be accounted for by steric factors.

Grishchuk showed for the first time[28] that the anionarylation and arylation reactions can take place simultaneously. Thus the interaction of arenediazonium tetrafluoroborates with buta-1,3-diene in the 1 : 2 water–acetone mixture in the presence of formic acid or its salts proceeds with formation of a mixture of compounds via the following mechanism:

$$C_6H_5N_2BF_4 + CH_2{=}CH{-}CH{=}CH_2 + X{-}O{-}\overset{\overset{O}{\|}}{C}{-}H \longrightarrow$$

X = H, Na.

$$\longrightarrow C_6H_6 + C_6H_5OH + C_6H_5CH_2{-}CH{=}CH{-}CH_2O{-}\overset{\overset{O}{\|}}{C}{-}H$$

1.8% 11.2% 4.3%

$$+ C_6H_5CH_2{-}CH{=}CH{-}CH_2OH + C_6H_5CH_2{-}\underset{\underset{OC(O)H}{|}}{CH}{-}CH{=}CH_2$$

26.3% 7.8%

$$+ C_6H_5CH_2{-}\underset{\underset{OH}{|}}{CH}{-}CH{=}CH_2 .$$

48.6%

Gas–liquid chromatography is used to separate and identify the reaction products.

It has been found that arenediazonium tetrafluoroborates interact vigorously with buta-1,3-diene and isoprene under the conditions of oxidation-reduction catalysis in the presence of added sodium nitrite, chloride, bromide, fluoride, propionate, butyrate, and acetate with formation of anionarylation products (in 32%–47% yield).[14] The aryl group and the anionic residue add regioselectively in the 1,4-positions in the diene fragment.

$$ArN_2X + CH_2{=}CR{-}CH{=}CH_2 \xrightarrow[-MX,\,-N_2]{MA} \longrightarrow ArCH_2{-}CR{=}CH{-}CH_2{-}A$$

X = BF_4, HSO_4, NO_3.
R = H, CH_3.
A = NO_2, F, Cl, Br, Ac.

Nitro-, fluoro-, chloro-, bromo-, and carboxy-arylbutenes have been obtained in this way.

Ganushchak et al.[14] were the first to find that arenediazonium tetrafluoroborates interact with isoprene in the presence of an excess of sodium sulfide in anhydrous acetone to form sulfidearylation products [arylalkenyl sulfides] in 25% yield.

$$2\,ArN_2BF_4 + 2\,CH_2{=}C(CH_3){-}CH{=}CH_2 + Na_2S \xrightarrow[-N_2]{} \longrightarrow [ArCH_2{-}C(CH_3){=}CH{-}CH_2]_2S$$

Ar = C_6H_5, p-$CH_3C_6H_4$.

Arenediazonium tetrafluoroborates were introduced into the reaction in the form of dry salts in acetone, whilst the sulfates and nitrates were introduced in solution in aqueous acetone (pH 5–7). The catalysts employed were copper acetate in the case of the tetrafluoroborates and copper and iron(II) sulfates or copper nitrate and iron and copper powders respectively in the case of the sulfates and nitrates.

In order to investigate the influence of the nature of the anion of the diazonium salts further, a study has been made[12] of the interaction of buta-1,3-diene, isoprene, and chloroprene with arenediazonium acetates in aqueous acetone in the presence of copper acetate. It was established that arenediazonium acetates react under the above conditions with dienes, the process involving the evolution of nitrogen and the addition of the aryl residue and of the acetoxy-group preferentially in the 1,4-positions in the diene chain respectively. Only in a few individual instances were the products of 1,2-acetoxyarylation isolated in small amounts. The corresponding aromatic hydrocarbons (10% to 15%) and esters $ArOCOCX_3$ (5%–7%) are formed as side products.

The familiar 1-acetoxy-4-phenylbut-2-ene and the isomeric 2-acetoxy-1-phenylbut-3-ene were synthesised in proportions of 6 : 1 by the interaction of benzenediazonium acetate with buta-1,3-diene. The reactions of benzene- and toluene-p-diazonium acetates with isoprene afforded the 2-acetoxy-1-phenyl and 4-acetoxy-1-phenyl derivatives. After the reaction of ring-substituted benzenediazonium acetates with buta-1,3-diene and isoprene, only the products of 1,4-acetoxyarylation were isolated.

$$ArN_2O\overset{\overset{O}{\|}}{C}CX_3 + CH_2{=}CR{-}CH{=}CH_2 \xrightarrow[-N_2]{Cu(CH_3COO)_2}$$

$$\longrightarrow ArCH_2CR{=}CHCH_2O\overset{\overset{O}{\|}}{C}CX_3$$

$$\longrightarrow ArCH_2{-}\underset{\underset{OC(O)CX_3}{|}}{CR}{-}CH{=}CH_2$$

Ar = C_6H_5, p-$CH_3C_6H_4$, p-$CH_3OC_6H_4$, p-ClC_6H_4.
X = H, Cl, F.
R = H, CH_3.

Arenediazonium trichloroacetates and trifluoroacetates were also tested in the anionarylation reactions of 1,3-dienes, which led to the corresponding acetoxy(aryl)butenes. The yields of 1-acetoxy-4-arylbutenes were 25%–40%.

A number of studies have been devoted to the interaction of diazonium salts with dienes under both catalytic and non-catalytic conditions with participation of thiocyanates.[29–31] It was established that arenediazonium tetrafluoroborates interact vigorously with buta-1,3-diene and isoprene in the presence of catalytic amounts of copper salts and alkali metal thiocyanates. This entails the coupled addition of the aryl group in the 1-position and of the isothiocyanate group predominantly in the 2-position in the diene chain. The reaction was carried out in acetone or aqueous acetone at temperatures between –30 and –15 °C.

$$ArN_2BF_4 + CH_2{=}CR{-}CH{=}CH_2 + MSCN \longrightarrow$$

$$\longrightarrow ArCH_2{-}\underset{\underset{N{=}C{=}S}{|}}{CR}{-}CH{=}CH_2 + N_2 + MBF_4$$

Ar = C_6H_5, p-$CH_3C_6H_4$, p-$CH_3OC_6H_4$.
R = H, CH_3.

Table 1. Conditions in the reactions of aromatic diazonium salts with 1,3-dienes in the presence of nucleophiles.

Anionarylation reaction	Diazonium salt	Diene	Anionoid reagent	Catalyst	Diazonium salt : diene : catalyst	Reaction medium	Yield[a] (%)	Ref.

[a] The yield of 1,4-adducts is quoted.
[b] The overall yield of 1,2- and 1,4-adducts.
[c] The yield of the 1,2-adducts is quoted.

It was established that, together with copper acetate and bicarbonate, copper(II) tetrafluoroborate is an effective catalyst of the isothiocyanatoarylation of dienes. The yields of 1-aryl-2-isothiocyanatobut-3-enes are almost the same when the above catalysts are employed and amount to 45% – 63%. It was shown that the reaction can occur also in the absence of copper(II) salts, but the yields of 1-aryl-2-isothiocyanatobut-3-enes are then lower by 17% – 24%. Small amounts of side products (~ 10%) resulting from the reduction of the diazonium salts and substituted isothiocyanatobenzenes were isolated.

1-Aryl-2-isothiocyanatobut-3-enes proved to be fairly convenient starting reagents for the synthesis of previously unknown mono-1,3-di- and 1,1,3-tri-substituted thioureas, namely *N*-(1-arylbut-3-en-2-yl)thioureas, by reaction with ammonia and aliphatic amines.[31]

$$ArCH_2-\underset{\underset{N=C=S}{|}}{CR^1}-CH=CH_2 + HNR^2R^3 \longrightarrow$$

The absence, until recently, of data on the iodoarylation of unsaturated compounds can be explained, in our view by the fact that copper salts and arenediazonium iodides were used as the catalyst by analogy with the Meerwein reaction. Arenediazonium iodides are known to be extremely unstable and, in addition, the iodide anion is readily oxidised to molecular iodine under the experimental conditions.

$$ArN_2X + CH_2=C(CH_3)-CH=CH_2 + MI \longrightarrow$$

Ganushchak et al.[33] achieved for the first time the iodoarylation of isoprene. They used ethyl alcohol, acetone, DMSO, dimethylformamide (DMF), and water as the solvents. The best yields of the iodo-derivatives are obtained when DMF and arenediazonium tetrafluoroborates are used. The conditions in the reactions of aromatic diazonium salts with 1,3-dienes in the presence of nucleophiles are presented in Table 1.

IV. Anionarylation of monounsaturated compounds

The possibility of the anionarylation of monounsaturated compounds was first described by Grishchuk.[34] It was shown that arenediazonium tetrafluoroborates interact with acrylonitrile, methyl methacrylate, vinyl chloride, and vinylidene chloride in the presence of sodium nitrite, chloride, and bromide and catalytic amounts of copper salts in such a way that coupled addition of the aryl group and the anion takes place at the point of rupture of the double bond and arylchloro(bromo)ethanes are formed in 25% – 75% yield.

$$ArN_2BF_4 + CH_2=CX^1X^2 + NaA \xrightarrow[-N_2]{}$$

$$\longrightarrow ArCH_2CX^1X^2A + NaBF_4$$

Ar = C_6H_5, *p*-$CH_3C_6H_4$.
X^1 = H, CH_3; X^2 = Cl, Br, CH_3COO, CN, C_6H_5.

The reaction of benzenediazonium tetrafluoroborate with styrene in the presence of sodium nitrite leads to the formation of 1-nitro-1,2-diphenylethane and *trans*-stilbene,[34] while the reaction of acrylonitrile, methyl methacrylate, and vinylidene chloride in the presence of an excess of sodium sulfide affords the corresponding sulfide in 25% yield under catalytic conditions.[34]

$$C_6H_5N_2BF_4 + CH_2=CX^1X^2 + Na_2S \xrightarrow[-N_2]{}$$

$$\longrightarrow [C_6H_5CH_2CX^1X^2]_2S$$

X^1 = H, CH_3, Cl; X^2 = CN, CH_3COO, Cl.

It has been established[35] that *p*-nitrobenzenediazonium sulfates react vigorously with acrylonitrile at 5 – 10 °C in aqueous acetone in the presence of copper and potassium thiocyanate to form β-(*p*-nitrophenyl)-α-thiocyanatopropionitrile in 50% yield.

It was later established[21] that, regardless of the anion of the diazonium salt, arenediazonium sulfates, nitrates, and tetrafluoroborates form the same anionarylethanes on interaction with acrylonitrile, methyl methacrylate, vinyl acetate, styrene, and vinylidene chloride in the presence of sodium chloride, bromide, thiocyanate, and nitrite as well as the catalyst (copper acetate).

$$p\text{-}NO_2C_6H_4N_2HSO_4 + CH_2=CHCN + KSCN \longrightarrow$$

$$\longrightarrow p\text{-}NO_2C_6H_4CH_2-\underset{\underset{SCN}{|}}{CHCN} + N_2 + KHSO_4$$

Under the same conditions, the corresponding sulfides are formed in the presence of sodium sulfide.[21]

$$ArN_2X + CH_2=C\begin{matrix}R^1\\R^2\end{matrix} \xrightarrow{NaA} ArCH_2-\underset{\underset{A}{|}}{\overset{\overset{R^1}{|}}{C}}-R^2 + N_2 + NaX$$

30% – 35%

Naidan et al.[36] investigated the thiocyanatoarylation of acrylonitrile, methyl methacrylate, and styrene. They showed that benzenediazonium sulfates interact with the above monounsaturated compounds in aqueous acetone in the presence of thiocyanate ions.

$$CH_2=CR^1R^2 + ArN_2HSO_4 + NH_4SCN \longrightarrow$$

$$\longrightarrow ArCH_2C(SCN)R^1R^2 + N_2 + (NH_4)_2SO_4$$

R^1 = H, CH_3; R^2 = CN, $COOCH_3$, C_6H_5.

The thiocyanatoarylation reaction in a sulfur dioxide-saturated acetic acid–acetone mixture at temperatures between −16 and −20 °C results in the addition of the thiocyanato- and arenesulfonyl groups to the unsaturated compound. For example, the thiocyanato-group adds in the α-position of styrene, while the arenesulfonyl group adds in the β-position. The yield of 2-arene-sulfonyl-1-phenyl-1-thiocyanatoethane is 53%–58%.

$$ArN_2HSO_4 + SO_2 + C_6H_5CH{=}CH_2 + NH_4SCN \xrightarrow{Cu(SCN)_2} C_6H_5CH(SCN)CH_2SO_2Ar + N_2 + (NH_4)_2SO_4$$

It has also been noted[36] that the earlier hypothesis[35] that copper(II) thiocyanate is the reaction catalyst is incorrect; in fact the catalyst is copper(I) thiocyanate, which is formed readily under the reaction conditions.

In aqueous acetone at 5–10 °C in the presence of copper(I) ethylxanthate and potassium xanthate, acrylonitrile reacts with benzene- and *p*-nitrobenzene-diazonium sulfates.[37] The reaction proceeds with evolution of nitrogen and leads to α-(ethoxythiocarbonylthio)-β-phenylpropionitrile (51%) and α-(ethoxythiocarbonylthio)-β-(*p*-nitrophenyl)propionitrile (40%).

$$CH_2{=}CHCN + ArN_2HSO_4 + C_2H_5OC(S)SK \longrightarrow ArCH_2CH(SC(S)OC_2H_5)CN + N_2 + KHSO_4$$

Ar = C_6H_5, *p*-$NO_2C_6H_4$.

It has been established[38] that in the anionarylation reaction *p*-nitrobenzene-diazonium sulfate interacts with acrylonitrile in the presence of sodium diethyl phosphorodithioate to form α-(diethoxythiophosphorylthio)-β-(*p*-nitrophenyl)-propionitrile in 72% yield.

$$p\text{-}NO_2C_6H_4N_2HSO_4 + CH_2{=}CHCN + (C_2H_5O)_2P(S)SNa \longrightarrow p\text{-}NO_2C_6H_4CH_2CH(CN)SP(S)(OC_2H_5)_2 + N_2 + NaHSO_4$$

The reaction takes place at room temperature and the catalyst is copper *O,O*-diethyl phosphorodithioate.

Interesting data have been published on the anionarylation of acrylic and methacrylic acid esters.[20,39] It was shown that arenediazonium tetrafluoroborates react with acrylic and methacrylic acid esters in acetone or the 1 : 2 water–acetone mixture in the presence of potassium thiocyanate with evolution of nitrogen and the addition of the aryl and thiocyanato-groups at the site of rupture of the double bond in the monounsaturated compound to form 1-alkoxycarbonyl-2-aryl-1-thiocyanatoethanes.

$$R^1C_6H_4N_2BF_4 + CH_2{=}CR^2COOR^3 + KSCN \longrightarrow R^1C_6H_4CH_2{-}\underset{SCN}{CR^2}COOR^3 + KBF_4 + N_2$$

R^1 = H, *m*(*p*)-CH_3, *p*-CH_3O.
R^2 = H, CH_3; R^3 = CH_3, C_2H_5, C_4H_9, *iso*-C_4H_9.

Thiocyanatoarylation takes place at temperatures from −30 to −15 °C. The structure of the diazonium salt and of the monounsaturated compound as well as the nature of the reaction medium (acetone or aqueous acetone) hardly affect the yields of 1-alkoxycarbonyl-2-aryl-1-thiocyanatoethanes, which are ~50%–70%. When toluene-*m*-diazonium tetrafluoroborate is introduced into the reaction, the yields of 1-alkoxycarbonyl-1-thiocyanato-2-(*m*-tolyl)ethanes are somewhat lower (~40%). Isothiocyanatobenzenes are formed in ~20% yield together with the thiocyanatoarylation reaction.

Copper(II) salts were tested as the catalysts: the acetate, bicarbonate, and tetrafluoroborate. It was established that the catalysts ensure comparable yields of 1-alkoxycarbonyl-2-aryl-1-thiocyanatoethanes, i.e. the anion of the copper salt does not affect the anionarylation process.

The study of the thiocyanatoarylation of acrylic and methacrylic acid esters in the absence of copper salts is of definite interest. In this case, the yield of isothiocyanatobenzenes predominates over that of thiocyanatobenzenes [the yield of the corresponding 1-alkoxycarbonyl-2-aryl-1-thiocyanatoethanes in the absence of copper(II) salts is lower by 40%–50%].

It has been shown[40] that arenediazonium tetrafluoroborates interact with α,β,β′-trifluorostyrene and potassium thiocyanate in acetone, forming the thiocyanatoarylation products—2-aryl-1,2,2-trifluoro-1-phenyl-1-thiocyanatoethanes (yield 36% to 46%).

$$ArN_2BF_4 + C_6H_5CF{=}CF_2 + KSCN \longrightarrow ArCF_2CF(SCN)C_6H_5 + KBF_4 + N_2$$

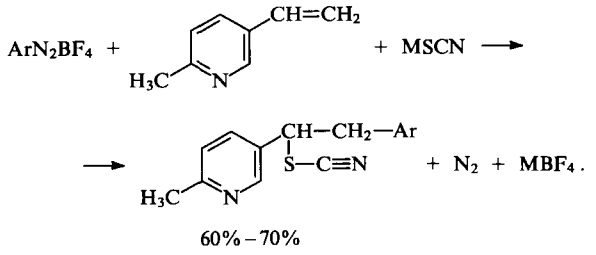
Ar = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$.

This reaction proceeds also in the absence of catalysts—copper or iron salts. Apparently, depending on the degree of electron saturation of the double bond and the nature of the anion, the reaction proceeds via different mechanisms.

$$C_6H_5CHal{=}CH_2 + ArN_2BF_4 + KSCN \xrightarrow{(CH_3)_2CO} \begin{cases} C_6H_5C(SCN){=}CHAr \\ 19\% \\ C_6H_5CH{=}CHAr \\ 22\% \end{cases}$$

The interaction of α-bromo- and α-chloro-styrenes[41] with potassium thiocyanate and arenediazonium salts in acetone in the presence of copper(II) salts leads to *trans*-α-thiocyanatostilbenes and *trans*-stilbenes. The ratio of the reaction products depends on the nature of the solvent: both compounds are formed in acetone whereas *trans*-stilbenes are formed predominantly in aqueous acetone.

It has been established that[22,42] arenediazonium tetrafluoroborates actively interact with vinyl chloride and vinylidene chloride in acetone or the 1 : 4 water–acetone mixture in the presence of copper or iron thiocyanate and potassium (sodium or ammonium) thiocyanate at temperatures between −15 and −5 °C with evolution of nitrogen, affording the products of the addition of the aryl and thiocyanato-groups at the site of the dissociation of the double bond of the monounsaturated compound—2-aryl-1-chloro-1-thiocyanatoethanes and 2-aryl-1,1-dichloro-1-thiocyanatoethanes (yield 73%–82%).



$$ArN_2BF_4 + CH_2{=}CR^1Cl + MSCN \longrightarrow ArCH_2{-}\underset{SCN}{CR^1Cl} + N_2 + MBF_4$$

Ar = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$.
R^1 = H, Cl; M = K, Na, NH_4.

The optimum diazonium salt : unsaturated compound : thiocyanate reactant ratios are 1 : 2 : 1.5. Isothiocyanatobenzenes are formed as side products (10%–15%). The excess of the olefin in the reaction system promotes the main reaction and is also necessary to compensate for the amount of the olefin carried away by the evolved nitrogen.[22]

Arenediazonium tetrafluoroborates interact with allyl chloride and bromide between −15 and −5 °C in the presence of alkali metal thiocyanates to form 1-aryl-3-chloro(bromo)-2-thiocyanatopropanes.[43] The reaction takes place only with participation of copper or iron salts. The yields of the thiocyanatoarylation products are 35%−40%.

2-Methyl-5-vinylpyridine reacts with arenediazonium tetrafluoroborates in the 1:4 water−acetone mixture in the presence of thiocyanates[44] to form 5-(2-aryl-1-thiocyanatoethyl)-2-methylpyridines in accordance with the following mechanism:

60%−70%

The reaction proceeds at a temperature between −65 and −50 °C both in the presence and absence of the catalyst−copper or iron salts. Isothiocyanatobenzenes are formed as side products in a yield of ~7%−10%.

It has been shown[45] that a sulfur-dioxide-saturated solution of benzenediazonium chloride containing copper chloride reacts with styrene at room temperature. The chlorine atom and the benzenesulfonyl group then add at the site of the dissociation of the carbon−carbon double bond, forming 2-benzenesulfonyl-1-chloro-1-phenylethane in 42% yield. Apparently, when benzenediazonium chloride is saturated with sulfur dioxide, benzenesulfonyldiazonium chloride is formed and subsequently reacts with styrene after splitting off nitrogen.

$$C_6H_5N_2Cl + SO_2 + C_6H_5CH{=}CH_2 \xrightarrow{CuCl_2}$$
$$\longrightarrow C_6H_5CHClCH_2SO_2C_6H_5 + N_2$$

In a sulfur-dioxide-saturated mixture of acetic acid and acetone, styrene reacts with aromatic diazonium salts in the presence of chloride and bromide anions, *O,O*-diethyl phosphorodithioates, xanthates, and catalytic amounts of copper ions, affording respectively 1-chloro-, 1-bromo-, 1-(diethoxythiophosphorylthio)-, and 1-(ethoxythiocarbonylthio)-derivatives of 2-arenesulfonyl-1-phenylethanes in 28%−83% yields.[46]

$$ArN_2X + SO_2 + C_6H_5CH{=}CH_2 + MA \xrightarrow{CuA_2}$$
$$\longrightarrow C_6H_5CH(A)CH_2SO_2Ar + N_2 + MX$$

X = Cl, Br, HSO_4.

It has been suggested[41] that an important factor promoting the anionarylation reaction in the absence of a catalyst is an increase in the nucleophilicity of the anion in the added anionoid reagent. In order to confirm this hypothesis, a study has been made[47,48] of the interaction of diazonium salts with acrylic and methacrylic acid esters in the presence of the *N,N*-diethyldithiocarbamate anion, which is more nucleophilic than the thiocyanate anion.

Arenediazonium tetrafluoroborates, sulfates, and nitrates react vigorously with acrylic and methacrylic acid esters, evolving nitrogen and forming 2-aryl-1-(*N,N*-diethylthiocarbamoylthio)-1-methoxycarbonylethanes. The reaction takes place at a temperature between −50 and −20 °C in acetone or aqueous acetone for a 1:1.5 molar ratio of the diazonium salt and the salts of *N,N*-diethyldithiocarbamic acid. The presence of a catalyst — copper(II) or iron(II) salts — hardly affects the *N,N*-diethyldithiocarbamatoarylation of acrylates. The yields of the products are 51%−62%. Those of the target products are independent of the order in which the reagents are introduced into the reaction medium. When arenediazonium sulfates and nitrates are used, the yields of aryl(*N,N*-diethylthiocarbamoylthio)ethanes are lower by 25%−30% than in the case where tetrafluoroborates are used. This can be explained by the fact that aqueous solutions of diazonium salts have pH 3−4 and *N,N*-diethyldithiocarbamic acid is formed under these conditions. The acid is unstable and immediately decomposes.

$$ArN_2X + CH_2{=}CR^1C(O)OCH_3 + MS(S)CN(C_2H_5)_2 \longrightarrow$$
$$\longrightarrow ArCH_2CR^1(COCH_3)SCN(C_2H_5)_2 + N_2 + MX$$

Ar = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$.
X = BF_4, HSO_4, NO_3; R^1 = H, CH_3; M = Na, K, NH_4.

The considerable difference between the nucleophilicities of the thiocyanate and *N,N*-diethyldithiocarbamate groups as well as the presence in the second case of unshared electrons at the second sulfur atom (α-atom) joined to the nucleophilic centre can apparently explain why the dithiocarbamatoarylation process proceeds also in the absence of a catalyst.

It has been shown[47,48] that diazonium salts interact with salts of *N,N*-diethyldithiocarbamic acid in acetone or aqueous acetone at temperatures between −50 and −10 °C, forming *N,N*-diethylthiocarbamoylthiobenzenes in 60%−70% yields.

The iodoarylation of methyl acrylate and methacrylate was described for the first time by Ganushchak et al.[49]

$$ArN_2X + CH_2{=}CR^1R^2 \xrightarrow{MI} ArCH_2{-}\overset{I}{C}R^1R^2$$

X = Cl, BF_4, HSO_4; R^1 = H, CH_3; R^2 = $COOCH_3$.

Alcohol, acetone, dimethyl sulfoxide, dimethylformamide, and water were used as solvents.

The iodoarylation of acrylic ar ylic acid esters and acrylonitrile has been investiga· ·ie fully.[50] It has been established that these compounds interact with aromatic diazonium salts and iodide ions, the aryl group and the iodide ion being added to the double bond. The aryl group adds to the extreme methylene group.

$$ArN_2X + CH_2{=}CR^1R^2 + MI \longrightarrow$$
$$\longrightarrow ArCH_2{-}\overset{I}{C}R^1R^2 + MX + N_2$$
22%−60%

R^1 = H, CH_3, C_3H_7; R^2 = $COOC_4H_9$, CN; X = Cl, BF_4, HSO_4.
R^2 = $C(O)OCH_3$; M = K, Na, NH_4.

The optimum diazonium salt:monomer:iodide reactant ratios are 5:3:5. The reaction takes place in an aqueous medium and in various organic solvents (alcohol, benzene, dioxane, dimethyl sulfoxide, dimethylformamide). The yields of aryliodoethanes are influenced by the structure of the substrate and also by the nature and position of the substituent in the aromatic ring of the diazonium salt. The iodoarylation of acrylonitrile proceeds more vigorously than that of the acrylic acid esters. The yields of the aryliodo-derivatives increase on passing from methyl esters of acrylic acids to the butyl esters and following the introduction of alkyl substituents in the α-position, which may be accounted for by the stability of the intermediate $Ar{-}CH_2\dot{C}(R^1)C(O)OAlk$. Arenediazonium salts containing electron-donating substituents in the *para*-position afford higher yields of the target products compared with the *ortho*- and *meta*-isomers.

Table 2. Conditions in the reactions of aromatic diazonium salts with alkenes in the presence of nucleophiles.

Anionarylation reaction	Diazonium salt	Alkene	Anionoid reagent	Catalyst	Diazonium salt : diene : catalyst	Reaction medium	Yield (%)	Ref.
Nitroarylation	ArN_2BF_4	Acrylonitrile, styrene, methyl methacrylate	$NaNO_2$	$Cu(CH_3COO)_2$	1 : 1 : 0.1	Acetone – water (4 : 1)	20 – 30	21
Sulfidoarylation	ArN_2BF_4	"	Na_2S	$Cu(CH_3COO)_2$	1 : 1 : 0.1	"	20 – 32	21

Together with the iodoarylation products, the products of the iodination of the aromatic ring are formed in all cases. Both reactions apparently begin with the reduction of the diazonium cation by the iodide anion to give the aryl group, which forms an iodoarene or an aliphatic-aromatic radical. The radical reaction mechanism has been confirmed by the formation of aryliodo-derivatives in the presence of other anions.

When 2-aryl-1-iodo-1-methoxycarbonyl(cyano)alkanes are treated with alcoholic alkali, the compound is dehydroiodinated and the ester group is hydrolysed; derivatives of cinnamic acid, containing substituents in the α-position and in the aromatic ring, are then formed in high yields (48%–90%).[50]

In order to extend the limits of the iodoarylation reaction, a study has been made[51] of the interaction of arenediazonium tetrafluoroborates with phenyl-acetylene and lithium iodide in aqueous dimethyl sulfoxide at pH 5–7 and at a temperature of 20–37 °C.

$$ArN_2X + HC{\equiv}C{-}C_6H_5 + LiI \longrightarrow \underset{H\ \ I}{\overset{Ar\ \ C_6H_5}{C{=}C}} + LiBF_4 + N_2$$

Ar = C_6H_5, *o*(*m*,*p*)-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$.

The yields of *cis*-(*E*)-α-iodostilbenes are 36%–48%.

The influence of heteroatomic substituents on the possibility of the involvement of the double bond in the iodoarylation reaction has also been investigated[51] in relation to vinyl derivatives of phosphorus containing the $\geq P(O)-CR{=}CH_2$ fragment. The ethyl esters of vinylphosphonic and 2-propenylphosphonic acids were chosen as the objects of study.

It was established that arenediazonium tetrafluoroborates react with the above phosphorus-containing olefins in the presence of lithium fluoride in the same way as with acrylic acid esters and acrylonitrile.

$$ArN_2BF_4 + CH_2{=}C(R^1)P(O)(OC_2H_5)_2 + LiI \longrightarrow$$

$$\longrightarrow ArCH_2{-}\underset{I}{C}(R^1)P(O)(OC_2H_5)_2 + LiBF_4 + N_2$$

21%–49%

Ar = C_6H_5, *o*(*m*,*p*)-$CH_3C_6H_4$; R^1 = H, CH_3.

The direct iodoarylation of unsaturated compounds has not so far been achieved because arenediazonium iodides have not been obtained and, furthermore, Cu_2I_2 is sparingly soluble under the reaction conditions.

Ganushchak et al.[52] investigated anionarylation reactions with the aid of diazonium salts synthesised from benzidine and di(4-aminophenyl) ether. It was shown that the tetrafluoroborates of the diazonium salts derived from benzidine and di(4-aminophenyl) ether react with acrylic and methacrylic acid esters and potassium *O*,*O*-dialkyl phosphorodithioates in the presence of copper acetate and copper powder, forming 4,4′-bis[2-(dialkoxythiophosphorylthio)-2-methoxycarbonylethyl(propyl)]-biphenyls and 4,4-bis[2-(dialkoxythiophosphorylthio)-2-methoxycarbonylethyl(propyl)]-diphenyl ethers.

$$2\,CH_2{=}C(R)COOCH_3 + BF_4N_2{-}C_6H_4{-}X{-}C_6H_4{-}N_2BF_4$$

$$+\ 2\,(R^1O)_2P(S)SK \xrightarrow[-N_2,\ -KBF_4]{Cu(CH_3COO)_2/Cu}$$

$$\longrightarrow H_3COOC(R)CH_2{-}C_6H_4{-}X{-}C_6H_4{-}CH_2C(R)COOCH_3$$

$SP(S)(OR^1)_2$ $SP(S)(OR^1)_2$

14%–15%

X = bond, O; R^1 = n-C_3H_7, *iso*-C_3H_7.

The majority of the olefin anionarylation products, for example, 1-chloro-1-thiocyanato-, 1,1-dichloro-1-thiocyanato-, and 1-alkoxycarbonyl-1-thiocyanato-derivatives of 2-arylethanes exhibit antifungal and antibacterial properties.[39,42]

The conditions in the reactions of aromatic diazonium salts with alkenes in the presence of nucleophiles are presented in Table 2.

V. The mechanism of the anionarylation reaction

A necessary condition for the occurrence of the anionarylation reaction is in many cases the presence of a catalyst — copper or iron salts — in the reaction mixture. The reaction occurs in the absence of a catalyst only occasionally. This depends on the structure of the unsaturated compound and the nucleophilicity of the anion introduced.

The data available at present concerning different aspects of the reaction of diazonium salts with unsaturated compounds suggest that it proceeds via a radical-anion mechanism in the presence of a catalyst and via a radical mechanism in its absence.

We shall now consider the mechanism of the anionarylation reaction catalysed by copper and iron compounds, which is presented in Scheme 1. The principal stages of this reaction have been described in detail.[8] In stage (1), arenediazonium tetrafluoroborates interact with anionoid reagents to form the anion-arenediazonium. Under the reaction conditions, copper(II) is readily reduced to copper(I).[3,4,22] Next, the copper(I) salt formed in stage (2) forms a double bond with the anionarenediazonium in which the diazo-group is coordinated to the complex anion $(CuA_2)^-$. In individual instances, such salts have been isolated in a pure form[53] or their existence has been demonstrated conductometrically.[4,55] Next, the double salt forms with the unsaturated compounds a ternary reaction complex A [stage (3)] in which the diazo-group and the olefin are bound to the copper ion.[3,34,54]

Scheme 1

$$ArN_2X + MA \longrightarrow ArN_2A + MX \quad (1)$$

$$ArN_2A + CuA \longrightarrow ArN_2^+(CuA_2)^- \quad (2)$$

$$ArN_2^+(CuA_2)^- + CH_2{=}CR^1R^2 \rightleftharpoons$$

$$\rightleftharpoons \underset{(A)}{\left[ArN_2^+(CuA_2)^- \overset{CH_2}{\underset{CR^1R^2}{\|}}\right]} \quad (3)$$

$$\left[ArN_2^+(CuA_2)^- \overset{CH_2}{\underset{CR^1R^2}{\|}}\right] \xrightarrow[-N_2]{} \left[Ar{-}CH_2{-}\dot{C}R^1R^2{\cdots}CuA_2\right] \quad (4)$$

$$\left[Ar{-}CH_2{-}\dot{C}R^1R^2{\cdots}CuA_2\right] \xrightarrow[-CuA]{} Ar{-}CH_2{-}CR^1R^2A \quad (5)$$

The formation of transition metal, including copper and iron, complexes with arenediazonium salts has been demonstrated.[34,53–55] Such complexes are relatively stable in aqueous organic, organic, and aqueous solutions in the cold and at room temperature, but begin to decompose after the addition of the unsaturated compound.

It has long been known that copper(I) salts form π-complexes with diene and monounsaturated compounds in organic and aqueous media[54,56] (this factor constitutes the basis of the industrial chemisorption separation of hydrocarbons[57]). The evolution of nitrogen, which occurs only after the addition of the unsaturated compound, is a sign of the onset of the reaction.

Electron transfer from copper(I) to the diazonium cation in complex A (see Scheme 1) leads to the evolution of nitrogen from the diazo-group and the formation of the radical Ar$^\cdot$ and copper(II). It has been shown[58] that, on exposure to the polarising action of the copper ion, the arenediazonium cation is reduced to the radical Ar$^\cdot$ via a one-electron mechanism.

$$C_6H_5N_2^+ + e \longrightarrow C_6H_5N_2^{\cdot} \longrightarrow C_6H_5^{\cdot} + N_2$$

Next, the radical Ar$^{\cdot}$ forms an aliphatic–aromatic radical with the unsaturated compound without passing to the bulk of the solution [stage (4)]. On interaction with CuA_2, the aliphatic–aromatic radical then affords anionarylation products as a result of the transfer of the radical-anion [stage (5)]. The formation of such radicals has been detected by EPR with the aid of spin-trapping agents.[59]

When iron(II) salts are used, the reaction proceeds in accordance with the following scheme in our view.

Scheme 2

$$ArN_2A \longrightarrow A\dot{r} + N_2 + A^{\cdot} \quad (6)$$

$$A\dot{r} + CH_2{=}CR^1R^2 \longrightarrow \underset{\textbf{(B)}}{Ar{-}CH_2{-}\dot{C}R^1R^2} \quad (7)$$

$$Ar{-}CH_2{-}\dot{C}R^1R^2 + A^{\cdot} \longrightarrow Ar{-}CH_2{-}\underset{\displaystyle A}{\underset{|}{C}}R^1R^2 \quad (8)$$

$$A\dot{r} + A^{\cdot} \longrightarrow ArA \quad (9)$$

$$Ar{-}CH_2{-}\dot{C}R^1R^2 + CH_2{=}CR^1R^2 \longrightarrow Ar{-}CH_2{-}CR^1R^2{-}CH_2{-}\dot{C}R^1R^2 \longrightarrow \text{tarry polymeric substances.} \quad (10)$$

Apart from copper and iron salts, the salts of other variable-valence metals with similar oxidation–reduction potentials can also play the role of catalysts.

We shall now proceed to the consideration of the anionarylation of olefins in the absence of a catalyst (Scheme 2). In this case, the diazonium salts interact in the first stage with the anionoid reagents to form the anionarenediazonium, which then readily decomposes via reaction (6).[60,61] The aryl radical formed interacts with the olefin, affording the aliphatic–aromatic radical **B** [stage (7)].[58,62] The subsequent mode of reaction is determined by the stability of this radical. If radical **B** is sufficiently stable, the anionarylation of unsaturated compounds [stage (8)] takes place, but if radical **B** is unstable, reaction (10), leading mainly to tarry polymeric substances, occurs.

The presence of anionoid reagents in systems containing a diazonium salt is known to lead to its decomposition via a radical mechanism. The aryl radicals formed have been detected by EPR.[63]

* * *

In conclusion we may note that the expansion of the range of unsaturated compounds and aromatic diazonium salts used in the anionarylation reaction in order to obtain aliphatic-aromatic synthons containing several reaction centres, which are otherwise difficult to obtain, is of undoubted interest for organic synthesis. The improvement of methods used in anionarylation reactions is an important aspect. It will make it possible to reduce competing reactions to a minimum.

Abstract. Studies carried out in recent years on the radical chemistry of organobromine compounds, primarily on their application as addends in addition and telomerisation reactions, are surveyed. The use of metal complex initiating systems based on iron pentacarbonyl, together with traditional peroxide initiators, is described. This made it possible to expand significantly the synthetic possibilities of these reactions in view of their highly selective course involving the C–Br bond, and the involvement in the reaction of organic monobromo- and dibromo-compounds which hardly react under the conditions of peroxide initiation. The first examples of the stereocontrolled occurrence of the radical addition of organobromine addends to chiral monomers, leading to one of the stereoisomers, are presented. The bibliography includes 36 references.

I. Introduction

The radical reactions occurring with dissociation of the C–Br bond have been investigated to a lesser extent than the analogous processes with organochlorine compounds, but the greater ease of the dissociation of the C–Br bond as well as the high reactivity of even single bromine atoms activated by neighbouring groups lead to extensive possibilities for the synthesis of a wide variety of polyfunctional organic compounds. Organic bromo-derivatives readily enter into radical addition and telomerisation reactions; in the initiation stage, they actively generate radicals as a consequence of the dissociation of the C–Br bond, while in the chain-transfer stage their reactivity is caused by the greater ease (than for the chloro-derivatives) of electron transfer in the transition state as a consequence of the ready polarisability of the C–Br bond. This determines also the wide range of initiators and initiating influences which may be used—peroxides, azo-compounds, irradiation, oxidation–reduction systems, and, in certain cases, also ordinary illumination.

The significant difference in the chemical behaviour of chloro- and bromo-derivatives as telogens (addends) can be clearly seen on comparing the reactions of chloro- and bromoacetic acid esters: the esters of monochloroacetic acid react under radical conditions exclusively via a C–H bond, while monobromoacetic acid esters react via the C–Br bond. Experimental results have shown that the greater the number of halogen atoms at the carbon atom to which bromine is attached, the greater the reactivity of such a compound in addition and telomerisation reactions both in the initiation and chain-transfer stages. The C–Br bond is also activated by electron-accepting substituents in the α-position, for example by ester groups.

Among the bromine-containing compounds investigated, CBr_4 and CCl_3Br are the most reactive. When suitable initiators are used, the reactions involving them proceed at 50–70 °C, which is close to the optimum temperatures.

Dibromodichloromethane is fairly reactive in radical reactions. Among hydrogen-containing polybromomethanes, bromoform is outstanding. In contrast to chloroform, it reacts exclusively with dissociation of the C–Br bond regardless of the initiation conditions. However, the nature of the secondary and side reactions occurring is determined primarily by the nature of the initiating system (see below). Methylene bromide, which also reacts predominantly via the C–Br bond although isolated instances of reactions proceeding via the dissociation of a C–H bond are known,[1] is less effective.

Nonactivated α-alkyl bromides react nonselectively under radical conditions because the radicals formed in the chain propagation stage actively abstract hydrogen atoms from the alkyl chain of the bromoalkane. On the other hand, organic monobromo-compounds with functional group substituents enter readily into addition and telomerisation reactions exclusively via the C–Br bond.

The high effectiveness of bromine-containing compounds in homolytic processes makes it possible to involve readily polymerising monomers—vinyl chloride, acrylic esters, and styrene—in reactions with them. This affords individual adducts or, in isolated instances, mixtures of lower telomers. The first examples of stereocontrolled radical reactions with participation of chiral monomers, which make it possible to drive the process towards the formation of only one of the stereoisomers, have been described. The reaction of bromomethanes with vinyl carbonate provides a simple path to the synthesis of carbohydrates.[2]

The use of monomers with functional group substituents in addition and telomerisation reactions with organobromine compounds, taking into account the possibility of the successive replacement of bromine atoms by other groups, leads to polyfunctional compounds with different lengths of the main chain.

Acetylenes are not very promising in these reactions because they require fairly severe conditions which are incompatible with their explosive nature. The reactions with dienes frequently

A B Terent'ev, T T Vasil'eva Laboratory of Homolytic Reactions of Organoelement Compounds, Nesmeyanov Institute of Organoelement Compounds, Russian Academy of Sciences, ul. Vavilova 28, 117 813 Moscow, Russian Federation, Fax (7-095) 135 50 85

Received 14 December 1993
Uspekhi Khimii **63**(3) 280–288 (1994); translated by A K Grzybowski

proceed in different ways (1,2- and 1,4-addition), which hinders the isolation of individual compounds.

The comparatively high reactivity of even a single bromine atom in the adduct and telomers determines the possibility of the occurrence of secondary processes. The adducts formed may react with a new monomer molecule, affording stepwise telomerisation products. The presence of a bromine atom next to the radical centre leads to the probability of fragmentation with ejection of a bromine atom, which initiates a new reaction chain. Finally, under the conditions of metal complex initiation in the presence of a hydrogen donor, there is a possibility of the reduction of the tri- and di-halomethyl groups in the adduct and also of chain transfer via a C–H bond.

In the present review, we shall consider the literature data obtained during the last 6–7 years; earlier studies have been surveyed fairly completely in a monograph[3] (in the chapter devoted to organobromine compounds). The earlier data will be included when necessary.

II. Reactions of bromine-containing addends

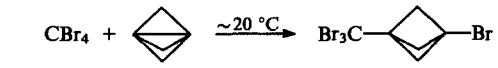
1. Polybromomethanes

a. Reactions of carbon tetrabromide

A series of interesting features have appeared in recent years in reactions involving CBr_4. They are associated with the use of initiators, which are new for reactions of the given type, and also with the expansion of the range of monomers employed.

The addition of CBr_4 to a series of monomers, including monomers with functional group substituents (hept-1-ene, oct-1-ene, styrene, methyl acrylate) has been achieved in the presence of divalent samarium iodide under mild conditions; the yield of the adducts reaches 80% under these conditions.[4] The reaction is carried out in the presence of 5%–10% SmI_2 in solution in acetonitrile at 60 °C. The overall reaction mechanism described by the authors[4] includes the formation of an intermediate initiating complex **A** and subsequent chain transfer by the radical-adduct **B** to the initial polyhalomethane.

$$YCX_3 + SmI_2 \longrightarrow \underset{\mathbf{A}}{(YCX_3)^{-\cdot}SmI_2^{+}}$$



$$\mathbf{A} \longrightarrow SmI_2Y + \dot{C}X_3$$

$$\dot{C}X_3 + CH_2{=}CHR \longrightarrow \underset{\mathbf{B}}{CX_3CH_2\dot{C}HR}$$

$$\mathbf{B} + YCX_3 \longrightarrow CX_3CH_2CHYR$$

Trivalent samarium compounds do not participate in the chain transfer; the reconversion of Sm^{3+} into Sm^{2+} apparently requires a fairly powerful reductant. This constitutes a significant difference between the given reaction and the analogous processes initiated by systems based on $Fe(CO)_5$, where the halogen-containing iron carbonyl complex formed as an intermediate participates in the chain-transfer stage (the halogen passes from the complex to the radical-adduct), after which a zerovalent iron species, capable of propagating the reaction, is regenerated.[3]

The reaction of carbon tetrabromide with 1,1,1-propellane proceeds almost instantaneously, affording the corresponding adduct in a high yield.[5]

The process does not require illumination and proceeds at room temperature. The radical nature of the process has been confirmed by the presence of the corresponding signals in the EPR spectrum.

The ready homolysis of the C–Br bond in CBr_4 made it possible to carry out under the usual conditions (with benzoyl peroxide as the initiator) a radical chain reaction between carbon tetrabromide and 3,3,3-trifluoropropene, although in this instance highly electrophilic compounds function as the reactants (the addend and the monomer), i.e. a combination of polar factors highly unfavourable for the reaction is present.[6]

$$CBr_4 \xrightarrow{(C_6H_5CO)_2O_2} \dot{C}Br_3$$

$$\dot{C}Br_3 + CH_2{=}CHCF_3 \longrightarrow CBr_3CH_2\dot{C}HCF_3$$

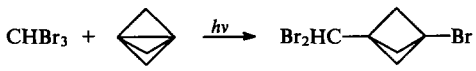
The presence of the CF_3 group next to the radical centre imparts to the radical a highly electrophilic character and only the low dissociation energy of the C–Br bond makes it possible to achieve the subsequent process as a chain reaction.

$$CBr_3CH_2\dot{C}HCF_3 + CBr_4 \longrightarrow \underset{\mathbf{T_1}}{CBr_3CH_2CHBrCF_3} + \dot{C}Br_3$$

However, the unfavourable combination of polar factors renders this stage less effective, as a result of which the radical-adduct also participates in the competing chain propagation reaction with formation of the telomer $\mathbf{T_2}$, which is in principle atypical for reactions with carbon tetrabromide.

$$CBr_3CH_2\dot{C}HCF_3 + CH_2{=}CHCF_3 \xrightarrow{CBr_4} \underset{\mathbf{T_2}}{CBr_3CH_2CH(CF_3)CH_2CHBrCF_3}$$

The partial chain transfer constants $C_n = k_{tr}/k_p$ (k_{tr} is the transfer rate constant and k_p the chain propagation rate constants) have been estimated for this reaction involving the first three growing radicals ($C_1 = 15$, $C_2 = 64$, $C_3 = 60$), their values indicating in this case that chain transfer by the growing radicals is appreciably more effective than chain propagation. Similar values of the constants were obtained earlier also for the reaction with vinyl chloride,[7] although the properties of this monomer differ significantly from those of trifluoropropene (vinyl chloride readily polymerises, whereas this is not a characteristic feature of trifluoropropene).



From the subsequent exposition, it will be clear that a less effective addend (for example, $CHBr_3$) reacts differently with these monomers. This applies to both chemical and kinetic results. The reaction of CBr_4 with vinyl chloride proceeds under the usual conditions as telomerisation mainly with formation of the first two telomers having the structure $CBr_3(CH_2CHCl)_nBr$, an appreciable amount (up to 10%) of the third telomer being formed only for high monomer : telogen ratios.[7]

Asahara and Chou[8] estimated the quantitative composition of the mixture of telomers by thin-layer chromatography and obtained values of C_n significantly less than unity (0.33), which is unlikely bearing in mind the high effectiveness of the telogen. The results were subsequently checked using gas–liquid chromatography.[7] In this case $C_1 = 14.6$ and $C_2 = 73.5$ were obtained, these values being in better agreement with the real reactivities of the reactants.

b. Reactions of bromoform

The C–Br bond in bromoform undergoes homolysis with greater difficulty than in CBr_4, which is the reason for a number of characteristic features of the reactions involving it: the use of effective initiation methods (up to the metal complex method) and comparatively severe reaction conditions. Relatively small differences in the nature of the reactants have a more marked effect on the results. Thus, in contrast to CBr_4, the reactions with $CH_2{=}CHCl$ and $CH_2{=}CHCF_3$ proceed differently; in certain cases, nonselective processes are observed under the conditions of peroxide initiation.

The reaction of bromoform with 1,1,1-propellane requires irradiation.[5]

The adduct is formed in a high yield (88%) and the process is not accompanied by the formation of telomers. The presence of a bromine atom at a tertiary carbon atom in the adduct molecule makes these compounds promising synthons for further chemical reactions.

As mentioned above, because of the smaller effectiveness of bromoform, compared with CBr_4, as a reaction chain-transfer agent, the intermediate radicals begin to participate also in competing reactions.

The interaction of bromoform with 3,3,3-trifluoropropene, in which the nature of the products and the composition of the reaction mixtures depend significantly on the method of initiation, is instructive in this respect.[9] Investigation showed that, in the presence of benzoyl peroxide, the reaction proceeds in a complex manner with formation of a mixture of compounds containing from two to four bromine atoms in the molecule. Together with telomers with the normal structure, the reaction mixture contains substances formed as a result of the involvement of the intermediate radical in rearrangements, hydrogen-transfer reactions, successive addition of a new monomer molecule, etc. This reaction was carried out selectively[9] using the $Fe(CO)_5$+DMF system. In this case, the reaction proceeds exclusively via the C–Br bond with formation of only one series of telomers containing three bromine atoms in the molecule.

$$CHBr_3 \xrightarrow{Fe(CO)_5+DMF} \dot{C}HBr_2$$

$$\dot{C}HBr_2 + CH_2{=}CHCF_3 \longrightarrow CHBr_2(CH_2CHCF_3)_n^{\cdot}$$

$$CHBr_2(CH_2CHCF_3)_n^{\cdot} \xrightarrow{DBr} CHBr_2(CH_2CHCF_3)_nBr$$

(DBr = bromine donor)

Telomers with $n = 1-3$ have been isolated in a pure form. The nature of the activity of metal complex initiating systems in radical reactions of polyhalomethanes with unsaturated compounds has been examined in detail in a monograph.[3] Their employment proved particularly promising when the reactions were carried out with readily polymerising acrylic monomers when initiation by peroxides is ruled out. The $Fe(CO)_5$+DMF system made it possible to achieve selective homolytic addition of bromoform to acrylic monomers at the C–Br bond without significant polymerisation.[10]

$$CHBr_3 + CH_2{=}CRX \xrightarrow{Fe(CO)_5+DMF} CHBr_2CH_2CRBrX$$

R = H; X = CN, CO_2CH_3;
R = CH_3; X = CO_2CH_3.

The radical nature of the process is confirmed in this instance by the structure of the adducts obtained (addition as a result of the dissociation of the C–Br bond). Haloforms are known to undergo ionic addition to a C–H bond, which leads to adducts with a CX_3 group at the end of the chain.[11] The best yield of the adduct with bromoform has been noted for methyl acrylate (78% relative to the unreacted $CHBr_3$); for acrylonitrile and methyl methacrylate, the yields are significantly lower (25% and 15% respectively).

The radical addition of bromoform to ketene silyl acetals, initiated by azobisisobutyronitrile (AIBN) or $B(C_2H_5)_3$, has been described.[12] Polyfunctional silicon-containing complexes of the type $CHBr_2CR^1R^2CBr(OR^3)OSiR^4_3$ or the products of their chemical reactions (hydrolysis, fragmentation, etc.) have been obtained as a result of such addition.

c. Reactions of methylene bromide

Methylene bromide is much less effective as a chain-transfer agent for the reaction via the C–Br bond than other polybromomethanes and the reaction with this compound is therefore as a rule nonselective and involves a low conversion of the addend. The reaction requires more severe conditions in this case. Thus the telomerisation of methylene bromide with 3,3,3-trifluoropropene has been carried out at 140–145 °C using the $Fe(CO)_5$+DMF initiating system. Telomers having the general formula $CH_2Br(CH_2CHCF_3)_nBr$ are the main but by no means the only reaction products.[9] The first two telomers (n = 1, 2) were isolated in a pure form. The reactions of methylene bromide with other monomers had been investigated earlier.[3]

2. Bromochloromethanes

The reactivity of polyhalomethanes in the reactions with the same monomer depends mainly on the number of halogen atoms in the polyhalomethane, while the nature of the halogen (chlorine or bromine) has much less influence. Comparison of relative kinetic data for the reactions of a series of polyhalomethanes with vinyl chloride makes it possible to arrange the addends investigated in the following series:[7] $CBr_4 > CCl_2Br_2 > CCl_3Br \gg CHBr_3$. Evidently, bromochloromethanes with two C–Br bonds and even one such bond in the molecule are more effective as reaction chain-transfer agents than bromoform.

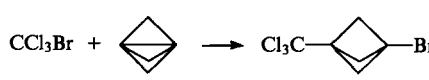
a. Reactions of bromotrichloromethane

Among the mixed bromochloromethanes reacting via the C–Br bond, bromotrichloromethane has been most widely investigated. Monomers of different nature have been involved in the reaction with this compound and a wide variety of initiation procedures have been used.[3]

The employment of divalent samarium salts, which actively initiated these reactions under mild conditions, is fundamentally new, as for CBr_4.[4]

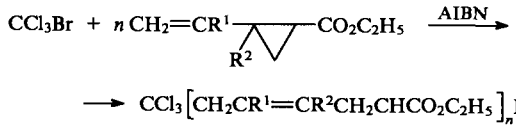
$$CCl_3Br + CH_2{=}CHR \xrightarrow[60\ ^\circ C,\ 10\ h]{SmI_2,\ CH_3CN} CCl_3CH_2CHBrR$$

R = C_4H_9, C_6H_{13}, C_6H_5, CO_2CH_3.



The authors suggest that one-electron transfer takes place with participation of the $(BrCCl_3)^{-\cdot}/SmI_2^+$ species (possibly a charge-transfer complex), which generates the chain-propagating $\dot{C}Cl_3$ radical.

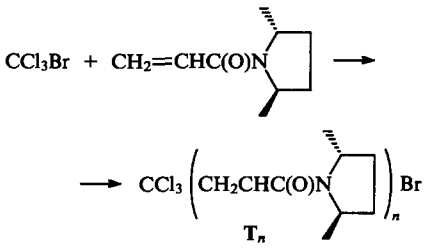
Despite the high effectiveness of bromotrichloromethane as a chain-transfer agent, its reactions with the readily polymerising methacrylic acid esters are accompanied by the formation of telomers with two and three monomer units in an expectedly large amount.[13]



$$CCl_3Br + CH_2{=}C(CH_3)CO_2R \longrightarrow CCl_3\left[CH_2C(CH_3)CO_2R\right]_nBr$$

n = 1–3; R = *iso*-C_3H_7, *tert*-C_4H_9.

