$$R^1COR^2 + CH_2{=}CH\text{—}CN \xrightarrow[THF,\ KOH]{2\ SmI_2} R^1R^2C(OH)\text{—}CH_2CH_2CN\quad 17\%\text{–}20\%$$

It has been observed recently that, on treatment with samarium diiodide, allyl acetates also interact with carbonyl compounds in the presence of catalytic amounts of a palladium complex [$Pd(OAc)_2$ + PPh_3 or $Pd(PPh_3)_4$] to form homoallyl alcohols in a good yield.[46]

$$R^1CH{=}CHCH_2OCOCH_3 + R^2COR^3 \xrightarrow[SmI_2,\ 0\ ^\circ C,\ 2\ h]{Pd(PPh_3)_4} R^1CH{=}CHCH_2C(OH)R^2R^3.$$

Aromatic and α,β-unsaturated carbonyl compounds react differently, affording mainly dimerisation products — pinacols.[46] The use of readily available allyl acetates in the aldehyde and ketone reduction reactions makes it possible to replace allyl halides, which are difficult to obtain, unstable, and toxic.

In the presence of SmI_2, aldehydes and ketones also react with chloromethyl sulfides $ClCH_2SR$ to form hydroxythioethers.[48]

$$ClCH_2SR + R^1R^2CO \xrightarrow{SmI_2,\ THF} R^1R^2C(OH)CH_2SR$$

R = Me, Ph.

A reaction involving the coupling of carbonyl compounds $R^1C(O)R^2$ [$R^1 = PhCH_2$, $R^2 = Me$; $R^1 + R^2 = (CH_2)_{11}$; $R^1 = cyclo\text{-}C_6H_{11}$, $R^2 = H$] with alkynes $R^3C{\equiv}CX$ (X = Ph, CH_2OAc, Bu^t) has also been described. The reaction is promoted by the SmI_2–HMPA–THF system (Bu^tOH, 20 °C, 5 min); it results in the formation of the allyl alcohols $R^1R^2C(OH)CH=CHX$.[49]

Thus the use of samarium diiodide in reactions involving reductive addition to the carbonyl group makes it possible to obtain alcohols with a wide variety of structures in satisfactory yields.

c. Hydroxymethylation of carbonyl compounds

The interesting reaction involving the hydroxymethylation of carbonyl compounds on treatment with samarium diiodide has been recently achieved by Imamoto et al.[50] Ketones readily interact in this reaction with benzyl chloromethyl ether at room temperature, forming alcohols, which afford diols on subsequent hydrogenation.

$$R'\underset{\underset{O}{\|}}{C}R + ClCH_2OCH_2Ph \xrightarrow{2\ SmI_2,\ 20\ °C}$$

$$\longrightarrow RR'\underset{\underset{OH}{|}}{C}CH_2OCH_2Ph \xrightarrow[Pd/C]{H_2} RR'\underset{\underset{OH}{|}}{C}CH_2OH$$

Aldehydes are not reduced to alcohols but are converted into pinacols in 80%–90% yield. However, in the presence of equimolar amounts of the dimethyl or dibenzyl ether of tetraethylene glycol, which form a complex with SmI_2, it is possible to obtain alcohols in 50%–70% yield.

$$PhCH_2CH_2CHO + ClCH_2OCH_2Ph \xrightarrow{2\ SmI_2,\ 20\ °C}$$

$$\longrightarrow PhCH_2CH_2CH(OH)CH_2OCH_2Ph \xrightarrow[Pd/C]{H_2}$$

66%

$$\longrightarrow PhCH_2CH_2\underset{\underset{OH}{|}}{C}HCH_2OH$$

90%

In the interaction of carbonyl compounds with diiodomethane in the presence of metallic samarium or SmI_2, an iodohydrin is formed as an intermediate, its hydrolysis subsequently affording the corresponding diol.[51, 52]

$$R^1\underset{\underset{O}{\|}}{C}R^2 + CH_2I_2 \xrightarrow{SmI_2\ or\ Sm} R^1R^2\underset{\underset{OH}{|}}{C}CH_2I$$

Thus the hydroxymethylation of carbonyl compounds may be an effective reaction in the synthesis of 1,2-diols.

d. Reactions with carboxylic acids and their derivatives

Carboxylic acids and their derivatives (esters, amides, and anhydrides) are as a rule resistant to the action of SmI_2.[5] However, it has been shown recently that, in the presence of bases and a proton donor, they are readily reduced by SmI_2 to the corresponding alcohols at room temperature.[53]

$$PhCOOR^1 \xrightarrow[THF,\ R^1OH,\ 20\ °C]{SmI_2,\ HB} PhCH_2OH$$

$$+ \left\{[PhCH(OH)]_2 + PhCH_2CH(OH)Ph + PhCH_2COPh\right\}$$

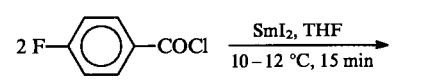
R^1 = Me, PhCO; HB = $LiNH_2$, LiOMe, KOH.

$$PhCONHR^2 \xrightarrow[THF,\ R^2OH,\ 20\ °C]{SmI_2,\ HB} PhCH_2OH + PhCH_2NHR^2$$

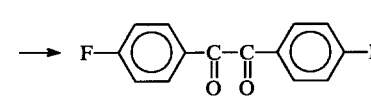
R^2 = H, Ph.

Carboxylic acid chlorides do not form the expected reduction products, such as aldehydes or primary alcohols, on reaction with SmI_2. On the other hand, they enter very rapidly into an addition reaction. The main product obtained is then an α-diketone RCOCOR in a yield ranging from 40% (R = Alk) to 80% (R = Ar), an α-ketol RCOCH(OH)R being formed as a side product.[55]

$$2\ RCOCl + 2\ SmI_2 \xrightarrow{25\ °C,\ 2-4\ min} R\underset{\underset{O}{\|}}{C}\text{–}\underset{\underset{O}{\|}}{C}R + 2\ SmI_2Cl$$

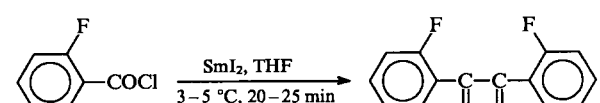


R = Ph (78%), *p*-ClC_6H_4 (72%), *p*-$MeOC_6H_4$ (69%), $Cl(CH_2)_4$ (54%).



The product yields vary depending on R.

The asymmetric reduction of benzil to benzoin takes place in the presence of optically active compounds such as quinine or quinidine. This reaction proceeds even more effectively in the presence of HMPA.[54]



$$Ph\underset{\underset{O}{\|}}{C}\text{–}\underset{\underset{O}{\|}}{C}Ph \xrightarrow[[H]]{SmI_2} Ph\underset{\underset{OH}{|}}{\overset{\overset{H}{|}}{C}}\text{–}\underset{\underset{O}{\|}}{C}Ph$$

We have obtained difluorobenzils by condensing under mild conditions the chlorides of *p*- and *o*-fluorobenzoic acids by treatment with SmI_2 in THF.[10]

50%

65%

These products were then used to synthesise high-molecular-mass aromatic ethers by the nucleophilic substitution of the fluorine atom by alkali metal bisphenoxides and subsequent conversion of the α-diketone groups into quinoxaline groups.[10]

A paraffin-like admixture of C_{23-25} alkanes was also detected in the unpurified product of the reactions of acid chlorides or fluorides.[56] They can be produced in the oligomerisation

of ethylene, formed at an early stage in the interaction of metallic samarium with diiodoethane. SmI_2 or SmI_2Cl might have served as the oligomerisation initiator both in the samarium diiodide formation stage and in the stage involving the synthesis of the diketones.

According to ideas put forward in the literature,[57] the acid chloride condensation reaction proceeds via the formation of radical-ions, which are cleaved to acyl radicals and these are reduced to acyl anions. The latter react in their turn with a second molecule of the acid chloride, affording an α-diketone (the direct recombination of the acyl radicals is insignificant).

$$RCOCl + SmI_2 \longrightarrow [RCOCl]^{\cdot -}\ SmI_2^+$$

$$[RCOCl]^{\cdot -} \longrightarrow RC\dot{O} + Cl^-$$

$$RC\dot{O} + SmI_2 \longrightarrow$$

$$\longrightarrow RCO^-SmI_2^+ \xrightarrow{RCOCl} ROC{-}COR + SmI_2Cl$$

$$2\,RC\dot{O} \longrightarrow ROC{-}COR$$

The last process takes place to a very insignificant extent. The proposed mechanism explains the satisfactory yield (75%) of the α-diketone from $PhCH_2COCl$. It is known that the acyl radical $PhCH_2CO^{\cdot}$ is rapidly decarbonylated ($k_c = 5.2 \times 10^7\ s^{-1}$) to $PhCH_2^{\cdot}$. The absence of toluene and 1,2-diphenylethane from the reaction products is evidence that the acyl radical is reduced to the acyl anion at a rate greatly exceeding $5.2 \times 10^7\ s^{-1}$. The anion is then acylated by the acid chloride, affording the α-diketone. The presence of the intermediate acyl anion $RCO^-SmI_2^+$ in the reaction is also confirmed by its interaction with electrophiles other than RCOCl, for example aldehydes and ketones, which results in the formation of α-hydroxyketones after hydrolysis: their formation can be accounted for by nucleophilic acylation.[57]

$$Bu^tCOCl + EtC(=O)H \xrightarrow[20\ ^\circ C,\ 4\ min]{2\ SmI_2} Bu^t{-}C(=O){-}CH(OH){-}Et$$

64%

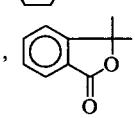
The direct synthesis of α-diketones from carboxylic acid chlorides by treatment with SmI_2 has undoubted advantages over other methods of synthesis of these compounds based on multistage procedures such as the oxidation of monocarbonyl compounds or their α-substituted derivatives (for example acyloins, derivatives of enediols, glycols, etc.) or their synthesis from aromatic compounds and oxalyl chloride by the Friedel–Crafts reaction.[58]

A new strategy for the synthesis of α-hydroxyketones by the reaction of an alkyl halide, isonitrile, and a carbonyl compound with SmI_2 has also been proposed.[59]

$$R^1Hal + ZNC \xrightarrow[-15\ ^\circ C,\ 3\ h]{2\ SmI_2,\ THF/HMPA} R^1C(=NZ){-}SmI_2 \xrightarrow[0\ ^\circ C,\ 14\ h]{R^2R^3C=O}$$

$$\longrightarrow R^1C(=NZ){-}CR^2R^3(OH) \xrightarrow{H_3O^+} R^1C(=O){-}CR^2R^3(OH)$$

Z = 2,6-dimethylphenyl (Me, Me)



The mild conditions make it possible to employ this method for the synthesis of compounds with various functional groups, including, for example, terminal acetylenic and trimethylsilyl ether groups, and also for the synthesis of α-hydroxyaldehydes.

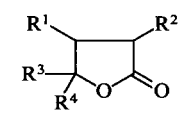
The formation of α-diketones in the reaction of carboxylic acid chlorides with SmI_2 may serve as a basis for the formation of the corresponding polymers. The available information about the synthesis of such polymers by other methods is extremely scant. The possibility of obtaining polyhydroxyketones and polybenzoins by the acyloin or benzoin condensation of terephthalic acid chloride and terephthalic anhydride respectively, which were oxidised to poly-α-diketones by prolonged refluxing in nitric acid, has been described.[60,61] Only insoluble high-molecular-mass oligomers were obtained in 50%–70% yield.[62]

We synthesised for the first time α-diketone homopolymers and copolymers in a quantitative yield[63] by the reaction of aromatic dicarboxylic acid chlorides with SmI_2 in THF at room temperature for 10–15 min. It was found that the acid fluorides are also reactive in this process.

$$XOCRCOX + SmI_2 \longrightarrow -\left[R{-}CO{-}CO\right]_n-$$

R =  ,

R′ = —O—, —C(CF₃)₂—,  ;



X = Cl, F.

The polymers synthesised have an amorphous structure, a molecular mass of the order of 25×10^3, and a softening temperature of 250–290 °C. They are readily soluble in various organic solvents.

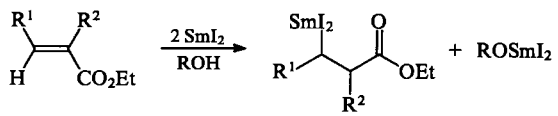
e. The cyclisation reactions of carbonyl compounds

Intermolecular cyclisation. In the presence of samarium diiodide and a proton donor, aldehydes and ketones interact with alkenes containing electron-accepting substituents.[47]

$$R^1CH{=}CR^2CO_2Et + R^3COR^4 \xrightarrow[ROH,\ 3\ h]{2\ SmI_2}$$

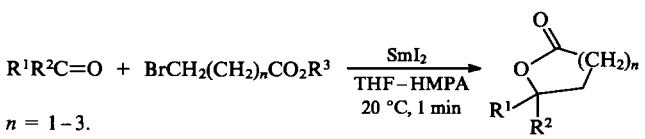
Methyl, ethyl, and especially butyl alcohols can be used as the proton donor. In order to suppress the reduction of the ketone, the dimethyl ether of tetraethylene glycol, which forms a complex with SmI_2, is added to the reaction mixture.[64]

Whereas in the routinely used method of the electrochemical synthesis of γ-lactones from activated olefins and ketones or aldehydes in the presence of chlorotrimethylsilane only aliphatic compounds are reactive, when samarium diiodide is used the reaction can be extended to aromatic aldehydes and ketones.[64] The reaction apparently proceeds via a radical mechanism.[47]



$$R^3R^4C{=}O \xrightarrow{SmI_2} R^3R^4\dot{C}{-}OSmI_2 \xrightarrow{H\ =\ CR^1R^2CO_2Et}$$

$$\longrightarrow R^3R^4C(OSmI_2){-}HCR^1{-}\dot{C}R^2{-}CO_2Et \longrightarrow$$

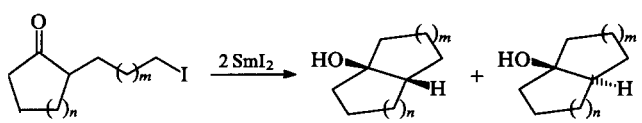


$$\xrightarrow{ROH,\ SmI_2} R^3R^4C{-}HCR^1{-}HCR^2{-}CO_2Et$$

$$\xrightarrow{-EtOSmI_2}$$

However, another mechanism involving the formation of samarium homoenolate is not ruled out either.

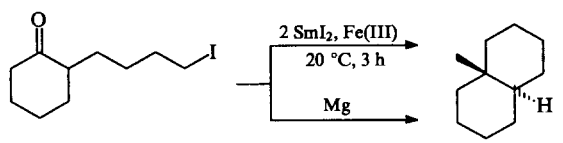
The use of small amounts of HMPA in this reaction makes it possible to achieve the direct synthesis of γ-, δ-, or ε-lactones from the corresponding bromoesters, in particular from the readily available industrially produced β-bromopropionate, γ-bromobutyrate, or δ-bromovalerate, in satisfactory yields. [52,65]



$n = 1-3$.

75%–82%

Thus the use of SmI_2 has made it possible to develop a new single-stage method of synthesis of lactones, the distinctive features of which are simplicity, technological convenience, and effectiveness.

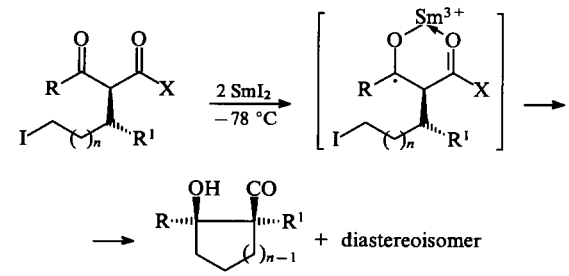


Intramolecular cyclisation. Molander and coworkers [66–68] have shown that, when SmI_2 is used as the reagent, the Barbier as well as Reformatsky reactions take place readily and smoothly. [69]

The intramolecular cyclisation reaction (the Barbier reaction) plays an important role in organic synthesis. A series of methods for carrying out a reaction of this type have been developed. [70] The most common include the cyclisation of 2-(ω-iodoalkyl)cycloalkanones with formation of the corresponding mixture of diastereoisomeric bicyclic alcohols.

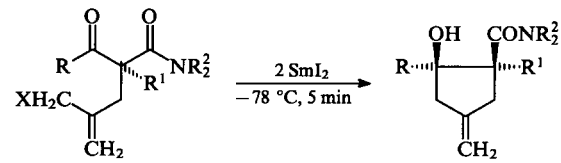
By regulating the length of the iodoalkyl side chain and the ring size in the initial cycloalkanone, it is possible to obtain a wide variety of bicyclic compounds. However, the use of traditional reductants, in particular alkali [71] and alkaline earth metals, [72] in this process led to the formation of bicyclic alcohols with only three-, four-, and five-membered rings.

The use of SmI_2 makes it possible to achieve the intramolecular cyclisation of haloketones accompanied by the formation of bicyclic alcohols with six-membered and in certain cases also with seven-membered rings in a high yield. [66]



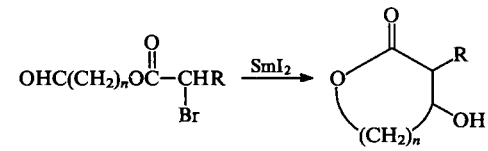
95%

In addition, the stereocontrolled cyclisation of 2-(ω-iodoalkyl)β-ketoesters and 2-(ω-iodoalkyl)-β-ketoamides‡ takes place on treatment with SmI_2, affording high yields of the esters and amides respectively of *cis*-2-hydroxycycloalkanecarboxylic acids with five-, six-, and even seven-membered rings. [67]



‡ When activated magnesium is used at room temperature, cyclisation does not occur and the initial reagent is isolated. [73]

In view of the very strong affinity of the samarium ion for the oxygen atom in the reactions of carbonyl compounds with SmI_2, a stable chelate is formed fairly readily and the process proceeds via an intermediate stage involving the formation of a samarium-containing metallocycle. The stereoselectivity of all the processes is exceptionally high under these conditions.

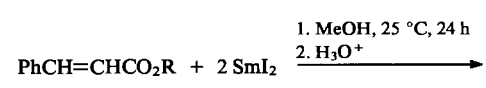


$X = NR^2_2, OR^2$.

2-(ω-Haloallyl)-β-ketoamides also cyclise readily.

In the presence of SmI_2, the reaction proceeds under mild conditions, which makes it possible to obtain cyclic systems with various functional groups which remain unaffected. Thus SmI_2 proved to be an extremely effective reagent in the stereocontrolled intramolecular Barbier reactions.

Tabuchi et al. [74] established that the use of SmI_2 proved to be most effective in the synthesis of medium and large lactone rings. In particular, eight- and nine-membered rings, the synthesis of which by the traditional method has been extremely difficult, can now be obtained fairly readily. Inanaga and coworkers have also been working on these lines. [12]



76%–96%

$n = 4-10$.

3. Reduction of C=C double bonds

On treatment with SmI_2 solutions, the conjugated double bond is reduced even at room temperature in contrast to an isolated double bond. [5] Thus α,β-unsaturated acids and esters are reduced in a high yield by samarium diiodide in THF in the presence of methanol. [1]

R = H, Et.

However, for conjugated esters, this reaction is not the only one possible. For example, when an unsaturated ester having a more complex structure is acted upon by SmI_2, the following reaction takes place with 90% conversion: [2]

$$MeCH(OH)CH{=}C(Me)CO_2Et + 2\,SmI_2 \xrightarrow[2.\,2\,H_2O^+]{1.\,THF} MeCH{=}CHCH(Me)CO_2Et\,.$$

The carbonyl groups in α,β-unsaturated ketones and aldehydes are also partially reduced, so that competing reactions involving the reduction of the C=O and C=C groups are possible.

4. Reactions with nitrogen-containing compounds

The effect of SmI_2 on various nitrogen-containing functional groups has been investigated. Aromatic and aliphatic nitriles do not undergo any changes in its presence.[75] Aromatic nitro- and azo-compounds are readily reduced by SmI_2 in THF at room temperature.[76]

$$PhNO_2 \xrightarrow[20\ ^\circ C,\ 5\ min]{8\,SmI_2} PhNH_2 \quad 85\%$$

$$NO_2C_6H_4NH_2 \xrightarrow[20\ ^\circ C,\ 5\ min]{8\,SmI_2} NH_2C_6H_4NH_2 \quad 89\%$$

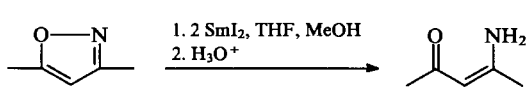
$$Ph{-}N{=}N{-}Ph \xrightarrow[2\%\ MeOH,\ 20\ ^\circ C]{2\,SmI_2} PhNHNHPh \quad 95\%$$

Picoline and pyridine *N*-oxides are converted into the corresponding bases.[75]

$$MeC_5H_4NO \xrightarrow[20\ ^\circ C,\ 5\ min]{2\,SmI_2} MeC_5H_4N \quad 83\%$$

$$C_5H_5NO \xrightarrow[65\ ^\circ C,\ 10\ min]{2\,SmI_2} C_5H_5N \quad 80\%$$

Arsenic oxides are reduced similarly.[76]



The rapid and selective reduction of *m*- and *p*-nitrobenzonitriles to the corresponding cyanoanilines is particularly remarkable.[75]

$$m\text{-}NCC_6H_4NO_2 + 8\,SmI_2 \xrightarrow[MeOH,\ 25\ ^\circ C]{THF} m\text{-}NCC_6H_4NH_2\,.$$

It may be that the reactivity of the nitro-group in these compounds is enhanced by the electron-accepting effect of the CN group.[75]

Schiff bases, for example benzylideneaniline, are reduced to the amines by samarium diiodide in the presence of methanol. Oximes form complex mixtures; isomeric amines have been isolated for benzaldehyde oxime.

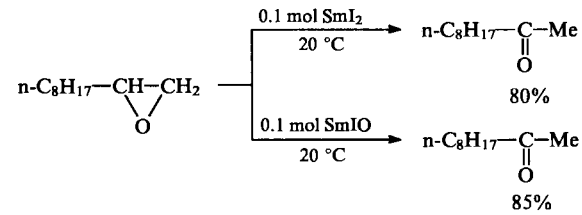
It has been observed recently that the N–O bond in isoxazoles is cleaved selectively by SmI_2.[77]

96%

5. Reactions with epoxides and sulfoxides

On treatment with samarium diiodide, epoxides are converted into olefins even at room temperature.[5]

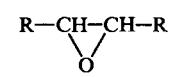
$$PhCH_2CH{-}CH_2 \xrightarrow[25\ ^\circ C,\ 24\ h]{2\,SmI_2} PhCH_2CH{=}CH_2\,.$$



82%

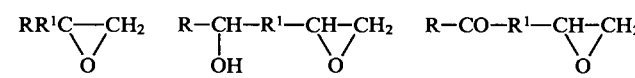
Sulfoxides are similarly reduced to sulfides.

$$R{-}\overset{\overset{O}{\|}}{S}{-}R^1 \xrightarrow[65\ ^\circ C,\ 2\ h]{2\,SmI_2} R{-}S{-}R^1 \quad 90\%$$

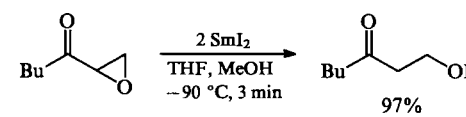


The deoxidation of organic heteroatomic oxides takes place almost instantaneously in the presence of HMPA in a quantitative yield; even triphenylphosphine oxide is reduced under these conditions.[23]

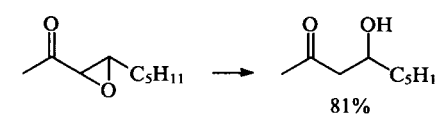
$RCOCH_3$ is obtained as a side product in the reactions of SmI_2 with terminal epoxides. Its formation is apparently associated with the effect of Sm^{3+}, which accumulates during the reduction process.[78] During the reaction, SmI_2 is converted into $I_2SmOSmI_2$, which decomposes slowly, affording a mixture of SmI_3 and SmIO. The authors suggest that it is in fact the latter compound which acts as the catalyst of the rearrangement of the terminal epoxide to the corresponding methyl ketone. The following reactions indicate this:



Consequently small amounts of samarium diiodide catalyse the isomerisation of terminal epoxides RCOMe, in contrast to other catalysts which lead to the exclusive formation of an aldehyde.[74]

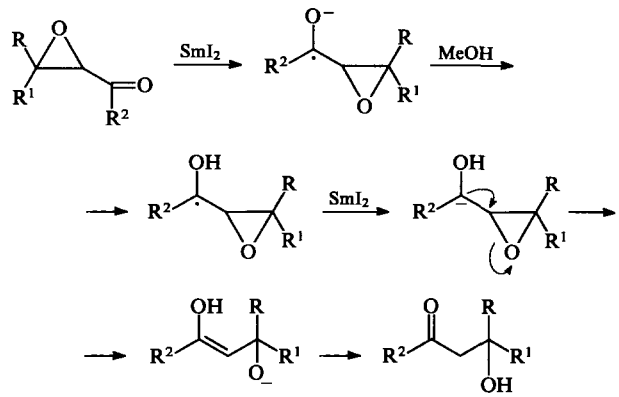


The rearrangement of 1,2-disubstituted epoxides to the corresponding methyl ketones proceeds with greater difficulty. Internal epoxides



are also converted into ketones very slowly. The reaction is altogether uncharacteristic of epoxides of other types.

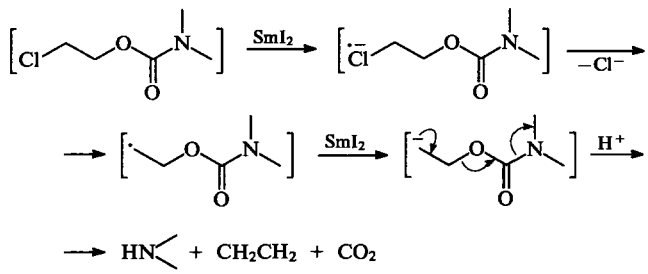
It has been shown recently that α,β-epoxyketones are converted into β-hydroxyketones (aldols) on treatment with SmI_2.[79]



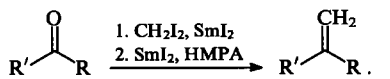
97%

81%

Primary, secondary, and tertiary cyclic and alicyclic aldols can be obtained in high yields by this procedure.



It has been suggested[79] that the reaction proceeds via the formation of a ketyl, which is rapidly protonated by methanol. On treatment with a second equivalent of samarium diiodide, a carbanion, which induces the opening of the epoxide ring, is obtained. Tautomerisation of the enol formed leads to the formation of a ketone.



Thus a wide variety of aldols, including chiral aldols which are not obtainable by traditional methods, can be synthesised by treatment with samarium diiodide.[80–82]

6. Other reactions

The use of SmI_2 as a very powerful reducing agent frequently makes it possible to solve problems in organic chemistry of the kind which it has not so far been possible to solve using other reductants. Thus it has been impossible for a long time to obtain an amine from 2-chloroethyl carbamate; the use of all the reagents known for reactions of this kind led to the formation of hydroxyethyl carbamate as the main product.[83] On the other hand, samarium diiodide cleaves 2-chloroethyl carbamate effectively, forming an amine.[84] The rapid and selective course of the reaction can be accounted for by the ability of samarium diiodide to reduce rapidly the intermediate radical to the anion.

It has also been possible to achieve the monoiodomethylation of carbonyl groups at room temperature (with subsequent reductive elimination), i.e. to achieve a reaction which had been regarded hitherto as impossible.[27,85] The process is completed after 3 min and the product yield is extremely high (73%–80%).

Thus, by virtue of the very high reduction potential of divalent samarium, it has become possible to carry out various kinds of substitutions for functional groups which cannot be achieved by traditional methods.

* * *

The range of organic reactions with participation of SmI_2 has been expanding continuously. Thus it has been possible to achieve recently the reduction of triple bonds (in combination with a catalyst based on transition metals),[12] the cyclisation of aromatic radicals,[86] dimerisation reactions with reduction of derivatives of conjugated unsaturated carboxylic acids,[12] intramolecular cyclisation of nonactivated unsaturated ketones,[87] etc.

Samarium diiodide is used in the synthesis of new functional polymers and oligomers. It is of interest to employ the reactions with SmI_2 not only for the synthesis of new polymers but also for the modification of known polymers by incorporating reactive groups in their main chain. This leads to extensive prospects for subsequent chemical reactions of the polymers, including the formation of heat-resistant and thermostable linear, branched, and network heterochain high-molecular-mass compounds, including organometallic compounds.

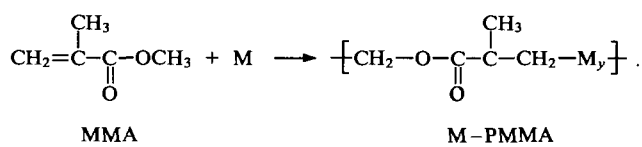
II. Effect of metals on the thermal degradation of polymers 357
III. Thermal degradation of polymers in the presence of metal halides 358
IV. Effect of metal acetylacetonates on the thermal degradation of polymers 362



Abstract. The effect of additions of metals and of their halides and acetylacetonates on the thermal degradation of polymers [mainly, poly(methyl methacrylate)] has been studied by various physicochemical methods (thermogravimetry, NMR, IR, and UV spectroscopy, X-ray structural analysis, DSC, etc.). The results are analysed in terms of the use of these additives in polymers as ecologically clean retardants. The bibliography includes 40 references.

I. Introduction

The study of the pyrolysis of polymers with formation of gaseous combustible thermal degradation products is important from the point of view of the protection of polymer materials from contact with flames. Nonmetallic compounds containing chlorine, bromine, phosphorus, boron, and sulphur have previously been used[1,2] as additives in order to protect the polymers from combustion. The study of the effect of metals and their compounds on the thermal degradation of polymers was stimulated by the current search for retardants in which the currently used toxic additives[3,4] are replaced by other materials.

II. Effect of metals on the thermal degradation of polymers

Cardenas and Retamal[5] studied the effects of the metals Au, Cu, Ga, In, Ge, Sn, Sb, and Bi (when dispersed in methyl methacrylate MMA) on the polymers (PMMA) produced by the polymerisation of MMA in the presence of azo-isobutyronitrile. The following reaction was proposed[5–8] for the synthesis of polymers containing a metal previously dispersed in the monomer:

MMA M–PMMA

Uspekhi Khimii **63** (4) 373–382 (1994); translated by J I Carasso

The polymer samples contained only 2% of the metal; the molecular mass of the polymers was $(2.7-5) \times 10^5$ (see Ref. 8).

The thermogravimetric curves obtained in the study of the polymer samples are shown in Fig. 1. The temperatures of the onset of decomposition (T_d) of these polymers are given in Table 1. The highest T_d values are found for Au–PMMA and Bi–PMMA.

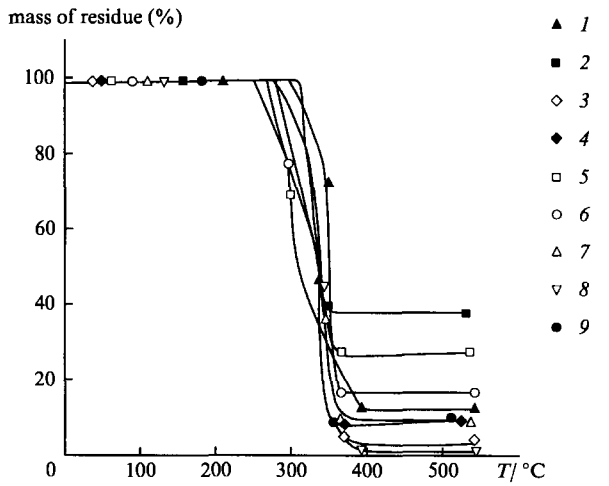

Figure 1. Thermogravimetric curves for the dissociation of M–PMMA compositions containing Bi (*1*), Sn (*2*), Au (*3*), Pd (*4*), Cu (*5*), Ge (*6*), Ga (*7*), In (*8*), and Sb (*9*) at a heating rate of 10 °C min^{-1}.

Table 1. Kinetic parameters for metal polymethacrylates.

Polymer	Z/s^{-1}	E_a/kJ mol^{-1}	T_d/°C
Au–PMMA	2.6×10^4	99.3	300
Bi–PÛÛÀ	2.3×10^2	78.9	325
In–PÛÛÀ	1.4×10^2	74.2	275
Cu–PÛÛÀ	2.4×10^2	70.6	240
Ge–PÛÛÀ	4.8×10^1	64.1	225
Sb–PÛÛÀ	2.5×10^1	63.9	275
Pd–PÛÛÀ	1.5×10^1	61.5	250
Sn–PÛÛÀ	1.4×10^1	61.0	250
Ga–PÛÛÀ	4.3	51.5	200

By analysis of the kinetic data on the loss of mass of the samples in an inert medium it was found that the metal polymers dissociate by a zero-order reaction whose activation energies (E_a) and pre-exponential factors (Z) are given in Table 1. It follows from these results that the activation energy depends on the nature of the metal. In particular, Au–PMMA is a very stable system, just as gold is stable towards oxidation. On the other hand gallium is an easily oxidised metal, and in the Ga–PMMA system we observe the lowest values of the activation energy and of the incipient decomposition temperature.

Systems containing rhodium and cobalt were studied in detail by Wilkie and coworkers,[9–12] who reported a continuing study of the effect of metals on the thermal degradation of polymers aimed at the possibility of using these compounds as retardants of the combustion of polymers.

The aim of this review is to discuss some other recently reported studies of the mechanism of the effect of metal compounds on the thermal degradation of polymers in the case of the halides of chromium and magnesium.

III. Thermal degradation of polymers in the presence of metal halides

Beer et al.[12] studied the effects of Cr(III) in anhydrous salts and crystal hydrates on the oxidation of PMMA. The prepared compositions of these materials were placed in glass tubes which were evacuated and sealed. The tubes were then heated for 2 h at predetermined temperatures. The IR spectra of the uncondensed reaction products detected 6% of methane and carbon monoxide from the starting material. The condensed gases amounted to 44% of the sample (mainly the monomer, CO_2, HCl, and water). The fraction soluble in chloroform was 13%. The IR spectra of this fraction showed the presence of carbonyl and carboxyl products.

In the pyrolysis of pure PMMA the products contain many oligomers, but if the reaction is carried out in the presence of $CrCl_3$ no oligomers are detected.

The fraction insoluble in chloroform contained 36% of the initial sample. The IR spectrum in this case suggests the presence of anhydrides with absorption bands at 1800, 1760, and 1150 cm^{-1}. An X-ray analysis of the solid residue showed the presence of CrOCl and CrO_3.

The chromium crystal hydrate $CrCl_3 \cdot 6H_2O$ is a mixture of the three isomers $[Cr(H_2O)_6]Cl_3$, $[Cr(H_2O)_5Cl]Cl_2 \cdot H_2O$ and $[Cr(H_2O)_4Cl_2]Cl \cdot 2H_2O$, which behave in different ways during thermolysis.[13] At temperatures below 100 °C the first and the third isomer evolve only water, whereas the second isomer evolves only HCl. Since the sample of chromium chloride used in this work evolved both HCl and H_2O at temperatures below 100 °C it must have been a mixture of hydrated isomers. Between 200 and 300 °C all these isomers form chromium hydroxide chloride $Cr(OH)Cl_2$. At higher temperatures chromium oxide chloride CrOCl is formed. At these high temperatures the anhydrous chromium chloride $CrCl_3$ can lose a chlorine atom and give the chloride $CrCl_2$ (see Gmelin's Handbook[14]). It follows that the system contains several chemical compounds of chromium, and it is difficult to establish which of these actively influences the degradation of the polymer.

The results of a thermogravimetric analysis[12] of a mixture of PMMA and $CrCl_3 \cdot 6H_2O$ (taken in a mass ratio of 1 : 1) are shown in Fig. 2. As can be seen, the decomposition of the polymer becomes marked at ~250 °C, above which the rate of the reaction increases rapidly, though 22% of the sample is lost below it. The reaction products include water, HCl, and the monomer. Water and HCl are formed by the thermolysis of aqueous $CrCl_3$: anhydrous $CrCl_3$ produces only HCl, and the monomer is formed by the depolymerisation of the PMMA.

Most of the mass (62%) is lost between 250 and 500 °C. In this case the volatile products include the monomer, carbon oxides, an unidentified organic acid, and traces of methane. The monomer is

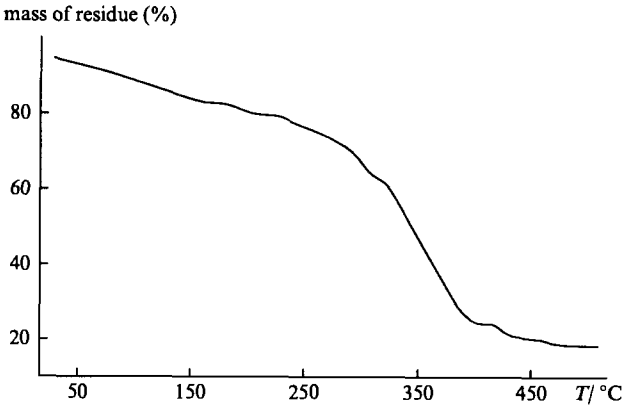

Figure 2. Thermogravimetric curve for a 1 : 1 mixture of aqueous $CrCl_3$: PMMA at a heating rate of 20 °C min^{-1}.

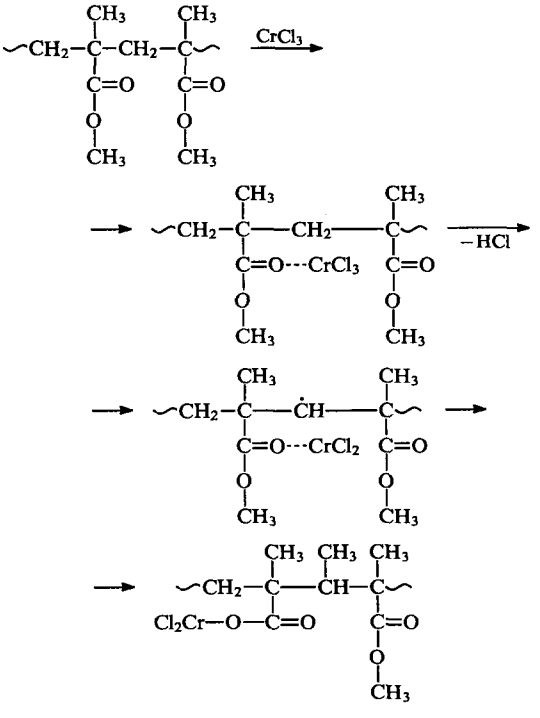
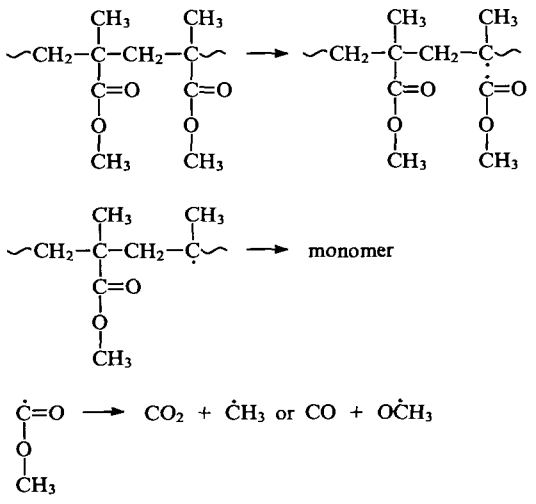


the main product of the decomposition at 430 °C. Above this temperature the relative amount of monomer decreases, and the amount of carbon oxides and of the organic acid increases.

In the decomposition of mixtures containing aqueous chromium salts evolution of HCl takes place at 150 °C as a result of the decomposition of aqueous $CrCl_3$, and again at temperatures above 450 °C. In compositions containing anhydrous chromium chloride HCl begins to be evolved at 430 °C and continues to be formed up to 500 °C.

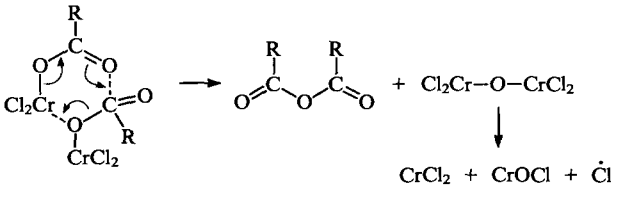
The solid residue beyond 500 °C contains 16% of the initial mass of the sample. However, if the whole of the water had been evolved from the hydrated $CrCl_3$ and the whole of the PMMA had depolymerised the fraction of $CrCl_3$ in the solid residue would have been 30% of the initial mass of the sample, and if $CrCl_2$ and CrOCl had been formed the solid residue would have been 23% and 20% respectively. The finding that, in reality, the solid residue amounts to 16% shows that none of these compounds can be (in the pure form) the final product of the reaction.

These results have been explained[12] in terms of Scheme 1. Most probably the $CrCl_3$ is coordinated at the carbonyl group of PMMA. This postulate has been confirmed independently.[15–17]



Scheme 1

We know that $CrCl_3$, when heated, splits off a chlorine atom [14] which then removes a hydrogen from the main chain of the PMMA, forming a polymeric radical. This scheme is confirmed by the presence of HCl among the reaction products.



Manring and coworkers [18–21] have attributed the presence of CO, CO_2, and CH_4 among the decomposition products of PMMA to the removal of carbomethoxy groups from the main chain of the polymer, accompanied by the formation of an unstable carbomethoxy radical which then decomposes, giving CO and $CH_3\dot{O}$ or CO_2 and $\dot{C}H_3$ (Scheme 2).

Scheme 2

Scheme 2 is confirmed by the detection by NMR of unsaturated oligomers among the reaction products. All the gaseous products are also formed by Scheme 2. The presence among the solid products of chromium anhydride and chromium oxides is ascribed to processes described by Scheme 3. The atomic chlorine removes a hydrogen atom from the PMMA chain, generating polymeric radicals which can decompose or become cross-linked.

Scheme 3

Thus in the pyrolysis of compositions consisting of chromium chloride and PMMA the most important reactions are: (1) the coordination of the chromium chloride at the carbonyl group of PMMA with subsequent elimination of a chlorine atom; (2) the removal by the chlorine atom of a hydrogen atom from the PMMA; (3) the corresponding migration of the methyl ether to the main chain of the PMMA, leading to the formation of a chromium carboxylate salt; (4) the dissociation of this salt to the anhydrides; (5) the stabilisation of the polymer by the chromium carboxylate or through the cross-linking of the polymeric radicals formed in the preceding stage. The interaction of the chromium chloride with the PMMA does not affect the formation of the monomer, and therefore it seems unlikely that $CrCl_3$ may act as an inflammation retarder.

Wilkie et al. [22] studied the thermal degradation of PMMA–$MnCl_2$ (anhydrous) mixtures by standard methods. The more volatile reaction products contained carbon monoxide and traces of methane. The condensable gas consisted of carbon dioxide, the monomer, and traces of methyl chloride and methanol. The IR spectrum of the fraction soluble in chloroform [23] showed the presence of ether and an anhydride. The insoluble products were washed free from $MnCl_2$ with methanol, which left a fraction consisting of MnO_2 and an organic salt. It should be noted that the proportion of the monomer in the thermal degradation products of PMMA in the presence of anhydrous $MnCl_2$ decreases as compared with pure PMMA, and depends on the method of preparation of the system. [24] Thus, in samples prepared by simple mixing of PMMA and $MnCl_2$ the yield of monomer after vacuum heat treatment (400 °C, 2 h) was 30%–35%, whereas pure PMMA under the same conditions produced 50%–70% of the monomer. With compositions prepared from solutions of $MnCl_2$ and PMMA in an acetone–methanol mixture, followed by removal of the solvents, thermal decomposition does not usually produce any monomer.

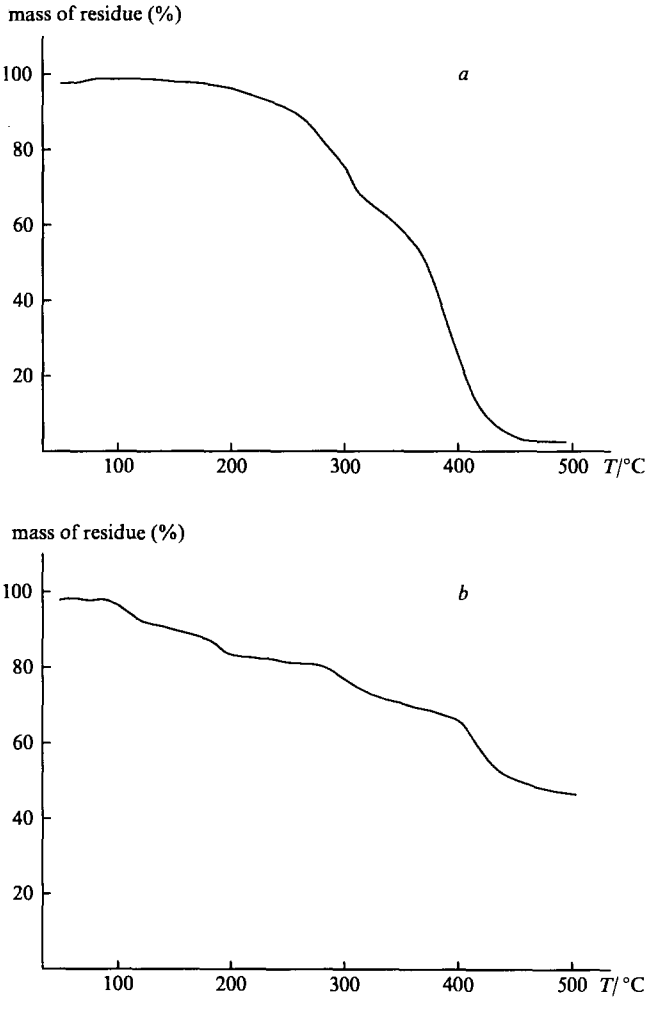


Figure 3. Thermogravimetric curves: (*a*) PMMA, (*b*) PMMA : $MnCl_2$ (1 : 1); heating rate 20 °C min^{-1}.

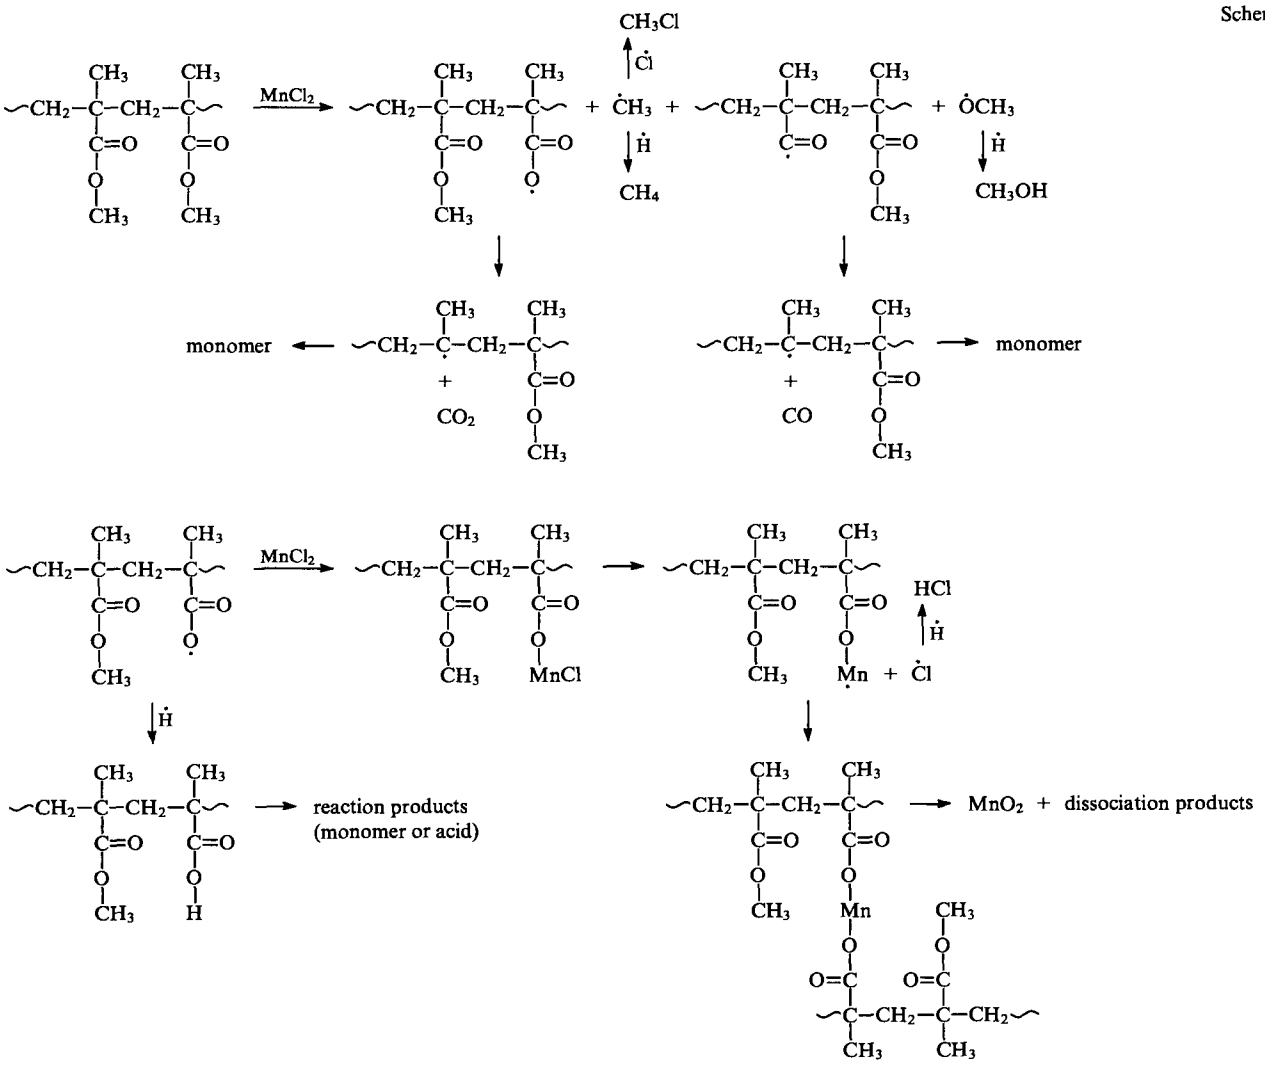
The molecular mass of the fraction dissolved in chloroform was 10% of that of the initial polymer. [25] It follows that the greater part of the polymer decomposes to the monomer, and the latter repolymerises with formation of a low-molecular oligomer; this reoligomerisation is probably catalysed by $MnCl_2$. By using thermogravimetric analysis methods it was confirmed that the monomer is formed and then slowly consumed. The TGA curves of $MnCl_2$–PMMA mixtures prepared from solutions are shown in Fig. 3. It can be seen from Fig. 3*b* that the breakdown of this composition is characterised by five temperature regions.

Between 100 and 145 °C 7.5% of the composition is gasified. The Fourier transform IR spectra of the gaseous products show that this loss is mainly water introduced into the system with the salt and easily removed. A further 9.5% of the composition is gasified between 145 and 215 °C: the IR spectra show that in this regime the monomer is evolved. In the case of pure PMMA the evolution of the monomer begins at higher temperatures.

The third plateau of the weight-loss curve is found at 215 to 345 °C. It is characterised by the evolution of the monomer and by the formation of methyl chloride and methanol. The formation of methyl chloride is evidence of the interaction between $MnCl_2$ and PMMA, involving the ester group of the latter.



A further 19% of the composition is dissociated between 345 and 455 °C. CO_2, CO, CH_4, HCl, and an aliphatic acid were identified among the gaseous products.

A further 5% of the composition is decomposed in the region of 455–600 °C with formation of HCl.

The overall result is that up to 600 °C 51.5% of the composition is gasified, leaving a 48.5% residue of involatile products. Since the ratio of PMMA to $MnCl_2$ in the initial composition is 1 : 1 it might be thought that the whole of the PMMA is gasified and the residue consists of $MnCl_2$. However, an analysis of the thermal degradation products does not confirm this assumption: firstly, because the IR spectrum of the solid residue shows the presence of organic substances (hydrocarbon and carbonyl groups), and secondly because the solid residue is found to contain a new, insoluble organomanganese compound in addition to $MnCl_2$.

Wilkie et al.[22] proposed the following scheme to account for the degradation of the PMMA–$MnCl_2$ compositions (Scheme 4). The manganese chloride initiates the breaking of the carbonyl bonds in PMMA, giving methoxy and methyl radicals. These radicals can abstract a proton, giving methanol and methane respectively. The methyl radical can also recombine with a chlorine radical, forming methyl chloride. The carbonyl radical can be further converted into carbon monoxide and a tertiary radical, and the carboxyl radical can produce carbon dioxide and the same tertiary radical. These tertiary radicals initiate the decomposition of PMMA with preferential formation of the monomer and other low-molecular products. Since the decomposition products contain more CO_2 than CO it follows that the methyl radicals are consumed faster than the methoxy radicals. The carboxyl radical can react in various directions. Firstly it can interact with $MnCl_2$, giving MnCl and Cl˙. The latter can recombine with any other radical, giving different products. Methyl chloride mentioned above is one of these products; the manganese chloride salt of PMMA can split off a chlorine radical and form a manganese radical attached to the PMMA chain. The recombination of this radical with the carboxyl radical gives the manganese monomer of PMMA. This monomer can dissociate thermally, giving MnO_2 and other products. This reaction also produces an aliphatic acid, which can also be formed during the abstraction of hydrogen by a carboxylic radical, followed by depolymerisation, to give monomeric methacrylic acid and other dissociation products.

Scheme 4

The limiting oxygen index (OI) for the PMMA – $MnCl_2$ system shows that manganese chloride has some flame-retardant properties.[26] Thus, as compared with pure PMMA, whose OI is 14, the OI of a PMMA – $MnCl_2$ composition (1 : 1 ratio) increases to 25. This increase in the OI is convincing evidence of the effectiveness of $MnCl_2$ as an additive.

These results differ from those reported by McNeill and McGuiness[15,16] for the $ZnBr_2$ – PMMA system. The gaseous products are the same for the two systems, but different reaction paths were proposed in the two cases. Whereas in the presence of $ZnBr_2$, methyl bromide appears at 160 °C, in the $MnCl_2$ system methyl chloride is formed at temperatures above 220 °C; furthermore, in the $MnCl_2$ system the monomer appears at temperatures well below those observed in pure PMMA. In both cases the reaction product is the metal salt of methacrylic acid.

When the common features of these two reactions are examined it seems very likely that all the main processes are the same in the two cases. Wilkie et al.[22] conclude that $MnCl_2$ plays a dual role in the system. On the one hand it accelerates the initial depolymerisation of PMMA, and thus assists its combustion, but on the other hand it also markedly increases the amount of incombustible reaction products.

Kochneva et al.[27] studied the effect of $ZnCl_2$ on the thermal stability of polymethacrylates and polyacrylates. These polymers were found to decompose by different mechanisms. The polymethacrylates are almost completely depolymerised, whereas the polyacrylates are degraded by breakdown of the ester groups.

The loss of mass of PMMA and polymethacrylate (PMA) after 2 h at 300 °C in a vacuum is shown in Fig. 4 as a function of the concentration of $ZnCl_2$. Increasing the concentration of $ZnCl_2$ lowers the degree of decomposition for PMMA (curve *1*) and increases it for PMA (curve *2*). The decomposition products of these polymers in the presence of $ZnCl_2$ are listed in Tables 2 – 5.[27]

In the decomposition of PMMA in the presence of $ZnCl_2$ the yield of monomer decreases, which suggests a depolymerisation process, whereas the yields of alcohol, of chain breakdown products, and of CO_2 increase (Table 2). Similar effects have been observed in poly(n-butyl methacrylate) (PBMA) (Table 3).

In the thermal degradation of PMA (Table 4) the yields of alcohol and CO_2 rapidly increase after even small additions of $ZnCl_2$. A similar effect is found in poly(n-butyl acrylate) (PBA) (Table 5).

Alkyl chlorides were determined qualitatively in the thermal degradation products of the polymethacrylic and the polyacrylic ester in the presence of $ZnCl_2$. On the basis of these results Kochneva et al.[27] suggested that CH_3Cl is formed mainly by the reaction of $ZnCl_2$ with the carbonyl group of the ester.

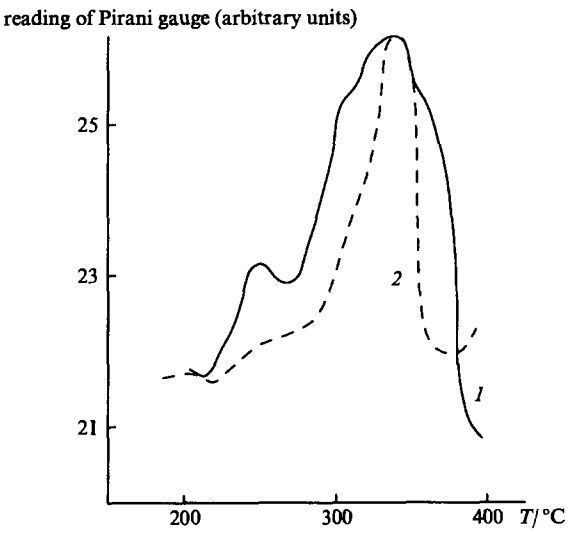
0.5	0.3	0.4	0.1	0.1
2	1.3	1.2	0.4	0.3
10	2.6	5.1	–	–

Table 6 shows the effect of the concentration of $ZnCl_2$ on the yield of alkyl chlorides during the thermal breakdown of polymethacrylates and polyacrylates after 2 h at 300 °C *in vacuo*.

It follows from the data in Table 6 that the rate of formation of alkyl chlorides decreases with increasing length of the hydrocarbon radical in the ester group. Zinc chloride has similar effects on the formation of the insoluble fraction in the thermal degradation of PMMA and PMA, and therefore the authors suggest that reticular cross-linking of the polymer takes place mainly through the interaction of the ester groups with $ZnCl_2$. The contribution of this reaction is not large, but it is neverthe-less significant in compositions including large quantities of zinc chloride.



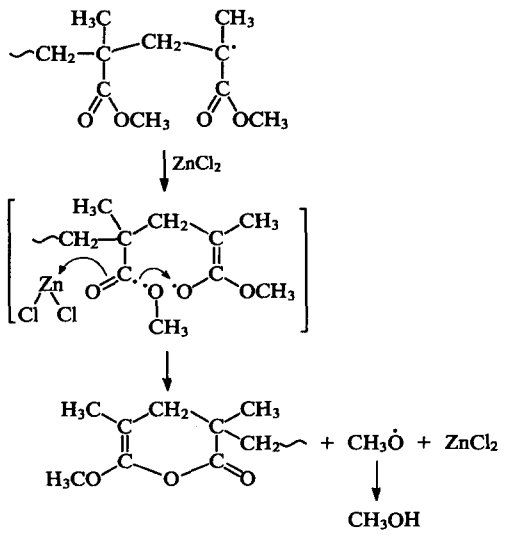


Figure 5. Thermovolumetric curves: (*1*) PMMA; (*2*) PMMA + 2 mass % $ZnCl_2$.

Scheme 5

A thermovolumetric analysis [28] of the thermal degradation of PMMA showed that $ZnCl_2$ when present in the system suppresses the formation of the monomer by removing the unsaturated end groups (note the disappearance of the characteristic monomer peak at 250 °C in Fig. 5).

The formation of a complex between $ZnCl_2$ and the end groups of the macroradicals leads to the evolution of alcohol and inhibits the depolymerisation. This process is described [27] by Scheme 5.

The IR spectrum of samples of PMMA dissociating in the presence of $ZnCl_2$ includes an absorption band at 1760 cm^{-1} corresponding to γ,δ-unsaturated lactones.

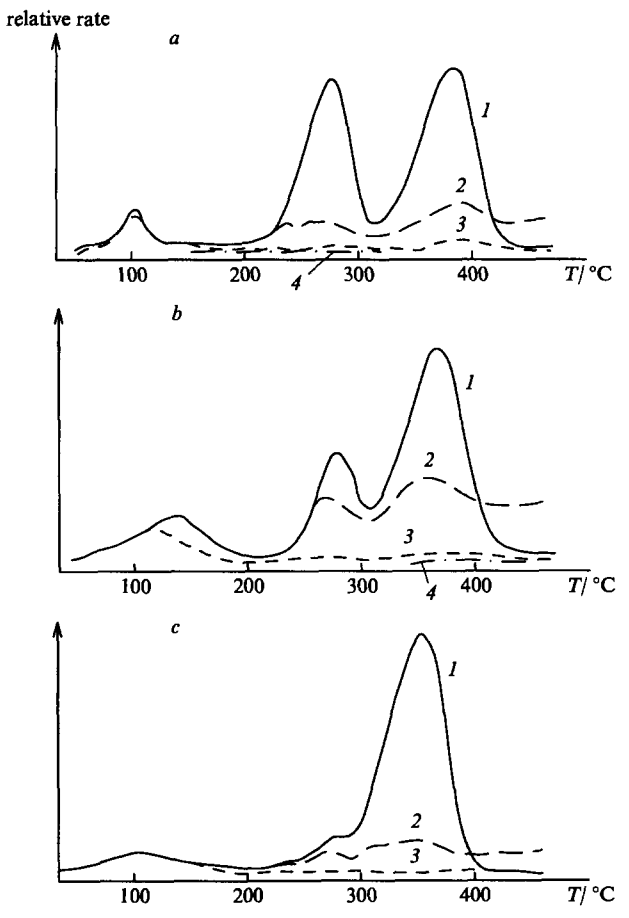
IV. Effect of metal acetylacetonates on the thermal degradation of polymers

Metal acetylacetonates are of interest because they are used as polymerisation indicators, accelerators, and antioxidants for polyolefins. As a result it has been suggested [29–33] that these compounds could act as flame retardants and suppress the formation of smoke in various polymers.

McNeill and Liggat [34] studied the effect of cobalt(III) acetylacetonate on the thermal degradation of PMMA, and concluded that this effect is responsible for the formation of an acetylacetonato complex of cobalt with the ester groups of PMMA.

Very different compositions were studied: from 1 part of $Co(acac)_3$ per 400 monomer units to 1 part per 10 monomer units.

The thermal degradation was studied by the thermovolumetric analysis method, [35,36] which allows four fractions of products to be studied: (1) uncondensable gases, (2) condensable gases and volatile liquids, (3) solid fractions (resins, waxes, etc.), (4) the residue at any stage in the decomposition.



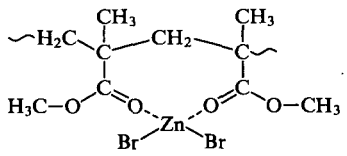


Figure 6. Thermovolumetric curves (vacuum, 10 °C min^{-1}). $\bar{M}_n$ = 2 × 10^4 (*a*), 1.5 × 10^5 (*b*), 10^6 (*c*); *T*/°C = 0 (*1*), 75 (*2*), 100 (*3*), 196 (*4*).

Fig. 6 shows the thermovolumetric curves for PMMA samples of different molecular mass: we observe two peaks, corresponding to two stages in the decomposition (initiation at the end groups and random initiation respectively).

The rate of degradation of PMMA is strongly influenced by the presence of complexing agents such as metal halides or acetylacetonates. For example, in the presence of $ZnBr_2$ the main decomposition products are methyl bromide and methanol, and the yield of monomer is negligibly small.[37,38] This is due to the formation of a complex having the following structure:

It could be expected that stable metal acetates will interact with the ester groups of PMMA, and that this process will be reflected in the stability and dissociation mechanism of the polymer.

The thermal degradation of $Co(acac)_3$ at 210 °C takes place by the scheme

$$Co(acac)_3 \longrightarrow Co(acac)_2 + acac^{\cdot};$$

$$acac^{\cdot} \xrightarrow{H^+} Hacac.$$

The UV spectra of PMMA films with additions of $Co(acac)_3$ show that in this case the $Co(acac)_3$ does not contribute to complex formation with the PMMA at the ester groups, whereas the UV spectra of PMMA films with additions of $Co(acac)_2$ indicate the formation of these complexes.

It follows that during the degradation of the composition $Co(acac)_3$–PMMA the $Co(acac)_3$ first changes into $Co(acac)_2$, which then forms a complex with the PMMA.

The four stages in the breakdown of the composition $Co(acac)_3$–PMMA are shown diagrammatically in Fig. 7.[34]

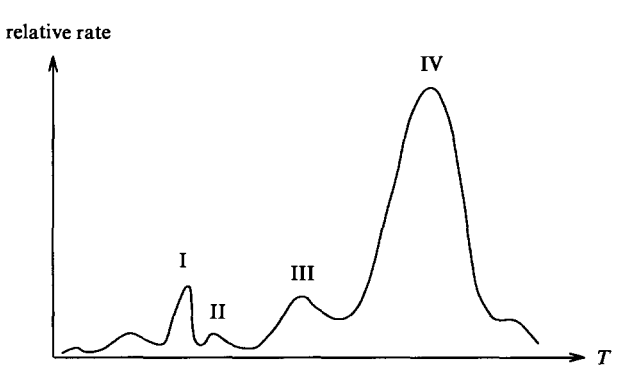

Figure 7. Schematic diagram of the decomposition of a $Co(acac)_3$–PMMA mixture, based on an analysis of the thermovolumetric curves.

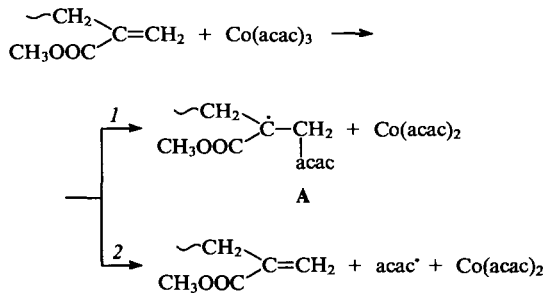
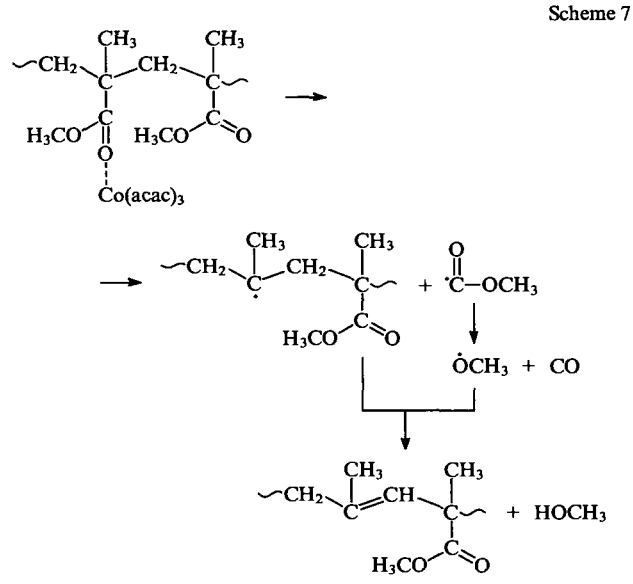
Stage I: $T_{max} \approx 135$ °C. The height of the peak is inversely proportional to the molecular mass of the polymer, and is independent of the concentration of $Co(acac)_3$. The main decomposition product in this stage is the monomer. It is assumed that depolymerisation initiated at the ends of the molecule takes place in stage I, so that the $Co(acac)_3$ forms a complex with the unsaturated end groups (on average, one unsaturated end group per 400 monomer units in a sample of low molecular mass).

Stage II: $T_{max} \approx 190$ °C. The height of the peak is proportional to the molecular mass of the polymer and to the concentration of $Co(acac)_3$. The only exceptions to this rule are samples with a high molecular mass of the polymer and a high concentration of $Co(acac)_3$. The main decomposition product in this stage (as in the previous stage) is the monomer. In addition, gaseous acetylacetone and methanol are formed towards the end of stage II (above 200 °C). At high concentrations of $Co(acac)_3$ traces of an uncondensable gas are formed. The authors note that in this stage the chain length for the reaction is greater.



Stage III: $T_{max} \approx 270$ °C. The height of the peak decreases in all the compositions with respect to the peak height for pure PMMA, irrespective of the concentration of $Co(acac)_3$. As a rule the monomer is formed in this stage. The main process is depolymerisation, initiated at the end groups. Unsaturated end groups are nevertheless present, or can be formed in stage I. The chain length of the reaction decreases.

Stage IV: $T_{max} = 360-380$ °C. This peak is characterised by the formation of uncondensable gases. The authors attribute this to a decrease in the length of the reaction chain and to the development of new reactions accompanying the depolymerisation reaction. In addition to the monomer the following gaseous products are formed towards the end of this stage: acetylacetone, methanol, carbon oxides, keten, methyl acetate, acyclic anhydride, isobutene (traces), and dimethyl ether (traces).

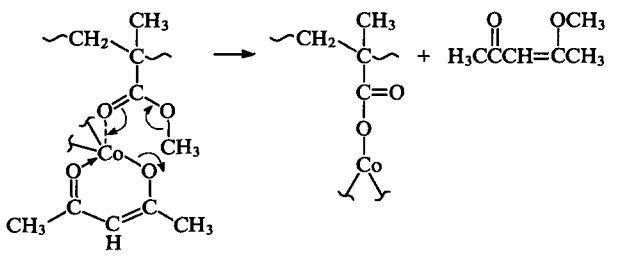


The IR and UV spectra of films of PMMA compositions containing $Co(acac)_3$, heat treated at temperatures up to 500 °C, have also been studied. The results were used to produce the following interpretation of the dissociation mechanism of these compositions.

1. At low temperatures (100 °C) the monomer is thought to be formed by the dissociation of the complex between $Co(acac)_3$ and the unsaturated end groups in the polymer (Scheme 6).

Scheme 6

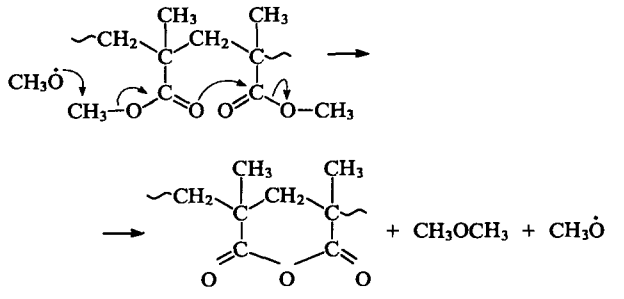
Scheme 7



In the depolymerisation of the radical A by path *1* not all the unsaturated end groups can be removed when the part of the chain being broken down in the polymer molecule is shorter than the same molecule (a short length of the part being broken down probably corresponds to temperatures close to the glass transition temperature of the polymer).

During depolymerisation by path *2* the unsaturated end groups are not used, and the depolymerisation is initiated by attack on the chain by the acac radical.

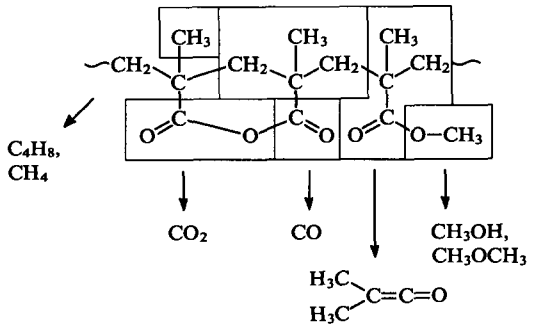
2. The thermal degradation of $Co(acac)_3$ produces $Co(acac)_2$ and acac radicals. Complex formation of $Co(acac)_2$ with the ester groups accelerates the reactions of these groups and the formation of CH_3OH, CO, and double bonds in the main chain of the polymer (Scheme 7).



The complex can also decompose to a cobalt carboxylate structure (Scheme 8).

Scheme 8

3. The CH_3O radicals can also attack some ester groups, forming anhydride rings (Scheme 9).



Scheme 9

4. The presence of these rings in the chain decreases the chain length and stabilises the polymer in the high-temperature region.

5. The fragmentation of the modified polymer structures gives mainly monomers, and small quantities of other products characteristic of these structures (Scheme 10).

Scheme 10

McNeill and Liggat[39] carried out a similar study for the PMMA–$Mn(acac)_3$ system, using the procedure of Wilkie et al.[22] The DSC curve for $Mn(acac)_3$ (Fig. 8) shows a characteristic combination of endothermic and exothermic peaks at 170, 175, and 257, 260 °C. The peaks at 170 and 175 °C are assigned to the homolytic breaking of the single bond between the ligand and Mn in $Mn(acac)_3$, with formation of acetylacetone and the bischelate,[40] whereas the peaks at 257 and 260 °C (and at higher temperatures) correspond to the breakdown of the bischelate.

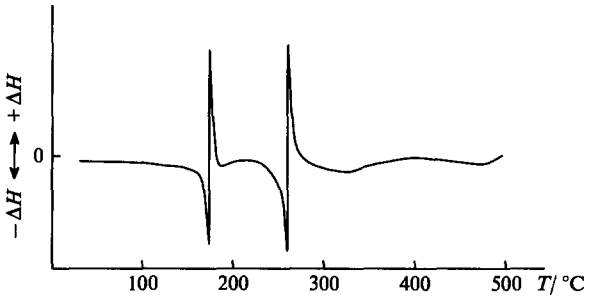


Figure 8. DSC curve for $Mn(acac)_3$ (nitrogen, 10 K min^{-1}).

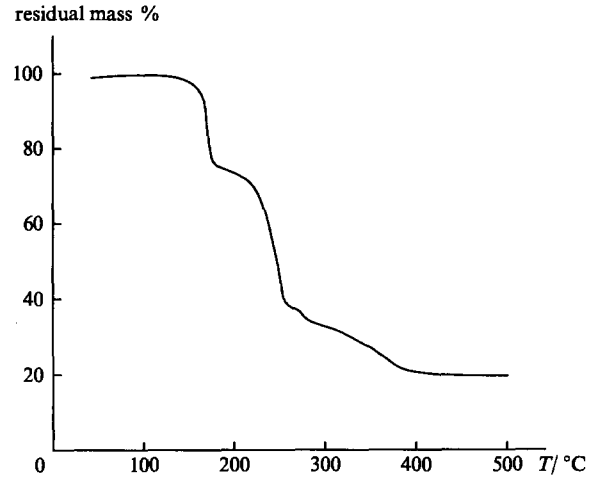

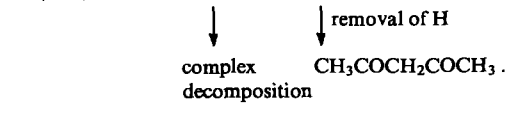

Figure 9. Thermogravimetric curve for $Mn(acac)_3$ (rate of decomposition 10 K min^{-1}).

The data from the thermogravimetric curve (Fig. 9) are fully consistent with the above conclusions, since the initial weight loss (24%) corresponds to the removal of one acac group. The next loss of mass has a more complex explanation: it is assumed that radicals can be formed in this stage, and that the final reaction product is the metal oxide. Hence the thermal degradation of $Mn(acac)_3$ can be represented as follows:

This mechanism is similar to the mechanism of the dissociation of $Co(acac)_3$, and therefore it was assumed that the thermal degradation of the PMMA system with a Mn(III) salt has a similar nature.

Table 7. Comparison of the thermal stability of PMMA and of its compositions with $Mn(acac)_3$.

	PMMA of high molecular mass			PMMA of intermediate molecular mass		
	PMMA	50:1 [a]	10:1 [a]	PMMA	50:1 [a]	10:1 [a]
T_d/ °C	210	130	125	220	130	130
T_{max} of the main decomposition / °C	350	365	400	360	365	400

[a] Number of monomer units per molecule of $Mn(acac)_3$.

In Table 7 we show results on the thermal stability of PMMA – $Mn(acac)_3$ compositions. It can be seen that pure PMMA is not gasified at temperatures up to 210 °C when heated at 10 °C min^{-1}. In the compositions with $Mn(acac)_3$ the decomposition of PMMA begins at 125 °C. The data in Table 7 show that although under these conditions the temperature of the onset of degradation in PMMA is lowered, the onset of the main process is moved to higher temperatures. From this point of view $Mn(acac)_3$ behaves like $Co(acac)_3$ in compositions with PMMA.

The dissociation diagram as a function of temperature for the composition PMMA – $Mn(acac)_3$ is shown schematically in Fig. 10. Three main dissociation stages can be identified. In stage I two overlapping processes at 150–160 °C are associated with the formation of acetylacetone and a small quantity of the monomer. These products are formed through the dissociation of $Mn(acac)_3$, initiated by the depolymerisation of the polymer produced by attack from the acac radicals and by the corresponding rupture of the chain with formation of a macroradical which can disproportionate as far as the monomer.

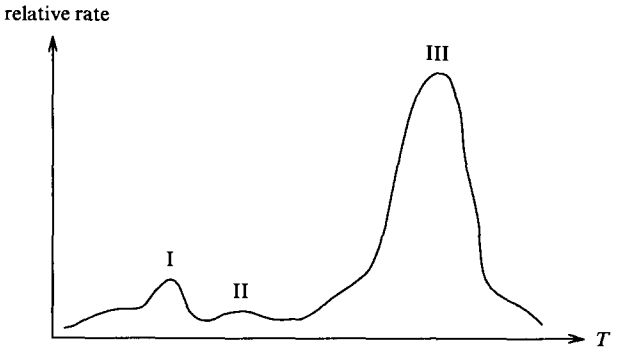

Figure 10. Schematic decomposition diagram for a $Mn(acac)_3$ – PMMA mixture.

In stage II acetone and carbon dioxide are formed. This process is ascribed to the breakdown of the $Mn(acac)_2$ produced in the preceding phase. The breakdown of the complex at the bond between $Mn(acac)_2$ and the ester side groups is accompanied by the formation of carboxylate structures which suppress the breaking of the PMMA chain in stage III.

The mechanism of the processes taking place during the thermal degradation of the PMMA – $Mn(acac)_3$ system has been treated like the corresponding mechanism for the PMMA – $Co(acac)_3$ system, discussed in detail in this review. It is stressed that the ability of $Mn(acac)_3$ to form complexes at the ester groups is not reflected, in general, by the mechanism of the thermal degradation processes of the system. This conclusion is again confirmed by the important role played by $Co(acac)_2$ and $Mn(acac)_2$ in the thermal degradation of PMMA compositions containing these salts.

Abstract. Polymer films based on poly(vinylidene fluoride) and its copolymers, which exhibit piezo- and pyro-electric properties after appropriate treatment, are described. The principal advantages of materials of this class include high values of the piezomoduli, which permit their practical use. Another valuable property, which is difficult to achieve in inorganic materials, is the wide range of frequencies over which the given active element can operate. The possibility of achieving large areas and fairly simple methods of preparation of thin films also leads to the assignment of the above polymers to the category of promising materials for the creation of new classes of recording devices. The trends in the development of new instruments based on these materials, where use is made of the phenomenon of photopyroelectric activity, are demonstrated. The advantages of using these materials for medical techniques are noted. The flexibility of the film and its acoustic impedance, which is close to that of a biological tissue, as well as the properties noted above place it beyond competition with other materials. Furthermore, the ferroelectric nature of the above polymers makes them promising for use in nonlinear optics. The bibliography includes 89 references.

I. Introduction

In the search for new materials to be used in energy converters, Kawai[1] observed in 1969 intense piezoelectricity in poly(vinylidene fluoride) (PVDF). Vigorous investigation of this phenomenon began afterwards. There have been numerous individual communications and fairly detailed reviews (see, for example, Refs. 2–5), where certain current established ideas concerning the mechanisms of piezo- and pyro-activity of the given class of polymers are described. The principal results reduce to the fact that the nature of the piezo-effect is not unique. It has come to be assumed that three phenomena contribute to the magnitude of the piezoelectric response: (1) the piezo-effect in the classical sense, which requires the presence of noncentrosymmetric crystals, (2) electrostriction (which has been very little investigated in polymers), and (3) the dimensional effect, which takes into account the change in volume on deformation resulting in a change in polarisation. The contributions of these effects to the macroscopic response may vary according to the results of different workers. Poly(vinylidene fluoride) and its copolymers belong to the class of flexible chain crystallisable polymers characterised by a low glass point (−40 °C). In the initial (isotropic) state, the material has the texture of a polycrystalline substance in which the crystallites (with a volume fraction of 0.4–0.5) have a random orientation. After averaging over a fairly large volume, this is equivalent to the presence of an effective centre of symmetry in this system, and the material does not exhibit piezo- and pyro-activity. Such activities are induced by treating the film with a high-frequency field.

It has been established[6] that the above polymers are ferroelectric and that the principal coefficients of piezo- and pyro-activity are linear functions of the residual polarisation P_r. The relation between the ferroelectric characteristics of the crystallisable polymers and their structure has been poorly elucidated and much that is obscure still remains to be solved. In particular, the role of the amorphous or mesomorphic phases in ferroelectric phenomena is not understood. Such phases are frequently represented by an inert matrix in which the crystals of the polar (β) and nonpolar (α) phases are immersed. There is no doubt that the contributions of these liquid-like phases (their fraction may reach 0.7) is by no means trivial. The influence of the characteristics of the nonordered region both on the quantity[7] P_r and on other piezoelectric constants[8] may serve as evidence for this. Data[9,10] concerning the influence of small irradiation doses (whereupon the changes refer mainly to the nonordered phase) and the ferroelectric properties of PVDF also confirm the above idea. Films of PVDF and its copolymers, obtained for practical purposes, are usually uniaxially extended. The role of the extension cannot be reduced solely to the method for the conversion of the polymorphic α-form into the β-form, although a decrease in coercive fields and an increase of P_r on polarisation have in fact been noted under these conditions.[11]

Experiments involving stretching the films crystallising immediately in the piezoactive β-phase[8–12] indicate that the piezoresponse and the ferroelectric characteristics in textured films are more pronounced and that the ultimate procedure for the latter is the creation of the 'ideal single crystal' texture. The above series of studies[8–12] indicate that the piezo- and pyro-effects in these compounds are dipolar in nature, although there is no doubt that here one should take into account the contribution of the space charge generated by the injected carriers in high polarisation fields. Under the usual conditions (at room temperature, normal pressure), the nonordered phase in the above polymers is in the highly elastic state and its pliability is an order of

magnitude higher than that of the crystal. Thus, when such polymers are acted upon by a mechanical (acoustic) perturbation, the phase exhibits a local response (while the specimen as a whole exhibits a macroscopic response). The high mobility of the chains in the amorphous phase ensures their response to the thermal perturbation in the observation of the pyroeffect.

The difficulty of creating a rigorous molecular model of the above noted phenomena in such polymers is partly associated with the absence of ideas, worked out in all their details, concerning the structure of textured crystallising polymers. One may, for example, take the view that simplified ideas concerning the two-phase nature of the crystallising polymers do not help to elucidate the true mechanisms of the piezo- and pyro-response in PVDF and its copolymers. The lack of true (in the thermodynamic sense) interfaces between the ordered and amorphous phase can create a qualitatively new situation in the description of the mechanisms of the piezo- and pyro-responses in such polymers. In particular, attention has been drawn recently to the fact that the strained chains, passing through the amorphous phase and connecting neighbouring crystallites, play a special role in the response of textured crystallising polymers to the electric field.[7] In the vicinity of the interface between the above phases, which exists in a partially ordered (mesomorphic) state, the chains also behave in an unusual manner on exposure to an acoustic or thermal perturbation. This hypothesis is supported indirectly by data demonstrating an increase in the acoustic modulus and in the double refraction on deformation of textured films of the copolymer of vinylidene fluoride and tetrafluoroethylene.[8] Direct evidence for this was obtained by the X-ray diffraction method.[13] A change in the form of the azimuthal distribution of the 110 and 200 reflections after the immersion of the film was noted and was treated from the standpoint of reversible paraelectric $\rightleftarrows$ ferroelectric transitions when these phases coexist. The VDF homopolymer, a characteristic feature of which is reversible changes in crystallinity during the observation of the pyroeffect, behaves similarly.[14]

As stated in the Introduction, the mechanisms of the piezo- and pyro-effects in the compounds of the class considered are insufficiently clear. The very extensive experimental data available on this question need to be surveyed separately. Despite this, compounds of the given class have been most thoroughly investigated as regards their practical application. The aim of the present review is therefore to draw the readers' attention to branches of engineering where the given polymers are already used as the active element in the finished primary energy converters. The discovery of specific properties of the polymeric materials which make it possible to devise instruments with novel characteristics is emphasised.

Piezo- and pyro-coefficients which enable the above compounds to compete seriously with traditional piezoceramic materials have been reported in the latest communications. Thus PVDF films with the piezocoefficient $d_{31} = 60$ pC N^{-1} and the pyrocoefficient $p = 6$ nC cm^{-1} K^{-1} have been obtained by a modification of the polarisation method.[15] Table 1 presents a comparison of a series of characteristics of films of PVDF and of its copolymer with trifluoroethylene (TrFE) with the analogous characteristics of quartz and the PZT-4A ceramic.[16,17]

The choice in favour of the above materials may be dictated by a series of their specific properties and advantages. These include the following: (1) the existence of an effective technology (here one can use the equipment already available for the manufacture of polymeric film materials); (2) the possibility of achieving high areas of the active elements, which permits the construction of second generation sensors;[18] (3) a wide transmittance band (a realistic specification is 0–500 MHz), which is required in diagnostic systems;[19,20] (4) the closeness of the acoustic impedance of PVDF to that in human tissue and water, which is used in the construction of sensors for medical diagnostics; (5) the high impact strength of polymer films (this quality of PVDF is used in shock wave sensors); (6) the high corrosion stability of PVDF (this property becomes essential for work involving reactive media); (7) the low relative permittivities of the materials ($\varepsilon' = 10-14$) and the correspondingly higher values (almost by an order of magnitude and above) of the piezoconstant g and the pyrosignal (p/ε') sensitivity; (8) the lower thermal conductivity of PVDF compared with the piezoceramic and the possibility of obtaining thin films (one micrometer and less), which ensures a higher transverse resolution in the analysis of the spatial separation of the incoming electromagnetic radiation; (9) the possibility of imparting to the material an arbitrary form (cone, self-supporting dome, etc.), which makes it possible to produce elements with unusual forms of directional emission.