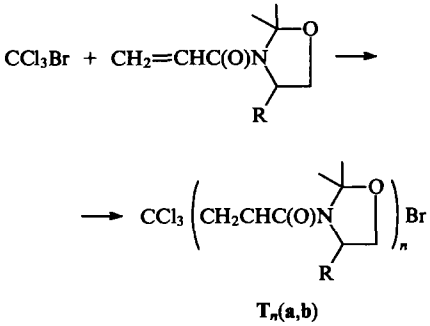
On the other hand, the reaction with propellane leads to the formation mainly of an adduct even in an excess of propellane.[14]



From the standpoint of the synthesis of polyfunctional compounds, the reaction of bromotrichloromethane with alkenylcyclopropanes is of interest.[15]

R^1, R^2 = H, CH_3; n = 1–7.

Telomers are formed mainly in the (*E*)-form and the partial chain transfer constants C_n for the growing radicals are close to unity and hardly change with increase in the chain length of the radical. This is quite reasonable because, even in the first growing radical ($n = 1$) the CCl_3 group is fairly remote from the radical centre and hardly affects its reactivity, which is determined for all the growing radicals mainly by the presence of ethoxycarbonyl groups in the neighbouring positions. The closeness to unity of the partial constants reflects the equal probability of the involvement of the growing radical in the chain-transfer and propagation stages.

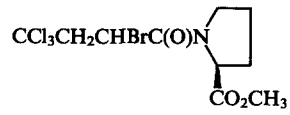


Several studies demonstrating the possibility, in principle, of stereocontrol in radical addition and telomerisation processes have been published recently.[16-18] In particular, the photochemical telomerisation of bromotrichloromethane with the chiral *N*-acryloyl-2,5-dimethylpyrrolidine has been described.[16]

T_n

The first five members of the series ($n = 1-5$) have been isolated and identified. It has been shown that the telomers T_2 and T_3 are formed predominantly in one stereoisomeric form (in the presence of small amounts of other possible stereoisomers), i.e. the radical addition reaction permits asymmetric control in the addition and chain transfer stages. The partial constants C_n are also given in the above communication, their values lying in the range 0.3–0.5. These quantities are not very reliable because, judging from the chromatograms presented in the communication (liquid and gel chromatography), the telomer ratio can be estimated quantitatively only very approximately.

The addition of bromotrichloromethane to substituted *N*-acryloyloxazolidines also proceeds with stereochemical selectivity.[17]



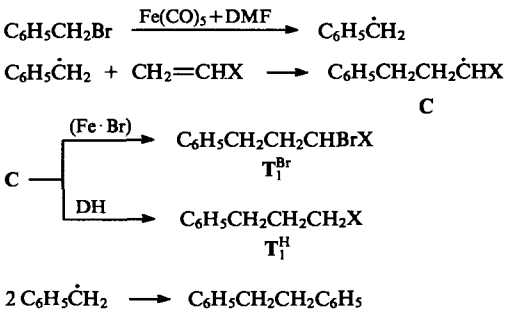
T_n(a,b)

R = C_6H_5 (a), *iso*-C_3H_7 (b).

The stereospecificity of this reaction for the telomer T_3^a reaches 15:1. The telomer T_3^a proved to be crystalline; this made it possible to use X-ray diffraction to investigate its stereochemistry. The stereoselectivity of the formation of T_3^a demonstrates that stereochemical control is achieved both in the addition stage and in the stage involving the transfer of the halogen to the growing radical.

Yet another example of this type of reaction is the addition of CCl_3Br to (*S*)-1-acryloyl-2-methoxycarbonylpyrrolidine catalysed by the $Fe(CO)_5 + P(C_6H_5)_3$ system.[18] In this case, it proved possible to achieve the virtually complete exclusion of the formation of telomers and to obtain the adduct

in 80% yield. It is one of the two possible diastereoisomers. This first example of the stereoselective occurrence of radical reactions initiated by $Fe(CO)_5$-based metal carbonyl complexes demonstrates the possibility and likely usefulness of metal complex initiators in the synthesis of stereoisomerically pure adducts.



b. Reactions of dibromodichloromethane

The reaction of dibromodichloromethane with vinyl chloride under the usual conditions proceeds as telomerisation[7] and, when the monomer:telogen ratio is varied from 1.5 to 15, the content of the adduct in the reaction mixture falls from 80% to 30%. The first three telomers $CCl_2Br(CH_2CHCl)_nBr$ ($n = 1-3$) were isolated in a pure form. The values of C_n obtained ($C_1 = 7.7$; $C_2 = 54.3$) indicate a high effectiveness of dibromodichloromethane as a chain-transfer agent, comparable with the effectiveness of CBr_4 ($C_2 = 74.2$) in the analogous process with vinyl chloride.[7]

3. Benzyl bromide

Organic monobromo-compounds which have not been activated by functional groups do not enter as a rule into radical reactions under the conditions of peroxide initiation. The selective homolysis of the C–Br bond with a satisfactory yield of the adducts can be achieved under these conditions only when metal complex initiators are employed. Benzyl bromide has been most widely investigated among the monobromo-derivatives. Studies have shown that $Fe(CO)_5$-based initiating systems are most promising for its reactions with unsaturated compounds. Thus, in the presence of the $Fe(CO)_5$ + DMF(HMPA) (HMPA = hexamethylphosphoramide) system, the reactions of benzyl bromide with a wide range of monomers, differing significantly from one another by the polar characteristics of their substituents and by their capacity for polymerisation, have been achieved.[19,20] The addition of $C_6H_5CH_2Br$ to monomers with functional group substituents constitutes a promising method of synthesis of polyfunctional aliphatic–aromatic compounds. This reaction is a model for the study of the reactivity of benzyl radicals.

The addition of $C_6H_5CH_2Br$ to the $CH_2=CHX$ [X = H, C_4H_9, $Si(CH_3)_3$, Cl, CF_3, CO_2CH_3, CN] monomers using $Fe(CO)_5$ (up to 10%) combined with DMF or HMPA as the reaction initiator has been investigated under comparable conditions.[19,20] The reactions proceed in accordance with the general mechanism

The authors suggest that the radical-adduct **C** transfers the chain as a result of the abstraction of a bromine atom from the bromine-containing iron carbonyl complex whereupon the adduct T_1^{Br} is formed. The stabilisation of the radical **C** by the abstraction of hydrogen leads to the formation of the adduct T_1^H.

The identification of bibenzyl in the reaction mixture constitutes, according to the authors, one of the pieces of evidence in support of the radical nature of the reaction. It was noted that the amount of bibenzyl in the reaction mixture decreases with increase in the monomer concentration. For all the monomers, the main reaction product is T_1^{Br}. From the standpoint of the reactivity of the monomers, it was noted that the best results have been obtained with trimethylvinylsilane and somewhat worse ones with hex-1-ene. In the reaction with hex-1-ene using DMF and HMPA as initiators, an appreciable difference was observed between the yields of the adducts—in the case of HMPA the yield of the adduct increases by a factor of 2.5 for virtually the same degree of conversion of the telogen, i.e. the $Fe(CO)_5$+HMPA system is more effective as a complex initiator of the reaction. When the reaction is carried out with CH_2=CHX monomers containing electron-accepting groups (Cl, CF_3, CO_2CH_3, CN), the yield of the adducts is lower while the degree of conversion of benzyl bromide is high. 3,3,3-Trifluoropropene is of special interest in the above series of monomers. A multiplicity of reactions of the intermediate telomeric radicals have been noted for this compound, which stimulated a more detailed study of this process. Together with telomers having the structure $C_6H_5CH_2(CH_2CHCF_3)_nBr$ (n = 1, 2), the compound $C_6H_5CH{=}CHCH(CF_3)CH_2CH_2CF_3$ was detected in the reaction mixture. The authors explain its formation by a rearrangement of the radical with two monomer units and its subsequent ready dehydrobromination:

$$C_6H_5CH_2CH_2CH(CF_3)CH_2\dot{C}HCF_3 \xrightarrow[k_{re}]{1.5\text{-H}} \longrightarrow C_6H_5\dot{C}HCH_2CH(CF_3)CH_2CH_2CF_3,$$

where k_{re} is the rearrangement rate constant.

The intramolecular mechanism of the rearrangement was demonstrated and the rearrangement rate constant was determined [$k_{re} = (5.0 \pm 0.3) \times 10^4 s^{-1}$] at 22 °C on model radicals, generated by abstracting a bromine atom from T_2^{Br}, in a special EPR investigation.[21,22] In addition, the fragmentation of the radical $C_6H_5CH_2CH_2\dot{C}HCF_3$ was observed for the first time by the EPR method, i.e. a third process—fragmentation which introduces certain corrections to the kinetic process parameters—is added to the two competing processes with participation of the radical (chain transfer and propagation).[23]

$$C_6H_5CH_2CH_2\dot{C}HCF_3 \longrightarrow C_6H_5\dot{C}H_2 + CH_2{=}CHCF_3$$

A similar process has been detected by the EPR method also for the $C_6H_5CH_2CH_2\dot{C}H_2$ radical (the reaction of benzyl bromide with ethylene), whereas fragmentation is not observed under similar conditions for the radicals $C_6H_5CH_2CH_2\dot{C}HX$ [X = Cl, $Si(CH_3)_3$]. Concerning the kinetics of the addition reactions, the rate constants $k_{add}(X)$ for the addition of the radical $C_6H_5\dot{C}H_2$ to the unsaturated compounds listed above were estimated under the conditions of metal complex initiation using the method of competitive kinetics;[24] the addition of the benzyl radical to trimethylvinylsilane was adopted as the standard: $k_{add}[Si(CH_3)_3]$.

X	$k_{add}(X)/k_{add}[Si(CH_3)_3]$
C_4H_9	0.29
CF_3	0.22
$Si(CH_3)_3$	1
Cl	1.02
CO_2CH_3	11.9
CN	24.0

It is seen from these data that the benzyl radical adds much more readily to the electrophilic methyl acrylate and acrylonitrile than to the relatively nucleophilic hex-1-ene. This is one of the pieces of evidence for the nucleophilic nature of the benzyl radical. Judging from the ratios $k_{add}(CN)/k_{add}(C_4H_9)$ = 83 and $k_{add}(CO_2CH_3)/k_{add}(C_4H_9)$ = 41, the polar effect influences significantly the kinetic parameters of the processes. In the study of the kinetics of the addition of the nucleophilic cyclohexyl radical to the monomers $CH_2=CXC_6H_5$, for which the decisive influence of the polar factor on the rate of addition has been established,[25] the ratio $k_{add}(CO_2C_2H_5)/k_{add}(CH_3)$ = 46, i.e. of the same order of magnitude as that obtained for $C_6H_5\dot{C}H_2$, was found.

The authors also drew attention to a fairly unexpected result—the ratio $k_{add}(CF_3)/k_{add}[Si(CH_3)_3]$ is close to that for hex-1-ene but not for methyl acrylate. One of the possible explanations is the fragmentation of the radical-adduct mentioned above, which ultimately decreases the content in the reaction mixture of the adduct whose concentration is used in the calculation. The same feature has been noted also for the reaction of benzyl bromide with vinyl chloride: $k_{add}(Cl)/k_{add}[Si(CH_3)_3]$ = 1. Although fragmentation was not observed in the EPR study of the $C_6H_5CH_2CH_2\dot{C}HCl$ radical, under real conditions (140 °C) it may play a decisive role. This appears particularly likely, since calculation of the activation energy[20] for the stage involving the addition of $C_6H_5\dot{C}H_2$ to vinyl chloride yielded a significantly lower value (by 7 kcal mol^{-1}) than that for the reaction of trimethylvinylsilane, i.e. there are no anomalies whatever in the addition stage. For vinyl chloride, this stage is more favourable in energy terms than for trimethylvinylsilane.

The reaction of benzyl bromide with trimethylvinylsilane has been used to investigate the overall kinetics of the addition reaction under the conditions of metal complex initiation.[26] One of the fundamental problems in this case is the mechanism of the chain transfer stage:

(a) 'purely' homolytic mechanism—via benzyl bromide:

$$C_6H_5CH_2(CH_2\dot{C}HX)_m + C_6H_5CH_2Br \longrightarrow C_6H_5CH_2(CH_2CHX)_mBr + C_6H_5\dot{C}H_2,$$

(b) redox-catalytic mechanism:

$$C_6H_5CH_2(CH_2\dot{C}HX)_m + [Fe(CO)_nL_{4-n}Br] \longrightarrow C_6H_5CH_2(CH_2CHX)_mBr + \left[Fe(CO)_nL_{4-n}\right].$$

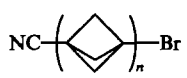
Naturally, the overall kinetic equation is different in each case. For a radical process, we have

$$V(T_1^{Br}) = k_{rad}[Fe \cdot L]_0^{1/2}[S]_0^{1/2}[M]_0^{1/2},$$

where V is the rate, T_1^{Br} is the adduct, L is the ligand, S benzyl bromide, and M the monomer. For a redox process, we have

$$V(T_1^{Br}) = k_{red}[Fe \cdot L]_0[S]_0.$$

The study of the reaction order with respect to each reactant [for the 1 : 3 $Fe(CO)_5$+DMF initiator] showed that in the given competitive case the radical mechanism of chain transfer is more likely. The authors believe that the mechanism may change in other reactions depending on the nature of the reactants and their capacity to form more or less stable complexes with $Fe(CO)_5$.



In the study of the competitive kinetics in the reaction of benzyl bromide with acrylonitrile and trimethylvinylsilane, modelling the cotelomerisation reaction of one telogen with two monomers,[27] an interesting feature was observed—the virtually complete alternation (rigorous alternation) of the monomer units under the conditions of the decisive influence of the polar factor. This reaction results in the formation of only one of the possible cotelomers

$$C_6H_5CH_2CH_2CH(CN)CH_2CHBrSi(CH_3)_3,$$

in which the nucleophilic benzyl radical adds effectively to acrylonitrile and the electrophilic radical $C_6H_5(CH_2)_2\dot{C}HCN$ formed adds to the relatively nucleophilic trimethylvinylsilane.

4. Reactions of functional bromine-containing compounds

The reaction of bromocyanogen with 1,1,1-propellane differs significantly from the reaction with bromotrichloromethane. In the case of BrCN, the telomers

are mainly formed,[14] but their proportions are unusual for telomerisation — the main reaction products are the second ($n = 2$) and third ($n = 3$) telomers in proportions of 4 : 1. It may be that their formation is a consequence of the secondary reaction of the adduct via the third bromine atom, i.e. stepwise telomerisation takes place.[3] Furthermore, bromocyanogen behaves in this reaction also as a brominating agent — the corresponding dibromo-derivative was detected among the products.

The photochemically initiated reaction of 1,2-dibromo-1-chlorotrifluoroethane with chlorotrifluoroethylene results in the formation of mainly the first two telomers.[28]

$$BrCFClCF_2Br + CClF{=}CF_2 \longrightarrow Br(CF_2CFCl)_n(CClFCF_2)_mBr$$

$n = 1$; $m = 1, 2$.

The general formula of the telomers adopted by the authors implies the possibility of the involvement of several molecules of not only the monomers but also of the telogen in the same molecular chain, although the corresponding compounds were not identified in the above investigation.

On irradiation or heating, *N*-bromodifluoromethyleneimine readily reacts with the fluoroolefins $CF_2{=}CFX$ (X = F, Br), affording the adducts $CF_2{=}NCF_2CFBrX$ in satisfactory yields (the yield is 82% for X = F and 67% for X = Br).[29]

The examples considered are summarised in Table 1.

III. Charge-transfer complexes as possible intermediates in radical processes

Complex systems based on $Fe(CO)_5$ combined with nucleophilic coinitiators (DMF, HMPA) are extremely effective as initiators of radical processes with participation of organic polybromo-compounds. Extensive experimental data indicate the existence of a relation between the effectiveness of the systems, the nature of the reactants, and the polar character of the intermediate radicals. Using UV spectroscopy, the nature of the transition state was discovered and the quantitative parameters correlated with the effectiveness of the system were found.[30,31] It was shown that charge-transfer complexes (CTC) are formed in many reactions with participation of organic bromo-compounds and that the quantitative characteristics of the charge-transfer band (CTB) (the intensity and the shift of the band in the spectrum compared with its position for the initial systems) are correlated with the effectiveness of the given metal complex system as the reaction initiator.

Selected data for the charge-transfer complexes of various metal carbonyls (MC) are presented in Table 2.[30-32] In the first place, one should note that a charge-transfer band whose position (λ_{max}) and intensity (I) differ significantly from the parameters for the initial compounds is observed in the metal carbonyl + CBr_4 system, i.e. a charge-transfer complex is indeed formed. In this connection, metal carbonyls can be clearly divided into two groups: for $Fe(CO)_5$ and $Mn_2(CO)_{10}$, there is a bathochromic shift of the charge-transfer band, whereas for the chromium, molybdenum, and tungsten carbonyls there is a hypsochromic shift. The same significant difference has been observed also between the initiating capacities of the systems based on the carbonyls: $Fe(CO)_5$ and $Mn_2(CO)_{10}$ are highly effective initiators of the reactions involving the dissociation of the C–halogen bond, while the remaining carbonyls are relatively ineffective as initiators.

Table 2. Charge-transfer complex formation data for various metal carbonyls.[30-32]

Compound	λ_{max}/nm	CTB for reaction with CBr_4	
		λ_{max}/nm	I
$Fe(CO)_5$	202.0	218.0	10200
DMF	204.0	221.0	3030
$Fe(CO)_5$+DMF	224.0	221.0	11000
$Mn_2(CO)_{10}$	202.4	227.0	14390
$Cr(CO)_6$	227.0	217.0	4545
$Mo(CO)_6$	229.6	219.0	3800
$W(CO)_6$	226.0	218.4	3800

I is the relative intensity.[32]

The shift of the charge-transfer band in the reaction with CBr_4 is much smaller for $Fe(CO)_5$ than for $Mn_2(CO)_{10}$ and reaches approximately the same level only in the system containing DMF. There is a distinct correlation in this instance with chemical data—$Mn_2(CO)_{10}$ actively initiates the reactions without any additives, whereas $Fe(CO)_5$ initiates the reactions virtually only in the presence of additives (DMF, HMPA). Furthermore, $Mn_2(CO)_{10}$ is a much more effective initiator in the reaction with methyl bromoacetate than $Fe(CO)_5$ and the systems based on it.[33]

Analysis of data obtained when the reactants are added in succession suggests that the initial stage of the reactions with participation of organic bromo-compounds is the formation of an involved charge-transfer complex incorporating all the reactants. On the other hand, the study of the complexes formed in the case of simpler systems—binary, ternary, and finally quaternary [reaction components: $Fe(CO)_5$, DMF or HMPA, CBr_nH_{4-n}, CH_2=CHX]—enabled the authors to estimate fairly objectively the initiating activity of each complex system and its likely usefulness for initiation precisely for the given combination of reactants.[30]

In practice, this can facilitate significantly the choice of the initiating systems without carrying out a complex chemical experiment.

A similar study was later carried out also using chromium, molybdenum, and tungsten carbonyls.[32] Satisfactory quantitative correlations were obtained for these systems between the characteristics of the charge-transfer band and the effectiveness of the initiation of the homolytic addition and telomerisation proceeding with dissociation of the C–Br bond.

IV. Application of ^{13}C NMR spectroscopy in the establishment of the structures of organobromine compounds

Extensive and systematic study of radical reactions with participation of organobromine compounds led, as regards synthesis, to the formation of bromine-containing compounds with a fairly complex structure, sometimes including several different bromine-containing groups and functional groups. The ^{13}C NMR method proved to be one of the most promising for the study of their structures. The accumulated experimental data have been surveyed.[34] The tables in the above communication, in which the chemical shifts of carbon atoms involved in a C–Br bond and having different environments are compiled, are significantly helpful in the study of the structures of new compounds and in the determination of certain characteristics of the variation of the chemical shifts of the signals due to carbon atoms in particular groups as a function of the presence and nature of neighbouring substituents. Thus analysis of the spectra of 48 bromopolychloroalkanes showed that, in contrast to chlorine-containing groups for which the ^{13}C chemical shifts are usually in the range 38–105 ppm, the chemical shifts of the bromine-containing fragments (with the exception of $-CBr_2-$) are mainly in the range 25–50 ppm and are as a rule displaced upfield compared with the analogous organochlorine groups. These investigations showed[35] that the additivity of the influence of the α-, β-, and γ-halogen atoms on the ^{13}C chemical shifts frequently breaks down. Therefore the application of the usual additive schemes for calculations based on structural increments to organobromine compounds involves large discrepancies between the calculated ^{13}C chemical shifts and the experimental values.

The specific values of the α-, β-, and γ-effects have been obtained, taking into account the influence of the binary and ternary interactions of the halogen atoms, on the basis of ^{13}C NMR data for the most frequently encountered bromine-containing groups in 60 bromopolychloroalkanes. The increments reflecting the overall influence of the halogen atoms in *gem*-halogen-containing groups and also groups with a halogen atom attached to a secondary carbon atom on the ^{13}C shift in polyhaloalkanes were calculated. The increments obtained for the calculation of the chemical shifts of polyhaloalkanes make it possible to assign the ^{13}C signals of the isomers, their mixtures, and structurally similar compounds, when the differences between the chemical shifts of isotypical carbon atoms are small. A fairly detailed topological scheme for the empirical estimation of the ^{13}C NMR chemical shifts of polybromoalkanes, having definite predictive possibilities, was developed subsequently on the basis of these data.[35,36] An attempt was made in the above investigations to find an equation relating the topological image of the molecule to the experimental ^{13}C chemical shifts of polybromoalkanes taking into account the possibilities of interaction both through the chain and through space.

V. Conclusions	286

Abstract. Data on one of the most urgent problems in modern theoretical chemistry are reviewed: the calculation of the acid strength of the complexes formed by the interaction of Lewis acids with proton donors, and the correlation of the acid strength with the activity and selectivity of these complexes as catalysts of electrophilic processes. Complexes based on aluminium and magnesium chlorides and on boron fluorides are discussed. It is shown that increasing the acid strength of these complexes as catalysts of electrophilic polymerisation reactions increases their activity but lowers their selectivity. The bibliography includes 43 references.

I. Introduction

Complex catalysts based on non-transition metal halides (R_nAlCl_{3-n}, R_nMgCl_{2-n}, R_nBF_{3-n}, where $n = 0 - 3$, R = OH, CH_3, C_2H_5, *iso*-C_3H_7, *tert*-C_4H_9) and on proton donors (H_2O, HCl, HF, ROH) are the classical initiators of electrophilic processes. The donor–acceptor interaction of the components leads to the formation of complexes having an acid strength greater than that of the initial compounds.[1,2] The strengthening of the acidic properties of the systems during complex formation is accompanied by a marked increase in their catalytic activity.[3] The formation of complexes between individually inactive protogenic compounds such as alcohols (or water) and the appropriate Lewis acids offers an enhanced selectivity in the cationic polymerisation of olefins.[3,4] However, in spite of significant progress in the study of the behaviour of complexes of this type in various electrophilic reactions, the role of the acid strength is still unclear.[1,5] Therefore the current interest in the theoretical calculation of the acid strength of complex catalysts of different chemical nature is not surprising. A reasonably precise estimate can be obtained by calculating the charges on the hydrogen atoms in the proton donors (q_{H^+}). These values are well correlated with the universal acidity indicator of chemical compounds δpK_a.

Received 7 September 1993
Uspekhi Khimii **63** (3) 289–298 (1994); translated by J I Carasso

The characteristics of the acid strength (q_{H^+}, Δq_{H^+}) of the adducts of R_nAlCl_{3-n}, R_nMgCl_{2-n}, and R_nBF_{3-n} with proton donors are determined by calculating the models of the complexes with a 1 : 1 stoichiometric composition by the semiempirical CNDO/2 quantum-mechanical method specially parametrised to give the best description of the charge characteristics.[7] This approach has been used successfully in calculations of the acidic catalyst properties of complex electrophilic catalysts.[6]

The structures of the model complexes (usually in the form of tetrahedra, or distorted tetrahedra) are close to the structures recently discussed by various workers.[8–11] The calculations were carried out without allowing for the effect of the solvent, i.e. in the isolated molecule approximation. This approach does not detract from the value of the chosen method of modelling the complex catalyst, since these catalysts are extremely active in hydrocarbon (indifferent) media.

The aim of the present review is to generalise data on the acid strength of the complexes R_nAlCl_{3-n}, R_nMgCl_{2-n}, and R_nBF_{3-n} with proton donors (HCl, H_2O, HF, ROH), and on the relationship between the acid strength of these compounds and their activity and selectivity as catalysts of electrophilic processes (in particular, of the cationic polymerisation of olefins). Establishing correlations between these parameters is important from the standpoint of rationalising the choice of the most effective catalysts for chemical processes, and also as an approach to establishing fundamental concepts on the effect of the acid strength on the behaviour of complex catalysts in electrophilic reactions.

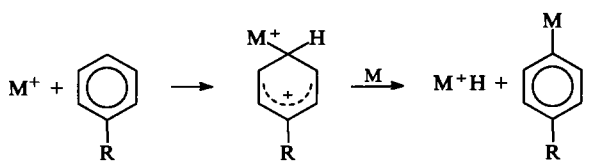
II. Complexes based on aluminium chlorides

The formation of complexes based on aluminium chlorides R_nAlCl_{3-n} and on proton donors (HCl, H_2O, ROH) has been demonstrated both experimentally and theoretically.[12–15]

1. Complexes based on aluminium chlorides and hydrogen chloride

The formation of complexes between R_nAlCl_{3-n} and HCl has to compete with processes involving the substrate and the relatively stable counterion in the reaction with a proton.[15,16] Depending on the nature of the Lewis acid and on some other factors, the complexes formed with HCl have H–Cl bonds with different levels of looseness. In proton complexes, or in the Gustavson complexes (GC), ionisation of the $H^{\delta+}...Cl^{\delta-}$ bond is responsible for the high acid strength.[2,17] This gives the GC an enhanced activity towards the electrophilic polymerisation of olefins and of some other monomers, which is seen, in particular, as the

formation of polymeric products with a higher molecular mass (isobutene, styrene, vinyl butyl ether), as the ability to initiate the oligomerisation of propene, etc. These effects are associated both with a greater stability of the complex counterion towards dissociation into its components under the influence of the carbenium ion and with the acid strength of the GC. The characteristic features of the cationic fragment (positive charge delocalised over the aromatic system) explain the unique properties of these complexes as electrophilic agents. For example, the proton-donor activity of the GC decreases in the sequence



$$3\,C_6H_5CH_3\cdot HCl\cdot Al_2Cl_6 > 4\,(CH_3)_3C_6H_3\cdot HCl\cdot Al_2Cl_6 > > 3\,(CH_3)_6C_6\cdot HCl\cdot AlCl_3\,.$$

This series is the opposite of the basicity series of aromatic hydrocarbons

$$(CH_3)_6C_6 > (CH_3)_3C_6H_3 > CH_3C_6H_5\,.$$

The role of the basicity of the aromatic component of the GC in the initiation of the polymerisation is ambiguous: increasing the basicity increases the stability of the arenonium ion, but it weakens the bond between the carbenium ion and the counterion. [18]

Polymeric GC are formed in a similar way from their low-molecular analogues. However, the presence in the GC of a solvation shell of aromatic nuclei bound to the polymer chain (polystyrene, styrene–divinylbenzene copolymer) affects the stoichiometric composition and other properties of the resulting complexes. [19] Irrespective of the composition of the GC, initiating the polymerisation of olefins reduces to accepting a proton from the arenonium ions. The free aromatic hydrocarbon formed from the arenonium ions by H-initiation can be alkylated by a growing carbenium ion. The reaction which terminates the polymeric chain leads to the formation of new (polymeric) σ complexes, more stable than the initial GC and able (under appropriate conditions) to reinitiate the polymerisation of the olefin:

The mechanism of the catalytic action of the $R_nAlCl_{3-n}\cdot HCl$ complexes (where R = CH_3, C_2H_5, etc.) is simple and self-evident. [10] Therefore a confirmation of the experimentally observed behaviour of the HCl complexes by calculation can be used as a test of the validity of the CNDO/2 method in calculations for other complexes. A calculation of the parameters of the known complexes of hydrogen chloride with aluminium chloride was therefore carried out first.

Some quantum chemical characteristics of the complexes $R_nAlCl_{3-n}\cdot HCl$ [the charges on the hydrogen atom in the HCl (q_{H^+}), the increase in the charge on the hydrogen atom in HCl upon forming the complexes with R_nAlCl_{3-n} (Δq_{H^+}) and the acidity indicator (δpK_a) are shown in Table 1].

Table 1. Acid strength of the $R_nAlCl_{3-n}\cdot HCl$ complexes. [10]

Complex	q_{H^+}	Δq_{H^+}	δpK_a
HCl	+0.09	–	−7
$HCl\cdot(CH_3)_3Al$	+0.18	0.09	−16.3
$HCl\cdot(CH_3)_2AlCl$	+0.18	0.09	−16.3
$HCl\cdot CH_3AlCl_2$	+0.18	0.09	−16.0
$HCl\cdot C_2H_5AlCl_2$	+0.18	0.10	−16.0
$HCl\cdot AlCl_3$	+0.19	0.10	−16.0
$HCl\cdot HOAlCl_2$	+0.20	0.11	−18.0

When the complexes of R_nAlCl_{3-n} with HCl are formed the charge on the hydrogen atom increases from +0.09 in the free HCl to +0.18 to +0.20 in the complexes. The removal of H^+ is accompanied by an evolution of energy of 260–340 kJ mol^{-1}, i.e. it is energetically favourable. [10] The acidity indicators of the complexes are only very slightly dependent on the nature of the Lewis acid (R_nAlCl_{3-n}, $HOAlCl_2$) varying from −16 to −18.

Thus the quantum chemical calculations of the $R_nAlCl_{3-n}\cdot HCl$ complexes are consistent with the experimental data on their high acidity and thus confirm the validity of the CNDO/2 method for calculations of other models based on the aluminium chlorides. The lack of dependence of the acid strength of the complexes on the nature of the Lewis acid shows that all the complexes of R_nAlCl_{3-n} with HCl have a propensity towards self-ionisation. This conclusion is consistent with experimental data on the high activity of the complexes of HCl with Lewis acids (from $AlCl_3$ to AlR_2Cl) in the cationic polymerisation of olefins. [1] At the same time the data obtained in these calculations show that the preferred scheme for the direct initiation of the electrophilic polymerisation reaction is

$$HCl + R_nAlCl_{3-n} \rightleftharpoons H^{\delta+}, [R_nAlCl_{4-n}]^{\delta-} \xrightarrow[-M]{} \longrightarrow M_1^{\delta+}, [R_nAlCl_{4-n}]^{\delta-}$$

However, it should be noted that the increase in the acidity of the $R_nAlCl_{3-n}\cdot HCl$ catalysts in the electrophilic polymerisation of the olefins is accompanied by a large decrease in the selectivity of their action (Table 2).

Table 2. Polymerisation of isobutene from the C_4 hydrocarbon fraction under the influence of $R_nAlCl_{3-n}\cdot HCl$.

Catalyst	Selectivity for *iso*-C_4H_8/ vol.%
$HCl\cdot 3\,C_6H_5CH_3\cdot 2\,AlCl_3$	36 ± 2
$HCl\cdot C_6H_5CH_3\cdot C_2H_5AlCl_2$	43 ± 2
$HCl\cdot C_6H_5CH_3\cdot (C_2H_5)_2AlCl$	53 ± 3

Notes. Composition of fraction, wt.%: C_3H_6, 0.6; C_4H_{10}, 55.1; *iso*-C_4H_8, 14.9; α,β-C_4H_8, 29.5; $[R_nAlCl_{3-n}] = 7.3 \times 10^{-3}$ mol dm^{-3}, $[C_4] = 1.3$ mol dm^{-3}, solvent CH_2Cl_2, 253 K, reaction time 10 min.

2. Complexes based on aluminium chlorides and water

The formation of 1:1 complexes (aqua complexes) by the interaction of R_nAlCl_{3-n} with water has been established. [4,12] Like other electron donors, water easily undergoes donor–acceptor interaction with aluminium compounds.

In inert solvents the aqua complexes of aluminium ($R_nAlCl_{3-n}\cdot H_2O$) have a reasonably high thermal stability and stability towards hydrolysis of the Al–Cl bond, and a low electric conductivity ($\sigma \approx 10^{-10}$ S cm^{-1}). As shown by a qualitative reaction with xanthone they are not H-acids. [12]

The H-activity of the complexes, established for model systems of the type of $CH_3CH(CH_3)=CH_2-C_2H_5AlCl_2\cdot D_2O$ and resulting from the low Brønsted acidity, is not obvious, [16,20] and therefore it does not look as if the ionisation of the aqua complex in the absence of a monomer can take place by the scheme

$$C_2H_5AlCl_2 + H_2O \longrightarrow H^+, [C_2H_5AlCl_2\cdot OH]^-$$

When the cationic polymerisation of olefins is initiated by aqua complexes of the aluminium chlorides the latter undergo various transformations, in particular into aqua complexes of alumoxane or ternary complexes of the $HCl\cdot R_nAlCl_{3-n}\cdot H_2O$

Table 3. Acid strength of the aqua complexes of some aluminium chlorides. [10,20,23]

Aqua complex	q_{H^+} (±0.02)	δpK_a
Group I		
$H_2O \cdot AlCl_3$	+0.20	+7.1
$H_2O \cdot HOAlCl_2$	+0.18	+8.5
$H_2O \cdot (HO)_2AlCl$	+0.17	+12
$H_2O \cdot (HO)_3Al$	+0.17	+12
Group II		
$H_2O \cdot CH_3AlCl_2$	+0.19	+7.7
$H_2O \cdot (CH_3)_2AlCl$	+0.16	+14.4
$H_2O \cdot (CH_3)_3Al$	+0.16	+14.4
Group III		
$H_2O \cdot C_2H_5AlCl_2$	+0.20	+7.5
$H_2O \cdot (C_2H_5)_2AlCl$	+0.18	+8.5
$H_2O \cdot (C_2H_5)_3Al$	+0.17	+12
Group IV		
$H_2O \cdot (C_3H_7)_nAlCl_{3-n}$	+0.19±0.17	+7.7 to +12
Group V		
$H_2O \cdot (C_4H_9)_nAlCl_{3-n}$	+0.19±0.17	+7.7 to +12
Group VI		
$H_2O \cdot Al_2Cl_4O$	+0.21	+4.4
$H_2O \cdot CH_3Al_2Cl_3O$	+0.20	+7.1
$H_2O \cdot (CH_3)_2Al_2Cl_2O$	+0.20	+7.1
$H_2O \cdot (CH_3)_3Al_2ClO$	+0.18	+8.5
$H_2O \cdot (CH_3)_4Al_2O$	+0.18	+8.5
GroupVII		
$HCl \cdot H_2O \cdot AlCl_3$	–	+1.5
$HCl \cdot H_2O \cdot CH_3AlCl_2$	–	+1.3

type.[20] Therefore other models, appropriate to these transformations, were calculated together with the models of the initial complexes (Table 3). The tendency to form aqua complexes between R_nAlCl_{3-n} and H_2O increases as the strength of the Lewis acid is increased: $(HO)_3Al < (CH_3)_3Al < (C_2H_5)_3Al < (C_3H_7)_3Al < (C_4H_9)_3Al < AlCl_3$. This is suggested by the nature of the changes in q_{H^+} and in δpK_a and by other experimental results.[22] For example, acidic catalysts are universally found in the composition of various complexes of $AlCl_3$ or $RAlCl_2$, and the $R_3Al(R_2AlCl) \cdot H_2O$ system (whose acidic properties are weaker) catalyses preferentially the low-temperature polymerisation of strongly basic monomers (styrene, isobutene).[23]

The aqua complexes $R_nAlCl_{3-n} \cdot H_2O$ have a relatively low acid strength (see Table 3). The extraction of a proton from complexes of this type is not energetically favourable, requiring an expenditure of energy of between 70 and 790 kJ mol^{-1} (see Sangalov et al.[10]). Nevertheless these complexes have a relatively high activity in electrophilic polymerisation processes (isobutene), with a selectivity of almost 100% (Table 4), suggesting either the formation (during initiation) of active centres with an enhanced acid strength, susceptible to protonation, or a more complex initiation mechanism for the process.[20]

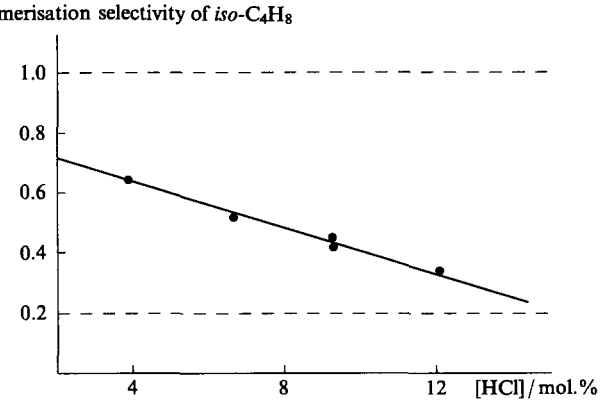


Figure 1. Dependence of the selectivity of the polymerisation of isobutene on the concentration of HCl added to $H_2O \cdot C_2H_5AlCl_2$. The upper broken line shows the selectivity of the process in the presence of $H_2O \cdot C_2H_5AlCl_2$ (without additives); the lower broken line is the selectivity in the presence of $HCl \cdot C_2H_5AlCl_2$. Polymerisation conditions: $[C_4] = 3 \times 10^{-6}$ mol g^{-1}, $[C_2H_5AlCl_2] = 8 \times 10^{-6}$ mol dm^{-3}, 250 K.

The ternary aluminium complexes listed in group VII of Table 3 have a high acid strength. However, in a comparative study of the selectivity of catalysts for the polymerisation of isobutene ($H_2O \cdot C_2H_5AlCl_2$, $HCl \cdot C_2H_5AlCl_2$, and $HCl \cdot H_2O \cdot C_2H_5AlCl_2$) it was shown experimentally that the activity of the starting aqua complex $R_nAlCl_{3-n} \cdot H_2O$ is independent of the intermediate formation of HCl (Fig. 1). The addition of HCl to $C_2H_5AlCl_2 \cdot H_2O$ markedly lowers the selectivity, which approaches that of the process initiated by $HCl \cdot C_2H_5AlCl_2$.

The lowest Brønsted acidity among the catalysts of the first six groups (see Table 3) is found in the aqua complexes $Al_2Cl_4O \cdot H_2O$ ($\delta pK_a = +4.4$), $Al_2Cl_3O \cdot H_2O$ ($\delta pK_a = +7.1$), and $C_2H_5AlCl_2 \cdot H_2O$ ($\delta pK_a = +7.5$). These same aqua complexes are universal acidic catalysts for a large number of electrophilic reactions, including the polymerisation of olefins. The aluminium complexes $Al_2Cl_4O \cdot H_2O$ and $C_2H_5AlCl_2 \cdot H_2O$ have similar acidic catalyst properties. Theoretical calculations are consistent with experimental data on the equality of the first alkylation rate constants of benzene by propene in the presence of $C_2H_5AlCl_2 \cdot H_2O$ [$k = (21.5 \pm 0.6) \times 10^{-4}$ s^{-1}] and

Table 4. Oligomerisation of isobutene from mixtures of hydrocarbons in the presence of the complexes of aluminium chlorides with proton donors.

Catalyst	Composition of the hydrocarbon mixture before the reaction/vol.%				Conversion of *iso*-C_4H_8/ mass%	Selectivity for *iso*-C_4H_8/ mass%
	C_3H_8	C_4H_{10}	*iso*-C_4H_8	α,β-C_4H_8		
$H_2O \cdot C_2H_5AlCl_2$	3.0	55.5	37.9	3.5	96	100
$H_2O \cdot C_2H_5AlCl_2$	3.9	67.5	11.3	17.3	98	100
$H_2O \cdot C_2H_5AlCl_2$	0.9	45.1	31.1	23.0	99	100
$H_2O \cdot C_2H_5AlCl_2$ [a]	4.9	63.2	8.5	23.5	100	57
$C_2H_5AlCl_2$	3.0	55.5	37.9	3.5	95	60
$(C_6H_5)_3COH \cdot C_2H_5AlCl_2$	0.6	55.1	14.9	29.5	90	79
$CH_3OH \cdot C_2H_5AlCl_2$	0.6	55.1	14.9	29.5	95	74

Notes. Polymerisation conditions: volume of the mixture of C_4 hydrocarbons 30 cm^3; concentration of catalyst 5.6×10^{-2} mol dm^{-3}; solvent, heptane (20 cm^3); 293 K; reaction time 10 min.
[a]Solvent CH_2Cl_2.

of $Al_2Cl_4O \cdot H_2O[k = (19.8 \pm 1.2) \times 10^{-4}\ s^{-1}]$ at 297 K. However, the low acid strength of the aqua complexes based on aluminium chlorides and on some of their transformation products (alumoxanes, aluminium alkoxides) implies that the electron donors (olefins, arenes) play an active role in the development of acidic catalyst properties in these materials.

3. Complexes based on aluminium chlorides and alcohols

The ability of alcohols to display both proton-donor (H^+) and carbo-cation activity (R^+) is the most distinguishing feature of the behaviour of the $R_nAlCl_{3-n} \cdot ROH$ aluminium complexes as electrophilic catalysts for the polymerisation of olefins. In particular, in the $AlCl_3 \cdot ROH$ complexes we observe the classical H-initiation scheme for the cationic polymerisation of olefins: [21]

$$ROH + AlCl_3 \rightleftharpoons ROH \cdot AlCl_3 \rightleftharpoons H^+, [AlCl_3 \cdot OR]^-$$

In this process the catalytic acitivity of $AlCl_3 \cdot ROH$ increases with the acidity of the alcohol. [23,24]

The carbo-cation activity of $C_2H_5AlCl_2 \cdot ROH$ has also been demonstrated and shown to vary in the following sequence with the coordination of ROH to $RAlCl_3$: *tert*-C_4H_9OH < < C_6H_5OH < $(C_6H_5)_3COH$. This order is confirmed by quantum chemical calculations on the aluminium complexes $R_nAlCl_{3-n} \cdot ROH$ or similar compounds. [10,15,25]

The parameters of the acid strength, the bond orders, and the predominant type of activity in complexes of alcohols with various reagents are shown in Table 5. About 70 model compounds were studied, including the individual alcohols ROH (CH_3OH, C_2H_5OH, C_3H_7OH, *tert*-C_4H_9OH), and also the compounds $H^+ \cdot ROH$, $R_nAlCl_{3-n} \cdot ROH$, $H_3C^+ \cdot ROH$, and $(CH_3)_3C^+ \cdot ROH$, i.e. complexes with Brønsted and with Lewis acids.

As can be seen, the bond orders P_{OH} and the charges on a hydrogen atom q_{H^+} are almost the same for all the alcohols. This is consistent with the experimental values [26] δpK_a = (+16) to (+19). The bond order P_{OC} tends to decrease with increasing branching of the radical R in the alcohol molecule; a minimum value of P_{OC} is found for *tert*-C_4H_9OH.

In protonated alcohols (models 5–8 in Table 5) the bond order P_{OC} and the charge on a hydrogen atom (of the same order of magnitude as the charge on a hydrogen atom in a hydroxonium ion) [5] remain almost unchanged. At the same time P_{OC} decreases as the extent of replacement of the carbon atom attached to the OH group in the alcohol molecule increases. The charge per hydrogen atom q_{H^+} is thereby increased by a factor of 2–3, which corresponds to a substantial increase in the acid strength of the complex to δpK_a = −29 to −20. When the alcohols are coordinated to acids stronger than H^+ [the carbocations H_3C^+ and $(CH_3)_3C^+$] this behaviour persists, but the

Notes. The sequence of numbers and symbols in the columns corresponds to the alcohol series with R = CH_3, C_2H_5, *iso*-C_3H_7, *tert*-C_4H_9; the following symbols are used: H^+ denotes a dominant proton-donor activity; R^+ denotes a dominant carbo-cation activity; H^+-R^+ states that the two activities have equal probabilities.

acidity of the resulting complexes is lower (δpK_a = −24 to −11). On the whole the complexes $H^+ \cdot ROH$, $H_3C^+ \cdot ROH$, and $(H_3C)_3C^+ \cdot ROH$ (models 5–16) have a high acid strength and usually display a carbo-cation activity.

In the $R_nAlCl_{3-n} \cdot ROH$ complexes (models 17–68) we find a levelling of the differences in the bond orders P_{OH} and P_{OC} for each alcohol and of the bond orders P_{OC} for different alcohols. Therefore there is no overall dominant path for the fragmentation of the alcohols in these complexes, and depending on the nature of R in the alcohol molecule they can display either proton-donor or carbo-cation activity. Like the $R_nAlCl_{3-n} \cdot H_2O$ complexes the $R_nAlCl_{3-n} \cdot ROH$ complexes are characterised by a low acid strength, with δpK_a in the range of −15.1 to −7.1. In the light of the negative values[27] of the energy of proton removal (−590 to −390 kJ mol^{-1}) the removal is energetically unfavourable in the complexes of alcohols with aluminium chlorides. Therefore their activity can manifest itself only in the presence of direct participation of electron donors (olefins, arenes, etc.).[28] As regards selectivity the complexes of this type occupy an intermediate place between $R_nAlCl_{3-n} \cdot H_2O$ and $R_nAlCl_{3-n} \cdot HCl$ (see Tables 2 and 4).

Thus increasing the strength of the Lewis acid coordinated to the alcohol increases the probability of forming a carbo-cation. This trend is quite easily observed, for example in the case of *tert*-C_4H_9OH, i. e. of an alcohol with a strongly branched hydrocarbon radical. Obviously, we can expect to find the same trend in other alcohols containing branched R radicals. A calculation of the complexes of alcohols with different Lewis acids based on aluminium chlorides (not allowing for the effect of the anion, the solvent, and other factors) confirms the dependence of the fragmentation path followed by the alcohol (H^+ or R^+ activity) on the nature of its radical and on the type of the acid.

Published experimental data on the cationic properties of systems consisting of an alcohol and an acidic agent can also be classified according to the behaviour of the alcohol during the formation of the active centres, i. e. according to whether proton or carbo-cation activity (or both simultaneously) predominates. By comparing calculated with experimental data we can test the validity of the fragmentation paths suggested for the alcohols in the complexes.

The stability of the resulting ionic fragments is one of the fundamental factors determining the fragmentation path chosen by the alcohols. The presence of substituents on the α carbon atom and the possibility of binding an hydroxyl group as a stable anion produce reliably identified carbonium ions: for example, in the $(C_6H_5)_3COH - H_2SO_4$ system.[29] The presence of stable carbo-cations, owing to the high stability (low nucleophilicity) of the counterions, has been observed[1] also by NMR during the formation of complexes of the alcohols with 'superacids':

$$(CH_3)_3COH \xrightarrow{SbF_5,\ FSO_3H} (CH_3)_3C^+, SbF_5 \cdot FSO_3^- + H_2O$$

The formation of $(CH_3)_3C^+ \cdot BF_4^-$ was observed also[1] in the interaction of *tert*-butanol with another strongly acid system: $BF_3 \cdot HF$. Thus, *tert*-substituted alcohols in the presence of strong acids are easily dissociated at the C–O bond.

If the experimental conditions do not adequately stabilise the carbonium ions, the fragmentation path adopted by the alcohol bound in a complex with a Lewis acid is determined by other factors, and in particular by the chemical bonding of the detached groups to form stable compounds. For example, according to a calculation[30] the interaction of *tert*-butyl cations with ROH in the presence of a proton acceptor (ammonia) takes place through the breaking of the O–H bond (not the C–O bond). When phenols are used the fragmentation along the O–H bond in the cationic polymerisation of isobutene[30] is favoured by the H-acidity, which is higher than in aliphatic alcohols, and by the p_π-p_π conjugation of the oxygen atoms with the aromatic nucleus, which suppresses the breaking of the bond between the aromatic carbon and the oxygen.

It follows from the calculations on the complexes of Lewis acids (R_nAlCl_{3-n}) with alcohols that the fragmentation of the alcohols by either of the possible directions (H^+ or R^+) has comparable probabilities. This conclusion is confirmed by experimental results. For example, when diisobutene (which is polymerised with difficulty) is used as a nucleophilic acceptor the protonation of the olefin is accompanied by a parallel reaction with the carbo-cation of the alcohol.[31]

Therefore according to both experimental and calculated data the fragmentation of alcohols substituted at the α carbon atom in complexes with strong acids takes place along the C–O bond, with formation of carbonium ions (i.e. R^+ activity is displayed). Conversely, decreasing the acid strength of the complex former, and especially using alcohols with unbranched radicals, strengthens the H^+ activity.

III. Complexes based on magnesium chlorides

The complexes of the magnesium chlorides with proton donors $R_nMgCl_{2-n} \cdot n_1 H_2O$ (n = 0–2; n_1 = 1, 2, 4, 6, 8, 12; R = OH, CH_3, C_2H_5, *iso*-C_3H_7, *tert*-C_4H_9) have a low activity towards the polymerisation of olefins, but nevertheless they allow us to prepare (under comparable conditions) a polymer having a molecular mass higher than would be obtained with other electrophilic initiating systems.[22]

1. Complexes based on magnesium chlorides and water

The values of the universal acidity indicator δpK_a and the charges on the hydrogen atom of the proton donor in the compounds of magnesium with H_2O are shown in Table 6.

Table 6. Acid strength of the aqua complexes $R_nMgCl_{2-n} \cdot n_1 H_2O$ (R = CH_3, C_2H_5, *iso*-C_3H_7, *tert*-C_4H_9).[10,32]

$8\,H_2O \cdot MgCl_2$	+0.160	+14.4
$12\,H_2O \cdot MgCl_2$	+0.150	+15.1
$H_2O \cdot RMgCl$	+0.175 ± 0.005	+8.1 to +10
$2\,H_2O \cdot RMgCl$	+0.175 ± 0.005	+8.5 to +10
$H_2O \cdot R_2Mg$	+0.175 ± 0.005	+8.5 to +10
$2\,H_2O \cdot R_2Mg$	+0.175 ± 0.005	+8.5 to +10

The aqua complexes of the magnesium chlorides are characterised by high negative values of the overall energy of the system. These features are responsible for their stability and for the high energy of complex formation [E = −265 to −167 kJ mol^{-1}].

Irrespective of the nature of the ligands surrounding the magnesium the aqua complexes $R_nMgCl_{2-n} \cdot H_2O$ have a low Brønsted acidity (δpK_a = +7.1 to +15.1). The highest acid strength is found in the complexes $MgCl_2 \cdot H_2O$ (δpK_a = +7.1) and $MgCl_2 \cdot 2\,H_2O$ (δpK_a = +7.7), which suggests a high activity as catalysts for the polymerisation of isobutene.[22] However, the acid strength alone cannot account for the electrophilic properties of these complexes. It should not be forgotten that the geometry and the electronic structure of the $MgCl_2 \cdot H_2O$ aqua complexes are determined by the unusual type of coordination[10] of the H_2O to the $MgCl_2$. Under these conditions the size of the $MgCl_2 \cdot H_2O$ aqua complex (0.7–0.8 nm) increases in comparison with the $(CH_3)_2Mg \cdot H_2O$ aqua complex (0.3–0.4 nm).[9] Kennedy[22] came to the same conclusion. The polymerisation of isobutene under the influence of $MgCl_2$ takes place only in the presence of water and is associated with the complex nature of

Table 7. Characteristics of the $MgCl_2 \cdot n_1 H_2O$ complexes and some kinetic parameters of the thermocatalytic selective degradation of polyisobutene ($\overline{M}_n^0 = 5.75 \times 10^5$) and of butyl rubber ($\overline{M}_n^0 = 3.2 \times 10^5$) for $[MgCl_2 \cdot n_1 H_2O] = 1$ mol dm^{-3} (see Ref. 32).

Notes. υ is the rate of the reaction; υ_i is the rate of initiation.

the catalyst. The polymerisation requires the participation of growing carbonium ions, and the electric conductivity of the system is due to the presence of large complex counterions which may be incorporated in the solid phase. In the $MgCl_2 \cdot n_1 H_2O$ series of aqua complexes, with $n_1 = 4$, 6, 8 and 12, the energy of complex formation decreases, the charge on the hydrogen atom q_{H^+} decreases from 0.20 to 0.15, and δpK_a increases from +7.3 to +15.1. The charges on the hydrogen atoms in the water molecule, the energies of complex formation, and the δpK_a values in $RMgCl \cdot H_2O$ and $R_2Mg \cdot H_2O$ are effectively independent of the nature of the ligand surroundings of the magnesium. Similar results were obtained for the $R_2Mg \cdot 2H_2O$ and $R_2MgCl \cdot 2H_2O$ complexes.

Because of the low acid strength of the aqua complexes based on the magnesium chlorides (see Table 6), for example when used as catalysts for the electrophilic polymerisation of olefins, it is reasonable to suggest that the initiation stage of the process can be affected by the reacting bases (in particular, by the monomer molecules). An experimental confirmation of the views outlined above is provided by data obtained in studies of the electrophilic depolymerisation of isobutene polymers (PIB) and of butyl rubber (BR), containing ~1.6% of isoprene units, in the presence of $MgCl_2 \cdot n_1 H_2O$ (Table 7). We find a substantial (7-fold) decrease in the total yield of degradation products of PIB in the hydrogenation of the C=C end bonds. Because of the predominance of reactions proceeding by the 'laws of chance' over reactions proceeding by the 'law of end groups' (depolymerisation) in the degradation of polymers, the length of the kinetic chain z in the selective degradation of PIB and BR is much less than the length of the material chain $\overline{P}_n^0$. The lengths of the kinetic chain and the rates of initiation in the depolymerisation of PIB are commensurate with the values of these parameters in the purely thermal polymer degradation process. The presence of a second water molecule in $MgCl_2 \cdot 2H_2O$ (in contrast to $MgCl_2 \cdot H_2O$) has no effect on the rate of depolymerisation of PIB and BR, since the temperature of the transition of the dihydrate $MgCl_2 \cdot 2H_2O$ to the monohydrate $MgCl_2 \cdot H_2O$ (515 K) lies below the reaction temperature (523–623 K). The decrease in the positive charge in the series of magnesium aqua complexes ($MgCl_2 \cdot n_1 H_2O$) results in a marked decrease in the conversion of PIB into BR.[31,32]

These results show that the activity of the $MgCl_2 \cdot n_1 H_2O$ complexes in electrophilic processes, and in particular in the thermocatalytic selective degradation of PIB and BR, is due to their low acid strength.