Table 1. Comparative characteristics of piezo- and pyro-electric materials.[16–19]

Characteristic	Material			
	PVDF	PVDF/TrFE	Quartz	PZT-4A
Density, ρ/g cm^{-3}	1.78	1.88	2.65	7.5
Velocity of sound, v/km s^{-1}	2.25	2.40	5.7	4.63
Acoustic impedance, $Z = \rho v/10^6$ kg m^{-2} s^{-1}	4.02	4.51	15.1	34.8
Modulus of elasticity, C_{33}/GPa	9.1	11.3	86	159
Electromechanical coupling coefficient, k_t	0.2	0.3	0.1	0.51
Piezoconstants:				
d_{31}/pC N^{-1}	60	25	–	–
g_{31}/V m N^{-1}	0.18	0.16	–	–
e_{33}/C m^{-2}	0.16	0.23	0.17	15.1
g_{33}/V m N^{-1}	0.32	0.38	0.05	0.017
Relative permittivity, ε'	12	20	4.6	625
Pyroelectric coefficient, p/nC cm^{-2} K^{-1}	6	–	–	38
Pyroelectric Q factor (p/ε')/nC cm^{-2} K^{-1}	0.5	–	–	0.061

II. Technical applications of poly(vinylidene fluoride) and its copolymers

A number of devices are described below in which the above qualities of the materials under considerations are actually employed. One of the most important properties is the presence in films of PVDF and its copolymers of longitudinal and transverse piezoeffects, which is used in the construction of headphones and high-frequency speakers. The possibility of using such films in piezoelectric piano-key switches and in the receptor sensors of electric pianos has been demonstrated.[17]

Piezoelectric polymer films are most widely used as bimorphic elements consisting of two combined films. By virtue of the elasticity of the polymeric materials, high vibration amplitudes are achieved in the bimorphic elements. As early as 1981, the Kodak company reported the development on the basis of PVDF of bimorphic elements operating under the conditions of the reverse piezoeffect and generating high-amplitude low-frequency vibrations.[21] Bearing in mind the low density and high pliability of the PVDF piezofilm, it was possible to achieve on the latter, under the conditions of the same fixing geometry, parameters of the excited bending vibrations approximately twice as high as on traditional materials such as $BaTiO_3$ and PZT.[21] An attempt has been made recently to use this property in displays, small pumps, light switching devices, etc.[22]

Because of the flexibility of the polymer films, completely new aspects of their application arise under these conditions. For example, it has become possible for the first time to focus sound waves. Thus standing concentric ultrasonic waves have been

achieved in water (with a frequency of 10 MHz) with the aid of PVDF [23] and have been recorded from the diffraction of light. Piezoelectric speakers, the operation of which is based on the transverse piezoeffect, have already become commercially available. Sound waves arise in them as a result of the bending movements of the polymer membrane.[24] A spherical emitter with a unique directional diaphragm has been constructed from PVDF.[25] PVDF is a suitable material for use in pressure measuring devices, for example, in presses operating in the quasi-static region, and also as a pressure switch in various switching devices.[24]

Bearing in mind that polymeric piezoelectric elements have a low Q factor, it is possible to generate short pulses with a low reverberation. This property ensures the wide-band characteristics of these materials, noted above, which has been used to construct an ultrasonic spectrometer for the simultaneous measurement of the absorption and velocity of ultrasound over a wide frequency range. For example, it has been possible to obtain with its aid information about the mechanisms of the phase transition in liquid crystals from the nematic state to the isotropic phase.[26,27] The changes in strongly frequency-dependent properties can be inferred from the analysis of the form of a single pulse. The principle of this measurement was proposed a long time ago, but its practical realisation became possible only after the appearance of polymeric piezoelectric converters with wide-band characteristics. Yet another advantage of materials based on PVDF is the possibility of creating very small sensors, which are used, for example, in the study of the elastic characteristics of certain superconductors and their anomalies in the region of transitions.

Taking into account the wide-band property of the converters considered, it has been suggested [28] that they be used to estimate all the components of the elasticity tensor in an anisotropic body. The possibilities of the methods were tested on quartz crystals. A satisfactory agreement was found between the elastic constants obtained by this method and those measured by other procedures.

Among the new applications of piezoelectric polymers, mention should be made of their use in the stereospecific vision sensors in robots,[27] in field sensors where the optical fibres are coated by the piezoelectric polymer,[29] and also in sonic pressure sensors of a hybrid type consisting of layers of the piezopolymer and semiconductor in direct contact.[30] Digital signals can be converted directly into sound signals in digital speakers based on piezoelectric polymers.[31]

The possibility of creating sensors (in the form of an elastic body), one of the elements of which is a piezoelectric PVDF film, has been discussed.[32] The mechanical stresses developing as the sensor moves along the object generate a charge on PVDF. The available mathematical procedure makes it then possible to estimate the rate of sliding of the sensor along the object and its coefficient of friction respectively from the real and imaginary components of the signal arising on PVDF. PVDF piezofilms can be used to create a gas sensor, the resonance parameters of which in the torsional and bending modes depend on the composition of the binary gas (SF_6 + air) and on its pressure. It has been found that, although such a sensor is less sensitive than the sensor based on silicon resonators, it can compete with other sensors. The possible region of application is in the monitoring of binary gas mixtures with known components.[33]

PVDF-based piezofilms are also used to combat deposits arising from microorganisms on the bottoms of ships. The film operates under the conditions of the reverse piezoeffect where the supplied electrical energy is transformed into the vibrational energy of the surface. The film adheres to the surface in contact with the aqueous medium. Here it has been noted that the control panel (without the piezofilm) becomes fully covered by microorganisms after only 2 months, whereas the panel with PVDF, on which vibrations developed (at a frequency of 5 kHz for a 0.05 g level), remained completely clean even after 5.5 months.[34]

Because of the ability of PVDF to be moulded into any shape, one can use it to construct ultrasonic converters and hydrophones with a spherical or needle-shaped receiving surface.[35] The high flexibility of the PVDF films makes it possible to construct sensors that can be used to estimate the nature of the air stream in aerodynamics. It has been shown that such sensors are fairly simple to construct and make it possible to record the transition from the laminar flow of air to a turbulent flow around the relevant body.[36] The piezoactive PVDF is used in sensors for the recording of shock waves, where the maximum pressure reaches 100 MPa. It is emphasised that sensors of this kind can find an application in underwater studies and in medicine, where one has to deal with focussed waves.[37]

The possibility of achieving high working areas and the high flexibility of the PVDF films provide a basis for the conversion of the energy of sea waves into electrical energy. According to the data of Hausler and Stein,[38] this idea may be not only ecologically attractive but also economically promising.

III. The use of piezopolymer films in medicine

Studies concerning the use of such materials in medicine need a separate consideration. Their advantages are associated with their low acoustic impedance Z and its closeness to the value for water and biological objects ($Z = 1.4 \times 10^6$ kg m^{-2} s^{-1}). Since the amplitude coefficient of the transmittance T_{12} for an ultrasonic element having an acoustic impedance Z_1 into a medium having an impedance Z_2 is given by the relation

$$T_{12} = \frac{2Z_1}{Z_1 + Z_2},$$

it follows that an important factor is that the impedances should be matched. This makes it possible to transmit 50% of the energy generated in the film into water, whereas in the case where a piezoceramic is used this amount is an order of magnitude smaller.[19] The above quality of the PVDF films permits their employment for the recording of electrocardiograms or for the monitoring of respiration.[19] By virtue of the large area of the sensor, the signal arising under these conditions is fairly high, so that it is possible to record it immediately on the pen recorder without preliminary amplification. The possibility of observing the difference between the incoming blood flow pulses at two different points on the human body may be of interest for physicians.[19] The copolymer of VDF and TrFE, for which the electromechanical coupling coefficients k is higher than for PVDF (see Table 1), is used widely in ultrasonic probes for medical diagnostics where bulky resonators are normally employed (see Yagi [17] and contained references). Owing to the similarity of the acoustic impedances of the probe and the living tissue, in this case the presence of an adjusting layer is no longer required. By virtue of the ability of the polymer film to assume the shape of the given body, there is also no need to employ an acoustic lens. All these factors lead to a better focussing of the ultrasonic waves and make it possible to record defects with a satisfactory resolution even for deep regions. Therefore, such probes are employed for the diagnostic investigation of internal organs — mammary glands, vocal chords, and the liver (see Yagi [17] and contained references).

The use of PVDF-sensors make it possible to obtain a series of characteristics of the pulse (frequency and rhythm), the pulse rate (in the two sensors version), and also a property which may be characterised by the form of the pressure wave.[39] The high flexibility of the piezofilm and its low acoustic impedance serve as a basis for transducers used to monitor the parameters of the contractions of the heart and of intrauterine contractions.[40]

The low Q factor of PVDF films makes it possible to generate short pulses with a low reverberation, while the high degree of resolution as regards position in space permits their application in elements for ultrasonic diagnostics in medicine.[41-43] Using piezoelectric bimorphic polymer films, it is possible to monitor the movement of the lips and to recognise vocal sounds and words (see Yagi [17] and contained references). Piezoelectric polymers can be used in medical diagnostics to monitor the blood flow pressure

and heart beat.[44] There have been reports of the use of PVDF films for the treatment of osteopathic affections, which is based on the influence of piezoelectricity on the human organism.[44,45]

IV. Thermal radiation sensors based on piezofilms

Films based on PVDF have found application as pyroelectric materials in local IR radiation sensors. They are used in fire detectors, in security signalling devices,[46] in contact-free instruments for the measurement of temperature, and in radar calorimeters. The employment of these materials in two-dimensional sensors, in particular in pyrovidicons, is expected in the future. An IR detector has been described[47] in which a small thickness (several micrometers) of the active element is achieved by spinning a solution of the vinylidene fluoride–trifluoroethylene copolymer immediately onto a silicon support. The use of this polymer arises from the fact that it crystallises as the polar ferroelectric β-phase, which renders the material pyroactive after polarisation. As a comparative detector, the pyrosensor based on PVDF can operate over a wide spectral range: from visible light to $\lambda = 12$ μm.[48] When an active layer of the VDF/TrFE copolymer is deposited onto an optical fibre, phase modulation is achieved.[49] Comparison of the characteristics of pyrovidicons based on triglycine sulfate crystals and PVDF films have shown that the sensitivity of the former is only 30% higher, while PVDF has a significant advantage as regards resolving power.[50]

The Siemens company has reported that PVDF is likely to be useful as a material for passive IR detectors.[51] The latter may be used to record the presence of a heat source, the directions and distances between the detector and the heat source, and also the rate of movement of the latter.[51,52] According to the ideas being developed and experiments on the recording of a moving object, it has been concluded that the response times of the above sensors are an order of magnitude shorter than those of traditional pyroelectric materials.

In discussing the question of the use of a pyroelectric PVDF-based calorimeter for the measurement of thermal diffusion, it was shown that the material has a number of undoubted advantages. In the first place, there is the possibility of making measurements under the conditions of minimal heating of the specimen and with a very low temperature gradient in the latter. This may be useful in studies on materials with a low thermal conductivity or materials extremely sensitive to temperature. On pulsed excitation, thermal diffusion may be recorded in a time interval of several milliseconds.[53] The possibility of using this type of calorimeter for the investigation of transient thermal processes with a time resolution of several nanoseconds and a sensitivity to within several nanocalories has been demonstrated.[54] A study has been devoted to technical problems associated with the improvement of the characteristics (including resolution) of such calorimeters.[55] Problems concerning the conditions in the preparation of the active element of such pyrodetectors have been touched upon.[56] PVDF-based pyrodetectors have proved successful in the estimation in a single experiment of a series of properties: specific heat, thermal diffusion, etc.[57]

The wide-band nature of photopyroelectric PVDF-based receivers has been used to estimate the distribution of the absorption coefficient in depth in specially formulated multilayer thin-film structures.[58] The form of the response curve, transformed into an optical absorption profile as a function of depth, has been analysed. The improvement of contrast in such spectra in the case of a discrete multilayer structure, combined with other procedures, makes it possible to minimise the thickness of the PVDF detector.

One of the latest reviews by Lang[59] surveys the possible applications of pyrodetectors based on ferroelectric polymers. Detectors for the monitoring of laser power in the range from 1 mW to 50 W,[60] for the determination of the energy of microwave radiation,[61,62] for the investigation of the change in temperature on nerve excitation,[63] for the recording of phase transitions in solids,[64] for the detection of defects in CdS crystals,[65] for the recording of changes in the surface of copper following the desorption of xenon from the latter by a laser pulse,[66] for the detection of thermal waves by measuring radiative emission,[67] for the investigation of adsorption phenomena,[68] for the detection of ultraheavy nuclei,[69] and for the detection of cosmic radiation[70–72] have been noted among them (in addition to those listed above). Such detectors are used in medicine,[73] in the optical fibre technology,[74,75] in photopyroelectric spectroscopy[76–78] (including the pulse response version[79]), and in photopyroelectric scanning microscopy.[80]

Reports on the potential possibility of using PVDF in vibrodiagnostics[81] and in calibration measurements of the rate of deformation[82] also merit attention.

There are definite prospects of using PVDF as a material with nonlinear optical properties. This is based on the conclusion, reached by Tsutsumi et al.,[83] according to which the internal field in the PVDF—poly(methyl methacrylate) polymer mixture can reach values of the order of 1 MV cm^{-1}. Combined with a high optical transparency of the above mixture, this makes it possible to obtain the optical nonlinearity coefficient $d_{33} = 9 \times 10^{-9}$ esu. Compared with other organic materials used in nonlinear optics, the stability of the characteristics of which is as a rule low, in the case of PVDF there is a definite possibility of increasing it by modifying the technological film preparation process. It has been shown, for example, that, on vacuum sputtering of PVDF in an electric field onto a support at a specified temperature, the stability of the resulting optical nonlinearity was increased significantly.[84] At the present time, attempts have been made to achieve these properties of PVDF films in memory elements. One of the latest reports[85] concerns advances in the use of the vinylidene fluoride–trifluoroethylene copolymer in optical memory elements. Bearing in mind that these polymers are characterised by high coercive fields and that control is usually achieved by a potential of several volts, it proved possible to obtain by a spinning method films with thicknesses less than 1 μm. It was then shown that a decrease in film thickness to ~0.2 μm is not accompanied by any significant changes in the ferroelectric characteristics. An increase in the coercive field and a decrease in the residual polarisation have been noted in films with $d < 0.2$ μm. When recording is carried out with the aid of a focussed laser beam, the minimum area employed for the recording is ~50 μm^2. Information can also be recorded and read over a period of about 1 μs and the signal-to-noise ratio has been estimated as 50 dB.[86] It appears that the presence of large internal fields in such ferroelectric materials makes them promising for use as elements in electrooptical light modulators operating in the mode involving the reflection of the light beam from a polarised polar polymer films with a dye.[87,88] On the basis of the foregoing considerations, a device has been constructed for the recording of an image in which use is made of a thin (2 μm) film of a vinylidene fluoride–trifluoroethylene copolymer. It has been shown that there are good prospects for the employment of such devices in electrophotography.[89]

Abstract. The results of studies of the molecular dynamics and structure of direct, polymeric and reverse micelles by the spin probe method using stationary ESR spectroscopy and electron spin echo spectroscopy are considered. The spin probes permit the determination of the characteristic rotation times, shapes and sizes of micelles and the local molecular mobility and polarity of different micelle regions. They also make it possible to record the processes involving the formation of micelles and premicellar aggregates and to determine the state of water in the cores of reverse micelles. Electron spin echo spectroscopy provides information about the detergent conformation and the permeability of the hydrocarbon regions of micelles. The bibliography includes 78 references.

I. Introduction

Spin probes are fine instruments for the study of complex heterogeneous systems.[1–4] Ordered micellar systems (direct and reverse micelles, microemulsions, vesicles, etc.) are important in solving many fundamental and applied problems (see, for example, Refs 6 and 7) and are convenient objects for investigations using the spin probe method. For these reasons, micellar systems have been of great interest for many years.[5] The continuing development of the ESR spectroscopic methods and the synthesis of new spin labels make it possible to solve many problems at a new level.

The present work discusses the recent results of studies on direct, reverse, and polymeric micelles by the spin probe technique.

II. Determination of the shape and size of micelles by ESR spectroscopy

The shape of a direct micelle formed by an ionic detergent in water near the critical micelle concentration (CMC) differs only slightly from spherical symmetry. The micelle consists of a hydrocarbon core, a water–hydrocarbon layer whose thickness is determined by the depth of penetration of water molecules into the hydrocarbon part of the micelle, hydrated polar groups, and a layer of aqueous solution adjacent to the micelle.[7] The charged polar groups form a compact zone several ångstroms thick on the surface of the micelle (the Stern layer), where the majority of the counterions compensating the total micelle charge are localised. The remaining counterions are located in the Gouy–Chapman layer (with a thickness up to several hundred ångstroms). They are totally dissociated and can be exchanged with other ions present in the solution.[8]

The micelle is a dynamic formation: the lifetime of a detergent molecule in the micelle is normally $10^{-7}-10^{-6}$ s, whereas the half-life of the micelle is $10^{-3}-1$ s.[7,9]

Different physicochemical experiments reveal different effective sizes of the micelle. For example, the rotational and translational dynamics of the micelle as a whole are determined by its outward size (R), evidently including the Stern layer, whereas the kinetics and recombination mechanism of hydrophobic active radicals[10] are governed by the size of the hydrocarbon core, where these radicals are dissolved.

Table 1 presents some parameters of alkyl sulfate micelles in water: the critical micelle concentration, the aggregation number, i.e. the average number of detergent molecules localised in the micelle, the micelle radius (R), and the rotational correlation time of the micelle as a whole calculated by the Stokes–Einstein equation using the values of R reported in Ref. 13.

$$\tau = \frac{4\pi\eta R^3}{3kT} \qquad (1)$$

Here η is the viscosity of water.

The rotational correlation time can be easily determined from the ESR spectrum of the spin probe,[1–4] and the radius of the rotating particle can be calculated by Eqn (1). Furthermore, the anisotropy of the rotation of the probe, i.e. the ratio of the rotation frequencies around different molecular axes,[2,14] can be determined from the ESR spectrum of the spin probe. If the rotating species is represented by an ellipsoid of rotation whose rotational anisotropy is determined by the shape of the particle, then the degree of nonsphericity of the particle, i.e. the ratio of the main axes of the ellipsoid, can be determined from the rotational diffusion data.

In order to find the rotational correlation time of the micelle and its nonsphericity from the ESR spectra of the spin probe, one important condition must be fulfilled: the spin probe should rotate only together with the micelle. In other words, rotation of the probe relative to the micelle is inadmissible.

Table 1. Critical micelle concentrations, aggregation numbers, and rotational correlation times of micelles of sodium alkyl sulfates in water at 25 °C.

Detergent	CMC/M	n	R/Å		τ/ns
			I	II	
C-6	4.2×10^{-1}	17			
C-7	2.2×10^{-1}	22		16.0	0.40
C-8	1.3×10^{-1}	27	15.5	17.1	0.45
C-9	6.0×10^{-2}	33	18.0[a]	19.2	0.65
C-10	3.3×10^{-2}	41	19.8	21.3	0.90
C-11	1.6×10^{-2}	52	22.2	23.5	1.20
C-12	8.2×10^{-2}	64	25.2	25.6	1.50
C-14	2.05×10^{-3}	80			
C-16	4.5×10^{-4}	100			

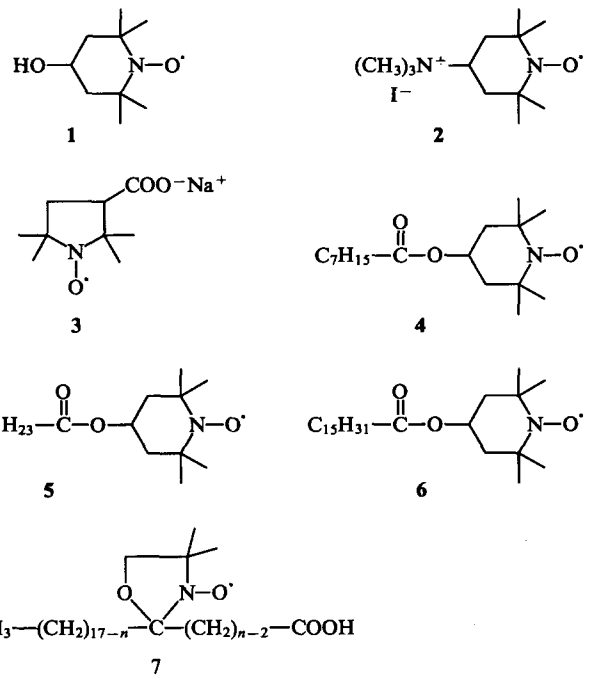
Note. The first column indicates the number of carbon atoms in the detergent alkyl chain; the values of n are based on data reported in Ref. 12; (I) determined by the light scattering method[11] at [NaCl] = 0.1 M; (II) estimated from the sizes of detergent molecules.[13]
[a] [NaCl] = 0.2 M.

An attempt to determine the shape of a sodium dodecyl sulfate micelle (concentration 0.1 M) in water by the spin probe method has been undertaken.[15] This attempt is undoubtedly interesting since the spherical micelles adopt a cylindrical shape as the detergent and electrolyte concentrations are increased;[16] this process can be monitored by the spin probe method.

3-Doxylcholestane, with a molecular size comparable to the size of the micelle, was chosen[15] as the probe:

It was assumed that the probe rotates only together with the micelle and the nonsphericity of the micelle, i.e. the ratio of the main axes of the ellipsoid of rotation (d), was determined from the data on the anisotropy of the rotation. It turned out that the shape of the micelle at 22 °C is not spherically symmetrical but can be approximated by an ellipsoid of rotation whose long axis is 7.4 times longer than the short axis. The value of d increases as the temperature is increased, but even at 59 °C $d = 5.7$, i.e. the micelle is not spherical.

Unfortunately, in this case, the rotation of the probe itself relative to the micelle cannot be excluded. Also, one cannot rule out the fact that the rotational anisotropy is due not only to the nonsphericity of the micelle but also to the nonsphericity of the spin probe molecule. Therefore, it is difficult to agree with the authors above[15] that the sodium dodecyl sulfate micelles are nonspherical. However, further investigations with probes of various sizes differing in the shape and structure of the molecule might allow the separation of the two factors — rotation of the micelle and rotation of the spin probe itself — and provide a technique for the determination of the shapes and sizes of micelles using spin probes.



III. Direct micelles

Direct micelles are constructed in such a way that the molecules of a surface-active compound (surfactant) are combined via their hydrophobic hydrocarbon (or fluorocarbon) chains, whereas the polar groups are directed towards water.[7] Let us consider the results of studies on the local molecular dynamics and structure of such micelles by the traditional ESR spectroscopic and spin echo methods.

1. ESR spectroscopy of spin probes

A micelle is a complex heterogeneous system. Therefore, the question of the location of the probe in micelles is of fundamental importance. In essence, it concerns the region (hydrocarbon core, interface, the Stern layer, etc.) about which the spin probe provides information.

The formulae of several nitroxyl radicals used as spin probes in the study of the molecular dynamics and structure of direct micelles[17–21] are given below.

The solubility of radical **1** in water is 100 times higher than in heptane.[2] It is believed[17] that this radical is located in the aqueous solvate layer surrounding the micelles of anionic detergents such as sodium octyl sulfate $C_8H_{17}SO_4Na$ (SOS), sodium dodecyl sulfate $C_{12}H_{25}SO_4Na$ (SDS), and sodium hexadecyl sulfate $C_{16}H_{33}SO_4Na$ (SHS). This radical is located mainly outside the micelle; it has not found wide use as a spin probe for studying micellar systems.

The positively charged radical **2** and the negatively charged radical **3** interact electrostatically with the negatively charged surfaces of anionic detergents (radical **2**) and the positively charged surfaces of anionic detergents (radical **3**). Radical **2** is located closer to the surface of the sodium dodecyl sulfate micelle than radical **3** is to that of the dodecyltrimethylammonium bromide micelle. This explains the fact that the ESR spectra of radical **2** are more sensitive to the structure and dynamics of the micelle than those of radical **3**.[20]

The hydrocarbon regions of radicals **4**, **5**, and **6** are located in the hydrocarbon core of the direct micelle, but the nitroxy-group is located near the micelle surface.[18,20] When using probes **5** and **6**, one should keep in mind that these probes can themselves form micellar solutions.[18]

Doxylstearic acids **7** (n-DSA, n = 5, 7, 10, 12, 16) are located in direct micelles in such a way that the carboxy-group is in the polar layer of the interface, whereas the nitroxy-group resides in the hydrocarbon core of the micelle.[21]

Spin probes make it possible to find the critical micelle concentration, determine the polarity and local molecular mobility of micelle regions where the probe is located, and detect the formation of premicellar aggregates.

At the critical micelle concentration redistribution of the probe in solution occurs which results in an abrupt change in its ESR spectrum. At concentrations below the CMC, the probe is dissolved in water. If the concentration is above the CMC, the probe is located in the micelle or on its surface. At a detergent concentration equal to CMC, a sharp change in the polarity of the probe environment and in its rotational mobility occurs. As a rule, the values of CMC determined by the spin probe method differ insignificantly from the corresponding values determined by other methods. For example, CMC values of 0.14, 8.3×10^{-3}, and 5.5×10^{-4} M were found for sodium octyl, dodecyl, and hexadecyl sulfates, respectively using probe **2**.[17] These values differ only slightly from the CMC values presented in Table 1.

The determination of the polarity of the probe environment and of its location in the molecule is based on the fact that the isotropic hyperfine coupling constant of the unpaired electron of the radical with the nitrogen nucleus (a_N) and its g-factor depend on the polarity of the medium where the spin probe is sited.[1] For example, a_N = 17.16 G for the di(*tert*-butyl)nitroxyl radical in water, whereas in heptane[3] a_N = 15.10 G. For many nitroxyl radicals, the difference between the a_N values in water and heptane is ~2 G. The value of a_N changes monotonically as the polarity of the environment changes. Hence, measurement of a_N makes it possible to determine the polarity of the probe environment and to draw a conclusion as to where the probe is located in the micelle. For example, the formation of micelles by sodium hexadecyl, dodecyl, or octyl sulfates results in a 1.0, 0.62, or 0.32 G decrease in a_N for probe **2** (in water, a_N = 16.85 G for this radical) respectively. In the opinion of the authors[17,20] such changes may be due to two reasons. First, the longer the hydrocarbon chain of the radical, the closer is the spin probe to the micelle core. Second, the arrangement and polarity of the aqueous layer in the vicinity of the micelle surface can depend on the length of the hydrocarbon group of the detergent. In our opinion, the first reason is more probable.

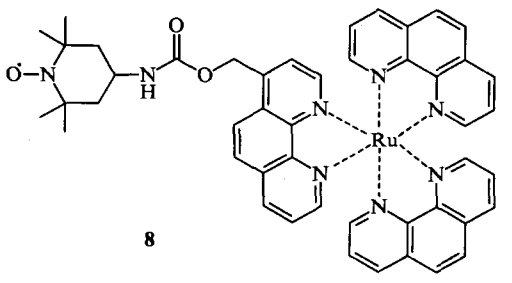
The determination of the local molecular mobility is based on the measurement of the rotational correlation time[1-4] of the radical. This value is linked to the viscosity of the system by the Einstein–Stokes relation [see Eqn (1)] and characterises the microviscosity and the local molecular mobility of the micelle at the location of the probe. However, it is important to be sure that the rotation of the probe is governed by the local mobility rather than the rotation of the whole micelle. This condition is fulfilled if the rotational mobility of the probe is much greater than that of the micelle.

The rotational correlation times of probe **2** on the surfaces of micelles of sodium octyl, dodecyl, and hexadecyl sulfates (which amount to 5.8×10^{-11}, 2.2×10^{-10} and 1.6×10^{-10} s) are much lower than the rotational correlation times of the micelle as a whole (see Table 1) and 5–20 times greater than the rotational correlation time of the probe in water.[17] This is explained by the fact that the local microviscosity of the surface layer of the micelle, where the spin probe is located, is markedly greater than the microviscosity of water. However, it is important to emphasise that the mobility of the surface layer is rather high.

The conclusion about the high local mobility of the surface layer of the micelle is also confirmed by results obtained using spin probes with long hydrocarbon radicals. The rotational correlation times of radical **4** in a micelle of sodium octyl sulfate, radical **5** in a micelle of sodium dodecyl sulfate, and radical **6** in a micelle of sodium hexadecyl sulfate are 1.2×10^{-10}, 2.4×10^{-10}, and 1.6×10^{-10} s, respectively; they differ insignificantly from the rotational correlation times of radical **2**. The hydrocarbon regions of these radicals are dissolved in the micelle hydrocarbon core, whereas the nitroxy-group is located in the surface layer, and its mobility is determined predominantly by the local molecular mobility of the micelle in the vicinity of the surface layer.[18,19]

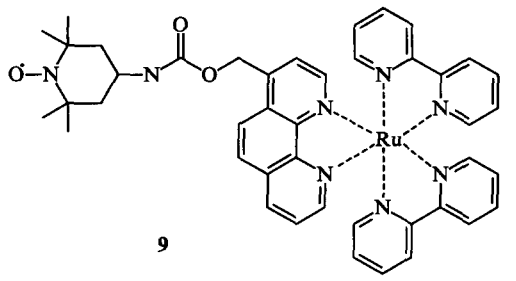
Of particular interest are the results in Ref. 21 obtained using doxylstearic acids (*n*-DSA), in which the nitroxy-group is bound to different atoms of the alkyl chain, as spin probes. These probes are located in the micelle in such a way that the carboxy-group is in the polar layer of the micelle, whereas the nitroxy-group is in the hydrocarbon core. The correlation times of these probes in micelles are fairly high (Table 2) and are comparable with the rotational correlation times of the micelle as a whole (cf. the data in Table 1).

Table 2. Rotational correlation times of doxylstearic acids in sodium dodecyl sulfate and dodecyltrimethylammonium bromide micelles at 25 °C (concentration 0.1 M) (cf. Ref. 21).



Detergent	τ/ns		
	5-DSA	12-DSA	16-DSA
Sodium dodecyl sulfate	1.1	0.82	0.43
Dodecyltrimethylammonium bromide	1.0	0.82	0.43

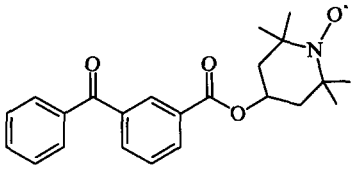
Apparently, the times observed are mainly determined by the intramolecular mobility rather than the rotation of the micelle as a whole. In the latter case, the values of τ for the three doxylstearic acids should not differ.



The local motions in the hydrocarbon core of the micelle occur at frequencies of $\sim 10^{-9}$ s^{-1}; the mobilities in the core of anionic (sodium dodecyl sulfate) and cationic (dodecyltrimethylammonium bromide) micelles are practically equal. The mobility of the hydrocarbon chains near the polar shell is lower than in the micelle centre. This explains the fact that the rotational correlation times of spin probes decrease as the nitroxy-groups move further away from the micelle surface.

Let us consider the results obtained using spin-labelled ruthenium complexes, whose formulae are shown below, as spin probes.[22] These complexes without spin probes are often used in the studies of photophysical processes in micelles.[23]

The sizes of the complexes are fairly large and comparable to the sizes of micelles (e.g. the diameter of complex **8** is ~18 Å). The rotational correlation times increase monotonically for micelles of sodium alkyl sulfates with hydrocarbon chains of different sizes (the number of carbon atoms varied from 7 to 14), while a_N decreases as the alkyl chain length increases. This is explained by the fact that the ruthenium complex is submerged deeper into the micelle the longer the hydrocarbon chain of the detergent. However, the difference between the a_N values for the complex in water and in the micelle is not high; for example, it does not exceed 0.4 G for $C_{14}H_{27}SO_4Na$. This implies that even for the largest micelles, the spin-labelled complex is located near the micelle surface and its mobility is determined by the molecular dynamics of the surface layers of the micelle. The rotational mobility of the complex is well correlated with the translational mobility determined from photophysical experiments.[24] The rotational and translational dynamics of large species, such as ruthenium complexes, on the micelle surface are probably correlated and the local molecular mobility of the micelle affects these motions similarly.



8

9

The rotational mobility of the complex depends not only on the length of the hydrocarbon group of the detergent but also on the nature of the polar group: the rotational correlation times of the ruthenium complex in the sodium dodecyl sulfate micelle are greater than in the sodium laurate micelle. This difference arises from the fact that a micelle containing sulfate groups interacts with the complex more strongly than a micelle containing carboxy-groups (in both cases, the hydrocarbon group of the detergent contains 12 carbon atoms).

The rotational correlation time of the spin probe

in the micelle increases by a factor of ~2.5 [10] when the number of carbon atoms in a sodium alkyl sulfate molecule increases from 7 to 14. Unfortunately, the value of a_N has not been reported in Ref. 10. Therefore, it is difficult to reach a conclusion as to why its rotational mobility changes, i.e. due to a change in the microviscosity of the micelle or due to a change in the site of the latter in the micelle. In our opinion, the second reason is more important.

It is interesting to note that an attempt has been made to determine the lifetime of radical **2** on the micelle surface by analysing the widths of the ESR spectral lines. [17,24] This value characterises the rate of transfer of the spin probe from the micelle into the aqueous solution. The values of $> 5.7 \times 10^{-7}$, $\sim 0.93 \times 10^{-7}$, and $\ll 1.8 \times 10^{-7}$ s were obtained for micelles of sodium hexadecyl, dodecyl, and octyl sulfates respectively. These values differ only slightly from those characterising the lifetime of molecules of the respective detergents in micelles determined by other methods. [25]

Recently, [26] the results of measuring the rotational mobility of a spin probe (doxylstearic acid) were used to establish the compatibility of hydrocarbon and fluorocarbon ionic detergents in a micelle; [26] earlier, the spin probe method was used extensively to diagnose the compatibility of polymers in mixtures. [4]

The formation of premicellar aggregates has been detected in solutions of alkyl sulfate detergents by using spin-labelled ruthenium complexes as spin probes. [22] The ESR spectrum of a spin probe at concentrations of the detergent far below the CMC (for example 1.5×10^{-3} M for sodium dodecyl sulfate at CMC $\simeq 8.3 \times 10^{-3}$ M) represents a superposition of a narrow triplet (the spectrum of the probe in water) and a broad triplet arising from the molecules of the probe located on premicellar aggregates. These aggregates are small and their sizes are much smaller than those of a micelle. Several spin probe molecules are adsorbed on one premicellar aggregate. The spin probes are spaced so closely that their dipole interaction results in a noticeable broadening of the ESR spectrum. The formation of premicellar aggregates has been observed for sodium alkyl sulfates with 7 – 14 carbon atoms in the hydrocarbon chain.

Naturally, one cannot rule out the possibility that the formation of the premicellar aggregates can be initiated in this case by the spin probe molecules. However, it is important to emphasise that the conclusion that premicellar aggregates exist in detergent solutions [22] is in good agreement with the results of thermodynamic calculations, [7] photophysical measurements, [27] and data obtained by other methods. [28,29]

2. Electron spin echo modulation spectroscopy

The idea of applying the electron spin echo modulation method to determine the structure of the micelle consists in the following. The electron spin echo signal of the probes can be modulated by the weak dipole hyperfine interaction of the unpaired electron of the probe with the magnetic moments of the surrounding nuclei. The modulation depth depends on the number of surrounding atoms and their distance from the unpaired electron, provided that this distance does not exceed ~6 Å. [30] Usually, the depth of modulation by deuterium atoms is determined. Once the modulation depth has been determined, one can conclude which magnetic nuclei surround the spin label and how far away they are located.

Experiments on the determination of the micelle structure by the electron spin echo modulation method are normally performed in quickly frozen solid solutions at 4.2 K (the dipole interaction in the liquid is averaged to zero due to molecular motion). [31–41]

Much effort has been devoted to ensuring that the structure of the micelles does not change upon rapid freezing. For example, the radical-cation of *N, N, N′, N′*-tetramethylbenzidine (TMB) is readily formed when TMB is illuminated. This radical-cation is stable in micellar systems, but is quickly destroyed in homogeneous media. [42] It turned out that if this radical-cation is obtained in a micellar system which is then quickly frozen and allowed to thaw, then the ESR spectrum of the radical-cation is observed for a long time at room temperature. [34] A similar result is observed when the radical-cation is generated in a frozen micellar system, and the ESR spectrum is observed at room temperature. [33] According to the authors [31–41], these results imply that the micellar structure of the system is retained upon freezing.

There is also other evidence that the micellar structure is retained upon rapid freezing. In particular, the aggregation numbers of sodium dodecyl sulfate micelles in water at room temperature and in a frozen system differ only slightly. [43] The conclusion that the micellar structure is retained upon rapid freezing is also confirmed by electron microscopy. [44]

The most interesting data were obtained by the electron spin echo modulation method; doxylstearic acids, in which the nitroxy-group is linked to different carbon atoms of the alkyl chain, were used as spin probes. [31–41]

Let us now consider the results obtained for ionic and nonionic detergents.

a. Ionic micelles

Studies of the micelles formed by sodium, lithium, and tetramethylammonium dodecyl sulfates showed [31–34,41] that the structures of these micelles differ strongly, although the lengths of the alkyl parts of the detergent molecules are the same (12 carbon atoms). The differences in the structure and permeability of these micelles are governed by the nature of the counterion. Detergent molecules deuteriated at the terminal methyl groups, deuteriated water, and the deuteriated tetramethylammonium cation were used in these studies.

The modulation depth of the spin echo of sodium dodecyl sulfate micelles, which characterises the dipole interaction of the lone pair belonging to the spin label with the deuteriated terminal methyl groups of the detergent, increases monotonically as the nitroxy-group moves further away from the carboxy-group of the doxylstearic acid (i.e., as *n* in the formula of compound **7**, *n*-DSA, increases). This implies that the distance between the spin label and the terminal methyl groups increases.

The depth of modulation due to dipole interaction with the magnetic moments of the deuterium in D_2O decreases as the spin label moves further away from the carboxy-group, since this results in an increase in the distance between the spin label and the micelle surface. According to the authors,[32,33] the doxylstearic acids in a sodium dodecyl sulfate micelle have an extended conformation and the detergent molecules are ordered in such a way that the terminal methyl groups are located near the micelle centre. Water hardly penetrates into the hydrocarbon micelle core.

Quite different behaviour is observed in the case of micelles of tetramethylammonium and lithium dodecyl sulfates. They are characterised by a nonmonotonic variation of the spin echo modulation depth due to interactions with the terminal methyl groups of the detergent and with D_2O as the spin label in *n*-DSA moves away from the carboxy-group. Furthermore, the depth of modulation due to the interaction with D_2O is much greater for these micelles than the corresponding value for the sodium dodecyl sulfate micelles.

The features observed can be explained by the fact that the doxylstearic acid in micelles of tetramethylammonium and lithium dodecyl sulfates, in contrast to that in micelles of sodium dodecyl sulfate, has the bent conformation[32] drawn schematically in Fig. 1. Moreover, the structures of the micelles of lithium and tetramethylammonium dodecyl sulfates differ significantly from that of sodium dodecyl sulfate (Fig. 2). In the former case, the detergent molecules in the micelle are bent and the micelle has an open structure, where the counterion can be located between the anionic 'heads' of the micelle. As a result, water penetrates much deeper into the hydrocarbon core of these micelles than into the core of the sodium dodecyl sulfate micelle.

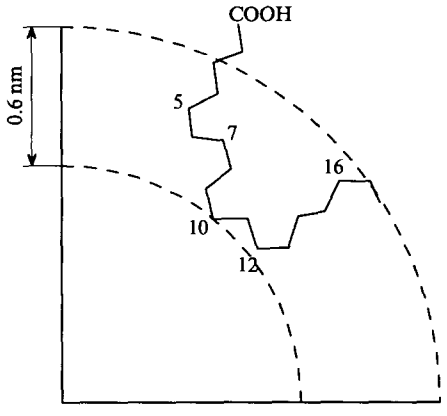


Figure 1. Conformation of *n*-DSA in a tetramethylammonium dodecyl sulfate micelle.[32] The numbers specify the carbon atoms to which the nitroxy-group is attached.

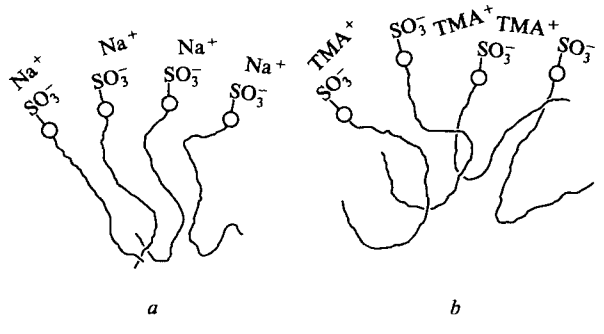

Figure 2. Fragments of a sodium dodecyl sulfate micelle (*a*) and a tetramethylammonium dodecyl sulfate micelle (*b*).[32] TMA^+ is the tetramethylammonium cation.

The results obtained[31–34,41] demonstrated that minor changes in the detergent structure, i.e. replacement of the Na^+ cation by Li^+ or the tetramethylammonium cation, result in significant changes in the micelle structure and in the permeability of the hydrocarbon core.

A study of the effect of urea on the structure of micelles of anionic (sodium dodecyl sulfate) and cationic (dodecyltrimethylammonium bromide) detergents has shown[35] that in both cases urea interacts with the polar groups of the micelle surface. Since this interaction is stronger for dodecyltrimethylammonium bromide, more urea molecules are solubilised on the micelle surface. This explains the fact that urea changes the CMC of dodecyltrimethylammonium bromide more strongly than that of sodium dodecyl sulfate.

The results obtained by the spin echo method are in good agreement with the results of studies on the effect of urea on the structure of the micelles of sodium dodecyl sulfate and dodecyltrimethylammonium bromide by ESR spin probe spectroscopy.[21] The latter show that urea is solubilised on the micelle surface and partially penetrates into the hydrocarbon core near the surface. Urea partially substitutes water in the micelle hydrate shell; this has a weak effect on the polarity but increases markedly the microviscosity of the micelle surface layer.

Crown ethers are also localised on the surfaces of sodium and lithium dodecyl sulfate micelles, giving rise to complexes of the crown ether with the counterion.[36,37] The complex is localised on the micelle surface; as a result, the hydration of the surface decreases.

The addition of an alcohol results in an increase in the penetration of water into the sodium dodecyl sulfate micelle core; at high concentrations of alcohol, destruction of the micelle can occur. The effect of the alcohol depends on the length and degree of branching of the alkyl chain of the aliphatic alcohol in the series 1-propanol < 2-propanol < 1-pentanol < 1-octanol.[38,39]

The spherical micelles of ammonium perfluoroctanoate $[CF_3(CF_2)_6COONH_4]$ were studied by the electron spin echo method[45] using doxylstearic acids **7** whose nitroxy-groups were linked to the hydrocarbon chain at the 5-, 12-, or 16-positions (5-DSA, 12-DSA or 16-DSA). The study of the structures of the micelles of perfluorinated detergents is undoubtedly of interest, since the properties of these micelles differ significantly from those of similar hydrogen-containing detergents. For example, the aggregation number (*n*) for the $CF_3(CF_2)_6COONH_4$ micelles is about twice that for the $CH_3(CH_2)_6COONH_4$ micelles.

It has been found that doxylstearic acids in ammonium perfluoroctanoate micelles are arranged in such a way that the carboxy-group is located in the polar layer of the interface and is surrounded by the polar groups of the detergent. The hydrocarbon chain of the spin probe is not directed to the micelle centre (along the fluorocarbon chains) but is located in the micelle core close to the interface. It turned out that the distances from different carbon atoms of the alkyl chain in *n*-DSA to the interface differ insignificantly. The nitroxy-groups of all *n*-DSA are accessible to water molecules, but the nitroxy-group of 12-DSA is slightly closer to the interface (it is surrounded by four water molecules) than the nitroxy-groups of 5-DSA or 16-DSA (each of them is surrounded by two water molecules). It is noteworthy that the local environment of the nitroxy-groups of 5-DSA in an ammonium perfluoroctanoate micelle is apparently not the same as that of 16-DSA. This follows from the fact[46] that the rotational correlation time of the probe determined by ESR is much lower for 5-DSA (2.3×10^{-10} s) than for 16-DSA (1.1×10^{-9} s).

b. Nonionic micelles

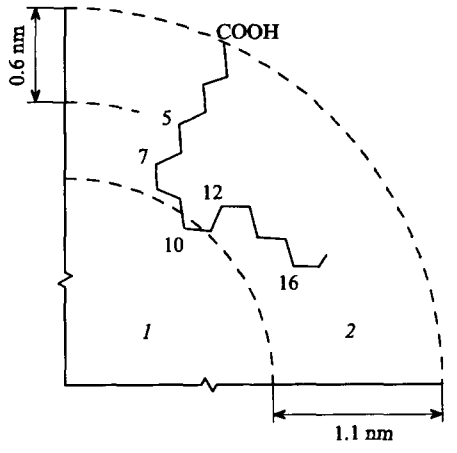
The micelles formed by nonionic detergents in water can solubilise organic compounds. These detergents have a low toxicity and are extensively used in the food and pharmaceutical industries.[47]

Typical representatives of nonionic detergents are polyoxyethylene compounds with the general formula[48] $n\text{-}C_nH_{2n+1}.(OCH_2CH_2)_mOH$. They consist of an alkyl chain comprising 8–12 carbon atoms and the more polar oxyethylene groups. The structure of the micelles formed by these detergents has been studied in detail by the spin echo method.[40,41]

Detergents containing a different number of carbon atoms in the alkyl chains (C_n) and a different number of oxyethylene groups (E_m) were used: $C_{12}E_6$, $C_{12}E_8$, C_6E_8, and C_8E_8. The detergent molecules were selectively deuteriated, either at the alkyl chain or at the oxyethylene groups. The same doxylstearic acids (7, *n*-DSA) with the spin labels at different carbon atoms of the alkyl chain were used as spin probes. D_2O was used to elucidate whether water can penetrate deeply into the micelle.

The following results were obtained.

1. The doxylstearic acid introduced as the spin probe into a micelle is predominantly localised in the polyoxyethylene part of the micelle and has a bent conformation (Fig. 3). The spin label does not penetrate deeply into the hydrocarbon core (for example, not more than by ~1 Å for the $C_{12}E_6$ micelle). The hydrocarbon and polyoxyethylene parts do not mix with each other and are separated by a distinct boundary.



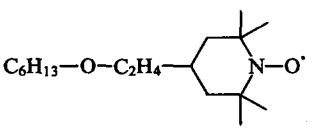


Figure 3. Conformation of *n*-DSA in a polyoxyethylene $C_{12}E_6$ micelle. The numbers specify the carbon atoms to which the nitroxy-group is attached:[40] (*1*) hydrocarbon core; (*2*), polyoxyethylene shell.

2. Water virtually does not penetrate into the micelle hydrocarbon core and penetrates only slightly into the outer polyoxyethylene shell. The polyoxyethylene layer is a reliable protection against the penetration of water into the hydrocarbon core. Only 1–2 oxyethylene moieties, located in the immediate vicinity of the micelle boundary are in contact with water. The longer the hydrocarbon and polyoxyethylene groups, the greater the difficulty with which water penetrates into the micelle. The surfaces of nonionic micelles are hydrated much more weakly than those of ionic micelles.

IV. Polymeric micellar systems

Polymer chains can be involved in the formation of ordered micellar structures in water. Polyelectrolyte complexes, i.e. the products formed by polyelectrolytes and surfactants,[49] are an example of these structures. The electrostatic interaction of the oppositely charged groups of the polyelectrolyte and the detergent and the hydrophobic interaction of the hydrocarbon regions of the detergent molecules play the major role in the formation of polyelectrolyte complexes. When a polyelectrolyte complex is formed, the detergent molecules form an internal macromolecular hydrophobic region (the micellar phase) reinforced by a polymer chain. Either water-soluble or insoluble polyelectrolyte complexes can be formed, depending on the polymer/detergent ratio in the aqueous solution. For example, the polyacrylic acid—dodecyltrimethylammonium bromide system at pH 6 with the concentration ratio of the surfactant and the polyacrylic acid monomer units $\varphi \leqslant 0.3$ yields a water-soluble complex whose composition (φ) is the same as that of the reaction mixture. The solubility of this complex is determined by the length of the polymer regions not bonded with detergent molecules. If the molar fraction of the detergent is increased, a complex is formed whose composition corresponds to $\varphi = 1$. Not all polyelectrolyte molecules dissolved in water participate in the formation of these complexes. However, all the units of the polymer chain participating in the complex formation interact with the detergent molecules. These complexes are insoluble in water and form precipitates.

A spin probe, whose structure is shown below, has been used to study the structure and molecular dynamics of both water-soluble and insoluble polyacrylic acid — dodecyltrimethylammonium bromide complexes.

The structure of this complex and the assumed location of the probe are presented in Fig. 4.

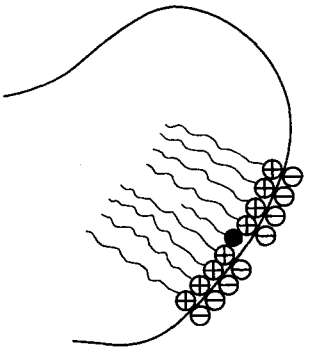

Figure 4. Structure of a polyelectrolyte–detergent complex.[50] The filled circle represents a spin probe.

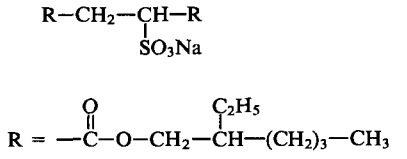
The following results were obtained:[50]

1. The a_N constant for a polymeric micellar system (16.2 G) is lower than that for an aqueous solution of the polymer (16.9 G). Evidently, the nitroxy-group of the probe is located near the polymer chain of the complex and not in water (see Fig. 4).

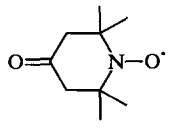
2. The rotational correlation time of the probe in the polymer complex (7.2×10^{-10} s) is almost twice as long as that in a dodecyltrimethylammonium bromide micelle. This implies that the local mobility in polymeric micelles is much smaller than in spherical micelles of the same detergent. It cannot be ruled out that detergent molecules are more densely packed in a polymeric micelle than in a spherical micelle.

The rotational correlation time of a spin probe at $\varphi \leqslant 0.3$ does not depend on the composition of the complex. Moreover, the rotational correlation time of the probe in a water-soluble complex is almost equal to that in an insoluble complex. These results are consistent with the hypothesis of the block structure of polyelectrolyte–detergent complexes[49] and permit the conclusion that the phase separation accompanied by the formation of insoluble complexes does not result in an appreciable change in the molecular mobility and hence in the packing density of the detergent molecules in ordered polymeric micellar systems.



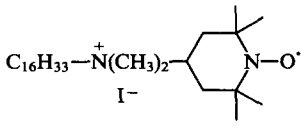
V. Reverse micelles

Many ionic and nonionic detergents form reverse micelles in nonpolar solvents.[51] These micelles consist of a polar core and a nonpolar shell. The main feature of these micelles is their ability to solubilise the polar molecules localised in the micelle core; for example, water molecules. When the water content is high, thermodynamically stable microemulsions are formed. Their use as microreactors opens up new prospects for conducting photochemical, catalytic, polymerisation, oxidation, and other processes. Reverse micelles are also of interest as models of biological membranes.[52–55]

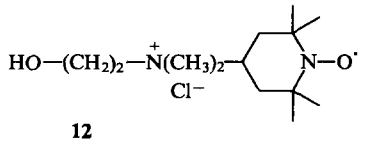


The conditions for the appearance of reverse micelles, their structure and properties, and the characteristics of the kinetics and mechanisms of the reactions occurring in them have been thoroughly studied by various physicochemical methods.[51–55] We shall discuss certain results obtained by the spin probe method.[56–65]

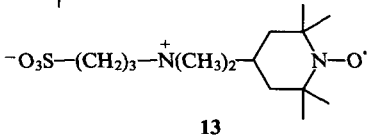
1. Ionic reverse micelles



In the studies by the spin probe method particular attention has been devoted to reverse micelles of sodium bis(2-ethylhexyl)-sulfosuccinate or Aerosol OT (AOT).[56–59, 61, 62, 64]



Various probes, soluble either in the aqueous core or in the hydrocarbon shell of the micelle, were used.



10

11

12

13

n-DSA (where n = 5, 6, 7, 9, 10, or 16) were also used as probes.

It was shown by use of the light scattering technique[66] that the aggregation number of micelles formed by AOT molecules in nonaqueous media is ~23 in the absence of water. The micelle is almost spherical with a diameter of ~24 Å. The addition of water results in an increase in the micelle size and an improvement in its sphericity. Moreover, a cavity consisting of water molecules and surrounded by a monolayer of AOT molecules is formed inside the micelle. The monolayer thickness is ~11 Å and the radius of the aqueous cavity can be calculated (in ångstroms) according to the formula [58, 62, 67]

$$r \sim 1.5\, W_0,$$

where W_0 is the ratio of the concentrations of water and AOT in the system.

It is interesting to note that the length of the hydrocarbon part of the AOT molecule calculated on the basis of the standard interatomic distances in organic molecules[68] is 12.57 Å, whereas the length of the hydrophilic head ($Na^+O_3S^-$) is 5 Å.

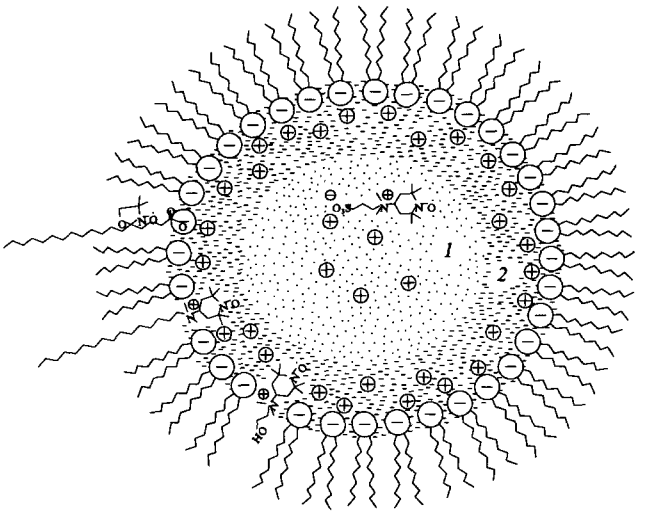


Figure 5. Schematic illustration of an AOT reverse micelle with spin probes:[62] (*1*) 'free' water; (*2*) hydrate layer.

Fig. 5 illustrates schematically an AOT reverse micelle in isooctane and shows the assumed locations of the probes.

The following questions are of interest when the results of studies on the molecular dynamics and structure of reverse micelles by the spin probe method are discussed.

1. What is the state of the water in the centre of a reverse micelle? Is the water 'free', i.e. with the properties of bulk-phase water, or does it participate in the formation of the hydrate layer?

2. Does water penetrate into the micelle hydrocarbon shell and is this penetration sufficiently deep?

3. What is the mobility of the micelle hydrocarbon shell, and how does this depend on the distance from the polar group and on the water content in the micelle?

The conclusion was reached on the basis of analyses of the isotropic hyperfine coupling constants and the rotational mobility of spin probes located in different micelle regions [52–59, 62, 64] that, for a high water content ($W_0 > 20$), the central region of the micelle contains 'free' water whose properties do not differ from those of the usual water. Not all the water solubilised in the micelle is free, a proportion of its molecules participating in the formation of the hydrate layer. For a low water content ($W_0 < 10$), all the water participates in the formation of the hydrate layer. For $10 < W_0 < 20$, the formation of free water begins.

Specimens with $W_0 = 30$ studied at low temperatures display a superposition of the ESR spectra for radicals **10** localised in water and in the micelle hydrocarbon shell.[58] The activation energy for probe transfer from the hydrocarbon shell to water was determined (~30 kJ mol^{-1}) from the temperature dependence of the line widths. The conclusion was reached[59] on the basis of detailed modelling of the spectra that fast probe exchange between the hydrocarbon shell and the hydrate layer and slow exchange between the hydrate layer and free water occur. However, the question why the frequency of probe exchange between the two aqueous phases is lower than between the aqueous phase and the hydrocarbon shell remains open.

Fig. 6 presents the dependence of the hyperfine coupling constant for doxylstearic acid in an AOT reverse micelle on the number of the carbon atom linked to the nitroxy-group. The value of a_N is a maximum for 5-DSA and decreases as n increases, i.e. as the nitroxy-group moves away from the micelle core. An analysis of the a_N constants for doxylstearic acids incorporated into the shells of micelles with different water contents led to the conclusion[62] that water penetrates into the hydrocarbon shell and that the accessibility of the shell to water is greater the closer the given shell region to the micelle centre and the higher the water content in the micelle core.

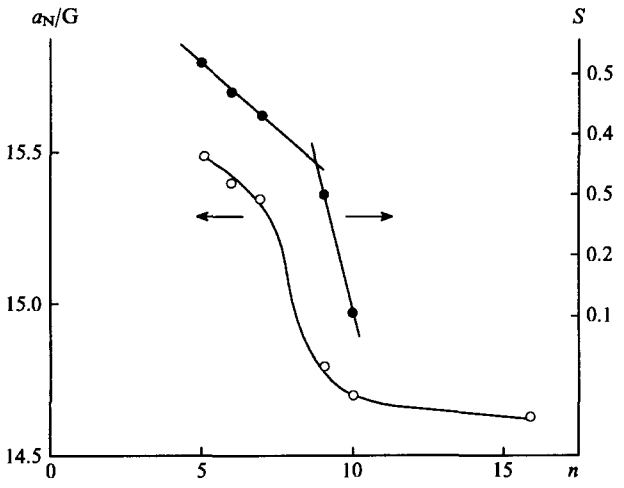

Figure 6. Dependence of the isotropic hyperfine coupling constant (a_N) and the order parameter (S) of the spin probe on the number of the carbon atom (n) to which the nitroxy-group in the n-DSA incorporated in the micelle is attached.[62]

The molecular mobility of doxylstearic acids in the shell of the AOT micelles was characterised[62] by the order parameter S calculated by the equation[69,70]

$$S = \frac{A_{\parallel} - A_{\perp}}{A_{zz} - \frac{1}{2}(A_{xx} + A_{yy})} \frac{a_0}{a_N}. \quad (2)$$

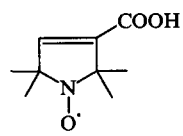
Here A_{xx} = 6.3, A_{yy} = 5.8, and A_{zz} = 33.6 G are the main values of the hyperfine coupling tensor for doxylstearic acids, $A_{\parallel}$ and $A_{\perp}$ are the corresponding parameters determined from the experimental ESR spectra,[69,70] and a_0/a_N is a correction for the polarity of the probe environment: $a_0 = (1/3)(A_{xx} + A_{yy} + A_{zz})$, $a_N = \frac{1}{3}(A_{\parallel} + 2A_{\perp})$. The S parameter is frequently used to characterise the strongly anisotropic rotation of spin labels, for example, the rotation of lipid spin labels in biomembranes.[69]

The S parameter depends on the frequency and amplitude of the motion of the spin label. In particular, the model of the rapid oscillation of the long axis of a lipid spin label (at frequencies above 10^8 s^{-1}) assumes that $S = 0$ if the oscillation half-amplitude is 90° and $S = 1$ if the oscillation half-amplitude is zero.[70] The S parameter is normally used to characterise the relative variation of the molecular mobility, for example, for constructing the flexibility profiles of biomembranes.[70]

The S parameter determined for doxylstearic acid in AOT reverse micelles decreases almost linearly as the spin label moves further away from the carboxy-group (Fig. 6).[62] Simultaneously, the rotation of the label becomes increasingly more isotropic. This implies that the amplitude of the movement of the hydrocarbon chain segment of the AOT molecule in the micelle increases as it moves further away from the micelle centre. In other words, the mobility of the micelle hydrocarbon shell increases as it approaches the terminal methyl groups. The conclusion that the molecular mobility of the micelle shell depends on the distance from its centre is consistent with the results[71] obtained by the ^{13}C NMR method.

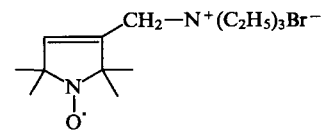
The S parameter depends not only on the distance of the spin label from the micelle centre but also on the water content in the micelle: it increases with the diameter of the aqueous core of the micelle. An increase in the water content in the micelle is accompanied by a decrease in the intensity of the molecular motion in the hydrocarbon shell.

It is important to emphasise that the S value could be determined reliably only for micelles with $W_0 > 10$ whose radii were above 25 Å.[62] The rotation of small micelles (for $W_0 < 10$) as a whole and the lateral diffusion of the spin probe along the micelle surface to a large extent average out the hyperfine coupling anisotropy, thus preventing the correct determination of the S parameter.



The structure and permeability of the AOT reverse micelle in isooctane were determined by the electron spin echo modulation method,[64] using the same doxylstearic acids as in the ESR studies of the structure of this micelle.

Analysis of the dipole interaction of the spin label with the magnetic moments of deuterium in D_2O and deuteriated isooctane led to the conclusion that the doxylstearic acid is incorporated into the micelle in such a way that the carboxy-group is located near the hydrophilic SO_3^- group of the detergent. The doxylstearic acid in the AOT micelle has an extended conformation similar to that in direct micelles of sodium alkyl sulfates. Isooctane virtually does not penetrate into the bulk of the micelle but readily enters the outer regions of the hydrocarbon shell. An increase in the volume of the aqueous cavity results in a decrease in the hydrocarbon shell permeability to isooctane. For a low water content ($W_0 < 10$) the area of the hydrocarbon shell–water interface is too small to accommodate all the polar 'heads' of the molecules at this boundary. An increase in the water content leads to a structural rearrangement. As a result, all the polar 'heads' are located at the interface. The results obtained[64] confirm the existing idea that the shell almost completely prevents the penetration of the hydrocarbon into the micelle core.

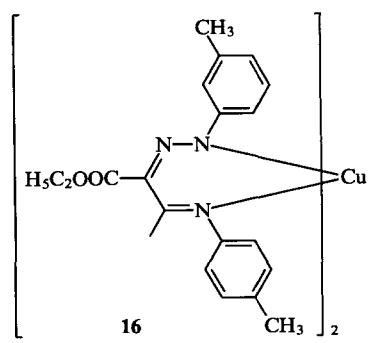


2. Nonionic reverse micelles

The compound $CH_3(CH_2)_8C_6H_4(OCH_2CH_2)_4OH$ readily forms reverse micelles in cyclohexane in the presence of a small amount of water.[72]

The following nitroxyl radicals were used in the study of the molecular dynamics and structure of these micelles by spin probe ESR spectroscopy.[65]

14



15

5-DSA was also used as the probe.

Radical **14** is soluble in water and cyclohexane, but its solubility in water is 10^3 times greater than in cyclohexane.[2] Radical **15** is only soluble in water and practically insoluble in cyclohexane and other nonpolar solvents. The 5-DSA radical is readily soluble in the micelle hydrocarbon shell and also in cyclohexane.

Apart from nitroxyl radicals, paramagnetic copper compounds were also used: $CuCl_2$ (water-soluble) and complex **16** (soluble in cyclohexane and other nonpolar solvents).

16

Specimens with $W_0 = [H_2O]/[\text{surfactant}] = 0.1-6.9$ were used (nonionic reverse micelles solubilise less water than ionic micelles).

For probe **14** in all the specimens with $W_0 > 0.3$, a superposition of the ESR spectra of the radicals in the aqueous core (a_N = 16.1 G in water) and in cyclohexane (a_N = 14.1 G) was

observed. The solubility of the radical in water is much higher than in cyclohexane, but the amount of cyclohexane in the specimen is much greater than that of water. As a result, the number of radicals dissolved in water is comparable to that in cyclohexane and a superposition of the spectra is therefore observed.

If $CuCl_2$ is added to the water involved in the formation of the micelle core, then the spectrum of radical **14** is observed only in cyclohexane. If paramagnetic complex **16** is added to cyclohexane, the ESR spectrum of the radical is observed only in the aqueous core of the micelle. In both cases, the disappearance of one of the spectra is caused by its broadening due to the exchange interaction with the paramagnetic copper ion. This method for the separation of complex spectra [2,73] is extensively used in the study of complex microheterogeneous systems. Not only paramagnetic copper compounds, but also iron compounds such as $K_3Fe(CN)_6$, are used as broadening agents that penetrate differently into different regions of a complex system.

Radical **15** is insoluble in cyclohexane or in the micelle hydrocarbon shell and is localised in the aqueous core. The results obtained using radicals **14** (with the addition of complex **16** to cyclohexane) and **15** are in good agreement.

The aqueous core of the micelle has a minimal local mobility for $W_0 = 0.6$ (for radical **15** $\tau = 5.4 \times 10^{-10}$ s and $a_N = 15.1$ G). An increase in the water content in the micelle results in a decrease in the rotational correlation time of the radical, while τ and a_N approach the corresponding values for this radical in water ($\tau = 0.5 \times 10^{-10}$ s, $a_N = 15.9$ G).

Comparison of the values of τ and a_N and of the temperature dependences of the rotational correlation times for radical **15** in the aqueous core of the micelle and in a model system — polyoxyethylene swollen in water — shows [65] that an aqueous cavity, whose formation involves free water molecules, appears in the micelle centre. The micelle core is inhomogeneous and water is not distributed uniformly along the oxyethylene chains, at least a fraction of the water being segregated as a separate phase in the centre of the micelle.

When complex **16** is added to cyclohexane, the intensity of the ESR spectrum of radical **15** localised in the aqueous core of the micelle decreases. This is explained by the dipole interaction of the complex with the radical depending on their distance of closest approach. [74–76] The distance of closest approach is the minimum distance that can be reached between the complex and the radical as they approach each other. When the water content in the micelle increases (W_0 increases from 0.6 to 6.9), the distance of closest approach of the complex (in cyclohexane) and the radical (in the micelle core) increases approximately by a factor of two. This is explained by the fact that an increase in the water content results in a decrease in the permeability of the micelle hydrocarbon shell to the molecules of cyclohexane and the organic compounds dissolved in it. The decrease in the shell permeability can be due to a decrease in the intensity of the molecular motion of the hydrocarbon chains.

The conclusion that the intensity of the molecular motions of the hydrocarbon chains of the micelle shell decreases with increase in the water content has been confirmed by studying the ESR spectra of the 5-DSA radical. This radical is almost totally solubilised in the micelle hydrocarbon shell. The ESR spectrum of the radicals dissolved in cyclohexane is fully broadened [is broadened until its complete disappearance? (Translator)] when complex **16** is added to cyclohexane. The radical is localised in the micelle shell so that the nitroxy-group is located in the region consisting of the polyoxyethylene groups. In the $1.8 < W_0 < 6.9$ range, ESR spectra indicate a highly anisotropic rotation of the probe. An increase in the water content in the micelle leads to a monotonic growth of the S parameter calculated according to Eqn (2) ($S = 0.35$ and 0.44, respectively for $W_0 = 1.8$ and 6.9). The reason is that an increase in the volume of the micelle aqueous phase results in a decrease in the intensity of the molecular motion of the micelle shell.

Thus the molecular structure, dynamics, and permeability of the hydrocarbon shells of nonionic reverse micelles depend markedly on the amount of water solubilised by the micelle core. [65]

It is interesting to note that the ESR spectra of spin probes **14** and 5-DSA for low water contents ($W_0 < 0.3$) indicate that a fast exchange (at frequencies above 10^8 s^{-1}) of the radicals localised in the micelle shell and in cyclohexane occurs. Evidently, a fast exchange between detergent molecules localised in the micelle shell and dissolved in cyclohexane also takes place under these conditions. If the content of water increases, the rate of exchange decreases, and the process becomes slow (on the ESR time scale).

VI. Conclusion

Spin probes are a unique instrument for studying the molecular dynamics and structure of ordered micellar systems. They make it possible to determine the characteristic rotational times and the shape of the micelles, to record the micelle formation process and the formation of premicellar aggregates, and to determine the local molecular mobility and polarity of different micelle regions. The use of electron spin echo spectroscopy provides interesting information about the conformational state and permeability of the micelle hydrocarbon regions. It has been found unexpectedly that small changes in the structure of the detergent molecule, for example, the replacement of the Na^+ cation by Li^+ or the tetramethylammonium cation, result in substantial changes in the packing, conformation, and permeability of the hydrocarbon core of an alkyl sulfate micelle. Water hardly penetrates into the hydrocarbon cores of nonionic direct micelles of polyoxyethylene detergents and penetrates into the outer polyoxyethylene shell only to a very slight extent.

Polymeric membrane systems, whose detailed investigation has recently begun, are of particular interest. It has been shown by the spin probe method that the local mobility of detergent molecules in a polymeric micelle is much lower than in micelles of the same detergent containing no polymer.

The studies on reverse micelles have revealed the state of water in the micelle core (bound water participating in the formation of the hydrate layer or free water possessing the properties of the usual water). It was found how the local mobility and permeability of the hydrocarbon shell of the micelle depend on its water content and on the distance from the shell to the micelle centre.

It is important to stress that the above principles and approaches, developed during the study of the molecular dynamics and structure of direct, reverse, and polymer micelles, are used successfully to study more complex ordered molecular systems, such as multicomponent emulsions and vesicles (see, for example, Refs 77, 78).

This review has been written within the scope of works supported by the Russian Fund for Fundamental Research (grant 94-03-08572).

Abstract. Nonpolar hydrocarbons which vitrify at a low temperature constitute a 'classical' model system for the investigation of the characteristic features of the radiolysis of nonpolar organic compounds. Considerable experimental data have now accumulated for hydrocarbon glasses, which permit in many instances quantitative assessments of the applicability of various theories. 3-Methylpentane occupies a special place among these substances. Attention is concentrated mainly in this review on the recombination, polarisation, and separation of the electron–ion pairs generated by ionising radiation. The bibliography includes 163 references.

I. Introduction

The greatest advances in the study of reactions involving excess electrons have been achieved previously for liquid media (see the relevant reviews[1–4]). However, free electrons were first detected in weakly polar glasses. The results of many investigations of liquid and solid hydrocarbons have shown that most of the electrons generated by ionising radiation are thermalised during the interaction with the molecules of the given substance over distances at which the Coulombic potential of the attraction of 'own' positive ions is greater than the thermal energy.[1,5] The charge separation in space depends on the type of ionising radiation. For example, radiation with a low linear density of energy losses (high energy electrons, ^{60}Co γ-radiation, etc.) leads, according to Mozumder,[5,6] to the formation of mainly isolated pairs of charges, in a proportion of 60%–70%. The fraction of pairs forming part of groups containing between 4 and 30 pairs is ~14% while that of pairs in groups with more than 30 pairs is <10%.

The behaviour of 'geminate' pairs of charges (or groups forming a track) is not described by the equations of 'usual' homogeneous kinetics.[7] The unusual feature involving the generation of charged particles on exposure to ionising radiation was noted long ago.[8] At the present time, it has been established that this determines the nature of the kinetics of the ionic processes in the liquid-phase radiolysis of hydrocarbons. Again, this feature must not be disregarded in considering the kinetics of the various phenomena induced by ionising radiation in solid hydrocarbons: isothermal and thermostimulated luminescence, optical absorption, electric conductivity, and photoconductivity.

Extensive experimental data have now accumulated from studies on the behaviour of electrons in solid and liquid nonpolar hydrocarbons. These data indicate the similarity of such systems. The appreciable difference between the time scales of the processes led in the beginning to more active studies on solid hydrocarbons. Certain details of the processes were then elucidated, but these became available to experimenters studying liquid systems only during the last decade. In particular, this applies to the electric polarisation of electron–ion pairs. Many questions concerning the behaviour of electrons in various solid nonpolar media have been answered in a series of review publications (see, for example, Refs 9–12). However, the 'classical' system—vitrifying nonpolar hydro-carbons—still remains under consideration by investigators. This review is devoted to the behaviour of electrons in such a system during processes involving the ionisation, recombination, and separation of electron–ion pairs.

1. Yield of separated pairs of charges

Two very important processes control the kinetics of the reactions involved in the generation of charges by ionising radiation in nonpolar glasses: separation and recombination of electron–ion pairs. The diffusion-drift ideas, based on the consideration of the motion of classical particles with a mean free path much shorter than the characteristic dimension of the problem, are usually employed to describe these processes in an amorphous nonpolar substance.[13,14] The simplest case is that of isolated pairs.

Having applied the Smoluchowski equation to this case, Onsager[15] obtained the exact expression for the probability $\phi(\boldsymbol{r},\boldsymbol{E})$ of the separation of charged particles, the position of which is specified by the vector $\boldsymbol{r}$ directed at an angle θ relative to the external field $\boldsymbol{E}$ with a strength E (Fig. 1).

$$\phi(\boldsymbol{r},\boldsymbol{E}) = \exp\left[-\frac{r_c}{r} - \beta r(1+\cos\theta)\right] \times \sum_{m,n=0}^{\infty} \frac{\beta^{n+m}(1+\cos\theta)^{n+m} r_c^m r^n}{m!(m+n)!} \quad (1)$$

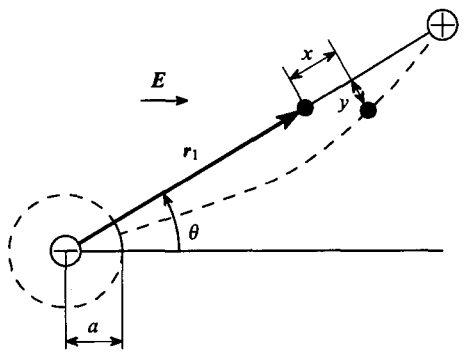

Figure 1. Schematic explanation of the notation. The radius vector of the electron in the absence of an external field is r_1; the trajectory in the mutual approach of ions without allowance for diffusion in the presence of an external field E is shown dashed; x and y are respectively the radial and tangential deviations of the position of the electron from r_1 in the presence of an external field.

After averaging with respect to the angle θ, we have[16]

$$\phi(r,E) = 1 - (2\beta r)^{-1} \sum_{m=1}^{\infty} P(m,2\beta r) P\left(m,\frac{r_c}{r}\right) , \qquad (2)$$

where

$$\beta = \frac{eE}{2k_B T}, \quad P(m,x) = [(m-1)!]^{-1} \int_0^x \exp(-t) t^{m-1} dr .$$

For $E = 0$, Eqn (1), known as the Onsager formula, reduces to

$$\phi_0 = \exp\left(-\frac{r_c}{r}\right) , \qquad (3)$$

where r_c, given by

$$r_c = \frac{e^2}{\varepsilon k_B T} ,$$

is the so called Onsager radius, ε is the relative permittivity, k_B is the Boltzmann constant, and e is the charge on the electron. According to Mozumder,[17] the Onsager model can be used also for electron–ion pairs generated by ionising radiation.

On this hypothesis, it is possible to relate the initial distribution function of thermalised electrons $F(r)$ to the yield $G_{fi}(E)$ of the separated pairs of charges (or the number of separated pairs per unit ionising radiation energy absorbed by the substance):

$$G_{fi}(E) = G_0 \int_0^{\infty} F(r)\,\phi(r,E) dr , \qquad (4)$$

where G_0 is the overall initial yield of the pairs of charges. Eqn (4) makes it possible to infer from the experimental data for G_{fi} the distribution function of the thermalised electrons. This approach has been hitherto one of the important sources of information about $F(r)$.[18,19]

For many liquids, the experimental $G_{fi}(E)$ data were obtained as early as the 1970s, mainly with the aid of electrical methods based on the measurement of the number of charges drawn by the electric field onto the electrodes under conditions preventing the influence of bulk-phase recombination (see, for example, Freeman[20] and Schiller and Vass[21]). The yield in a zero field $G_{fi}(0)$ may be found by extrapolating the $G_{fi}(E)$ relation to $E = 0$. Another, more reliable method for the estimation of $G_{fi}(0)$ involves the use of the cleaning field method.[22] In this method, the electric field withdrawing charges onto electrodes is applied after a short electron–ion pair generation pulse for a period sufficient to complete pair recombination.

Until recently, experimental G_{fi} data referred almost exclusively to liquid dielectric materials. For solid amorphous substances, the determination of G_{fi} by the method involving the withdrawal of charged species is handicapped by the fact that the mobility of such species is as a rule very low. G_{fi} data for solid organic glasses were obtained much later.

2. The spatial distribution function of thermalised electrons

The form of $F(r)$ is difficult to determine from experimental $G_{fi}(E)$ data and Eqn (4). For practical purposes, some kind of simple form of the $F(r)$ relation is normally employed.[1,13] In the analysis of experimental data for liquids, most attention has been devoted to the following types of distribution:

simple exponential:[23]

$$F(r) = C\exp\left(-\frac{r}{b}\right) , \qquad (5)$$

Gaussian:[24]

$$F(r) = Cr^2 \exp\left(-\frac{r^2}{b^2}\right) , \qquad (6)$$

amplified Gaussian:[25]

$$F(r) = \begin{cases} Cr^2 \exp\left(-\dfrac{r^2}{b^2}\right) & r < 2.4b , \\ Cr^2 \exp\left(-\dfrac{r^2}{b^2}\right) + 0.5\left(\dfrac{b^2}{r^2}\right) & r > 2.4b . \end{cases} \qquad (7)$$

Here C is the normalising multiplier and b the parameter of the distribution function.

Apart from Eqns (5)–(7), others have also been tested: the delta-function, the Gaussian relation with a displaced maximum, etc. Among these relations, functions (5) and (7) yielded the most satisfactory agreement with experimental data for $G_{fi}(E)$.[13,18,19,26]

Estimates based on Eqn (4) and G_{fi} data for different liquids yield approximately identical values of b for functions (5) and (7). In the case of unbranched hydrocarbons, the values of parameter b are in the range 50–70 Å,[20–26] which indicates a fairly narrow (compared with the Onsager radius) distribution of the thermalised electrons.

In order to compare the paths traversed by superthermal electrons in various substances, it is convenient to employ the values of b normalised with respect to density (or the product $b\rho$, where ρ is the density of the substance). The values of $b\rho$ in liquid hydrocarbons (in contrast to gases) are independent of ρ and depend only slightly on the temperature of the substance.[18,19]

II. Trapped electrons in solid nonpolar hydrocarbons

1. Detection of a trapped electron

The study of trapped (stabilised) electrons e_{tr}^- in solid hydrocarbons was initiated long ago. The first attempts to detect e_{tr}^-, undertaken in 1962,[27] did not lead to positive results. Subsequently, using an improved technique for the measurement of the optical absorption spectra in frozen hydrocarbons γ-irradiated at 77 K, it was possible to observe an absorption band in 3-methylpentane,[28] extremely sensitive to 'bleaching' by IR light, the maximum of which was at a much higher wavelength than the absorption band of a trapped electron in alcohols with a relatively low IR sensitivity.

Later a broad ($\Delta E_{1/2} \approx 0.5$ eV) structureless optical absorption band with a maximum in the range 1500 to 2000 nm was observed in the spectra of other substances: on radiolysis of alkane

and olefin glasses and also on UV irradiation of substances with a low ionisation potential or containing the anions of aromatic hydrocarbons in alkane glasses as additives. This absorption, attributed in all cases to trapped electrons, is readily bleached by visible and by near IR irradiation within the limits of the absorption band, disappearing gradually in the dark even at 77 K.[12]

The use of electron-accepting additives is of decisive importance for the identification of the optical absorption bands in the near infrared in irradiated hydrocarbons at a low temperature. In their presence, the intensity of the optical absorption diminishes with the simultaneous formation of the radical-anions of the additive, which have been reliably identified from the known optical absorption or EPR spectra.

The concentration of electrons stabilised in hydrocarbons decreases also in the presence of substances reacting with slow electrons via a dissociative capture mechanism (alkyl halides, esters, etc.). On the other hand, the addition of positive charge acceptors (olefins, alcohols, ethers, aromatic amines) increases the radiation yield of the stabilised charges. All these data as well as the presence of a narrow signal in the EPR spectra[29] permitted the conclusion that the optical absorption band in the near infrared in the irradiated hydrocarbons is due to trapped electrons.[12]

On exposure to light or with increase in the temperature of the specimen, the electrons stabilised in the irradiated specimens are liberated. In the presence of an acceptor, this entails an increase in the concentration of the radical-anions, since the electrons leaving the traps are captured by the additive.[30] After successive illumination of the specimens, Gallivan and Hamill[31] observed reversible electron transfer between the 3-methylpentane and added biphenyl from the absorption spectra at wavelengths corresponding to the absorption bands of e_{tr}^- and the biphenyl radical-anion. The molar absorption coefficient of the trapped electron (λ = 1600 nm) $\epsilon(e_{tr}^-) = 3 \times 10^4$ litre mol^{-1} cm^{-1} was first determined from these data. From this value, the radiation yield G_{tr} of the trapped electrons in 3-methylpentane was found.[31,32] Immediately after γ-irradiation at 77 K, G_{tr} was ~0.8, but this value diminishes rapidly with increase in the dose. The estimated $\epsilon(e_{tr}^-)$ agrees to within 25% with the estimate of 4×10^4 litre mol^{-1} cm^{-1} (for λ = 1600 nm) based on the EPR spectrum.[29] The values of $\epsilon(e_{tr}^-)$ for the majority of saturated hydrocarbons are similar.[31,33–35]

2. The nature of the optical absorption of the trapped electron

In the first studies[32] on γ-irradiated alkanes at 77 K, it was found that the quantum yield φ of the photobleaching of e_{tr}^- is ~0.8 for λ = 950 nm, ~0.4 for λ = 1300–1600 nm, and 10^{-2} for $\lambda >$ 1700 nm. The low quantum yield for the long-wavelength absorption edge of e_{tr}^- is caused, according to Hamill,[36] by the transition to the bound state at $\lambda >$ 1700 nm, while $\varphi \approx 1$ for the short-wavelength edge is due to the transition to a continuum with formation of a mobile electron e_m^-:

$$e_{tr}^- + h\nu \rightarrow e_m^- \ . \qquad (8)$$

A more detailed study of this relation for the range 1300 < λ < 2150 nm in 3-methylpentane was undertaken by Miller and Willard,[37] who observed that φ(1800 nm) = 0.7 φ(1600 nm) and φ(2000 nm) = 0.2 φ(1600 nm). Some photobleaching at $\lambda \approx$ 2150 nm was also noted, while at $\lambda >$ 2300 nm photobleaching was not observed. The decrease in φ with increase in λ in the region $\lambda > \lambda_{max}$ could not be induced by the transition to a bound state in the trap but might be caused by the recapture of electrons[37] or the absorption of light by the hydrocarbon molecules.[38]

The dependence of the induced photoconductivity current on the wavelength $I_{ph}(\lambda)$ was later used to obtain the similar dependence of the number of photoionisation steps per absorbed photon $\beta'(\lambda)$†.[39] This is a more direct method for the study of the photoionisation of e_{tr}^- than photobleaching and recombination luminescence. It was found by this procedure[39] that $\beta'(\lambda) \approx$ const for $\lambda <$ 1150 nm in 3-methylhexanes; the decrease in the photocurrent in the region $\lambda >$ 1150 nm was attributed to[39] the decrease in $\beta'(\lambda)$. Narrow 'dips' in the induced photoconductivity spectra of γ-irradiated isooctane, cyclohexane, methylcyclohexane, and 3-methylpentane have been observed;[39,40] a correspondence between the dips in the spectra and the overtone absorption of the hydrocarbon matrices was established.

The slight 'temperature-induced' changes in the form of the absorption spectra of e_{tr}^- in the long-wavelength region (a hypsochromic shift) have been observed for 3-methylpentane at a constant temperature (T = 76 K) at time intervals from milliseconds to minutes[41] and also on varying the irradiation temperature of 3-methylpentane (in the range from 4 to 73 K[35] and from 77 to 110 K[42,43]) and on annealing the specimen before irradiation.[44]

The available literature data, based mainly on spectroscopic measurements, permit the following conclusions:

1. The decrease in the intensity of the absorption of light by e_{tr}^- observed following the introduction of acceptor additives, on isothermal decay, on photobleaching, and after annealing the specimens before irradiation, accompanied by significant changes in the form of the optical absorption band of e_{tr}^-, indicates the stabilisation of electrons in traps of the same nature.

2. Integration of the absorption band of e_{tr}^- yields the oscillator strength $f \approx 1$. This quantity is characteristic of the 'initial' absorption spectra of e_{tr}^- in alkane glasses.[31,34,35,45]

3. The broad structureless absorption band of e_{tr}^- cannot be fully caused by optical transitions to the bound state. At least its short-wavelength edge is due to the transition to a continuous spectrum with a quantum yield close to unity.[30,32,37,40,41,46–54]

The problem of the nature of the optical absorption of e_{tr}^- in nonpolar hydrocarbons — transition to a bound state in a trap or transition to a continuum — has still not been solved.[53] Both views have been maintained in numerous publications. In particular, it has been suggested that detailed comparison of the spectra of the induced photoconductivity and the induced optical absorption in optical glasses would make it possible to separate these transitions for trapped electrons.[30,40,50–52,54] For example, it is assumed that, for transitions to a continuous spectrum, the photoconductivity spectra should be superimposed on the optical absorption spectra.[49] However, this conclusion is evident only for free electrons.[53] The characteristic features of the contributions to the photoconductivity by bound and free electrons are discussed below.

a. The nature of electron traps

The molecules of saturated hydrocarbons have no electron affinity in the ground state. It is natural to expect that in the solid phase for low irradiation doses the physical inhomogeneities in the matrix serve as electron traps.[55,56] This is indicated by the following facts: (1) the dependence of the recombination luminescence and the electrical conductivity induced by the ionising radiation on the degree of crystallinity of the specimen; (2) the influence of preliminary annealing of the 3-methylpentane glass at 77 K on the yield of stabilised electrons; (3) the continuous variation of the optical spectra of stabilised electrons in irradiated glasses following the addition of another glass-forming component.

For large irradiation doses, free radicals, which may serve as electron traps, accumulate in low-molecular-mass hydrocarbons.[57,58] An estimate of the radius of the reaction involving electron capture by a radical from measurements of the induced photoconductivity[59] and of the thermostimulated current in γ-irradiated 3-methylpentane yielded the following value:[60]

$$R_r = \frac{k_R}{4\pi D} = 15 \pm 3 \text{ Å} \ ,$$

where k_R is the constant for the trapping of the electron by the radical, and D is the diffusion coefficient.

† It is necessary to distinguish the quantities $\beta'(\lambda)$ and $\varphi(\lambda)$. The latter decreases, according to Skelly and Hamill,[32] during the bleaching of e_{tr}^-.

Data for the concentrations of traps in hydrocarbons have been obtained largely by the method of competing electron-accepting additives. The concentrations of the traps estimated in studies by different workers vary within wide limits—from 10^{16} to 10^{20} cm^{-3}. Reversible electron transfer between the traps in methylcyclohexane and 3-methylpentane matrices (specially freed from electron acceptors) and the added pyrene and also between traps in isooctane and isooctane free radicals has been observed on the basis of induced photoconductivity spectra.[30] These investigations led to the following concentrations of traps (in cm^{-3}): 1×10^{18} for 3-methylpentane, 3×10^{17} for methylcyclohexane, and 1×10^{15} for isooctane.

The first estimate of the depth of electron traps was probably made for 3-methylpentane and amounted to 0.09 eV.[31] The same depth of traps was found in early studies on recombination luminescence at 77 K; traps with energies of 0.1 and 0.25 eV have been detected in 3-methylpentane[61,62] and traps with energies of 0.18 and 0.21 eV have been found in n-heptane.[63] Relatively small depths of electron traps in hydrocarbon glasses are characteristic of the early investigations. In later studies, the authors of which used many fewer substances and applied better founded theoretical models, greater depths were found. For example, an activation energy of 0.65 ± 0.05 eV has been obtained from the analysis of the form of the radiothermoluminescence peak of specially pure γ-irradiated 3-methylpentane.[64] This result agrees with data obtained in other investigations[65,66] (the temperature jump method). In order to account for the great depth found for the traps, the authors of these studies suggested that the molecular rearrangement of the hydrocarbon matrix plays a significant role in the thermal liberation of an electron.

Fig. 2 presents the temperature dependence of the drift mobility μ_d of an electron in 3-methylpentane.[67] Evidently, in the temperature range 94–296 K, the value of μ_d changes by more than eight orders of magnitude when account is taken solely of data obtained by the direct method. When account is taken of the estimate for 77 K (the lifetime of the electron in the trap is $\tau_{77} \approx 1.5 \times 10^3$ s[68]), the changes in μ_d are by more than fourteen orders of magnitude. On the $\mu_d(1/T)$ relation, it is possible to distinguish two temperature ranges to which activation energies of ~0.14 and ~0.4 eV correspond; the boundary between them corresponds approximately to the melting point of 3-methylpentane. The form of the $G_{fi}(1/T)$ relation changes sharply in the same temperature range.