2. Complexes based on magnesium chlorides and alcohols

The quantum chemical characteristics of the magnesium complexes $R_nMgCl_{2-n} \cdot ROH$ are shown in Table 8. Models of the complexes of alcohols with the magnesium haldies have been proposed by Sangalov et al.[10] To simplify the analysis all the models are divided into nine groups, depending on the nature of the ligand surroundings of the magnesium and on the extent of branching of the radical in the alcohol molecule. Aqua complexes of this type are characterised by high negative values of the total energy, which ensures the stability of catalysts based on complexes of alcohols with magnesium halides. The energy of formation of these complexes is quite high. The possibility of forming $R'_nMgCl_{2-n} \cdot ROH$ donor-acceptor complexes has been confirmed by quantum-chemical calculations (see Table 8).[10] Irrespectively of the nature of the substituents on the magnesium atom the complexes of magnesium halides with alcohols are characterised by a low Brønsted acidity ($\delta pK_a = +7.1$ to +12.0). The increase in δpK_a in the series CH_3OH, C_2H_5OH, C_3H_7OH, C_4H_9OH is dictated by the chemical structure of the compounds.

In the case of methanol the values of P_{OH} and P_{OC} for the R'_nMgCl_{2-n} complexes suggest a predominantly proton-donor activity, but with isopropanol (and, especially, *tert*-butanol) a carbo-cation activity is found. The $R'_nMgCl_{2-n} \cdot C_2H_5OH$ complexes can show H^+ and R^+ activities with equal probability.

To conclude this section we should note that irrespective of the ligand surroundings the acid strength of the complexes based on the magnesium chlorides and alcohols is relatively small (as it is with the $R'_nMgCl_{2-n} \cdot n_1 H_2O$ complexes). It follows that H^+ or R^+ activity can be displayed only through the direct participation of the reacting bases (olefins, arenes) in the initiation stage of the electrophilic polymerisation process.

IV. Complexes based on boron fluorides

Published reports of quantum-chemical calculations on complex cation-active centres of the type H^+, $[BF_4]^-$; H^+, $[BF_3 \cdot OH]^-$; R^+, $[BF_3 \cdot OH]^-$, and R^+, $[BF_3 \cdot OR]^-$ are not very abundant.[9,22,33–36] H^+ activity of the alcohols has been observed in compositions of the $BF_3 \cdot ROH$ complexes with R = CH_3, C_2H_5, n-C_3H_7, *iso*-C_3H_7, and others during the oligomerisation and polymerisation of propene, isobutene, and but-2-ene, and also in the alkylation of phenols by olefins.[37–39] However, the arguments put forward in support of H^+ initiation, such as the tenfold increase in the rate of polymerisation of styrene under the influence of $BF_3 \cdot C_2H_5OH$ as compared with the rate of the same reaction in the presence of $BF_3 \cdot O(C_2H_5)_2$ (see Refs 39 and 40) are not fully convincing. For this reason the formulae given to the electrophilic complex catalysts of the R^+, $[BF_3 \cdot OR]^-$ and H^+, $[BF_3 \cdot OH]^-$ type, widely used for the initiation of electrophilic reactions by the hydrates and etherates of boron trifluoride, are only hypothetical (though apparently reasonable).

Table 8. Quantum chemical parameters of the $ROH \cdot R_nMgCl_{2-n}$ models ($n = 0-2$; R = CH_3, C_2H_5, *iso*-C_3H_7, *tert*-C_4H_9).

Notes. Here and in Table 10 the sequence of numbers and symbols in the columns corresponds to the alcohols series with R = CH_3, C_2H_5, *iso*-C_3H_7, *tert*-C_4H_9; the following symbols are used: H^+ denotes a dominant proton-donor activity, R^+ denotes a dominant carbo-cation activity, H^+-R^+ states that the activities have equal probabilities.

1. Complexes based on boron fluorides and hydrogen fluoride

The quantum-chemical characteristics of the acid strength of the $R_nBF_{3-n} \cdot HF$ complexes are shown in Table 9. The structures calculated for the complexes based on the boron fluorides and hydrogen fluoride are distorted tetrahedra, similar to the structures of HBF_4 and $H_3O \cdot BF_4$ (see Eizner and Erusalimskii[9]). The very high positive charge concentrated on the hydrogen atoms (the proton donors) is surprising. The numerical values of the charges on the hydrogen atoms, $q_{H^+} = +0.48$ to $+0.50$, correspond to very low values of δpK_a. Therefore, according to Olah,[1] the complexes based on R_nBF_{3-n} and HF have 'superacid' properties. As in the case of the complexes based on the aluminium chlorides with strong proton donors ($R_nAlCl_{3-n} \cdot HCl$) the acidity of $RBF_{4-n} \cdot HF$ is independent of the nature of the ligand surroundings of the heteroatom.

Table 9. Acid strength of the complexes based on boron fluorides $R_nBF_{3-n} \cdot HF$ and $R_nBF_{3-n} \cdot H_2O$.

Complex	q_{H^+}	δpK_a
$HF \cdot BF_3$	+0.50	−60
$HF \cdot CH_3BF_2$	+0.49	−59
$HF \cdot (CH_3)_2BF$	+0.49	−59
$HF \cdot (CH_3)_3B$	+0.48	−58
$HF \cdot C_2H_5BF_2$	+0.49	−59
$HF \cdot (C_2H_5)_2BF$	+0.48	−58
$HF \cdot (C_2H_5)_3B$	+0.48	−58
$H_2O \cdot BF_3$	+0.23	+1.5
$H_2O \cdot CH_3BF_2$	+0.22	+4.4
$H_2O \cdot (CH_3)_2BF$	+0.22	+4.4
$H_2O \cdot (CH_3)_3B$	+0.21	+7.1
$H_2O \cdot F_4B_2O$	+0.24	+1.0

The removal of a proton H^+ is energetically favourable and offers a gain in energy of more than 350 kJ mol^{-1}. These electron-energy characteristics do not indicate the preliminary formation of a complex between HF and R_nBF_{3-n}, leading to the formation of stronger Lewis acids: rather, they suggest a preferential direct initiation of the cationic polymerisation of olefins by the scheme

$$HF + R_nBF_{3-n} \rightleftharpoons H^{\delta+}, [R_nBF_{4-n}]^{\delta-} \xrightarrow{M} HM^+, [R_nBF_{3-n}]^-.$$

Therefore the consensus of the quantum-chemical calculations and of the experimental data points to an ordinary, classical H^+ initiation mechanism for the electrophilic polymerisation process in the presence of complexes of boron fluoride with proton donors.

2. Complexes based on boron fluorides and water

The aqua complexes $R_nBF_{3-n} \cdot H_2O$ are characterised by high negative values of the total energy and of the overall energy of the bonds, which ensure the stability of the complexes. Additional evidence of the donor–acceptor nature of the complexes based the boron fluorides and water has been provided by data[10] on their geometry and on their electron-energy characteristics. The parameters of the acid strength of $R_nBF_{3-n} \cdot H_2O$ (q_{H^+} and δpK_a) show that these complexes have a low acidity irrespective of the chemical nature of the ligand surroundings of the heteroatom. However, the aqua complexes of the $R_nBF_{3-n} \cdot H_2O$ type have a slightly greater acid strength than the aqua complexes based on the chlorides of magnesium and aluminium. This corresponds to well known experimental data on the greater activity and slightly lower selectivity of the $R_nBF_{3-n} \cdot H_2O$ as compared with $R_nAlCl_{3-n} \cdot H_2O$ complexes in the cationic polymerisation of olefins.[13,23] The spontaneous protonation of the compound $R_nBF_{3-n} \cdot H_2O$ is effectively impossible because the removal of a proton requires an expenditure of energy of more than 150 kJ mol^{-1}. Therefore even in the aqua complexes of the boron fluorides the appearance of proton-donor activity is determined by the acceptor function of the base (olefin, arene, etc.).

3. Complexes based on boron fluorides and alcohols

Quantum-chemical calculations for the complexes $R'_nBF_{3-n} \cdot ROH$, analogous to the calculations for $R'_nAlCl_{3-n} \cdot ROH$ and $R'_nMgCl_{2-n} \cdot ROH$, have established the mutual dependence of their electrophilicity and of the appearance of proton-donor (as opposed to carbo-cation) activity.

Table 10. Quantum chemical parameters of the ROH · R_nBF_{3-n} · ROH complexes (n = 0–3; R = CH_3, C_2H_5, *iso*-C_3H_7, *tert*-C_4H_9).

A detailed collection of the quantum-mechanical evidence for the existence of the R'_nBF_{3-n} · ROH (electronic structure, geometry) has been published.[10] The charges on the hydrogen atoms of the alcohol, which are well correlated with the values of the universal acidity indicator, and the predominant type of activity of the alcohol are listed in Table 10. In all 13 groups the positive charge on the hydrogen atom in the complexes based on boron fluorides and alcohols decreases as the branching of the radical in the molecule is increased. Therefore the q_{H^+} values are independent of the ligand surroundings of the heteroatom, and are determined by the chemical structure of the radical in the ROH molecule. The acid strength of the R'_nBF_{3-n} · ROH complexes decreases in the alcohol series methanol > ethanol > > isopropanol > *tert*-butanol, but the P_{OH} bond orders remain practically unchanged for all 52 models of the alcohol–boron fluoride complexes. The P_{OC} bond order tends to decrease when the acidity indicator of the complexes δpK_a is lowered. The complexes of CH_3OH and C_2H_5OH with the boron fluorides show preferentially H^+ activity. When isopropanol is used the proton-donor and the carbo-cation activity appear with equal probabilities. Alternative possibilities for the fragmentation of the alcohol molecules in the complexes with boron fluorides have been identified experimentally[25,37–40] is a function of the chemical structure of the alcohol residue R.

Thus the R'_nBF_{3-n} · ROH complexes are characterised by a low Brønsted acidity irrespective of the nature of the ligands. The development of proton-donor or of carbo-cation activity in the alcohols is determined by the chemical structure of the radical in the alcohol molecule, and is associated with the direct participation of bases in the polymerisation reactions of the olefins (in particular, molecules of the monomer, of the aromatic solvent, etc.).

V. Conclusions

The accumulated fund of experimental data on the acid strength and catalytic activity of adequately stable complexes consisting of the halides, alkyls, and alkyl halides of the nontransition metals (Al, B, Mg) and of proton donors (H_2O, ROH, HCl, HF) in electrophilic polymerisation processes, in conjunction with corresponding quantum-chemical calculations, justify the conclusion that the acid strength of the proton donors in these complexes is a measure of the activity and selectivity of their action as catalysts in electrophilic reactions. Important new information has been acquired, offering a deeper understanding of the role of the acid strength of these complexes in electrophilic polymerisation processes.

1. Complexes of the R_nAlCl_{3-n} · HCl and R_nBF_{3-n} · HF type have a high acid strength, independent of the ligand surroundings of the heteroatom (Al, B) ($\delta pK_a = -16$ to -60). The removal of a proton is energetically favourable. The complexes undergo spontaneous ionisation and can initiate electrophilic polymerisation.

2. Complexes of the R_nAlCl_{3-n} · H_2O, R_nMgCl_{2-n} · H_2O, and R_nBF_{3-n} · H_2O type, and products of their transformation ($HOAlCl_2$ · H_2O, Al_2Cl_4O · H_2O, R_nAlCl_{3-n} · H_2O · HCl, etc.), have a low acid strength ($\delta pK_a = +1.3$ to $+14.4$). The removal of a proton is energetically unfavourable. Complexes of this type are not prone to spontaneous ionisation, and they can initiate electrophilic polymerisation in the presence of weak bases.

3. Complexes of the R'_nAlCl_{3-n} · ROH, R'_nMgCl_{2-n} · ROH, and R'_nBF_{3-n} · ROH type are characterised (like the corresponding aqua complexes) by a small acid strength ($\delta pK_a = +1.0$ to $+15.1$). The removal of a proton is energetically unfavourable. Complexes of this type do not undergo spontaneous ionisation. Depending on the chemical structure of the radical R in the alcohol molecule, on the acid strength of the complex former, and (if the acid strength is low) on the specific interactions of the reactants, and also depending on the special features of the coordination of the proton donors (H_2O, ROH) with the Lewis acids (mainly, magnesium compounds), the alcohol molecules bound in complexes can display either a proton activity or a carbo-cation activity. In the electrophilic polymerisation of olefins this effect influences the initiation stage, and therefore also the character of the end groups in the resulting macromolecules. Increasing the size of the ligand in the Lewis acid (see Table 2) or the volume of the

radical R in the alcohol molecules (see Table 4) included in the composition of complexes of nontransition metal halides with proton donors increases the selectivity of the polymerisation.

Thus the complexes of the halides of nontransition metals with weak proton donors (H_2O, ROH) have a low acid strength, which casts doubts on the ability of these materials to show a catalytic activity in electrophilic processes, and a weak dependence of the acid strength on the chemical nature of the initial Lewis acid. In this case the role of the monomer as an electron donor and its direct participation in the formation of active centres become the dominant factors.[41]

The method of calculating the acid strength of the complex catalysts in the R_nAlCl_{3-n}–proton-donor system[41–43] can be extended to a wider class of complexes based on the halides of nontransition metals (B, Mg, etc.) and on proton donors (H_2O, ROH, HCl, HF, etc.). The method is convenient and promising for calculating the acid strength of newly synthesised H complexes in order to predict their catalytic activity and selectivity in electrophilic processes. The acidity parameters q_{H^+} obtained in this way by calculations on appropriate models of the complex catalysts are expressed in the form of δpK_a by using a well known correlation expression.[6] An analysis of the acidity of more than 300 compounds and complexes thought to be potential catalysts for electrophilic polymerisation processes in olefins identified the following ranges of δpK_a values (see Fig. 2):

from +50 to +12 (very low values); complexes having these acidities show no catalytic activity towards electrophilic polymerisation processes (the individual compounds ROH and H_2O, and also $AlR_3 \cdot H_2O$, $AlR_3 \cdot ROH$, etc., see Tables 3, 5, and 6);

from +12 to +1 (optimum values); catalysts having these acidities have a high activity and selectivity ($C_2H_5Cl_2Al \cdot H_2O$, $AlCl_3 \cdot H_2O$, $MgCl_2 \cdot H_2O$, $C_2H_5AlCl_2 \cdot ROH$ etc., see Tables 3, 5, 6);

from +1 to −60 (high values); at these acidities the H complexes are much more active, but very much less selective ($R_nAlCl_{3-n} \cdot HCl$, $R_nBF_{3-n} \cdot HF$, protonated alcohols, see Tables 1 and 2).

We may conclude from the above that increasing the acid strength of electrophilic polymerisation catalysts increases the activity of the catalysts but lowers the selectivity of the process.

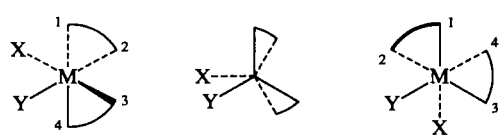
Abstract. Nontransition metal (d^0, d^{10}) chelate complexes possessing a tetrahedral configuration at the metal centre undergo fast intramolecular stereoisomerisation and intermolecular ligand exchange reactions in solution. Inversion of the stereochemical configuration is governed by two types of intramolecular reaction: (1) polytopal rearrangement (digonal twist) and (2) dissociation-recombination reaction due to the cleavage-formation of one of the metal–ligand bonds. The energetically preferred mechanism for the inversion is chiefly determined by the nature of the metal, but it also depends on the type of ligating atoms and their environment. The energy barriers to the inversion of the tetrahedral configuration vary in the range of 10–30 kcal mol^{-1}. The bibliography includes 175 references.

I. Introduction

As long as two or three decades ago, the structure of a molecule was regarded as fully described by its three-dimensional geometrical representation. Currently, such a description may be considered as inadequate if it is not complemented by data on the degree of stereochemical nonrigidity of the molecule. Stereochemical nonrigidity implies the ability of the molecule to undergo fast and reversible intramolecular isomerisation. The energy barrier to this is lower than that allowing for the preparative isolation of individual isomers at room temperature. Owing chiefly to the remarkable progress in the development of NMR spectroscopic technique and its wide application to the study of dynamic processses, the tendency of virtually all types of molecular structures to display stereochemical nonrigidity has been established. The degree of such nonrigidity is regulated by electronic and steric factors. It is the rigidity of the molecular structure (i.e. its association with a very deep minimum on the potential energy surface) that is to be regarded as a characteristic molecular property, whereas stereochemical nonrigidity—the ability of the molecule to fluctuate between several isomeric or topomeric forms separated by an energy barrier lower[1,2] than 20–25 kcal mol^{-1}—is a general property of the molecular structure. Thus the full structural description of a molecule must also include, in addition to three spatial dimensions, a fourth, time (or energy) dimension—the lifetime of the molecule in the given geometrical coordination.

The mechanisms of stereochemical nonrigidity are extremely varied. For metal coordination compounds, these may be categorised, in principle, into two main types: (1) rearrangements of compounds with multicentre bonds (π-complexes, organometallic clusters, polyhedral boranes and carbaboranes); (2) isomerisations and topomerisations (i.e. degenerate rearrangements) of the coordination poly-hedra formed by the central atom by means of two-centre two-electron bonds. In the terminology of the topological and graph-theoretical descriptions of the isomerisations of metal clusters and polyhedral structures, the two types are classified as globally delocalised and edge delocalised mechanisms respectively.[3]



Formally, the rearrangements of coordination polyhedra may be thought of as permutations of the ligands in the central atom environment. The character of such a permutation defines the so called permutation mechanism[4,5] of the rearrangement. Nuclear magnetic resonance (NMR) spectroscopy serves as the most powerful tool for the differentiation of various permutational rearrangements including those of the degenerate type. It should be borne in mind, however, that in some cases certain types of permutation mechanisms are not NMR-distinguishable. In recent years, the potential of NMR spectroscopy in the study of the kinetics and selection of the mechanisms of chemical reactions has been substantially enhanced by the development of two-dimensional (2D) NMR spectroscopic methods.[6] The applications of 2D NMR in studies of chemical exchange reactions occurring in solutions of organometallic and metal coordination compounds have been reviewed.[7,8] Examples of the successful use of three-, four-, and even five-dimensional NMR spectroscopy in characterising the dynamics of organic and metal coordination compounds are known.[9]

The determination of the permutation mechanism of the rearrangement is the initial stage of the investigation into the real (physical) mechanism of the processes determining the stereochemical nonrigidity. After the permutation mechanism has been elucidated, it must be assigned to a specific physical process involving the displacement of atoms and atomic groups within one or several interacting molecules, i.e. attributed to definite isomerisation or topomerisation reactions. Several different physical mechanisms can correspond to the same permutation mechanism. This general approach to the analysis of the mechanisms of stereochemical nonrigidity has been currently employed in the study of a wide range of metal complexes with central atom coordination numbers varying from 2 to 9.[10] As the number of ligands attached to the central atom grows, the number of possible permutation mechanisms increases rapidly and the types of the corresponding metal-centred intramolecular rearrangements become more diverse. Nevertheless, regardless of the complexity of the initial structure, the intramolecular rearrangements can be divided into two main classes in terms of the type of isomerisation: isomerisation (topomerisation) of the coordination centre without intermediate breakage of individual bonds (polytopal rearrangements[11]), and isomerisation via a dissociation-recombination mechanism. In the latter case, an intermediate with a reduced coordination number of the central atom usually arises in the course of the rearrangement.

The above mechanisms of the stereochemical nonrigidity have been most fully characterised in the case of pentacoordinate[1,12,13] and hexacoordinate[14–18] metal complexes. Depending on the structure of the complex and to a lesser extent on the nature of the medium, a particular mechanism predominates. Thus in the case of bischelate hexacoordinate complexes *cis*-$M(AB)_2XY$, a polytopal rearrangement of the trigonal twist type constitutes the only low energy barrier mechanism of the inversion of the octahedron for titanium(IV) dialkoxybis(β-diketonates)[17] and phenylchlorobis(benzoylacetonato)tin(IV).[16] One of the four rearrangement mechanisms, determined by the rotation relative to one of the four C_3 axes of the octahedron, is presented below.

1a **1c** **1b**

However, in the case of the (2,6-diisopropylphenoxy)titanium bischelate complexes based on 8-hydroxyquinoline or 8-hydroxyquinaldine[19] the rate-limiting stage of the configurational rearrangement involves the dissociation of one of the Ti–N bonds of the chelate ring, while in the case of dialkoxy(dimethyl phosophorodithioate)titanium(IV), the dissociation of the Ti–S bond assumes this role.[20] Pentacoordinate trigonal-bipyramidal structures arise as intermediates. Their importance for the mechanism of the stereoisomerisation of octahedral complexes was already predicted by Werner.[21]

Intermolecular associative mechanisms, involving the formation of intermediates with an increased coordination number of the central atom, are an alternative to the intramolecular stereoisomerisation mechanisms.[22–24] In those cases where nucleophilic catalysis of the stereoisomerisation is ruled out and a noncoordinating solvent is employed, the role of the nucleophilic species may be assumed by a second molecule of the complex, one (or two) donor atoms of which are coordinated to the central metal atom of the first molecule. The addition process is usually followed by a polytopal rearrangement in the intermediate with an increased coordination and then by a stage involving the splitting off of the leaving group (dissociation of one of the initial bonds). If the leaving ligand passes to the coordination environment of the metal in the second complex molecule (Scheme 1), such autosubstitution or degenerate ligand exchange reaction can be regarded as a manifestation of the stereochemical nonrigidity of the dimeric associated species.

Scheme 1

$$ML_n + M^*L_n^* \rightleftharpoons [MM^*L_nL_n^*] \rightleftharpoons \rightleftharpoons ML_{n-1}L^* + M^*L_{n-1}^*L$$

The present review deals with processes in which the stereochemical nonrigidity of tetracoordinate chelate complexes of nontransition metals (i.e. having unfilled d^0 or filled d^{10} electron shells according to IUPAC rules[25]) with a tetrahedral configuration in the ground electronic state is manifested. For comparison, data on intramolecular stereoisomerisation processes in solutions of tetrahedral chelate nickel complexes, occurring on the NMR time scale, are also considered. The identification and kinetic characteristics of the three fundamental types of rearrangement mechanisms (polytopal rearrangement, dissociation-recombination mechanism, and associative degenerate ligand exchange mechanism) are emphasised.

The stereoisomerisation of compounds of dicoordinate and tricoordinate nontransition elements (planar, pyramidal, and edge forms of inversion) are usually considered in the context of ideas concerning the stereochemistry of organic compounds (see, for example, Refs 26–28). The permutation and physical mechanisms of the stereochemical nonrigidity of pentacoordinate[12,13,29,30] and hexacoordinate[4,12–14,18,29] structures have been analysed in fair detail. Theoretical[29,31–33] and experimental[34,35] data on fluctuating hepta- and octa-coordinate metal complexes as well as complexes with higher (up to 12) coordination numbers[3,36,37] are rapidly accumulating. On the other hand, only short sections in an early review by Holm[1] and in a recent review[38] have been devoted, apart from the original communications, to the molecular dynamics of tetracoordinate metal complexes. The aim of the present review is to fill this gap.

II. Stereochemically nonrigid structures with tetracoordinate centres

The main type of dynamic rearrangements of stereochemically nonrigid structures of tetracoordinate transition and nontransition metal complexes is the interconversions of the tetrahedral and planar forms. The case of bischelate complexes based on asymmetric bidentate ligands (AB), which includes the interconversion of enantiomeric tetrahedral structures and the geometrical isomerisation of *cis*- and *trans*-planar structures, is fairly general. The scheme presented in Fig. 1 reflects two possible cases:† (1) the tetrahedral form corresponds to the most stable structure of the ground state (Fig. 1*a*) and (2) the planar (square) form is energetically more favourable (Fig. 1*b*). The latter version is more characteristic of transition metal complexes.

Not only the relative energies of the tetrahedral and planar structures but also the type of the stationary point on the potential energy surface corresponding to them depend critically on the nature of the central atom and the ligand structure. In the case of nontransition metal complexes of the type $M(AB)_2$, it has not been possible hitherto to detect reliably planar forms in equilibrium with tetrahedral forms‡ and, as follows from the results of

† The true symmetry of the coordination unit in the $M(AB)_2$ complexes (Fig. 1) is lower than the symmetry of the tetrahedron or square. However, it has become usual in the literature to designate these complexes as tetrahedral or square planar, emphasising the topological and not the geometrical characteristics.

‡ Individual communications concerning the existence in solution of equilibrium between the tetrahedral and planar tetracoordinate nontransition metal structures can be encountered in the literature. Thus, according to ^{1}H NMR data, magnesium(II) bisacetylacetonate exists[34] in solutions as two forms: tetrahedral (D_{2d}) and planar (D_{2h}).

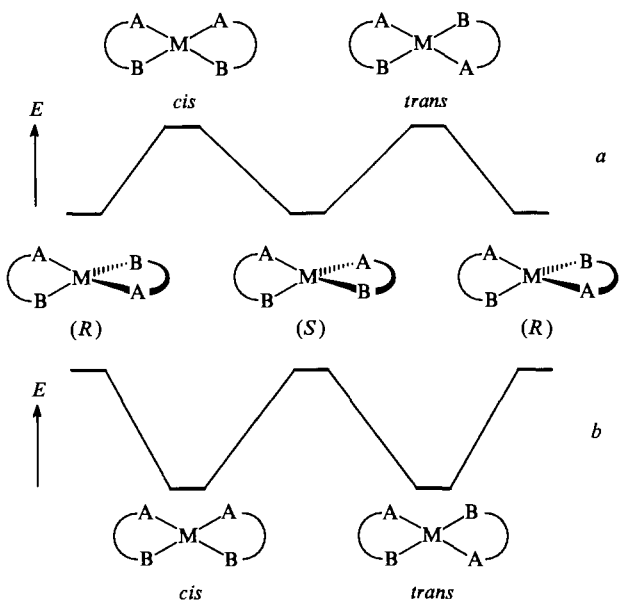

Figure 1. Schematic illustration of the configurational isomerisation of the tetrahedral structures of bischelate metal complexes: (*a*) M = non-transition metal; (*b*) M = transition metal.

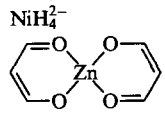

quantum-chemical calculations discussed below, they represent not metastable forms but the structures of transition states or even correspond to higher-order saddle points[39] in the interconversions of tetrahedral structures.§ The reverse situation, where tetrahedral structures correspond to transition states in the *cis–trans* isomerisation reactions of planar forms, is characteristic of Pt(II) and Pd(II) complexes.[35] The *trans*-planar and tetrahedral[41,42] or *cis*-planar and tetrahedral[43,44] forms of Ni(II) complexes may be stable and may coexist in solution. In the crystalline state, complexes of tetracoordinate Cu(II) and Ni(II) can assume configurations over a wide range, intermediate between planar and tetrahedral, depending on the structure of the ligands.[38,45]

The rate of the interconversions of the tetrahedral and planar structures of nickel(II) complexes in solution reaches 10^6-10^{13} s^{-1}.[1,46] In contrast to this, the tetrahedral structures formed by Group IVA elements possess a high degree of stereochemical rigidity. As can be seen from the data in Table 1, which presents the energy differences between the stable tetrahedral and square planar structures of the hydrides AH_4 calculated by nonempirical quantum-chemical methods, these quantities exceed the A–H bond dissociation energies, which implies that polytopal rearrangements of the type square ⇆ tetrahedron cannot be achieved.

Direct calculations and analysis based on allowance for the second-order Jahn–Teller effect[47-49] indicate the principal ways in which tetracoordinate structures can undergo a structural modification leading to a decrease in the energy gap between the tetrahedral and planar configurations. For the MX_4 structures with d^0 or d^{10} electronic configurations of the central atom, which is less electronegative than the carbon atom, the highest occupied molecular orbital of the square planar form has the b_{1g} symmetry, while the electronic ground state is $^1A_1(\delta)$. The lower the electronegativity of the central atom M and the higher the electronegativity of the ligand atoms X, the smaller the energy

§ A communication based on STO-3G calculations[40] concerning the possibility of the existence of a local minimum for the $C_{21}H_{28}$ (octaplane) structure, containing a planar tetracoordinate carbon atom between two chair-shaped cyclooctane rings, has appeared recently. However, the strain energy is ~15 kcal mol^{-1} per carbon atom for this hydrocarbon.

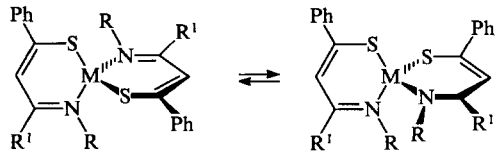

Table 1. The energy barriers to the planar inversion of the tetrahedral hydrides and fluorides MX_4 according to the results of nonempirical quantum-chemical calculations.

MX_4	Method of calculation	$\Delta(E_{D_{4h}}-E_{T_d})$ /kcal mol^{-1}	Ref.
CH_4	MP2/6-311+G**	141 [a]	47

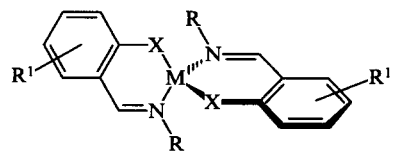
	MINI	12	53

[a] The most rigorous of the currently available estimates[39] [MCSCF-6-31G(*d*,*p*), all the singly and doubly excited configurations are taken into account] is 159.5 kcal mol^{-1}.
[b] The energy difference between the C_{2v} and C_{3v} forms is presented.
[c] The planar D_{4h} form is stable.

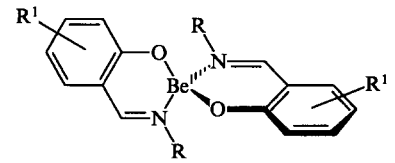
difference between the planar and tetrahedral forms. Indeed, in the case of SnF_4 the energy difference expected on the basis of calculated data is close to the range of energy barriers for stereochemically nonrigid structures, while in the case of the bischelate Zn(II) complex with the ZnO_4 coordination unit it falls within this range.

The structure of the first stereochemically nonrigid transition metal complexes **2**, investigated in the pioneer study by Eaton and Holm,[54] corresponds fully to the criteria considered. These investigators observed for the first time that the tetrahedral bischelate Zn(II) and Cd(II) complexes of type **2**, containing electronegative nitrogen and sulfur atoms coordinated to the metal atom, undergo in solution the reversible enantiomerisation (*R*) ⇄ (*S*) associated with the inversion of the configuration of the tetrahedral metal atom occurring on the ^1H NMR time scale.



2(*R*) **2**(*S*)

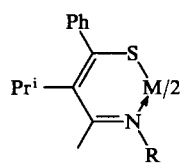
M = Zn, Cd; R = Pr^i, CH_2Ph; R^1 = H, Me



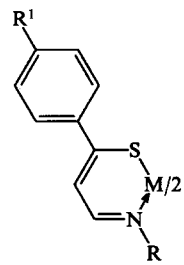
The presence of prochiral substituents R in dissymmetric chelate structures **2** makes it possible to detect the enantiomerisation process by NMR without resorting to the preliminary separation of the (*R*)- and (*S*)-enantiomers. The energy barriers to the enantiomerisation process, found from data for the temperature dependence of the diastereotopic averaging of the signals due to the methyl protons of the isopropyl group or the methylene protons of the benzyl group, amounted to ~21 kcal mol^{-1} for Zn(II) complexes and 12–15 kcal mol^{-1} for Cd(II) complexes.

It was soon shown that the tetrahedral bischelate Zn(II) and Cd(II) type **3** complexes[55] and Be(II) type **4** complexes[56,57] also exhibit stereochemical nonrigidity, whereas the kinetic and activation parameters of the enantiomerisation process $(R) \rightleftarrows (S)$ depend greatly on the nature of the donor atom X and the substituents R^1.

3

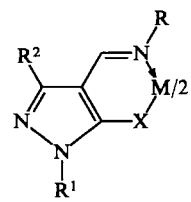


M = Zn, Cd; X = O, S, Se;
R = Pr^i, CH_2Ph
$\Delta G_{25}^{\neq}$ = 9.8–22.3 kcal mol^{-1}.



4

R = Pr^i, CH_2Ph
$\Delta G_{25}^{\neq}$ = 22–24.5 kcal mol^{-1}.



A fairly wide range of chelate complexes of nontransition (as well as transition) metals exhibiting stereochemical nonrigidity in solutions has now also been investigated. The principal structural types of such complexes are represented below by formulae **5**–**15**.

The tetrahedral configuration inversion processes have been studied in much less detail for compounds of Group IVA elements. Early communications stating that the bicyclic orthosilicic acid esters can have a preferred planar structure[58] or a low barrier to the conversion of the tetrahedral (D_{2d}) form into the planar form[59] were not subsequently confirmed. However, for another tetracoordinate silicon derivative (compound **16**), the energy barrier to the intramolecular inversion with transition through a planar structure, estimated as 28 kcal mol^{-1} from the data quoted by Martin et al.,[60] is close to the upper limit of the energy scale for stereochemically nonrigid structures.

16

17

Apparently the first true stereochemically nonrigid structure with a tetrahedral centre (a tetracoordinate Group IVA element) was the germanium spirane **17**.[61] The inversion barrier determined from data derived from the temperature dependence of the ^1H NMR spectrum in the region of the signals of the diastereotopic methylene protons (toluene-d_8) amounted to 22.2 ± 2.5 kcal mol^{-1}.

III. The mechanisms of the stereochemical nonrigidity of tetracoordinate structures

An important question arising in the study of inversion processes is that of the choice of the energetically preferred reaction pathway. Three principal mechanisms, capable of leading to the inversion of the configuration of the central atom of the coordination polyhedron, were indicated above. They are presented in Fig. 2 for a specific case—the inversion of the configuration of the central atom in the tetrahedral bischelate complexes of Group IIA–IVA elements, to which all the compounds of types **2**–**17** belong.

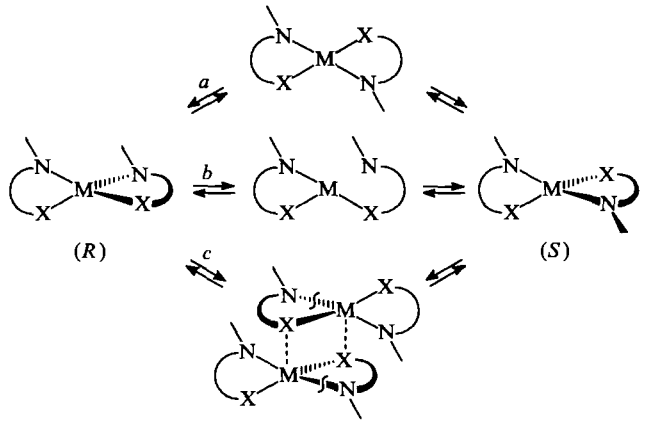

Figure 2. General scheme of the inversion mechanisms for tetrahedral bischelate complexes **2**–**17**: (*a*) polytopal rearrangement of the digonal twist type involving passage through a planar *trans*-structure; (*b*) intramolecular process determined by the dissociation-formation of one of the M–N bonds; (*c*) intermolecular degenerate ligand exchange process.

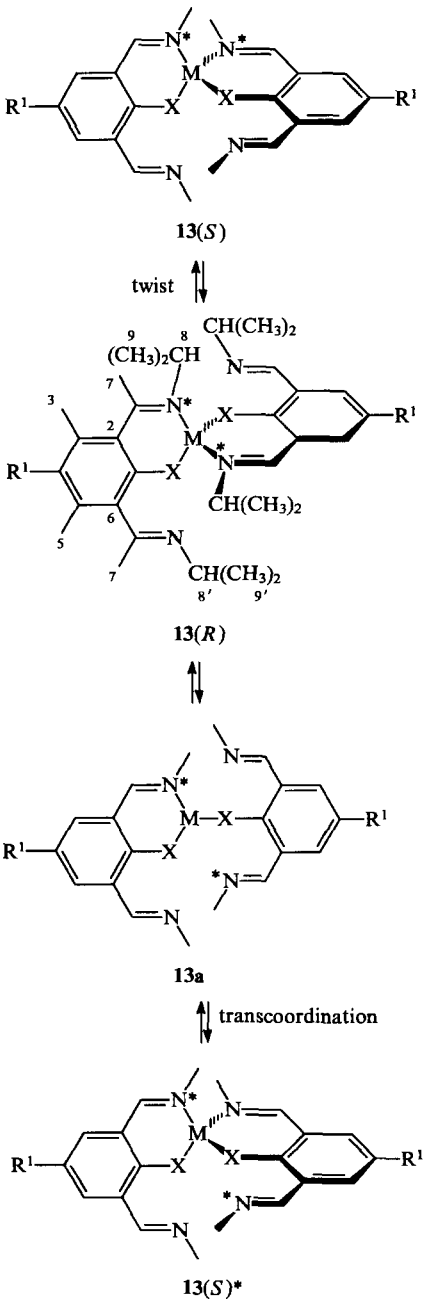
The intramolecular processes include, apart from the polytopal rearrangement occurring via the digonal twist mechanisms without the dissociation of the metal–ligand bonds (see, for example, Muetterties[11]) with formation in the transition state (or as intermediates) of *trans*- or *cis*-structures (the latter are not shown in Fig. 2) (pathway *a*), also a mechanism involving the dissociation of one of the metal–ligand bonds. The dissociation of this bond leads to the formation of an intermediate tricoordinate achiral structure, which then rapidly recyclises (pathway *b*). The third mechanism leading to the inversion of the configuration of the tetrahedral metal atom is associated with intermolecular ligand exchange proceeding via the formation of a dimeric structure via pathway *c* or *b*+*c*.

Studies have shown that all three types of mechanisms considered operate in thermal reactions involving the inversion of the configuration of the tetrahedral centre in metal chelate complexes. The choice of the preferred pathway in the inversion process is dictated mainly by the nature of the metal, but it depends significantly also on other structural features of the complex.[38] The general methodology, widely applied in various studies, is based on the following four effective approaches: (1) the introduction into the structures of the stereochemically nonrigid complexes **2**–**15** of prochiral groups R as substituents at the nitrogen atoms as well as into other parts of the molecules of the complexes; (2) the introduction of 'spin labels', usually magnetic ($S = ½$) isotopes of the metal atoms and the ligating atoms; (3) structural modelling of the dissociation-recombination mechanism in complexes of types **13**–**15** based on alterdentate ligands, i.e. ligands in which the number of structurally equivalent donor centres exceeds the coordination capacity of the metal;[62] (4) the determination of the kinetic orders (n) of the observed degenerate transformations by investigating the dependence of the lifetime (τ) of the exchanging states on the solute concentration and using the relation

$$\tau^{-1} = kc^{n-1} , \qquad (1)$$



where k is the rate constant for the reaction of kinetic order n and c is the concentration of the solute.

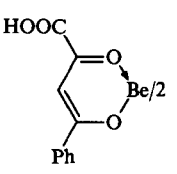
We shall consider briefly what information about the mechanism of the inversion process can be extracted when each of the above approaches is employed.

1. The standard procedure for the introduction of prochiral groups such as Pr^i or CH_2Ph into an asymmetric or dissymmetric structure and analysis of the temperature-dependent diastereotopic averaging[24,63–65] makes it possible to detect the interconversion of enantiomers, by-passing the operation involving their preliminary separation, under conditions of unrestricted monitoring of the reversibility and reproducibility of the experiment. The dynamic process recorded in this way does not, however, permit the differentiation of the possible ways in which the molecule can undergo a structural reorganisation, leading to the inversion of the tetrahedral configuration of the central metal atom.

2. The introduction into the molecular structure of a 'spin' label — a metal isotope with a half-integral spin ($^{111,113}Cd$, ^{199}Hg, ^{207}Pb) linked by spin–spin coupling to the ligand nuclei — makes it possible to observe directly the metal–ligand bond dissociation-formation processes via pathways *b*, *c*, or *b* + *c* (Fig. 2). These processes can be detected both by investigating the temperature dependence of the line forms of the corresponding spectral multiplets (the disappearance of the metal–ligand nucleus spin–spin coupling constant on dissociation of the bond) and with the aid of two-dimensional NMR spectroscopic methods.

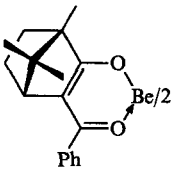
Scheme 2

If, however, the lifetime of the intermediate structure [the tricoordinate intermediate on pathway *b* (Fig. 2)] is shorter than the relaxation time of the metal and ligand nuclei linked by spin–spin coupling, the correlation of the spins of these nuclei is retained, while the spin–spin coupling is manifested in the spectrum despite the occurrence of an intense intramolecular dissociative process.[66] In this admittedly rare case, the observation of a temperature dependence of the spin–spin coupling constant is not diagnostic in the study of the inversion process mechanism.



3. The dissociative type *b* inversion mechanism (Fig. 2) has been detected, for example, in the study of the structural nonrigidity of complexes **13** with bischelate rings based on alterdentate ligands, i.e. ligands providing the metal with two equivalent imine donor centres. In view of the steric hindrance, the alternative donor centres in complex **13** cannot participate simultaneously in intramolecular coordination. However, in the presence of dissociative processes (modelling pathway *b* in Fig. 2), the recombinations of the metal–nitrogen bond on recyclisation of the intermediate tricoordinate structure **13a** with participation of each of the unoccupied donor centres are equally probable. The intramolecular transcoordination (bond switching) process occurring under these conditions, illustrated in Scheme 2, has been reliably detected by the NMR method from the averaging of the signals due to the nuclei, separated by the effective plane of symmetry, under the conditions of rapid exchange.

4. The observation of a concentration dependence for the exchange processes detected by NMR spectroscopy is a clear indication of the intermolecular nature of the reaction and of the inclusion of degenerate ligand exchange processes in the overall stereochemical result of the reaction. The importance of taking this process into account (pathway *c* in Fig. 2) had been already indicated in the pioneer study of Eaton and Holm,[54] who noted that, in the case of Cd(II) chelates (complex **2**), the rate of associative processes involving the inversion of the tetrahedral configuration of the metal atom is very close to the rate of the intramolecular reaction. Careful allowance for the associative reactions proceeding via the ligand exchange mechanism (Scheme 1) is essential, particularly in the light of data[67] indicating the appreciable association of the chelate complexes in solutions in noncoordinating solvents.



The combination of the above approaches to the study of the kinetics of processes involving the inversion of the tetrahedral configuration of metal chelate complexes, with specific structural modelling of the latter, has made it possible to penetrate to a considerable extent details of the mechanisms of structural nonrigidity in solution and also to establish the principal characteristics of the influence of the nature of the metal atom, the donor atoms, and substituents in the ligands on the kinetics of the inversion process $(R) \rightleftarrows (S)$ and the possible ways of achieving it. The data obtained are presented and discussed in the present review in conformity with the type of metal, starting with beryllium and boron complexes and ending with heavy metal (lead and mercury) complexes. The review also contains a section on the dynamic tetrahedral configuration inversion processes in bischelate Ni(II) complexes. Reactions whose rates permit their direct observation on the NMR time scale are discussed. Although nickel in its usual oxidation state Ni(II) is a typical transition metal, the nature of the stereodynamic processes in solutions of its complexes is extremely close to that of the processes determining the inversion of the configuration of the central nontransition metal atom in complexes **2**–**15**.

IV. Beryllium complexes

In the early experiments on the preparative separation of optical isomers of bischelate Be(II) complexes — bis(benzoylpyruvato)-beryllium **18** and bis(benzoylcamphorato)beryllium **19** — based on the crystallisation of the diastereoisomeric salts with brucine, an enrichment of the racemic mixture in one of the enantiomers was already achieved and mutarotation was observed in solution at the usual temperature.[68,69] The energy barriers to the racemisation reaction, calculated later[56] from the polarimetric data presented in the above studies,[68,69] are 21–25 kcal mol^{-1} depending on the solvent.

18

19

Energy barriers to the $(R) \rightleftarrows (S)$ enantiomerisation of beryllium bis(*N*-alkyl-5-R^1-salicylaldiminates) **4** close to the above values were found from the temperature dependence of the change of line shape of the signals due to the diastereotopic methyl and methylene groups of the Pr^i and CH_2Ph substituents at the nitrogen atom.[56,57,70]

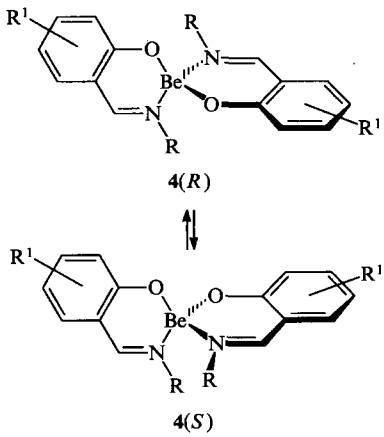


Table 2 presents the results of the kinetic studies on processes involving the inversion of the tetrahedral configuration of beryllium in complexes **4** (Scheme 3), obtained with the aid of the dynamic ^{1}H NMR method.

Table 2. Kinetic and activation parameters of the enantiomerisation of type **4** Be(II) bischelate complexes (solvent — nitrobenzene).[56,57,70]

R	R^1	$10^4 k_{25}$/s^{-1}	$\Delta H^{\neq}$/kcal mol^{-1}	$\Delta S^{\neq}$/cal mol^{-1} K^{-1}	$\Delta G^{\neq}_{25}$ [a]/kcal mol^{-1}
Pr^i	H	3.6	24.0	6.4	22.1 (22.2/143 °C)
CH_2Ph	H	5.8	22.0	−3.9	23.2

Pr^i	3-NO_2	2.2	21.2	−3.2	22.4
Pr^i	5-OMe				(22.4/131 °C)
Pr^i	5-Me				(21.7/139 °C)
Pr^i	5-Cl				(22.1/144 °C)

[a] The free energies of activation estimated[56,70] at the temperature corresponding to the coalescence of the signals of the diastereotopic groups are presented in brackets.

Scheme 3

The energy barriers increase with increase in the electron-accepting capacity of the substituent R^1 and are satisfactorily correlated with Hammett's σ constants.[70]

$$\Delta G^{\neq}_{T_c} = 1.81\sigma + 21.96 \text{ (kcal mol}^{-1}\text{)} \quad (2)$$

The variation of the concentrations of solutions of complexes **4**, listed in Table 2, in the range $10^{-3}-10^{-1}$ M is not reflected in the rate of isomerisation. This indicates the absence of a contribution by degenerate ligand exchange intermolecular processes (pathway *c* in Fig. 2) to the observed kinetics of the inversion of the configuration of the tetrahedral beryllium atom: $4(R) \rightleftarrows 4(S)$.

In order to choose between the alternative intramolecular pathways *a* and *b* (Fig. 2), a study was made of the thermal enantiomerisation of the bischelate type **13** (X = O) beryllium complexes obtained from alterdentate ligands (Scheme 2).[71,72]

The ^{1}H NMR spectra of beryllium complexes **13** at room temperature include two sets of signals due to nonequivalent protons of the chelated and nonchelated aldimine fragments [(7,7′), (8,8′), and (9,9′)] and the benzene ring (3,5) (for the numbering of the atoms, see Scheme 2). The protons of the diastereotopic methyl groups 9 and 9′ are anisochronic and are represented by doublets of doublets in the spectra. If the stereoisomerisation occurred solely via the digonal twist mechanism *a*, the chemical exchange process would reduce to the temperature-dependent exchange-induced broadening and coalescence of the signals due to the diastereotopic groups of the prochiral substituents. In contrast to this, the dissociative mechanism *b*, which involves the formation and recyclisation of the tri-coordinate intermediate **13a** (M = Be), should lead not only to diastereotopic averaging but also to averaging of the signals due to the ^{1}H and ^{13}C nuclei in the 3,5-, 2,6-, 7,7′-, 8,8′-, and 9,9′-positions.

The observed temperature-dependent evolution of the line shapes of the indicator signals of all the type **13** beryllium complexes corresponds to the transcoordination of the metal atom with dissociation of the M–N bonds and enantiomerisation involving both possible types of reactions: $\mathbf{13}(R) \rightleftarrows \mathbf{13}(S)$ and $\mathbf{13}(R) \rightleftarrows \mathbf{13a} \rightleftarrows \mathbf{13}(S)'$.

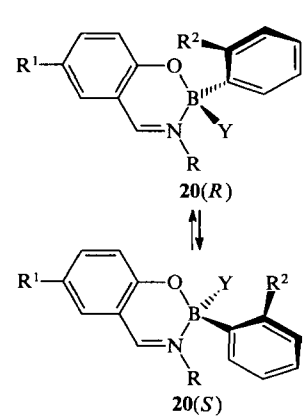
It has been found[71,72] that, within the limits of the usual experimental errors, the energy barriers to the dynamic processes detected from exchange averaging of the (7,7′) and (3,5) pairs of indicator signals and the signals due to the diastereotopic 9,9′-groups, calculated using the full analysis of the line shape, are the same. Variation of the concentrations of the solutions hardly affects the kinetics of the observed reactions, which agrees with the first-order kinetics of the reaction (n = 1) in Eqn (1). The rate constants and activation parameters for the enantiomerisation of complexes **13** (M = Be) in solution in nitrobenzene-d_5 are presented in Table 3.

Table 3. Kinetic and activation parameters of the enantiomerisation of type **13** (X = O, R = Pr^i) Be(II) bischelate complexes (solvent—nitrobenzene-d_5).[71,72]

R	$10^5 k_{25}$/ s^{-1}	$\Delta H^{\neq}$/ kcal mol^{-1}	$\Delta S^{\neq}$/ cal mol^{-1} K^{-1}	$\Delta G^{\neq}_{25}$/ kcal mol^{-1}
H	7.2	23.7	2.3	23.1
Me	4.2	27.3	13.3	23.4
Br	46	23.8	5.5	22.2
OMe	52	23.8	6.3	21.9
NO_2	0.16	28.8	11.8	26.3

Comparison with the data on the kinetics of the enantiomerisation of complexes **4** (Table 2) shows that the free energies of activation for the dynamic processes involving both types of complexes with analogous substitution are very similar. This serves as a basis for the hypothesis that the enantiomerisation $4(R) \rightleftarrows 4(S)$ (Scheme 3) also takes place via a dissociative mechanism (pathway *b*, Fig. 2) and not via the alternative pathway *a* involving a polytopal rearrangement.

The results of theoretical modelling with the aid of the MNDO method of the mechanism of the inversion of the tetrahedral configuration of the Be atom in the bis(*N*-methylaminopropenoato)beryllium complex, differing from complex **4** by the absence of condensed benzene rings, fully agrees with this conclusion. The energy barrier calculated for the dissociation-recombination inversion mechanism is lower by 8–10 kcal mol^{-1} for the stereoisomerisation involving transition through planar *trans*- or *cis*-tetracoordinate structures.[73]



An attempt[74] to investigate by dynamic ^{1}H NMR the inversion process in Be(II) and Zn(II) β-diketonates containing a prochiral isopropyl group in the 2-position was unsuccessful. The diastereotopic methyl groups in these complexes remained isochronic up to −80 °C.

Since, as mentioned above, the bischelate Be(II) complexes with the analogous type of chelate unit BeO_4 can be separated into optical isomers by a preparative procedure (see also Ferroni and Cini[75]), Ronsisvalle et al.[74] attribute this fact to the extremely small diastereotopic splitting in the prochiral substituent which is more remote from the stereogenic centre in these complexes than in complexes **4**.

V. Complexes of boron, gallium, and indium

The thermal inversion of the configuration of the tetrahedral boron atom was first investigated quantitatively in 2,2-diaryl-5,6-benzo-1,3,2-oxazaborines **20**—chiral monochelates formed by the imine derivatives of aromatic *o*-hydroxyaldehydes and asymmetric diarylborinic acids incorporating an asymmetric boron atom (Scheme 4). The tetrahedral configuration of the bonds at the boron atom was characterised by X-ray diffraction of

Scheme 4

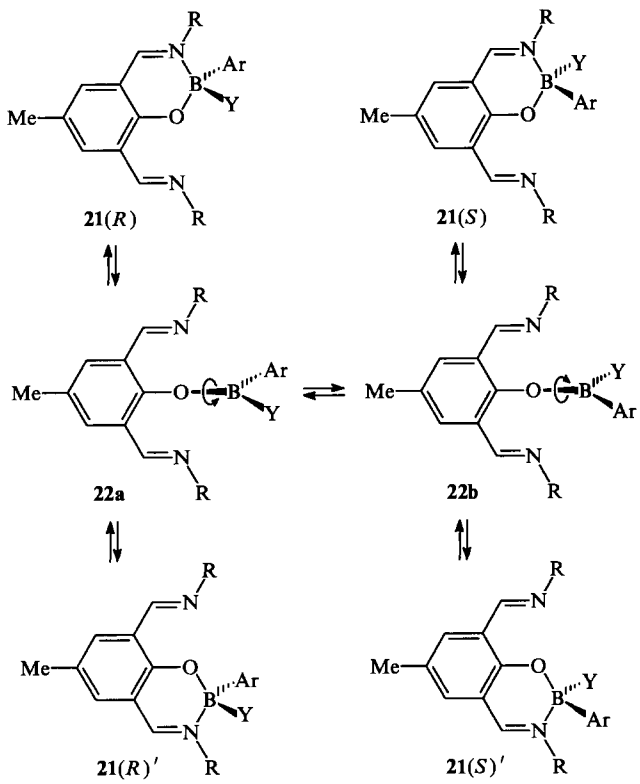
Note. *o*-Dichlorobenzene was the solvent in the first nine cases and bromobenzene in the remaining cases.

certain compounds of this type.[76,77] The presence of prochiral isopropyl and benzyl groups in compound **20** (Y = Ar) makes it possible to investigate the dynamics of the enantiomerisation in accor-dance with Scheme 4 by means of dynamic ^1H and ^{13}C NMR without enriching the racemate in one of the enantiomers. The energy barriers to the inversion process (Table 4) are in the range 19.6–21.5 kcal mol^{-1} [78–80] which is lower by 1–2 kcal mol^{-1} than the barriers observed in the enantiomerisation (Scheme 3) of beryllium complexes **4** based on the analogous salicylaldimines.