The activation energies for nondeuteriated and deuteriated amorphous methylcyclohexane have been found from the initial sections of the low-temperature radiothermoluminescence and thermostimulated current peaks. At 92 K, they amounted to 0.32 ± 0.05 and 0.37 ± 0.08 eV in the former case and 0.34 ± 0.05 and 0.38 ± 0.08 eV in the latter.[69]

Estimates of the minimum depth of traps from the threshold of the photoabstraction of an electron from the e_{tr}^- state lead to somewhat higher energies than in the thermal liberation of electrons from traps. Thus the following estimates have been obtained for the minimum energy of the light quantum necessary to liberate an electron in 3-methylpentane (eV): 0.7,[32,36] 0.53,[37] 0.37,[46] and 0.62.[51] Data concerning the influence of IR irradiation on the yield of free charges and 3-methylpentane are best explained for a photoabstraction threshold of 0.5 eV.[70] For methylcyclohexane, the results of experiments designed to investigate the influence of photobleaching on the initial induced photoconductivity spectra have shown that 80% of the traps have an electron photoabstraction energy in the range 0.44–0.62 eV.[40] It may be that the smaller photo- and thermal-abstraction energies correspond to the e_{tr}^- in 'closer' pairs. The observed higher electron photoabstraction energies compared with the thermal abstraction are usually attributed, in most investigations, to the fact that the photoabstraction of an electron takes place in conformity with the Franck–Condon principle.

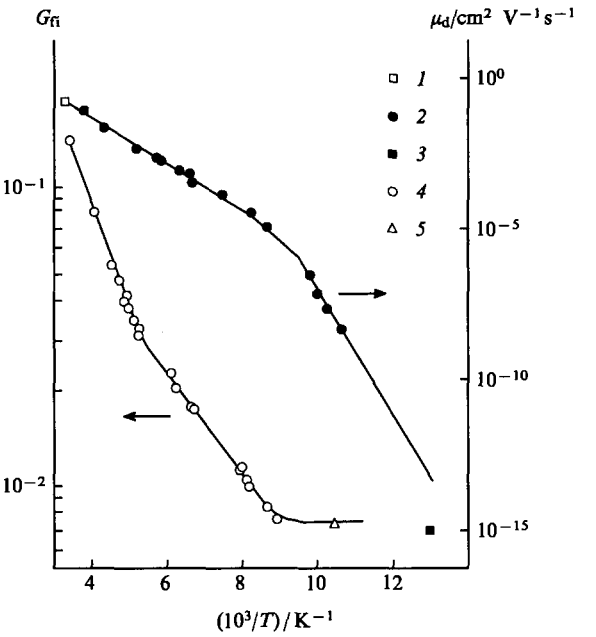

Figure 2. Temperature dependence of the radiation yield G_{fi} (1/100 eV) and of the drift mobility μ_d of electrons in 3-methylpentane.[67] The results were obtained by different methods: (*1*) from the time of flight and the conductivity amplitude; (*2*) from the conductivity amplitude; (*3*) calculation of the mobility based on the quantity $G\mu_0\tau_0$ for ^{60}Co γ-irradiation and of the lifetime of the electron in the trap τ_{77}; (*4*) from the range of conductivity currents; (*5*) from the integration of the thermostimulated current peak.

b. 'Polaron' and 'nonpolaron' models of a trapped electron

Theoretical models of trapped electrons in hydrocarbon glasses have been discussed frequently (see, for example, the relevant reviews[12,56]), but so far there is no reliable model. Despite the fact that this topic is not the main one under consideration in the present review, we shall make several comments.

One might postulate that, when a thermalised electron enters the stabilisation region, a potential well arises as a result of the polarisation of the surrounding molecules and one should consider a model analogous to the polarised cavity model for polar substances.[71] However, soon after the detection of e_{tr}^- it was noted[72] that the polaron model is not applicable to the description of the localised state of an electron in nonpolar substances; the total energy of the electron in the polaron model can be formulated as follows:

$$E' \propto \frac{h^2}{8mr^2} - \frac{e^2}{r}\left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0}\right), \qquad (9)$$

where the first term on the right-hand side is the kinetic energy of an electron bounded by a sphere with a radius r and an infinite potential barrier and m is the mass of the electron; the second term represents the attraction energy, while ε_∞ and ε_0 are the optical and static relative permittivities. In polar media, the difference between ε_∞ and ε_0 is fairly large, so that the second term in Eqn (9) is greater than the first. In nonpolar media, ε_∞ and ε_0 differ only by the contribution of the atomic polarisation, which does not exceed 5%–10% of ε_∞.

The experimental band of e_{tr}^- is narrower than the band for the dependence of the cross-section for the photoabstraction of an electron from H^- on the energy[73] when the latter is recalculated for $\lambda_{max} = 1600$ nm.[46] For a theoretical description of the form of the e_{tr}^- spectrum, the form of the potential of the trap has been varied[45] using the hydrogen-like atom model. Best agreement with experiment was achieved in a calculation on the assumption that the absorption spectrum of e_{tr}^- is due to the

transition to a continuum. The required form of the potential of the trap proved to be more 'rectangular' than in the case of a Coulombic well. The first attempt to relate the absorption spectrum of e_{tr}^- to the structure of the frozen hydrocarbon was apparently made in the paper of Funabashi and Maruyama.[74] These workers indicated the possibility, in principle, of describing the form of the e_{tr}^- spectrum in both visible and IR regions on the assumption that the traps in solid hydrocarbons consist of regions with a nonordered arrangement of the molecules.

The results of the majority of studies indicate that regions with a low density (cavities) serve as traps in alkanes.[56] This agrees with the 'bubble' model, which has been used successfully to describe the properties of the localised state of an electron in liquefied and solid noble gases,[75] which also have no electron affinity in the gas phase. The stability criterion obtained when this model is extended to solid hydrocarbons[72] differs from that found in the case of the polaron model:

$$\frac{h^2}{8mr^2} - \frac{n'e^2\alpha_0 4}{2r} \leq V_0 \ , \qquad (10)$$

where the second term on the left-hand side takes into account the energy of electronic polarisation (n' is the density of the substance for r greater than the radius of the cavity, and α_0 is the polarisability), while V_0 is the energy level of the quasi-free state of an electron in the given substance relative to the level in vacuo. In contrast to Eqn (9), the criterion specified by Eqn (10) satisfied reasonable values of V_0, α_0, and r.[72]

According to the results[76] for deuteriated 3-methylpentane (77 K, spin echo), the contribution to the stabilisation of the electron comes not only from the dipoles of the C–H bonds of the neighbouring molecules, as postulated previously, but also from the polarisability of the C–C bonds. A satisfactory agreement between the calculation within the framework of the 'bubble' model (potential well with vertical walls) and the initial experimental photoionisation spectrum of e_{tr}^- in methylcyclohexane has been achieved for a cavity radius of 3.73–3.85 Å and a photoionisation threshold of 0.40–0.44 eV.[40]

III. Photo- and thermo-stimulated electron–ion recombination

Studies on the radiation-induced luminescence should apparently be regarded as the initial experimental data which determine the direction adopted in the investigation of the recombination of geminal electron–ion pairs in nonpolar glasses. This method made it possible to observe the changes in the rate of recombination over a wide dynamic range.

1. Studies on recombination luminescence

A prolonged afterglow (half-life $\tau_{1/2}$ = 5–20 min at 77 K)—isothermal luminescence (IL)—has been noted in solid saturated,[77] unsaturated,[78] and aromatic[79] hydrocarbons subjected to the action of ionising radiation. After its decay, a new flash of luminescence may be induced by a rise in temperature—radiothermoluminescence (RTL)—or by illumination by light at wavelengths corresponding to the region in which e_{tr}^- absorbs—radiophotoluminescence (RPL).

It had already been established in early studies that the kinetics of the decay of the isothermal luminescence $L^*(t)$[46,80] and of the optical density of the trapped electron $D(t)$[31,32,80] are inconsistent with either first- or second-order kinetics for the process and cannot be expressed in terms of their combination. Joint studies on the decay of $D(t)$ and $L^*(t)$ showed[32,80] that the optical density and the intensity of isothermal luminescence are linked by the relation

$$\int_0^t L^*(t)\mathrm{d}t \propto D^0 - D(t) \ , \qquad (11)$$

where D^0 is the initial optical density of e_{tr}^- at $t = 0$.

The decay of $D(t)$ and $L^*(t)$ in solid nonpolar hydrocarbons is independent of the irradiation dose. In many cases the decay of $L^*(t)$ can be described by the relation[78]

$$\frac{L_0^*}{L^*(t)} = 1 + \varrho(t - t_0) \ , \qquad (12)$$

(ϱ is a constant and t_0 the time at the start of the observation), formally corresponding to a second-order reaction. However, since ϱ is independent of the irradiation dose, it follows that $L^*(t)$ is not determined by the average concentration of charges in the bulk of the substance and in this sense the decay law (12) corresponds to a pseudo first-order reaction.[81]

Pure hydrocarbons give rise to a weak RTL. Typical RTL curves consist of several peaks (for example, two peaks at $T_1 \approx 81$ K and $T_2 \approx 85$ K for 3-methylpentane[32,82–86]). The luminescence intensifies after the addition of electron acceptors[85,86] and both monomeric and dimeric luminescence due to the added acceptor is then observed (in conformity with studies on the luminescence arising on excitation of liquid solutions by ionising radiation[87]).

If the γ-irradiated specimens are bleached by IR light before heating, the low-temperature peaks are suppressed. This fact has been attributed to the recombination of the electrons e_{tr}^- liberated by light from the traps.[32,82] Together with this effect, a sharp increase in the RTL intensity was observed at higher temperatures and for low irradiation doses in specially pure substances, which was manifested by the appearance of new peaks.[84–86] The new RTL peaks are not associated with geminate recombination but are due to the recombination of free ions, the irradiation yield of which increases on photostimulated (in contrast to thermostimulated) separation of the geminate pairs.

With increase in the γ-irradiation dose (for example, from 5×10^2 to 3×10^4 rad for 3-methylpentane),[64] the form of the RTL peaks does not change and their intensity remains proportional to the dose. Such a dose dependence is usual for RTL in organic dielectric materials[88–90] and has been attributed to the pair recombination mechanism.

The difference between the RTL curves for the specimens unbleached and bleached by IR light initially increases sharply during bleaching and then reaches saturation (for 3-methylpentane in the range from 10^2 to 10^3 in units of $\sigma_{ph}Lt$, where σ_{ph} is the photoionisation cross-section and L is the light intensity). The decay of the RPL by a factor greater than 10^3 has been observed in 3-methylpentane at 77 K.[64,91] The integral RTL_{bl} intensity agrees with the integral RPL intensity during IR illumination (this has been tested for 3-methylpentane as far as the decrease in the RPL by a factor of 400).[64]

2. The problem of the kinetics of the thermo- and photo-stimulated electron–ion recombination

In the analysis of experimental data on the kinetics of inhomogeneous processes in liquid hydrocarbons (geminate recombination, the trapping of an electron from a geminate pair by an acceptor, separation of the pair), both deterministic and stochastic approaches are used nowadays to equal extents (see, for example, the relevant review publications[7,13,92,93]). No examples of the analysis of data within the framework of the stochastic approach are known for solid hydrocarbons (including numerical calculations by the Monte Carlo methods).

Two types of processes differing appreciably in time have been differentiated in solid hydrocarbons: (1) recombination of quasi-free electrons which had never been captured by traps before recombination; (2) comparatively slow recombination of electrons which had been captured by a trap at least once. The recombination of the first type proceeds with a characteristic time $t \approx \varepsilon b^3/3\mu_0 e \approx 10^{-13}$–$10^{-9}$ s, where b is the thermalisation length and μ_0 the mobility of the quasi-free electrons.[94] The characteristic time of the recombination of the second type is determined by the lifetime of the electron in the localised state and

for systems at a low temperature can attain considerable durations (minutes and hours). Almost all the experimental studies on the kinetics of recombination in solid amorphous substances have been devoted to this particular type of recombination.

A general approach to the description of the kinetics of the pair recombination of e_{tr}^- and a positive ion M^+ must take into account three factors: firstly, the distribution with respect to distances in the pair $\{e_{tr}^-, M^+\}$; secondly, the distribution of e_{tr}^- with respect to the depth of the traps; thirdly, the possibility of transcapture, i.e. of the transfer of an electron from one trap to another. The case of recombination where it is possible to disregard the last factor is easiest for the description of the kinetics. In such recombination, the electron passes from the localised state e_{tr}^- to M^+ without being captured by another trap. The transition can occur either as a result of a tunnelling process or via the photo- or thermo-abstraction of an electron from the trap. Regardless of the mechanism of the transition, the problem reduces to the summation of the rates of unimolecular reactions occurring with different characteristic times.[95,96]

We shall consider the proportion of e_{tr}^- recombining without transcapture. For photostimulated recombinations, an answer to this question is provided by measurement of the quantum yield φ of the bleaching of e_{tr}^-. According to the data of Skelly and Hamill[32] and Oka et al.,[97] φ for irradiated 3-methylpentane glass diminishes in the course of bleaching from 0.4–0.8 to zero. These data show that a considerable proportion (40%–80%) but by no means all the captured electrons recombine without transcapture. This fraction includes mainly electrons located at short distances from M^+.

Allowance for the other part of the e_{tr}^-, recombining as a result of one or several transitions between traps, appears important for the analysis of the kinetics of various phenomena.[98] This part is in fact mainly responsible for the trapping of electrons by acceptor molecules at relatively low concentrations and also for the postradiative change in the electrical and optical properties of dielectric substances.

The solution of Smŏjuchowski's equation in the form proposed by Ichikawa et al.[99] has been used to describe the kinetics of the recombination of such pairs in studies[83] of the isothermal luminescence of 3-methylpentane at 77 K:

$$\frac{1}{D_0}\frac{\partial W(r,\tau)}{\partial \tau} = \frac{\partial^2 W(r,\tau)}{\partial r^2} + \left(\frac{2}{r}+\frac{r_c}{r^2}\right)\frac{\partial W(r,\tau)}{\partial r}\ , \qquad (13)$$

where $\tau = t/t_{1/2}$ is dimensionless time, $t_{1/2}$ the half-life of the luminescence, $D_0 = Dt_{1/2}$ the temperature-independent diffusion coefficient, and $W(r,\tau)$ the probability of observing the electron at time τ at a distance r from the cation. Having expressed the time variation of the luminescence intensity $L^*(t)$ as the sum of the exponential functions,

$$L^* = \sum a_i \exp(-k_i\tau) \qquad (14)$$

(a_i and k_i are coefficients), with the aid of the substitution $W(r,\tau) = \sum R_i \exp(-k_i\tau)$, Eqn (13) can be reduced to a system of ordinary differential equations:

$$\frac{d^2R_i(r)}{dr^2} + \left(\frac{2}{r}+\frac{r_c}{r^2}\right)\frac{dR_i(r)}{dr} + \frac{k_i}{D_0}R_i(r) = 0\ , \qquad (15)$$

subject to the conditions $[R_i(r)]_{r=r_0} = 0$ and $[dR_i(r)/dr]_{r=r_0} = k_i a_i/4\pi r_0^2 D_0$. After adjusting the calculated experimental data for consistency, a half-life of 140 s and an electron diffusion coefficient of $\sim 10^{-13}$ cm^2 s^{-1} were obtained[83] at 77 K.

The use of the concept of the diffusion of classical species for the description of the pair recombination in solid amorphous substances cannot be justified in the general case, since the diffusion of the species is strongly hindered in this case: an appreciable proportion of the electrons are stabilised in traps, forming a comparatively long-lived e_{tr}^- state. Discrepancies between the diffusion theory and experiment may be expected in the early stages of the electron–ion recombination.[100]

The tunnelling mechanism of the recombination has been reliably established for glasses at $T \sim 4$ K and also for hard hydrocarbon glasses (of the type of methylcyclohexane) at higher temperatures (see, for example, the relevant reviews[95,96]). The conclusion that such a mechanism operates has been based on the weak temperature dependence of the rate of decay of the isothermal recombination luminescence or on the concentration of the radical-ions detected by optical or EPR methods. The concentration dependence, which can be expressed in a linear form by plotting the concentration against lg t, is characteristic of the tunnelling mechanism.[101] Such a dependence corresponds to a decrease in the intensity of the recombination luminescence in accordance with the law defined by Eqn (12).

As in the case of the reactions of heavy particles,[102] the dominant role of the tunnelling mechanism of recombination is to be expected at low temperatures and for short distances between the reacting particles. With increase in the temperature of the medium or in the distance between the reacting particles, the role of transitions over the barrier should increase. The temperature at which the effectiveness of these processes becomes equal can be estimated from the relation[103]

$$\tilde{T} = \frac{\hbar}{\pi k_B l}\sqrt{\frac{\Delta E}{2m}}\ , \qquad (16)$$

where l is the distance between the reacting species, and ΔE is the height of the tunnelling barrier or the difference between the energies of the ground states of the quasi-free and trapped electrons.

According to Eqns (16), the predominance of the activation mechanism in the electron–ion recombination may be expected in nonpolar hydrocarbons at $\tilde{T} \geqslant 100$ K. This agrees with the estimate[101] of the typical average distance (40–50 Å) between the anion and the cation in a nonpolar medium, whereupon the tunnelling mechanism of the reactions begins to predominate. One of the examples of the thermoactivated recombination is provided by the electron–ion recombination in the 3-methylpentane glass at $\tilde{T} \geqslant 70$ K.[66,83,104]

3. The distribution function of the pairs with respect to the number of electron transitions between traps before recombination

It is frequently convenient to divide charges arbitrarily into two groups—bound or geminate and free—depending on whether they recombine with positive ions in their own or another track respectively, and the rate of recombination can be written in the form[64,68,91,105]

$$W_r(t) = W_g(t) + W_{fi}(t)\ . \qquad (17)$$

The term $W_g(t)$—the rate of recombination of bound charges—should correspond to a pseudo first order of the reaction according to numerous experimental data.

The recombination of free charges can be described by the equations of normal homogeneous kinetics, whereupon

$$W_{fi} = k_r \bar{n}_+ \bar{n}_-\ , \qquad (18)$$

where $\bar{n}_+$ and $\bar{n}_-$ are the average concentrations of the positive and negative charges and k_r is the recombination reaction rate constant.

We shall consider a simple model taking into account the electron recapture.[68,105] In the analysis of the kinetics of the recombination, we shall take into account only that part of $W_r(t)$ which is associated with the recombination of electrons which have been captured by traps. We shall assume that only one current carrier (an electron) is mobile and that the contribution of the tunnelling transitions to the rate of the recombination reaction is negligible compared with the thermal liberation of the electrons from traps.

One can then write for the rate of the recombination reaction

$$W_r(t) \propto \sum_{N=1}^{\infty} Y(N)\, \omega_N(t)\left(\frac{1}{\tau}\right) , \qquad (19)$$

where $Y(N)$ is the initial distribution function for electrons with respect to the number of captures N by traps before recombination, ω_N is the probability that the electron executes $N-1$ transitions between traps at time t, τ is the lifetime of the electron in the trap equal, for example, to $(\sigma_{ph}L)^{-1}$ on photoliberation, σ_{ph} is the photoionisation cross-section, and L is the light intensity.

The functions $\omega_N(t)$ satisfy the equations

$$\frac{d\omega_1}{dt} = -\frac{1}{\tau}\omega_1 , \qquad \frac{d\omega_{i>1}}{dt} = \frac{1}{\tau}(-\omega_i + \omega_{i-1}) , \qquad (20)$$

and the initial conditions

$$\omega_{i=1}(t=0) = 1 , \qquad \omega_{i>1}(t=0) = 0 .$$

The Poisson function

$$\omega_N(x) = \frac{(x)^{N-1}}{(N-1)!}e^{-x} , \qquad (21)$$

where

$$x = \int_0^t \frac{dt}{\tau} ,$$

is a solution of Eqn (20). The type (21) functions $\omega_N(x)$ are normalised with respect to unity and have a maximum at $x = N-1$ with a width at half the height $\Delta_{1/2} \approx \sqrt{N}$ for $N \gg 1$.

When account is taken of the number of light quanta corresponding to one recombination step, Eqns (19) and (21) make it possible to find the relation $L^*(t) \propto W(t)$ for the recombination luminescence when the functions $Y(N)$ and $\tau(t)$ are known.

a. The lifetime of the electron in the trap.
Data on the distribution $Y(N)$

Since the optical absorption of e_{tr}^- at $\lambda = 1000$ nm leads to the liberation of the electron from the trap with a quantum yield $\beta \approx 1$ (see Section II.2), the characteristic lifetime of the electron in the trap during bleaching can be expressed as follows:

$$\tau_b^{-1} = \sigma_{ph}L + \tau_{77}^{-1} ,$$

where τ_{77} is the 'dark' lifetime ($L = 0$, $T = 77$ K). It follows from Eqn (19) that, for example, for RPL,

$$\frac{L^*}{L} \propto \sum_{N=1}^{\infty} Y(N)\omega_N(x) , \qquad x = \int_0^t \sigma_{ph}L\, dt . \qquad (22)$$

Using Eqn (22) and the data for the decay of RPL, one can obtain information about the distribution $Y(N)$ when account is taken of the thermal liberation of the electron from the trap during the period from the instant of generation to the beginning of the IR illumination:

$$x_0 = \frac{0.5\Delta t_\gamma + \Delta t_{77}}{\tau_{77}} ,$$

where Δt_γ is the duration of the γ-irradiation and Δt_{77} the time after the cessation of irradiation and before the start of illumination. Such an estimate yielded $\tau_{77} = 20-35$ min.[64] Analysis of literature data,[31,32,46,80] carried out by the present authors,[68] also led to a similar value of τ_{77} ($\approx 26.5 \pm 3$ min). A satisfactory agreement with experiment has been achieved[64,91] for the distribution function

$$Y(N) = \begin{cases} 2.5 & N = 1 ; \\ N^{-3/2} & N > 1 . \end{cases} \qquad (23)$$

Naturally, this is one of the possible distributions. The version involving a similar distribution $Y(N) \propto N^{-3/2} + 6N^{-6}$ has been described.[68] However, one should note that this distribution is based on experimental data up to $N \approx 90$ because $x \leqslant 90$ in the experiment and the functions $\omega_N(x)$ have a sharp maximum at $x \approx N$ for $N \gg 1$. Under such conditions, the derivation of the function $Y(N)$ for $x \gg 1$ from the decay of $L^*(x)$ at $x \gg 1$ reduces in essence to the use of the relation $Y(x) \propto L^*(x)$.

The marked difference between the forms of the relations $\omega_N(x)$ for different values of N when N and x are approximately unity justifies fairly reliable conclusions concerning the nature of the $Y(N)$ relation also when $N \approx 1$. For example, the change in the quantity $Y(1)$ by 30% from 2.5 [for the same values of $Y(N)$ with $N > 1$ as in Eqn (23) and for $\tau_{77} = 26$ min] already gives rise to a discrepancy with experiment greater than 15% in the region where $x \approx 1$ for any $Y(N)$ with $N \geqslant 1$. When account is taken of the accuracy of the determination of τ_{77} (20–35 min.) for the same values of $Y(N > 3)$ as in Eqn (23), a satisfactory agreement with experimental relations can be obtained for $Y(1) = 1.5-3.5$.

Numerical calculation has shown[64] that the theoretical form of the RTL_{bl} curve, including the maximum, agrees satisfactorily with the experimental curve for $\tau(T) = \tau_0 \exp(E/k_BT)$, where the activation energy $E = 0.65 \pm 0.05$ eV and $\tau_0 = \tau_{77} = 26$ min. An important feature is that only data on $Y(N)$ for $N \leqslant 10$, which corresponds to the range of values of x in which the RPL curve can be satisfactorily recorded, were needed to describe the initial section of the RTL_{bl} curve, including the maximum.

b. The quantum yield in the bleaching of e_{tr}^-.
Isothermal decay of the optical density

The available information about the $Y(N)$ relation makes it possible to calculate the rate of change of the bleaching quantum yield or of the number of trapped electrons recombining on absorption of a single light quantum:

$$\varphi = \frac{1}{D}\frac{dD}{dx} , \qquad x = \sigma_{ph}Lt , \qquad (24)$$

where $D(t)$ is the concentration of e_{tr}^- at time t given by the following equation in the model with a single depth of traps:

$$D(t) = \sum_{N=1}^{\infty} Y(N) \sum_{i=1}^{N} \omega_i(t) . \qquad (25)$$

Numerical calculation of the $\varphi(D/D_0)$ relation from Eqns (21), (24), and (25) agrees satisfactorily with experimental data[32,97] according to the result of a number of studies.[64,68,91]

Eqns (19)–(21), (23), and (25) can be used to describe the kinetics of the isothermal decay of the optical density of e_{tr}^-. The experimental relations $\varphi(t)$ and $D(t)$ then make it possible to determine τ from the relation

$$\tau = \varphi\left(\frac{dD}{dt}\frac{1}{D}\right)^{-1} . \qquad (26)$$

The use of data[32] for φ and D in the time interval 0.3–30 h leads to $\tau = 26 \pm 3$ min.[68] The data for the isothermal decay of $D(t)$ in 3-methylpentane at 77 K, quoted in the literature,[31,32,80] are also described satisfactorily under these conditions.

Thus the approach based on the use of the distribution function for electrons with respect to the number of captures by traps before recombination makes it possible to consider from a single standpoint the kinetics of the electron–ion recombination luminescence arising both on thermo- and photo-liberation of electrons from traps in an amorphous nonpolar dielectric material.

c. Comparison of $Y(N)$ with data on the radiolysis of liquid hydrocarbons

The significance of the distribution $Y(N)$ can be readily understood by comparing data for the kinetics of the recombination of electron–ion pairs in hydrocarbon glasses with the results of the study of the radiolysis of liquid hydrocarbons. According to Rzad et al.,[106] the yield of the electron–ion pairs which avoided recombination at time t in liquid hydrocarbons is given by the relation

$$G(t) = G_0 \exp\{\lambda' t\} \operatorname{erfc}\{\lambda' t\}^{1/2} , \quad (27)$$

where $G_0 \approx 4$ is the overall initial yield of the electron–ion pairs and λ' is a constant characterising the rate of recombination. For long times ($\lambda' t \gg 1$), Eqn (27) can be expressed approximately as

$$-\frac{d}{dt}G(t) \approx \frac{\lambda' G_0}{2\sqrt{\pi}}(\lambda' t)^{-3/2} . \quad (28)$$

Eqn (28) describes satisfactorily the decay of the optical density of excess electrons in a number of liquid hydrocarbons with a relatively low mobility.[107] If it is assumed that in both liquid and solid hydrocarbons the motion of the electron can be represented as a sequence of jumps from one trap to another,[94] so that the electron spends the same time τ in each trap, then one can write the following expression for the electron–ion recombination in a liquid:

$$G(t) = G_{tr}^0[1 - \zeta(t)] , \quad (29)$$

where $\zeta(t)$ is the probability of the neutralisation of the pair at time t. Since we have

$$d\zeta_N = \frac{1}{\tau}\omega_N(t)\,dt , \quad (30)$$

for pairs executing N transitions between traps before recombination, we obtain from Eqns (21), (29), and (30)

$$\frac{d\zeta}{dt} = \sum_{N=1}^{\infty} Y'(N)\frac{d\zeta_N}{dt} = \frac{1}{\tau}\sum_{N=1}^{\infty} Y'(N)\omega_N\frac{t}{\tau} , \quad (31)$$

where

$$Y'(N) = \frac{Y(N)}{\sum_{N=1}^{\infty} Y(N)}$$

is a function normalised with respect to unity. We have from Eqns (29) and (31)

$$-\frac{dG(t)}{dt} = G_{tr}^0\frac{1}{\tau}\frac{\sum_{N=1}^{\infty} Y(N)\omega_N\frac{t}{\tau}}{\sum_{N=1}^{\infty} Y(N)} . \quad (32)$$

For $N \gg 1$, the functions $\omega_N(t)$ have a single sharp maximum at $t_{max} \approx N\tau$. Therefore we obtain from Eqns (28) and (32) for $t \gg \tau$ and $t \gg (\lambda')^{-1}$

$$\frac{\lambda' G_0}{2\sqrt{\pi}}(\lambda' t)^{-3/2} \approx G_{tr}^0\frac{1}{\tau}\frac{Y(t/\tau)}{\sum_{N=1}^{\infty} Y(N)} . \quad (33)$$

It follows from Eqn (33) that $Y(N) \approx N^{-3/2}$ for $N \gg 1$. This result agrees with Eqn (23) obtained for solid hydrocarbons. In other words, for the same spatial distribution of thermalised electrons and positive ions in the liquid and solid phases, the photostimulated recombination time for an electron executing N jumps is proportional to the number of these jumps: $t_r \propto N$.

IV. Electric polarisation of electron–ion pairs

The conductimetric method, involving the recording of changes in the electric conductivity of the specimen on exposure to a short ionising radiation pulse, is the most direct procedure for the investigation of the kinetics and mechanisms of chemical reactions of charged species in a condensed phase. If only free ions participate in conduction, the conditions governing the application of this method are evident. However, such a relatively simple situation arises in nonpolar substances when most of the generated charges, having an initial inhomogeneous distribution in space, have already reacted. The contribution to the electric conduction by 'bound' charges (for example, the electrons of geminate pairs recombining in the absence of acceptors over short periods) requires special consideration.

1. Characteristic features of the relaxation of the electrical conductivity induced by ionising radiation in low-molecular-mass hydrocarbons

Polarisation by an external electric field may result in the participation of electron–ion pairs in nonstationary electrical conduction. The kinetics of the polarisation current of such pairs differ significantly from the kinetics of the polarisation current for the usual mechanisms of the polarisation of dielectric substances associated with the inhomogeneity of the specimens, the nonuniformity of the generation of current carriers, etc. Indeed the recombination of the electron with its 'own' positive ion implies zero integral charge transfer:

$$\int_0^{\infty} I_r dt = 0 , \quad (34)$$

which should lead to an unusual involvement of this electron in conduction. The unusual feature consists in the fact that, for example, in a constant electric field, the electron initially contributes to the conduction and then 'takes back' this contribution, moving against the external electric field.

This feature of the electrical conduction by electrons participating in pair recombination was apparently first noted by Frankevich and coworkers.[108,109] Later, similar considerations were used in the interpretation of the results of the study of quasi-stationary electrical conductivity,[10,11,110–112] thermostimulated current,[60,70] and photoconductivity[10,59,68,112–116] induced by ionising radiation in an organic dielectric substance.

For a sufficiently high intensity of light with a wavelength in the region corresponding to the absorption by e_{tr}^-, a decrease in the photocurrent as a function of time is observed after an initial increase. This can be explained by the decrease in the concentration of the trapped electrons.[10,113]

For isooctane at 77 K, the decrease in photoconductivity is described by a hyperbolic relation.[68] For 3-methylpentane and methylcyclohexane, the form of the initial section of the curve describing the decrease in photoconductivity $\tilde{\omega}_{ph}(t)$ is independent of the dose up to 10^5 rad,[68] while the rate of decrease corresponding to longer times rises with increase in dose.[59] The form of the photocurrent decrement curves for $x = \sigma_{ph}Lt < 30$ in 3-methylpentane ($L \approx 10^{14}$ photons cm^{-2} s^{-1}) remained unchanged, within the limits of experimental error, for a tenfold alteration in the γ-irradiation dose, whereas for $x > 30$ the form of the curves depended significantly on the dose.

Direct measurements of the polarisation current of electron–ion pairs in the 3-methylpentane glass at 77 K have been undertaken.[113] An increase in the electrical conductivity (radiation conductivity) of solid 3-methylpentane at 77 K was observed directly on exposure to γ-radiation. The time required to establish a quasi-stationary value of the current I_γ was shorter than the time taken to measure the current, whilst I_γ was independent of the duration of γ-irradiation up to doses of $\sim$0.1 Mrad.

The characteristic time variations of the photocurrent induced by IR light in a solid dielectric material (for example, in 3-methylpentane) for different combinations of the electric potential on the electrodes during (V_γ) and after (V_{ph}) exposure to radiation are presented in Fig. 3.

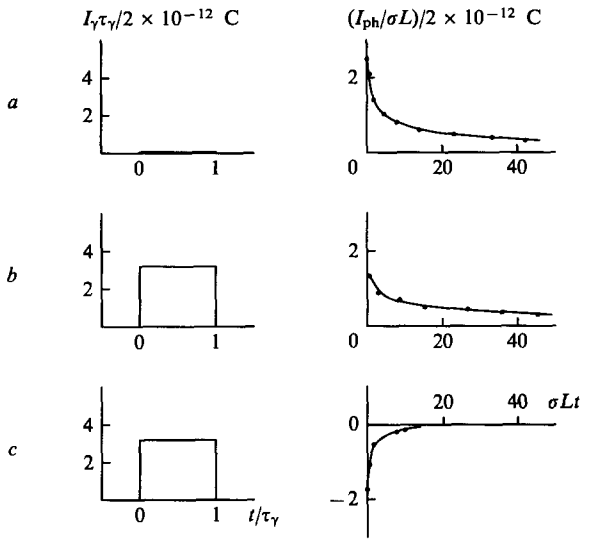

Figure 3. Time variation of the current due to the γ-induced conductivity and of the photocurrent for different combinations of the potential on the electrodes of a 3-methylpentane specimen at 77 K during γ-irradiation and IR illumination.[113] Dose 0.01 Mrad, λ = 1600 nm, $L = 3 \times 10^{14}$ photons cm^{-2}: (*a*) $V_\gamma = 0$, $V_{ph} = 1$ kV; (*b*) $V_\gamma = 1$ kV, $V_{ph} = 1$ kV; (*c*) $V_\gamma = 1$ kV, $V_{ph} = 0$.

In the case where $V_\gamma = 0$ and $V_{ph} = 1$ kV, the $I_{ph}(x)$ relation (Fig. 3*a*) is similar to that obtained by Yakovlev and coworkers.[59,68] Fig. 3 shows that the application of an electric field ($V_\gamma = 1$ kV, $V_{ph} = 1$ kV) during γ-irradiation (Fig. 3*b*) is accompanied by a decrease in the initial value and in the rate of decrease in the photocurrent (λ = 1600 nm) compared with the $I_{ph}(x)$ relation for the first case. For $V_\gamma = 1$ kV and $V_{ph} = 0$ (Fig. 3*c*), a reverse photocurrent or depolarisation current, comparable in absolute magnitude with the photocurrent in the case illustrated in Fig. 3*a*, is observed. Comparison of the normalised current amplitudes $\tilde{I}_\gamma = I_\gamma\tau_\gamma$ and $\tilde{I}_{ph} = I_{ph}/L$ shows that $\tilde{I}_\gamma : \tilde{I}^a_{ph} : \tilde{I}^b_{ph} : \tilde{I}^c_{ph} = 1 : 0.7 : 0.4 : 0.5$. Under these conditions, $\int_0^{\tau_\gamma} \tilde{I}_\gamma dt = \int_0^\infty \tilde{I}_\gamma dt$ with an accuracy to within 50%.

2. Kinetics of conduction in the presence of transcapture

a. Dependence of the current kinetics on the number of electron capture steps

If the photoconductivity is due to the involvement of free electrons, in the absence of recombination (which corresponds to the linear section of the $I_{ph} \propto D_r$ relation) the decrease in photoconductivity as a function of illumination time at the wavelength corresponding to the e^-_{tr} absorption band can be represented as follows:[68]

$$\tilde{\omega} = \frac{\tilde{\omega}_0}{1 + k_r\tau_0 n_0 L\sigma_{ph} t}, \qquad (35)$$

where $\tilde{\omega}_0 = en_0\mu_0\tau_0 L\sigma_{ph}$, $n_0 = GD_r$ is the initial concentration of free electrons, and k_r, μ_0 and τ_0 are respectively the recombination reaction rate constant, the mobility, and the lifetime of an electron liberated by light from a trap to the conducting state.

Since the photoconductivity decrement curves in isooctane are described satisfactorily by Eqn (35), the present authors assume[68] that the free charges are responsible for the main component of the photocurrent, i.e. $I_{ph} \approx I_{fi}$. Furthermore, the ratio $k_r/\mu_0 \approx 10^{-6}$ cm V, calculated using Eqn (35) and the measured quantity $(d\tilde{\omega}/dt)|_{t=0}$, proved to be $\sim 4\pi e/\varepsilon$, which is characteristic of free charges for the Langevin recombination law. The $\tilde{\omega}(t, D_r)$ relation for 3-methylpentane is not described by Eqn (35); the quantity k_r/μ_0, calculated formally using Eqn (35), proved to be much greater than $4\pi e/\varepsilon$, which indicates that the photocurrent in 3-methylpentane is associated with charges recombining in pairs,[68] i.e. $I_{ph} \approx I_{gi}$.

The difference between the kinetics of the photocurrent in isooctane and 3-methylpentane can be understood if one takes into account the difference between the values of $\mu_0\tau_0$ for these substances. The product $\mu_0\tau_0$ determines the number of steps N in which an electron is captured during its motion towards the positive ion. For an isolated pair of charges (e^-_{tr} and a positive ion), we have

$$N \approx \frac{t_r}{\tau_0}, \qquad (36)$$

where $t_r \approx r_0^3\varepsilon/3e\mu_0$ is the recombination time for a pair with an initial distance r_0 without allowance for the lifetime in the localised state. For $N \approx 0$ and a constant duration of the recording of the current $\tau_d \gg \tau_0$, there is no photocurrent due to bound charges. The occurrence of even one transcapture of an electron by a trap and hence a contribution by the bound pair of charges to the photoconductivity should be expected when

$$\mu_0\tau_0 < \frac{r_c^3}{3e} \approx 5 \times 10^{-9} \text{ cm}^2\text{V}^{-1}. \qquad (37)$$

For isooctane, $\mu_0\tau_0 \gg 10^{-8}$ cm^2V^{-1} and, on the photoabstraction of an electron from a trap, the bound charges recombine without repeated capture. On the other hand, for 3-methylpentane $\mu_0\tau_0 \ll 10^{-9}$ cm^2V^{-1} and, in the case where $r_0 \approx r_c$ and $G \approx 0.1$, the number $N \sim 10^3$.

By postulating the involvement of only free electrons in conduction, it is difficult to explain the independence of the form of the photocurrent decrement curve of the irradiation dose observed for $x < 30$[59] and the linear dependence of the amplitude of the reverse current I^c_{ph} on the γ-irradiation dose D_γ. On this hypothesis, the appearance of the reverse current could be attributed to the formation of a space charge in the regions near the electrodes, but in this case one would have to expect that $I^c_{ph} \propto D^2_\gamma$.

On the other hand, the form of the $I_{ph}(x)$ and $I_{ph}(D_\gamma)$ relations, the ratios of the amplitudes of the photocurrents in the cases presented in Fig. 3 and of the radiation conductivity current can be described satisfactorily if it is assumed that the observed current is determined largely by the polarisation of the electron pairs.[113]

Taking into account the differences between the characteristics of the changes in the induced electrical conductivity in different hydrocarbons, it is frequently possible to divide the photocurrent induced by the ionising radiation into two components:[10,68]

$$I_{ph} = I_{gi} + I_{fi}, \qquad (38)$$

where I_{fi} and I_{gi} are the parts due to the free and bound electrons respectively.

b. Polarisation of electron–ion pairs

Numerous studies have been devoted to the analysis of the behaviour of an isolated pair of ions initially located in a dielectric medium at short distances from one another. The use of the Onsager model[15] is apparently most justified for thermalised pairs in a nonpolar liquid.[2] The influence of an external electric field on the behaviour of the pair has been considered in a number of investigations,[17,117,118] but the effect of the external field on the electric dipole moment of the pair has been little investigated within the framework of this model.

If the pairs are isolated and only thermalised electrons‡ in a conducting state, with a constant mobility μ_0 ($\approx 1\ cm^2\ V^{-1}\ s^{-1}$ for 3-methylpentane at 77 K [119]) and having an initial spherically symmetrical distribution with respect to radii, participate in the polarisation, then the radiation and photoconductivity currents can be expressed in the form [113]

$$I_\gamma = \frac{1}{\tau_\gamma}\sum_{N=1}^{\infty} Y(N) q_0^N \ , \tag{39}$$

$$I_{ph} = \sum_{N=1}^{\infty} Y(N) I_q^N(t) \ . \tag{40}$$

Under these conditions, we have for the photocurrent $I_q^N(t)$, determined by electrons executing N jumps before recombination,

$$I_q^N(t) = \sum_{i=1}^{N} q_i^N \omega_i(t) \frac{1}{\tau} \ , \quad \frac{1}{\tau} = \sigma L \ , \tag{41}$$

where q_i^N is the charge, averaged for pairs with different initial orientations, transferred to an external circuit either during the period from the instant of the generation of the electron to its capture by the trap (q_0) or during the time taken for the transfer of the electron from the ith to the $(i+1)$th localised state($q_{i\neq 0}$).

According to the present authors, [68, 113] the hypothesis that the dependence of the distance r between the positive ion and an electron on the residence time of the electron in the conducting state t_0 is determined mainly by the drift of the ion in the electric field is justified for the estimation of q_i in weak external electric fields. The average number of captures of an electron with an initial distance r_0 from the positive ion before recombination is defined by Eqn (36). This leads to a value of q_0^N approximately equal to the charge transferred along the direction of the external field by the free electron during its lifetime before capture by the trap: [68, 70]

$$q_0^N \approx q_0 = \frac{e\mu_0\tau_0 E}{d} \ , \tag{42}$$

where d is the distance between the electrons.

The model considered describes satisfactorily the characteristics of the variation of the radiation conductivity current in a nonpolar dielectric substance [111] and the ratio of the currents for different combinations of the electric potential on the electrodes of the specimen during exposure to ionising radiation and photoexcitation of e_{tr}^-. [59, 68, 113]

If the pairs interact with one another, then, in view of the possibility of the recombination of the electron with a foreign ion, one cannot generally speaking neglect the contribution to the conductivity by electrons recombining after preliminary capture by a trap and Eqn (34) cannot be regarded as valid, as in the case of isolated pairs. However, in view of the fact that the Coulombic field (generated by all the charges at the location of the given electron), averaged with respect to all the electrons at the site of their thermalisation, is zero ($E_k' = 0$), Eqn (42) remains in force for the polarisation current also in the case of interacting pairs. [68, 113]

3. The diffusion-drift model

In the early investigations, [68, 113, 120] the polarisation of the pairs was considered without taking into account the diffusion of the species. This approximate approach did not allow, in principle, the study of significant features such as the appearance of a negative current and the change in the current at long times. The kinetics of the electric polarisation of an isolated pair of ions have been studied [112, 116, 121–123] on the hypothesis that the ions execute Brownian motion in the Coulombic field of their partners and in the weak external electric field (see also the review of Tyutnev et al. [11]).

If the current of free electrons I_{fi} is adopted as the unit current and the mobility is assumed equal to the overall mobility of the positive and negative ions, then the polarisation current of N isolated pairs can be expressed in the form [112]

$$I(t) = \frac{1}{e\mu NE}\frac{d}{dt}P_E(t) \ , \tag{43}$$

where P_E is the projection of the overall electric moment of all the pairs on to the direction of the electric field $\boldsymbol{E}$ generated by the charges at the electrodes. In view of the axial symmetry of the problem, we have

$$P_E(t) = N\int_0^\infty \int_{-1}^{1} 2\pi e r^3 n(r, \tilde{\mu}, t)\, d\mu\, dr \ , \tag{44}$$

where r is the distance between the ions of the pair, $n(r, \tilde{\mu}, t)$ is the density of the probability of finding a pair of ions with the parameters r and $\tilde{\mu}$, and $\tilde{\mu} = \cos\theta$.

We shall assume that the charged species execute Brownian motion in the Coulombic field of their partners $\boldsymbol{E}_c$ and in the external field $\boldsymbol{E}$ and recombine when they approach an oppositely charged species to a distance a approximately equal to the molecular size. The calculation of the current then reduces to the solution of the Smŏjuchowski equation

$$\begin{cases} \dfrac{\partial n}{\partial t} = -\operatorname{div} \boldsymbol{J} \\ \boldsymbol{J} = -D\vec{\nabla} n + \mu(\boldsymbol{E}_c + \boldsymbol{E})n \end{cases} \tag{45}$$

with the initial and boundary conditions

$$n(r, \tilde{\mu}, 0) = f(r) \ , \tag{46}$$

$$n(a, \tilde{\mu}, t) = 0 \ , \tag{47}$$

where D is the overall diffusion coefficient of the positive and negative ions. The case where it is possible to neglect the diffusion of the species and to consider only their drift in the electric field is simplest to analyse. Since the ratio of the rates of diffusion and drift diminishes with decrease in temperature, this case corresponds to low temperatures.

a. Low temperatures

If one neglects the diffusion of the species, the problem reduces to finding the time variation of the radius vector $\boldsymbol{r}(r_0, \tilde{\mu}, t)$ for a pair of ions the relative positions of which are described by the equation

$$\frac{d\boldsymbol{r}}{dt} = \mu(\boldsymbol{E}_c + \boldsymbol{E}) \ . \tag{48}$$

The significance of the notation is clear from Fig. 1.

The polarisation current has been examined [112] for four types of spherically symmetrical initial distributions, usually postulated in order to interpret the kinetics of ionic processes in photochemistry and radiation chemistry: [124, 125] the δ-function and the exponential Gaussian, and displaced Gaussian $\{f(r) \propto \exp[-16(r-b')^2/(b')^2]\}$ distributions (b' is a constant). For the $f(r) \propto \delta(r - r_0)$ distribution and short times, the polarisation current is approximately equal to the current of the same number of free ions; with increase in t, the current initially increases and then, following the onset of recombination, falls and becomes negative.

It is not difficult to understand such variation of the current. Taking into account Eqns (43) and (48), we have

$$I \propto \bar{E} = \bar{E}_c + E \ , \tag{49}$$

‡Only those electrons which during their lifetime before recombination t_r have been captured by a trap at least once are of interest; the electrons recombining without being captured by a trap do not contribute to the measured current in view of Eqn (34) and the relation $t_r \approx \tau_0 \ll \tau_d$.

where $\bar{E}$ and $\bar{E}_c$ are respectively the projections of the $\boldsymbol{E}_c + \boldsymbol{E}$ field averaged for all the pairs and of the field $\boldsymbol{E}_c$ on to the direction of the external field. $\bar{E}_c \approx 0$ for $t \approx 0$, so that the initially $I \propto E$, as for free ions. As a result of the motion of the ions, the pairs for which the vectors $\boldsymbol{E}_c$ and $\boldsymbol{E}$ are pointed in the same direction fall within the regions of a stronger Coulombic field sooner than the pairs with the opposite orientation. This leads to an increase in $\bar{E}$ and hence to an increase in I. The monotonic increase in the current occurs before the onset of recombination. The pairs for which the directions of the fields $\boldsymbol{E}_c$ and $\boldsymbol{E}$ are identical are the first to begin recombining. The dipole moment of such a pair is $p < 0$, so that the onset of their destruction leads to an abrupt increase in the current. A similar variation of the current (from negative values to zero) occurs when recombination is completed. The maximum absolute negative and positive currents are approximately equal to $5aE_c^0/r_0E$, where $E_c^0 = e/\varepsilon r_0^2$.

In contrast to the distribution $f(r) \propto \delta(r - r_0)$, in the case of other distributions the current initially diminishes monotonically with increase in t, becomes negative, and then increases, tending to zero. For sufficiently wide distributions ($b' \gg a$), the maximum negative current is almost independent of b'. Under these conditions, the values of I_{max}^-/I_{fi} for these distributions are respectively 6×10^{-3}, 0.09, and 0.6.[112]

b. Allowance for the diffusion of ions

Various approaches have been used for the numerical solution of Eqn (45).[17,117,118] The most rigorous and general method of solution, proposed by Noolandi and Hong,[117,118] is based on the calculation of the Green's function for Eqn (45). Since solutions for smooth initial distribution $f(r)$ are usually of interest, in analysing the experimental data it is more convenient to use a simpler approach to the numerical solution of Eqn (45)—the method of finite differences. The difficulties which arise in the solution of Smoluchowski's equation, subject to the boundary condition (47), by this method were associated with the high gradient $n(r, \tilde{\mu}, t)$ at the boundary, which requires the application of small steps. However, we may note that, for the attraction potential between the ions and $a \leqslant 1$ nm, the rate of destruction of the species near the boundary is mainly determined not by diffusion but by the drift of the species in the Coulombic field. Therefore in many cases the numerical calculation can be significantly simplified[112] by dividing the region corresponding to the solution into two parts: the narrow boundary region in which it is possible to neglect diffusion, i.e. one can put $D = 0$ in Eqn (45), and the main region where Eqn (45) is solved without neglecting the diffusion of the species subject to the following condition at the inner boundary:

$$\left.\frac{\partial n}{\partial r}\right|_{r=a'} = 0 \ . \qquad (50)$$

Fig. 4 presents the results of the calculation of the pair polarisation current for the initial exponential and displaced Gaussian distribution functions.[112] The same figure also illustrates the time variation of the 'survival' function $\Omega(t)$ for the overall number of pairs of ions at time t. For $t \geqslant 0.2r_c^2/D$, the values of $\Omega(t)$ obtained correspond to the asymptotic formula[17]

$$\Omega(t) = \Omega_\infty\left(1 + \sqrt{\frac{r_c^2}{\pi D t}}\right) .$$

The time variation of the average field $\bar{E} = I(t)/\Omega(t)$ has a minimum at $tD/r_c^2 \approx 10^{-4} - 10^{-3}$, which is associated with the polarisation of the spatial distribution of the geminal electrons in the external field.[123]

The characteristic features of the polarisation current arising after the formation of ion pairs at $t = 0$ in a permanent electric field can be summarised as follows:

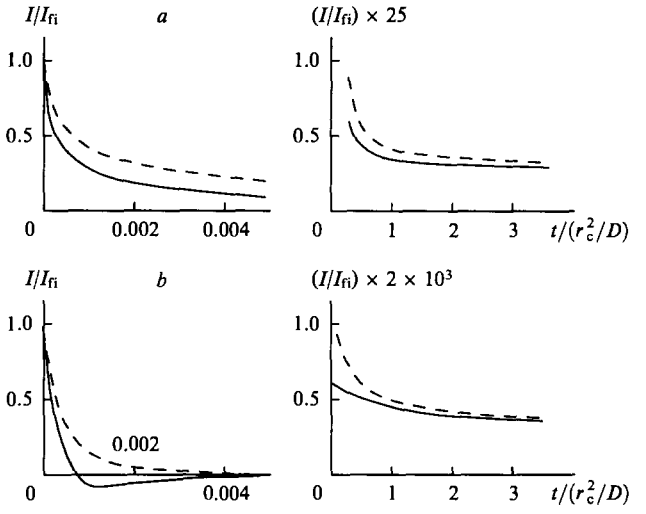

Figure 4. Time variation of the current calculated from the numerical solution of the Smoluchowski equation for the exponential initial distribution (*a*) and a displaced Gaussian distribution (*b*) of the pairs.[112] $a = 0.05r_c$, $b' = 0.1r_c$; the time variation of the probability of the survival of the pairs $\Omega(t)$ is shown dashed.

1. For the exponential and Gaussian distribution functions of the pairs with respect to the initial distances between the ions, the polarisation current is initially [for $\Omega(t)/\Omega(0) \geqslant 0.5$] approximately equal to the current due to the same number of free ions.

2. The maximum negative current I_{max}^- depends significantly on the form of the initial distribution.

3. Allowance for the diffusion of the species (or transition to high temperatures) leads to the appearance, at long times, of a direct current associated with the separation of ion pairs into free charges (Fig. 4). The maximum negative current I_{fi} diminishes with increase in temperature and the time when the current changes sign increases. Whether or not this current is negative depends on the form of the distribution.

c. Induced photoconductivity in the 'two states of the electron model'

The kinetics of the current due to the geminate ions have been frequently discussed by many investigators.[68,112–116] However, all these studies were concerned solely with thermalised charged species. On the other hand, the observed influence of the wavelength of the IR illumination on the yield of free charges (see below) shows that the characteristic features of the stage involving the thermalisation of the electrons liberated from traps by light are important for the description of the kinetics of the processes with their participation.

In order to take this factor into account, a model has been proposed[53,126,127] postulating that the photoexcitation of e_{tr}^- creates nonthermalised 'hot' electrons e_{hot}^-, which undergo a transition to a new trapped state having passed through the stage involving the thermalised state e_0^-. This hypothesis does not conflict with the idea that the electron is trapped in a molecular medium, which was put forward by Mozumder.[128] Furthermore, if one assumes that the drift displacement Δ_{hot} of e_{hot}^- in a single electric field is negligibly small § compared with the displacement Δ of a thermalised electron e_0^- during the period before its solvation, i.e. $\Delta_{hot} \ll \Delta$, then an additional term must be included in the Smoluchowski equation in such a 'two-step' model for the description of the diffusion and drift of charged species.

§ The hypothesis is based on the estimate $\Delta_{hot} = 4 \times 10^{-13}$ cm^2 V^{-1} for hydrocarbon liquids similar to 3-methylpentane with a low mobility of the excess electrons[129] and on the estimate $\Delta \approx 5 \times 10^{-12}$ cm^2 V^{-1} for the photoliberated electron in the 3-methylpentane glass at 77 K.[126]

The calculation of the photocurrent $I(t)$ can be reduced to the calculation of a new distribution function $f_i(r,\theta)$ for the pairs $\{e_{tr}^-, M^+\}$ after the ith e_{tr}^- photoionisation step:

$$I(t) = \frac{1}{d}\frac{dP_E}{dt}, \tag{51}$$

where P_E is the projection of all dipoles on to the direction of E:

$$P_E(t) = \sum_{i=0}^{N} p_i \omega_i(\sigma_{ph} L t), \tag{52}$$

$$p_i = eN \int 2\pi r_i^2 \sin\theta \cos\theta f_i(r,\theta)\, d\theta\, dr. \tag{53}$$

Here p_i is the projection of the dipole moment of the pairs for which the trapped electrons have been photoionised i times onto the direction of E and $\omega_i(x) = x_i \exp(-x)/(i!)$ is the Poisson function. The function $f_i(r,\theta)$ is given by

$$f_i(r,\theta) = \int n(r,\theta,t)\,\tau_0^{-1}\, dt, \tag{54}$$

where τ_0^{-1} is the rate constant for the reaction $e_0^- \rightarrow e_{tr}^-$, and $n(r,\theta,t)$ is the density of e_0^- defined by the Smołuchowski's equation

$$\frac{\partial n}{\partial t} = -D_0 \Delta n + \mu_0 (E_c + E)\,\mathrm{grad}\, n - \tau_0^{-1} n, \tag{55}$$

subject to the initial condition

$$n(r,\theta,t=0) = n_i(r,\theta) = \int b(|r - r'|) f_{i-1}(r,\theta)\, d(r')^3. \tag{56}$$

Here E_c is the Coulombic field, $b(a)$ is the distribution of e_{hot}^- with respect to the thermalisation lengths, and $D_0 = \mu_0 k_B T/e$ and μ_0 are respectively the average diffusion coefficient and the mobility of e_0^-. Thus in this model $\Delta = \mu_0 \tau_0$. If the form of the distributions $b(a)$ and $f_0(r,\theta)$ is known, then in this approach one can estimate $I(t)$ from the experimental values of $\mu_0\tau_0$ and σ_{ph}.

It has been shown[53] that the two states model predicts a marked dependence of the photocurrent, induced by the excitation of the geminate electrons, on the thermalisation length for the liberated electron. In this case, the spectral dependence of the photocurrent, normalised with respect to the optical absorption of e_{tr}^-, may depend on the wavelength of the exciting light even when the ionisation quantum yield is unity throughout the absorption band of e_{tr}^-. Therefore the conclusion concerning the nature of the optical absorption of e_{tr}^-, postulating that it is due to the transition to a bound state and based on the difference between the photocurrent and optical absorption spectra for geminate electrons, as well as the use of the equations of the usual homogeneous kinetics for the photocurrent cannot be regarded as sufficiently justified.

V. Thermo- and photo-stimulated separation of electron–ion pairs

Despite the fact that a large number of publications have been devoted to the localisation of excess electrons in nonordered molecular media, the mechanism of this process remains unelucidated.[128,130–137] Three cases have been differentiated in the formation of thermodynamically stable localised electrons: thermalisation, localisation, and solvation:

$$e_{hot}^- \rightarrow e_{qf}^- \rightarrow e_{loc}^- \rightarrow e_{sol}^-. \tag{57}$$

These describe the degradation of the energy of the 'hot' electrons e_{hot}^- with formation of a quasi-free electron e_{qf}^- and the solvation of the electron e_{loc}^- localised beforehand (for nonpolar media—the 'trapped' electron e_{tr}^-). By virtue of the effective application of the optical absorption method, most data have been accumulated on e_{tr}^-. However, very little is known about the precursors of e_{tr}^- and, in particular, about the spatial evolution of the low-energy electrons during their transformation into e_{sol}^- or e_{tr}^-. On the other hand, this process involves the migration of e_{hot}^- before thermalisation, the migration of the thermalised electron e_{qf}^- before thermalisation, and also the possible displacement of e_{loc}^- during solvation.

In discussing the processes involving the thermalisation of low-energy electrons in hydrocarbon glasses, three stages are also differentiated:[138,139] (1) excitation of the electronic states of molecules with a threshold energy of ~6 eV; (2) intramolecular excitations for electron energies in the range $6 \geqslant E_e \geqslant 0.4$ eV; (3) excitation of the rotational and intermolecular vibrations for $E_e < 0.4$ eV. For solid amorphous dielectric substances, the available information about the spatial distributions of thermalised $[F(r)]$ and trapped $[F_{tr}(r)]$ electrons is extremely limited and is based mainly on the analysis of the few existing data concerning the radiation yield of free ions.

1. The influence of the external electric field on the radiation yield of free ions

The method based on the integration of the thermostimulated current, arising on heating specimens γ-irradiated at low doses at 77 K, has been applied[67,70] to the determination of G_{fi} in 3-methylpentane and methylcyclohexane. The integral Q of the difference between the currents I_{TCT} for γ-irradiated and non-irradiated specimens in 3-methylpentane is proportional to the irradiation dose D_γ for $D_\gamma < 10$ rad. A similar $Q(D_\gamma)$ relation for methylcyclohexane has been obtained in the dose range < 3 rad. The quantity Q and the linear relation $Q(D_\gamma)$ indicated that most of the charged species generated by the ionising radiation in the space between the electrodes were drawn on to the electrodes and did not recombine in the bulk of the specimen.[140] The radiation yield of the separated pairs of charges in 3-methylpentane has been estimated from the linear section of the $Q(D_\gamma)$ relation.[67,70]

$$G_{fi}(E = 6 \times 10^3 \text{ V cm}^{-1}) = \frac{Q}{\rho v D_\gamma} = 1.2 \times 10^{-2} \text{ (1 pair per 100 eV)}, \tag{58}$$

where v is the volume between the electrodes.

In order to determine G_{fi} in a zero field, a method similar to the cleaning field method[22] applied to liquid dielectric substances has been used.[70] According to the results of a study of thermostimulated recombination luminescence of γ-irradiated 3-methylpentane, on heating 3-methylpentane above 77 K the electron–ion recombination is largely complete at ~90 K. Therefore, if after γ-irradiation of 3-methylpentane the specimen is initially heated at $E = 0$ to ~90 K and then recooled and again heated at $E \neq 0$, then most of the electron–ion pairs will be separated in a zero field. The number of electron–ion pairs separated on heating in a zero field has been determined[70] by integrating I_{TCT} on reheating the specimen in the field $E_{TCT} = 6 \times 10^3$ V cm^{-1}. $G_{fi}(0) = (6 \pm 1) \times 10^{-3}$ pairs of free ions per 100 eV of the absorbed radiation energy has been obtained for the 3-methylpentane glass. The observed value of $G_{fi}(0)$, like that of G_{fi} for $E_\gamma = E_{TCT} \neq 0$, was referred to the temperature 85 ± 5 K.

The same method has been applied[70] to the determination of $G_{fi}(0)$ in methylcyclohexane with the sole difference that the specimen γ-irradiated at 77 K was subjected to preliminary heating to ~100 K. This temperature corresponds to the region in which the methylcyclohexane RTL peak is observed.[141,142] The yield of the separated pairs of charges in methylcyclohexane is $(2.0 \pm 0.03) \times 10^{-2}$ per 100 eV; it was referred to the temperature $T \approx 100 \pm 10$ K at which most of the electron-ion pairs are separated.[70] As was to be expected from Eqn (1), in the low field limit the $G_{fi}(E)$ relations in 3-methylpentane and methylcyclohexane were found to be linear.

2. The influence of IR illumination on G_{fi}, the rate of recombination, and trapping

It has been observed [143] that the IR illumination of a γ-irradiated 3-methylpentane specimen before heating increased I_{TCT} appreciably. Since the optical absorption in the range 600–2000 nm of 3-methylpentane γ-irradiated at 77 K is mainly due to the trapped electrons, the increase in G_{fi} on IR illumination was attributed [143] to the fact that electron–ion pairs are separated more effectively on photoliberation of e^-_{tr} than during the thermoactivated motion of the charged species.

According to Onsager, [15] the probability of the separation of charged species (within the framework of diffusion-drift ideas concerning the separation of ion pairs in thermal equilibrium with the medium) is independent of their diffusion coefficients and is defined by Eqn (3). Assuming that Eqn (3) is valid for the electron–ion pairs in γ-irradiated 3-methylpentane, the increase in G_{fi} on IR illumination has been attributed [70, 143] to the formation of hot electrons [having an average kinetic energy greater than $\frac{3}{2}k_BT$] on IR illumination. This hypothesis agrees with the interpretation of the optical absorption of e^-_{tr} in 3-methylpentane in the range 600–2000 nm as being due to the direct transition to a continuum, [30, 40, 132] since a photoliberated electron e^-_{hot} is then formed in the initial stage of reaction (8):

$$e^-_{tr} + h\nu \rightarrow e^-_{hot} \quad . \tag{59}$$

It has an initial kinetic energy $E_0 = h\nu - E_t$, where $h\nu$ is the energy of the light quantum and $E_t = 0.5$ eV [38, 40] is the threshold energy of the photoabstraction of e^-_{tr}.

a. Dependence of G_{fi} on the energy of the bleaching light quantum

It has been observed [70, 143] that, on IR illumination, G_{fi} increases with the duration of bleaching and with increase in $h\nu$ (Fig. 5), reaching the limiting values $G^{h\nu}_{fi}$. This can be understood if the estimated distance $l \approx 80$ Å which the mobile electron e^-_m traverses in 3-methylpentane at 77 K before localisation [144] is adopted and if account is taken of the fact that the distance from the positive ion to most of the e^-_{tr} ($\sim 10^2$ Å) [25] is much smaller than $r_c \approx 10^3$ Å, i.e. the electron must execute several transitions from one localised state to another before it escapes from its positive ion. The number of such transitions can be estimated from the relation

$$N \approx \frac{r_c^2}{l^2} \approx 200 \ .$$

As for the separation of pairs in the dark, the $G^{h\nu}_{fi}$ relations proved to be linear.

Analysis showed [70] that the increase in the yields $G^{h\nu}_{fi}$ limiting in terms of the bleaching time, with decrease in the wavelength of the bleaching light cannot be related to the distribution of traps with respect to the electron photoabstraction threshold E_t: if after bleaching by light with a wavelength of 2000 or 1800 nm the specimen is also bleached by light with $\lambda = 1000$ nm, the effect is smaller than for light with $\lambda = 1000$ nm alone (Fig. 5).

The observed increase in G_{fi} following the additional bleaching of the specimen by light with $\lambda \approx 1000$ nm [70, 143] can be associated with the fact that, after prolonged bleaching by light (for example with $\lambda \approx 2000$ or 1800 nm), a proportion α of the total number of e^-_{tr} before the start of bleaching still remains in the vicinity of their 'own' positive ions. An estimate [70] yielded the following values of α: 0.18 ($\lambda \approx 2000$ nm) and 0.13 ($\lambda \approx 1800$ nm). Hence it follows that the structural traps with a photoabstraction threshold $E_t > 0.65$ eV constitute only a small proportion $\delta \approx 10^{-3}$ in 3-methylpentane.

b. Participation of hot electrons in reactions

The influence of IR illumination on the yield of free electrons and also on the recombination luminescence [84–86] caused by free electrons confirms the participation of hot electrons in photostimulated electron–ion recombination processes. It may be expected that the hot electron is appreciably involved also in other reactions initiated by the photoionisation of the trapped electron. This is apparently indicated by data [44, 145–147] which permit the hypothesis that the effectiveness of the trapping of an electron by an alkyl radical [44] and certain halogen-containing acceptors [147] in solid hydrocarbons is different in the photo- and thermostimulated liberation of electrons from traps.

The involvement of hot electrons in the formation reaction of pyrene dimers in 3-methylpentane at 77 K has been demonstrated. [85, 86] An increase by a factor greater than 20 in the intensity of the RTL peaks associated with the dimer luminescence of pyrene, arising as a result of the reaction of free ions on photobleaching of e^-_{tr}, was observed in these investigations.

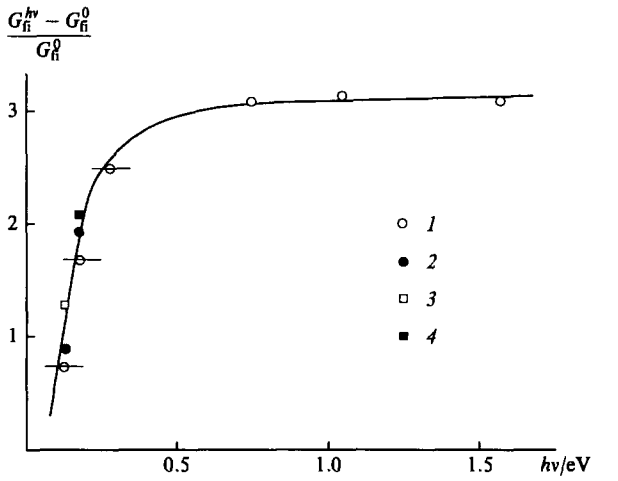

Figure 5. Dependence of the yield of free ions in 3-methylpentane on the energy of the bleaching light quantum: [70] (*1*) bleaching by light at a single wavelength; (*2*) allowance for ions remaining after bleaching; (*3*) point obtained after illuminating the specimen initially by light with $h\nu = 0.62$ eV and then by light with $h\nu = 1.2$ eV; (*4*) point obtained after illumination initially by light with $h\nu = 0.69$ eV and then by light with $h\nu = 1.2$ eV.

3. Drift displacement of the photoliberated electron in a unit electric field

Measurements of the radiation conductivity and the induced photoconductivity have proved hitherto the most reliable method for securing data on the drift displacement of electrons in a unit field $\mu_0\tau_0$. These data are usually quoted as the product $G\mu_0\tau_0$, where G is understood as the radiation yield of the charges participating in the conduction and μ_0 and τ_0 are the mobility and the lifetime in the conducting state. According to Ametov et al., [113] the dependence of the specific radiation electrical conductance on the power of the radiation J for γ-irradiated 3-methylpentane can be expressed as $\tilde{\omega} = 10^{-19} J\,\Omega^{-1}\,\mathrm{cm}^{-1}\,\mathrm{rad}^{-1}\,\mathrm{s}$. For the electronic mechanism of the radiation conduction in solid saturated hydrocarbons, this relation yields the product [10]

$$G\mu_0\tau_0 = \frac{10^2\tilde{\omega}}{eJ} = 1 \times 10^{-12}\ \mathrm{cm^2\,V^{-1}}. \tag{60}$$

In order to determine $G\mu_0\tau_0$ on UV- and γ-excitation, many workers [10, 30, 40, 50, 51, 54, 148] investigated the induced photoconductivity in hydrocarbons. The initial slope of the dependence of the conductivity on the dose $\tilde{\omega}(D_r)$ makes it possible to estimate the quantity

$$G\mu_0\tau_0 = \frac{1}{e\sigma_{ph}L}\frac{d\tilde{\omega}}{dD_r} \ . \tag{61}$$

This quantity is different in crystalline and amorphous hydrocarbons. For example, for isooctane, methylcyclohexane, and 3-methylpentane which have been specially freed from electron

acceptors, its values are[68] 1.2×10^{-7}, 2.3×10^{-10}, and 0.8×10^{-12} $cm^2 V^{-1} eV^{-1}$ respectively (the radiation yield G was calculated per 100 eV of the energy absorbed in 1 cm^3). The value of $G\mu_0\tau_0$ obtained in 3-methylpentane at 77 K agrees to within 30% with the estimate[113] based on measurements of the radiation conductivity. When account was taken of the quantities G and β', the photoconductivity data led to a drift displacement of the electron in 3-methylpentane at 77 K $\mu_0\tau_0 = 1.6 \times 10^{-12}$ $cm^2 V^{-1}$,[68] which is close to the value 1.5×10^{-12} $cm^2 V^{-1}$.[51]

Nevertheless one should note (despite such agreement between the experimental data of different workers) that the majority of the estimates were made under the conditions of the photoexcitation of the electrons of geminate pairs.[126] The estimation of $\mu_0\tau_0$ requires in this case a detailed analysis of the contributions of the free and bound charges to the photoconductivity, which is not a simple task.[53,112]

Apparently there has been only one study[59] in which the photocurrent in γ-irradiated 3-methylpentane at 77 K was measured over sufficiently long times such that almost complete separation of the pairs $\{e_{tr}^-, M^+\}$ occurred. Together with the yield of free ions, $G_{fi}^{h\nu} = 0.05$, measured during the photobleaching of a γ-irradiated specimen under the same conditions ($h\nu = 1.2$ eV and $E = 6 \times 10^3$ V cm^{-1}), and the photoionisation quantum yield $\beta' \approx 1$,[70] these data lead to $\mu_0\tau_0 = (5 \pm 1) \times 10^{-12}$ $cm^2 V^{-1}$.[59,126]

4. Spatial distribution of thermalised and trapped electrons

The G_{fi} data for solid dielectric materials make it possible to obtain information about the initial spatial distribution of the thermalised electrons $F(r)$ using Eqn (4), as for liquid systems. Furthermore, the yields G_{fi} obtained make it possible to infer the initial spatial distribution of trapped electrons $F_{tr}(r)$ from the radiation yields of such electrons G_{tr}^0:

$$G_{fi}(0) = G_{tr}^0 \int_0^\infty F_{tr}(r) \exp\left(-\frac{r_c}{r}\right) dr \,, \tag{62}$$

where $F_{tr}(r)$ is a function normalised with respect to unity.

The numerical calculation of $G_{fi}(0)$ by Eqn (4) using simple distributions $F(r)$ [functions (5)–(7)] has been carried out.[70] For $G_0 = 4$,[23,149] agreement of both function (5) and (7) with experimental yields $G_{fi}(0)$ was obtained (with $b \approx 60$ Å for 3-methylpentane and $b = 70$ Å for methylcyclohexane). The values of b found are close to the analogous quantities known for the same hydrocarbons in the liquid phase. Such a result might have been expected on the hypothesis of approximately the same electron thermalisation processes in liquid and solid amorphous hydrocarbons. However, if an exponential distribution [Eqn (5)] is postulated also for $F_{tr}(r)$, then Eqn (62) with $G_{tr}^0 = 0.8$ for 3-methylpentane[32] and $G_{tr}(0) = 6 \times 10^{-3}$ yields $b = 105$ Å,[70] which is significantly greater than the analogous distribution parameter for thermalised electrons. When the characteristic features of the electron thermalisation process are taken into account within the framework of the two states model (see Section VI), other results are obtained.

If the increase in G_{fi} on IR illumination is attributed to the fact that the kinetic energy of the electron e_m^- is higher than the thermal energy, then it is natural to assign to such an electron an effective temperature T_{ef}. T_{ef} may be estimated from the quantity $G_{fi}^{h\nu}(0)$ in a zero field from a relation similar to Eqn (62):

$$G_{fi}^{h\nu}(0) = G_{tr}^0 \int_0^\infty F_{tr}(r) \exp\left(\frac{-e^2}{\varepsilon k_B T_{ef} r}\right) dr \,. \tag{63}$$

Calculation of the dependence of T_{ef} on the energy of the bleaching light quantum[70] by means of Eqn (63) from G_{fi} data,[143] based on the hypothesis that the function $F_{tr}(r)$ is exponential with the parameters $b = 105$ Å and $G_{tr}^0 = 0.8$,[32] shows that, for $h\nu < 0.6$ eV, the temperature T_{ef} differs little from the temperature of the medium. But, after an increase in $h\nu$, the temperature T_{ef} initially rises rapidly and then, for $1.0 < h\nu < 2.5$ eV, hardly changes and amounts to ~140 K. A satisfactory agreement between the calculated and experimental temperatures T_{ef} for $h\nu < 0.8$ eV was achieved with $E_t = 0.5 \pm 0.1$ eV. The small change in T_{ef} with increase in $h\nu$, for $h\nu > 0.1$ eV, may be associated with the postulated[138] sharp increase in the rate of consumption of the electron energy on excitation of intramolecular vibrations in the region of the kinetic energy of the electron ~0.4 eV.[150]

The use of the Onsager formula might be justified by the fact that the photoliberated electron is captured many times (~200) by traps before it escapes from the 'Coulombic well' of its ion. Indeed, within the framework of the Onsager model, ϕ is independent of the mechanism of the migration of species. In essence, the probability of the separation of the pair is determined by the competition between two processes: the diffusional motion of the species during the transition between localised states, leading on average to the 'escape' of the species from the centre, and its displacement to the centre as a result of the drift in the Coulombic field of the ion during the same period. The first process may be characterised by the mean square of the distance between the successive localised states (l_s^2) and the second by the mean displacement Δ between the localised states in a unit field. For a thermalised species, the ratio of these quantities,

$$\frac{l_s^2}{\Delta} = 6\frac{k_B T}{e} \,, \tag{64}$$

corresponds to the Einstein relation

$$\frac{D}{\mu} = \frac{k_B T}{e} \,,$$

because the diffusion coefficient $D = l_s^2/6\tau$ and the drift mobility $\mu = \Delta/\tau$, where τ is the time of the transition between localised states.

However, the participation of nonthermalised species in the migration process would seem to infringe Eqn (64). In order to avoid this contradiction, it has been suggested[53,126,127,151] that the effective temperature be defined by the relation

$$T_{ef} = \frac{e}{6k_B}\frac{l_s^2}{\Delta} \,. \tag{65}$$

This approach makes it possible to determine the ratio l_s^2/Δ from the values of $G_{fi}^{h\nu}$ obtained after prolonged bleaching of the irradiated specimens and to find l_s^2 from the known value of Δ. Estimation of the lower limit yields $l_s \approx 20$ Å[151] on the basis of the results of Yakovlev et al.[70]

A more detailed approach to the description of the separation process, based on the application of the two states model, has been used.[126] The following estimates were made: the mean square thermalisation distance in 3-methylpentane $l_{hot} \approx 49$ Å, the mean square distance traversed by the thermalised precursor of the electron $l_0 \approx 45$ Å, the mean square solvation distance $l_s = (l_{hot}^2 + l_0^2)^{1/2} \approx 66$ Å, and the effective temperature $T_{ef} \approx 169$ K. The following feature may be noted: if it is assumed that the estimates[144,152] refer not to l_{hot} (as claimed by the authors) but to l_s, then the values of l_s quoted by Yakovlev[126] agree also with the estimated values of ~80 Å for 3-methylpentane (injection of electrons at 77 K)[144] and of ~65 Å for methylcyclohexane (thermoluminescence).[152]

The mean square electron thermalisation length in 3-methylpentane estimated by Yakovlev[126] agrees also with the experimental data for the thermalisation of low-energy electrons (20–60 Å) in liquid hydrocarbons with a low electron mobility. Various methods were used to obtain these data: photoemission from metals into a liquid,[153] electron transport across thin films,[154] and photoionisation of liquid solutions.[155–159]

The above value is also close to the analogous value for liquid solutions,[160,161] although its monotonic increase with increase in the energy of the electrons, observed in a later study,[162] is outside the calculated limits of the error[126] in the range of electron energies 0.5–2 eV.

If it is assumed that the electrons generated by the ionising radiation are localised like the photoliberated electrons, then, in order to determine $f_0(r)$ by Eqns (54) and (55), it is necessary to have data only on the initial distribution of the thermalised electron–ion pairs and the product $\mu_0\tau_0$. Best agreement with experimental results has been achieved[53] using in the calculation the distribution of the trapped electrons $f_0(r)$ corresponding to the initial distribution of the thermalised pairs and consisting of two parts: a Gaussian function with a maximum of 20 Å and a half-width of 35 Å and an exponential function which begins at 240 Å with a parameter of 70 Å (the overall density of the second part is ~5% under these conditions). Similar distributions of pairs with respect to thermalisation lengths and with a high initial density and a long 'tail' had been postulated also in previous studies in order to interpret data on the yield of free ions in liquid hydrocarbons[19,163] and for the description of the kinetics of recombination luminescence in glasses.[83]

V. Double orthophosphates	405

Abstract. The results of the spectroscopic studies (IR absorption, spontaneous Raman scattering) on orthophosphates of Group I–III elements are presented. The characteristic features of the vibrational spectra and the influence of the characteristics of the crystal structure on such features are discussed. The bibliography includes 58 references.

I. Introduction

The orthophosphates of various elements and the materials based on them have found extensive application in many branches of modern engineering and technology. This constitutes a natural stimulus to the search for new compounds and to the investigation of their physicochemical properties. It is not surprising that a number of monographs and reviews containing extensive information concerning the crystal structure of orthophosphates have appeared in recent years. Thus the nomenclature and certain characteristic features of the structure of the phosphates of Group I and II elements have been described in a review,[1] numerous data on the phosphates of divalent elements have been compiled in a monograph,[2] and a classification of the phosphates and X-ray diffraction data for the latter are presented in a book.[3] A review has been devoted to the X-ray diffraction and spectroscopic methods for the investigation of materials based on inorganic phosphates.[4] The IR absorption spectra of many phosphates are presented in the atlas of Mel'nikova et al.,[5] while those of double phosphates are in the atlas of Pechkovskii et al.[6]

However, despite the fact that vibrational spectroscopy (IR absorption and spontaneous Raman scattering) constitutes a powerful method for the investigation of the details of the structure and of the nature of the chemical bonds in compounds, while orthophosphates are convenient objects for study by this method by virtue of the characteristic features of their structure (the presence of discrete tetrahedral PO_4 groups in the structure) and the ratio between the atomic masses and bond energies, the known spectroscopic studies have not been far-reaching and systematic. Qualitative approaches have been used as a rule for the interpretation of the experimental data obtained.

In all the known investigations, the vibrational spectra have been described, quite justifiably, on the assumption that the vibrations can be divided into internal vibrations (stretching and deformation vibrations of the PO_4 groups) and external vibrations (translational vibrations of the cations and the librations of the PO_4 groups). The assignment of the internal vibration frequencies is in its turn based, as has become customary in the case for compounds with tetrahedral anions such as $[SO_4]^{2-}$, $[CrO_4]^{2-}$, $[MoO_4]^{2-}$, $[ReO_4]^-$, etc., on the vibration frequencies of the 'free' ion. Group-theoretic analysis yields the following distribution of the vibrations of the free ion in terms of irreducible representations of the T_d symmetry point group and their activities in the IR absorption and Raman spectra:

$$\Gamma_{vib} = A_1(R) + E(R) + 2F_2(IR, R).$$

(R = Raman).

Frequencies of 980 cm^{-1} and 1082 cm^{-1} have been found[7] respectively for the fully symmetrical $\nu_1(A_1)$ stretching vibration of the free $[PO_4]^{3-}$ ion and the triple degenerate $\nu_3(F_2)$ stretching vibration. The deformation vibrations are characterised by lower frequencies: 363 cm^{-1} for the doubly degenerate $\nu_2(E)$ vibration and 515 cm^{-1} for the triply degenerate $\nu_4(F_2)$ vibration.

Naturally, in the vibrational spectra of crystalline substances containing phosphate anions, the frequencies of the corresponding vibrations vary as a function of the nature of the cations and the crystal structure. The latter determines the symmetry of the PO_4 groups in the crystal lattice and the possibility of the splitting of the degenerate modes and of the resonance interaction of the vibrations, which increases the number of bands in the spectra and gives rise to appreciable difficulties in their interpretation. Unfortunately, the occurrence of such interaction, leading to the factor-group (Davydov) splitting is by no means always taken into account by investigators. A correct analysis of the manifestations of this effect is possible only when studies are performed on single crystal specimens in polarised light.

In the present review, the authors' aim was to survey as fully as possible the results of studies on the orthophosphates of Group I–III elements by vibrational spectroscopic methods, promoting thereby further researches on these lines.

II. Alkali metal orthophosphates

The vibrational spectra of alkali metal orthophosphates have been investigated for solutions,[8] melts,[9] and the crystalline state.[9,10] The tetrahedral symmetry of the $[PO_4]^{3-}$ anions is retained in aqueous K_3PO_4 and Na_3PO_4 solutions. This follows from the maintenance of the selection rules determined for the free ion.

The intense absorption band at 1004 cm^{-1} has been recorded in the IR absorption spectra. It corresponds to the triply degenerate F_2 stretching vibration to which corresponds a line at a frequency of 1014–1026 cm^{-1} in the Raman spectrum. The fully symmetrical stretching vibration is manifested only in the Raman spectrum by a line at 936 cm^{-1}.

Despite the fact that the phosphate anion does not include hydrogen atoms, in aqueous solutions there is a possibility of the formation of hydrogen bonds as a result of the interaction of the oxygen atoms of the anions with the protons of the water molecules. These fairly strong bonds influence the nature of the spectrum of the $[PO_4]^{3-}$ anions and are manifested significantly in the region of the stretching vibration frequencies of water molecules. In particular, an intense broad shoulder is observed[8] on the low-frequency slope of the IR absorption band due to the ν(OH) stretching vibration at 2900–3000 cm^{-1} (at 2200–2300 cm^{-1} in solutions in D_2O).

It has been noted that the hydrogen bonds involving phosphate anions are much stronger than those between water molecules. On partial deuteriation of water, the fully symmetrical stretching vibration becomes active in the IR absorption spectrum at a frequency of 936 cm^{-1} as a consequence of the decrease in the symmetry of the hydrogen-bonded phosphate ion. The strength of the phosphorus–oxygen covalent bonds in the $[PO_4]^{3-}$ tetrahedra ensures the stability of the latter as structural assemblies also in alkali metal phosphate melts.[9] Whereas the vibrational spectra of lithium and sodium phosphates in the condensed state[5] are fairly complex and differ appreciably owing to the differences between their crystal structures, in the Raman spectra of their melts only four lines corresponding to the internal vibrations of the free phosphate anion remain: at 1012, 930, 587, and 442 cm^{-1} for Li_3PO_4; at 1017, 907, 571, and 412 cm^{-1} for Na_3PO_4.

The observed frequencies differ somewhat from those obtained for solutions of orthophosphates,[8] which is explained by the influence of the solvent already mentioned. On the other hand, the Raman spectra of $M^{I}_3PO_4$ phosphate melts differ as regards the positions of the lines, which is a consequence of the influence of the alkali metal cation on the vibrations of the anions. The existence of a prefusion region at 100–200 °C for alkali metal orthophosphates is characterised by a smooth decrease in the intensities of certain Raman lines corresponding to the external vibrations of the anions up to their complete disappearance and has been attributed by the investigators to the orientational disordering of the PO_4 tetrahedra. Unfortunately, the vibrational spectra of alkali metal phosphates have been studied at an insufficiently high level of sophistication[11] and cannot be discussed in the present review. Recently the crystal structures of these salts have attracted the attention of investigators.[12,14]

III. Alkaline earth metal orthophosphates

A more detailed analysis of the vibrational spectra has been carried out for the alkaline earth metal orthophosphates $M^{II}_3(PO_4)_2$, in particular for barium and strontium orthophosphates, on the basis of experimental IR absorption spectra[14] in the region up to 50 cm^{-1} and the Raman spectra for polycrystalline specimens, resorting to the results of the calculation of the frequencies and modes of the normal vibrations of the crystals.[15]

For the crystal lattices of the isostructural $Sr_3(PO_4)_2$ and $Ba_3(PO_4)_2$ (space group $R3m = D^5_{3d}$), the representation of the vibration of the crystals is

$$\Gamma_{vib} = 5A_{1g} + A_{2g} + 6E_g + A_{1u} + 5A_{2u} + 6E_u,$$

among which the $A_{2g} + E_g + E_u + A_{1u}$ librational modes and the $2A_{1g} + 2E_g + 2E_u + 2A_{2u}$ translational modes correspond to the lattice vibration.

The two translationally nonequivalent PO_4 groups in the unit cell occupy positions with the C_{3v} local symmetry. Table 1 presents a scheme for the correlations between the irreducible representations of the vibrations of the free ion and the PO_4 groups in the $Sr_3(PO_4)_2$ or $Ba_3(PO_4)_2$ structure. According to the results of group-theoretic analysis, the alternative prohibition rule holds in these spectra and, out of the twelve internal vibrations of the PO_4 group in each set, six should be active in IR absorption and six in the Raman spectrum.

Table 1. A scheme of correlations between the irreducible representations of the vibrations of the PO_4 group in $Ba_3(PO_4)_2$.

Vibration	'Free' ion (T_d point group)	C_{3v} symmetry of the position	Factor-group of the D_{3d} space group of the crystal
ν_1	A_1	A_1	A_{1g}(R) + A_{2u}(IR)
ν_2	E	E	E_g(R) + E_u(IR)
ν_3	F_2	$A_1 + E$	A_{1g}(R) + E_g(R) + A_{2u}(IR) + E_u(IR)
ν_4	F_2	$A_1 + E$	A_{1g}(R) + E_g(R) + A_{2u}(IR) + E_u(IR)

R = Raman (Ed. of Translation).

All the predicted modes have been recorded in the experimental Raman spectra of $Sr_3(PO_4)_2$ and $Ba_3(PO_4)_2$ crystals.[15] The frequencies and the assignments are presented in Table 2. The most intense lines correspond to the fully symmetrical $\nu_1(A_{1g})$ vibration and their frequencies, 955 cm^{-1} for $Sr_3(PO_4)_2$ and 931 cm^{-1} for $Ba_3(PO_4)_2$, agree well with the values obtained for the $[PO_4]^{3-}$ ion in solution. By analogy with data for the free ion, the next lines in terms of intensity were assigned to the $\nu_2(E)$ vibration. The high vibration frequencies (together with ν_1) and the relatively low intensity of the Raman lines served as the criteria for the assignment of the $\nu_3(A_{1g} + E_g)$ components. However, the lack of data for single crystal specimens precludes a correct assignment of the components of both stretching and deformation triply degenerate vibrations. As in the case of the alkali metal phosphates in the crystalline state, a relation between the internal vibration frequencies and the nature of the cation cannot be traced. Apart from those listed above, three lines due to the external vibrations of the crystal lattice were recorded in the Raman spectra[14] and these proved to be fairly sensitive to the replacement of the cation.