The energy barriers listed in Table 4 depend only slightly on the nature of the substituents R, R^1, R^2, and Y. However, as in the series of type **4** beryllium compounds, in complexes **20** the maximum barrier is attained when the electron-accepting NO_2 group is present in the *para*-position relative to the oxygen of the salicylaldiminate fragment.

Change in solvent polarity and increase in solute concentration from 0.1 to 3 M do not exert an appreciable influence on the stereoisomerisation kinetics. The intermolecular degenerate ligand exchange processes were modelled by mixing in solution various pairs of boron chelates **20** containing different substituents. The reaction proceeds at an appreciable rate only at temperatures above 90–100 °C. Thus, in the above temperature range the contribution of the intermolecular degenerate ligand exchange process to the inversion mechanism is insignificant, which makes it possible to make a choice between the intramolecular variants *a* and *b* (Fig. 2).



The hypothesis was put forward initially[80] that the digonal twist type polytopal rearrangement mechanism is more probable. This mechanism is favoured, in conformity with predictions,[59,81] by the presence at the boron atom of π-donor (O) and σ-acceptor (O, N) ligating centres, which stabilise the planar structure with a tetracoordinate boron atom. However, MNDO calculations carried out by Schleyer and Würthwein[82] for the model 1,3,2-oxazaborine led to the conclusion that structures with a tetracoordinate planar or pyramidal boron atom are in general unstable and cannot correspond to the transition states in the tetrahedral inversion reaction. The calculations[82] revealed another structure of the transition state, incorporating a tricoordinate boron atom with a single ruptured B–N bond. The calculated activation energy for the inversion of the configuration of the boron atom via this mechanism proved to be extremely close to the experimental values obtained for compound **20** (Table 4). Subsequent calculations[83] carried out with a higher degree of approximation (*ab initio*, 4-31G) yielded a different structure of the transition state in the tetrahedral inversion process, corresponding to the digonal twist type with a planar tetracoordinate boron atom, but its energy relative to the structure of the ground state (95 kcal mol^{-1}) was found to be much higher than the experimental inversion barriers.

Boulton and Prado[84] were the first to draw attention to the possibility of using the specific features of the spectroscopic behaviour of chiral chelate boron complexes of type **13**, based on alterdentate ligands, as a test which makes it possible to separate the intramolecular stereoisomerisation processes $(R) \rightleftarrows (S)$ via pathways *a* and *b* (Fig. 2). By analysing the temperature-dependence of the ^1H NMR spectra of a series of type **13** monochelates of diarylboron (M/2 = BArAr′, X = O, R = CH_2Ph, R^1 = Me), obtained from 2,6-bis(*N*-benzylideneamino)-4-methylphenol, the above investigators estimated the energy barriers to the B–N bond dissociation-formation reaction in these compounds at the temperatures corresponding to the coalescence of the signals due to the methylene protons of the benzyl groups in solutions in $CD_3OC_6H_4Cl$-*p* (~20 kcal mol^{-1}), which proved to be comparable with the energy barriers to the enantiomerisation of the boron chelates **20**. On this basis, it was concluded that the inversion of the tetrahedral configuration of the boron atom in compound **20** also proceeds via a dissociative mechanism involving the dissociation of the B–N bond.

However, a direct comparison of the dissociative reaction and the polytopal twist rearrangement (which should have been reflected by the diastereotopic averaging of the signals due to the methylene protons of the benzyl group) proved to be impossible for the type **13** compounds investigated in the above study.[84] As a result of the considerable temperature drift, the AB multiplet of the methylene protons of the benzyl group is transformed on raising the temperature into an average singlet virtually without intermediate broadening. For the same reasons, it proved impossible to characterise quantitatively the inversion processes for some of the compounds **20** with substituents R = CH_2Ph described by Korobov et al.[78]

A better justified identification of the mechanisms of the inversion of the configuration of the tetrahedral boron atom in chelate complexes was achieved in the study of compounds **13** (M/2 = BArAr′, R = Pr^i) and 2-alkoxy-5,6-benzo-1,3,2-azaborines of types **20** and **21**, containing a second prochiral substituent Y at the boron atom.[79]

Scheme 5

The tetrahedral inversion of the chelates **21** (Y = OPr^i, OCH_2Ph) is independent of concentration. It was characterised quantitatively on the basis of the diastereotopic averaging of the signals of the *N*- and/or *O*-isopropyl and the corresponding benzyl substituents. The energy barriers to the inversion reaction (Table 4) were found to be slightly lower (by 1–2 kcal mol^{-1}) than those found for the diarylboron chelates **20**.

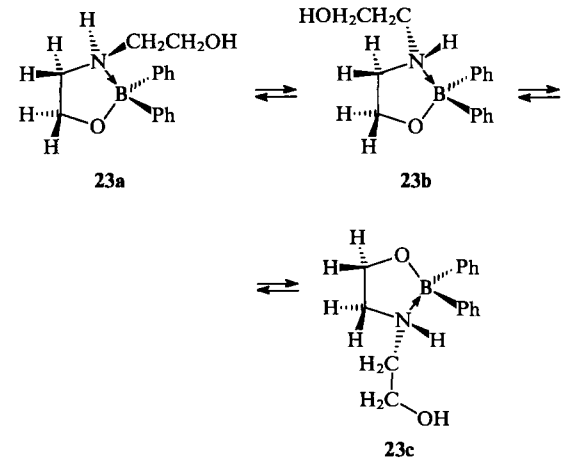
The dynamic ^{1}H NMR spectra of compounds **21** (Nos. *1–3* in Table 5) reveal separately the occurrence of two dynamic processes. The inversion of the enantiomers (*R*) ⇄ (*S*), which reflects overall both possible reaction pathways, *a* and *b* (Fig. 2), is detected from the diastereotopic averaging of the signals due to the Pr^i and $PhCH_2$ groups in the substituent Y. The dissociative reaction involving the dissociation-formation of the B–N coordinate bonds is detected from the dynamic averaging of the chemical shifts of the signals due to the protons of the chelated and non-chelated aldimine fragments and also from the averaging of the ^{1}H and ^{13}C signals from the benzene ring linked to the aldehyde fragments.

The overall mechanism of the stereodynamic processes in compounds **21** (Nos. *4–7* in Table 5) is reflected by the reactions presented in Scheme 5. Two parallel reaction pathways, which rule out the inconversion of the intermediates (**22a** ⇄ **22b**), correspond to the interconversion–transcoordination processes in the temperature range below 110 °C detected in the dynamic ^{1}H NMR spectra of compounds of this type. The stereoisomerisation mechanism presented in Scheme 5 is clearly visualised by 2D exchange ^{1}H NMR spectra. The dissociation of the B–N bond and the formation of intermediates are detected from the appearance of four multiplet cross-peaks for compound **21**, (R = Y = OCH_2Ph, Ar = Ph), with which the frequencies of the downfield and upfield components of the doublets of doublets due to the methyls of the isopropyl groups at different nitrogen centres are correlated.

Rotation about the B–O bond in complexes **22a–b** requires an additional energy expenditure and takes place at a higher temperature. The energy barriers to the interconversion (*R*) ⇄ (*S*) and transcoordination in compounds **21** (Table 5) as well as the inversion processes in complexes **20** (Table 4) are extremely similar, which shows that the dissociative mechanism of the inversion of the tetrahedral configuration of the boron atom in the types of complexes indicated is preferred.

The dissociation of the B–N bond is the rate-limiting stage also in a number of other stereoisomerisation reactions of tetracoordinate boron compounds. It has been shown by dynamic ^{1}H and ^{13}C NMR methods that the inversion of the configuration of the tetracoordinate nitrogen atom in the chelate boron complex **23** involves the opening of the 1,3,2-oxazaborolidine ring and its subsequent closure at the hydroxyethyl group accompanied by proton transfers (Scheme 6).[85]

Scheme 6



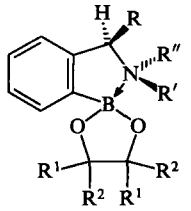


Table 5. Kinetic and activation parameters of the B–N bond dissociation and of the rotation of the boron-containing B(Ar)Y fragment about the B–O bond in type **21** compounds (solvent—nitrobenzene-d_5).[79]

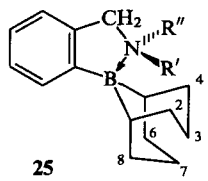
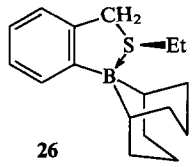
No. of compound	R	Ar	Y	Indicator group	k_{25}/s^{-1} for:		$\Delta G^{\neq}_{25}$/kcal mol^{-1} for:	
					B–N bond dissociation	rotation about B–O bond	B–N bond dissociation	rotation about B–O bond
1	Me	*o*-$MeOC_6H_4$	OPr^i	Pr^i	1.4×10^{-1}		18.8	
2	Me	*o*-$MeOC_6H_4$	OCH_2Ph	CH_2Ph	2.7×10^{-1}		18.2	
3	cyclo-C_6H_{11}	*o*-$MeOC_6H_4$	OCH_2Ph	CH_2Ph	1.1		17.4	
4	Pr^i	*o*-$MeOC_6H_4$	OMe	Pr^i	7.9×10^{-2}	4.6×10^{-4}	18.9	22.0
5	Pr^i	*o*-$MeOC_6H_4$	OCH_2Ph	Pr^i	4.9×10^{-1}	5.4×10^{-3}	17.9	21.4
6	Pr^i	Ph	OCH_2Ph	Pr^i	1.5	4.5×10^{-6}	16.9	24.5
7	Pr^i	Ph	*o*-$MeOC_6H_4$	Pr^i	3.0×10^{-2}	–	19.6	>30

The energy barrier in the reaction (in solution in CD_2Cl_2) is 14.7 ± 0.3 kcal mol^{-1}, which is close to 12.9 kcal mol^{-1} found for the barrier in the dissociation of the B–N bond in the trimethylamine–trimethylboron complex.[86]



The asymmetric transformation, which makes it possible to obtain individual diastereoisomers of optically pure tetracoordinate boron complexes (oxazaborolidinones) by crystallisation from a suitable solvent, also includes a slow stage—the dissociation of the B–N bond, similar to that presented in Scheme 6.[87]

The intramolecular stereotransformations of [2-(dialkylaminomethyl)phenyl]boronates **24**,[88,89] 9-[2-(dialkylaminomethyl)phenyl]-9-borabicyclo[3.3.1]nonanes **25**,[90] and 9-[2-(ethylthiomethyl)phenyl]-9-borabicyclo[3.3.1]nonanes **(26)**[91] have been investigated in fair detail.

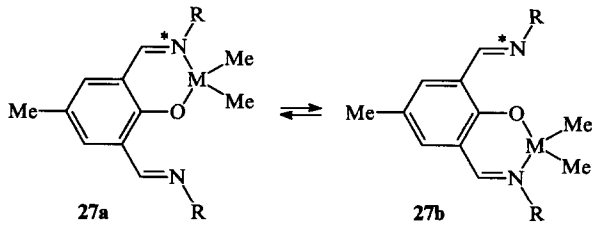


24

R = H, Me;
R′ = R″ = Me, Et;
$\Delta G_{25}^{\neq}$ = 11.5–11.6 kcal mol^{-1}.

25

R′ = R″ = Me, Et;
$\Delta G_{25}^{\neq}$ = 14.1–18.3 kcal mol^{-1}.



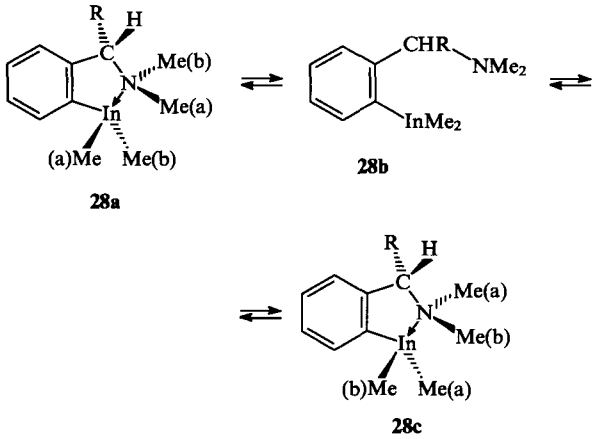
26

$\Delta G_{25}^{\neq}$ = 11.6 kcal mol^{-1}.

Depending on the type of substitution at the stereogenic centre—nitrogen, sulfur, and boron, the thermal dissociation of the B–N bonds in complexes **24** and **25** and of the B–S bond in compound **26** leads to the stereoisomerisation or topomerisation of the above centres. It has been found[89] that the energy barriers corresponding to the averaging of the signals due to the ^{13}C 3(7)-, 2(4)-, and 6(8)-atoms in compounds **25** are lower by 1.2 kcal mol^{-1} than those corresponding to the averaging of the signals due to the diastereotopic protons of the methylene group. This is because the first process reflects the dissociation of the B–N bond, whereas the averaging of the signals due to the methylene protons is attained after the inversion of the nitrogen atom following dissociation of this bond.

Particular attention has been devoted[89,90] to the quantitative determination of the contribution of the entropy of activation to the free energy of activation for the stereoisomerisation. The value of $\Delta S^{\neq}$ is regarded as an important diagnostic test of the mechanism and of the structure of the transition state of the reaction. The large positive values of $\Delta S^{\neq}$ found in the stereoisomerisation reactions of the intrachelate complexes **24–26** (15–20 e.u.) indicate[89–91] a significantly lower polarity of the transition state in the B–N bond dissociation reaction compared with the structure of the ground state. It follows from the kinetic data in Table 4 that positive activation entropies are likewise characteristic of the inversion of the configuration of the boron atom in the chelates **20**, which takes place via the dissociation of the B–N bond.

There are so far few quantitative data on the configurational lability of tetrahedral chelate Ga(III) and In(III) complexes. The enantiotopomerisation reactions of dimethylgallium and dimethylindium derivatives **27** have been investigated[92] on the basis of the temperature-dependent evolution of the line shape of the signals due to the nonequivalent protons of the phenyl and azomethine fragments in the dynamic ^1H NMR spectra.



27a **27b**

R = Pr^i; M = Ga; k_{25} = 0.44 s^{-1}; $\Delta G_{25}^{\neq}$ = 17.9 kcal mol^{-1}.
M = In; k_{25} = 7.3 × 10^3 s^{-1}; $\Delta G_{25}^{\neq}$ = 12.2 kcal mol^{-1}.

Another known example of the enantiotopomerisation of a tetracoordinate indium atom is provided by the configurational dynamics of *o*-dimethylaminomethylphenyl(dimethyl)indium **28** (Scheme 7).[93]

Scheme 7

28a **28b** **28c**

R = H, Me.

The prochiral tetrahedral centres—nitrogen and indium atoms—in the chelated inner complex **28a** are responsible for the diastereotopic splitting of the methyl group signals (R = Me), which vanishes at room temperature owing to the dissociation of the In–N bond.

With increase in the atomic number of the central atom, the strength of the M–N bond diminishes and the energy barriers in the transcoordination reaction (Schemes 5 and 7), associated with the thermal dissociation of these bonds, diminish in the sequence B > Ga > In.

VI. Zinc complexes

The Zn(II) ion in complexes is known to be able to adapt its configuration and coordination capacity readily to the structural features of the ligands linked to it.[94–96] As a result of this ability, induced to a large extent by the absence of stabilising crystal field effects, the zinc atom is incorporated in the macromolecules of many enzymes functioning as active catalysts of biological processes.[97,98] It is not surprising that the stereochemical nonrigidity of the coordination compounds of tetracoordinate Zn(II) is determined (depending on the ligand environment) by all the types of mechanisms presented in Table 2 and also by certain others which will be considered in this section.

The most complete data concerning the influence of various structural factors on the kinetics and mechanisms of the processes determining the stereochemical nonrigidity of the tetrahedral configuration of the tetracoordinate nontransition metal atom have been obtained for the bischelate Zn(II) complexes of types **2**, **3**, and **5**–**15**.[54,55,70,99–110] The influence of the following structural factors has been studied: (1) the nature of the chelating centre X = O, S, or Se; (2) the nature of the substituents R and R^1 in complexes **6** and **7** and also of the condensed arene and heteroarene rings in complexes **3** and **5**–**15**; (3) the steric and electronic characteristics of the substituents R attached to the coordinated nitrogen atoms in complexes **5** and **7**.

Some of the results of such investigations are compiled in Table 6. The observed energy barriers are in the range from 10 to 24 kcal mol^{-1}, while the rate constants are from 10^3 to 10^{-5} s^{-1} (at the usual temperature). Analysis of the data in Table 6 makes it possible to differentiate the following principal trends in the changes in the energy barriers to enantiomerisation as a function of the characteristics of the ligand structure:

1. When the nature of the donor centre X in isotypical series of compounds **3** and **7**–**9** is varied, the activation energies increase in the sequence O < Se < S.

2. The condensation of the benzene, benzothiophene, and benzocyclopentene rings with the chelate ring in type **2** complexes and their oxygen analogues (X = O) (complexes **3**, **9**, and **10**) diminishes $\Delta G_{25}^{\neq}$ [for complex **6** (R = Pr^i, R^1 = H), it amounts to 20.6 kcal mol^{-1} [54]], whereas the condensation of five-membered nitrogen-containing heterocycles — the pyrrole (compound **8**) and pyrazole (compound **7**) rings — increases the energy barrier to the inversion of the tetrahedral Zn(II) atom.

3. The differences between the electronic and steric characteristics of the substituents at the coordinated nitrogen atom in the series of compounds **5** have little effect on the inversion barriers.

4. In contrast to the beryllium complexes **4**, the introduction of electron-accepting substituents into the benzene rings of the analogous zinc complexes **3** (X = O) reduces the inversion barrier. The negative sign of the reaction constant in the correlation equation obtained by Bottino and Finocchiaro[70] is consistent with this [cf. Eqn. (2)].

$$\Delta G_{T_c}^{\neq} = -2.48\sigma + 15.44 \text{ (kcal mol}^{-1}\text{)}$$

This difference reflects in all probability the inversion mechanism of enantiomerisation in Zn(II) complexes for which the reaction pathway associated with the type *a* polytopal rearrangement (Fig. 2), proceeding without the preliminary dissociation of the Zn–N coordinate bond, becomes energetically preferred. This hypothesis is supported also by the negative entropies of activation for the inversion of the tetrahedral configuration of Zn(II) with the N_2O_2 ligand environment (Table 6).

Clear-cut evidence indicating that the digonal twist mechanism (a) (Fig. 2), not involving the dissociation-formation of coordinate bonds, is energetically preferred has been obtained in a study of the dynamic ^1H NMR spectra of bischelate zinc complexes **13** (X = O) with alterdentate ligands.[107]

Table 6. Kinetic parameters of the inversion of the configuration of the tetrahedral Zn(II) in bischelate complexes with a ZnN_2X_2 coordination unit.

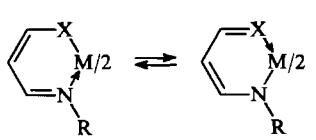
[a] For sulfur-containing compounds, $\Delta G^{\neq}_{twist} > \Delta G^{\neq}_{transcoord}$

In contrast to beryllium complexes, both types of dynamic transformations have been detected in the dynamic ^{1}H and ^{13}C NMR spectra of zinc complexes **13** (X = O) (Scheme 2): the digonal twist and the transcoordination process occurring at a higher solution temperature and detected from the complete averaging of the spectrum relative to the X–C(R^1) axes. The kinetic sequence of the above transformations is retained for all the complexes **13** (M = Zn, X = O) investigated regardless of the nature of the substituents R^1. The rate of the polytopal rearrangement is three orders of magnitude higher than the rate of the simultaneous dissociation-recombination reaction.

Variation of the solvent polarity and of the concentrations of the solutions hardly affects the kinetics of the observed dynamic reactions, which indicates their intramolecular nature. The kinetic parameters of the processes investigated are presented in Table 7.

The energy barriers to inversion via the digonal twist mechanism for zinc complexes **13**, presented in Table 7, are close to the values characterising the enantiomerisation of zinc bis-salicylaldiminates **3** (M = Zn) with identical substituents R^1 (Table 6), which confirms that this stereoisomerisation pathway is likewise preferred for complexes **3** (X = O).



The modification of the structure of the alterdentate ligand in zinc complexes **13** by replacing the donor oxygen atom by a sulfur atom alters radically the energy sequence of the enantiomerisation mechanisms. The dissociative mechanism of the inversion of configuration of the tetrahedral centre becomes preferred, as for the beryllium and boron chelates **13** considered previously. The barriers in the dissociation-recombination mechanism found in zinc complexes **13** (X = S) are significantly lower than those detected for the similar process in the analogous complexes with (X = O) (Table 7).

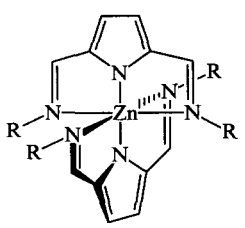
The difference between the mechanisms of the enantiomerisation of the Zn(II) complexes with the N_2O_2 and N_2S_2 chelate environments is reflected in the difference between the activation entropies for the enantiomerisation of complexes **3** of this type and also in the nature of the effect of the substituents R^1 on the free energies of activation. For the majority of complexes **3** (M = Zn, X = S), the activation entropies are positive or have low negative values (Table 6), which is characteristic of reactions proceeding with dissociation of metal–ligand bonds[91] (in this case, the reactions of complexes **13** in accordance with Scheme 2 are not quite so characteristic in view of the superposition of a number of secondary processes involving rotation about the M–N and M–X bonds). The correlation equation,[72] linking the inversion barriers in zinc complexes **3** (X = S) to the parameters of the 5-R^1 substituents, has a form similar to that of Eqn. (2) for the analogous Be(II) complexes.

$$\Delta G^{\neq}_{25} = 1.41\sigma + 16.74 \text{ (kcal mol}^{-1}\text{)}; \quad r = 0.984.$$

Such changes in the mechanisms of the inversion processes can be attributed to the lengthening of the Zn–N bonds (2.036–2.112 Å for three compounds of this type) and hence to their weakening in the six-membered chelate ring ZnN_2S_2 com-pared with the ZnN_2O_2 analogues (1.981–2.017 Å for the eight examples described in the literature).[38,110–114]

In type **3** complexes and their analogues, there is, in principle, a possibility of the dissociation-recombination mechanism involving the rupture of the M–X (X = O, S) and not M–N bonds, since the structure of the chelate ring is evidently reflected by the resonance of canonical structures of type **29**,[115] the relative contribution of which may vary greatly depending on the type of metal and of the substitution in the ligand.

29a **29b**



However, hitherto all attempts to observe the enantiomerisation of bischelate complexes with the MN_2X_2 coordination unit, where M is a main subgroup metal, proceeding via the M–X bond dissociation mechanism have been unsuccessful. The resultsof the study of the stereodynamics of chelate complexes **15** (M = Zn, R = Pr^i) with alterdentate ligands, the structure of which was selected in such a way that the transcoordination process involving the dissociation of the Zn–O bond can be modelled, are instructive. The tetrahedral configuration of Zn(II) is inverted via the intramolecular digonal twist mechanism ($\Delta G^{\neq}_{T_c} = 11.8$ kcal mol^{-1} in CD_2Cl_2, $T_c = -55$ °C). Transcoordination with dissociation of the Zn–O bond is not observed in solution in nitrobenzene-d_5 on heating to 150 °C ($\Delta G^{\neq}_{150} > 22$ kcal mol^{-1}), above which the decomposition of the complex begins.

The wide variety, characteristic of the Zn(II) central ion, of coordination types—ranging from planar tricoordinate in anionic complexes, for example in $Zn(SR)_3^-$,[116,117] to hexacoordinate, which occurs preferentially in cationic complexes[118]—in reactions of tetracoordinate zinc should be manifested respectively by tendencies to undergo dissociative or associative reactions. Examples of the stereoisomerisation of complexes of the first type were examined above.

At high concentrations of the solutions, the degenerate ligand exchange mechanism (pathway c in Fig. 2), involving the formation of dimeric association complexes with pentacoordinate zinc atoms [characteristic of many tetrahedral Zn(II) complexes in the

crystalline state[96]], actually begins to compete with mechanisms *a* and *b*. For the pyrrole complexes **11**, the degenerate ligand exchange mechanism is energetically preferred for the inversion of the configuration of tetrahedral Zn(II) even at very low concentrations (when the dynamic NMR method is used).

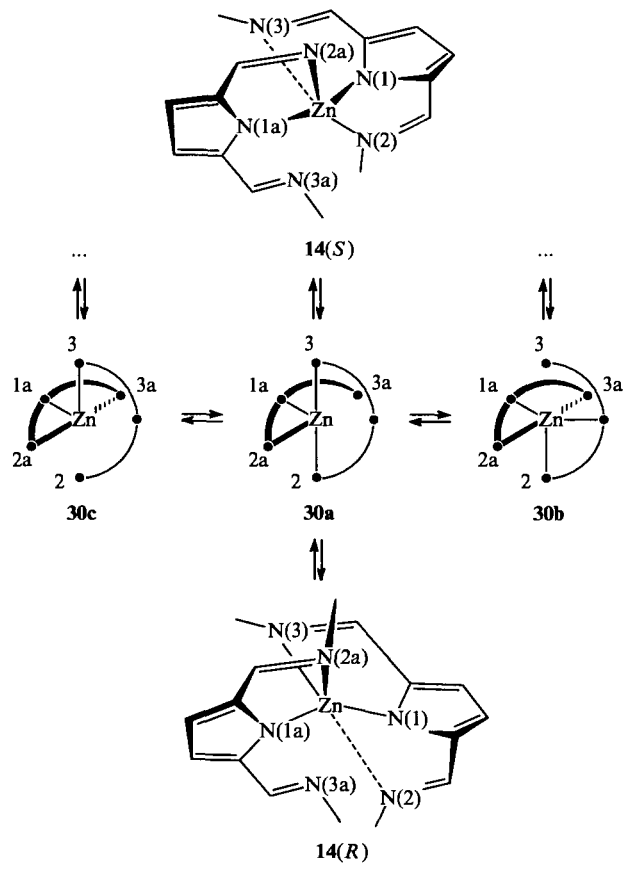
The associative mechanism of the enantiomerisation of tetrahedral Zn(II) complexes can be made also to operate intramolecularly by means of an appropriate design of the alterdentate ligands. Whereas the steric structure of the ligand in type **13** complexes rules out the possibility of an increase in the coordination number of the central metal atom as a result of the intramolecular interaction with the excess donor centres in the ligand with 6,6′-aldimine groups, in type **14** complexes, based on 2,5-diformylpyrrole bisimines, the formation of both pentacoordinate **30** and hexacoordinate **31** structures of the complexes is sterically unhindered.

31

The dynamic ^1H and ^{13}C NMR spectra of complexes **14** (R = Pr^i, cyclo-C_6H_{11}) are fully averaged in solution in CD_2Cl_2 even at −80 °C (f_0 = 300 MHz), which corresponds to an effective D_{2d} symmetry. Of the two possibilities — the stable octahedral structure **31** or the very rapid dynamic inversion of the configuration of the tetrahedral Zn(II) centre (Fig. 3) — the latter is actually realised.[106] This conclusion is supported by the following evidence: (a) nonzero dipole moments of complexes **14** (3.17 D for R = cyclo-C_6H_{11} in benzene), (b) X-ray diffraction data for this complex [pentacoordinate trigonal-bipyramidal structure with the central Zn(II) atom delocalised over two unequally populated positions], and (c) the deaveraging of the ^{15}N NMR spectrum of the $^{15}N{=}CH$ isotopomer occurring in solution in CD_2Cl_2–Et_2O at −110 °C. The energy barrier to the tetrahedral inversion estimated from the ^{15}N NMR spectroscopic data is 8.6 kcal mol^{-1} at −70 °C.

VII. Cadmium complexes

In solutions of cadmium(II) complexes **3**,[53] **5**,[119,120] **2**,[121] **7**,[100] **8** and **9**,[122] and **13**,[123] it is possible to follow separately and characterise quantitatively the kinetics of both intramolecular and intermolecular stereoisomerisation processes. The study of the dynamic behaviour of the ^{111}Cd ($S = \frac{1}{2}$) isotopomers of the above complexes has been widely used in the above investigations. The manifestation of the spin–spin coupling of the ^{111}Cd nuclei with ^{13}C nuclei and protons enriches significantly the spectroscopic information. Thus the dynamics of metal–ligand bond dissociation processes can be followed directly from the temperature dependence of the constants $^nJ_{^{111}Cd-H}$ and $^nJ_{^{111}Cd-^{13}C}$ as well as $^nJ_{^{111}Cd-X}$ (X = other nuclei). The dynamic pattern in the ^1H NMR spectrum of complex **5** (R = Pr^i), for example, is extremely characteristic.[119] Below −30 °C (CD_2Cl_2), all the exchange processes are 'frozen' — the methyl groups in both prochiral isopropyl substituents are anisochronic and we have the constant $^3J_{^{111}Cd-N=CH}$ = 30 Hz.[119] An increase in the solution temperature leads initially merely to a concentration-independent diastereotopic averaging of the signals due to the methyls of the isopropyl groups, which reflects the intramolecular inversion of the configuration of the tetrahedral Cd(II) (at T_c = −1 °C, the inversion rate constant is k = 115 s^{-1}).



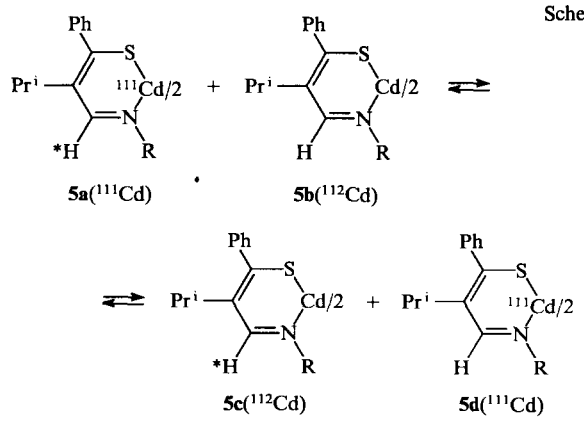


Figure 3. The associative (S_N2 type) mechanism of the intramolecular inversion of the tetrahedral configuration of Zn(II) in complexes **14** according to NMR and X-ray diffraction data.[106]

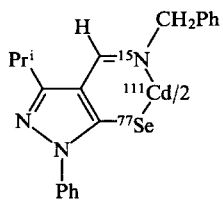
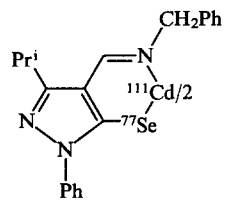
Above T_c, exchange processes, leading ultimately to the disappearance of the constant for the spin–spin coupling of the proton in the azomethine fragment of the ligand with the ^{111}Cd nuclei, begin to be manifested in the spectra. In contrast to the higher-temperature dynamic transformation observed for the first process, a linear relation has been established between τ and c^{-1}, showing that the process is kinetically second order and indicating the occurrence of a bimolecular degenerate ligand exchange reaction [n = 2 in Eqn. (1)] in the type **2** complex (pathway *c* in Fig. 2).

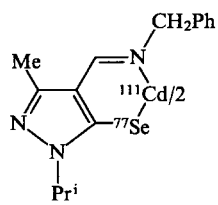


The intermolecular character of the degenerate ligand exchange processes is illustrated particularly clearly by the temperature-dependent two-dimensional ^1H NMR spectra of a mixture of the ^{111}Cd ($S = \frac{1}{2}$) and ^{112}Cd (S = 0) isotopomers of the type **5** complex (R = cyclo-C_6H_{11}) in the resonance region

Scheme 8



of the CH=N protons.[124,125] At temperatures below 10 °C, only diagonal (auto) peaks are present in the ^{1}H NMR spectra (f_0 = 100 MHz). The two extreme peaks among them correspond to the azomethine protons of the ^{111}Cd ($^3J_{^{111}Cd-N=CH}$ = 30 Hz) isotopomer, while the central peak corresponds to the ^{112}Cd isotopomer. An increase in the solution temperature to 33 °C leads to the appearance of six cross-peaks, two of which induce, at the resonance frequencies of the extreme auto-peaks, chemical exchange in the ^{111}Cd isotopomer, while the remaining four induce the intermolecular ligand exchange of the ^{111}Cd and ^{112}Cd isotopomers. This form of the spectra corresponds directly to the form of the exchange matrix for the reaction (Scheme 8). At a temperature above 53 °C, the coalescence of all the diagonal peaks and cross-peaks is observed in the ^{1}H NMR spectrum as a consequence of the intense ligand exchange.



It has been suggested that observation of the temperature dependence of the spin–spin coupling constants for the ^{111}Cd atom in the isotopomeric type **7** complexes, incorporating the ^{15}N and ^{77}Se magnetic nuclei in the coordination unit, would make it possible to answer the question which of the bonds (Cd–Se or Cd–N) in these and structurally similar complexes is the most labile in the ligand exchange reaction (Scheme 1).

7a

7b

7c

However, analysis of the dynamic ^{111}Cd, ^{77}Se, and ^{1}H NMR spectra of the series of complexes **7a–c** showed that the rate constants and activation barriers for the dissociation of these bonds, indicated by the dynamics of the disappearance of the spin–spin coupling constants $^3J_{^{111}Cd-N=CH}$ in the ^{1}H NMR spectra and $J_{^{111}Cd-^{77}Se}$ in the ^{77}Se{H} NMR spectra, are identical within the limits of the usual experimental errors.[126] The synchronous nature of the Cd–N and Cd–X (X = S, Se) bond dissociation-formation steps in the ligand-exchange reactions is also demonstrated by data indicating the thermoinduced disappearance of the spin-spin coupling constants for the ^{111}Cd nucleus of the ligand: $^4J_{^{111}Cd-N=C-CH}$ = 3.5 Hz and $^3J_{^{111}Cd-N=CH}$ = 22 Hz in the spectra of complex **6** (R = Pr^i, R^1 = Br), $^nJ_{^{111}Cd-^{13}C}$ for the α,β-carbon atoms and the carbon atoms of the benzene ring in the ^{13}C{H} spectra of the bischelates **5** (R = Pr^i) and **6** (R = Pr^i, R^1 = H), as well as $J_{^{111}Cd-^{77}Se}$ and $J_{^{111}Cd-^{15}N}$) in the dynamic ^{111}Cd NMR spectra of the triply labelled compound **7a**.

Selected kinetic parameters of the observed dynamic reactions of the bischelate cadmium [^{111}Cd(II)] complexes are presented in Tables 8 and 9. Analysis of these and other data obtained in the study of type **6** complexes shows that, at solution concentrations in the range 10^{-1}–10^{-2} M, the intramolecular enantiomerisation reaction proceeds in all cases at a rate 1–2 orders of magnitude higher and the energy barriers are then lower by 2.5–4 kcal mol^{-1} than the values characteristic of the degenerate ligand exchange process.[100,119,120]

Comparison of the data in Tables 6 and 8 shows that the energy barriers to the intramolecular enantiomerisation of the bischelate cadmium(II) complexes are lower by 4–7 kcal mol^{-1} than that observed for a series of isoligand zinc(II) complexes. The calculated entropies of activation have higher negative values both for the intramolecular inversion process and for the bimolecular association reaction. The influence of structural factors on the barriers in the intramolecular inversion of the tetrahedral configurations of Cd(II) and Zn(II) in isoligand complexes is largely of the same type. The significantly more marked dependence of the configuration inversion barrier in the intermolecular reaction (the energy barriers increase approximately in parallel with increase in the bulk of the

Table 8. Kinetic parameters of the intramolecular inversion of the configuration of the tetrahedral Cd(II) in bischelate complexes with a CdN_2X_2 coordination unit (solvents—$CDCl_3$, *o*-$Cl_2C_6H_4$).

[a] All the reactions investigated are kinetically second order. For comparison with the kinetic parameters of the intramolecular inversion of configuration of Cd(II) (Table 8), the rate constants were assumed to be pseudofirst order, i.e. $k = k_2 c$ for $c = 3 \times 10^{-2}$ M.
[The second entry of the table appears to be in error (Ed. of Translation)]

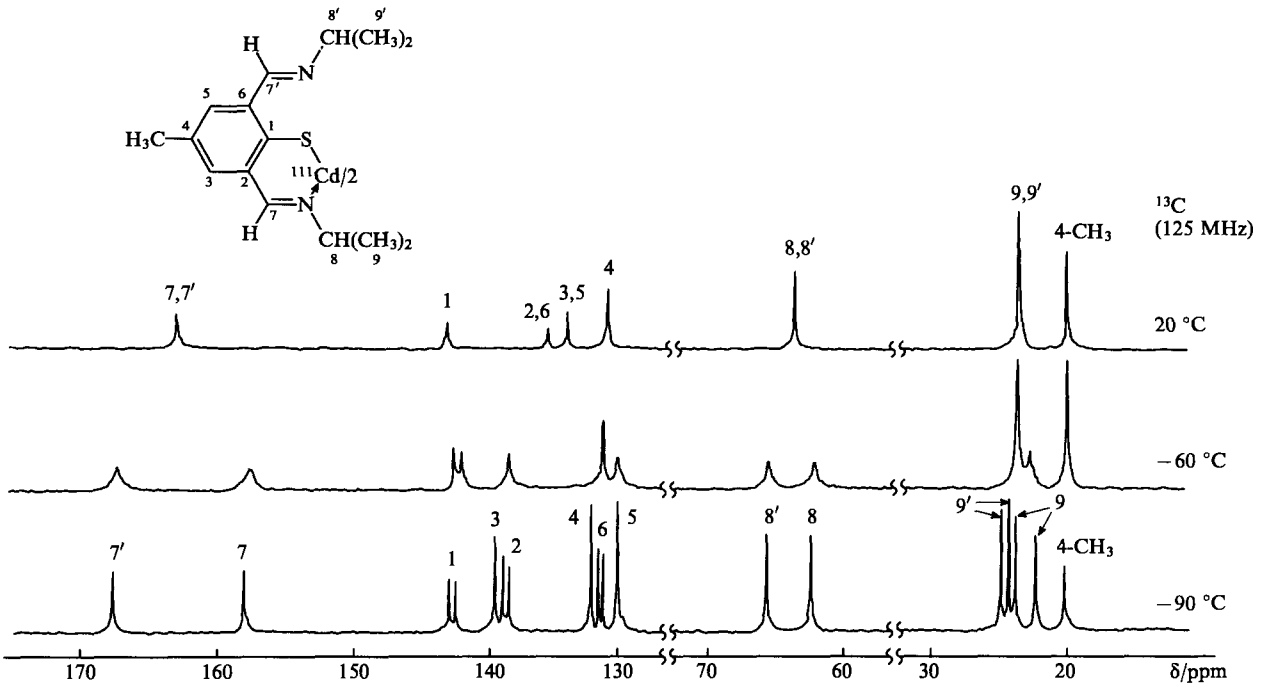
substituent: Et < Ar < CH_2Ph < Bu^t < cyclo-C_6H_{11}) compared with the intramolecular process constitutes an exception. The ligand exchange reaction mechanism (Scheme 8), which makes it possible to account for the synchronisation of the Cd–N and Cd–S bond dissociation-formation processes, is presented in Scheme 9, which presupposes the formation in solution of fairly stable dimeric intermediates with four-membered Cd_2S_2 rings.[119,121,124]

The formation of dimeric structures with planar M_2X_2 (X = O, S, Se, Te) metallocycles is extremely characteristic of zinc[117,127] and cadmium[128,129] phenoxides, thiophenoxides, selenoxides, and telluroxides. The configuration of the bonds at the metal atom in the dimeric intermediates **32a** is then close to the trigonal-bipyramidal configuration for the Zn(II)[95] and Cd(II)[130,131] complexes according to X-ray diffraction data. Intermolecular coordination leads to partial loosening of one of the metal–ligand bonds and promotes its dissociation with subsequent binding to the cadmium atom of another chelate complex. The series of concerted metal–ligand bond dissociation-formation processes, including the rearrangements of pentacoordinate structures of the Berry pseudorotation type, in the stages **32b** ⇄ **32c** ⇄ **32d** ensures the exchange of cadmium atoms between the two units of the dimer, i.e. degenerate ligand exchange. It has been shown[117,129] that a ligand exchange of this type does indeed occur in solutions of zinc and cadmium thiophenoxides via the dissociation and formation of M–S bonds in the dissociation and formation of the dimers respectively.

The energetically preferred mechanism of the intramolecular enantiomerisation of the bischelate complexes with the CdN_2X_2 coordination unit most probably involves the dissociation-formation of Cd–N bonds (pathway *b* in Fig. 2) and not a digonal twist (pathway *a*). This has been confirmed by the results of a study of the temperature dependence of the ^1H and ^{13}C NMR spectra of the bischelate cadmium complex **13** (M = ^{111}Cd, X = S, R = Pr^i, R^1 = Me) based on 2,6-diformyl-4-methylthiophenol bisalkylimine.[123] Fig. 4 shows that the ^{13}C {H} NMR spectrum of this compound at −90 °C does not reveal the occurrence of the chemical exchange reaction but does indicate $^{111}Cd-^{13}C$ spin–spin coupling for certain carbon nuclei of the ligand. An increase in solution temperature leads to the dynamic averaging of the signals due to the carbon atoms of the diastereotopic methyl groups in each of the isopropyl substituents and at the same time to the averaging of the ^{13}C chemical shifts of

Scheme 9

both groups as well as the ^{13}C nuclei in the 3,5-, 7,7′-, and 8,8′-positions. Examination of the dynamic ^1H NMR and two-dimensional exchange (2D EXSY) spectra of this complex leads to the similar conclusion that the intramolecular processes involving the inversion of configuration and the switching of coordination (Scheme 2) are synchronous. The observed disappearance of the constants for the spin–spin coupling of the ^{111}Cd nucleus with the C(1), C(2), and C(6) atoms of the ligand, observed in the temperature-dependent ^{13}C spectra (Fig. 4), is caused by the activation of the intermolecular degenerate ligand exchange process with a relatively higher barrier. Thus the inversion of the configuration of the tetrahedral Cd(II) atom in the given compound is determined by the intramolecular bond dissociation-formation process leading to the (*R*) ⇄ (*S*) inversion (the transcoordination pathway is indicated in Scheme 2).



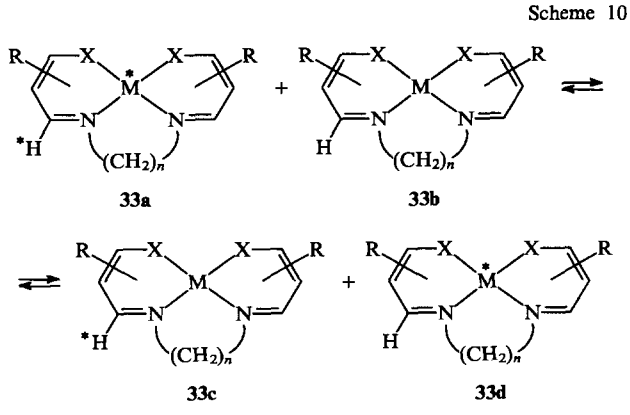


Figure 4. Temperature variation of the ^{13}C NMR spectra (125 MHz, CD_2Cl_2) of the type **13** (X = S, R^1 = CH_3) ^{111}Cd (95%) complex[123]. $J_{^{111}Cd-^{13}C}$ (Hz): 13.3 for C(1), 28.5 for C(2), and 15.6 for C(6); $\Delta G_{25}^{\neq}$ = 12.8 kcal mol^{-1}.

The free energy of activation for the process (12.8 kcal mol^{-1}) is very close to the corresponding value for the intramolecular inversion process in cadmium bis(*N*-isopropylthiosalicylaldiminate) **3**. This is evidence in support of the operation of a similar dissociative mechanism of the enantiomerisation $(R) \rightleftarrows (S)$ in Cd(II) complexes of types **5**, **7**, and **9** (Table 8).

The retention of the spin–spin coupling constants for the ^{111}Cd nucleus of the ligand in the temperature range in which the intramolecular dissociative process is detected in the cadmium complex **13** (M = ^{111}Cd, X = S, R = Pr^i, R^1 = Me) and in the cadmium complexes of types **3**, **5**, **7**, and **9** (Table 8), based on the usual bidentate ligands, may be justified by the argument that the lifetimes of the intermediate tricoordinate structures linked by spin–spin coupling of the ^{111}Cd and ligand nuclei are shorter than the relaxation time (Fig. 1 and Scheme 2).

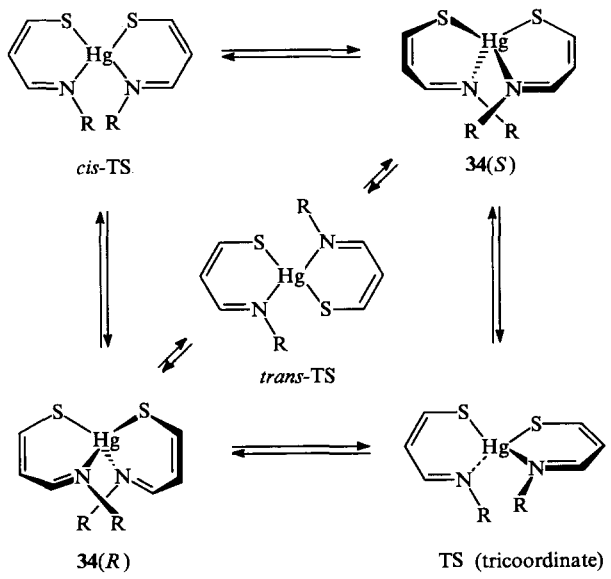
Evidently, this is the reason why it is impossible to detect the operation of the intramolecular metal–ligand bond dissociation-formation mechanism in solutions of the sterically strained bischelate ^{111}Cd (and ^{207}Pb) complexes **33** with an enforced (*n* = 2) *cis*-planar configuration at the metal centre (Scheme 10).[103,124]

Scheme 10

X = S, Se; M = Cd, Pb; *n* = 2, 4, 6.

Only the degenerate ligand exchange process, occurring at unexpectedly high rates and having energy barriers only 2.5–4.0 kcal mol^{-1} higher than in the analogous complexes with a tetrahedral configuration based on bidentate ligands, could be detected in the dynamic ^1H NMR spectra of these compounds.

With increase in the length and mobility of the polymethylene bridge in the tricyclic complexes **33**, the cadmium ion assumes (starting with *n* = 4) a tetrahedral configuration and these complexes exhibit, like their analogues **5** and **6**, two types of reactions in solutions: intramolecular inversion of the configuration of the tetrahedral centre and intermolecular degenerate ligand exchange also accompanied by the inversion of the configuration at the metal atom (Scheme 10).



VIII. Complexes of mercury and lead

Both the intramolecular and intermolecular exchange processes occurring in solutions of Hg(II) bischelate complexes are much faster than for the zinc and cadmium analogues and the determination of quantitative data is difficult in view of the small separations between the diastereotopic indicator signals. For these reasons, there are fairly limited data on the stereochemical lability of Hg(II) complexes. For complex **7** (M = Hg, X = S, R = cyclo-C_6H_{11}, R^1 = Pr^i, R^2 = Me), the rate of the inversion process, detected from the diastereotopic averaging of the signals due to the methyls of the isopropyl substituent R^1 ($\Delta\delta$ = 0.01 ppm in CD_2Cl_2) is independent of the solution concentration and the type of solvent employed, which indicates its intramolecular nature (k_{-80} = 4 s^{-1}, k_{25} = 1.9×10^3 s^{-1}, $\Delta G_{25}^{\neq}$ = 12.9 kcal mol^{-1}).[132]

A theoretical modelling of the possible mechanisms of the intramolecular enantiomerisation has been carried out[133] using the MNDO method for the tetrahedral bischelate complex **34** (Scheme 11), which serves as a model of complexes **7** (M = Hg).

The MNDO method reproduces satisfactorily the highly distorted tetrahedral configuration of the bonds at the mercury atom in complex **34**, which agrees with the X-ray diffraction data[132] for the pyrazole complex **7** (R = cyclo-C_6H_{11}, R^1 = Pr^i, R^2 = Me) having the identical chelate unit (the SHgS and NHgN bond angles are 141° and 103.2°, and the Hg–S bond length is

Scheme 11

2.39 Å). The greater SHgS bond angle indicates that the Hg–S bonds are highly covalent, while the Hg–N bonds in this complex are predominantly dative.[115]

Calculations revealed three structures of the transition state (TS), which are presented in Scheme 11.

As can be seen from the calculated data (Table 10), one may expect the energy barriers to depend fairly strongly on the steric bulk of the substituent R. For R = H, the digonal twist (*trans*-TS) is energetically preferred, while the replacement of hydrogen by the more bulky methyl group (R = Me) results, as expected, in the dissociative mechanism of the inversion of the configuration with dissociation of the Hg–N bond being preferred. For the type **7** complex, the calculated activation energies are fairly close to the experimental inversion barrier for mercury. They also illustrate clearly the extremely fine balance between the principal mechanisms of the intramolecular inversion of the configuration of the pseudotetrahedral mercury atom, providing evidence on the whole in support of the dissociation-recombination pathway *b* in the enantiomerisation of the type **7** Hg(II) chelates (Fig. 2).

Table 10. Modelling of the mechanisms of the intramolecular enantiomerisation of Hg(II) bischelate complexes by means of the MNDO method (with parameters taken from Minkin et al.[133]).

Parameter	**34**	Transition state		
		cis	*trans*	tricoordinate
R = H				
$\Delta\Delta H^{\neq}$/kcal mol^{-1}	0	12.5	8.2	16.0
Hg–N/Å	2.16	2.19	2.18	3.30
$\upsilon_{im}^{\neq}$ /cm^{-1}	–	61	52	64
R = Me				
$\Delta\Delta H^{\neq}$/kcal mol^{-1}	0	24.4	16.1	9.2
Hg–N/Å	2.23	2.27	2.40	3.01
$\upsilon_{im}^{\neq}$/cm^{-1}	–	141	129	94

The gradual decrease in the energy barriers in the dissociative configuration inversion reaction involving the dissociation of the M–N bonds in the type **13** and **7** chelate complexes in the sequence Zn > Cd > Hg correlates with the decrease in the energies of these bonds in the same sequence. According to calorimetric measurements[136] of the heats of hydrolysis of zinc, cadmium, and mercury bis(trimethylsilyl)amides M[N(SiMe$_3$)]$_2$, the M–N bond energies are (kcal mol^{-1}) 50.0 (Zn–N), 34.4 (Cd–N), and 25.8 (Hg–N).

The rate of the degenerate ligand exchange for the type **7** bischelate complexes of mercury is 2–3 orders of magnitude lower than the rates of the intramolecular inversion processes. The intermolecular ligand exchange processes, which are kinetically second order, have been detected in solution from the temperature dependent changes in $^3J_{CH=N-^{199}Hg}$ in the ^{1}H NMR spectra and in $J_{^{199}Hg-^{15}N}$ the ^{199}Hg NMR spectra. The corresponding kinetic data are presented in Table 11.

In the series of the bischelate lead complexes **7** (X = Se), the protons of the diastereotopic grounds remain isochronic (^{1}H NMR) when the solutions in CD_2Cl_2 are cooled to −80 °C, which may be associated with the extremely high rates of the inversion process ($\Delta G_{25}^{\neq} < 7$ kcal mol^{-1}). However, for a series of compounds of this type (Table 11) enriched in ^{207}Pb, it is possible to detect an intermolecular degenerate ligand exchange process, which is indicated by the disappearance of the spin–spin coupling constant $J_{^{207}Pb-^{77}Se}$ in the ^{77}Se{H} NMR and $^3J_{^{207}Pb-N=CH}$ in the ^{1}H NMR spectra. This is also found with the aid of two-dimensional ^{1}H NMR spectroscopy.[135] As in the case of the isoligand cadmium complexes, the reaction is kinetically second order and the Pb–N and Pb–Se bond dissociation-formation processes are synchronous. The rate of reaction diminishes with increase in the bulk of the substituent at the coordinated nitrogen atom.

IX. Complexes of copper, silver, and gold

In the +1 oxidation state, copper, silver, and gold have the d^{10} valence electron shell, like the zinc, cadmium, mercury, and lead complexes in the +2 oxidation state examined above. For this reason, their bonds at the metal centre have a tetrahedral configuration in the tetracoordinate structures.

The Cu(I), Ag(I),[137] and Au(I)[138] bischelate complexes with neutral bidentate ligands of type **35** and having the general formula $[ML_2]^+PF_6^-$ (**36**), where L represents bis(tertiary arsines) and bis(tertiary phosphines), have been investigated in fair detail.

Table 11. Kinetic and activation parameters of the degenerate ligand exchange in type **7** Hg(II) and Pb(II) complexes [solvents—$CDCl_3$, $(CHCl_2)_2$, toluene-d_8].[132,135]

M	R	$^3J_{M-N=CH}(S=\frac{1}{2})$/Hz	k_{25}/s^{-1}	$\Delta H^{\neq}$/kcal mol^{-1}	$\Delta S^{\neq}$/cal mol^{-1} K^{-1}	$\Delta G_{25}^{\neq}$/kcal mol^{-1}
Hg	cyclo-C_6H_{11}	33.0	5.75	7.3	−30.7	16.4
	Bu^t	45.0	17.7	3.4	−41.3	15.8

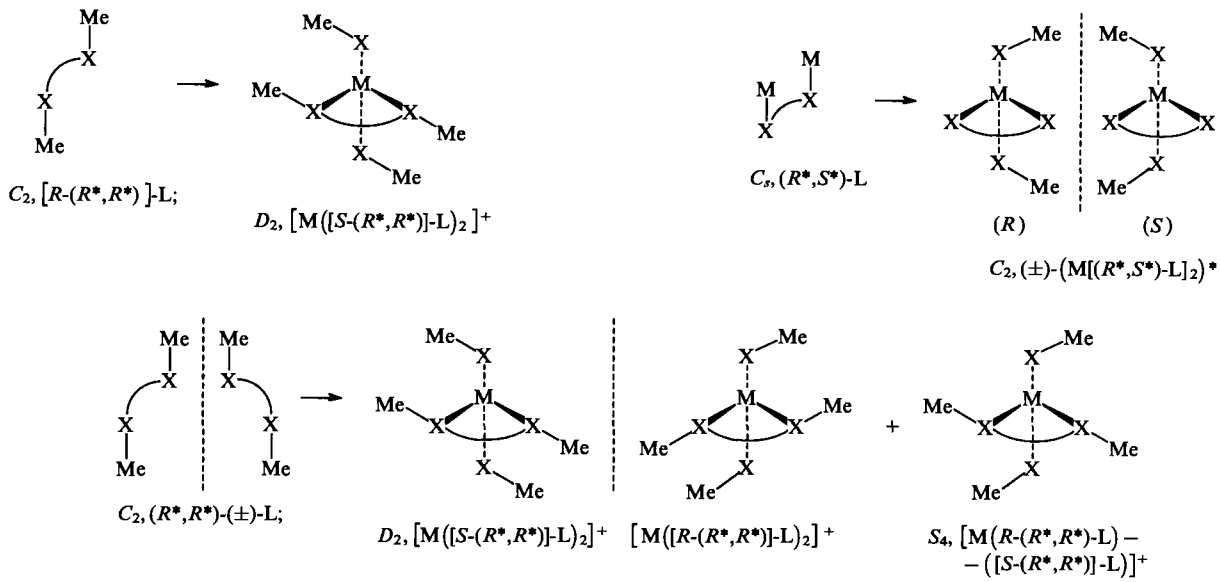
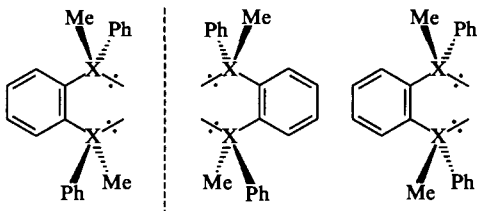
	C_6H_4Me-*p*	13.0	13.5	6.2	−32.3	15.9
Pb	cyclo-C_6H_{11}	14.0	7.1×10^2	8.2	−17.9	13.6
	CH_2Ph	16.5	2.7×10^3	10.3	−8.3	12.8
	C_6H_4Me-*p*	16.0	4.3×10^3	5.76	−16.2	10.6

Note. In the mercury complexes, X = S, R^1 = Pr^i, R^2 = Me; in the lead complexes X = Se, R^1 = Pr^i, R^2 = Me.





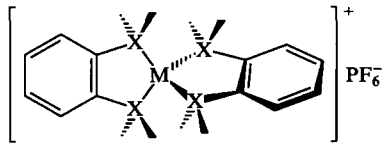


Figure 5. Stereochemical representation, according to the data of Salem et al.,[137] of the tetrahedral complexes **36** using the nomenclature of Cahn et al.[140] for the stereochemical descriptors.

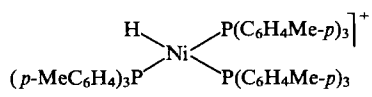
When the donor centres in these ligands are chiral, as in 1,2-phenylenebis(methylphenylphosphines) and the corresponding arsines,[139] the complexes formed by them constitute a complex mixture of diastereoisomers (Fig. 5).

36

X = PMePh, AsMePh;
M = Cu, Ag, Au

The optically active forms of the dissymmetric ligands **35** (C_2-symmetry) give rise to discrete enantiomers of the complexes with D_2 symmetry, in which the PMe or AsMe groups are equivalent. The (*R**,*R**)-forms afford a mixture of chiral (D_2 symmetry) and achiral (S_4 symmetry) chelate complexes. Evidently, the interconversion of these diastereoisomeric forms is possible only as a result of the intermolecular ligand exchange. The achiral (*R**,*S**)-diastereoisomers of the ligand **35** form complex cations with C_2 symmetry in which the PMe or AsMe groups are diastereotopic. The possibility of detecting the intramolecular inversion of configuration in complexes **36** appears in those cases where the tetrahedral metal complex, produced by the (*R**,*R**)-(±)-form of the ligand, is stable in relation to the ligand redistribution reaction between different metal centres.



Both types of processes involving the inversion of the configuration of the metal centre have been observed in solutions of the bischelate complexes **36**. For example, when the mirror enantiomers of the phosphinecopper complex **36** are mixed in solution in CH_2Cl_2, the signals due to the PMe groups of the achiral diastereoisomer (S_4-symmetry) gradually appear in the ^{1}H NMR spectrum. The equilibrium ratio is $D_2 : S_4 = 1 : 6$ (at 20 °C). The time of attainment of equilibrium between the above diastereoisomers, induced by the intermolecular liquid exchange reactions in solution in CD_2Cl_2, is between 1 and 20 min for the copper complexes **36** at the usual temperature and between 1 min and 1 month for the gold(I) complexes.[137,138] Since the ligand exchange reactions are fairly slow under these conditions for all the complexes investigated, there is a possibility of the independent detection of the intramolecular inversion of the tetrahedral configuration of the metal centre in complexes **36** from the diastereotopic averaging of the signals due to the XMe (X = P, As) groups. Table 12 presents the free energies of activation for the inversion process determined at the coalescence temperatures. The observed values are very close to those listed in Tables 7, 8, and 11 for the Zn(II), Cd(II), Hg(II), and Pb(II) bischelate complexes. Although Salem et al.[137] were unable to obtain definite evidence in support of one of the two possible intramolecular inversion mechanisms, they suggest that the reaction follows the digonal twist mechanism without involving the intramolecular dissociation of the bonds between the central atom and ligating atoms.

Table 12. Free energies of activation at the coalescence temperatures (f_0 = 200 MHz) for the intramolecular inversion of the tetrahedral configuration of the metal centre in type **36** complexes (±)-(M[(*R**,*S**)–L]$_2$)PF_6 (L = compound **35**).[137,138]

M	X	Solvent	T_c/°C	$\Delta G^{\neq}_{T_c}$/kcal mol^{-1}

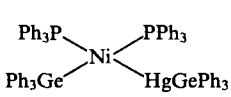
X. Complexes of nickel and other transition metals

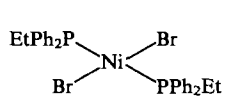
The principal cause of the instability of the planar configuration of the complexes of d^{10} metals — the filling of the antibonding b_{1g} molecular orbital with electrons — is eliminated for the complexes of d^8 metals.[141-143] The planar configuration is therefore energetically preferred for the 16-electron valence shell of the Ni(II), Pd(II), Pt(II), Au(III), etc. complexes. In a number of instances, the stable configuration in the crystalline state for Cu(II) and especially Ni(II) complexes is intermediate between the planar and tetrahedral configurations and the dihedral angle, which determines the transition from planar (θ = 0°) to tetrahedral (θ = 90°) coordination, can vary within very wide limits (see the references in the review of Garnovskii et al.[38]). The situation where tetrahedral structures play the role of the reaction transition states in the isomerisation or topomerisation of the planar forms is more general (Fig. 1).[35,144] In a number of instances, the relative energies of these structures — transition states in the isomerisation reaction — are fairly low and the planar complexes of the tetracoordinate metals are then fluctuating molecules and the isomerisation itself is recorded on the timescale of NMR spectra. Certain examples of such complexes (compounds **37-39**) are given below (the free energies $\Delta G_{25}^{\neq}$ for the *cis-trans* isomerisation are indicated).



37

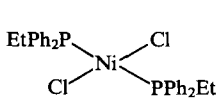
$\Delta G_{25}^{\neq}$ = 14.6 kcal mol^{-1}
(Eaton et al.[145])

38



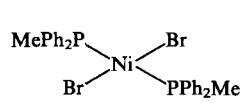
$\Delta G_{25}^{\neq}$ = 12.0 kcal mol^{-1}
(English et al.[146])

39



$\Delta G_{25}^{\neq}$ = 12.3 kcal mol^{-1}
(Grishin et al.[147])

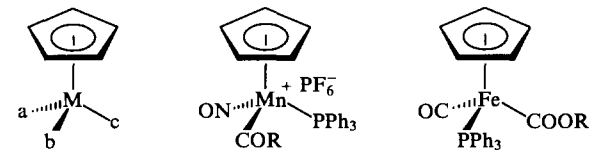
In some cases, the tetrahedral structures are isomeric in relation to the planar forms and exist in solution in equilibrium with them. The barriers to the interconversion of the planar and tetrahedral structures are usually very low (see the Introduction), but for certain complexes (compounds **40-42**) the barriers reach values which can be determined with the aid of the dynamic NMR method.



40

$\Delta G_{25}^{\neq}$ = 10.4 kcal mol^{-1}
(LaMar and Sherman[148])

41



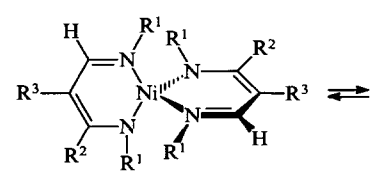
$\Delta G_{25}^{\neq}$ = 9.3 kcal mol^{-1}
(LaMar and Sherman[148])

42

$\Delta G_{25}^{\neq}$ = 9.2 kcal mol^{-1}
(Pignolet et al.[149])

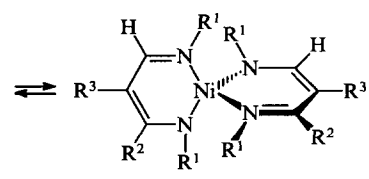
Within the framework of the present review, transition metal complexes for which the tetrahedral forms correspond to the structures of the ground states and the tetracoordinate metal centre is itself chiral are of special interest. A wide range of such complexes of the general type **43** are now known.

43 **43a** **43b**



M = Mn, Fe, Ru, Cr, Mo, W, Co.

Some of them, for example, complexes **43a** and **43b**, are configurationally stable compounds which can be resolved into their optical isomers on a preparative scale.[150,151] The mechanisms of the inversion of the tetrahedral configuration of the metal atom in type **43** complexes have been subjected to a careful kinetic analysis and have also been investigated by a computational method.[152] The most probable is the dissociative mechanism involving, for example in complex **43a**, the splitting off of the phosphine ligand and the formation of a chiral intermediate with a tricoordinate pyramidal metal atom undergoing rapid inversion.

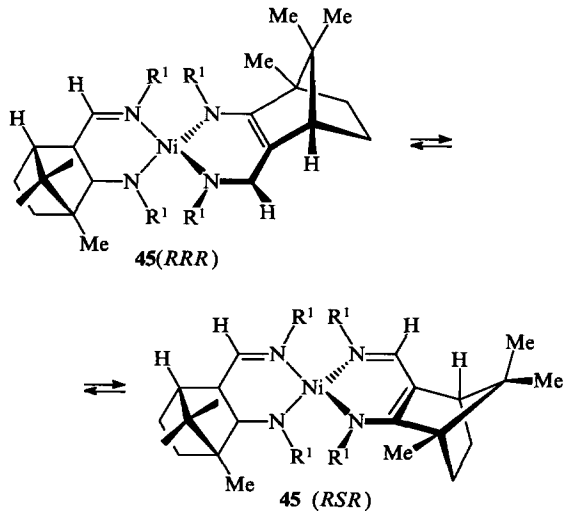


Knorr and coworkers[153-156] obtained the bischelate and configurationally stable nickel complexes **44** and **45** with high barriers to tetrahedral inversion.

The inversion process in complex **44** (Scheme 12) has been investigated from the temperature-dependent diastereotopic averaging of the signals due to the methylene groups of the ethyl substituent (R^3) or the methyl group of the *o*-tolyl substituent (R^3). The energy barriers to the inversion process at the temperatures of the coalescence of the indicator signals (at 95-180 °C in cyclohexane or tetralin) are in the range 17.2-23.8 kcal mol^{-1}.[153,155]

Scheme 12

44(*R*)



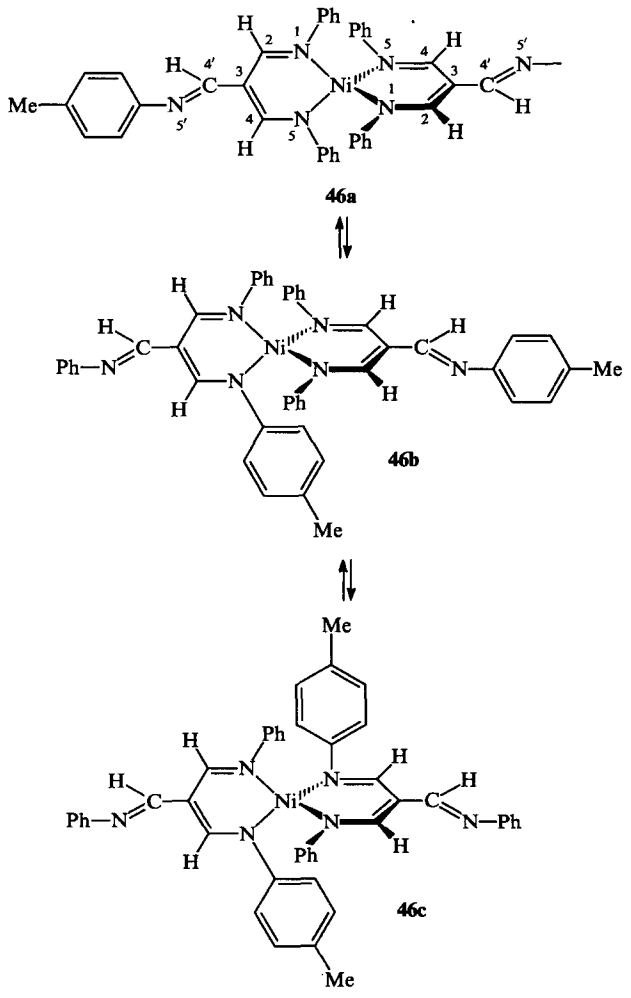
44(*S*)

R^1 = Me, Ph; R^2 = Me, Pr; R^3 = Et, C_6H_4Me-*o*.

The bischelate complexes **45** contain an additional chiral unit — the (*R*)-camphor fragment, so that the inversion of the tetrahedral Ni(II) (Scheme 13) (see over) represents not enantiomerisation but diastereoisomerisation, both diastereoisomers being chiral. It has been established[154] that this process is purely intramolecular. The kinetics have been investigated both by integrating the signals due to the pairs of hydrogen atoms involved in the exchange (in view of the paramagnetism of complexes **44** and **45**, the chemical shifts of their protons were very large) and polarimetrically (slow mutarotation). The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ ($\Delta H^{\neq}$ = 22.5 ± 0.8 kcal mol^{-1} and $\Delta S^{\neq}$ = −15 ± 3 cal mol^{-1} K^{-1} in tetralin) found for complex **45** (R^1 = Ph) indiate the possibility of the preparative separation of the enantiomers of tetrahedral paramagnetic bischelate Ni(II) complexes. For complex **45** (R = Me), the height of the barrier corresponds to $\Delta G^{\neq}$ = 17 ± 1 kcal mol^{-1}.

The possibility of the operation of the dissociative intramolecular mechanism of the enantiomerisation of the bischelate complexes of type **44** with the NiN_4 chelate unit and involving the

Scheme 13

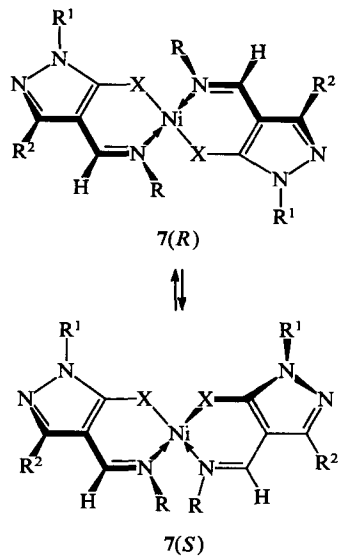


45(*RRR*)

45 (*RSR*)

dissociation of the Ni–N bond has been demonstrated in a study of the transcoordination of the metal atom in complex **46** (Scheme 14).[156] It was established that the transcoordination reaction is very slow [$k = (38 \pm 5) \times 10^{-8}$ s^{-1} at 24.5 °C in solution in the 3 : 1 $CCl_4/CDCl_3$ mixture] and cannot therefore make an appreciable contribution to the observed inversion transformations.

Scheme 14



46a

46b

46c

The possibility of the intramolecular tetrahedral inversion of Ni(II) with a fairly high barrier in the series of metal chelates with a NiN_2X_2 (X = O, S, Se) coordination unit, the rate of which corresponds to the characteristic time scale of dynamic ^{1}H NMR, was first demonstrated for type **7** complexes of the pyrazole series (Scheme 15).[157–160]

Scheme 15

7(*R*)

7(*S*)

The condensation of the pyrazole ring with the chelate ring in complexes **7** stabilises sharply the tetrahedral configuration relative to the planar structure,[43,157,161–163] which can be explained by the steric strain in the chelate ring induced by the condensation of the five-membered heterocycle with it.[164] The pseudotetrahedral structure of complexes **7** in the solid state has been confirmed by X-ray diffraction studies.[38,111,165]

The inversion of the tetrahedral configuration (Scheme 15) has been investigated from the temperature-dependent diastereotopic averaging of the signals due to the corresponding groups of prochiral substituents (Pr^i, CH_2Ph) at the coordinated nitrogen atom and in the 1- and 3-positions in the pyrazole ring. Although the multiplet structure of the signals due to the protons of the diastereotopic groups is not resolved in the spectra owing to the broadening of the signals ($\Delta\nu_{1/2}$ = 12 Hz) typical for paramagnetic complexes, the difference between their chemical shifts at low rates of the exchange processes is 25–500 Hz (f_0 = 100 MHz), which explains the adequate accuracy of the determination of the rate constants and energy barriers for the inversion process at temperatures corresponding to coalescence of the indicator signals.

The energy barriers to the inversion of the tetrahedral configuration of Ni(II) in the bischelate complexes **7** are presented in Table 13. It is seen that the barriers increase with increase in the steric bulk of the substituent R, the increase being particularly notable for R = Bu^t. This effect is fully consistent with a feature well known for complexes of tetracoordinate Ni(II) with NiN_2X_2 chelate units (complexes of types **2**, **3**, **5**, **9**, and **11**)—the shift of the square–tetrahedron equilibrium to the right in the series of substituents R: n-alkyl < *sec*-alkyl < *tert*-alkyl.[1,27,28]

It follows from data of Nivorozhin and coworkers[158,159] that the observed inversion process proceeds via the digonal twist mechanism (pathway *a* in Fig. 2) with formation in the transition state of the planar achiral *cis*-structure typical for the complexes NiN_2S_2 and NiN_2Se_2.[157,160,167–169] It may be expected that, in connection with the rapid development of the NMR methods for the investigation of the kinetics of reactions of paramagnetic compounds,[170] the available information on the dynamics of the stereoisomerisation of tetrahedral Ni(II) complexes will soon expand significantly.

Table 13. Energy barriers to the inversion of the tetrahedral configuration of Ni(II) in type **7** bischelate complexes (solvent—$CDCl_3$).[158,159]

XI. Conclusion

The data presented in this review show that all the theoretically possible types of mechanisms of the inversion of the tetrahedral configuration operate in the enantiomerisation reactions of dissymmetric chelate complexes of transition metals. The majority of these compounds have stereochemically nonrigid structures and the energy barriers to the tetrahedral inversion fit within the characteristic time scale of NMR spectroscopy. In the presence of suitable prochiral substituents in the complexes, the stereoisomerisation processes can be investigated and characterised quantitatively by means of the dynamic NMR method without the preliminary separation of the enantiomeric forms, while with the aid of structural modelling of the ligand, especially when alterdentate ligands are used, it is possible to differentiate reliably the different intramolecular stereoisomerisation mechanisms.

Table 14 summarises the principal results of the studies carried out in this field. For comparison, it also includes the energy barriers to the intramolecular inversion of the tetrahedral configuration of the sp^3-carbon centres. The preferred enantiomerisation pathway is determined mainly by the nature of the centre undergoing inversion.

The data available hitherto on the kinetics and mechanisms of the processes involving the inversion of the tetrahedral configuration in nontransition metal complexes, examined in this review, are still far from complete. Nevertheless, they are already sufficient to reveal certain general trends in the behaviour of the stereochemically nonrigid complexes of this type and to compare them with the much more detailed results obtained in the study of the stereodynamics and ligand exchange reactions for transition metal complexes.

This review has been written with financial support from the Russian Fundamental Research Fund (project 93-03-18692).

Table 14. Energy barriers (kcal mol^{-1}) to the inversion of the tetrahedral configurations of the tetracoordinate d^0 and d^{10} metals and Ni(II).

M(R^1,R^2,R^3,R^4)	Digonal twist	Dissociation-formation of M−R bonds	Intermolecular associative mechanism
C(IV)	Not found[a]	18–28[b]	$(RR^1CHLi)_4$[c]
Be(II)	"	18–25	20–27
B(III)	"	20–22	22–25
Ga(III)	Not investigated	18	$(RR^1R^2Ga)_n$[d]
In(III)	"	12	$(RR^1R^2In)_n$[d]
Zn(II)	9–20	>15	17–22

Hg(II)	11–13[e]	13	14–17
Pb(II)	Not investigated	10	9–14
Cu(I)	13–20	No data	[f]
Ni(II)	3–18	>26	14–20

[a] See Table 1.
[b] The energy barriers were determined by dynamic NMR for the intramolecular isomerisations of indolinospirobenzopyrans and 2-oxaindanospirobenzopyrans involving the thermal dissociation of the C_{sp^3}—O bonds.[170–173]
[c] This mechanism operates readily at the usual temperature in solutions of associated organolithium[174] and other organometallic compounds.
[d] This mechanism operates readily in solutions of dimers and polymeric associated species of organogallium and organoindium compounds.[175]
[e] The choice between the digonal twist intramolecular mechanism and the intramolecular mechanism involving the dissociation-formation of the M–N bond is not unambiguous.
[f] When enantiomers of Cu(I) complexes are mixed with type **35** ligands, racemisation takes place with a half-life $\tau_{1/2}$ = 1–20 min in solution in CH_2Cl_2 at 25 °C.[137,138]

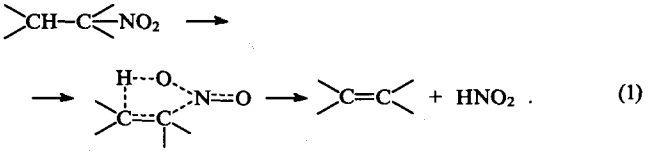
Thermal decomposition of aliphatic nitro-compounds

G M Nazin, G B Manelis

Contents

I.	Introduction	313
II.	Gas-phase decomposition via the molecular mechanism	313
III.	Gas-phase decomposition via the radical mechanism	316
IV.	Reactions in the condensed state	320



Abstract. Literature data on the thermal decomposition reactions of aliphatic nitro-compounds are surveyed and described systematically. Information concerning the influence of molecular structure on the rates and mechanisms of the gas-phase reactions is presented and the structures of the transition states in the C–N dissociation and HNO_2 elimination processes are examined. The characteristic features of the decomposition of nitro-compounds in the condensed phase are described. Data are presented on the C–N bond dissociation energy and the influence on the latter of electronic, steric, and conformational effects. The bibliography includes 86 references.

I. Introduction

The high rates of development of the chemistry of aliphatic nitro-compounds observed during recent decades were associated mainly with the search for new explosives and rocket fuel oxidants. The predominance of this aspect was responsible for the vigorous investigation of the thermal decomposition reactions of both the high-energy compounds themselves and of their numerous analogues and models. Thermal decomposition of virtually all the structural types of nitro-compounds has been studied: mononitroalkanes, *gem*-dinitroalkanes, 1,1,1-trinitroalkanes, pentane derivatives containing between 4 and 8 nitro-groups, unsaturated nitro-compounds, aliphatic-aromatic nitro-compounds, and α-halonitro-compounds, as well as numerous compounds with linked mixed functional groups in which the C–NO_2 fragments are the most reactive parts of the molecules. Whereas only 8 compounds were examined in the first (and hitherto the only) review on this topic published in 1968,[1] at the present time the number of systems investigated has exceeded 100 and in almost all cases the studies have reached the stage in which the decomposition mechanism has been established. This makes it possible to classify the available data not only in terms of the types of substances but also in terms of the reaction mechanisms. In the classification based on the mechanisms, large reaction series arise within the framework of which it is easy to trace the relation between structure and reactivity and to predict the stability of new compounds. It is also useful to consider separately the gas phase and the condensed state in which the decomposition reactions have a number of characteristic features.

On the basis of all the available data, one may conclude that the following principal decomposition mechanisms operate in the gas phase:

1. The molecular mechanism involving the elimination of HNO_2 via a five-membered transition state:

(1)

2. The radical mechanism, where the reaction proceeds via the dissociation of the C–N bond with formation of free radicals:

$$RNO_2 \longrightarrow \dot{R} + NO_2^{\cdot} . \qquad (2)$$

Mononitroalkanes having a hydrogen atom in the α-position, α-halonitro-compounds of the type RCH_2CHXNO_2 (X = halogen), and many α-nitroolefins decompose via the first mechanism at moderate temperatures (up to 300 °C). Owing to the reduced strength of the C–N bond, the decomposition of *gem*-dinitroalkanes, 1,1,1-trinitroalkanes, α,α-dihalo-derivatives RCX_2NO_2, and other compounds with a large number of nitro-groups proceeds via the second mechanism. At fairly high temperatures, reaction (2) becomes dominant in all cases because it has a higher pre-exponential factor in the expression for its rate constant than reaction (1).

II. Gas-phase decomposition via the molecular mechanism

1. Mononitroalkanes

The gas-phase decomposition of mononitroalkanes is complicated by a heterogeneous reaction on the surface.[2,3] The dependence of the rate of reaction on the ratio of the surface area to the volume of the vessel (S/V) is significant in the case of primary [2] nitroalkanes and is virtually absent for tertiary nitroalkanes.[3] Accordingly, an appreciable scatter of the literature data, due to failure to take into account heterogeneous reactions, is observed only in the case of primary nitroalkanes.[1] The 'elimination' of the heterogeneous reaction is achieved by calculating the dependence of the observed rate constants k_o on the parameter S/V.

Note. The thermochemical data for the calculation of D and Q were taken from Lebedev et al.[12]

The characteristics of the homogeneous gas-phase reactions are presented in Table 1.

The decomposition of nitroalkanes results in the formation of the corresponding olefins.[4–6] During the reaction, they are oxidised, but these processes do not proceed to an appreciable extent[3] and in all cases the final gas pressure is close to $2.5p_0$ (p_0 is the initial pressure), i.e. is the same as for the expected initial process.

In the decomposition of secondary and tertiary nitroalkanes, the yield of alk-1-enes and alk-2-enes is close to the statistical value and is almost independent of temperature (Table 2). Only in the case of 2,3-dimethyl-2-nitrobutane is steric hindrance to the formation of alk-2-ene observed.

a. The importance of the pre-exponential factor

The increase in rate on passing from primary to tertiary nitroalkanes is caused to a significant extent by the increase in the pre-exponential factor A. If account is taken of the change in the statistical reaction factor σ, which is equal to twice the number of hydrogen atoms in the β-positions, then, within the limits of the series of primary, secondary, and tertiary nitroalkanes, the values of lg(A/σ) are approximately constant and equal on average to 11.34, 11.80, and 12.35 respectively. These differences between the values can be explained by the stepwise increase in the barrier to the internal rotation V_{int} about the C–N bond on α-alkylation (from <4 kJ mol^{-1} for primary nitroalkanes to >40 kJ mol^{-1} for tertiary nitroalkanes). The increase in the barrier to the internal rotation about the C–C bond also exerts some influence on the change in A. The loss of this partly hindered rotation is responsible for the reduced value of A/σ in *tert*-nitroalkanes (compared with the 'normal' value $A = 10^{13.5}$ s^{-1}). The details of the calculation of A for reactions involving elimination from primary nitroalkanes have been published.[7]

Table 2. The relative yields (γ) of alk-1-enes on decomposition of nitrocompounds.[4]

Compound	T/ °C	γ(%)	
		experiment	calculation
2-Nitrobutane	250	55	60
	330	56	60
2-Nitrohexane	300	58	60
3-Methyl-2-nitrobutane	300	78	75
2-Methyl-2-nitrobutane	190	77	75
	250	77	75
3-Methyl-3-nitropentane	250	43	42.8
2,3-Dimethyl-2-nitrobutane	250	95	85.7

b. The polar nature of the HNO_2 elimination reaction

Reaction (1) is endothermic and its activation energy is

$$E = Q + \varepsilon_0,$$

where Q is the heat of reaction and ε_0 the activation energy for the reverse process involving the addition of HNO_2 to the olefin.

It is seen from Table 1 that under the influence of alkyl substituents Q and ε_0 change in opposite directions and the energy E therefore remains almost constant.

α-Methylation has comparatively little influence on the rate of reaction (1) (Table 3) and, in terms of this feature, the elimination of HNO_2 can be assigned (in Maccoll's terminology[9]) to weak quasi-heterolytic processes. However, in terms of another feature of these reactions, according to which the rate of elimination depends directly on the degree of charge separation in the transition state, reaction (1) can be assigned to highly polar reactions, since its rate exceeds those of any other reactions of this type. There is no doubt that the high electronegativity of the NO_2 group and the high dipole moment of the nitroalkane molecule (~3.5 D), which is almost twice as high as for haloalkanes (~2.0 D), facilitate the formation of a highly polar transition state. As a result of the low polarisability of the C–N bond and the simultaneously high electronegativity of the NO_2 group, the bond is polarised to the maximum extent already in nitroethane and, on further alteration of the structure of the alkyl residue, the state of this bond and the charge on the nitro-group hardly vary and hence the rate of the decomposition reaction varies only little. The extent of the change in the polarisation of the C–N bond on α-methylation may be estimated from the relative increase in the dipole moment $\Delta\mu$ on passing from CH_3X to *tert*-C_4H_9X. For example, $\Delta\mu$ is 20% for X = Cl and only 5% for X = NO_2. Similarly, $\Delta\mu$ is small in the series of alcohols, amines, esters, and isocyanates[8] and hence there is only a slight variation of the rate of α-methylation of these compounds.

Table 3. The influence of α-methylation on the relative rate of elimination of HX from the alkyl derivatives RX.[8]

X	R = *iso*-C_3H_7	R = *tert*-C_4H_9
Cl	223	41000
Br	280	78000
I	100	35000
CH_3COO	26	1600
HCOO	20	720
SCN	38	800
NO_2	12	172
$H_2C=CHO$	13	126
OH	10	38

Note. The relative rate is unity for R = C_2H_5.

In terms of the change in ε_0 ($\Delta\varepsilon_0$) for the reaction involving addition to olefins of different structure, HNO_2 does not differ from other acids HX (Table 4) and the above process is quantitatively consistent with the theoretical calculations for four-centre reactions based on the polar transition state model made up of two semi-ionic pairs in proximity.[10]

Using ε_0 for nitroethane, the $\Delta\varepsilon_0$ data for olefins,[11] and additive schemes for the calculation of the enthalpies of formation of nitro-compounds,[12] it is possible to estimate Q and E for the elimination reactions involving many nitroalkanes. Absence of a preferential elimination from *sec*-nitroalkanes has been explained by the mutual compensation of Q and ε_0 (Table 1).

2. α-Halonitroalkanes

The α-halogenation of nitroalkanes lowers the activation energy and increases the rate of reaction (Tables 1 and 5). However, this decrease is small (4–12 kJ mol^{-1}) and reaches 20 kJ mol^{-1} in only one case ($C_2H_5CHClNO_2$). However, on the whole the activation energy for the molecular decomposition of α-halonitroalkanes is in the range 166–184 kJ mol^{-1}, as for nitroalkanes.

In terms of their influence on the rate of the decomposition reaction, the halogens can be arranged in the sequence Cl > Br > F. This sequence in the influence of the halogens may be accounted for within the framework of the concept of the polar nature of the transition state. The inductive effect of the halogen atoms, which diminishes the electron density of the NO_2 group, should increase the rate of decomposition of halonitroalkanes in the sequence Br < Cl < F. On the other hand, the ability of the halogens to exhibit a positive mesomeric effect decreases the rate of decomposition in this series. The mesomeric effect may be expressed by the stabilisation of the transition state or by the supply of electrons to the NO_2 group in the ground state.

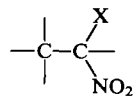

Table 5. Characteristics of the reactions involving the elimination of HNO_2 from halonitroalkanes.[13]

Compound	T/ °C	E/kJ mol^{-1}	$\lg(A/s^{-1})$	ω_{rel} [a]
CH_3CHFNO_2	300–340	184.3	12.62	5.4
$C_2H_5CHClNO_2$	250–300	165.9	12.55	174.0
$C_2H_5CHBrNO_2$	280–320	173.9	12.48	31.6
$(CH_3)_2CClNO_2$	240–300	176.8	13.62	24.5
$(CH_3)(C_2H_5)CClNO_2$	250–280	171.8	13.37	36.3
$(CH_3)_2CBrNO_2$	250–290	176.8	13.40	14.8
$(CH_3)_2CHCCl(NO_2)CH_3$	230–270	167.6	13.20	40.0
$(CH_3)_2CHCBr(NO_2)CH_3$	230–270	165.9	13.19	40.0

[a] ω_{rel} is the ratio of the rate of decomposition of the halonitroalkane to the rate of decomposition of the analogous unsubstituted nitroalkane at the temperature corresponding to $k = 10^{-4}\ s^{-1}$ for the nitroalkane.

The sequence in the influence of the halogens is in fact a consequence of the superposition of these two effects. The same sequence has been observed in the decomposition of α-polyhaloalkanes.[8,9,14]

3. α-Nitroolefins

In terms of the rate and kinetic parameters of their decomposition reactions, α-nitroolefins are close to their saturated analogues (Table 6). β-Alkylation influences the rate and activation energy more than does α-alkylation. The quantity $\lg(A/\sigma)$ for the decomposition of nitroalkenes is actually equal to that for the decomposition of *sec*-nitroalkanes. In the case of nitroalkenes, the internal rotation about the C–N bond is lost on formation of a cyclic transition state, while in the case of nitroalkenes the internal rotation about the C–N and C–C bonds is lost. Consequently the potential barrier to the internal rotation of the nitro-group in nitroalkenes is higher than in *sec*-nitroalkanes.

The decomposition of unsaturated nitro-compounds can also proceed via other mechanisms, but these too are of the molecular type. It has been shown for 2-methyl-3-nitroprop-2-ene that,[15] when the NO_2 and CH_3 groups are forced to

Table 6. Characteristics of the molecular decomposition of nitroalkenes.[13]

Compound	T/ °C	E/kJ mol^{-1}	$\lg(A/s^{-1})$	ω_1	ω_2
$CH_2=CHNO_2$	340–400	191.9	12.10	1.0	1.3
$CH_3CH=CHNO_2$	307–360	176.8	11.82	9.2	8.1
$C_2H_5CH=CHNO_2$	290–340	176.0	11.92	13.8	8.3
$C_6H_5CH=CHNO_2$	290–350	176.0	12.04	18.2	–
$C_2H_5C(NO_2)=CH_2$	323–380	187.3	12.16	2.6	0.25

Note. The following notation has been adopted: ω_2 is the relative rate at 350 °C and ω_2 is the ratio of the rates of decomposition of the nitroalkene and of its saturated analogue at the temperature corresponding to $k = 10^{-4}\ s^{-1}$ for the nitroalkene.

Table 4. The absolute change $\Delta\varepsilon_0$ (kJ mol^{-1}) in reactions involving the addition of HX to olefins.[8]

Olefin	Orientation [a]	Calculation	Experiment for HX					
			HCl	HBr	HI	H_2O	CH_3OH	HNO_2
C_2H_4	–	0	0	0	0	0	0	0
C_3H_6	M	−17.6	−23.1	−17.2	−19.7	−26.0	–	−17.6
	AM	+1.7	−3.3	−0.8	–	−0.8	–	+5.7
C_4H_8	M	−24.7	−35.2	−31.4	–	–	–	−23.9
	AM	−2.1	−3.3	−3.3	–	–	–	−3.7
iso-C_4H_8	M	−50.3	−62.0	−49.4	−42.7	−43.1	−44.0	−23.6

[a] The following notation has been adopted: M — addition in accordance with the Markovnikov rule, AM — addition contrary to the Markovnikov rule.

assume the *cis*-disposition, decomposition via isomerisation takes place readily.

$$(CH_3)_2C{=}CHNO_2 \longrightarrow H_2C{=}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{-}CHNOOH \longrightarrow \text{products}$$

For this compound, we have

$$k = 10^{11.8} \exp\left(-\frac{151680}{RT}\right).$$

The composition of the products of the decomposition of $PhCH=C(CH_3)NO_2$ at 600 °C and a pressure of 10^{-3} torr has been determined.[16] Since the main products are PhCHO and CH_3CN, one may conclude that the reaction proceeds via an intramolecular oxidation mechanism.

$$PhCH{=}C(CH_3)NO_2 \longrightarrow Ph{-}\overset{\displaystyle H}{\overset{\displaystyle |}{C}}{:::}\overset{\displaystyle CH_3}{\overset{\displaystyle |}{C}} \longrightarrow$$

$$\longrightarrow PhCHO + CH_3CN + O$$

However, in order to confirm this mechanism, it is essential to carry out further studies on this reaction and in the first place to determine its kinetic parameters, to elucidate the influence of p_0 on the composition of the products and on the rate, and to investigate nitrostyrene analogues.

It has been shown[17] that on hot (650 °C) iron and nickel surfaces nitroethylene loses an oxygen atom and is converted into nitrosoethylene. The reaction was carried out at low pressures with activation by collisions with the surface. Nitrosoethylene was in fact obtained for the first time by this method and its reactions on the surface were elucidated.

$$H_2C{=}CH{-}NO \longrightarrow CH_2{=}CH{-}N{:} \longrightarrow H_3CCN$$

III. Gas-phase decomposition via the radical mechanism

1. The chemical mechanism

The decomposition reactions the first stage of which is the dissociation of the C–N bond are complicated by chain processes only in the case of mononitro-compounds such as nitromethane[18–21] and chloropicrin.[22] For nitromethane, heterogeneous decomposition on the surface is also important.[18] The mechanism of the decomposition of nitromethane at all temperatures up to the inflammation temperature[23–25] includes at least 26 reactions. Some of the reactions presented in Scheme 1 are kinetically important and explain the formation of the principal intermediates (CH_2O, NO, NO_2) and final products (CH_4, CH_3OH, HCN, H_2O) at moderate temperatures.

Scheme 1

$$CH_3NO_2 \longrightarrow \dot{C}H_3 + NO_2$$

$$CH_3NO_2 + \dot{C}H_3 \longrightarrow CH_4 + \dot{C}H_2NO_2$$

$$\dot{C}H_3 + NO_2 \longrightarrow CH_3\dot{O} + NO$$

$$CH_3NO_2 + CH_3\dot{O} \longrightarrow CH_3OH + \dot{C}H_2NO_2$$

$$\dot{C}H_2NO_2 \longrightarrow CH_2O + NO$$

$$\dot{C}H_3 + NO \longrightarrow CH_3NO$$

$$CH_3NO \longrightarrow HCN + H_2O$$

Starting with *gem*-dinitroalkanes, the polynitro-compounds decompose unimolecularly. The surface, pressure, and impurities do not as a rule affect the rate. Nitrogen oxide and dioxide, formed in the decomposition, inhibit all the free-radical processes. Processes on the surface are characteristic only of substances of the type of di- and tri-nitromethane having a hydrogen atom in the α-position.[26] Typical decomposition reactions of polynitro-compounds are presented in Scheme 2. The scheme is based on the composition of the products of the decomposition of 1,1,1-trinitroethane (Table 7).[27] All the stages in this scheme, except the fourth, correspond to the generally accepted ideas concerning the reactions of free radicals in NO_2 and NO. The fourth reaction is new and is observed only for compounds having at least two nitro-groups at one carbon atom. The yield of nitriles increases following the addition of NO. RCN and ClCN are formed from $RCCl(NO_2)_2$.[14] When iodine is added to $C(NO_2)_4$ and $ClC(NO_2)_3$, ICN is formed in the first case, while in the second only ClCN is produced.[28]

Scheme 2

$$CH_3C(NO_2)_3 \longrightarrow CH_3\dot{C}(NO_2)_2 + NO_2$$

$$CH_3\dot{C}(NO_2)_2 \longrightarrow CH_3\dot{C}O + NO + NO_2$$

$$CH_3\dot{C}(NO_2)_2 + NO_2 \longrightarrow CH_3\dot{C}O + NO + 2\,NO_2$$

$$CH_3\dot{C}(NO_2)_2 + NO \longrightarrow CH_3C(NO)(NO_2)_2 \longrightarrow$$

$$\longrightarrow CH_3CN + NO_2 + NO_3$$

$$CH_3\dot{C}O \longrightarrow \dot{C}H_3 + CO$$

$$CH_3\dot{C}O + NO_2 \longrightarrow CH_3CO\dot{O} + NO$$

$$CH_3CO\dot{O} \longrightarrow \dot{C}H_3 + CO_2$$

$$CH_3CO\dot{O} + RH \longrightarrow CH_3COOH + \dot{R}$$

$$CH_3CO\dot{O} + \dot{C}H_3 \longrightarrow CH_3COOCH_3$$

$$\dot{C}H_3 + NO_2 \longrightarrow CH_3NO_2$$

$$\dot{C}H_3 + NO_2 \longrightarrow CH_3\dot{O} + NO$$

$$\dot{C}H_3 + NO \longrightarrow CH_3NO \longrightarrow HCN + H_2O$$

$$CH_3NO + 2\,NO \longrightarrow \dot{C}H_3 + N_2 + NO_3$$

$$CH_3NO + NO_2 \longrightarrow CH_3NO_2 + NO$$

$$\dot{C}H_3 + RH \longrightarrow CH_3OH + \dot{R}$$

$$CH_3\dot{O} + NO_2 \longrightarrow CH_3ONO_2$$

$$CH_3\dot{O} + NO_2 \longrightarrow CH_2O + HNO_2$$

$$CH_3\dot{O} + NO \longrightarrow CH_3ONO$$

$$CH_3\dot{O} + NO \longrightarrow CH_2O + HNO$$

$$2\,HNO \longrightarrow H_2O + N_2O$$

$$NO_2 + CH_2O \longrightarrow NO + CO_2 + H_2O$$

Table 7. Dependence of the yield of the products of the decomposition of 1,1,1-trinitroethane on the degree of reaction at 170 °C.[27]

Product	Degree of reaction (%)

[a] In an excess of NO_2.

The decomposition of compounds of the type of hexanitroethane with a vicinal disposition of the nitro-groups results in the formation of olefins. Thus it has been shown[29] that the vacuum pulse pyrolysis of hexanitroethane affords a high yield of tetranitroethylene. Since the kinetic parameters of the decomposition of this compound correspond to the abstraction of NO_2 and not the elimination of N_2O_4, it must be recognised that the olefin is formed as a result of a secondary reaction involving the ejection of NO_2 from the radical $(NO_2)_3CC(NO_2)_2$. The splitting off of two NO_2 molecules on decomposition of 1,2-difluorotetranitroethane in the gas phase at low pressures[30] and other instances of the decomposition of vicinal dinitroalkanes can be explained similarly.

The reactions of the 1-adamantyl radical, formed on radical decomposition of 1-nitroadamantane (600 °C), have been traced.[31]

2. Activation energies for the decomposition reactions and the strength of the C–N bonds in polynitro-compounds

Data on the radical decomposition of nitro-compounds are presented in Table 8. The activation energy for the decomposition reaction is determined by the strength of the C–N bond, $D(C-N) = E - RT_{av}$, and varies within wide limits. There is no doubt that D(C–N) is influenced by the inductive, steric, and resonance effects of the substituents. The resonance effect stabilises the transition state with a planar radical, remaining after the abstraction of the nitro-group. The mesomeric effect explains the sharp decrease in D(C–N) on passing from CH_3NO_2 to $PhCH_2NO_2$. It may be that the very strong influence of the sulfur atom in the α-position on D(C–N) (compounds **43–50**, Table 8) is associated with this effect. The steric effect of bulky α-substituents is reflected by the increase in the rate in the sequence H < Cl < Br < I for methane derivatives (compounds **6–10**, **14–16**, and **24–26**, Table 8 — see over).

The influence of all α-substituents on D(C–N) has been attributed[7] solely to the steric effect, which appears unlikely. The nitro-groups in polynitro-compounds are known to undergo mutual polarisation. Furthermore, the Cl, Br, and NO_2 substituents influence equally the strength of the C–H and C–F bonds, which are not subject to steric hindrance.[44] It has been shown[45] that the rate of reaction is influenced primarily by the electronic charges on the reaction centre. In a series of isotypical compounds without α-steric effects (compounds, **1**, **2**, **17**, and **27–32**, Table 8), the inductive effect is manifested in a pure form and is expressed by the relation

$$D(C-N) = 220 - 15.2\sigma^*. \quad (3)$$

The values of σ^* for substituents containing nitro-groups may be calculated from literature data.[46,47] Thus the constants σ^* are respectively 4.65, 4.54, and 2.93 for $C(NO_2)_3C(NO_2)_2$, $C(NO_2)_3$, and $CH_3C(NO_2)_2$.

We may also note that a method has been proposed[48] for the estimation of the activation energies for the radical decomposition of *C*-nitro-compounds based on the empirical correlation

$$E = 46.73 + 2.52(\Delta H_{CN} - 70) + 0.22(\Delta H_{CN} - 70)^2,$$

where ΔH_{CN} is a simplified energy characteristic of the C–N bond,[49] which is calculated by the MINDO/3 method and requires little computer time.

The study of the influence of molecular structure on D(C–N) has shown that there are two rules. The first is that a fluorine atom in the α-position acts on the bond not like an electronegative substituent but like a neutral hydrogen atom or alkyl group. Whereas D(C–N) decreases successively by 2–4 kJ mol^{-1} on replacement of the NO_2 group by Cl, Br, or I, its replacement by F increases D(C–N) by 20 kJ mol^{-1}. This increased stability of α-fluoronitro-compounds is associated with this fact. The unusual behaviour of fluorine as a α-substituent is characteristic not only of the C–N bond but also of the C–H and C–Hal bonds. The equivalence of hydrogen and fluorine as α-substituents was first noted by Vedeneev and Purmal'[50] and may be traced on the basis of data published in a handbook.[44]

The second rule concerns the manifestation of the field effect (the *F*-effect, anchimeric participation) in pentane derivatives with a large number of nitro-groups (compounds **33–36** and **38–42**, Table 8). In the main conformation of these compounds,[51] which is fixed under the influence of steric strain, one of the oxygen atoms of the γ-nitro-group approaches the terminal carbon atom to a distance corresponding to the van der Waals radius. This weakens the C–NO_2 bond as a result of the stabilisation of the radical, formed following the abstraction of NO_2, by the electron density on the oxygen of the γ-nitro-group. The effect intensifies with increase in the bulk of the second γ-substituents (H < F < Cl < Br).

The enthalpies of formation of the nitroalkyl free radicals (Table 9) and then D(C–H), D(C–C), or D(C–Hal) (Table 10) in nitro-compounds may be determined from the values of D(C–N) found by the kinetic method. The dissociation energies D calculated in this way differ somewhat from those found by a thermochemical method[12] from the variation of the enthalpies of formation of the compounds and supplement them. We may note that, with increase in the number of nitro-groups, D(C–H) also increases (owing to the polarisation of the C–H bond). Following a one-sided introduction of electronegative substituents, D(C–C) increases, whilst for a symmetrical disposition of the substituents it falls sharply.

Table 9. Enthalpies of formation of nitroalkyl radicals.

Radical R	D(R–NO_2)/ kJ mol^{-1}	$\Delta H_f^\circ(\dot{R})$/ kJ mol^{-1}

Note. The values of ΔH_f° for the compounds RNO_2 necessary for the calculation of $\Delta H_f^\circ(\dot{R})$ were taken from Lebedev and coworkers and Carpenter et al.[12,52,53]

3. Characteristics of the variation of the pre-exponential factor

The pre-exponential factor in the expression for the rate constant for the dissociation of the R_3C-NO_2 bond reaches high values for several reasons.[54] The principal of these are as follows:

1. The decrease in the frequencies of the deformation vibrations associated with the C–N bond. Judging from the secondary kinetic deuterium isotope effect,[55] the frequency of the deformation vibration, which becomes the out-of-plane vibration of the R_3C radical, diminishes by a factor of 2. The frequencies of the two rocking vibrations of the R_3C group and of the analogous vibrations of the NO_2 group also decrease by this factor.

Table 8. Kinetic characteristics of the radical decomposition of aliphatic nitro-compounds.

No.	Compound	T/ °C	E/kJ mol^{-1}	lg[(A/σ)/s^{-1}]	$\Delta S^{\#}$/e.u.	Ref.

2. The liberation of the internal rotation about the C–N bond. The maximum contribution by this factor to the activation entropy $\Delta S^{\#}$ is 3 e. u. (0.6 lg A).

3. The decrease in the frequencies of the torsional vibrations (up to free rotation) of the groups R adjoining the reaction centre. In the case of nitro-compounds, R may be alkyl groups and NO_2. The effect of the neighbouring groups can be very large but it was never observed previously.

4. In unsaturated and aliphatic-aromatic compounds, there is a possibility of a negative effect of the neighbouring groups owing to the conjugation of the double bond with a free valence on the reaction centre. Thus the order of the $C^{(1)}-C^{(2)}$ bond in the transition state of the reaction

is 1.5, as a result of which the torsional vibration frequency increases and $\Delta S^{\#}$ diminishes.

In the case of nitromethane, for which the barrier to the internal rotation V_{int} is low,[56] the factors 2–4 do not play any role and the slight increase in $\Delta S^{\#}$ compared with the normal value $\Delta S^{\#} = 0$ is due solely to the first cause. The decrease in the frequencies of the one asymmetric deformation vibration (1482 cm^{-1}) and the four rocking vibrations (1087, 1100, 605, and 477 cm^{-1})[57] by a factor of 2–2.5 increases $\Delta S^{\#}$ by 6 e. u., which is consistent with the experimental value.[18]

A detailed calculation of the pre-exponential factors for the decomposition reactions of $CH_3(NO_2)$, $HC(NO_2)_3$, $F_2C(NO_2)_2$, $HFC(NO_2)_2$, and $CH_3CF(NO_2)_2$ has been carried out by the MINDO/3 quantum-chemical method on the basis of the Rice–Ramsperger–Kassel–Marcus theory.[58] The best agreement with experiment was achieved within the framework of the semirigid activated complex model with a critical C–N bond length of 2.45 Å. The introduction of halogen atoms or of the NO_2 group into the nitromethane molecule leads to an increase in V_{int} and of $\Delta S^{\#}$ by a further 2 e. u.

The positive effect of the neighbouring groups is manifested only slightly for the NO_2 group (compounds **11–13**, **17**, and **18**, Table 8) and very markedly for alkyl substituents (compounds **19–23** and **27–29**, Table 8). NMR data indicate a marked hindrance of the rotation about the C–C bond in 1,1,1-trinitroethane.[59] A β-deuterium isotope effect is observed on decomposition of this compound,[55] which indicates a change in the vibration frequencies of the CH_3 group in the transition state.

There is no positive effect of the neighbouring NO_2 and alkyl groups in compounds having the large chlorine, bromine, and iodine atoms in the α-position (compounds **24–26**, Table 8), which hinder the rotation of the groups not only in the initial tetrahedral form but also in the planar form of the R_3C group. As already mentioned, steric factors influence also D(C–N) in these compounds.

$\Delta S^{\#}$ is smaller for $PhCH_2NO_2$ than for CH_3NO_2 owing to the negative effect of the Ph group.

4. Competition between the radical and molecular mechanisms

The quantitative characteristics described above make it possible to predict the characteristics of different decomposition pathways and to find the temperature T_{eq} at which the rates of elimination of HNO_2 and of the dissociation of the C–N bond are equal. The radical decomposition predominates above this temperature. The data for typical compounds are presented in Table 11. Approximate estimates of T_{eq} for certain mono- and di-nitro-compounds have also been carried out by Shaw.[60]

5. The nitro-nitrite rearrangement

Apart from the processes described above, which occur in the gas-phase reactions of nitroalkanes[15,16] the possibility of the nitro–nitrite rearrangement (NNR) as an alternative to the radical decomposition has been considered for several years. Thus the formation of CH_2O, which might have been a product of the NNR, has been observed in a study[61] of the decomposition of nitromethane in a molecular beam during laser heating (1078 cm^{-1}). The rate of rearrangement was 60% of the rate of dissociation of the C–N bond and its activation energy (233 kJ mol^{-1}) proved to be close to the C–N bond dissociation energy. The first theoretical calculation by the MINDO/3 method[62] yielded an activation energy of 188 kJ mol^{-1} for the NNR. However, later and more rigorous calculations[63] failed to confirm this result and indicate that the activation energy for the NNR is higher by 40 kJ mol^{-1} than the C–N bond dissociation energy.

In principle, the NNR can actually occur as a reaction accompanying the dissociation of the C–N bond and not as a kinetically independent process. This is possible when the decomposition proceeds via a loose transition state[64] in which there is a considerable distance between the fragments R and NO_2 being separated and when they execute three-dimensional rotation. The recombination of R with NO_2 can also occur in this state through an oxygen atom with the simultaneous elimination of NO. The loose transition state arising under these conditions is similar to that formed on decomposition of nitrobenzene and its

Table 11. Competition between the radical and molecular mechanisms of the decomposition reaction.

Note. The following notation has been adopted: I, III — E/kJ mol^{-1}; II, IV — lg (A/s^{-1}); I, II — calculated values; III, IV — experimental values.

derivatives [D(C–N) > 288 kJ mol^{-1}], for which the NNR is, incidentally, observed.[65] The decomposition of aliphatic nitro-compounds always proceeds via a semirigid transition state (this is indicated by the constants for the recombination of alkyl radicals with NO_2)[66] and the rearrangement of such compounds is unlikely to be a secondary process accompanying the dissociation of the C–N bond. An experimental solution of the problem of the occurrence of the NNR can be achieved by studying the decomposition of CH_3NO_2 in the presence of $N^{18}O_2$ (in a medium comprising RH hydrogen donors) from the dependence of the ratio $CH_3OH/CH_3{}^{18}OH$ on the $N^{18}O_2$ concentration.