Table 2. The vibration frequencies (cm^{-1}) in the spectra of $Sr_3(PO_4)_2$ and $Ba_3(PO_4)_2$ and their assignments.[14]

Raman		Assignment	IR absorption		Assignment
$Sr_3(PO_4)_2$	$Ba_3(PO_4)_2$		$Sr_3(PO_4)_2$	$Ba_3(PO_4)_2$	
142	108	External			
163	163	modes	166	146	External
242	203	(E_g)	232	220	modes
416	412				
			450	450	$\nu_2(E_u)$
572	564	$\nu_4^1(E_g)$	570	561	$\nu_4^1(E_u)$
621	602	$\nu(A_{1g})$		580	$\nu_4(A_{2u})$
998	982	$\nu_3^1(E_g)$	951	928	$\nu_1(A_{2u})$
1072	1046	$\nu_3(A_{1g})$	1029	1007	$\nu_3^1(E_u)$
955	931	$\nu_1(A_{1g})$	1099	1053	$\nu_3(A_{2u})$

It has been suggested that the IR absorption bands be assigned similarly. The two intense absorption bands in the high-frequency part of the spectra have been assigned to the A_{2u} and E_u components of the ν_3 mode. It is assumed that the higher-frequency moderately intense band corresponds to a vibration of the A_{2u} type of symmetry, while the most intense band corresponds to E_u. The low-intensity IR band in the spectra of the phosphates considered has been assigned to $\nu_1(A_{2u})$. The lack of evidence for this mode in studies on the spectra of other phosphates is probably

due to its unduly low intensity and its being masked by the two much more intense ν_3 components. However, this assignment is based on general considerations and is not sufficiently well founded.

The assignment of the $\nu_4(A_{2u} + E_u)$ and $\nu_2(E_u)$ deformation vibration bands has been extremely arbitrary. In each of the regions of the manifestation of these modes, two bands are recorded instead of the three predicted by the group-theoretical study of the vibrations of the crystals. Such a situation is actually observed for $Sr_3(PO_4)_2$: the absorption band at 570 cm^{-1} has been assigned to ν_4 (without resolution into components), while the band at 450 cm^{-1} has been assigned to $\nu_2(E_u)$. A fuller experimental picture has been obtained for $Ba_3(PO_4)_2$. The components of the ν_4 mode are manifested by two IR bands with different intensities at 580 and 561 cm^{-1}, whilst the ν_2 mode is manifested by a weak band at 450 cm^{-1}.

As a rule, the deformation vibration frequencies of the EO_4 oxo-anions depend on the nature of both the central atom and the external cation. The measured frequencies change slightly on passing from strontium to barium, demonstrating that the deformation vibrations of the PO_4 group are characteristic.

In the absence of polarisation measurements, the applicability of the alternative prohibition rule to the vibrations of the centrosymmetrical $Sr_3(PO_4)_2$ and $Ba_3(PO_4)_2$ crystals is an extremely significant factor, ensuring that the assignments of the frequencies are to some extent well founded. Since the inversion operation converts one of the PO_4 groups, within the framework of the unit cell, into another both components are not observed simultaneously in either IR or Raman spectra for any of the resonance doublets. This factor was taken into account by the authors of the proposed assignment.

The conclusions described above have been confirmed by calculations of the frequencies and modes of the normal vibrations [16] of these typical representatives of orthophosphates.

The zeroth approximation for the force constants of the PO_4 group was devised by resorting to the corresponding quantities obtained in the study of aqueous solutions of phosphoric acid.[7] The results of the calculation demonstrate that the interaction of the internal vibrations of the PO_4 groups and the crystal lattice vibrations is insignificant. This makes it possible to regard the complex anions as rigid fragments participating in the lattice vibrations and characterised by their mass, moments of inertia, and the forces linking the terminal oxygen atoms to the cations.

Analysis of the calculated lattice vibrational modes confirmed the legitimacy of a clear-cut separation of the orientational and translational modes not only in those cases where their symmetries differ but also within the framework of the same irreducible representations. The authors were able to subdivide comparatively reliably the translational lattice vibrations into those induced predominantly by the displacements of the PO_4^{3-} anions and the alkaline earth metal cations.

The double orthophosphates $Ca_{3-x}M^{II}_x(PO_4)_2$, where M = Sr or Ba, have been described.[17] At normal pressure, usually two phases of these substances coexist, undergoing a transition to a new phase with orthorhombic symmetry at 50 kbar. The double phosphate $BaZn_2(PO_4)_2$, crystallising in the monoclinic system (space group $P2_1/c$, $Z = 4$) is also known. The ZnO_4 and PO_4 tetrahedra are linked into a three-dimensional framework via their common vertices. The crystal structure of β-$Cd_3(PO_4)_2$ has been described.[17] In the monoclinic crystal lattice (space group $P2_1/c$, $Z = 12$), the cadmium atoms, distributed among nine nonequivalent positions, are surrounded by five oxygen atoms of the PO_4 groups arranged in a trigonal bipyramidal arrangement. We are not aware of any spectroscopic studies on these compounds.

IV. Lanthanide orthophosphates

The vibrational spectra of lanthanide orthophosphates have been investigated in fair detail.[18–21] It has been suggested that the spectroscopic data for $LnPO_4$ be interpreted [22] in accordance with their subdivision into the following three groups: La–Tb orthophosphates with the monazite structure, Sc, Y, Er, Tm, Yb, and Lu orthophosphates crystallising with the xenotime structure, and Dy and Ho orthophosphates, the symmetry of the crystal lattices of which is reduced compared with the second group of compounds.

Lanthanide phosphates crystallising with a monazite type of structure are characterised by a monoclinic system (space group $P2_1n = C_{2h}^5$) with four formula units in the unit cell.[19–21] The model of the crystal structure is made up of the coordination nonagons of the lanthanide cations linked to one another via distorted phosphate groups.

The crystal lattice of the orthophosphates with the xenotime structure has a tetragonal symmetry[18] [space group $I4_1/amd = D_{4h}^{18}$ ($Z = 4$)]. The lanthanide cations in crystals of this type are coordinated to eight oxygen atoms with two sets of interatomic spacings. The phosphate groups in compounds of this type have a distorted tetrahedral structure. The study of the EPR spectra of the impurity ions [23] in YPO_4 single crystals made it possible to obtain information about the crystal field parameters for the cations in this structure.

In crystals with the monazite structure, the anions can occupy only general positions, since the symmetry group of the possible specific positions of the C_i space group $P2_1/c$ is not a subgroup of the intrinsic symmetry group of the tetrahedral ion. This factor implies the complete removal of the degeneracy of the internal vibrations of the PO_4 group and the activity of all the modes in the IR absorption and Raman spectra. A detailed analysis of the IR absorption spectra of compounds of this type [24,25] confirmed the latter hypothesis. Nevertheless, all three components of the triply degenerate ν_3 stretching vibration of the tetrahedron of the orthophosphate anion could be resolved only in the spectrum of $EuPO_4$. The magnitude of the splitting of these components and the intensity of the fully symmetrical ν_1 vibrational band, which is not active in the spectrum of the free ion, constitutes quantitative characteristics of the distortion of the tetrahedron of the orthophosphate ion in the inner field of the crystal. The strength and anisotropy of the crystal field are determined by the interaction between the cations and anions. In the series of lanthanide elements from La to Eu, the intensity of the ν_1 band and the splitting of ν_3 into components increase, these increases being attributed to an increase in the strength of the inner field with decrease in the size of the lanthanide cation. An increase in the frequencies of the vibrations under consideration is observed at the same time.

A greater number of IR absorption bands have been recorded [22] in the spectra of phosphates of the first group than has been postulated on the basis of the results of a group-theoretic analysis (Table 3). In particular, in the range of ν_3 stretching vibration frequencies, five bands were observed in each case, while in the range of the ν_4 deformation frequencies four bands were observed for each compound. The authors believe that the reason for the appearance of the additional band is the manifestation of fairly intense overtones and compound vibrations. In the region of the ν_3 vibration, these bands can correspond to the $2\nu_4$ overtone or the $\nu_4 + \nu_2$ combination. Considerable difficulties arise when an attempt is made to explain the nature of the spectrum in the region of the ν_4 deformation vibration frequencies.

For the orthophosphates of the second group with the tetragonal xenotime symmetry,[18] the distribution of the PO_4 groups among positions with the D_{2d} symmetry leads to the splitting of the $\nu_3(F_2)$ vibration into two components with the E and B_2 symmetries. Both modes should be active in the IR absorption spectra. According to the scheme of correlations between the irreducible representations of the vibrations (Table 4), the $\nu_1(A_1)$ mode should retain its type A_1 symmetry and its activity in the IR absorption spectrum. Doublets corresponding to the ν_3 stretching vibration of the phosphate anion have been recorded in the experimental [25] IR spectra of

Table 3. The vibration frequencies (cm^{-1}) in the IR absorption spectra of lanthanide orthophosphates.[23]

Compound	Vibration frequencies											
$LaPO_4$	1087	1075	1053	1025	1010	980	946	621	575	559	532	487

Table 4. A scheme of the correlations of the irreducible representations of the vibrations of the PO_4 group in the xenotime structure.

Vibration	'Free' ion (T_d point group)	Symmetry of the D_{3d} position	Factor-group of the D_{4d} space group of the crystal
ν_1	A_1	A_1	$A_{1g}(R) + B_{2u}(in)^a$
ν_2	E	$A_1 + B_1$	$A_{1g}(R) + B_{2g}(R) + A_{1u}(in)^a + B_{2u}(in)^a$
ν_3	F_2	$B_2 + E$	$B_{1g}(R) + E_g(R) + A_{2u}(IR) + E_u(IR)$
ν_4	F_2	$B_2 + E$	$B_{1g}(R) + E_g(R) + A_{2u}(IR) + E_u(IR)$

[a] in = the given vibration is inactive in the spectra.
R = Raman (Ed. of Translation)

YPO_4, $GdPO_4$, and $YbPO_4$ (Table 3), but no absorption bands were observed in the range of frequencies where the ν_1 vibration might be manifested. The frequencies of the triply degenerate vibration of the PO_4 groups increase with decrease in the ionic radius of the lanthanide, similarly to the frequencies of the orthophosphates of the monazite group.

The presence of two PO_4 groups in the unit cells of compounds with the xenotime structure and the possibility of the resonance interaction of their vibrations have led to the hypothesis that the number of the corresponding IR absorption bands should be doubled. However, the authors[25] were unable to detect this effect apparently because of the small splitting of the vibration frequencies.

The decrease in the symmetry of the phosphate anions from T_d to D_{2d} also leads to the partial removal of the degeneracy of the ν_2 and ν_4 modes. The $\nu_2(E)$ mode is split into two components with the A_1 and B_1 symmetries, while the $\nu_4(F_2)$ mode is split, similarly to ν_3, into B_2 and E. All these vibrations are active in the Raman spectrum, whereas in the IR absorption spectrum the appearance of only components of the B_2 and E types is possible.

According to the results of group-theoretic analysis,[26] carried out taking into account the overall symmetry of the xenotime crystal lattice, the normal vibrations are distributed among the following irreducible representations of the factor-group D_{4h} of the space group

$$\Gamma_{mech} = 2A_{1g} + A_{2g} + 4B_{1g} + B_{2g} + 5E_g + A_{1u} + 4A_{2u} + B_{1u} + 2B_{2u} + 5E_u,$$

including the $A_{2u} + E_u$ acoustic modes, the $2B_{1g} + B_{2g} + 2E_u + 2E_g + A_{1u} + 2A_{1g} + 2A_{2u} + 2B_{2u}$ internal modes of the PO_4 groups, the $A_{2g} + E_g + B_{1u} + E_u$ librational modes, and the $2B_{1g} + 2E_g + A2_u + E_u$ translational modes.

In the case of $DyPO_4$, it was possible to record[26,27] virtually all the vibrations with even symmetry active in the Raman spectrum. The absence of two modes (B_{1g} and E_g) from the spectrum is apparently caused by their low intensity or masking by the more intense lines. The results of the IR spectroscopic study of $LnPO_4$ (Ln = Y, Er, Tm, Yb, Lu) [22] agree fully with the theoretical ideas. However, $DyPO_4$ and $HoPO_4$ have been segregated as a separate subgroup of the xenotime group, because their absorption spectra demonstrate the presence in each case of three ν_3 components and four components in the ν_4 region, ν_1 remaining inactive as before.

The X-ray diffraction patterns of these compounds also shows certain differences. On the basis of the analysis of the entire set of experimental data, Hesel and Ross[22] suggested that $DyPO_4$ and $HoPO_4$ have a structure with a symmetry higher than that of monazite but lower than that of xenotime.

Apart from the dependence of the nature of the spectrum on the symmetry in the arrangement of the PO_4 groups and the crystal lattice as a whole, the above investigators[22] considered the influence of the coordination of cations on the P–O bond. It has been suggested that the polarising effect of the cation be estimated in terms of the ratio e/r^2, where e is the formal charge of the cation and r is the ionic radius, and also from the decrease in the frequencies of the symmetrical stretching vibrations of the phosphate anion. It has been postulated that the Ln–OPO_3 bond is strongest for the polarised Tb^{3+}, which agrees with the minimal frequency of the symmetrical stretching vibration of the PO_4 groups. The steady tendency towards an increase in frequency with decrease in the polarising power of the cation was discovered in this connection.

The authors were unable to estimate the polarising power of the cations in the spectra of the phosphates of the second group owing to the absence of the ν_1 vibration bands from the IR spectrum.

A small number of absorption bands, compared with the number recorded in the IR spectra of phosphates with the monazite structure, are characteristic of these compounds,[22] again due to characteristic features of the symmetry. Thus in the region corresponding to the manifestation of the ν_3 and ν_4 vibrations, only two modes were measured in each case. As in the interpretation of the spectra of phosphates with the monazite structure, the authors attempted to explain the appearance of additional bands by the activity of harmonics or combined vibrations. However, selection rules prohibit the activity of harmonics and compound frequencies of the ν_4 components in

the IR spectra, although they become allowed on decrease to the overall C_1 symmetry. The authors were also unable to explain the appearance of additional bands in the region of the ν_4 frequencies.

In the spectra of the orthophosphates of the monazite group, two doublets are recorded in each case in the region of the ν_4 frequencies. The splitting for the high-frequency doublet is ~ 45 cm^{-1}, while that for the low-frequency doublet is ~ 25 cm^{-1}. The corresponding frequencies increase along the series of lanthanides. The latter factor does not permit the assignment of the measured bands to combinations with lattice modes because the frequencies of all of them should decrease in the La – Tb series.

The ratio of the ν_4 and ν_2 band intensities renders improbable, in its turn, the hypothesis that the additional band in the ν_4 frequency region is due to combinations with participation of the ν_2 component.

Somewhat different results were obtained by Elliott et al.[27] In particular, the orthophosphate $TbPO_4$ was assigned to compounds of the xenotime series and doubts were cast on the justification of the segregation of $DyPO_4$ and $HoPO_4$ in a separate group. Detailed analysis of experimental data (Table 3) revealed a series of spectroscopic features of lanthanide orthophosphates of the xenotime type. The theoretically predicted splitting of the ν_3 mode of the PO_4 tetrahedron into two components in conformity with D_{2d} symmetry of its position in the crystal lattice was manifested in the Raman spectra. A line at 1020 – 1040 cm^{-1} has been observed, together with the line at 1000 – 1030 cm^{-1}, for a series of compounds in the range of frequencies assigned to ν_3, while in the spectra of $TbPO_4$, $DyPO_4$, and $LuPO_4$ there is a distinct asymmetry of the lines at 990 – 1015 cm^{-1}. The $\nu_3(B_2)$ bands at 1040 – 1075 cm^{-1} correspond to them in the IR spectrum. The Raman lines corresponding to the high-frequency $\nu_3(E)$ shoulder at 1135 – 1140 cm^{-1} in the IR spectrum were not detected. The most intense Raman line at 986 – 1015 cm^{-1} was assigned to $\nu_1(A_1)$ with a high degree of probability.

Major difficulties arose in the analysis of the region corresponding to the deformation vibrations of the PO_4 groups. The bands referring to the ν_4 vibration have been measured in the IR spectra in the range 500 – 600 cm^{-1} and in the Raman spectra of $TbPO_4$ (525 cm^{-1}), $HoPO_4$ (580 cm^{-1}), and $YbPO_4$ (578 cm^{-1}). The ν_2 modes have been detected in the form of Raman lines (A_{1g}, B_{1g}) in the range 360 – 500 cm^{-1} but are absent from the IR absorption spectra. Although the frequencies below 350 cm^{-1} have in fact been assigned to ν(Ln – O), no well founded analysis of the vibrations in this part of the spectrum have been carried out.

The dependence of the positions of the Raman lines of $HoPO_4$ on the exciting light wavelength and the appearance of a series of additional narrow fluorescence lines create additional difficulties in the interpretation of the experimental data.[26]

The Raman spectra of xenotime type YPO_4 and $YbPO_4$ crystals have also been investigated by Richman.[28] The vibrational frequencies were assigned on the basis of semiempirical data, by using the results of factor-group analysis of the vibrations of the crystals.

A precision study of the Raman spectra of the isostructural YPO_4, $HoPO_4$, and $ErPO_4$ single crystals in polarised light, supplemented by calculation of the frequencies and modes of normal vibrations, has been carried out at a higher level.[29] It was shown that in the previous studies[28] it was not possible to detect all the resolved Raman lines for YPO_4 and $YbPO_4$.

The frequencies of the symmetrical and the antisymmetrical stretching vibrations of the orthophosphate ions in the compounds investigated increase somewhat with decrease in the ionic radius of the cation, i.e. with increase in the packing density in the isostructural crystal cells of the xenotime type, which corresponds to the known tendency for other lanthanide salts. Analysis of the behaviour of the deformation vibration frequencies demonstrated their parallel variation, apparently caused by the significant interaction of these vibrations with external lattice vibrations, which are strongly influenced by a change in the mass of the cation in the series of lanthanides.

The complex problem of the separation of the external lattice vibrations into librations and translational vibrations in the case where it is impossible to distinguish them in terms of symmetry in polarisation spectra has been solved[29] on the hypothesis of a significant dependence of the translational vibrations, in contrast to the librations, on the mass of the cations. Such a dependence has been noted for two E_u vibrations and a single type A_{2u} vibration. However, the assignment of the E_g (translational vibrations and librations) and B_{1g} (translational vibrations) frequencies on the basis of these postulates did not prove to be quite so unambiguous. Some increase in frequencies on moving along the series of cations Y – Ho and Er has actually been noted for one of the B_{1g} vibrations. These data indicate the limited nature of the quasi-isotopic approximation used in the study of the influence of the geometrical characteristics of the crystal lattice on its dynamic parameters.

In contrast to lanthanide orthophosphates of the monazite series, representatives of the xenotime series are characterised by an appreciable resonance interaction of the vibrations. Thus the factor-group splitting for the doubly degenerate component of the ν_3 mode of the free ion is of the order of 30 cm^{-1}, while for the ν_4 vibration it reaches 60 cm^{-1}.

The study of the IR reflection spectra[29] of YPO_4, $HoPO_4$, and $ErPO_4$ single crystals demonstrated a decrease in the band intensities in the series of lanthanides. Since the band intensities in the IR reflection spectra are determined, in particular, by the effective atomic charges, the authors suggested that the decrease in the deformation vibration frequencies of the PO_4 groups in the spectra of the orthophosphates of the series considered is determined by the weakening of the electrostatic oxygen – oxygen interaction within the framework of the phosphate tetrahedron.

In the same study,[29] an attempt was undertaken to estimate the contribution of the dipole – dipole mechanism to the splitting of the bands due to the internal vibrations of the PO_4 groups in xenotime type crystals. In this case where it exerts a dominant influence on the nature of the spectrum, one would observe a decrease in the splitting of the bands in the series of orthophosphates YPO_4, $ErPO_4$, and $LuPO_4$. However, this was not confirmed experimentally. Furthermore, the large splittings ($\sim 60 - 80$ cm^{-1} for ν_1) are also difficult to account for because, according to the symmetry conditions, this vibration in the given crystal lattice does not alter the dipole moment. The influence of the quadrupole moment, determined merely by the slight distortion of the phosphate anion, for which the fully symmetrical vibration is not accompanied by a change in the quadrupole moment in the case of an ideal tetrahedral symmetry, should also be small. Thus the above considerations led the authors to the conclusion that the dipole – dipole interactions model is inapplicable to the description of the splittings of the internal vibrations of the PO_4 groups in crystals with a xenotime type of structure observed experimentally in both Raman spectra and IR reflection spectra.

The normal vibrations of the crystal have been calculated for YPO_4.[29] The valence force field zeroth approximation was devised by resorting to the force constants obtained for the free ion $[PO_4]^{3-}$ in solution and the force constants of the Y – O bonds for the first coordination sphere of the cation. In the calculation, account was taken of the interaction between the oxygen atoms of the neighbouring PO_4 tetrahedra and between the yttrium and phosphorus atoms (Y – Y, P – P, Y – P). The results of the calculation of the frequencies and modes of the normal vibrations and of the distribution of the potential energy made it possible to specify in detail and refine the assignment of the vibration frequencies. A significant correction to the assignment of the vibration frequencies was made on the basis of theoretical data for the E_g and E_u modes of the translational vibrations and librations. It was found that in these representations it is impossible to separate fully the two types of external lattice vibrations and that the change in the mass of the cation exerts a definite influence on

the frequencies of predominantly those translational vibrations for which significant amplitudes of the displacements of atoms have been established. The distribution of the potential energy obtained demonstrates a slight mixing of the modes of the internal vibrations of the phosphate ions with those of the lattice vibrations. The latter confirms the legitimacy of the approach used to interpret the vibrational spectra of all the phosphates and based on the separation of the internal and external vibrations. Among the stretching vibrations, the symmetrical pulsating vibration of the PO_4 groups proved to be mixed to the greatest extent, in terms of mode, with the vibrations of the cationic sublattice.

Comparison of the partial derivatives of the frequencies with respect to the force constants led to the conclusion that the Davydov resonance splitting of modes with identical symmetries in the IR spectra may be predicted in the case where it is determined by the dipole–dipole interactions. Analysis of the data obtained led the authors to the conclusion that the force field model employed is of limited applicability because it cannot be used to describe the elastic forces arising in the reorientation of complex phosphate anions.

Agreement with the results described above was achieved in the study of the Raman spectra of the single crystals of the orthophosphates of all the lanthanides (with the exception of promethium), yttrium, and scandium,[30] the Raman spectra being recorded for the first time for the orthophosphates of the lanthanides of the monazite group. The polarisation measurements permitted a correct assignment of the fundamental frequencies in terms of the symmetry types (Table 5). The data presented agree well with those of Lazarev et al.[29] for YPO_4, $HoPO_4$, and $ErPO_4$, and of Elliott et al.[27] for $DyPO_4$, but there is some discrepancy between the frequencies and those found earlier[26] for other compounds with the xenotime structure.

Table 5. The vibration frequencies (cm^{-1}) in the Raman spectra of the tetragonal orthophosphates $LnPO_4$ (Ln = Y, Tb–Lu).[31]

The complete set of twelve allowed Raman vibrations has been recorded for orthophosphates with the xenotime structure. The interpretation of the spectra became possible only when account was taken of the resonance interaction of the vibrations within the framework of the unit cell in terms of the factor-group representations of the space group of the crystals.

The crystals of the phosphates with the monazite structure have much more complex spectra as a consequence of the low symmetry. The spectra were analysed resorting to IR absorption data.[22] The group-theoretic analysis of the vibrations of the orthophosphates with the monazite structure presupposes that 36 modes are active in the Raman spectrum and that 33 modes, obeying the alternative prohibition rule, are active in the IR spectra, but only 23 modes were recorded experimentally in the Raman spectra. Swanson et al.[31] suggest, on the basis of these data, that the vibration frequencies be assigned in terms of the representations of the local symmetry group C_1 for PO_4. In this case, it is assumed that all the internal vibrations of the PO_4 groups are active in both IR absorption and Raman spectra (Table 6).

Table 6. The vibration frequencies (cm^{-1}) in the Raman spectra of the monoclinic orthophosphates $LnPO_4$ (Ln = La–Gd).[31]

However, this approach does not appear to be well founded. Firstly, the occurrence of a fairly strong resonance interaction of the vibrations has been established experimentally. Only five of the recorded Raman lines have the same frequencies as those measured in the IR spectra. In particular, the frequency of the $\nu_1(PO_4)$ symmetrical stretching vibration in the Raman spectra proved to be higher by 20 cm^{-1} than in the IR absorption spectra. Secondly, in the experiment on a single crystal in polarised light, the identity of certain frequencies of the A_g and B_g components cannot be an obstacle to their assignment regardless of whether this is due to the inadequate resolving power of the instrument or to the small factor-group splitting.

The frequencies of the internal vibrations of the PO_4 groups in the spectra of lanthanide orthophosphates increase linearly with the atomic number and ionic radius of the lanthanide. Thus the symmetrical stretching vibration frequencies vary from 967 cm^{-1} ($LaPO_4$) to 1011 cm^{-1} ($LuPO_4$). On the other hand, the frequencies of the lattice vibrations demonstrate a very slight dependence on the atomic number of the lanthanide.

Such tendencies in the variation of the vibration frequencies in the series of lanthanide orthophosphates conflict with those established previously[29] but do agree with those presented for lanthanide hydroxides.[31] The decrease in ionic radius from lanthanum to lutitium ensures a closer packing of the PO_4 groups. The contraction of the latter is accompanied by the deformation of the anion, a decrease in the interatomic phosphorus–oxygen distances, and an increase in the stretching and deformation vibration frequencies.

V. Double orthophosphates

Much attention has been devoted in recent years to the investigation of the structures and properties of double orthophosphates.[1,6,32] The existence of structural information for representatives of this class facilitates the interpretation of their vibrational spectra, which have been investigated in fair detail. A number of studies[33–35] have been devoted to the analysis of the vibrational spectra of the double phosphates $M^{I}M^{II}PO_4$ (M^{I} = Li, Na; M^{II} = Mg, Sr, Ba, Pb, Cd, Mn, Fe, Co, Ni).

X-ray diffraction data[36] have shown that the double phosphates $NaM^{II}PO_4$ (M^{II} = Mn, Fe, Co, Cd) are isostructural with Na_2SO_4-III and have the $Cmcm = D_{2h}^{17}$ symmetry space group. The internal vibrations of the PO_4 groups lie in the same frequency ranges within the spectrum as in the case of the individual phosphates.[33] The lattice vibration frequencies at 100–350 cm^{-1} depend, as expected, on the nature of the divalent cation. In order to refine the assignments in this part of the spectrum, the cadmium isotope ($^{106}Cd-^{116}Cd$)-substituted $NaCdPO_4$ specimens were investigated. However, the data obtained did not permit a reliable differentiation of the librational and translational modes. The authors believe that one of the probable causes of this is the interaction of lattice modes of identical symmetry. Certain features observed in the spectrum led the authors to the idea that the Na_2SO_4-III structural type has been modified for the series of compounds considered despite the similarity of the ionic radii. The lower symmetry of the unit cell in the phosphates considered (factor-group C_{2v}) was postulated. Under these conditions, agreement is achieved between the number and activity in the spectra of the vibrations predicted by the group-theoretic analysis and observed experimentally. In this connection, it is useful to recall the X-ray and neutron diffraction studies on $LiCaPO_4$,[37] isostructural with $LiNaSO_4$, which showed that this compound crystallises in the trigonal system with the space group $P31c = C_{3v}^{4}$.

The interpretation of the IR absorption and Raman spectra of the orthophosphates $LiM^{II}PO_4$ (M^{II} = Mg, Cd, Mn, Fe, Co, Ni) with the olivine structure by Paques-Ledent and Tarte[34] was based on a comparative analysis of data for the individual compounds, their solid solutions, and specimens with isotope substitution of the cations. The crystal structure of olivine is described by the space group $Pnma = D_{2h}^{16}$ ($Z = 4$). In the unit cell, there are two types of positions with a distorted octahedral environment: the divalent M^{II} cations occupy positions with the C_s symmetry, while the alkali metal cations M^{I} occupy C_i positions. There is also a possibility of a statistical distribution of the cations among these positions. Phosphate groups occupy positions with the C_s symmetry. The frequency assignment was carried out in terms of the approximation involving the subdivision of the vibrations into internal and external. The IR absorption spectra of the isotope-substituted $LiMgPO_4$ ($^{6}Li-^{7}Li$, $^{24}Mg-^{26}Mg$) and $LiNiPO_4$ ($^{6}Li-^{7}Li$, $^{62}Ni-^{68}Ni$) specimens as well as the Raman spectra of $LiMnPO_4$ and $LiCdPO_4$ specimens have been studied in greatest detail. The spectra of the isostructural series of compounds $LiM^{II}PO_4$, differing significantly only in the low-frequency region, which is associated with the manifestation of the vibration of the cations of different chemical nature, have been recorded.[34] In the remaining regions (stretching and deformation vibrations of the PO_4 groups), they are similar.

The four intense fairly broad IR bands at 960–1200 cm^{-1} were assigned to the components of the antisymmetrical ν_3 stretching vibration of the phosphate anion, while the weak, narrow, and lower-frequency bands were assigned to the ν_1 symmetrical vibration. The argument used in support of this conclusion was the agreement between the observed frequencies ν_1 and those of the most intense Raman lines and the ν_1 frequency in the IR absorption spectrum of a solution of the orthophosphate. However, the proposed assignment is not entirely correct in view of the possibility of the complete removal of the degeneracy of the vibrations and of the interaction of components with identical symmetries. The factor-group, resonance interaction is not manifested in the spectra of dilute $LiM^{II}(P_{0.02}As_{0.98})O_4$ solid solutions, while the site-group splitting of the ν_3 mode of the anion is observed in the form of three components, which agree with the C_s symmetry of its position.

Analysis of the changes in the spectra of the isotope-substituted $LiM^{II}PO_4$ specimens (Tables 7–9) made it possible to differentiate three types of absorption bands:

the IR absorption bands at 550–700 cm^{-1}, for which isotopic shifts have not been detected or are insignificant, were assigned to the deformation vibrations of the anions;

several bands in the low-frequency part of the spectrum, which are also insensitive to the mass of the cation (the band at 372 cm^{-1} is the most characteristic in this respect), were assigned to librations bearing in mind that the frequencies are too low for deformation vibrations;

bands with appreciable isotopic shifts were assigned to external translational vibrations.

On the basis of the selective sensitivity to a particular isotope, it was possible in a number of instances to assign bands of the last type to the translational vibrations of various sublattices of the cations (Tables 7–9). Here one should note the fairly high (350–550 cm^{-1}) frequencies of the translational vibrations of

the cations in the lithium sublattices, demonstrating the isotopic effect in the $^6Li-^7Li$ replacement. These vibrations may be mixed with the deformation vibrations of the anions, hindering the assignment of the latter.

The most intense line at 950 cm^{-1} in the Raman spectra of $LiM^{II}PO_4$ was assigned to the symmetrical ν_1 stretching vibration of the anion. The lower-intensity lines at higher frequencies (1000–1100 cm^{-1}) were attributed to the components of the triply degenerate ν_3 vibration (Table 9). Raman lines sensitive to lithium isotope substitution were not detected. This situation agrees fully with the theoretical postulates. The lithium cations occupying positions with the C_i symmetry cannot participate in the vibrations active in the Raman spectra. This permitted a more reliable assignment of the deformation vibration frequencies of the PO_4 groups. The ν_2 and ν_4 deformation frequencies were assigned on the basis of the relative intensities of the corresponding Raman lines and the vibration frequencies of the free anion in solution. The Raman lines at frequencies below 350 cm^{-1} were assigned to librations and translation vibrations without further specification. On the basis of the results, the authors[34] suggest that the approximation involving the subdivision of the vibrations into internal and external is justified. However, allowance for the factor-group splitting of the vibrations and for the subsequent interaction of their components with identical symmetries may introduce corrections to the results.

The available data for dilute solid solutions of a series of compounds $LiM^{II}PO_4$ showed that the observed splittings of the degenerate stretching vibration are not associated with geometrical distortions. The study of the crystal structure of $LiMnPO_4$ demonstrated the similarity of the four phosphorus–oxygen interatomic distances in the PO_4 groups (the differences between them do not exceed the experimental error). The deformation of the tetrahedral anions, expressed by changes in the bond angles from 106° to 112°, should most probably affect the behaviour of the deformation modes but cannot induce a significant splitting of ν_3.

Since appreciable splittings of ν_3 have been observed for compounds of different composition with the olivine structure ($M^{II}_2SiO_4$, $M^{II}_2GeO_4$, $M^{I}M^{II}AsO_4$, $M^{I}M^{III}SiO_4$, and $M^{I}M^{III}GeO_4$) as well as the orthophosphates considered, the authors[34] concluded that this effect is determined not only by the chemical nature of the cations or the anions but also by the crystal structure. Even when the cations in two different octahedral positions in the olivine structure are chemically identical, two sets of nonequivalent cation–oxygen distances are postulated in the compounds $M^{II}_2SiO_4$. Each oxygen atom of the tetrahedral anion is linked to three cations located in different positions, namely $2\,M^{II}(C_i) + 1\,M^{II}(C_s)$ or $1\,M^{II}(C_i) + 2\,M^{II}(C_s)$. The difference between the energies of the cation–oxygen bonds leads in this case to the appearance of two types of bonds in the tetrahedral anions and is responsible for the splitting of the ν_3 mode. This is naturally also responsible for the dependence of the splitting on the nature of the cations in the octahedral positions. Indeed, there is a quantitative dependence of the splitting on the second ionisation potential of the divalent cation, which demonstrates the validity of the proposed explanation of the observed effect.[34]

The structures of the double phosphates $LiSrPO_4$, $LiBaPO_4$, and $LiPbPO_4$ have not been investigated, although it is known that they are not isomorphous. The crystal structure of $LiBaPO_4$ resembles[35] the orthorhombic structure of $LiKSO_4$ with the symmetry space group $Pna2_1 = C^9_{2v}$ ($Z = 4$). Despite the similarity of the ionic radii of strontium and lead, their double orthophosphates with lithium salts crystallise differently. The $LiPbPO_4$ crystals have the $Pna2_1 = C^9_{2v}$ symmetry with eight formula units in the unit cell, while the space group $P2_1/b = C^5_{2h}$ has been proposed for $LiSrPO_4$. Using vibrational spectroscopic methods, the investigators[35] attempted to establish certain details of the structures of these compounds. The measured IR absorption spectrum of $LiBaPO_4$ proved to be similar to those obtained for $LiKSO_4$ and $LiCsSO_4$ over the entire range (up to 50 cm^{-1}). The vibration frequencies and their assignments for $LiBaPO_4$ are compiled in Table 10. Apart from the stretching and deformation vibration frequencies of the PO_4 groups, the IR absorption spectra contain bands at 400–500 cm^{-1}, undergoing an appreciable isotopic shift following the $^6Li-^7Li$ substitution which permitted their assignment to the vibrations of the lithium sublattice cations. The relatively high corresponding frequencies suggest a tetrahedral coordination of the lithium cations and agree with X-ray diffraction data. The three IR absorption bands recorded in the low-frequency region were assigned to lattice vibrations with participation of the heavy barium atoms.

Analysis of the isotopic shifts enabled the authors[36] to conclude that there are no appreciable interactions between the internal and external vibrations of the crystals having the structure investigated. It was possible to detect experimentally only some of the theoretically predicted vibration frequencies. In many cases, it was noted that the frequencies in the Raman and IR absorption spectra do not agree, which is consistent with the centrosymmetrical space group proposed for $LiBaPO_4$.

The observed isotopic effect assisted significantly also in the assignment of the Raman spectroscopic frequencies. The 954 and 930 cm^{-1} lines were assigned to the components of the symmetrical stretching vibration of the PO_4 groups, while the three lines in the range 1000–1150 cm^{-1} were assigned to the components of the triply degenerate vibration. The intense line at 424 cm^{-1} as well as the 580 and 570 cm^{-1} lines, which do not shift following lithium isotope substitution, have been assigned to the components of the ν_2 deformation vibration. Lines assigned to the vibrations of the cations of the lithium sublattice have been detected in the same range (390–500 cm^{-1}). A more complex vibrational spectrum has been obtained[35] for $LiSrPO_4$, which is due to the lower symmetry of the crystals. However, the range of the stretching vibration frequencies of the PO_4 groups proved to be similar to that for $LiBaPO_4$. The most significant shifts following lithium isotope substitution ($^7Li-^6Li$) have been recorded for the 618 (639), 516 (555), and 343 (393) cm^{-1} bands in the frequency range corresponding to the tetrahedral coordination of lithium in the crystal lattice. The components of the ν_4 vibrations of the PO_4 group are manifested at 590 and 576 cm^{-1}, while those of the ν_2 vibrations are manifested at 428 cm^{-1}. The authors note an appreciable, compared with $LiBaPO_4$, interaction of the deformation vibrations of the PO_4 groups with the vibrations of the lithium cations.

The presence of two bands, at 964 and 919 cm^{-1}, in the range of the stretching vibration frequencies of the anions in the IR spectrum of $LiPbPO_4$, has been attributed[35] to the presence in the

Table 10. Frequencies of the vibrations (cm^{-1}) of $LiM^{II}PO_4$ (M = Ba, Pb).[35]

crystal lattice of two sets of nonequivalent PO_4 groups. The Raman lines sensitive to lithium isotope substitution have been detected in the frequency range 500–600 cm^{-1}. Identical absorption frequencies have been noted for many vibrations of $LiPbPO_4$, which agrees with the absence of a centre of symmetry in the crystal lattice (space group $Pna2_1 = C_{2v}^9$). The authors[35] do not propose any approaches to a detailed interpretation of the long-wavelength (below 300 cm^{-1}) part of the spectra of the group of compounds considered, postulating the manifestation in this region of vibrations involving the heavy cations. Nevertheless, comparison of the spectra of compounds differing appreciably in the mass of the cations permits the analysis also of this spectral region, thus differentiating also the librations of the PO_4 groups.

The IR absorption spectra of polycrystalline specimens (mulls in liquid paraffin) of $RbMgPO_4$ and $CsMgPO_4$ have been measured[37] in the restricted range 400–1800 cm^{-1}. The very great similarity of the spectra enabled the authors to conclude that the compounds have the same structure. The splitting of the bands due to the stretching and deformation vibrations of the PO_4 groups as well as the activity in the IR spectrum of the fully symmetrical ν_1 stretching vibration suggest a decrease in the symmetry of the anion in the crystal lattice. The lack of sufficient experimental data made it impossible to secure more complete information about the structure of these phosphates.

Apart from the compounds considered here, the crystal structures have been described for a further two orthophosphates $M^IM^{II}PO_4$. X-Ray diffraction analysis of $RbZnPO_4$ led to the conclusion[38] that this compound crystallises in the monoclinic system [space group $P2_1 = C_2^2$ ($Z = 4$)]. It was shown that the structure is based on a three-dimensional skeleton made up of ZnO_4 and PO_4 tetrahedra related to the tridymite skeleton. The heptacoordinated rubidium cations are located in the channels of the skeleton. The crystal structure of $KBaPO_4$[23] with the $Pnma = D_{2h}^{16}$ ($Z = 4$) symmetry belongs[39] to the β-K_2SO_4 (arcanite) type in which some of the potassium cations have been replaced by barium. Unfortunately, we do not possess spectroscopic data on these compounds.

The crystal structures and vibrational spectra of double orthophosphates of Group I and III elements have been most fully investigated. Extensive information about these substances has been surveyed in a series of reviews.[32,40–42] X-Ray and physicochemical studies on phases of the type of nasicon $Na_3M_2^{III}(PO_4)_3$, where M is Sc, Cr, or Fe, demonstrated[40,42] the possibility of the occurrence in the latter of a high-temperature orthorhombic γ-phase with superionic conductivity, an intermediate phase (β-phase), and a low temperature α-phase. A detailed analysis of the structure, ion transport, and phase transitions in compounds of the type of nasicon has been carried out.[43] On the basis of X-ray diffraction and spectro-scopic studies,[44,45] the structure of nasicon $M_3^IM_2^{III}(PO_4)_3$ has been described as a superposition of the sublattices of PO_4 tetra-hedra and the M^I and M^{III} cations which fill the existing cavities. For compounds with a wide range of cations (M^I = Li, Na, K, Cu, Ag; M^{III} = Fe, Sc), the distortion of the structure relative to the initial prototype[40] $NaZr(PO_4)_3$ with the space group $R3c = C_{3v}^6$ as the cavities in the skeleton are filled has been studied.[44] In the course of the investigation of the vibrational spectra, both the range of symmetrical and antisymmetrical stretching vibration frequencies of the PO_4 groups, sensitive to the distortions of the tetrahedral anion, and the long-wavelength range (50–300 cm^{-1}), analysis of the bands in which makes it possible to estimate the degree of ordering of the cations, were examined. The minimum activation energy for conduction was found for compounds with most local disorder in the distribution of the cation. The conductivity diminishes as the cavities are filled.

An interpretation of the temperature-induced changes in the IR absorption and Raman spectra of orthophosphates of the type of nasicon $M_3^ISc_2(PO_4)_3$, where M = Li, Na, K, or Ag, in the range 100–300 K has been proposed.[45] In particular, the frequencies of the internal vibrations of the PO_4 groups and the vibrations of the scandium sublattice and of the conducting M^I cations as well as the librations of the tetrahedral anions were assigned. A correlation was established between the local disorder, the phase transitions, and the changes in the activation energy for conduction. Studies of the Raman spectrum of

$Li_3Fe_2(PO_4)_3$ as a function of temperature were continued.[46] Investigation of the $\alpha-\beta$ and $\beta-\gamma$ phase transitions demonstrated that the disordering of the cationic sublattice of the orthorhombic γ-phase leads to the broadening of the lines due to both the internal stretching vibrations of the PO_4 groups and the lattice modes. Analysis of the calculated and experimental frequencies of the relaxation modes led the authors[28] to the assumption that low-frequency phonons are involved in the activation process.

The crystals of alkali metal lanthanide double phosphates can be divided into several types.[32] The parent of this structural family is glaserite $K_3Na(SO_4)_2$ [48] having a layered structure. The layers are formed by the tetrahedral sulfate anions and sodium cations, the potassium cations occupying the interatomic space.

Among compounds of this series, lithium compounds have been least investigated. The structure of the monoclinic $Li_3Sc_2(PO_4)_3$, corresponding to the space group $P2_1/n = C_{2h}^2$ ($Z = 4$), is known.[48] The crystal lattice is made up of the scandium coordination octahedra linked via the common vertices to the PO_4 tetrahedra. The lithium cations occupy the tetrahedral and trigonal-bipyramidal (two types) positions. The lithium polyhedra linked via common vertices form infinite chains. The results of a neutron diffraction study of $Li_3Sc_2(PO_4)_3$ [49] revealed insignificant differences between the parameters of the monoclinic cell and those obtained by X-ray diffraction.

A study of the structural features of the double sodium lanthanide orthophosphates $Na_3Ln(PO_4)_2$ showed[47] that the nature of the ordering of the cations in the glaserite-like lattice depends on the size of the lanthanide. Most of them have the orthorhombic symmetry and form a group of the $Na_3La(VO_4)_2$ structural type.[32] However, the available literature data are contradictory.[32,47]

Double potassium lanthanide orthophosphates have been investigated in greater detail[32,50] and, in conformity with their crystal structure, they can be divided into three groups:

Ln = La, or Sc—compounds with the triple glaserite unit cell;

Ln = Gd–Yb—compounds with a monoclinic distortion of the $K_3Lu(PO_4)_2$ lattice and the lattice volume increased by a factor of eight;

Ln = Nd—the intrinsic $K_3Nd(PO_4)_2$ structural type.

Among recent studies on the double orthophosphates, mention should be made of the investigation[51] devoted particularly to the phase relations in the $K_2O-Y_2O_3-P_2O_5$ system, where the existence of the $K_3Y(PO_4)_2$ phase was confirmed by the results of physicochemical and X-ray diffraction analysis and by IR spectra.

The more symmetrical trigonal structure occurs in the rubidium compounds of similar composition. This is ensured, firstly, by the 'moving apart' of the layers of the PO_4 tetrahedra and the lanthanide octahedra by the larger rubidium cations and their smoothing and, secondly, by the displacement of electron density and the increase in the covalent component of the Ln–O bond when potassium is replaced by rubidium, which also increases the symmetry of the layers. The intrinsic structural type occurs for $Rb_3Sc(PO_4)_2$.[32] According to the available data,[32] the double orthophosphate $Ag_3Sc(PO_4)_2$ has no structural analogues among the compounds described above. Silver compounds with lanthanides having this composition are unknown.