IV. Reactions in the condensed state

Mononitro- and halonitro-alkanes having a hydrogen atom in the α-position, dinitro-compounds with terminal $CH(NO_2)_2$ groups, and nitroform decompose in the liquid state much faster than in the vapour phase apparently as a result of isomerisation to nitronic acids or ionisation and autoprotolysis. For example, liquid nitroform decomposes at an appreciable rate at 80 °C whereas in the vapour phase the reaction does not begin until 180 °C. The liquid-phase reactions are subjected to fairly pronounced autocatalysis with the aid of NO and NO_2. They may be stabilised on acidification, which prevents the formation of the aci-form and ionisation.

The influence of the aci-form on the decomposition of liquid nitro-compounds and their capacity for detonation has been demonstrated convincingly in relation to nitromethane and nitroethane.[67] A characteristic feature of these compounds is the decrease in the critical detonation diameter under the influence of small amounts of added bases (dimethylenetriamine, pyridine), high pressure, which shifts the equilibrium towards the formation of the aci-form (the molar volume of which is smaller by 15% than that of the keto-form), and UV irradiation, under the influence of which isomerisation also occurs. A marked isotope effect in the decomposition of CD_3NO_2 is observed at a pressure of 10 kbar.[68]

The formal kinetic characteristics have been determined for liquid nitromethane and an expression has been obtained for its rate of decomposition with the maximum filling of the vessel by the test substance:

$$\frac{d\eta}{dt} = 10^{12.42}\exp\left(-\frac{173900}{RT}\right)(1-\eta) + 10^{3.64}\exp\left(-\frac{62850}{RT}\right)(1-\eta)\eta^2.$$

An even lower activation energy (136 kJ mol^{-1}) has been observed for the first-order decomposition reaction of nitromethane in the liquid phase at pressures of 40–50 kbar and temperatures of the order of 140 °C.[70] It was noted in the above study that the decomposition of nitromethane obeys a second-order equation at low pressures and temperatures below 120 °C.

In order to explain the decrease in the activation energy for the decomposition of nitromethane in the liquid state compared with the gas phase, a bimolecular decomposition mechanism, justified by quantum-chemical calculations, has been proposed.[69,70]

$$2\,CH_3NO_2 \longrightarrow (CH_3NO_2)_2 \longrightarrow TS \longrightarrow CH_3NO + HOCH_2NO_2$$

The enthalpies of formation of the dimer and the transition state (TS) proved to be −88.4 and 89.7 kJ mol^{-1} respectively.[69] Thus the calculated activation energy (178 kJ mol^{-1}) agreed with the experimental value. However, it is possible that this is merely fortuitous. The decrease in the activation energy in the liquid phase can be explained also by the decomposition of nitromethane via the aci-form and autoprotolysis and not via the transfer of oxygen. We may note that the calculation carried out by Khrapkovskii et al.[69] refers to free molecules and in no way takes into account the specific features of the condensed state. On the other hand, in the gas phase there is no bimolecular interaction. The question of the mechanism of the decomposition of nitromethane can apparently be elucidated, as pointed out by Khrapkovskii et al.,[69] by a detailed study of the kinetics of the decomposition of nitromethane in solutions. In order to identify the reactions involving the isomerisation of nitroalkanes, it is desirable to have information about the reactions of nitronic acids. Unfortunately, the kinetics and mechanisms of these reactions have not so far been investigated. These substances are known to be unstable.[71,72] On the basis of quantum-chemical estimates, the elimination of water has been suggested[7] for nitroalkanes having two hydrogen atoms in the α-position.

$$H_2C(NO_2)_2 \longrightarrow H(NO_2)C{=}NOOH \longrightarrow H_2O + O_2NC{\equiv}N^{+}{\rightarrow}O^{-}$$

$$CH_3NO_2 \longrightarrow H_2C{=}NOOH \longrightarrow H_2O + HC{\equiv}N^{+}{\rightarrow}O^{-}$$

The conversion of nitronic acids of the type $ArCH=NOOH$ into ArCHO and $ArCH=NOH$ has been postulated.[73]

The decomposition of nitromethane in the gas phase at high pressures and temperatures in the range 400–860 °C,[74] i.e. under supercritical conditions, apparently proceeds via the aci-form. For a vapour density of 0.6 g cm^{-3}, the activation volume is between −25 and −15 cm^3 mol^{-3}, i.e. has the same value as for the isomerisation reaction.

An ionic decomposition mechanism has been observed[75,76] for compounds containing the trinitromethyl group in structures of the type $ROCH_2C(NO_2)_3$. Analysis of the volumes of the evolved gas (cm^3 g^{-1}) over a period of 48 h at 100 °C, carried out by Khrapkovskii et al.,[7] showed that the stability of such compounds differs markedly from that of their $RCH_2C(NO_2)_3$ analogues.

$(NO_2)_3CCH_2CH_3$	0.5
$(NO_2)_3CCH_2OCH_2CH_3$	>25
$(CN)(NO_2)_2CCH_2OCH_3$	≫ 25
$(CN)(NO_2)_2CCH_2CH_2OAc$	>25
$(CN)(NO_2)_2CCH_2CH(OAc)_2$	≫ 25
$[(NO_2)_3CCH_2NH]_2C=O$	0.8
$[(NO_2)_3CCH(CH_3)NH]_2C=O$	>25 (5 h, 90 °C)
$(NO_2)_3CCH(OAc)CH_3$	19 (20 min, 100 °C)

The following reaction has been proposed for them:

$$(NO_2)_3CCH_2OCH_2CH_3 \longrightarrow (NO_2)_3C^- + {}^+CH_2OCH_2CH_3.$$

Branching at the β-carbon atom also stabilises the positive charge and promotes the heterolytic cleavage of the C–C bond.

It may be expected that the decomposition of polynitro-compounds having substituents separated by a large distance and not containing a α-hydrogen atom proceeds at the same rates in the liquid phase as in the vapour. Direct measurements have been made for $C(NO_2)_4$, $IC(NO_2)_3$, and $MeC(NO_2)_3$.[77] The activation energies for the decomposition reactions and their rates in the liquid and gas phases are virtually identical with the gas-phase parameters. Table 12 presents data on the decomposition of certain nitro-compounds in solutions.[78,79] The decomposition of all the compounds listed in the table with the exception of hexanitroethane hardly differs from their decomposition in the gas phase and is independent of the nature of the solvent. In the case of hexanitroethane, such a dependence is manifested. Presumably, being a strong acceptor, hexanitroethane is capable of being influenced by even weak donors owing to the formation of charge-transfer complexes.

An attempt has been made[80,81] at a direct determination by IR spectroscopy of the influence of solvation and other intermolecular interactions on the activation energies for unimolecular bond dissociation reactions. The method is based on the use of the relation

$$E = \frac{c\hbar\omega_0^2}{4(\chi_{11})},$$

where ω_0 is the bond vibration frequency and χ_{11} is the anharmonicity of the vibration in which the involvement of the bond is fairly considerable (the C–N bond stretching vibration with ω_0 = 920 cm^{-1} in nitromethane). An experiment with nitromethane yielded the following values of E: 211 kJ mol^{-1} for the liquid state, 193 kJ mol^{-1} for a solution in CCl_4, and 377 kJ mol^{-1} for the solid phase (experiments at −173 °C). This apparently requires a more rigorous justification and tests.

The influence of complex formation, the mechanism of the decomposition of nitronic acids, and kinetic study of the proposed heterolytic reactions are apparently not the only problems which must be investigated in order to understand the essential features of the liquid-phase decomposition of nitrocompounds. New aspects may appear in the study of compounds with mixed functional groups in which the di- and trinitromethyl groups are the most reactive components of the molecules. Such studies are already being carried out.[82–85] Thus processes involving the evolution of gaseous products on rapid (up to 200 K s^{-1}) heating of the compounds $(NO_2)_3CCH_2N(NO_2)CH_2C(NO_2)_3$, $[(NO_2)_3CCH_2N(NO_2)CH_2]_2$, and $Cl(NO_2)_2CCH_2N(NO_2)CH_2C(NO_2)_2Cl$ have been described.[82] There is no doubt that the decomposition of the trinitromethyl group is the primary process for the first two substances.

The introduction of nitroamino-, azide, or nitrate groups into nitroalkane molecules increases the melting points and intensifies the explosive properties of the compounds. Comparison of the kinetic characteristics of the decomposition of monofunctional compounds permits the conclusion that, in the absence of mutual influence, the trinitromethyl group always decomposes at a higher rate than reactive groups such as $-CH_2N(NO_2)CH_2-$, $-CH_2ONO_2$ and $-CH_2N_3$. On the other hand, the fluorodinitromethyl group is more stable than the above fragments. Intramolecular interactions and the solid phase may introduce significant corrections to the above prediction. In the series of nitroalkanes, the decomposition in the solid state has been investigated for only one compound — hexanitroethane,[79] which has a melting point of 135 °C and the rates of its decomposition in the solid state can be easily measured. Crystals of this substance exist in a plastic state and the crystal lattice inhibits the decomposition only slightly: the rate in the solid state is lower by a factor of 5–7 than in the vapour phase.[79] In compounds with high melting points and strong intermolecular interactions, the effect of the solid phase may be much greater[86] and the crystal lattice may exert different influences on the decomposition of different groups. In this case, polynitro-compounds of the mixed type can serve as convenient models for experimental studies.

Table 12. Characteristics of the decomposition reactions of polynitro-compounds in solutions.[78,79]

Compound	Solvent	T/ °C	E/kJ mol^{-1}	$\lg(A/s^{-1})$	ω_{rel} at 85 °C
$C(NO_2)_4$	Carbon tetrachloride	85–150	166.3	16.7	1
	Freon-114B	120–135	173.0	17.7	–
	Freon-113	100–135	166.7	16.8	–
$ClC(NO_2)_3$	Carbon tetrachloride	85–146	159.9	16.5	8.5
$BrC(NO_2)_3$	"	85–131	155.9	16.6	17
$ClC(NO_2)_2C(NO_2)_2Cl$	Freon-113	45–85	129.9	16.6	1.8×10^6
$C(NO_2)_3C(NO_2)_3$	Carbon tetrachloride	70–120	158.3	18.6	860
	Heptane	70–120	119.3	13.0	3296
	Cyclohexane	70–120	88.0	9.1	6593

Sulfides: synthesis and properties

I V Koval'

Contents

I. Introduction	323
II. The structure and physicochemical properties of sulfides	323
III. Methods of synthesis of sulfides	324
IV. Reactions of sulfides	332

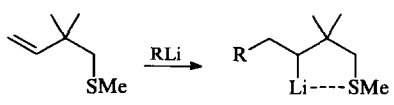
Abstract. The review gives a systematic account and surveys the results of recent studies of the chemistry of sulfides. The structure and physicochemical properties of sulfides, the methods for their synthesis, as well as their reactions are considered. The bibliography includes 211 references.

I. Introduction

Sulfides constitute one of the simplest classes of organosulfur compounds, which play an extremely important role in organic synthesis. This is due primarily to the presence of the sulfur atom — an active reaction centre with variable valence, the relatively high lability of the C–S bond which may be cleaved by nucleophiles and electrophiles, and also the tendency of sulfur to stabilise the α-carbanionic centre. Together with extensive synthetic possibilities, certain sulfides possess valuable practical properties, which has also aroused an increased interest in the chemistry of sulfides. They have found extensive applications as polymer stabilisers,[1,2] vulcanising agents,[3] pharmaceutical preparations,[4] and biologically active substances.[5] The importance of sulfides in biochemical processes, especially in the metabolism of lipids, is great.[6] In the conversion of the aliphatic acids of lipids into 2-carbon fragments, a key role is assumed by coenzyme A (Co-A), which forms a thioester bond with the aliphatic acid molecule.

Two excellent reviews,[7,8] covering the literature up to 1978, have been devoted to the chemistry of sulfides. However, many new data, which need to be surveyed, have accumulated since the time of their publication. This is in fact the topic of the present review.

II. The structure and physicochemical properties of sulfides

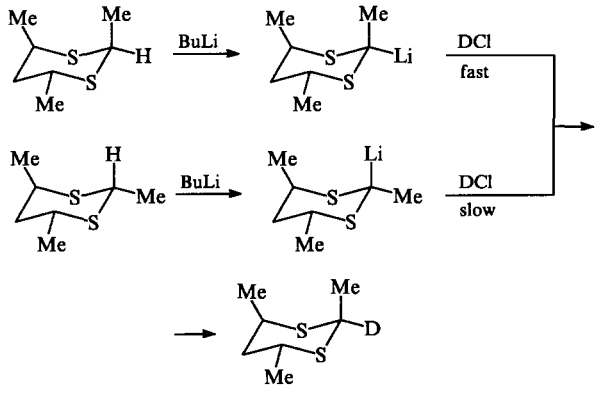


The structure of the groups attached to the sulfur atom exerts a strong influence on the C–S–C bond angle, the C–S bond length, and the dissociation energy of the latter (E_d), which varies over a relatively wide range:[9]

Sulfide	E_d/kcal mol^{-1}
MeS–Me	77.0 ± 1.5
MeS–Et	74.0 ± 1.5
MeS–CH_2Ph	59.4 ± 2.0
PhS–Me	67.4 ± 1.5
AlkS–Bu	71.0 ± 1.5
MeS–Ph	89.2 ± 2.0
MeS–CN	97.0 ± 1.5

The length of the C–S bond in sulfides varies in the range 175–180 pm depending on the structure of the group attached to the sulfur atom, while the C–S–C bond angle is 98.9° for dimethyl sulfide and 105.6° for hexafluorodimethyl sulfide.[7] The enthalpy of the C–S bond is 69 kcal mol^{-1}.[9]

Sulfides are 10^{14}–10^{17} times weaker bases than thiolate anions.[7] In contrast to their oxygen analogues, sulfides show a considerable tendency to generate α-carbanions and α-radicals, which has been explained by the increased stabilisation of these species by $p_\pi - d_\pi$ conjugation[7] or by the greater polarisability of sulfur compared with oxygen.[10,11] α-Carbonium ions based on sulfides are less stable than those based on the oxygen analogues. It has been suggested[10,11] that the stabilisation of the carbonium ions is due to the p,π conjugation and, since this stabilisation is directly proportional to the distance separating the two nuclei, the alkoxycarbonium ion is stabilised to a greater extent than the alkylthiocarbonium ion.

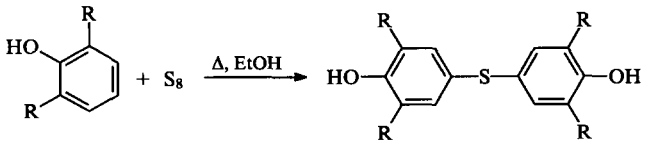


Aliphatic sulfides are very active photoexcitation 'quenching agents'. For example, 1 mol of dibutyl sulfide can prevent the photochemical reduction of 23 mol of benzophenone by alcohols, which has been explained[8] by the formation of the complex $Ph_2CO^{\bullet-}\cdots{}^{+}SBu_2$. According to ^{1}H NMR spectroscopic data obtained using shift reagents,[12] sulfides form unstable complexes with Eu(fod)$_3$. Macrocyclic sulfides are much stronger complex-forming agents for silver ions than macrocyclic ethers but are weaker for alkali metal ions, which is apparently associated with the greater size and lower electronegativity of the sulfur atom compared with oxygen. It has been noted that the addition of organolithium compounds to a nonconjugated carbon–carbon bond becomes possible by virtue of the formation of an alkali metal complex with participation of the sulfur atom.[12]

I V Koval' Department of the Chemical Technology of Macromolecular Compounds, Ukrainian Chemical-Technological University, Prosp. Gagarina 8, 320005 Dnepropetrovsk, Ukraine, Fax (7-056) 247 33 16

Received 20 July 1994
Uspekhi Khimii **63** (4) 338 – 360; translated by A K Grzybowski

1,3-Dithianes assume the twisted boat (twist) conformation more readily than the corresponding O- or C-analogues because nonbonding interactions are weakened in the larger 1,3-dithiane ring, while the torsional barriers are reduced for the C–S bonds compared with those for the C–O and C–C bonds. The twist-form of 3,3,6,6-tetramethyl-1,2,4,5-tetrathiane is actually more stable by 2.1–2.5 kJ mol^{-1} than the chair form. The equilibrium isomerisation of 2-substituted 1,3-dithianes on treatment with butyllithium leads to the formation mainly of isomers with an axial disposition of the substituents. Although such disposition is sterically unfavourable, it occurs even for 2-butyl-1,3-dithiane because lithium tends to occupy the equatorial position.[8] As a consequence of the above feature, there is a possibility of the stereospecific deuteriation of 2,4,6-trimethyl-1,3-dithiane.



The absorption bands in the UV spectra of alkyl sulfides lie in the region of 200, 220, and 240 nm,[13] while those in the spectra of alkyl aryl sulfides are in the region of 205–230, 235–270, and 275–300 nm.[14] The positions of the absorption bands depend significantly on the structure of the substituents at the sulfur atom and on the nature of the solvent. The long-wavelength absorption is usually very weak and is not characteristic of sulfides. The chemical shift (δ) of the protons in the CH_3S group is in the region of 2 ppm.[15] The mass spectra of alkyl sulfides[16] are characterised by fairly intense peaks due to molecular ions, the intensity of which diminishes with increase in the number of carbon atoms in the molecule and as the sulfur atom moves to one of the ends of the chain. Two types of fragment ions are mainly present: the sulfur-containing ions $[C_nH_{2n+1}S]^+$, $[C_nH_{2n}S]^{\cdot+}$, and $[C_nH_{2n-1}S]^+$ and the hydrocarbon ions $[C_nH_{2n+1}]^+$, $[C_nH_{2n}]^{\cdot+}$, and $[C_nH_{2n-1}]^+$. The main components of the chemical ionisation mass spectra of sulfides[17,18] are the quasi-molecular ions $[M-1]^-$. According to Tokarev et al.,[19] the relative ionisation cross-section of diethyl sulfide is 0.23 (reagent gas—isobutane, 14 Pa, 150 °C).

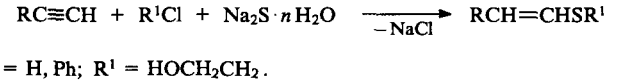
III. Methods of synthesis of sulfides

1. Syntheses based on elemental sulfur and its inorganic derivatives

Elemental sulfur is fairly rarely used in the synthesis of sulfides, which is due to the need for its activation or the application of highly reactive aromatic compounds, for example compounds such as dialkylphenols.[16]

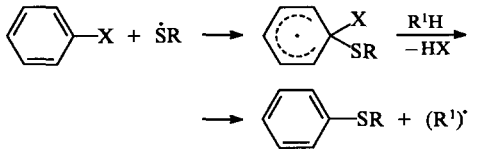
R = Me, Et, Bu^t.

Under chemical activation conditions (a superbasic medium), sulfur reacts with acetylene and its derivatives to form divinyl sulfide.[20]



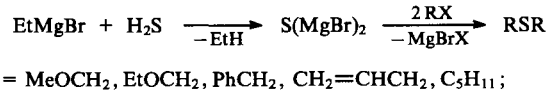
Unsaturated sulfides are also formed on interaction of unsaturated ethers with organomagnesium compounds and sulfur in the presence of palladium complexes.[21] Under electrochemical activation conditions (decomposing sulfur electrode), elemental sulfur reacts with aromatic ethers, amines, and phenols as well as certain heterocyclic compounds to form the corresponding sulfides.[22,23]

Inorganic sulfur derivatives, for example sodium sulfide, are used much more frequently in the synthesis of sulfides. A whole series of preparative methods for the synthesis of symmetrical sulfides have been developed on the basis of the reaction involving the alkylation and arylation of sodium sulfide by alkyl halides and activated aryl halides. As a rule, these reactions proceed in homophase systems. In the case of heterophase systems, phase transfer catalysts are employed.[24] These methods are applicable also in the synthesis of silicon-containing sulfides.[25]



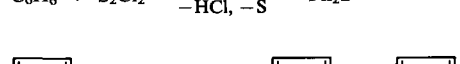
R = Me, Ph.

Another aspect of the use of sodium sulfide in the synthesis of organic sulfides involves its interaction with acetylenic hydrocarbons in the presence of halogen derivatives.[26]

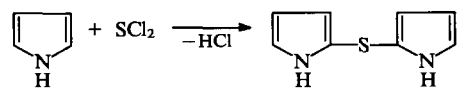


R = H, Ph; $R^1 = HOCH_2CH_2$.

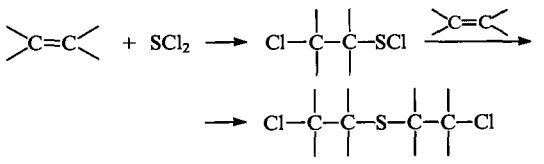
Hydrogen sulfide is much more rarely used in the synthesis of sulfides because its reactions with chloro- and bromo-substituted aromatic and heteroaromatic compounds proceed as a rule at high temperatures to form thiols and other products together with sulfides.[27–30] These reactions proceed via a radical mechanism with the formation of intermediate adduct-radicals stabilised by the π-system of the aromatic ring.[16]



R = H, Ar; X = Cl, Br.

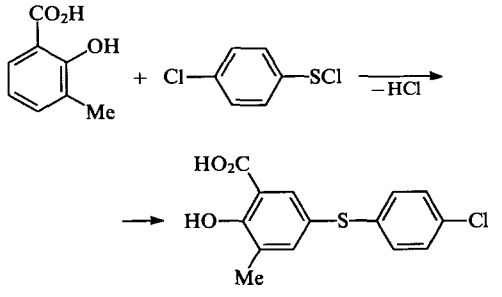


The reaction of hydrogen sulfide with ethylmagnesium bromide, affording bis(bromomagnesium) sulfide, which readily interacts with electrophiles to form organic sulfides, is of preparative interest.[31]

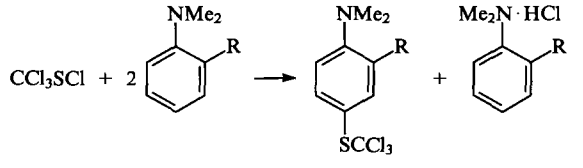


R = $MeOCH_2$, $EtOCH_2$, $PhCH_2$, $CH_2=CHCH_2$, C_5H_{11};
X = Cl, Br.

Among inorganic sulfur derivatives, sulfur monochloride and dichloride are also used in the synthesis of sulfides. The sulfenylation of aromatic and heterocyclic hydrocarbons by these reagents constitutes the basis of a preparative method for the synthesis of symmetrical sulfides.[8]

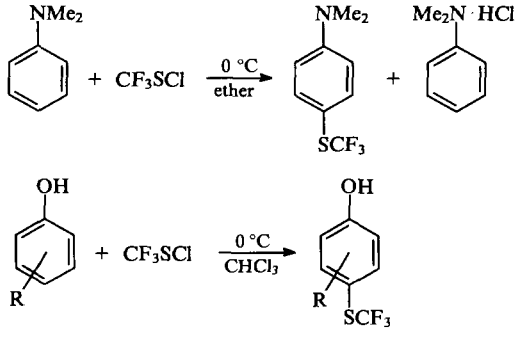


The addition of sulfur dichloride to ethylenic hydrocarbons leads to bis(β-chloroalkyl) sulfides.[16]



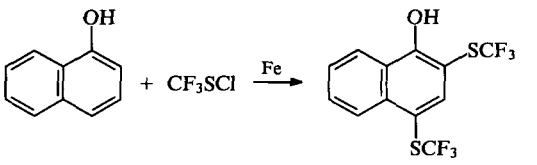
2. Syntheses based on sulfenyl halides

a. Sulfenylation of aromatic and heterocyclic compounds by sulfenyl chlorides

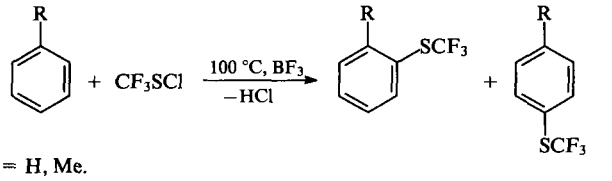


Sulfenyl chlorides react with aromatic hydrocarbons via the S_E2 electrophilic substitution mechanism to form both symmetrical and asymmetric sulfides. Aromatic sulfenyl chlorides react with benzene and its homologues only in the presence of catalysts ($AlCl_3$, $FeCl_3$, Fe, etc.). Sulfenyl chlorides react relatively easily with benzene and naphthalene derivatives containing strong electron-donating substituents (NMe_2, OH, OMe etc.). For example, *p*-chlorobenzenesulfenyl chloride reacts with 6-methylsalicylic acid in the absence of a catalyst to form the corresponding sulfide.[32]

Trichloromethanesulfenyl chloride reacts relatively easily with dimethylaniline and its derivatives, forming the corresponding aryl trichloromethyl sulfides.[33]

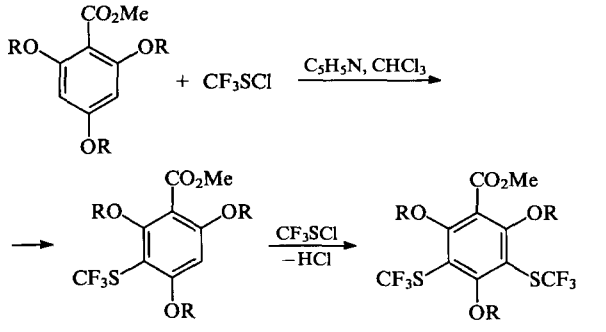


Trifluoromethanesulfenyl chloride reacts with dimethylaniline[4] and with phenol and its homologues[34] even at 0 °C. Under these conditions, the trifluoromethylthio-group adds in the *ortho*- and *para*-positions relative to the substituent.

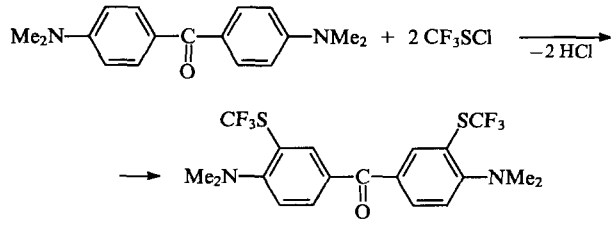


R = H, 2-Me, 3-Me, 2-OH.

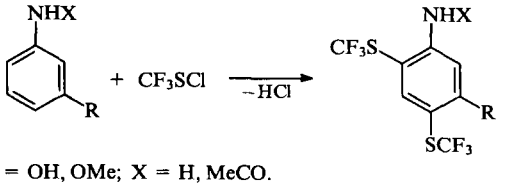
The reaction of trifluoromethanesulfenyl chloride with α-naphthol affords 2,4-bis(trifluoromethylthio)naphthol.[35]



Trifluoromethanesulfenyl chloride reacts with benzene and toluene in the presence of BF_3 at 100 °C in an autoclave, forming phenyl trifluoromethyl sulfide or a mixture of 2- and 4-tolyl trifluoromethyl sulfides.[4,33]

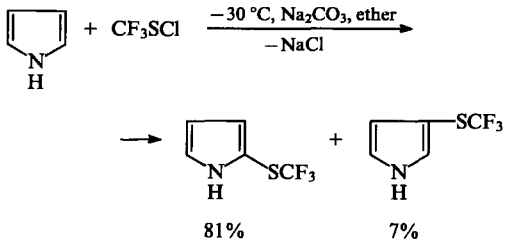


R = H, Me.

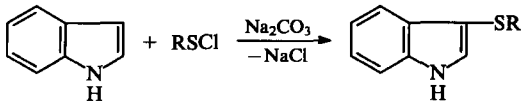


Trifluoromethanesulfonic acid is a more effective catalyst of the trifluoromethanesulfenylation of benzene. Its employment makes it possible to reduce the temperature of the above reaction to 20 °C.[36] The introduction of a second trifluoromethylthio-group into the benzene ring is difficult even in the presence of trifluoromethanesulfonic acid. Trifluoromethanesulfenyl chloride reacts with chlorobenzene under severe conditions in the presence of HF, forming two isomers—*p*- and *o*-chlorophenyl trifluoromethyl sulfides.[36] If there are electron-donating groups (OH, OMe, NMe_2) in the aromatic ring together with electron-accepting groups (MeCO, PhCO, MeOCO, CHO), then one, two, and even three trifluoromethylthio-groups enter into the reaction depending on the conditions.[4,37]

R = H, Me.

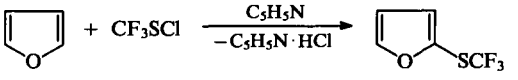


Derivatives of aniline and acetanilide containing the electron-donating OH or OMe groups in the *meta*-position also react readily with trifluoromethanesulfenyl chloride to form bis(trifluoromethylthio)-derivatives.[34]



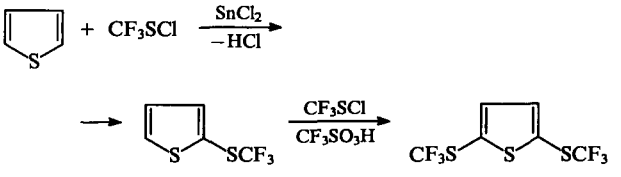
R = OH, OMe; X = H, MeCO.

Similar rules have been established for the interaction of sulfenyl chlorides with cyclic compounds.[4] The presence in the latter of a high π-electron density promotes this reaction. For example, pyrrole reacts with trifluoromethanesulfenyl chloride even at −30 °C, forming 2-trifluoromethylthiopyrrole and a small amount of 3-trifluoromethylthiopyrrole.[37–39]



81% 7%

In the presence of catalytic amounts of a perfluoroalkanesulfonic acid, two, three, and even four trifluoromethylthio-groups may be introduced into the pyrrole ring.[38] In indole, the substitution of a hydrogen atom by the sulfenyl group takes place in the 3-position.[37, 40]



R = CF_3, 2(3,4)-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$.

2-Trifluoromethylthiofuran is the product of the reaction of furan with trifluoromethanesulfenyl chloride in the presence of pyridine.[39]

Trifluoromethanesulfenyl chloride reacts with thiophene, giving rise to 2-(trifluoromethylthio)thiophene or 2,5-bis(trifluoromethylthio)thiophene depending upon which catalyst is employed.[36, 39, 41]

b. Sulfenylation of C-nucleophiles

Sulfenyl chlorides react vigorously with organomagnesium compounds via the nucleophilic substitution mechanism, forming sulfides.[33]

$$RSCl + R^1MgX \longrightarrow RSR^1 + MgXCl$$

R = CCl_3, CF_3; R^1 = Et, Ph, 3(4)-MeC_6H_4;
X = Cl, Br.

Under these conditions, a small amount (up to 15%) of halohydrocarbons is formed as a rule, which hinders the isolation of the sulfides obtained. Organomercury compounds react with sulfenyl chlorides similarly to organomagnesium compounds.[42] The substitution of the chlorine atom at the sulfur atom by a hydrocarbon group is then accompanied by the simultaneous replacement of the HgCl fragment by chlorine and also by demercuration.

$$RSCl + p\text{-}R^1C_6H_4HgCl \longrightarrow RSC_6H_4R^1\text{-}p + p\text{-}R^1C_6H_4Cl + PhR^1$$

R = CF_3; R^1 = H, Me, MeO, Cl, NO_2.

Electron-accepting groups promote the formation of sulfides, whereas electron-donating groups promote the formation of halo-derivatives. A method of synthesis of sulfides involving the interaction of arenesulfenyl chlorides with perfluoro-*tert*-butylcaesium in acetonitrile or diglyme,[43, 44] and also its interaction with perfluoromethyl(trimethyl)silane in tetrahydrofuran,[45] has been described in the literature. The yield of the sulfides is 75%–85%.

$$RC_6H_4SCl + (CF_3)_3CCs \xrightarrow[-CsCl]{} RC_6H_4SC(CF_3)_3$$

R = H, 3(4)-F, 4-Cl, 2(3,4)-NO_2, 3(4)-COOMe.

$$RC_6H_4SCl + Me_3SiCF_3 \longrightarrow RC_6H_4SCF_3 + Me_3SiCl$$

R = 4-Cl, 4-NO_2.

Treatment of copper acetylide with arenesulfenyl chlorides leads to the formation of alkynyl aryl sulfides.[8]

$$RC{\equiv}CCu + ArSCl \longrightarrow RC{\equiv}CSAr$$

R = H, Me; Ar = Ph, *p*-MeC_6H_4.

A whole series of methods of synthesis of sulfides are based on the sulfenylation of CH acids by sulfenyl chlorides and other sulfenylating agents. The choice of the reaction conditions is dictated both by the nature of the CH acid and that of the sulfenyl chloride. For example, the sulfenylation of nitromethane by trichloromethanesulfenyl chloride is carried out at 0 °C in an aqueous alkaline medium.[33]

$$CCl_3SCl + CH_3NO_2 \xrightarrow[-NaCl]{0\ ^\circ C,\ NaOH} CCl_3SCH_2NO_2$$

Nitromethane reacts with benzenesulfenyl chloride[46] in absolute alcohol in the presence of sodium ethoxide, while its reaction with *o*-nitrobenzenesulfenyl chloride takes place in anhydrous benzene in the presence of triethylamine and affords the corresponding sulfides. Diacetyl- and dibenzoyl-methanes and acetoacetic and malonic acid esters interact with arenesulfenyl chloride in anhydrous benzene in the absence of bases,[47–49] whereas diphenylmethane[50] and dicyanomethane[51] require the use of triethylamine.

$$ArSCl + CH_2XY \xrightarrow[-HCl]{} ArSCH(X)Y$$

Ar = Ph, 4-MeC_6H_4, 2(4)-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$;
X = Y = Ph, MeCO, PhCO, EtOCO, CN;
X = MeCO, Y = EtOCO;
X = H, Y = NO_2;
X = NO_2, Y = 2-$NO_2C_6H_4$.

The sulfenylation of tris(trifluoromethyl)methane by benzenesulfenyl chloride also takes place in the presence of triethylamine.[52]

$$PhSCl + HC(CF_3)_3 \xrightarrow[-Et_3N\cdot HCl]{Et_3N} PhSC(CF_3)_3$$

The trifluoromethanesulfenylation of the CH acids RCX.CH_2R^1 (X = O, NH; R = Ph, Me; R^1 = $CONH_2$, CN, C(S)NH.C_6H_4Br-*p*) is carried out in anhydrous chloroform at 0–20 °C with the use of bases.[53]

Numerous studies have been devoted to the sulfenylation of phosphorus-containing CH acids and their anions, studies that are associated with the search for new biologically active preparations.[54] For example, a study has been made[55] of the interaction of perhalomethanesulfenyl chlorides with the anions of tetraalkyl methylphosphonates, generated by treating tetraalkyl methylphosphonates with butyllithium, sodium hydride, or metallic sodium. The formation of sulfenylation and chlorination products was established. In the case of dichlorofluoro- and chlorodifluoromethanesulfenyl chlorides, sulfenylation products were obtained under these conditions, in which the trihalomethanesulfenyl groups are enriched in fluorine compared with those in the initial sulfenyl chlorides.

$$[(RO)_2P(O)]_2CHM + CCl_{3-n}F_nSCl \xrightarrow{AlCl_3}$$
$$\longrightarrow [(RO)_2P(O)]_2CHSCCl_{3-n}F_n + [(RO)_2P(O)]_2CHCl +$$
$$+ [(RO)_2P(O)]_2CHSCCl_{2-n}F_{n+1} + [(RO)_2P(O)]_2CHSCF_3$$

R = Pr^i; M = Li, Na.

It is believed[55] that the products with a fluorine-enriched trihalomethanesulfenyl group are formed as a result of the substitution of chlorine atoms by fluorine in the initial sulfenyl chloride and not in the sulfenylation products. The fluoride anion, appearing on decomposition of the trihalomethylthio-anion, which is a side product in the chlorination of tetraalkyl methylenediphosphonate, acts as the fluorinating agent under these conditions.

$$[(RO)_2P(O)]_2CHM + CCl_{3-n}F_nSCl \longrightarrow$$
$$\longrightarrow [(RO)_2P(O)]_2CHCl + CCl_{3-n}F_nS^-$$
$$CCl_{3-n}F_nS^- \longrightarrow Cl_{3-n}F_{n-1}C{=}S + F^- + M^+$$
$$CCl_{3-n}F_nSCl + F^- \longrightarrow CCl_{2-n}F_{n+1}SCl + Cl^-$$

The fraction of the chlorination products increases in the following sequence: $CF_3SCl < CF_2ClSCl < CFCl_2SCl$. This has been explained[54,55] by the increase in the same sequence in the steric hindrance to nucleophilic attack on the sulfur atom by the carbanion. It has been noted[56] that, when benzenesulfenyl chloride is added to an excess of sodium diethyl cyanomethylphosphonate, the corresponding sulfide is formed almost exclusively.

$$(EtO)_2P(O)\underset{CN}{\underset{|}{C}}HNa + ClSPh \xrightarrow{-NaCl} (EtO)_2P(O)\underset{CN}{\underset{|}{C}}H{-}SPh$$

The similar interaction of α-substituted ethylphosphonic acid esters with benzenesulfenyl chloride leads to the corresponding sulfides in an almost quantitative yield.[57]

$$(EtO)_2P(O)\underset{R}{\underset{|}{C}}HMe + ClSPh \xrightarrow[-NaCl]{NaH} (EtO)_2P(O)\underset{R}{\overset{Me}{\overset{|}{\underset{|}{C}}}}{-}SPh$$

R = CN, COOEt.

The reaction of triisopropyl phosphonoacetate with benzenesulfenyl chloride in the presence of aluminium isopropoxide[58] leads to the substitution of one or two hydrogen atoms by the phenylthio-group depending on the reactant ratio.

$$(Pr^iO)_2P(O)CH_2COOPr^i \xrightarrow{Al(OPr^i)_3}$$
$$\xrightarrow{PhSCl} (Pr^iO)_2P(O)CH(SPh)COOPr^i$$
$$\xrightarrow{2\,PhSCl} (Pr^iO)_2P(O)C(SPh)_2COOPr^i$$

The reaction of the chloride of diethoxyphosphorylacetic acid with benzenesulfenyl chloride takes place without a solvent. After treatment with water or methanol, the product is converted into α-diethoxyphosphoryl-α-phenylthioacetic acid or its ethyl ester (in 50% yield).[59]

$$(EtO)_2P(O)CH_2COCl + PhSCl \xrightarrow{H_2O} (EtO)_2P(O)\underset{COOH}{\underset{|}{C}}HSPh$$
$$\xrightarrow{MeOH} (EtO)_2P(O)\underset{COOMe}{\underset{|}{C}}HSPh$$

Phosphorus ylides readily exchange the hydrogen atom of the methylene group for an alkylthio- or arylthio-group.[60]

$$Ph_3P{=}CHR + R^1SCl \xrightarrow[-HCl]{} Ph_3P{=}\underset{R}{\underset{|}{C}}{-}SR^1$$

R = Me, EtOCO, CN, PhCO; R^1 = Alk, Ar.

Depending on the reactant ratio, it is possible to substitute one or two hydrogen atoms by the phenylthio-group in methylenetriphenylphosphorane.[60]

$$Ph_3P{=}CH_2 \xrightarrow{PhSCl} Ph_3P{=}CHSPh + HCl$$
$$\xrightarrow{2\,PhSCl} Ph_3P{=}C(SPh)_2 + 2\,HCl$$

Together with sulfenyl chlorides, other sulfenylating agents are also used in the reactions with C-nucleophiles. For example, aryl thiocyanates have been employed successfully for the sulfenylation of perfluorocarbanions[61] and organomagnesium compounds.[61,62] The yields of sulfides are then 50%–55%.

$$XC_6H_4SCN \xrightarrow[-KCN]{(CF_3)_2CFK} XC_6H_4SCF(CF_3)_2$$
$$\xrightarrow[-Mg(CN)I]{BuMgI} XC_6H_4SBu$$

X = H, 4-NO_2, 4-Cl.

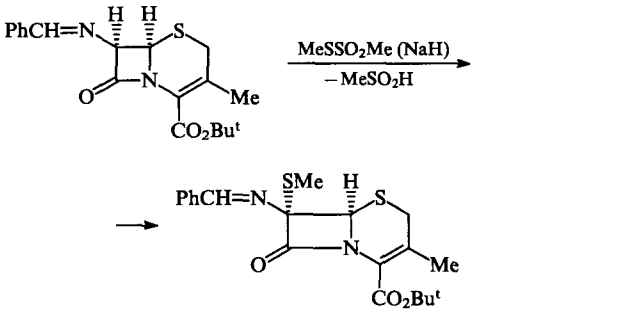
Two versions of the synthesis of alkyl trichloromethyl sulfides from alkyl thiocyanates have been developed. The first involves the interaction of alkyl thiocyanates with chloroform under the conditions of phase transfer catalysis.[63]

$$RSCN + CHCl_3 \xrightarrow[-HCN]{} RSCCl_3$$

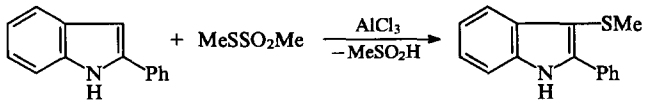
R = Me, Et.

The second version involves the interaction of alkyl thiocyanates with perchlorocarbanions obtained from perhalomethanes by treatment with KOH in the presence of phase transfer catalysts such as, for example, tetrabutylammonium bromide.[64]

$$CCl_3X + OH^- \underset{}{\overset{Bu_4NBr}{\rightleftharpoons}} \bar{C}Cl_3 \xrightarrow{MeSCN} MeSCCl_3$$

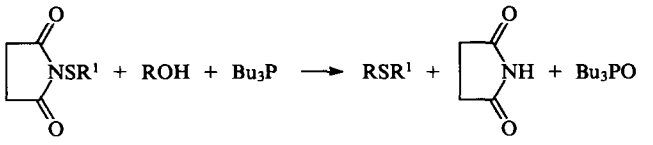


X = Cl, Br.



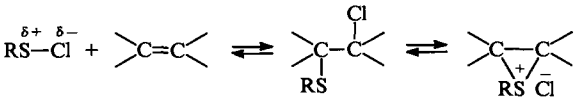
It has been noted[65] that in the presence of bases certain CH acids are sulfenylated by the RSH–CCl_4 system.

$$RSH + Na\underset{Y}{\underset{|}{\overset{X}{\overset{|}{C}}}}R^1 \xrightarrow[-CHCl_3]{CCl_4} RS\underset{Y}{\underset{|}{\overset{X}{\overset{|}{C}}}}R^1 + NaCl$$

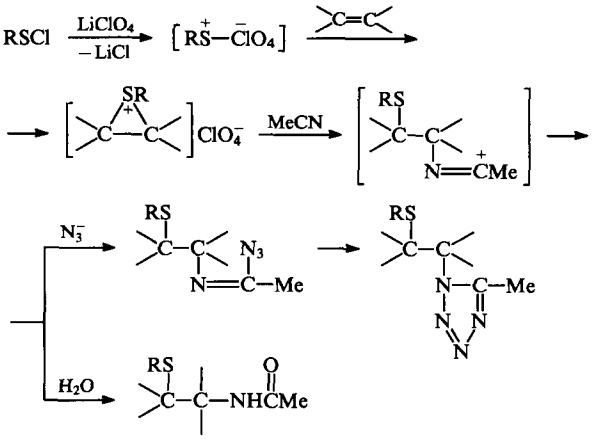


R = Alk, Ar; R^1 = H, Alk, Ar; X = Y = COMe, COOEt.

The use of thiolo-esters of sulfonic acids [66] and sulfenamides [67] as sulfenylating agents for CH acids has not come to be widely employed in the synthesis of sulfides owing to the formation of side products which hinder the isolation of the sulfides. However, in rare instances these compounds are nevertheless used as mild sulfenylating agents. For example, the methyl thiolo-ester of methanethiosulfonic acid is used to introduce the methylthio-group into certain derivatives of cephalosporin and indole. [8]

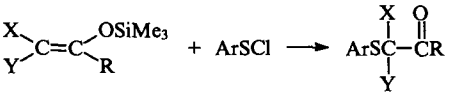


Certain sulfenamides form sulfides on interaction with alcohols in the presence of trialkylphosphines. [8]

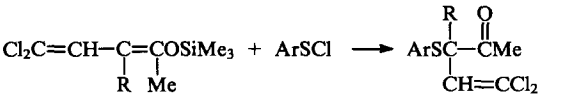


c. Addition of sulfenyl chlorides to the C = C bond

Sulfenyl chloride adds smoothly to alkenes with formation of β-chlorosulfides, [7,68,69] which are the starting materials for the synthesis of saturated and unsaturated sulfides. [69] It has been suggested that this reaction proceeds via an Ad_E2 mechanism, in which the cationic intermediate is an episulfonium ion, and leads as a rule to stereospecific *trans*-addition.

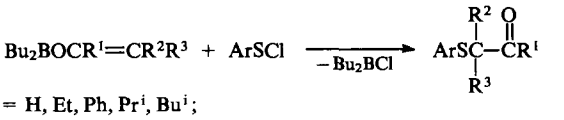


Sulfenyl chlorides are relatively weak electrophiles and the intermediate episulfonium cation has a small positive charge, which does not allow it to react with weak nucleophiles. A method developed by Zefirov and coworkers, [70,71] involving the coupled addition of sulfenyl chlorides to a double bond in the presence of a strong electrophile, for example lithium perchlorate, which increases the effective electrophilicity of sulfenyl chlorides ('doping process'), is therefore of interest. The episulfonium cation formed in this process reacts even with a weak nucleophile such as acetonitrile, affording an immonium ion, which is converted into the final products on treatment with various reagents.

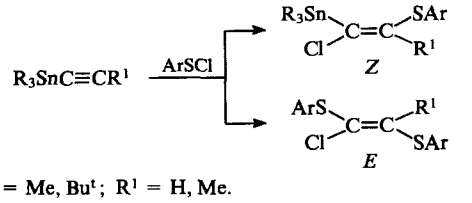


This reaction has been investigated for cyclohexene, norbornene, hept-1-ene and other olefins.

A novel method has been developed for the synthesis of aryl β-oxoalkyl sulfides involving the interaction of vinyloxysilanes [72–74] and divinyloxysilanes [75] with arenesulfenyl chlorides. The reaction proceeds via stages involving the 1,2-addition of ArSCl and the elimination of chlorotrimethylsilane. [74]



X = H, Cl, Br; Y = Cl; R = H, Bu^t, Ph, 4-ClC$_6$H$_4$, 4-BrC$_6$H$_4$;
Ar = 4-MeC$_6$H$_4$, 4-ClC$_6$H$_4$, 4-NO$_2$C$_6$H$_4$.



R = H, Ac, COOEt;
Ar = 4-MeC$_6$H$_4$, 4-ClC$_6$H$_4$.

Arenesulfenyl chlorides react similarly with the enols of dibutyl borinates. [76]

R^1 = H, Et, Ph, Pr^i, Bu^i;
R^2 = H, Me, Et, Pr; R^3 = H, Me, Ph;
R^3 = H, Me, Ph; Ar = Ph.

Arenesulfenyl chlorides react with trialkylstannylacetylenes to form either the products of addition to the triple bond or the products of their subsequent arylthiodestannylation—(*E*)-1,2-bis(arylthio)chloroethylenes. [77] The addition reaction takes place stereospecifically and regioselectively regardless of the structure of the alkyl groups at the tin atom.

R = Me, Bu^t; R^1 = H, Me.

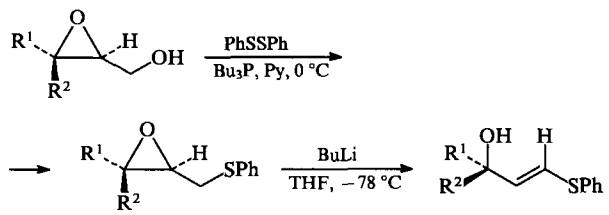
3. Syntheses of sulfides from thiols

The syntheses of sulfides from thiols have been described in detail in a previously published review by the author [78] and in the literature quoted therein and they will not therefore be considered here.

4. Syntheses from disulfides

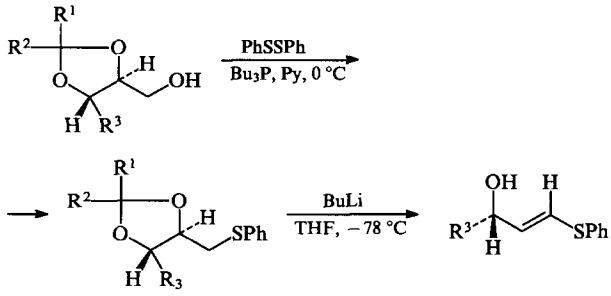
a. Cleavage of disulfides

The cleavage of disulfides by nucleophiles has not so far been used widely in the syntheses of sulfides owing to the formation of a series of side products. Nevertheless, some of these methods can be recommended for preparative purposes. For example, disulfides are frequently cleaved in the presence of NaCN in order to synthesise cyanoaryl sulfides.[7]



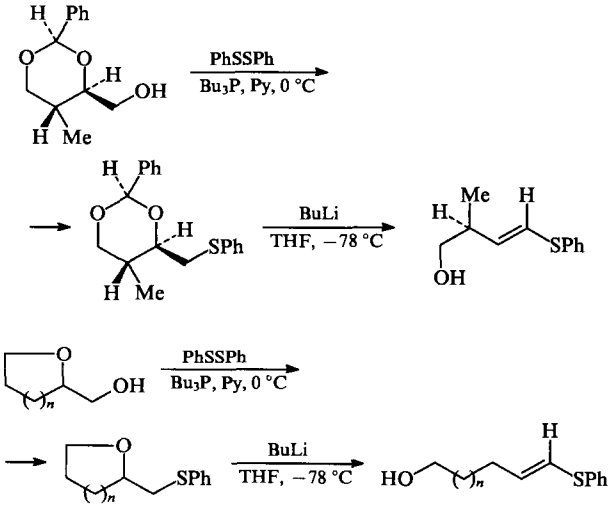
$$ArSSAr + NaCN \xrightarrow{\Delta} ArSCN + ArSNa$$

In the presence of alcohols, such cleavage is accompanied by the formation of sulfides containing alkoxy- and imino-groups.[8]



$$ArSSAr + ROH + \bar{C}N \longrightarrow ArSC(=NH)OR$$

Ar = Ph, *p*-MeC_6H_4; R = Me, Et.



The cleavage of diphenyl disulfide by tributylphosphine and the addition of the PhS radical to oxacyclic alcohols are used in the synthesis of ω-hydroxyalk-1-enyl phenyl sulfides.[79]

$R^1 = CH_2{=}CH(CH_2)_3$; R^2 = H;
R^1 = Ph, R^2 = H.

$R^1 = R^2$ = Me, R^3 = $BuOCH_2$;
$R^1 = R^2$ = Ph, R^3 = $BuOCH_2$;
$R^1 = R^2$ = Me, R^3 = $Me(CH_2)_4$.

n = 1, 2.

An oxidative decarboxylation method has been developed in recent years on the basis of the cleavage of dialkyl disulfides in the presence of sodium hydride in dimethyl sulfoxide (DMSO) or tetrahydrofuran (THF). It involves the replacement of a carboxy- or ester-group by an alkylthio-group.[80,81]

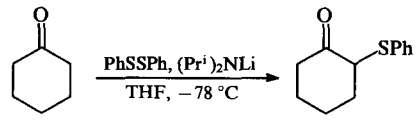
$$XCH_2COOR \xrightarrow[NaH,\ DMSO\ (THF)]{MeSSMe} XCH_2SMe$$

X = $(EtO)_2PO$, $PhSO_2$;
R = H, Et.

b. Interaction of disulfides with organometallic compounds

The interaction of disulfides with organomagnesium compounds leads to the formation of mixtures of sulfides and thiols, which is sometimes used in the synthesis of sulfides.[7]

$$RSSR + R^1MgX \longrightarrow RSMgX + R^1SR$$



R = R^1 = Et, Ph.

Disulfides react similarly with organolithium compounds.[7,82]

$$RSSR + R^1Li \longrightarrow RSR^1 + RSLi$$

R = Me, Et, C_6H_{11}, $PhCH_2$;
R^1 = HC ≡C, $(EtO)_2CHC{\equiv}C$, $ClC{\equiv}C$, 2-$(Me_2NCHMe)C_6H_4$.

The reaction of disulfides with organolithium compounds constitutes the basis of one of the methods for the introduction of the sulfide group, which is used widely in multistep organic syntheses. For example, in order to introduce the phenylthio-group in the α-position in cyclic ketones, the latter are treated with lithium diisopropylamide in the presence of diphenyl disulfide in THF.[16]

c. Alkylation and arylation of disulfides

The alkylation of diphenyl disulfides with triethyloxonium tetrafluoroborate leads to a sulfonium salt, the hydrolysis of which affords a mixture of two sulfides—PhSEt (51%) and *p*-$PhSC_6H_4SEt$ (30%).[8] Disulfides are also alkylated by alkyl fluorides in the presence of SbF_5 and trifluoroiodomethane in liquid ammonia on exposure to UV light.[83]

$$XC_6H_4SSC_6H_4X + CF_3I \xrightarrow{NH_3,\ h\nu} XC_6H_4SCF_3$$

X = H, 4-Cl, 2-NO_2, 4-NO_2.

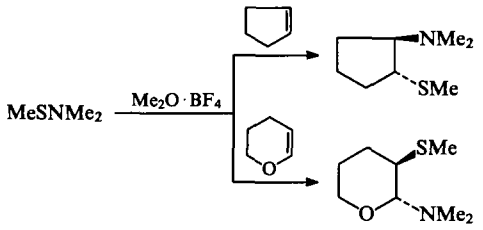
The yields of sulfides are 12% – 36% for X = H or 4-Cl and 58% and 72% respectively for X = 2-NO_2 and 4-NO_2.

Disulfides are arylated by aryl iodides in diphenyl ether at 230–270 °C.[84]

$$PhSSPh + ArI \xrightarrow{Ph_2O,\ 230-270\ ^\circ C} PhSAr$$

Ar = Ph, *p*-MeC_6H_4.

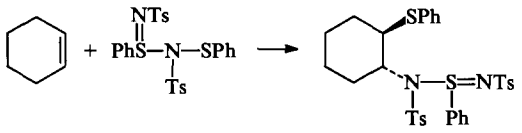
c. Desulfurisation of disulfides



The desulfurisation of certain disulfides usually proceeds on heating,[85] whereas the conversion of other disulfides into sulfides requires the use of desulfurisation reagents, for example $(Et_2N)_3P$ or $Et_4N^+F^-$.[86] In the presence of phosphines, thiolocarbonates and xanthates are also converted into sulfides.[8]

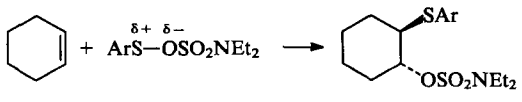
$$ArSSAr \xrightarrow[-S]{\Delta} ArSAr$$

Ar = 2,4-$(NO_2)_2C_6H_3$.

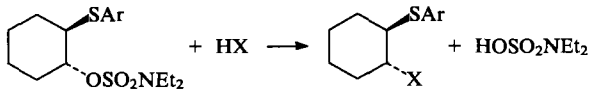


5. The syntheses from sulfenamides

The heterolytic cleavage of the S–N bond in sulfenamides in the presence of olefins is accompanied by the addition of the resulting fragments to the double bonds of the olefins with formation of aminosulfides.[87] Thus the heterolytic cleavage of the S–N bond in *N*-(dimethyl)methylsulfenamide in nitromethane in the presence of cyclopentene or 3,4-dihydro-2*H*-pyran leads to the formation of *trans*-1-dimethylamino-2-methylthiocyclopentane or *trans*-2-dimethylamino-3-methylthiotetrahydropyran.[88,89]

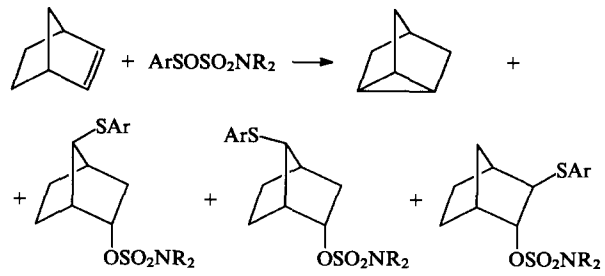


The addition of the sulfenamides $PhSNR^1R^2$ [R^1 = H, R^2 = Bu^t, $R^1+R^2 = (CH_2)_4$, $(CH_2)_2O(CH_2)_2$] to the C=C bond of cyclohexene, octene, and indene[90,91] also takes place preferentially in the *trans*-position. Strong proton-donating acids or Lewis acids are catalysts of the aminosulfenylation of olefins.

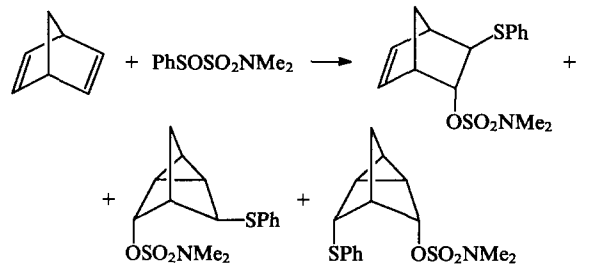


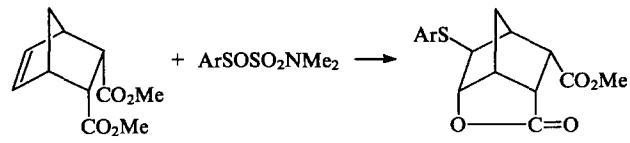
Under the conditions of acid catalysis, *N*-arenesulfenylamidines of sulfinic acids add to the C=C bonds of cyclohexene with formation of aminosulfides.[92]

The reactivity of sulfenamides in relation to olefins in the heterolytic addition reaction increases with increased electrophilicity of the sulfur atom, which can be achieved by inserting sulfur dioxide in the S–N bond of sulfenamides.[93] Using this procedure, Zefirov et al.[94] achieved for the first time the sulfamatosulfenylation of olefins, which involves the interaction of sulfenamides with sulfur dioxide in an inert solvent at a reduced temperature (–85 °C) with subsequent addition of the insertion products to the C=C bond of olefins. The reaction involving the sulfamatosulfenylation of cyclohexene is stereospecific and leads to the *trans*-1,2-adduct, which is converted into the corresponding sulfides on treatment with inorganic and organic acids.[94]



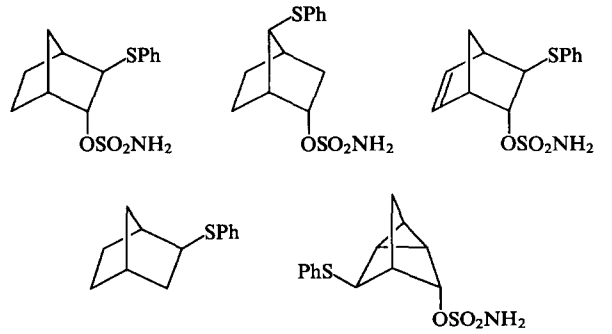
$$ArSNEt_2 + SO_3 \xrightarrow{-85\ ^\circ C,\ CH_2Cl_2} ArSOSO_2NEt_2$$

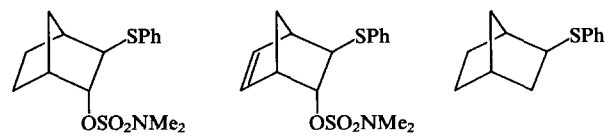




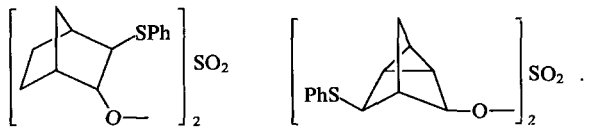
X = Br, MeCOO, CF_3COO, HCOO.

The sulfamatosulfenylation of norbornene and norbornadiene[95] is accompanied by a rearrangement of the carbon skeleton, which ultimately leads to a mixture of several products.





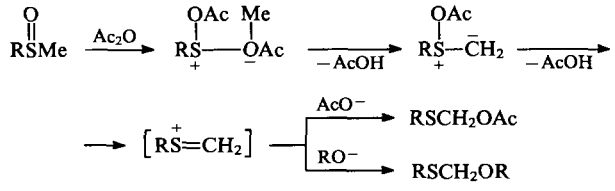
In the sulfamatosulfenylation of dimethyl *endo-cis*-bicyclo[2.2.1]hept-2-ene-5,6-dicarboxylate, the adducts cyclise with formation of arylthiolactones.[95]



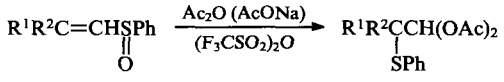
The addition of *N,N*-dimethylbenzenesulfinamide to the olefins RCH = CH_2 (R = H, C_5H_{11}, Ph) in chloroform in the presence of the sulfur trioxide–pyridine complex at 20–25 °C leads to a mixture of two aminosulfides: $RCH(SPh)CH_2NMe_2$ and $RCH(NMe_2)CH_2SPh$.[96,97] It has been suggested[97] that these compounds are formed as a result of the rearrangement of the esters of *N,N*-dimethylsulfamic acid formed in the first stage of the addition reaction. The reaction of the sulfenamide $PhSNEt_2$ with cyclohexene and sulfamic acid in acetonitrile at 90–100 °C affords an adduct, the treatment of which with 10% HCl leads to the hydrochloride of *trans*-2-phenylthiocyclohexylamine.[98] In the case of norbornene and norbornadiene,[99] a mixture of the following products is formed:

Together with the expected products

the interaction of norbornene and norbornadiene with *N,N*-dimethylbenzenesulfenamide in the presence of $K_2S_2O_7$ affords also[100]

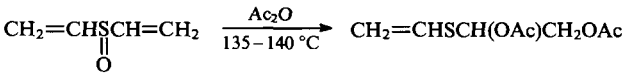


Consequently in the reaction of sulfenamides with SO_3 liberated from the pyrosulfate anion, the generation of the sulfenyl species PhS^+ is accompanied by the simultaneous formation of two counterions — the sulfate and sulfamate anions.

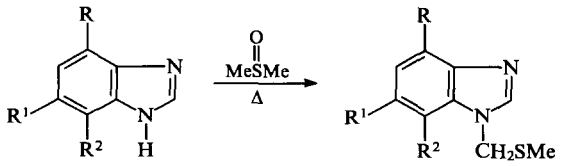


Ethyl benzenesulfenate also reacts with SO_3 in chloroform at −60 °C to form the highly reactive electrophile $PhSOSO_2OEt$, the reaction of which with norbornene and camphene affords a mixture of stereoisomeric sulfides.[101]

6. Syntheses from sulfoxides



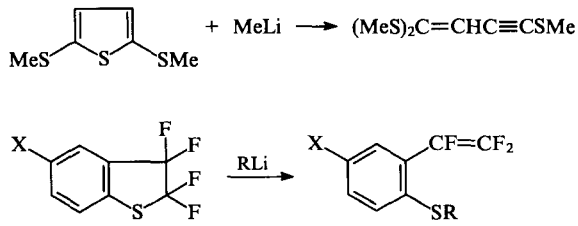
Sulfoxides are usually obtained from sulfides and the reduction of these compounds is therefore not used as a rule to synthesise simple sulfides. Other reactions of sulfoxides, which lead to the formation of sulfides whose structure differs from those of the sulfides used to synthesise the initial sulfoxide, are of preparative importance. For example, the Pummerer rearrangement of sulfoxides on treatment with acetic anhydride in the presence of alcohol leads to α-alkoxyalkyl sulfides, whereas in the absence of alcohol the formation of α-acetoxyalkyl sulfides is observed.[80]



The rearrangement of vinyl sulfoxide[102] and divinyl sulfoxide[103] in acetic anhydride leads to diacetoxyalkyl sulfides.

R^1 = Me, Et, 4-MeC_6H_4, 4-ClC_6H_4, 3(4)-$MeOC_6H_4$;
R^2 = H, Me.

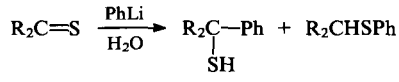
A convenient preparative method of synthesis of methyl sulfides has been developed. It involves the interaction of dimethyl sulfoxide with benzimidazole derivatives.[104]



R = H, Me; R^1 = H, NO_2; R^2 = H, NO_2.

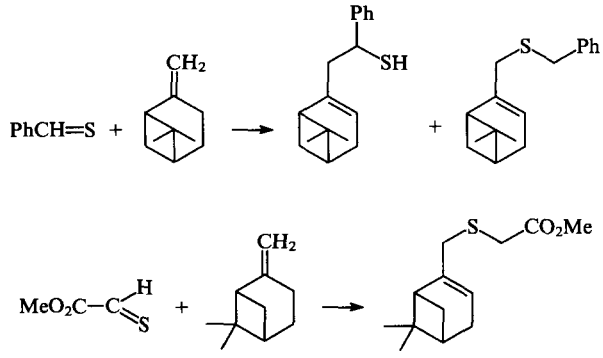
Dimethyl sulfoxide reacts similarly with phthalimide, isatin, saccharin, and pyridopyrimidines.[105]

7. Other methods of synthesis of sulfides



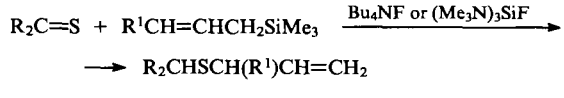
A preparative method of synthesis of bis(*o*-arylthiophenyl) sulfides by the reaction of 5-(4-R-phenyl)thianthrenium perchlorates (R = OMe) with thiophenols RC_6H_4SH (R = 4-Me, 4-MeO, 2-Cl, 2-NH_2) in THF in the presence of sodium hydride has been described.[106]

Polyfunctional sulfides are sometimes synthesised by opening the rings of sulfur-containing heterocyclic compounds on treatment with organolithium compounds.[8,107]



R = Alk, Ar; X = H, Br, Alk.

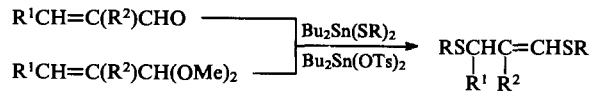
In the reactions of thiones with organometallic compounds,[78] there is a possibility of addition both to the carbon atom and to the sulfur atom, which results in the formation of a mixture of tertiary thiols and isomeric sulfides.



R = Bu^t.

The addition of thiones to the double bond of pinenes also leads to the corresponding sulfides.[9]

The interaction of thiones with silylated olefins, induced by the fluoride ion, is accompanied by the elimination of the silyl fragment and the formation of allyl sulfides.[108,109]

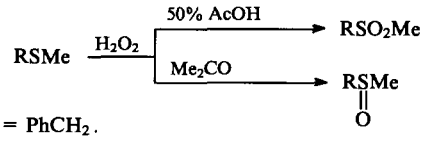


R = 2-MeC_6H_4; R^1 = H, Ph, PhMeCH.

In the presence of the complex $Et_2O.BF_3$, phenylthiosilanes react with alkenyl silyl ethers to form vinyl sulfides.[110,111]

R = Alk, *cyclo*-Alk.

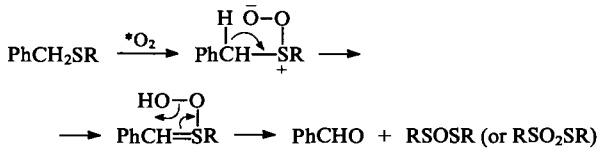
It has been noted[112] that the interaction of alkyl(aryl)-thiostannanes with α,β-unsaturated aldehydes or unsaturated acetals leads to the formation of 1,3-di-alkyl(aryl)thiopropenes in the form of a mixture of (*Z*)- and (*E*)-isomers.



R = Me, Ph, C_6H_{11}; R^1 = H, Me, Pr; R^2 = H, Me, Et.

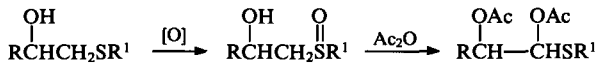
IV. Reactions of sulfides

1. Reactions involving an increase in the valence of sulfur

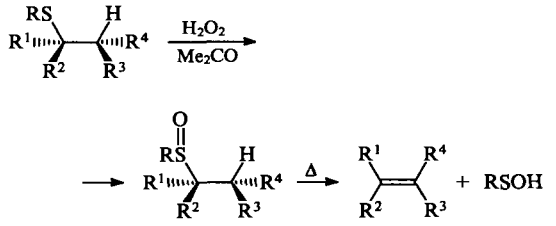


a. Oxidation of sulfides to sulfoxides

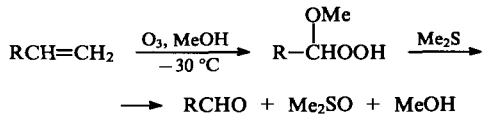
Mainly reagents of two types are used to convert sulfides into sulfoxides:[7,113] derivatives of peroxyacids [*m*-chloroperbenzoic and peroxydodecanoic acids activated by manganese(IV) peroxide and sodium periodate] and compounds which serve as sources of a halogen (*tert*-butyl hypochlorite, *N*-bromo- and *N*-chloro-succinimides, 1-chlorobenzotriazole, chlorine, etc.). Individual examples of the use of other reagents are also known, for example nitric acid,[4] cerium ammonium nitrate,[7] hydrogen peroxide in the presence of tellurium dioxide,[114] urea and phthalic anhydride,[115] *o*-iodosylbenzoic acid,[116] tetranitromethane,[117] the ozonides of phosphites,[118] and peroxides.[119] The use of hydrogen peroxide as the oxidant can lead to sulfoxides or sulfones depending on the conditions.[7]



R = $PhCH_2$.

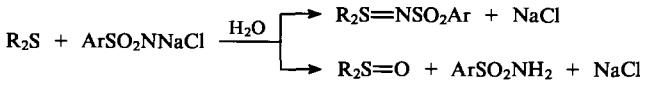


The photochemical oxidation of alkyl benzyl sulfides leads to the formation of a mixture of products, one of which is benzaldehyde.[120]

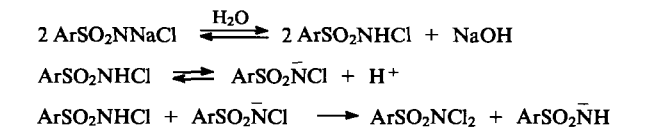


The oxidation of β-hydroxyalkyl sulfides leads to the formation of sulfoxides capable of undergoing the Pummerer rearrangement on heating in acetic anhydride.[8]

Taking into account the tendency of sulfoxides to undergo thermal *cis*-elimination, the oxidation of sulfides to sulfoxides is used in organic synthesis to convert sulfides into alkenes.[16]

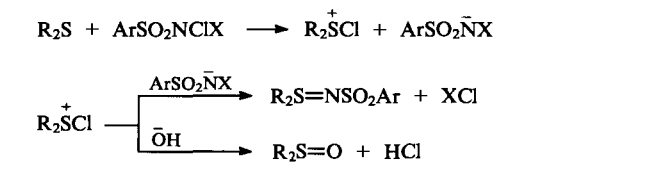


Dimethyl sulfide is used to reduce hydroperoxides.[8]



b. Oxidative imination of sulfides

The reactions accompanied by the oxidation of an element and the formation of the imino-group have come to be called oxidative imination.[121] The oxidative imination of sulfides by sodiochloroamides of sulfonic acids proceeds as a rule in aqueous media. Together with sulfilimines, sulfoxides are also formed in this reaction.



R = Alk, Ar, Het.

The ratio of sulfilimines and sulfoxides depends on the nature of the groups at the sulfur atom in the initial sulfide, the pH of the medium, and the nature of the solvent employed. It has been suggested[122] that the sulfonic acid sodiochloroamide is converted in an aqueous alcoholic medium via a reversible reaction into *N*-chlorosulfonamide (rapidly) and *N,N*-dichlorosulfonamide (slowly), which are fairly reactive electrophiles.

The reaction of a sulfide with *N*-chlorosulfonamide or *N,N*-dichlorosulfonamide[123–126] affords the chlorosulfonium cation R_2S^+Cl, which interacts with the sulfonamide anion $ArSO_2N^-X$ (X = H, Cl) to form a sulfilimine, whereas the hydrolysis of the chlorosulfonium cation leads to sulfoxides.[127]

R = H, Cl.

A low acidity of the medium promotes the conversion of the sulfonic acid sodiochloroamide into the more reactive *N*-chloro- and *N,N*-dichlorosulfonamides, but it reduces the probability of the existence of the sulfonamide anion. According to Tsujihara et al.,[128] pH 6 is optimum in the imination of dialkyl and alkyl aryl sulfides by the sodiochloroamide of toluene-*p*-sulfonic acid. Since aqueous solutions of sulfonic acid sodiochloroamides are alkaline, the addition of a small amount of acetic acid to the reaction medium increases the yield of sulfilimines.[128] In view of the sparing solubility of sulfides in water, aqueous solutions of methanol, acetone, and dioxan as well as two-phase systems, for example water–methylene chloride, are used for their imination, which naturally reduces the yield of sulfilimines and promotes the formation of sulfoxides. The use of anhydrous organic solvents, for example methylene chloride, as the reaction medium and of *N*-chloro-*N*-(tetraalkylamino)arenesulfonamides, readily soluble in these solvents, instead of sulfonic acid sodiochloroamides, leads to the formation of sulfilimines in a quantitative yield.[129]

R = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4, $PhCH_2$;
R^1 = Me, Bu; R^2 = Bu, $C_{12}H_{25}$, $C_{14}H_{29}$, $C_{18}H_{37}$.

An increase in the yield of sulfilimines in the case where two-phase reaction media are employed is also promoted by phase transfer catalysts.[130]

The susceptibility of the sulfur atom in the sulfide to electrophilic attack by the chlorine cation is directly related to the electron density on the sulfur atom, which depends on the nature

of the substituents. Electron-accepting groups at the sulfur atom hinder the imination reaction or preclude it altogether. Because of this, the search for and development of procedures designed to increase the electron density on the sulfur atom in sulfides is important from both theoretical and synthetic points of view. Analysis of the effective charges in the molecule of methanethiol and its carbanion, obtained as a result of quantum-mechanical calculations by the CNDO/2 method, showed[121,131] that one of these procedures involves the creation of an α-C-anionic centre in the sulfide molecule. The possibility, in principle, of arenesulfonylimination of aryl diacylmethyl sulfides containing a mobile α-H atom together with electron-accepting groups has been demonstrated,[139] but the sulfilimines formed in this case undergo further reactions as a result of the imino-ylide tautomerism.

$$X_2CH{-}\underset{\underset{NR}{\|}}{S}Ar \rightleftharpoons X_2C{=}\underset{\underset{NHR}{|}}{S}Ar \longrightarrow X_2\underset{\underset{NHR}{|}}{C}{-}SAr$$

X = PhCO, MeCO; Ar = 2(4)-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$;
R = $PhSO_2$, 4-$MeC_6H_4SO_2$.

The use of sodium salts of sulfides instead of the sulfides themselves promotes the arenesulfonylimination of these compounds in an anionic form and also the stabilisation of the resulting *N*-arenesulfonylsulfilimino-anions.[47,121,131,133–136]

$$\left[\begin{matrix}X\\ Y\end{matrix}\!\!>\!C{=}{=}SR\right]^{-}Na^{+} + ArSO_2NNaCl \xrightarrow[-NaCl]{} \left[\begin{matrix}X\\ Y\end{matrix}\!\!>\!C{=}{=}\underset{\underset{NSO_2Ar}{\|}}{S}R\right]^{-}Na^{+}$$

RN=CR, NH_2—N=CH, NH_2CO.

Chlorine,[137] *tert*-butyl hypochlorite,[138–140] sulfuryl chloride,[121] *N*-chlorosuccinimide,[141–143] and other *N*-chloro-compounds,[137] the reactions of which with sulfides at low temperatures afford chlorosulfonium intermediates which are converted into sulfilimines by treatment with *N*-nucleophiles, are also used as sources of the chlorine cation.

$$R_2S + ZCl \longrightarrow [R_2\overset{+}{S}{-}Z]\overset{-}{Cl} \xrightarrow{R^1NH_2}$$

$$\longrightarrow R_2\overset{+}{S}NHR^1\overset{-}{Cl} \xrightarrow[-HCl]{HB} R_2S{=}NR^1$$

R = Alk, Ar;
Z = Cl, Bu^tO, SO_2Cl_2, 

Aliphatic, aromatic, and heterocyclic amines, *N*-aminophthalimide, cyanamide, and the sodioamides of sulfonic and carboxylic acids are used as the *N*-nucleophiles.[121]

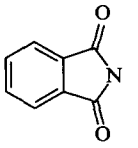
The oxidative imination of sulfides by hydroxyaminosulfonic acid[121] is a special case of the general reaction involving the imination of sulfides by derivatives of hydroxylamine, in particular by *N*-arenesulfonyl-*O*-*p* nitrobenzenesulfonylhydroxylamine, *N*-ethoxycarbonyl-*O*-*p*-nitrobenzenesulfonylhydroxylamine, and *O*-mesitylenesulfonylhydroxylamine.

$$R_2S + XYNOY \longrightarrow R_2\overset{+}{S}NH(X)\overset{-}{O}Y \xrightarrow[-HOY]{HB} R_2S{=}NX$$

R = Alk, Ar;
X = H, $ArSO_2$, EtOCO;
Y = HSO_3, 2,4,6-$Me_3C_6H_2SO_2$, 4-$NO_2C_6H_4SO_2$.

Sulfilimines are also formed in the reaction of sulfides with nitrenes generated by photochemical, thermal, and chemical methods. The procedure involving the photolysis of various organic azides in the presence of an excess of the sulfide has come to be most widely used.

$$XN_3 \xrightarrow{h\nu} :NX \xrightarrow{R_2S} R_2S{=}NX$$



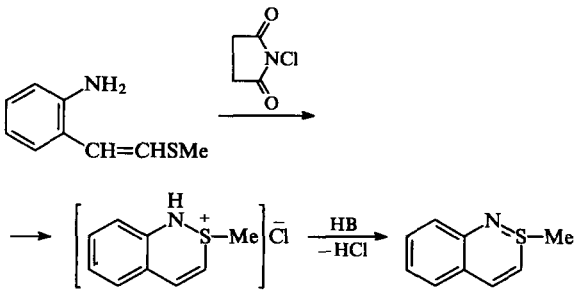
X = $ArSO_2$, PhCO, EtOCO, R_2PO;
R = Alk, Ar.

The reaction has been studied for a series of arenesulfonyl,[144] acyl,[121] alkoxycarbonyl,[121,144] diphenylphosphonyl, and dialkylphosphonyl azides.[145] It has been noted[121] that sulfides react with singlet nitrenes faster than with triplet nitrenes, since the presence in the reaction mixture of substances inducing the formation of triplet nitrenes inhibits the formation of sulfilimines. The low yields of the latter may be caused by their chemical instability. Under the conditions of photolysis, the sulfilimines are themselves sources of nitrenes, which has been noted[121] in the case of the photolysis of *N*-ethoxycarbonyl-*S*-*S*-dimethylsulfilimine. Certain unstable heterocyclic compounds, the photolysis of which in the presence of sulfides leads to the formation of sulfilimines, also function as sources of nitrenes.

$$Ph{-}\underset{\underset{O}{\|}}{\overset{N{-}O}{C}}{-}\underset{\underset{O}{|}}{C}{=}O + Me_2S \xrightarrow{h\nu} Me_2S{=}NCOPh + CO_2$$

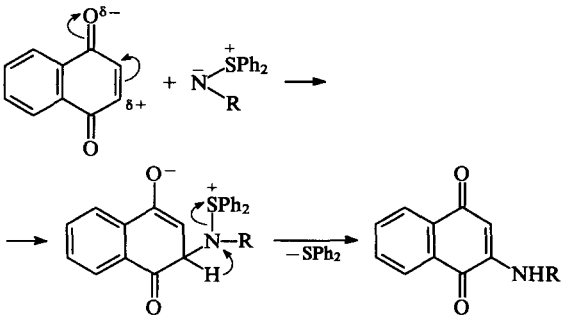
The main disadvantage of the methods of synthesis of sulfilimines by the reaction of sulfides with thermally generated nitrenes is the thermal instability of the sulfilimines formed, for example, in the thermolysis of acyl azides,[146] alkoxycarbonyl azides, and arenesulfonyl azides in the presence of sulfides.[146,147] In the presence of copper, the thermolysis of the azides and hence the interaction of nitrenes with sulfides proceed at a lower temperature, which promotes a higher yield of sulfilimines.[148] The chemical synthesis of nitrenes with the aim of obtaining sulfilimines is more rarely employed. The synthesis of certain sulfilimines by the reaction of sulfides with arenesulfonamides and *N*-aminophthalimide in the presence of lead tetraacetate has been described.[121]

$$R_2S + NH_2X \xrightarrow{Pb(OAc)_4} R_2S{=}NX$$



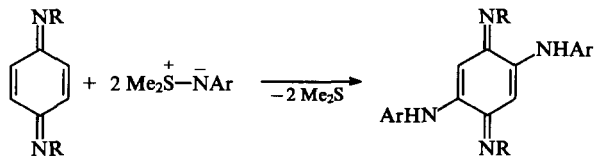
X = $ArSO_2$, 

One cannot rule out the possibility that the formation of sulfilimines in the reactions of sulfides with compounds having an E=N bond (E = S, I), which has been described in the literature,[149,150] also proceeds via a nitrene generation stage.



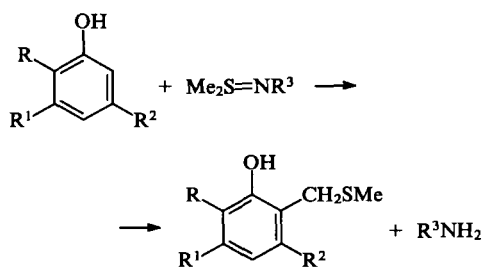
$$R_2S + X{=}NTs \longrightarrow R_2S{=}NTs$$

X = TsN =S, ArI.

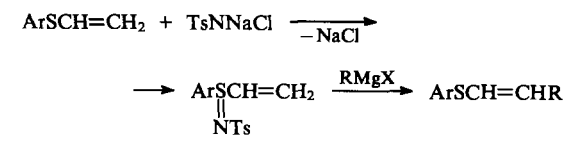


It has been shown[151] that, on treatment with *N*-chlorosuccinimide, aromatic amines containing an alkylthio-group in the *ortho*-position give rise to cyclic aminosulfonium salts, which are converted into cyclic sulfilimines in the presence of bases.

The conversion of sulfides into sulfilimines is of great synthetic importance, since the latter possess a series of valuable properties used in organic syntheses. Some of these syntheses are accompanied by the regeneration of the initial sulfides. For example, the high nucleophilicity of the nitrogen in *N*-arenesulfilimines makes it possible to use them for the introduction of aryl amino-groups into the quinonoid ring of quinone imines with regeneration of the initial sulfide.[121,152]



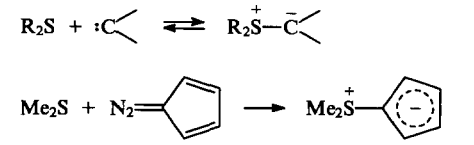
R = $PhCH_2$.



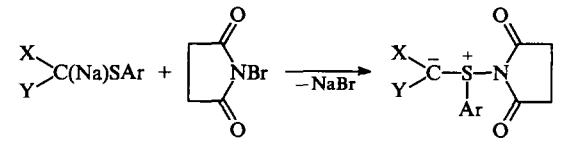
R = $PhSO_2$, *p*-$MeC_6H_4SO_2$;
Ar = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4, *p*-$NO_2C_6H_4$.

S,*S*-Dimethylsulfilimines are used to introduce the methylthiomethylene group into the aromatic ring of phenols.[121]

R = Me, OMe; R^1 = H, Me; R^2 = $ArSO_2$; 2,4-$(NO_2)_2C_6H_3$.

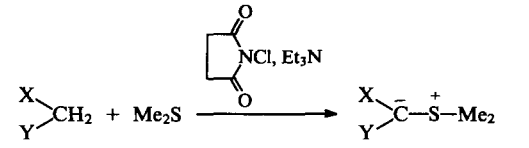


Substituents can also be introduced into vinyl sulfides $ArSCH=CH_2$ via the sulfilimine formation stage, whereupon the compounds ArSCH=CHR are formed.[8]



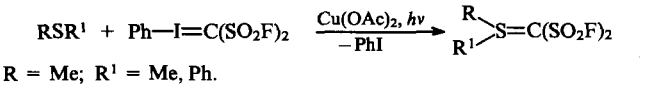
S-Alkyl-*S*-allyl-*N*-tosylsulfilimines cyclise intramolecularly on treatment with NaOH, affording 2-vinyl-substituted cyclic amines.[153]

c. The formation of sulfur ylides

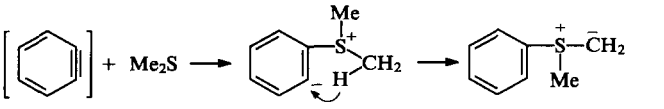


The interaction of sulfides with carbenes leads to sulfur ylides, which are not always stable and can undergo various rearrangements.[7]

The formation of relatively stable sulfur ylides on interaction of the sodium salts of α-arylthio-derivatives of CH acids with *N*-bromosuccinimide in acetone[154] and also on interaction of dimethyl sulfide and *N*-chlorosuccinimide with CH acids in the presence of triethylamine[155] has been noted.

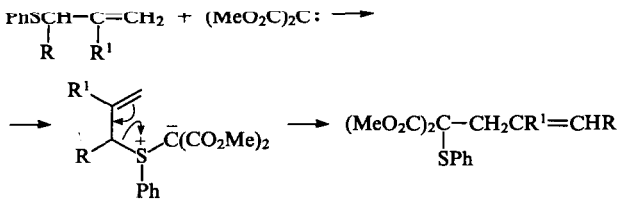


X = MeCO, Y = EtOCO; X = $PhSO_2$, Y = Ph;
Ar = 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$.



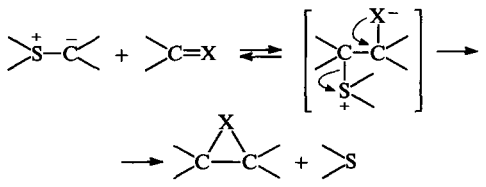
X = Br, Ac, CN, $PhCH_2$; Y = Br, $EtCO_2$, $MeCO_2$, Ph.

The thermal and photochemical decomposition of phenyliodonium bis(fluorosulfonyl)methylides in the presence of sulfides leads to the formation of relatively stable sulfur ylides.[156]



R = Me; R^1 = Me, Ph.

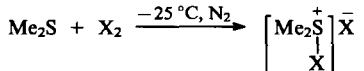
The addition of sulfides to dehydrobenzene also affords relatively stable sulfur ylides.[8]



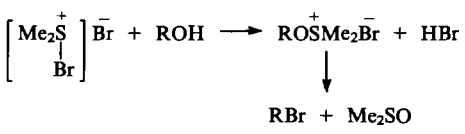
The insertion of carbenes in the allylic C–S bond[8,157] proceeds via the formation of ylides.

R = H, Me; R^1 = H, Me.

Sulfur ylides are used widely in organic synthesis for the transfer of the alkylidene group to an electrophilic double bond with formation of a three-membered ring.[121]

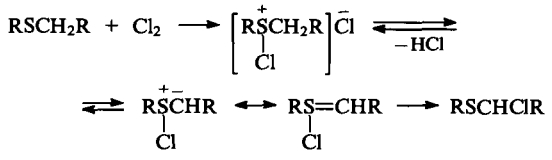


X = O, C.



It has been suggested[8] that the biosynthesis of the cyclopropane ring in a number of natural products proceeds via the copper-catalysed transfer of the methylene group of the ylide formed from *S*-adenosylmethionine.

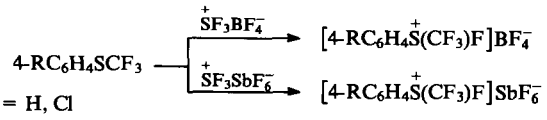
d. The formation of halosulfonium halides and other sulfonium salts



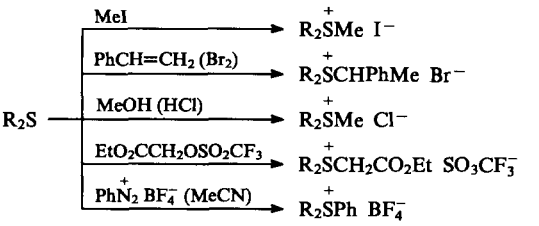
Dimethyl sulfide reacts with Cl_2 or Br_2 at −25 °C in $CHCl_3$ to form charge-transfer complexes or halodimethylsulfonium halides and is used in organic synthesis to convert alcohols into alkyl halides.[7]

X = Cl, Br.

Chlorosulfonium chlorides are intermediates in the α-chlorination of sulfides.[7]

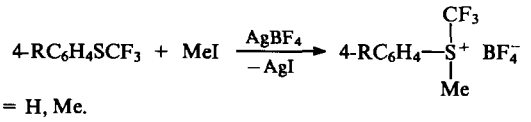


Aryl trifluoromethyl sulfides do not react with chlorine or bromine, but, on treatment with xenon fluoride, they combine with two fluorine atoms, affording readily hydrolysable aryldifluoro(trifluoromethyl)sulfuranes in a quantitative yield.[4]



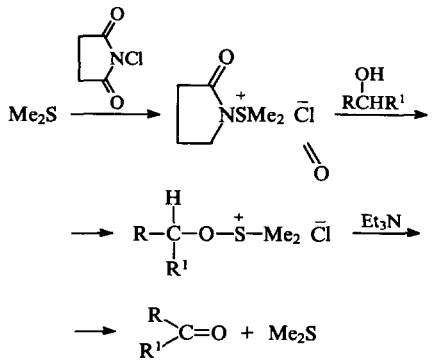
R = H, Cl, NO_2.

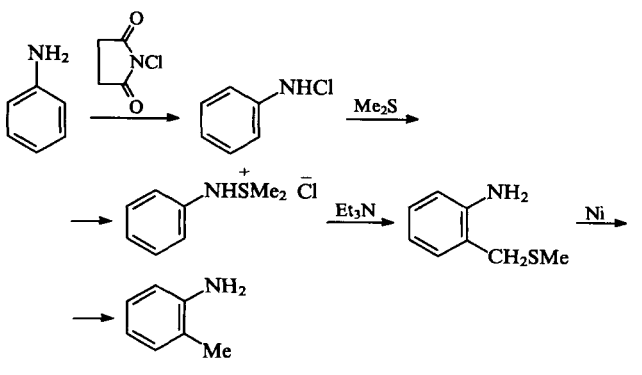
Treatment of aryl trifluoromethyl sulfides with the complexes $SF_3^+BF_4^-$ and $SF_3^+SbF_6^-$ yields arylfluoro(trifluoromethyl)-sulfonium salts,[158] which are used in the synthesis of *N*-arenesulfonyl-*S*-aryl-*S*-trifluoromethylsulfilimines.[4]



R = H, Me.

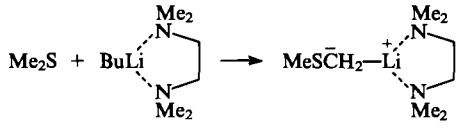
The interaction of sulfides with electrophiles or reagents capable of forming cationoid species results in the formation of sulfonium salts, which remain unchanged under the reaction conditions only in rare cases. The reaction involving the alkylation (arylation) of sulfides by alkyl halides, alkenes, alcohols, trifluoromethanesulfonates, and diazonium salts is usually employed to obtain sulfonium salts in a pure form.





Despite the low nucleophilicity of the sulfur atom, aryl trifluoromethyl sulfides are alkylated by methyl iodide in the presence of $AgBF_4$.[4]

R = H, Me.



Aminosulfonium salts, used to oxidise alcohols and to *ortho*-methylate anilines, are formed on interaction of sulfides with *N*-chlorosuccinimide and also with amines in the presence of *N*-chlorosuccinimide.[121]

2. Generation of α-sulfenylcarbanions

Sulfides containing a mobile α-H atom relatively easily form carbanions in the stabilisation of which the sulfur atom is directly involved.[159] Depending on the acidity of such sulfides, sodium methoxide,[131–136] potassium *tert*-butoxide,[160] alkali metal hydroxides,[161–163] sodium hydride,[167] and *tert*-butyllithium in THF[16] are used to synthesise carbanions. For example, dimethyl sulfide forms a carbanion on reaction with the butyllithium–tetramethylethylenediamine (TMEDA) complex.[16]

Methyl phenyl sulfide is converted into phenylthiomethyllithium on treatment with butyllithium in the presence of diazabicyclo[2.2.2]octane (DABCO).[16]

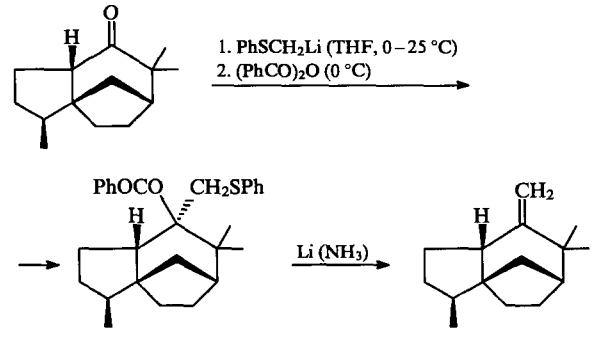
Reactions involving the substitution by a metal of atoms and groups such as Br, $SnBu_3$ and SePh as well as reactions involving the addition of organometallic reagents to the C=C bond of vinyl sulfides and to the C=S bonds of thioketones are much more rarely used in the synthesis of α-sulfenylcarbanions.[16,165]

The stability of the α-C-anionic centre increases following the enhancement of the *s* character of the carbon atom and also with increase in the number of sulfenyl groups linked directly to this atom, which is clearly confirmed by the comparison of the pK_a of the following compounds: PhSMe (49), $(PhS)_2CH_2$ (30.8), and $(PhS)_3CH$ (22.8).[166] The stability of the α-C-anionic centre is also influenced by other factors, in particular by the presence of neighbouring electron-accepting groups and atoms participating in the delocalisation of the negative charge,[47–51,167] the possibility of the transfer of the negative charge to other atoms as a result of tautomerism or isomerisation,[131,135] and also the possibility of the stabilisation of the counterion as a result of chelate formation.[16]

The question of the mechanism of the stabilisation of the α-C-anionic centre by a divalent sulfur atom has not so far been ultimately elucidated and still remains controversial. There are several concepts which explain the ability of sulfur to stabilise the α-C-anionic centre. According to one of them,[7] the α-C-anionic centre is stabilised by the sulfur atom as a result of the transfer of electrons from the carbanionic centre to the *d* orbitals of the sulfur atom. Despite the fact that doubts have been repeatedly cast on this concept, nevertheless investigators still prefer to resort to it even in recent years.[47,131–135]

According to another concept, the α-C-anionic centre is stabilised by the sulfur atom as a result of the dispersion of the negative charge owing to the more ready polarisability of the electron cloud of the sulfur atom compared with the carbon atom.[16] The polarisabilities of the sulfur and carbon atoms are 3.8×10^{40} and 1.9×10^{40} C m^2 V^{-1}, while the values for the C–S and C–C bonds are 2.1×10^{40} and 1.1×10^{40} C m^2 V^{-1} respectively.[16]

The concept of η,σ^*-delocalisation (hyperconjugation) has also been proposed, in satisfactory agreement with X-ray diffraction data for the lithio-derivatives of dimethyl sulfide, methyl phenyl sulfide, 1,3-dithiane, and 2-phenyl-1,3-dithiane as well as ^{13}C and ^6Li NMR spectrometric data.[16]



In studying the reactivity of α-sulfenylcarbanions and the reactions involving them, it is necessary to begin with the fact that α-sulfenylcarbanions are in essence ambident anions and their reactions with electrophiles proceed either via the carbon atom or the sulfur atom depending on the nature of the electrophile. By exerting its stabilising influence on the α-C-anionic centre, the divalent sulfur atom undergoes an increase in its electron density owing to the displacement of the latter from the anionic centre, which has been confirmed by quantum-mechanical calculations.[131] As a result of such increase in electron density, the sulfur atom becomes more susceptible to attack by the electrophile.

Examples of the reactions of α-sulfenylcarbanions with electrophiles involving the participation of the carbon atom are provided by the *C*-alkylation[16,47] and *C*-acylation[47] reactions and also by the reactions involving the addition of the α-C-anionic centre to the electron-deficient carbon atom of the carbonyl group.[161–163] In view of the possibility of the subsequent elimination of the sulfenyl group, these reactions play a major role in fine organic synthesis and, in particular, in the formation of the C–C and C=C bonds in the synthesis of various natural products. The formation of higher homologues of alkyl iodides[168] and the synthesis of the sesquiterpene zizaene may be quoted as clear-cut examples.[169]

The formation of higher homologues of alkyl iodides involves the alkylation of phenylthiomethyllithium by an alkyl iodide and subsequent replacement of the phenylthio-group by iodine on treatment with methyl iodide in the presence of sodium iodide. Ultimately one obtains an alkyl iodide containing one or several carbon atoms more than the initial compound.

$$PhSCH_2Li + RCH_2I \xrightarrow[-LiI]{} RCH_2CH_2SPh \xrightarrow[NaI]{MeI} RCH_2CH_2I$$

The synthesis of the sesquiterpene zizaene consists in the addition of phenylthiomethyllithium to the carbonyl group of a cyclic ketone and subsequent benzoylation of the resulting β-hydroxysulfide and the reductive elimination of the phenylthio-group with the aid of lithium in liquid ammonia.

The reactions of α-sulfenylcarbanions with electrophiles involving the sulfur atom were discovered comparatively recently. They include the reactions of the sodium salts of sulfides with *N*-halo-derivatives and in particular the oxidative imination[47,131,134,135] and oxidative imidation[154] of the sodium salts of sulfides, which were considered in the previous Section. The primary step in these reactions is attack on the positively charged halogen atom of the *N*-halo-compound by the sulfur atom with formation of a halosulfonium intermediate,[121] which reacts with the *N*-anion to form the reaction product. The sodium salts of *N*-arenesulfonylsulfilimines, synthesised by the arenesulfonylimination of the sodium salts of sulfides, readily undergo *C*-alkylation,[131,135] which is very important for the synthesis of new *N*-arenesulfonylsulfilimines.

$$RSC(Na)X_2 \,\|\, NSO_2Ar + MeI \xrightarrow[-NaI]{} RSC(Me)X_2 \,\|\, NSO_2Ar$$

R = 2(4)-$NO_2C_6H_4$; X = MeCO, EtOCO; Ar = 4-MeC_6H_4.

3. Reactions involving the cleavage of the C–S bond

The C–S bond is cleaved comparatively readily compared with the C–C bond or a nonactivated C–H bond under the influence of heat or chemical reagents. For example, the pyrolysis of benzyl phenyl sulfide in cyclohexane begins already at 200 °C with the homolytic cleavage of the C–S bond.[170] The composition of the products of the pyrolysis of sulfides is then determined both by the structure of the initial sulfide and by the pyrolysis conditions.

For example, in the gas phase at 400–800 °C diethyl sulfide decomposes to hydrogen sulfide and ethylene, which are formed as a result of the following reactions.[171]

$$CH_3CH_2SCH_2CH_3 \xrightarrow{\Delta} CH_3CH_2\dot{S} + CH_3\dot{C}H_2$$

$$CH_3\dot{C}H_2 + CH_3CH_2SCH_2CH_3 \longrightarrow$$

$$\longrightarrow CH_3CH_3 + CH_3CH_2S\dot{C}HCH_3$$

$$CH_3CH_2S\dot{C}HCH_3 \longrightarrow CH_3CH_2\dot{S} + CH_2{=}CH_2$$

$$CH_3CH_2\dot{S} + CH_3\dot{C}H_2 \longrightarrow CH_3CH_2SH + CH_2{=}CH_2$$

$$CH_3CH_2SH \longrightarrow H_2S + CH_2{=}CH_2$$

The formation of hydrogen sulfide and the corresponding alkenes has been observed[172] also in the thermolysis of other dialkyl sulfides. Under these conditions, dialkyl sulfides with the iso-structure and asymmetric dialkyl sulfides are thermally less stable than symmetrical sulfides with the normal structure. The pyrolysis of allyl methyl sulfide at 427 °C leads to thioformaldehyde and propene.[173] Other alkyl allyl sulfides are converted into the corresponding thiocarbonyl compounds and alkenes under the conditions of vacuum pulse pyrolysis at 615–650 °C.

$$>CH{-}S{-}CH_2{-}CH{=}CH_2 \longrightarrow >C{=}S + MeCH{=}CH_2$$

Diallyl and allyl benzyl sulfides form thioacrolein and thiobenzaldehyde respectively under these conditions.[174] The vacuum pulse pyrolysis of allyl phenyl sulfide proceeds with formation of phenylthiyl and allyl radicals, which dimerise under the pyrolysis conditions.[172] The vacuum pyrolysis of alkyl ethynyl sulfides at 500 °C leads to the formation of thioketene.[16]

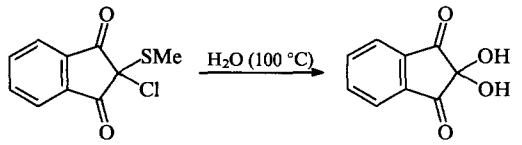
$$CH{\equiv}CSCMe_3 \xrightarrow{500\ ^\circ C} [CH{\equiv}C\dot{S} + \dot{C}Me_3] \longrightarrow$$

$$\longrightarrow CH{\equiv}CSH + CH_2{=}CMe_2$$

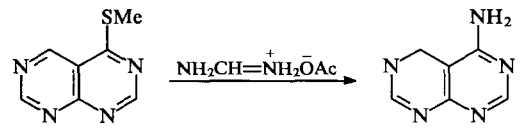
$$CH{\equiv}CSH \longrightarrow CH_2{=}C{=}S$$

The products of the pyrolysis of the sulfide $PhCH_2CH(Ph)SPh$ at 250 °C are H_2S, PhMe, $PhCH_2CH_2Ph$, PhCH = CHPh, PhSH, Ph_2S, thianthrene, and 2,3,4,5-tetraphenylthiophene.[175]

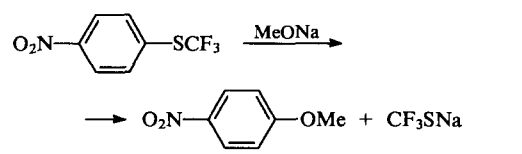
The thermal disproportionation of alkyl sulfides in the presence of carboxylic acid esters is one of the transesterification methods.[8]



$$RCO_2Me + R^1SR^1 \xrightarrow{\Delta} RCO_2R^1 + R^1SMe$$



The dealkylation of butyl methyl sulfide in the presence of alkanechalcogenolate anions, which proceeds with formation of butanethiolate and methanethiolate anions in 40% and 35% yields respectively, has been described.[176] The thiolate anions react with propyl iodide, affording the corresponding sulfides.



The reductive cleavage of sulfides, in which there is a clear tendency towards the preferential cleavage of one of the two C–S bonds, is used in the synthesis of thiols. The ease of the cleavage of the C–S bond diminishes in the sequence alkynyl > vinyl > allyl > alkyl.[78] Sodium in liquid ammonia or lithium in ethylamine are used for the reductive cleavage of allyl and benzyl sulfides. The reductive cleavage of 3-alkylthioindolenine to indole proceeds on treatment with $LiAlH_4$, Raney nickel in ethanol, or $NaBH_4$ in isopropyl alcohol. The reductive cleavage on treatment with CF_3COOH in the presence of a suitable nucleophilic trapping agent is also used.[177] One of the methods for the protection of the SH group involves its conversion into the sulfide group, which is as a rule achieved as a result of alkylation, acylation, or addition reactions. The protecting groups are removed by means of various methods for the cleavage of the C–S bond, using bases, acids, mercury acetate and sulfate, silver nitrate in pyridine, and trifluoromethanesulfonic acid, as well as electrolytic cleavage.[78]

The anodic[178] and oxidative[179] desulfurisation of cyclic dithioacetals by *N*-halo-compounds in the presence of sources of fluoride ions ($Bu_4N^+H_2F_3^-$, $Et_3N \cdot HF$) may be used as preparative methods of synthesis of geminal difluoroalkanes.

Certain sulfides undergo relatively easily hydrolysis, aminolysis, and alcoholysis with cleavage of the C–S bond.[4,8]

The sulfides in which the sulfur atom is linked to the benzyl or an acyl[180] group undergo chlorinolysis comparatively readily, which is frequently used in the synthesis of sulfenyl chlorides.

$$ArSCH_2Ph + Cl_2 \xrightarrow{CH_2Cl_2} ArSCl + PhCH_2Cl$$

$$RSAc + SO_2Cl_2 \xrightarrow{CCl_4} RSCl + AcCl + SO_2$$

R = Me, Bu, Bu^t, Ph, 2-MeC_6H_4, 4-$NO_2C_6H_4$.

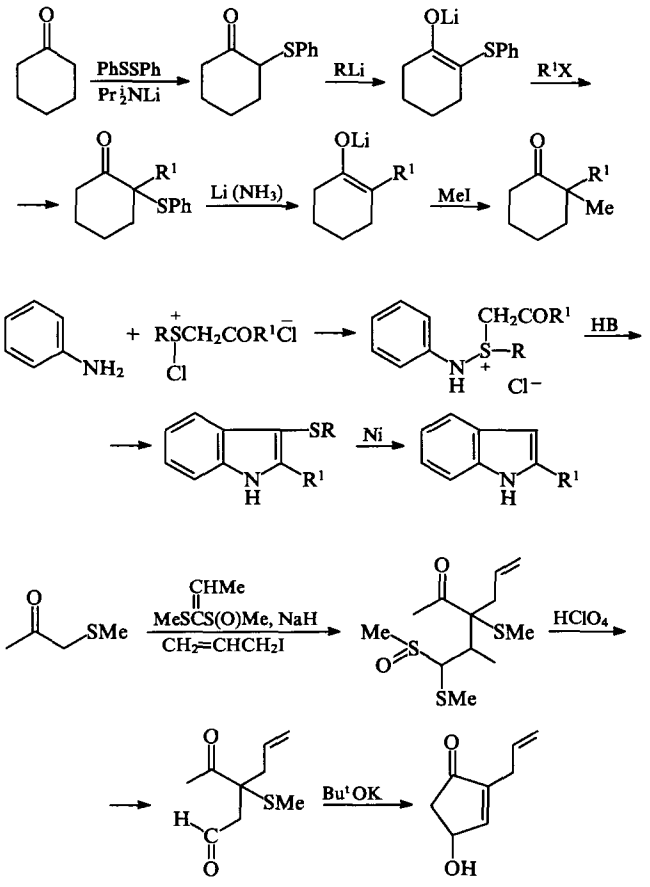
Asymmetric sulfides are obtained by the cleavage of the C–S bond in symmetrical sulfides in the presence of iodonium[181] or sulfonium[182] salts.

$$Me_2S + [\overset{+}{I}C_6F_{13}]BF_4^- \longrightarrow$$

$$\longrightarrow [Me_2\overset{+}{S}C_6F_{13}]BF_4^- \xrightarrow{Me_2S} MeSC_6F_{13} + \overset{+}{S}Me_3\ BF_4^-$$

$$R_2CHBr + R^1_2S \longrightarrow$$

$$\longrightarrow \left[\begin{array}{l} R^1_2\overset{+}{S} \\ \quad | \\ \quad CHR_2 \end{array}\right] \bar{B}r \xrightarrow{R^1_2S} R_2CHSR^1 + R^1_3\overset{+}{S}\ \bar{B}r$$



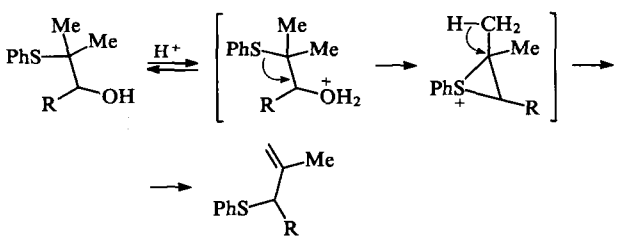
On treatment with bromocyanogen, the C–S bond in aliphatic sulfides is cleaved with formation of thiocyanates and alkyl bromides.[8] Asymmetric sulfides are then cleaved in such a way that the thiocyanate group is bound to the alkyl group.

$$BuSPr + BrCN \longrightarrow BuSCN + PrBr$$

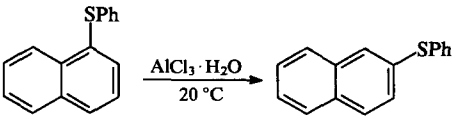
The sulfides in which the sulfur atom is linked to the carbon atom in the β-position relative to unsaturated groups, for example to a carbonyl group or a benzene ring, very easily undergo elimination with cleavage of the C–S bond, which is catalysed by bases;[15] the driving factor in this case is the formation of a system of conjugated bonds.

$$O{=}C{-}CH{-}C{-}SR \xrightarrow{\bar{O}H} O{=}C{-}C{=}C + H_2O + RS^-$$

The elimination of alkylthio- and arylthio-groups has found extensive application in recent years in the syntheses of various cyclic compounds.[8]

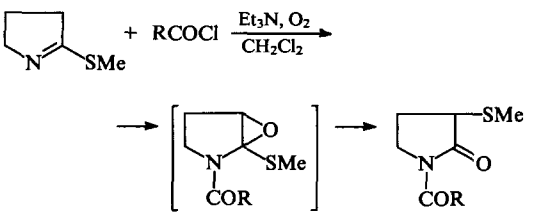


4. Rearrangements of sulfides



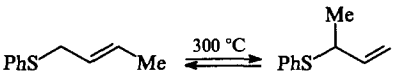
Among all the divalent sulfur compounds, sulfides show perhaps the greatest tendency towards various rearrangements in which the sulfur atom participates directly in the formation of transition states.[183] Sigmatropic rearrangements, which proceed with migration of σ-bonds via a transition state in which the sulfur atom is frequently involved, are characteristic of sulfides under these conditions. The theoretical possibility of the occurrence of a particular rearrangement in the series of sulfides is regulated by the selection rules for pericyclic reactions. In practice 1,2-, 2,3-, and 3,3-sigmatropic rearrangements are observed in the series of sulfides.

a. 1,2-Sigmatropic rearrangements

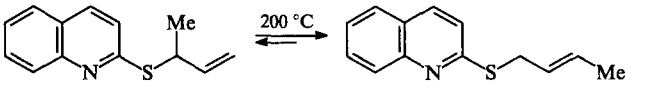


According to the correlation rules, the 1,2-migration of arylthio- and alkylthio-groups in the neutral molecules of sulfides is prohibited. It can occur either in a cation or on radical initiation.[183] Indeed, the 1,2-shift of the phenylthio-group, which occurs in aryl β-hydroxyalkyl sulfides on treatment with toluene-*p*-sulfonic acid, is due to the formation of a cationoid intermediate.[184]

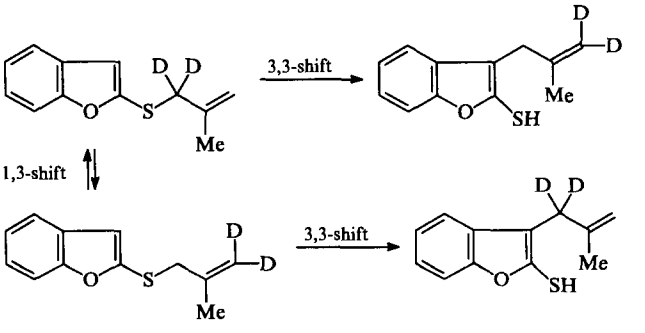
The intramolecular 1,2-migration of the arylthio-group in the molecule of 1-naphthyl phenyl sulfide in the presence of aluminium chloride also evidently proceeds via the stage involving the formation of a cationoid intermediate.[183]



The *N*-acylation of 2-methylthiodihydropyrroline, in which the initial compound is epoxidised by atmospheric oxygen with subsequent opening of the epoxide ring and the migration of the methylthio-group to the 3-position, may be quoted as an example of the 1,2-migration of the methylthio-group.[185]

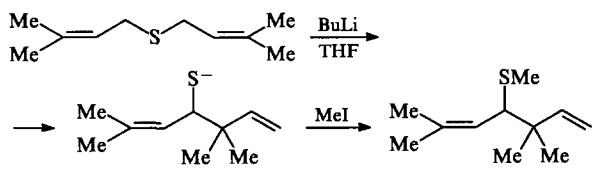


b. 1,3-Sigmatropic rearrangements

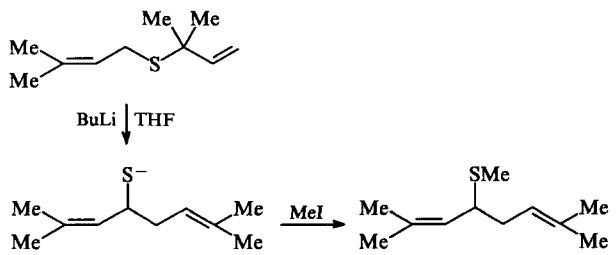


1,3-Sigmatropic rearrangements are characteristic primarily of allyl sulfides. For example, 2-butenyl phenyl sulfide is converted into 1-methylallyl phenyl sulfide at 300 °C as a result of the 1,3-migration of the phenylthio-group.[183]

The 1,3-sigmatropic rearrangement of 1-methylallyl 2-quinolinyl sulfide is a reversible reaction the equilibrium in which at 200 °C is appreciably displaced towards the formation of 2-butenyl 2-quinolinyl sulfide.[183]



In a number of instances, the 1,3-sigmatropic rearrangement of sulfides is accompanied by their subsequent 3,3-sigmatropic rearrangement. Thus, the 1,3-sigmatropic rearrangement of the deuterium-labelled 2-benzofuryl 2-methylallyl sulfide is accompanied by the 3,3-sigmatropic rearrangement, which occurs at a higher temperature.[186–188]



This behaviour is observed most frequently in the 1,3-sigmatropic rearrangement of allyl phenyl sulfide and allyl 2-thienyl sulfide.[187,188] The 1,3-sigmatropic rearrangement of allyl aryl sulfides is accelerated by singlet oxygen obtained photochemically or on decomposition of peroxides.[189] Diaryl sulfides also exhibit an accelerating effect on the 1,3-sigmatropic rearrangement of allyl aryl sulfides.[190]

c. 2,3-Sigmatropic rearrangement

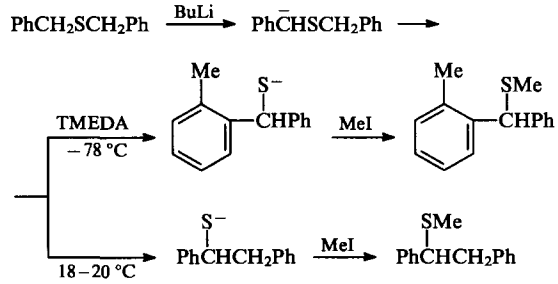
The 2,3-sigmatropic rearrangements of sulfides proceed as a rule under the influence of basic catalysts with formation of α-sulfenylcarbanions as intermediates. The possibility of the 2,3-sigmatropic rearrangement is then determined by the structure of the initial sulfide and the nature of the catalyst and the solvent. For example, on treatment with butyllithium in THF, diallyl sulfides undergo the 2,3-sigmatropic rearrangement with formation of the corresponding thiolates, which react with methyl iodide, affording dienyl methyl sulfides.[183–191]

In the DMSO – KOH system, diallyl sulfide merely isomerises to di(1-propenyl) sulfide.[192]

$$CH_2{=}CH{-}CH_2SCH_2{-}CH{=}CH_2 \xrightarrow{DMSO/KOH} CH_3{-}CH{=}CHSCH{=}CH{-}CH_3$$

Treatment of allyl benzyl sulfide with butyllithium in the presence of diaza-1,4-bicyclo[2.2.2]octane and methyl iodide at −15 °C leads to the formation of a mixture of three sulfides.[193]

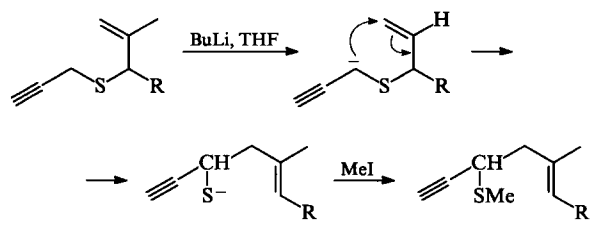
$$PhCH_2SCH_2CH{=}CH_2 \xrightarrow[MeI]{BuLi,\ DABCO} \begin{cases} PhCH(SMe)CH_2CH{=}CH_2 & 23\% \\ PhCH_2SCH(Me){=}CH_2 & 76\% \\ PhCH_2SCH{=}CHCH_2Me & 1\% \end{cases}$$



These results indicate the formation of two intermediate carbanions — with the negative charge on the benzyl and allyl carbon atoms. The carbanion with the negative charge on the benzyl carbon atom undergoes a 2,3-sigmatropic rearrangement whereas the carbanion with the negative charge on the allyl carbon atom is stable; it is merely methylated by methyl iodide and isomerises with migration of the double bond.

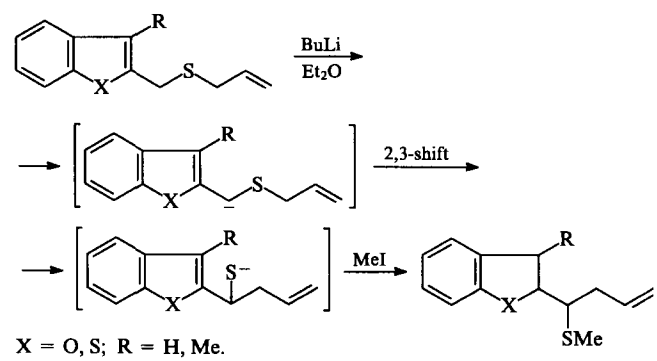
The 2,3-sigmatropic rearrangement of benzyl γ,γ-dimethylallyl sulfide under similar conditions leads to only one product.

$$PhCH_2SCH_2{-}CH{=}C(Me)_2 \xrightarrow[2.\ MeI]{1.\ BuLi,\ DABCO} Ph{-}CH(SMe){-}C(Me){=}CH_2$$



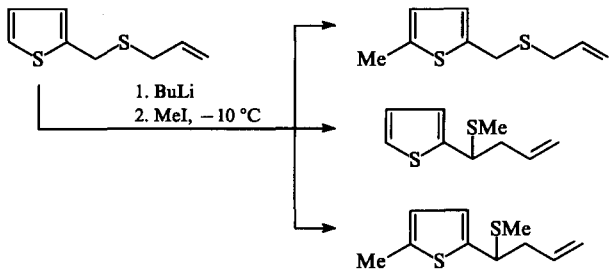
It has been suggested[183] that in this case only the carbanion with the negative charge on the benzyl carbon atom is involved in the 2,3-sigmatropic rearrangement, whereas the carbanion with the negative charge on the allyl carbon atom does not participate in the rearrangement and other reactions.

Depending on the conditions, the carbanion of dibenzyl sulfide can undergo the Stevens rearrangement or the 2,3-sigmatropic rearrangement.[193]

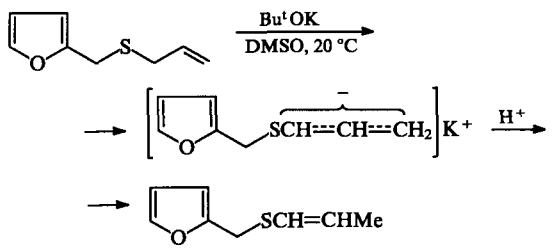


Since the Stevens rearrangement proceeds in the presence of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA), it has been suggested[193] that the 2,3-sigmatropic rearrangement occurs in the presence of free anions. On the other hand, if the anion is solvated, the Stevens rearrangement takes place.

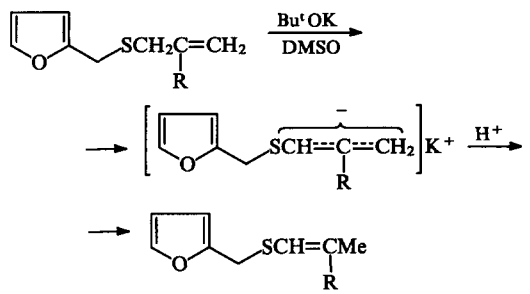
Sulfides containing the propargyl group also undergo the 2,3-sigmatropic rearrangement on treatment with butyllithium in THF.[183]



The possibility of the 2,3-sigmatropic rearrangement in the series of allyl heteroaryl sulfides is determined by the nature of the heteroaryl group.[194] For example, on treatment with butyllithium in diethyl ether at −70 °C, 2-(allylthiomethyl)benzofuran and 2-(allylthiomethyl)-3-methylbenzothiophene undergo the 2,3-sigmatropic rearrangement, affording the corresponding thiols, which give rise to sulfides on interaction with methyl iodide.

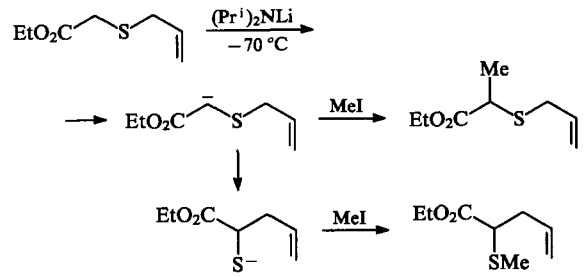


X = O, S; R = H, Me.

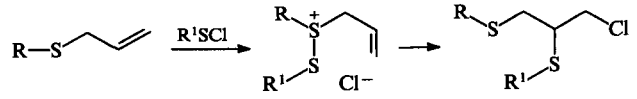


Under the same conditions, 2-(allylthiomethyl)thiophene remains unchanged and produces a mixture of sulfides only at −10 °C. Among these, the last two are the products of the 2,3-sigmatropic rearrangement of the initial sulfide.

The interaction of 2-(allylthiomethyl)furan with butyllithium leads to the metallation of the free α-position of the heterocycle. The replacement of butyllithium by potassium *tert*-butoxide leads to the selective formation of 2-(propenylthiomethyl)furan.

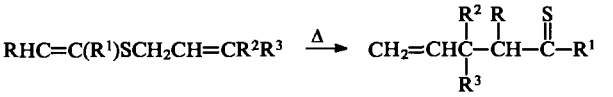


Other allyl furylmethyl sulfides undergo a similar isomerisation.[286]

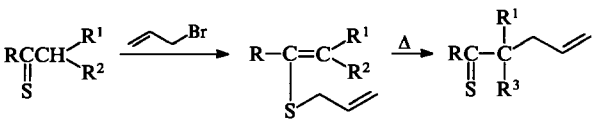


R = H, Me.

The 2,3-sigmatropic rearrangement of allyl ethoxycarbonylmethyl sulfide takes place in the presence of lithium diisopropylamide.[195]



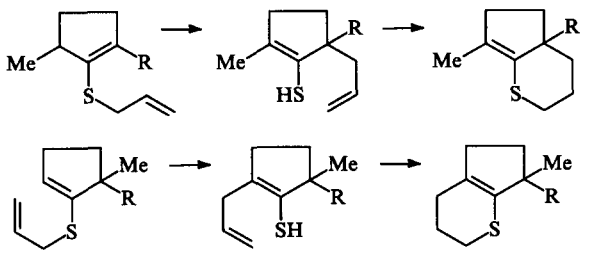
It has been suggested[196] that the products of the reactions of allyl sulfides with sulfenyl chlorides are formed not as a result of the addition of the sulfenyl chlorides to the allyl fragment but as a result of the 2,3-sigmatropic rearrangement of the sulfonium cation produced due to the attack by the sulfenyl chloride on the sulfur atom.



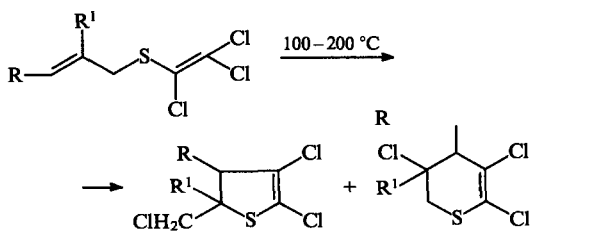
R = R¹ = Me.

d. The 3,3-sigmatropic rearrangement

The 3,3-sigmatropic rearrangement is characteristic primarily of allyl sulfides. The structure of the initial sulfide exerts a significant influence in this instance both on the rate of the rearrangement and on the nature of the product formed. The sulfides $RCH=C(R^1)SCH_2CH=CR^2R^3$ (R = H, Alk, Ph; $R^1 = NMe_2$, NEt_2, OEt, SEt; $R^2 = R^3$ = H, Me), for example, rearrange to the corresponding thiones even on slight heating.[183]

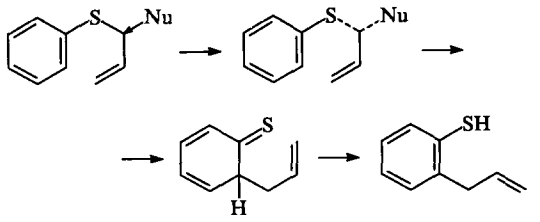


Substituted allyl vinyl sulfides, formed in the reactions of aliphatic thioketones with allyl bromides, undergo the 3,3-sigmatropic rearrangement even on distillation, affording thioketones.[183,197]

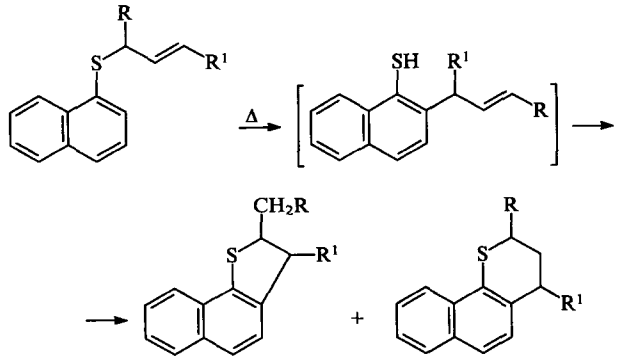


R = R¹ = R² = H, Me, Pr^i, Bu^t.

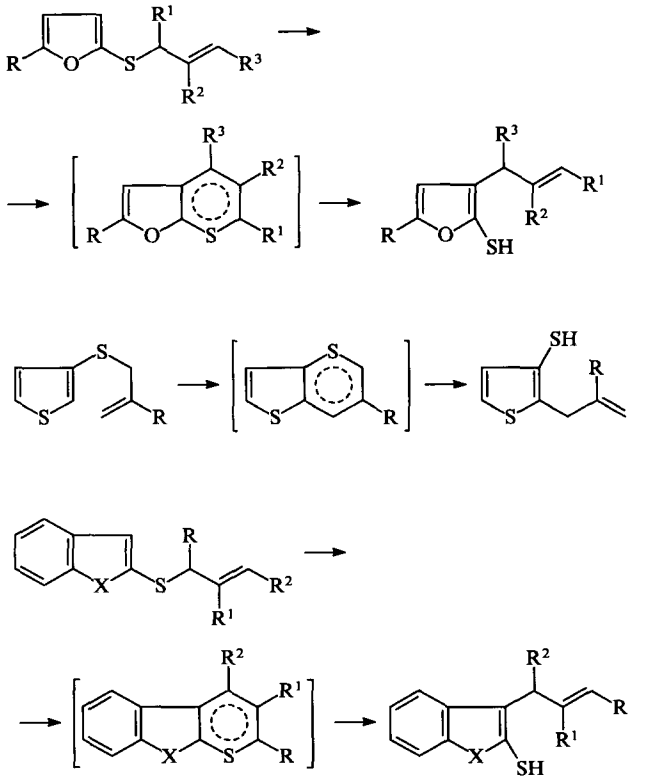
The presence of electron-accepting groups such as the nitrile group in the molecules of allyl vinyl sulfides hinders the 3,3-sigmatropic rearrangement. For example, dicyano-substituted allyl vinyl sulfides are converted into the isomeric ketones only after prolonged heating.



If one of the double bonds in allyl vinyl sulfides is part of an alicyclic system, the rearrangement results in the formation of enethiols, which slowly cyclise even at room temperature to the corresponding bicyclic sulfur-containing compounds.[183]

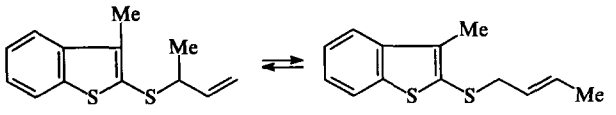


The thermal rearrangement of trichloro-substituted allyl vinyl sulfides involves the migration of the chlorine atoms, which results in the formation of chloro-substituted dihydrothiophenes and dihydrothiopyrans.[198]

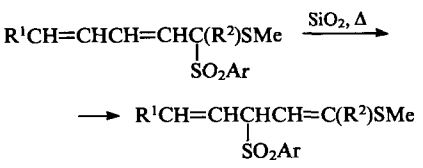


On distillation in the presence of quinoline and *N*,*N*-dimethylaniline, allyl phenyl sulfide rearranges to 2-allylthiophenol, which is converted under the reaction conditions into 2-methyl-2,3-dihydrobenzothiophene and other products. The study of this reaction provided Kwart et al.[199] with a basis which they used to put forward a mechanism of the nucleophilic catalysis with participation of solvent molecules.

Allyl 1-naphthyl sulfides rearrange similarly to allylnaphthalenethiols, which cyclise under the reaction conditions to 2,3-dihydronaphtho[1,2-*b*]thiophenes and 2,3-dihydronaphtho[1,2-*b*]thiopyrans.[188,200]

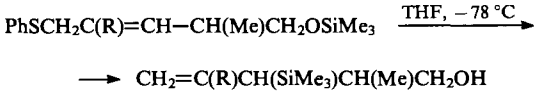


On heating in the absence of a solvent, substituted allyl furyl and allyl thienyl sulfides and their benzo-derivatives undergo a 3,3-sigmatropic rearrangement with formation of allyl-substituted heterocyclic thiols.[201–208]



X = O, S; R = R¹ = R² = R³ = H, Me, MeO, MeS, Cl, Br.

It has been noted[187,204] that the 3,3-sigmatropic rearrangement of alkenyl heteroaryl sulfides is as a rule accompanied by the 1,3-sigmatropic shift and this course of the reaction is virtually the only one for allyl benzothienyl sulfides containing a substituent in the 3-position in the thiophene ring.[206]



The replacement of the double bond in the allyl or vinyl fragments of allyl vinyl sulfide by a triple bond hardly affects the mode of the 3,3-sigmatropic rearrangement. The products of the 3,3-sigmatropic rearrangements of sulfides with a triple bond are also thiols, thiones, and cyclic compounds with the sulfur atom in the heterocycle.[183]

Among other rearrangements of unsaturated sulfides, mention should be made of the rearrangements of phenylthioacetylene, which is converted into 1,2-di(phenylthio)ethylene in the DMSO–KOH system[209] and also the rearrangement of allyl sulfides containing an arenesulfonyl group at the allylic carbon atom, which proceeds with migration of the arenesulfonyl group.[210]

R^1 = H, Et; R^2 = Et, $PhCH_2$; Ar = Ph, 4-MeC_6H_4.

The rearrangement of allyl sulfides containing the trimethylsiloxane group has been described.[211] The rearrangement takes place in the presence of di-*tert*-butylbiphenylyllithium with migration of the trimethylsilyl group, which results in the formation of allylsilanes with a high regioselectivity and stereoselectivity.

R = H, Me.

* * *

It is seen from the present review that studies in the field of the chemistry of sulfides during the last ten years have been directed mainly to the further development of the methods of synthesis of sulfides already available such as the sulfenylation of hydrocarbons, the alkylation of thiols, and the thiylation of unsaturated compounds, as well as to the search for new methods of synthesis (aminosulfenylation and sulfamatosulfenylation of olefins, etc.). Much attention has been devoted to further study of the reactivity of sulfides and in particular of the reactions occurring with formation of halosulfonium intermediates, α-sulfenylcarbanions, and sulfur ylides, as well as rearrangements. Many investigations have been devoted to syntheses based on sulfides.

The use of samarium diiodide in organic and polymer synthesis

N E Brandukova, Ya S Vygodskii, S V Vinogradova

Contents

I. Introduction 345
II. The synthesis and properties of divalent lanthanide salts 345
III. Reactions involving samarium diiodide 346

Abstract. The methods of synthesis and properties of samarium diiodide are examined and the results of its employment for the synthesis of a wide variety of compounds are surveyed. New reactions involving samarium diiodide are described and the prospects for its application in polymer chemistry are indicated. The bibliography includes 87 references.

I. Introduction

There has been considerable progress in recent years in the use of the unique properties of divalent lanthanide (Eu, Yb, Sm, etc.) halides in the synthesis of a wide variety of organic compounds.[1–3] Comparison of the oxidation–reduction potentials of lanthanide salts and various transition metal salts has shown that the former, in particular samarium and ytterbium diiodides, belong to the class of the strongest reductants soluble in organic media.

The standard oxidation–reduction potentials of the lanthanides in aqueous solutions are as follows:[2]

$$Eu^{2+}/Eu^{3+} = -0.35\ eV;\ Yb^{2+}/Yb^{3+} = -1.15\ eV;$$

$$Sm^{2+}/Sm^{3+} = -1.55\ eV;\ Tm^{2+}/Tm^{3+} = -2.10\ eV.$$

It is seen from the data presented that Tm^{2+} has the most pronounced reducing properties, but, because of this, it is much less stable than Sm^{2+} and Yb^{2+}. It has been shown[4] that, in the absence of O_2, solutions of Eu^{2+}, Yb^{2+}, and Sm^{2+} in THF are stable for a long time (several days),[5] in contrast to Tm^{2+} solutions. Furthermore, thulium is a naturally scarce element.

Bearing these data in mind, it becomes understandable why divalent lanthanide compounds have been isolated only for europium, samarium, and ytterbium.[5] At the same time Eu^{2+} is a very weak electron donor[1] and its reactivity in organic reactions is low. For the same reason, the reactivity of Yb^{2+} is relatively low, which limits significantly the range of reactions in which it is used, such reactions requiring as a rule comparatively severe conditions.

Among all the elements examined, samarium is most preferable because of its high oxidation–reduction potential, which gives rise to its pronounced reducing properties.

Received 10 March 1994
Uspekhi Khimii **63** (4) 361–372 (1994); translated by A K Grzybowski

Until recently divalent lanthanide halides have been obtained by complex procedures requiring the reduction of lanthanide trihalides with hydrogen or the corresponding metal at very high temperatures (700–900 °C), their thermal dissociation in a high vacuum, etc.[6,7]

A new comparatively simple method of synthesis of divalent lanthanide diiodides from diiodoethane and the corresponding metal was proposed in 1977,[8] which initiated their wide scale employment in organic and polymer chemistry. Thus the use of YbI_2 and especially SmI_2 promotes many organic reactions at high rates and with a high yield of the target product even at low temperatures (−78 to 20 °C) and also makes it possible to carry out reactions which could not be performed using other reductants (iodomethylation of carbonyl compounds, synthesis of large lactone rings, selective reduction of the aldehyde group in the presence of the keto-group, etc.[9]).

Using samarium diiodide as the reagent in the chemistry of high-molecular-mass compounds, we obtained a series of new functional polymers and demonstrated for the first time the formation of the Si–Si bond on treatment with SmI_2.[10]

In contrast to previously published reviews,[11,12] we shall consider here for the first time the possibility of using samarium diiodide in the chemistry of high-molecular-mass compounds as well as new reactions in organic chemistry.

II. The synthesis and properties of divalent lanthanide salts

Lanthanide diiodides are obtained nowadays by the reaction of the corresponding metal with 1,2-diiodoethane (DIE) in anhydrous tetrahydrofuran (THF) under an inert atmosphere at room temperature.[5] The LnI_2 synthesised in this way are used, without being isolated from solution, in reactions with various compounds.

In contrast to other procedures, an interesting feature of this method is the possibility of obtaining exclusively a Ln^{2+} compound and not a mixture of the Ln^{2+} and Ln^{3+} salts. This is

$$Ln + ICH_2CH_2I \longrightarrow LnI_2 + CH_2{=}CH_2$$

Ln = Sm, Yb.

indicated by the colour of the solutions obtained (blue-green for SmI_2 and yellow-green for YbI_2) and the results of various analytical methods: iodometric titration, complexometric titration with ethylenediaminetetraacetic acid (EDTA), absorption spectroscopy, NMR, etc.[13,14]

Since the most stable oxidation state of the lanthanides is +3, Ln^{2+} salts should behave as powerful reductants. The stability of solutions of divalent lanthanides is therefore determined primarily by the stability of the solvent employed under the conditions of high reduction potentials.

As mentioned above, THF is one such stable solvent, but the necessity for the thorough removal of the accumulated peroxides from the initial THF and for its preparation in an anhydrous form give rise to certain difficulties.

Apart from THF, certain other aprotic solvents are resistant to powerful reductants.[15] Kamenskaya et al.[16] showed that lanthanide diiodides do in fact react with, for example, hexamethylphosphoramide (HMPA), whereas in common aprotic solvents such as diethyl ether, dioxane, methylal, and 1,2-dimethoxyethane samarium diiodide does not react with DIE at all; in pyrrolidinone the reaction takes place but solutions containing divalent and trivalent lanthanide compounds are then obtained.[17]

The study of the physicochemical properties of divalent Nd, Sm, Yb, Eu, etc. salts showed that these compounds are in fact most stable in THF.[18] Thus THF is nowadays the most suitable solvent for experiments with divalent lanthanide salts, especially SmI_2. Unfortunately the solubility of these compounds in THF is limited, amounting to 0.1 mol litre^{-1} for SmI_2 and 0.04 mol litre^{-1} for YbI_2 at 20 °C.[1]

An improvement in the solubility of SmI_2 can be achieved by employing organic complexones such as crown-ethers and sodium tetraphenylborate.[18] Thus the Yb^{2+} and Sm^{2+} ions form complexes readily with crown-ethers, which are 3–4 orders of magnitude more stable than the Yb^{3+} and Sm^{3+} complexes. This is associated with the greater size and smaller charge on the Ln^{2+} ions.[19,20] These complexes are readily soluble in the majority of organic solvents, including even nonpolar or weakly polar solvents such as benzene, hexane, halohydrocarbons, etc. (by virtue of the hydrophobic properties of the aliphatic groups of crown-ethers).[21]

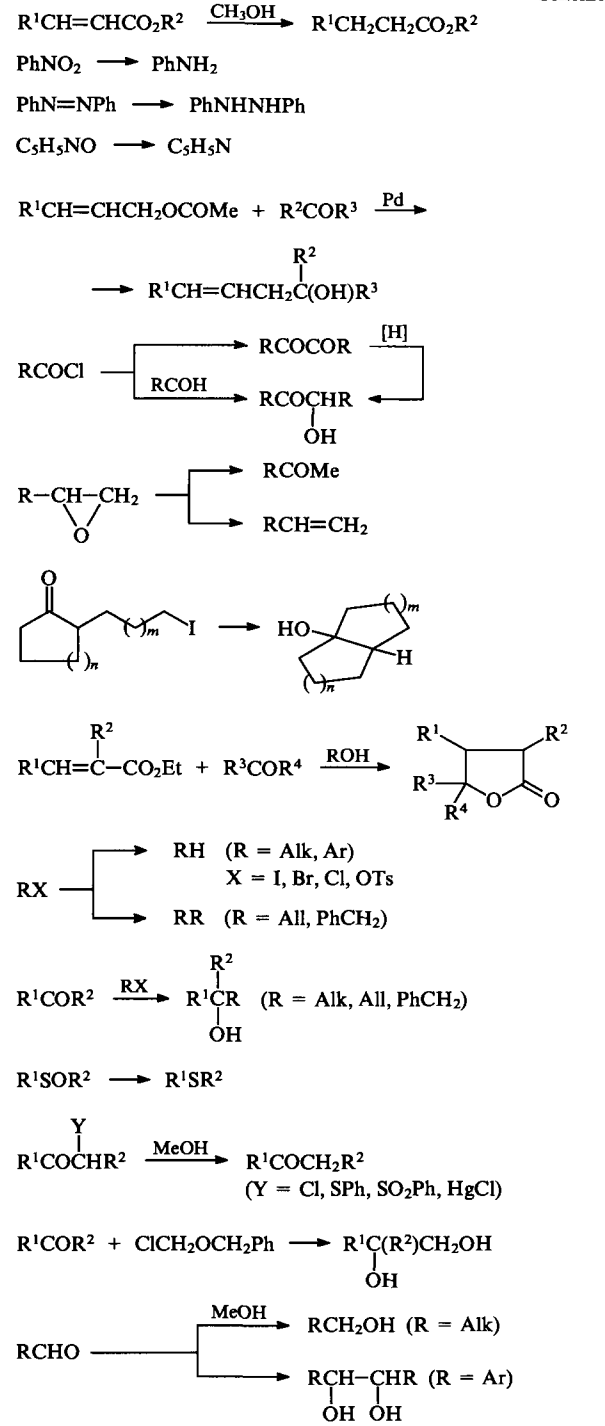
The use of crown-ethers also makes it possible to increase greatly the stability of Ln^{2+} solutions in many solvents, which can be accounted for by the shielding effect of the complexone molecule.[18]

Various diiodoalkanes such as diiodomethane and 2,2-diiodobutane can be used for the preparation of SmI_2 instead of DIE.[17] Other haloalkanes react much less effectively. Thus the reaction with 1,2-dibromoethane in THF is very slow and leads to sparingly soluble samarium dibromide,[17] and the reaction with 1,2-dichloroethane does not occur at all.[9]

In contrast to the dichloride and dibromide, samarium diiodide is readily soluble not only in THF but also in HMPA, acetonitrile, and ethanol.[22]

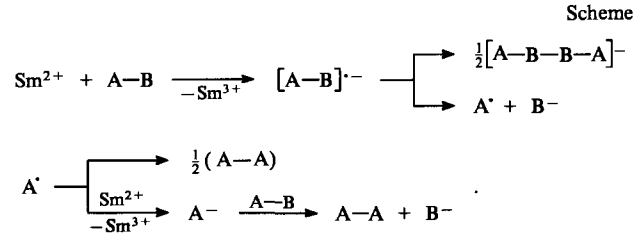
Thus samarium iodide is best among all the salts because of its high reactivity, higher solubility in organic solvents, and the comparative ease of its formation and storage.†

III. Reactions involving samarium diiodide



Samarium diiodide is a powerful reductant, soluble in organic solvents, which behaves under the conditions of organic synthesis as an electron donor and is therefore a reagent capable of promoting reactions involving electron transfer.[24]

In a general form, the known reactions that are carried out successfully in the presence of samarium iodide are presented in Scheme 1. The mechanism of organic reactions involving SmI_2 can be represented by Scheme 2 in the most general form.



It is noteworthy that the reactions involving electron transfer from SmI_2 to the organic substrate A–B with formation of a radical-anion, which subsequently dimerises or is cleaved into an anion and a radical, the latter being capable of reacting subsequently in different ways, have a stepwise radical-ion mechanism.

† SmI_2 is distributed by Aldrich in the form of a 0.1 M solution in THF.[23]

Scheme 1

Scheme 2

The ability of Sm^{2+} and Sm^{3+} ions to form highly coordinated compounds also exerts a specific effect on the reaction. This probably accelerates electron transfer and can affect the mode of reactions with participation of a free radical (see below).

It is seen from Scheme 2 that processes with participation of reactive species of three different types can take place in the system: free radicals, radical-anions, and carbanions, which lead to extensive possibilities for a wide variety of chemical reactions — reduction, condensation, addition, and nucleophilic substitution. It is very significant that reactions of this type take place effectively in the given instance in a virtually neutral medium.

Various types of reactions carried out with the aid of SmI_2 and their mechanisms are examined below.

1. Reduction of halogen-containing hydrocarbons and tosylates

On refluxing for several hours in 0.1 M solution of SmI_2 in THF, primary and secondary alkyl bromides and iodides RHal produce the corresponding alkanes RH in a high yield (80%–95%).[5] Hydrocarbons are obtained similarly from the corresponding tosylates ROTs.[5]

$$RX \xrightarrow[65\ ^\circ C,\ 2\ h]{SmI_2,\ THF} RH$$

X = Hal, OTs.

For X = OTs, the reaction is accelerated in the presence of small amounts of NaI. This gives grounds for the hypothesis that the tosylates are initially converted into the iodides and then into the alkanes (small amounts of alkyl iodides have been detected among products of the reation even when the latter was carried out in the absence of NaI).[25]

Inanaga et al.[26] observed that the redution potential of SmI_2 increases abruptly after the addition of HMPA to a THF solution of SmI_2. Thus phenyl and vinyl halides react with SmI_2 only in the presence of 5% HMPA as the catalyst. Tertiary alkyl halides also react under similar conditions and in both cases even chlorides, which do not usually enter into a reaction of this kind, are reduced. It has been shown that the use of the SmI_2–THF–HMPA system makes it possible not only to expand significantly the range of halogen-containing hydrocarbons reduced with the aid of SmI_2 but also to eliminate the need for prolonged treatment by refluxing. In this case the thermal conditions are milder and the process proceeds at a higher rate and with a quantitative yield of the product.[27]

The addition of HMPA proved to be effective also in a series of other reactions involving samarium diiodide (see below).[28]

In contrast to alkyl halides, benzyl or allyl halides are not reduced by SmI_2 but dimerise in several minutes at room temperature.

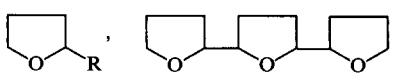
$$2\ PhCH_2Br + 2\ SmI_2 \xrightarrow[20\ min]{20\ ^\circ C} PhCH_2CH_2Ph + 2\ SmBrI_2$$

The following mechanism has been proposed for the reactions of halogen-containing hydrocarbons with SmI_2 in THF:[24]

$$RX + Sm^{2+} \longrightarrow RX^{\cdot -} + Sm^{3+},$$

$$RX^{\cdot -} \longrightarrow \dot{R} + X^-,$$

$$\dot{R} + Sm^{2+} \longrightarrow R^- + Sm^{3+},$$



$$\dot{R} + THF \longrightarrow RH + (THF)^{\cdot},$$

$$R^- + THF \longrightarrow RH + (THF)^-,$$

$$\dot{R} + \dot{R} \longrightarrow R{-}R,$$

R = All, $PhCH_2$.

The presence of THF radicals or carbanions in the reaction medium has been confirmed by the formation of small amounts of different 2-substituted THF derivatives, for example:

Under these conditions, the reaction $R^{\cdot} + SmI_2 \rightarrow R^-SmI_2^+$ apparently does not occur because $RSmI_2$ is absent from the reaction products, although in principle such compounds are known and are entirely stable in an organic medium.[1]

It has been suggested[1] that alkyl halides are hydrogenated in the coordination sphere of the samarium(II) ion bound to several THF molecules (like all lanthanide derivatives, samarium diiodide has the high coordination number 8). This can account for the absence of dimerisation products in the reaction of samarium diiodide with aliphatic halides, while benzyl and allyl halides afford only dimerisation products because the radicals formed are too stable to attack THF molecules and can diffuse into the bulk of the solution and recombine there with another radical.

It is of interest to note that benzyl and allyl halides in many instances form under the influence of samarium diiodide dimeric hydrocarbons in higher yields than in the presence of other reagents, for example Cr^{3+} salts.[29]

A similar recombination of silyl radicals with formation of the Si–Si bond was first observed by the present authors in a study of the effect of SmI_2 on organochlorosilanes.[30] The common method of synthesis of polysilanes used previously, namely from organodichlorosilanes by the Wurtz–Fittig reaction using alkali metals, suffers from a series of disadvantages: severe reaction conditions, low process selectivity, and difficulty in the regulation of the molecular weight characteristics of the polymers formed and in the synthesis of polysilanes with functional group substituents.[31] The methods proposed in recent years are complex, comprise many stages, and are characterised by low yields of the target products.[32]

At the same time, polysilanes, which have specific optical properties, have attracted increased attention.[33] We have developed a single-stage method of synthesis of hexaorganodisilanes from triorganochlorosilanes and SmI_2.

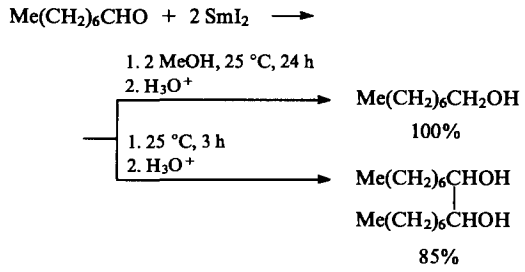
$$2\ R^1R^2R^3SiCl + 2\ SmI_2 \longrightarrow (R^1R^2R^3Si)_2 + 2\ SmI_2Cl.$$

Radicals	Yield (%)
$R^1 = R^2 = R^3 = Me$	< 5
$R^1 = R^2 = Me$, $R^3 = CH_2{=}CH{-}$	75
$R^1 = R^2 = Me$, $R^3 = Ph$	85
$R^1 = R^2 = R^3 = Ph$	90

It was established that, as in the case of the carbo-analogues, the mode and rate of the reaction and the yield of the target product depend on the structure of the organochlorosilane employed (compounds with benzyl and allyl substituents dimerise most effectively). It was also shown that the reaction of diorganodichlorosilanes with SmI_2 affords oligosilanes.

$$n\ R^1R^2SiCl_2 \xrightarrow{SmI_2} Cl{-}\left(R^1R^2Si\right)_n{-}Cl;$$

$R^1 = R^2 = Me$; $R^1 = CH_3$, $R^2 = Ph$.

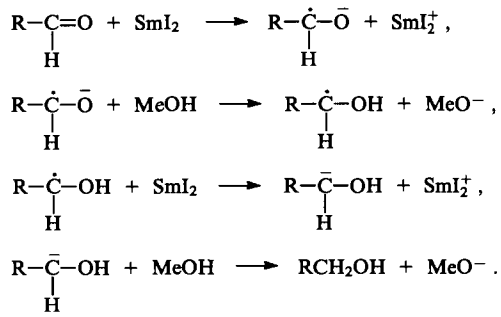


Thus the reduction method based on the use of SmI_2 may be assigned to the class of the most progressive and effective methods of synthesis of hydrocarbons and organosilanes from organic and organosilicon halides.

2. Reactions with carbonyl compounds

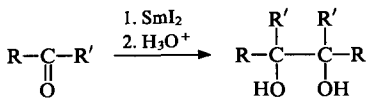
Aldehydes and ketones are reduced by SmI_2, the mode of the reaction depends on its conditions and on the structure of the initial compounds. One of the most interesting features of SmI_2 is its ability to promote the formation of a C–C bond between ketones and aldehydes, on the one hand, and various organic compounds having the general formula RX (X = Hal, OTs, OSO_2Me, OAc), on the other.[24]

a. Reduction of aldehydes and ketones



The interaction of aliphatic aldehydes with SmI_2 in THF in the presence of a proton donor (for example, 1% methanol solution) affords alcohols, whilst in aprotic media the products are pinacols.[2]

Aliphatic ketones are also reduced under analogous conditions but much more slowly. For example, the yield of 2-octanol in the reaction of 2-octanone with SmI_2 is only 12%.[5]

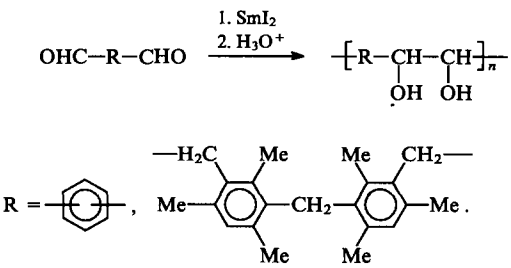


The nature of the proton donor exerts a strong influence on the reaction. Thus, when water is used instead of methanol, 2-octanone is reduced in a satisfactory yield, whereas phenol suppresses the formation of the ketone [alcohol ?].[5]

The selective reduction of the aldehyde group in the presence of a keto-group, which constituted previously a complex problem, is based on the significant difference between the reactivities of the above compounds. Suitable reagents, including modified hydroborates and hydroaluminates, have been proposed for this reaction only recently,[34] but SmI_2 is the most selective. It has been suggested[1] that the reaction proceeds via the following mechanism:

This mechanism is confirmed by the fact that, when MeOD is used instead of MeOH, 90% of RCHDOH and 10% of RCH_2OH is formed. The formation of a small fraction of the protonated rather than deuteriated product can apparently be accounted for by the possibility that hydrogen may be abstracted from THF by the hyroxyalkyl radical.

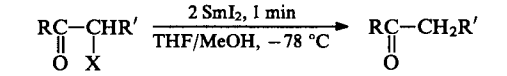
Table 1. The synthesis of pinacols from aldehydes and ketones by treatment with SmI_2.



R	R′	Reaction time/min	Yield (%)
H	Ph	0.5	95
H	*p*-CNC_6H_4	0.5	95
H	*p*-$NO_2C_6H_4$	0.5	95
H	*p*-$HOOCC_6H_4$	0.5	66
H	*p*-$MeOC_6H_4$	1.0	90
Me	Ph	0.5	95
Me	n-C_6H_{13}	1440	80

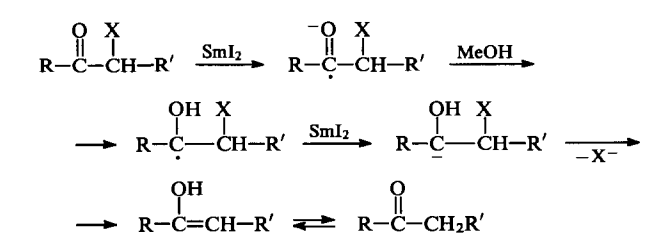
In the absence of a suitable proton donor (methanol), recombination of the intermediate radical-anions leads to a pinacol. Pinacols are formed almost exclusively from aromatic aldehydes and ketones, the reaction involving aldehydes being very fast (taking only 30–60 s at room temperature) with an almost quantitative yield, while the degree of reaction with aliphatic ketones after 24 h is 80%.[35]

The possibility of obtaining pinacols in high yields from aromatic aldehydes containing various substituents in the *para*-position is especially attractive (Table 1). The above method has significant advantages over other procedures for the synthesis of pinacols because of the attainment of high yields of the target product and the exceptionally high reaction rate.



For example, when CeI_2 in THF is used, 12 h is required to synthesise a pinacol from benzaldehyde in 94% yield,[36] while in the presence of aqueous $TiCl_3$ in an alkaline medium the reaction with benzaldehyde is rapid, mainly an alcohol being formed as a side product.[37]

By treating dialdehydes with SmI_2, we synthesised polypinacols with a molecuar mass of the order of $(12-15) \times 10^3$.[38]



Previously only oligomeric pinacols with a molecular mass not exceeding 2×10^3 were obtained by treating terephthalic aldehyde with a zinc complex of $TiCl_4$.[39]

Although ketones are reduced via a mechanism similar to that described for aldehydes, α-substituted ketones require special consideration.[40] Analysis of literature data shows that the α-substituent can be abstracted from such compounds only under extremely severe conditions at an elevated temperature.[41,42] The use of SmI_2 for this purpose in the presence of a proton donor makes it possible to obtain unsubstituted ketones from a wide range of α-substituted ketones in high yields at low temperatures.

X = OAc, $OSiMe_3$, OTs, Cl, SPh, SO_2Ph, OCO_2CH_2Ph, HgCl.

It has been suggested[40] that the reaction proceeds via the formation of a ketyl, which is rapidly protonated by methanol. Treatment with a second equivalent of SmI_2 leads to the formation of a carbanion from which X is then split off. The unsubstituted ketone is obtained as a result of the tautomerisation of the enol produced.

b. Reactions of aldehydes and ketones via the CO group

One of the remarkable properties of samarium diiodide is its ability to promote the formation of a C–C bond between ketones or aldehydes and compounds of different types. It has

been shown that halogen-containing hydrocarbons and tosylates undergo reductive addition to ketones under the influence of SmI_2.[5] Formally this reaction is analogous to the reactions of ketones with a Grignard reagent.

$$n\text{-}C_6H_{13}COMe + MeI \xrightarrow[2.\ H_3O^+]{1.\ SmI_2,\ 65\ ^\circ C,\ 1\ h} n\text{-}C_6H_{13}C(OH)Me_2;\quad 75\%$$

$$n\text{-}C_6H_{13}COMe + Bu^nOTs \xrightarrow[2.\ H_3O^+]{1.\ SmI_2,\ THF} n\text{-}C_6H_{13}C(Me)(OH)\text{—}Bu^n.\quad 95\%$$

Various ketones, both alicyclic and aromatic, interact with the SmI_2–RX system and their reactivities hardly differ from that of 2-octanone described above. The reactivity of the halides diminishes in the sequence RI > RBr ≫ RCl. It is of interest to note that allyl and benzyl halides, which usually tend to dimerise rapidly on treatment with SmI_2, in the presence of a ketone react readily with the latter, forming tertiary alcohols.

$$n\text{-}C_6H_{13}COMe + ICH_2CH{=}CH_2 \xrightarrow[25\ ^\circ C,\ 25\ min]{2\ SmI_2} n\text{-}C_6H_{13}C(Me)(OH)CH_2CH{=}CH_2.\quad 72\%$$

On the other hand, vinyl halides and aromatic halo-compounds do not react with ketones in the presence of SmI_2; in such cases, only the conversion of the ketones into pinacols to the extent of 10%–20% is observed.[5]

The following mechanism has been proposed for the alkylation of ketones, involving the formation of intermediate radical compounds:[24]

$$RX + SmI_2 \longrightarrow RX^{\bullet-}SmI_2^+ \longrightarrow \dot{R} + SmI_2X, \quad (1)$$

$$\dot{R} + SmI_2 \longrightarrow R^-SmI_2^+, \quad (2)$$

$$R^1R^2C{=}O + SmI_2 \longrightarrow R^1R^2\dot{C}O^-SmI_2^+, \quad (3)$$

$$R^1R^2\dot{C}O^-SmI_2^+ + \dot{R} \longrightarrow RR^1R^2CO^-SmI2^+ \xrightarrow{H_3O^+} RR^1R^2COH, \quad (4)$$

$$R^1R^2C{=}O + R^-SmI_2^+ \longrightarrow RR^1R^2CO^-SmI_2^+ \xrightarrow{H_3O^+} RR^1R^2COH. \quad (5)$$

The mechanism of the reactions of the radical R$^\bullet$ has not been elucidated in detail: it may be that it is reduced by SmI_2 to R^- [reaction (2)] or recombines with the ketyl radical arising as a result of electron transfer from SmI_2 to the ketone [reaction (4)]. At any rate, the radical mechanism explains the presence in the reaction product of small amounts of compounds such as the α-R-alkylated THF.

The reaction is much faster when small amounts of $FeCl_3$ (1 mass % of SmI_2) are added. The catalytic effect of $FeCl_3$ may be due to its ability to promote the formation of ketyl radicals (this was demonstrated for the Grignard reaction) or the conversion of Sm^{2+} into Sm^{3+}.[43] In one way or another, $FeCl_3$ behaves as a compound facilitating electron transfer in reactions with SmI_2. HMPA also functions as a catalyst of the reaction.[44]

The reduction of aliphatic aldehydes, leading to a mixture of products, proceeds in a more complex manner.[45]

$$n\text{-}C_7H_{15}CHO + MeI \xrightarrow[2.\ H_3O^+]{1.\ SmI_2,\ 25\ ^\circ C} n\text{-}C_7H_{15}CH(OH)Me\ (16\%) + n\text{-}C_7H_{15}COMe\ (6\%) + n\text{-}C_7H_{15}CH_2OH\ (38\%) + n\text{-}C_7H_{15}C(OH)Me_2\ (32\%).$$

The observed reactions may be based on the Meerwein–Ponndorf reaction, which proceeds very rapidly with participation of secondary samarium alkoxides: $n\text{-}C_{17}H_{15}CH(Me)OSmI_2$ is formed initially and then reacts rapidly with the aldehyde, forming $n\text{-}C_7H_{15}COMe$ and $n\text{-}C_7H_{15}CH_2OSmI_2$; a tertiary alcohol is obtained from the ketone and CH_3I in the presence of SmI_2.

It has been shown recently[43] that dicyclopentadienylsamarium, readily and rapidly obtained by the exchange reaction between SmI_2 and cyclopentadienylsodium, is significantly more effective in the reaction of aliphatic aldehydes with halogen-containing hydrocarbons. In contrast to SmI_2, it does not catalyse the Meerwein–Ponndorf or Tishchenko side reaction.

It has also been found that secondary alcohols are formed from aldehydes in a satisfactory yield when the more reactive benzyl or allyl halides are employed.[45]

$$n\text{-}C_7H_{15}CHO + ICH_2CH{=}CH_2 \xrightarrow[25\ ^\circ C,\ 5\ min]{2\ SmI_2,\ THF} n\text{-}C_7H_{15}CH(OH)CH_2CH{=}CH_2\quad 75\%$$

A mechanism similar to that discussed above for the reduction of ketones has been proposed for this reaction.

$$RX + SmI_2 \longrightarrow RX^{\bullet-}SmI_2^+ \longrightarrow \dot{R} + SmI_2X$$

$$R'CHO + SmI_2 \longrightarrow R'CHO^{\bullet-}SmI_2^+$$

$$R'CHO^{\bullet-}SmI_2^+ + \dot{R} \longrightarrow RR'CHO^-SmI_2^+ \xrightarrow{H_3O^+} RR'CHOH$$

It is interesting to note that the CN, NO_2, CO_2R, and other groups are not then involved.[35]

$$n\text{-}C_6H_{13}COMe + TsO(CH_2)_9CO_2Me \xrightarrow[2.\ H_3O^+]{1.\ 2\ SmI_2,\ 65\ ^\circ C,\ 2\ h} n\text{-}C_6H_{13}C(OH)(CH_2)_9CO_2Me\ (CH)\quad 63\%$$

γ-Hydroxynitriles have been obtained in a low yield in the reaction of ketones with acrylonitrile.[47]