The vibrational spectra of $M_3^IM_2^{III}(PO_4)_3$, where M^I = Li or Na and M^{III} = Sc, Cr, Fe, or In, have been investigated.[52] Attention was concentrated on the temperature-induced changes in the Raman and IR absorption spectra of $Na_3Fe_2(PO_4)_3$. The two crystalline modifications of this phosphate differ by the distribution of the sodium cations—it is fully ordered for the monoclinic α-phase but is only partly ordered for the hexagonal β-phase. The authors[52] were able to discover certain significant differences between the vibrational spectra of these two modifications of $Na_3Fe_2(PO_4)_3$.

Analysis of the temperature dependence of the behaviour of the IR absorption bands of $Na_3Fe_2(PO_4)_3$ made it possible to divide the spectrum arbitrarily into two regions:

the 300–650 cm^{-1} frequency range, assigned to the deformation vibrations of the PO_4 groups and the translational vibrations of the iron cations, this part of the spectrum hardly changing in the given temperature range;

the higher frequency range 900–1250 cm^{-1}, corresponding to the stretching vibrations of the PO_4 groups, in which the fine structure of the absorption bands undergoes changes (a slight bathochromic shift and a broadening of the bands) at 84 °C.

More significant changes in the spectrum were recorded in the temperature range of the $\alpha-\beta$ polymorphic transition at 95–102 °C. The spectrum of β-$Na_3Fe_2(PO_4)_3$ obtained resembles that of $NaZr_2(PO_4)_3$ with a structure having hexagonal symmetry. However, solely on the basis of symmetry consideration without allowance for the disordering of the cations, the authors were unable to interpret all the recorded temperature-induced changes.

The results of the studies on the IR spectrum agree satisfactorily with the results of Raman measurements as a function of temperature. The fine structure of the Raman lines in the range 400–1250 cm^{-1} is almost completely smeared on raising the temperature to 110 °C, whilst in the region of moderate and low frequencies no significant changes take place. The 238 cm^{-1} line, which completely disappears with increase in temperature, is an exception.

The synthesis and study[53] of the double orthophosphates $Na_3Ln(PO_4)_2$ and $Na_3Ln_2(PO_4)_3$, where Ln = Tb–Lu, have been described. The formation of several polymorphic modifications with different symmetries is characteristic of each of the compounds investigated. The authors obtained the γ-phase for the first time. The phosphates of the series considered can be divided into four structural types. The X-ray diffraction pattern and the Raman spectrum of the γ-phase isolated differ from those known for any other phosphates. The temperature-induced changes in the Raman spectrum of the double phosphate $Na_3Ho(PO_4)_2$ are of considerable interest. At 465 °C, the three most intense lines of the Raman spectrum in the range of the stretching vibration frequencies of the PO_4 groups were broadened and exhibited two absorption shoulders on their slopes. The frequencies of the maxima increased and then remained unchanged up to 940 °C. A roughly similar behaviour has been demonstrated by the Raman lines of $Na_3Dy(PO_4)_2$. The single line generated when the three components merge in the region of the stretching vibration frequencies of the PO_4 groups at 750 °C has a frequency 16 cm^{-1} lower than that of the most intense initial line. The authors explained the observed effect by the occurrence of a phase transition. Manifestations of a phase transition have been noted[53] also in the Raman spectra of $Na_3Yb_2(PO_4)_2$. On the basis of the spectroscopic data obtained, the authors established the temperature limits of the stability of different polymorphic modifications of the phases studied.

The double orthophosphates $M_3^{II}M^{III}(PO_4)_3$ have been examined.[54,55] The formation of cubic crystals with the space group $I43d = T_d^6$ is characteristic of compounds of the series with M^{II} = Sr, Ba, or Pb and M^{III} = Y, Sc, Ln, or Bi. $Ca_3Bi(PO_4)_3$ and $Ca_3Eu(PO_4)_3$ have also been obtained. The results of the X-ray diffraction and IR spectroscopic study of the double calcium europium orthophosphate indicate[55] that its structure is the same as that of β-$Ca_3(PO_4)_2$.

Double lanthanide orthophosphates have been vigorously investigated in recent years.[56–58] They are isostructural with monazite or zircon and with the lanthanide orthophosphates. It may be expected that the distribution of lanthanides of different masses at the cationic sites would lead to changes in the longer-wavelength part of the vibrational spectra.

* * *

The foregoing demonstrates the possibility of securing extensive information, which is also predictive in character, in those cases where systematic spectroscopic studies have been carried out using all the possibilities of the method. Unfortunately, such investigations have been carried out fully for a very limited number of phosphates. The existing frequently controversial results have not been confirmed by theoretical calculations of the vibrations of the crystals. The vibrational spectra of alkali metal orthophosphates have not been investigated. On the other hand, vigorous studies are being prosecuted on the synthesis and X-ray diffraction of new complex orthophosphates and also compounds with systems of condensed phosphate anions. Reliable information can be secured from the analysis of the vibrational spectra of the latter only on the basis of a detailed knowledge of the nature of the vibrations of simpler orthophosphates.

V. Conclusion	424

Abstract. The methods of synthesis of refractory carbides, borides, nitrides, and oxides in the form of ultradisperse powders, consolidated materials, and films with a grain size less then 100 nm are examined. Information about the properties of nanocrystalline refractory compounds is described systematically and discussed. The bibliography includes 233 references.

I. Introduction

It is believed that one of the most important roles of chemical synthesis is in the establishment and improvement of the properties of modern ceramic, polymeric, and other materials (see, for example, Refs 1 – 5). The dimensional, phase, impurity, morphological, structural, and other features, which to a significant extent determine the physicochemical, physicomechanical, and operational properties of the materials, are in fact established at this stage of the synthesis. The important role of chemical synthesis is also indicated by the following facts: since 1984, the American Materials Science Society has held regular symposia, twice a year, on 'Chemical Methods for the Improvement of Ceramics'; the journals Chemistry of Materials and Journal of Materials Chemistry have been published by the American Chemical Society and the British Royal Society since 1989 and 1991 respectively.

Interest in the methods of synthesis used to create a new class of substances — nanocrystalline materials (NM) the characteristic structural size (grain or subgrain size) of which is less than 100 nm — is understandable. It has been shown for many nanocrystalline materials based on metals and intermetallic compounds (Ni, Pd, Ag, Cu, TiAl, $NbAl_3$, etc.) that a significant change in properties, the nature of which is frequently nonmonotonic, is observed for this grain size.[6-8]

The available review publications mainly describe the properties of the above nanocrystalline materials but are hardly concerned with the problems of refractory compounds (RC). The latter usually include carbides, nitrides, borides, oxides, and other phases with a melting point above 2000 °C.[9] The remarkable properties of these compounds (high hardness and high modulus of elasticity and strength; chemical inertness and low rate of evaporation; a wide range of electrical properties, including superconductivity, etc.) have long attracted to them the attention of a wide range of specialists in the field of the physical chemistry and technology of materials. Recently this interest has intensified in connection with the creation of nanocrystalline materials. The available information about the synthesis and properties of nanocrystalline materials based on refractory compounds is scattered and needs to be surveyed and treated systematically.

The problems of the synthesis of nanocrystalline materials from refractory compounds have several aspects. These are, firstly, the preparation and consolidation of ultradisperse powders and, secondly, the preparation of nanocrystalline films. Apart from these, there are also the characteristic features of the synthesis of amorphous substances which are converted into nanocrystalline materials after crystallisation. Our review is devoted predominantly to nanocrystalline materials in the powder and film form, in both consolidated and discrete states. For this reason, certain questions concerning the complex problem of the consolidation of nanocrystalline materials are also dealt with. So far as we are aware, such an approach had not been used previously although individual data are available in some communications.[10-13]

Clearly, the temperature limit of refractory compounds indicated above is extremely arbitrary and is largely dictated by convenience. According to estimates,[14] there are about 240 two-component refractory compounds for which T_f† > 2000 °C. On the other hand, the number of thoroughly investigated refractory compounds which are used in practice is much smaller. Therefore the subject of our review concerns nanocrystalline refractory compounds such as Si_3N_4, SiC, TiN, TiC, TiB_2, NbC, NbN, WC, Al_2O_3, AlN, ZrO_2, Y_2O_3, MgO, BN, and certain others. It is easily seen that they virtually all form part of the promising group of ceramics popular at present (Advanced Ceramics).

II. Ultradisperse powders and their properties

1. Preparation

The problem of the preparation of ultradisperse powders has long been discussed in publications devoted to ceramics, powder metallurgy, catalysis, and other fields. Various methods for the chemical synthesis of ultradisperse powders of oxygen-free refractory materials, used in ceramics and catalysis, have been

	ZrO_2, Y_2O_3;	74, 77, 78
	NbN;	79
	Si_3N_4 + SiC	80, 81
gaseous precursors	TiB_2, ZrB_2;	16, 82, 83
	BN	84

analysed in a review.[15] Its authors reduced arbitrarily the wide variety of synthetic methods to four types of reactions — solid-phase, gas-phase, liquid-phase, and reactions of the gas–solid type. Nontraditional methods of synthesis of oxygen-containing and oxygen-free powders such as the sol-gel process, hydrothermal synthesis, pyrolysis of polymers, reactions in nonaqueous solutions, and different versions of the gas-phase synthesis (plasmochemical, laser, etc.) have come to be widely used in recent times.[1,16] One can add to these mechanosynthesis, electrochemical synthesis, self-propagating high-temperature synthesis (SHS), and synthesis in shock waves. The methods of preparation of solid powders of refractory compounds can be divided into two groups — physical and chemical (Table 1). This subdivision is naturally arbitrary because, for example, virtually all the physical methods include an appreciable chemical component and it is indeed frequently difficult to draw a clear-cut boundary between different procedures. Table 1 includes by no means all the examples of the preparation of ultradisperse powders of refractory materials, only the most characteristic being listed. We shall examine certain characteristic features of the methods of preparation of such powders.

a. Vaporisation and condensation

The condensation methods of preparation of clusters and ultradisperse powders have long been known and their theory has been described in many publications (see, for example, Uyeda[18] and Morokhov et al.[85]). There are at least two necessary and sufficient conditions for the condensation of ultradisperse powders — a high supersaturation and the presence in the condensed vapour of the molecules of a neutral gas. An interpretation of the phenomena in the gas-phase condensation, including homogeneous and heterogeneous nucleation, the mechanism of the growth of particles, the influence of impurities, etc., may be found in the sources mentioned above.[18,85]

In relation to nanocrystalline materials, condensation methods have developed after the publication of the communications of Birringer et al.[86] and Siegel and Hahn.[87] They describe the apparatus which makes it possible to combine the condensation process leading to the formation of ultradisperse powders with the vacuum pressing of small specimens (with a diameter up to 10–15 mm and thickens up to 0.2–0.5 mm) at high pressures (up to 3–5 GPa). This made it possible to avoid contamination to a large extent, by excluding contact between the ultradisperse powder and the surrounding medium, which is particularly important in the case of metallic and intermetallic substances. Ultradisperse aluminium, zirconium, yttrium, etc. oxide powders can be obtained in such apparatus by vaporising the oxide targets in a helium vacuum,[19] by the magnetron atomisation of zirconium cathodes in an argon–oxygen medium,[20] and also by forming an ultradisperse yttrium powder with subsequent controlled oxidation.[22] The reactive laser ablation synthesis, designed to obtain spherical Al_2O_3 and AlN particles on evaporation of aluminium, has been described.[23]

Mention should be made of the work of Japanese investigators on the vaporisation of transition metals in a nitrogen or ammonia vacuum (130 Pa) using electron-beam heating[21] and also on the application of the plasma, laser, and arc methods of heating in order to obtain ultradisperse MgO, Al_2O_3, and SiC powders.[17,18]

An advantage of the condensation method is the possibility of obtaining fairly pure ultradisperse powders with an extremely small particle size (with a particle diameter d down to 5–10 nm and less) over a comparatively narrow range of the latter. However, their productivity is low and the energy consumption is considerable. Naturally one has to bear in mind also the possible complications associated with the maintenance of the specific composition, which applies particularly to compounds with a wide range of homogeneity (for example, transition metal carbides and nitrides).

b. High-energy disruption

The usual grinding process is employed comparatively rarely to obtain ultradisperse powders because a grindability limit exists corresponding to the attainment of a kind of equilibrium between the disruption of the particles and their agglomeration.[4] Even when brittle materials are ground, the diameter d is usually not less than 50–100 nm. Furthermore, during grinding the product is contaminated by the material of the spheres and of the lining and also by oxygen. Admittedly, this can be avoided to a large extent by employing special spheres and lining prepared from the same material as the product being ground but the contamination with oxygen of oxygen-free refractory compounds

cannot be prevented. This can be illustrated by the example of the grinding of silicon nitride in a specially lined attrition mill:[26]

	Initial characteristics	4-h grinding	12-h grinding
d/nm	220	95	60
O_2 (mass %)	0.9	2.1	3.9

The characteristics of the preparation of ultradisperse powders of refractory materials by mechanosynthesis have been vigorously investigated recently. This was preceded, starting in the 1970s, by the study of the characteristic features of the so called mechanical alloying — the formation of alloys and intermetallic compounds under the conditions of high-energy grinding. One of the first mentions of the possibility of the synthesis of titanium (TiB_2), molybdenum (MoB), and niobium (NbB_2) borides when the corresponding metallic powder and boron are ground together in a planetary mill can be found in a monograph.[88] The mechanism and characteristics of the mechanosynthesis of refractory materials have been the subject of a lively discussion in the literature.[89-91]. The formation of refractory compounds during grinding is attributed both to the vigorous generation of new active surfaces and intense mixing (which intensifies diffusion processes) and to the exothermic nature of the reactions of the metals with the nonmetallic components (carbon, boron, and nitrogen). Mechanical activation as it were initiates the subsequent development of the self-propagating high-temperature synthesis. In some cases (systems of the Ti–C, Zr–B, and Nb–C type) explosive mechanosynthesis has been noted. This was detected thermographically from the abrupt increase in temperature.[92]

Fig. 1 illustrates the dependence of the nitrogen content in Group IV–VI transition metal nitrides on the duration of mechanosynthesis.[93] The relative disposition of the saturation curves, corresponding to the known differences between the exothermicities of the formation reactions of the nitrides of the test metals, is a characterisic feature. In experiments described by Atsumi et al.,[93] a vibromill of the YAMP-2SND type with a working volume of 1300 cm^3 and a ball charge of 90 : 1 was used; nitrogen was supplied continuously to the reaction space from a 34 litre reservoir. When a mill of the SPEX 8000 type (working volume 90 cm^3, ball charge 13 : 1) was employed, the duration of grinding was reduced severalfold (for example, it was approximately 30 h for TiN with a nearly stoichiometric composition.[35] Electron microscope and X-ray diffraction studies have shown that the particle size of such powders amounts to several nanometers.

Investigators working in the field of mechanosynthesis suggest that this method of preparation of ultradisperse powders can be used on a fairly large scale and is one of the promising procedures for the preparation of nanocrystalline materials.[31] Its advantage consists also in the possibility of obtaining alloyed and composite powders and in the use of nonconditioned raw material. However, the purity and technological properties of the powders obtained in this way have so far been inadequately investigated.

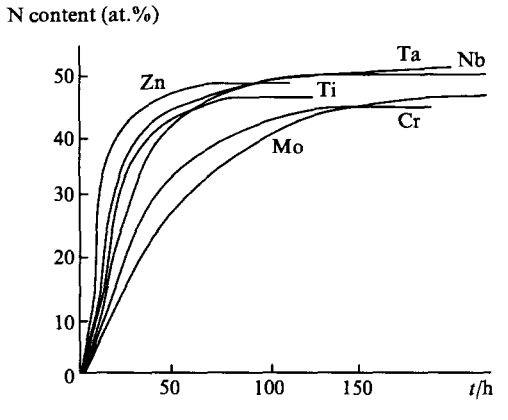

Figure 1. The influence of the duration of grinding on the nitrogen content in the nitrides.[93]

Detonation treatment (synthesis in shock waves and fragmentation) has long been known,[37-41] but, so far as we are aware, there have been few studies of such treatment in relation to nanocrystalline materials. The preparation of ultradisperse powders by the electrical explosion of wires belongs to the class of high-energy disruption methods, but this procedure has not so far been applied to brittle refractory compounds.

c. Synthesis

The chemical methods of the preparation of ultradisperse powders are more universal than the physical methods. Plasmo-chemical synthesis is one of the most popular. Extensive studies on these lines have been carried out in Russia,[10,42] Latvia,[43,44] Ukraine,[45,46] Japan,[18] and other countries.[15,94] The synthesis in a low temperature plasma is carried out at high temperatures, up to $(6-8) \times 10^3$ K, which ensures a high level of supersaturation and high rates of reaction and condensation processes. Examples of the modelling of the thermodynamic equilibrium, the vaporisation and condensation processes, as well as the coagulation of particles in the plasmochemical synthesis of ultradisperse powders of refractory compounds have been described in detail in the literature (see, for example, Refs. 10, 42–46, 95, and 96) and we shall not dwell on them here.

There is, in principle, the possibility of plasmochemical synthesis of virtually all ultradisperse refractory compound powders. Table 1 presents only a proportion of them. In addition, one may point to tungsten, tantalum, niobium, and boron carbide powders.[15,97,98] In order to obtain ultradisperse powders of refractory compounds, both arc plasmatrons[43-47,49,51-53,98] and high-frequency (including UHF) plasma generators[10,42,48] are employed; hybrid apparatus has also been described.[50] Arc plasmatrons are more productive and more readily available, but high- and ultrahigh-frequency devices ensure a higher purity of the products synthesised. Thus an ultradisperse β-SiC powder with a particle size of 5–20 nm and a high purity as regards cationic impurities (99.999%) has been obtained from silane and ethylene in an argon high-frequency plasma.[48] The oxygen content in these powders was ~1%.

It is also significant that plasmochemical technology ensures the preparation of multicomponent ultradisperse refractory compound powders: Si_3N_4+SiC, Ti(N, C), Nb(N, C), $TiN+TiB_2$, Si_3N_4+TiN (MgO, Al_2O_3, Y_2O_3), etc.[10,11,50,53] The manufacture of such powders on a semi-industrial scale has been introduced in a number of countries.

Electric spark dispersion, which combines the discharge-induced metal and alloy fragmentation process in reactive media with the synthesis of carbides and oxides (for example, TiC, SiC, WC, Al_2O_3), is closely related both to plasmochemical synthesis and to high-energy fragmentation.[99,100]

An effective procedure for the stimulation of the gas-phase synthesis involves the use of laser radiation. The optical heating source initiates and maintains the chemical reaction, promoting thereby the uniform 'self-heating' of the molecule, which ensures controlled homogeneous nucleation and rules out the possibility of contamination and of the influence of surfaces. Different versions of the thermochemical effect of laser radiation and the kinetics of these processses have been analysed.[101,102] Detailed studies of the characteristics of the laser synthesis of ultradisperse Si_3N_4, SiC, and TiB_2 powders have been carried out.[54,57] Study of the influence of the radiation intensity, pressure, and flow rate of the gas and its dilution on the dispersity of Si_3N_4 powders, obtained by the reaction

$$3\,SiH_4 + 4\,NH_3 \longrightarrow Si_3N_4\downarrow + 12\,H_2, \qquad (1)$$

showed that an increase in radiation intensity makes the greatest contribution to the decrease in the particle size and to the content of free silicon:

CO_2 laser radiation intensity/W cm^{-2}	760	2×10^4	1×10^5
d/nm	17.6	11.4	9.8
Free silicon (mass %)	35	2	traces

The influence of the intensity is attributed to the increase in the reaction temperature (from ~870 °C to > 1020 °C) and to the higher degree of saturation due to the increase in heating [rate] (from 10^6 to 10^8 K s^{-1}), which promotes an increase in the rate of nucleation, a high degree of completion of reaction (1), and a decrease in grain size. In order to improve the process efficiency, two laser sources, arranged opposite one another in such a way that the radiation axes coincide minimising losses thereby, are used; the stream of gas mixture is usually introduced at right angles to the beam. However, so far as we are aware, the laser synthesis of ultradisperse refractory compound powders has not so far gone beyond the limits of laboratory research or the preparation of small experimental batches.

In the concept 'thermal synthesis', we included various processes such as carbothermal reduction of oxides,[59-61,103] carbothermal and borothermal reduction combined with magnesiothermal reduction of oxides,[62,63] including reduction under SHS conditions,[62] direct solid-phase synthesis,[65] thermolysis of zirconium chloride under a NO_2 atmosphere,[67] etc. Whereas in some of the studies [59-61,65,103] comparatively low-temperature conditions were employed and the starting material was highly disperse, which in fact ensured the formation of ultradisperse powders, in others [62,63] the magnesium oxide formed played the role of a coalescence preventing agent. The synthesis of ultradisperse TiN powders in accordance with the scheme

$$\mathrm{Ti} \xrightarrow[400\ ^\circ\mathrm{C}]{\mathrm{NH_4Cl}} \mathrm{TiH_{1.924}} \xrightarrow[>500\ ^\circ\mathrm{C}]{\mathrm{NH_4Cl,\ NH_3}\ (p = 1\ \mathrm{MPa})} \mathrm{TiN}, \qquad (2)$$

has been described.[66]

It has been suggested that ultradisperse TiN and ZrN powders ($d \approx 10$ nm) are formed as a result of the dispersion of the initial metal powders (their particle size is much greater than 150 nm) and their hydrides at a low nitrogenation temperature under pressure; ammonium chloride plays the role of the hydrogen source and activator of the transfer process through the gas phase and to some extent prevents recrystallisation.

The development of a technology for the preparation of nanophase solid-alloy WC + Co compositions using as precursors triethylenediaminecobalt tungstate and tungstic acid or ammonium metatungstate and cobalt chloride $\{Co(en)_3WO_4 + H_2WO_4$ or $[(NH_4)_6(H_2W_{12}O_{40}) \cdot 4H_2O] + CoCl_2 \cdot nH_2O$ respectively$\}$ has been reported.[64] These carefully prepared solutions are spray-dried and subjected to low-temperature reduction and carbidisation in a fluidised bed in special reactors, which ensures, on the one hand, a high dispersity, and, on the other, a strict constancy of composition and hence satisfactory physicomechanical properties.

It has been suggested that boron-containing polymers of the type of polyborazole $[B_3N_3H_4]_x$ be used as additives to a titanium powder in order to synthesise nanophase TiN + TiB_2 compositions.[68] Finely disperse Group IV and V transition metal diborides are also synthesised from the oxides with the aid of boron- and carbon-containing precursors of the type decaborane-dicyanopentane, $[-B_{10}H_{12}NC-(CH_2)_5-CN-]_n$.[104]

The familiar sol-gel technology and different versions of the coprecipitation procedure play an appreciable role in the preparation of ultradisperse oxide powders; the synthesis and thermolysis are closely intertwined in this technology.[105,106] The preparation of monodisperse β-SiC powders with spherical particles by the hydrolysis of a mixture of triethoxyphenylsilane and tetraethyl orthosilicate $[C_6H_5Si(OC_2H_5)_3 + Si(OC_2H_5)_4]$ followed by heat treatment under argon at 1500 °C may serve as an example of the synthesis of oxygen-free compounds.[107] Fig. 2 presents the structure of such ~0.6 μm spherical particles. Each particle consists of primary ~40 nm β-SiC nanoparticles. Such agglomeration of particles is undoubtedly useful for the improvement of the technological characteristics, but the properties of the nanocrystalline materials obtained from the conglomerates have to be investigated.

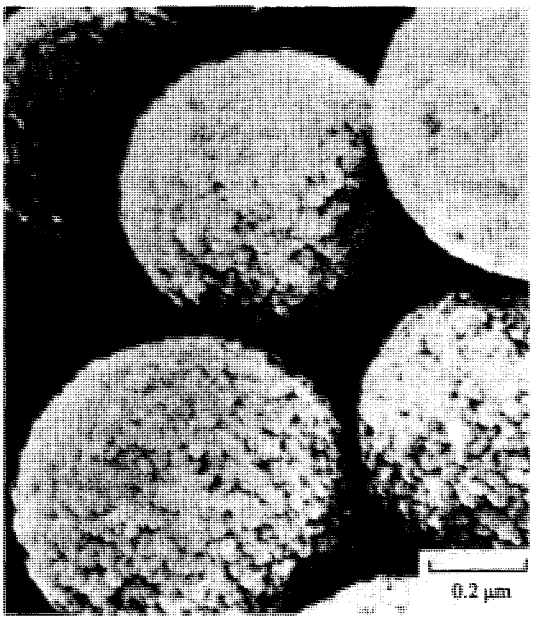

Figure 2. The microstructure of monodisperse β-SiC powders with spherical particles obtained in the sol-gel process [107]

Methods for the hydrothermal synthesis of ultradisperse oxide powders are less common, although some examples of the preparation of such ZrO_2 and Al_2O_3 powders may be found in the literature, for example in Refs. 74, 108, and 109.

An interesting method for the comparatively low-temperature gas-phase synthesis of titanium borides has been described.[73] Vaporising liquid sodium mixed with argon as the carrier gas reduces gaseous titanium boron chloride; the exothermic nature of the reactions ensures the maintenance of combustion conditions and the formation of ultradisperse powders.

The electrochemical synthesis of ultradisperse tungsten carbide and tungsten and molybdenum boride powders in melts and of zirconium oxide powder in aqueous solution has been investigated.[69-71] There is a communication [110] concerning the preparation of ultradisperse AlN powders ($d \sim 25$ nm) by the anodic dissolution of aluminium in a NH_4Br-NH_3 solution at −70 °C without subsequent annealing of the electrolysis products at 1100 °C. The electrochemical method has also been used to synthesise the polymeric precursor $[Al(NH_2)_3NH]_n$, which was subsequently subjected to annealing in ammonia at 600 °C with formation of an ultradisperse AlN powder (particle size ~8 nm).[111]

The liquid-phase synthesis of certain carbides and borides is likewise carried out under low-temperature conditions. Thus an ultradisperse TiB_2 powder may be synthesised by the following reactions:[15,73]

$$\mathrm{TiCl_4(l) + 2\,BCl_3(l) + 10\,Na(s)} \xrightarrow[100-160\ ^\circ\mathrm{C}]{\text{heptane}} \mathrm{TiB_2(s) + 10\,NaCl(s)}, \qquad (3)$$

$$TiCl_4(l) + 4\,NaBH_4(l) \longrightarrow \quad (4)$$
$$\longrightarrow Ti(BH_4)_3 \cdot n\,Solv + 4\,NaCl + \tfrac{1}{2}B_2H_6 + \tfrac{1}{2}H_2,$$

$$Ti(BH_4)_3 \cdot n\,Solv \xrightarrow[\sim 215\ ^\circ C]{} \quad (5)$$
$$\longrightarrow TiB_2(s) + \tfrac{1}{2}B_2H_6 + \tfrac{1}{2}H_2 + n\,Solv.$$

l = liquid; s = solid.

The powder thus obtained is amorphous to X-rays but after annealing at 900–1000 °C, which is also necessary to distill away sodium chloride, it crystallises. The size of the particles obtained by reaction (3) is ~50 nm,[15] while reactions (4) and (5) afford also larger particles of different morphology.[73] In the last investigation, triglyme was used as the solvent.

d. Thermal decomposition

Many ultradisperse refractory compound powders are prepared by the thermal decomposition (thermolysis) of solid, liquid, and gaseous precursors. We differentiated arbitrarily two varieties, although it is evident that the gas phase plays a role in virtually all cases. It is important to emphasise that, together with traditional precursors of oxide powders such as nitrates, oxalates, sulfates, hydroxides, and other compounds, recently the expansion of research into the refractory compounds of silicon, boron, titanium, and aluminium entailed appreciable use of organometallic polymers of these elements. A new term — preceramic polymers — has come to be widely used. Compounds of this type, used in synthetic procedures, were mentioned above.

Some of these polymers, used for the pyrolysis, are presented in Table 2. For example, polycarbosilane has an average molecular mass of 1200–2000 with a molecular mass distribution of 300–10 000; its softening temperature is in the range 130–180 °C, while fusion begins at 250–330 °C.[115] The pyrolysis temperature is usually ~1300 °C. As shown for ultradisperse Si–C powders, plasma heating (for example, with the aid of a nitrogen arc plasmotron) is preferable to the usual thermal heating.[115] The application of an industrial CO_2 laser for the pyrolysis of liquid silazane $[CH_3SiHNH]_n$, supplied to the reaction zone via a special ultrasonic nozzle in the form of an aerosol, has also been described. The pyrolysis results in the formation of an ultradisperse Si_3N_4 + SiC powder.[81]

Table 2. Organometallic polymers and monomers used as precursors in the preparation of refractory compounds.[112–114]

Precursor		Product
name	formula	
Polycarbosilanes	$\{Si(CH_3)(C_6H_5)-Si(CH_3)_2\}_n$,	SiC
	$\{SiH(CH_3)-CH_2\}_n$	SiC
Polycarbosiloxane	$\{Si(R_2)-O\}_n$, (R = H, alkyl, siloxyl)	SiC
Polysilazanes	$\{Si(R_2)-N(R)\}_n$,	Si_3N_4;
	$\{Si(R_2)-Si(R_2)-N(R)\}_n$, (R = H, alkyl)	Si_3N_4 + SiC
Aluminium amides and polyimides	$[AlR_2(NR_2)]_2$, (R = H, alkyl), $\{Al-NR\}_n$, (R = alkyl)	AlN
Polyborazole	$[B_3N_3H_4]_n$	BN
Polyvinylborazole	$\{C_2H_3(B_3N_3H_5)\}_n$,	BN
Polyvinylpentaborane	$\{C_2H_3(B_5H_8)\}_n$,	B_4C
Poly(titanium imide)	$\{Ti(NR)_2\}_n$, (R = alkyl)	TiN
Titanium tetrakis-(dimethylamide)	$[(CH_3)_2N]_4Ti$	Ti(C,N,O)

Certain features of the reactions occurring in the pyrolysis of preceramic polymers have been studied.[114,116] One should bear in mind that, after the laser or plasma treatment, the products of pyrolysis of preceramic polymers must be subjected to additional annealing for the final stabilisation of the structure and composition. The temperature of such treatment of the SiC, Si_3N_4, and SiC + Si_3N_4 powders is usually 1100–1200 °C, but it sometimes reaches as much as 1400–1600 °C.[81,114,115]

Heat treatment (calcining) invariably forms part of the technological cycles in the technologies of the sol-gel and coprecipitation processes mentioned above. Certain schemes for processes combining hydrolysis, synthesis, and decomposition are presented below.[74]

$$ZrOCl_2 + 2\,H_2O \longrightarrow \underline{ZrO(OH)_2} + 2\,HCl \quad (6)$$
$$\xrightarrow{\text{heat treatment}} ZrO_2$$

$$Zr(C_3H_7O)_4 + Y(C_3H_7O)_3 + 7\,H_2O \longrightarrow \quad (7)$$
$$\longrightarrow \underline{Zr(OH)_4 + Y(OH)_3} + 7\,C_3H_7OH$$
$$\xrightarrow{\text{heat treatment}} (Zr, Y)O_x$$

$$Zr(C_2H_5O)_4 + C_2H_5OH \quad (8)$$
$$\downarrow +\,H_2O$$
$$Zr(OH)_x(C_2H_5O)_{4-x}$$
$$\downarrow +\,H_2O$$
$$\underline{Zr(OH)_4}$$
$$\xrightarrow{\text{heat treatment}} ZrO_2$$

The first two schemes [reactions (6) and (7)] refer to the technologies for hydrolytic coprecipitation, while the last refers to the sol-gel process, where zirconium alkoxide in alcoholic solution is subjected to slow hydrolysis under controlled conditions. The conditions in the hydrolysis, coprecipitation, and heat treatment determine the composition, structure, morphology, and particle size of the ultradisperse powders. Preparation with the aid of oxalate precipitation of the monoclinic and tetragonal forms of the particles of ultradisperse ZrO_2 powders, including Y_2O_3-modified powders, has been described[117].

Fig. 3 presents a thermogravimetric curve for the heat treatment of yttrium hydroxide chloride prepared by sol-gel technology from yttrium trichloride.[77] The temperature of the final heat treatment, attained after 2 h, is 950 °C. A powder with a specific surface at ~20 $m^2\,g^{-1}$ is formed at this temperature.

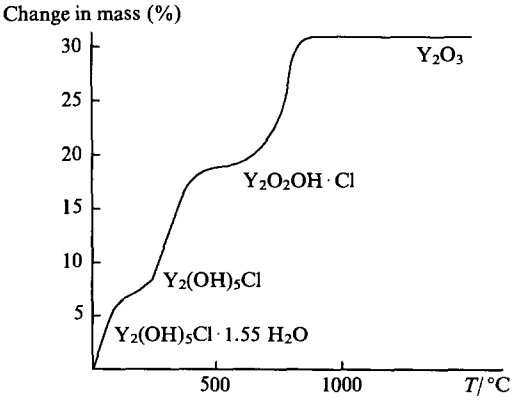

Figure 3. Variation of mass during the heating of an yttrium hydroxide chloride powder.[77]

In recent years, interest has been shown in ultradisperse transition metal boride powders. In this connection, we shall consider the possibility of obtaining them by the thermolysis of highly volatile hydroborates. The latter can dissociate in the range 300–400 °C, which is much lower than the usual temperatures for the preparation of borides. The thermolysis of zirconium tetrakis(tetrahydroborate) $Zr(BH_4)_4$ by a pulse type CO_2 laser has been described;[82] the preparation of powders having the overall composition $ZrB_{3.3-3.7}$, i.e. apparently containing an appreciable amount of free boron, with a specific surface of 40–125 $m^2\ g^{-1}$ has been reported. The thermal decomposition of $Zr(BH_4)_4$ at 300 °C results in the formation of an amorphous $ZrB_{2.76}$ powder, while at 350 °C the product is $ZrB_{3.74}$.[83] Experiments also showed that the excess content of free boron in the borides can be accounted for by the decomposition of the diborane formed.

$$Zr(BH_4)_4 \longrightarrow ZrB_2 + B_2H_6 + 5\,H_2\,. \qquad (9)$$

Indeed analysis of the gas phase showed that the ratio $[H_2]/[B_2H_6]$ is 9 and 12 at 300 and 400 °C respectively. This is appreciably higher than the theoretical value of 5 corresponding to reaction (9). During the annealing of the amorphous powders formed, crystallisation begins at 350 °C and terminates at 1000 °C. Work with transition metal tetrahydroborates requires much caution because they are explosive on contact with air and moisture.

2. Properties

a. Particle size. Morphology and structure

Particle size is one of the most important characteristics of an ultradisperse powder. In order to determine the size and shape of the particles, transmission and scanning electron microscopy (TEM and SEM respectively) is usually employed. Measurement of the specific surface (S) by the method involving the low-temperature adsorption of nitrogen and other gases with subsequent estimation of the so called average particle diameter or the equivalent diameter (d_s) by the familiar formula

$$d_s = \frac{6}{\gamma_t S}, \qquad (10)$$

where γ_t is the theoretical density, is likewise extremely common. Table 3 presents the values of S for certain ultradisperse refractory compound powders as a function of d_s and γ_t. Evidently the range of specific surfaces S extends from several to several hundreds of square metres per gram.

Some information about the particle size (more correctly about the regions corresponding to coherent scattering — blocks) can also be obtained by analysing the broadening of the reflections on the X-ray and neutron diffraction patterns for ultradisperse powders taking into account the possible contribution of lattice deformation. Agreement of the values of d obtained by measuring S and from the X-ray diffraction data for the TiN ultradisperse powder has been observed only for $S > 30$ $m^2\ g^{-1}$ ($d < 30$ nm).[118] In the study of ultradisperse ZrN powder, a satisfactory agreement of the results of the determination of d by different methods (TEM, low-temperature adsorption of nitrogen, and neutron diffraction) was noted for particles with $d \approx 20$ nm.[119] For the ZrO_2 ultradisperse powder with a particle size of 8–20 nm, a satisfactory agreement between the values of d measured by different methods has likewise been observed.[120] In the vast majority of cases, it is necessary to resort to several methods of measurement in order to increase the reliability of the information about the particle size of ultradisperse powders because factors such as particle shape, the capacity of the particles for agglomeration, and the presence of lattice distortions cannot be always unambiguously taken into account.

The morphology of ultradisperse powders has been studied in many investigations (see, for example Refs 10, 18, 21, and 121–125). The results of the investigation of Al_2O_3 and SiC powders by high-resolution TEM methods have been reported in a review.[18] Polyhedral (in many cases cubic) forms of particles of carbides and nitrides obtained by plasmochemical synthesis have been frequently noted. Fig. 4 presents electron photomicrographs of TiN particles illustrating the characteristic crystal form of the plasmochemical titanium nitride. A cubic crystal form has also been noted for γ-Al_2O_3 and $TiC_{0.95}$ ultradisperse powders; titanium diboride has a hexagonal form.[123] The nitride powders obtained by the reactive atomisation method has a less distinct crystal habit.[21] NbN particles synthesised by the plasmochemical method had a spherical form.[122] The change in the ammonia concentration in the plasma promoted a transformation of the AlN particles from the spherical to the polygonal form.[45] The ZrB_n particles formed in the thermolysis of zirconium tetrakis-(tetrahydroborate) also have a nearly spherical form.[83] Various morphologies are characteristic of ultradisperse powders synthesised by the electrochemical method.[127] The majority of the particles formed on exposure to high energy influences have an irregular form.

Since the conditions in the preparation of ultradisperse powders are in most cases far from equilibrium, the particle form cannot always be predicted on the basis of any kind of *a priori* postulates. The latter can be based on the crystallographic analysis of Wulf polyhedra taking into account the contribution of the surface energy (see, for example, Refs 5, 85, and 128). Since close-packed structures are known to possess the minimum surface energy, crystal shapes characteristic of face-centred cubic and hexagonal close-packed lattices therefore frequently occur in small particles. Various complicating factors associated with the crystal form of the clusters have been discussed in a review.[128] Processes involving the possible interaction with impurities (for example, oxidation), capable of distorting particular estimates, are also important in relation to ultradisperse powders.

It has been noted in a monograph[85] that the nature of the size distribution of the particles may indicate the condensation mechanism. A logarithmic normal distribution may be a consequence of the coagulation crystallisation of the vapour–liquid–crystal type; on deviation from this relation, the vapour–crystal mechanism (a normal type of distribution) is more probable. Experiments have shown that[124] in the case of ultradisperse tungsten powders, the first version applies, while in the case of titanium there is an appreciable deviation from the logarithmic normal distribution. The coagulation mechanism of the growth of ultradisperse tungsten powders has been confirmed by the

Table 3. The specific surfaces of certain ultradisperse powders of refractory compounds ($m^2\ g^{-1}$).

d_s/nm	B_4C, BN	Si_3N_4, SiC, MgO, AlN	Al_2O_3, TiB_2, TiC	TiN, Y_2O_3	NbN	WC
	(2.3–2.5)	(3.3–3.5)	(4–4.9)	(5.0–5.4)	(8.3)	(15.8)
100	24–26	18–19	12–25	11–12	7	4
50	48–52	36–38	24–25	22–24	14	8

Note. The theoretical density (g cm^{-3}) is indicated in brackets.

spherical shape of the particles; the noncoagulation crystallisation of TiN is indicated in its turn by the shape of these particles (Fig. 4). However, the logarithmic normal distribution is sometimes accompanied also by a crystalline form of the particles (TiC, TaC, and NbC ultradisperse powders).[121]

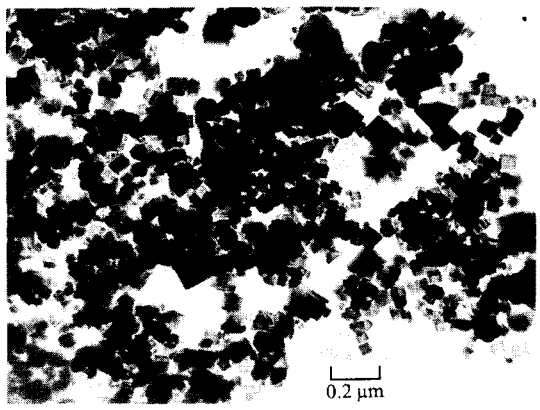

Figure 4. Electron photomicrograph of a plasmochemical ultradisperse TiN powder.[126]

Much attention has been devoted in the literature to the study of the structures of ultradisperse powders by X-ray, neutron, and electron diffraction methods. A detailed description of these results is outside the framework of the present review and we shall therefore quote only the most important of them.

1. Many compounds (Si_3N_4, Al_2O_3, SiC, TiB_2, etc.) may exist in the amorphous state.[19,49,56,76,83]

2. In certain cases (Al_2O_3, ZrO_2), anomalous structures are observed.[85,120]

3.Particle size influences the lattice period and microdeformation (distortions) of the lattice and also the mean square displacement of the atoms.[118,119,125,129,130]

4. The absence of dislocations has been noted in small particles.[118]

The influence of the excess surface free energy on the thermodynamic conditions in phase equilibria has been analysed in a general form in a monograph[85] and in a review.[5] It is evident from general considerations that the phase transition temperatures and the limits of the existence regions of the phases may be different in ultradisperse powders from those in large particles. It has been shown for aluminium oxide that mainly the γ-phase is present in ~30 nm particles, whereas coarser ultradisperse powders ($d \approx 110$ nm) contain also other modifications (ε, β, and θ).[85] Certain structural-morphological features of AlN, Si_3N_4, and Al_2O_3 ultradisperse powders have been analysed in a review.[131]

Table 4 presents data demonstrating the influence of the particle size on the lattice period and the mean square displacements of the atoms in TiN particles.[130] With decrease in d_s, the lattice period diminishes appreciably, while the evolution of the mean square displacements can be less clearly traced. A decrease in the lattice period has been observed also for many small metallic particles[85] and for ZrN particles.[119] This has been attributed to the manifestation of capillary compression. The capillary forces in ultradisperse powders may be appreciable: thus the capillary pressure for ~10 nm particles with a surface tension of ~2 N m^{-1} may be ~1 GPa and this can induce in its turn a deformation of ~10^{-3} nm, which is comparable with the data presented in Table 4.

Two remarks must be made here. Firstly, the capillary compression effect is not always accompanied by a decrease in the lattice constant.[128] Secondly, it has been noted in a review[125] that many results of the investigation of the phase composition and the lattice period of particles of ultradisperse refractory compound powders are to a large extent vitiated by the lack of a detailed specification of the oxygen content in the substances and their nonuniform composition in the region of homogeneity. An attempt has been made to take into account the latter factor to some extent,[130] but the oxygen content in the substances listed in Table 4 was not indicated. Furthermore, both the deviation from stoichiometry and the presence of oxygen affect significantly the lattice period in transition metal carbides and nitrides.[9] Many results of diffraction studies on these ultradisperse powders are distorted by various factors which have not been taken into account. The question of the influence of the refractory compound particle size on the lattice period requires additional study.

Table 4. Certain characteristics of ultradisperse TiN powders.[130]

Composition	$S/m^2\ g^{-1}$	d_s/nm	Lattice period, 10^5 a/nm	Overall square atomic displacements 10^4 a/nm
$TiN_{0.96\pm0.02}$	39	27	42402 ± 8	98 ± 7
$TiN_{1\pm0.05}$	50.3	22	42381 ± 8	100 ± 20
$TiN_{0.98\pm0.03}$	53.2	21	42384 ± 9	80 ± 20
$TiN_{0.87\pm0.08}$	76.4	14	42371 ± 10	100 ± 10
$TiN_{0.98\pm0.04}$	83.5	13	42367 ± 11	101 ± 5
$TiN_{0.96\pm0.04}$	95.4	11	42354 ± 14	131 ± 2

In conclusion, we emphasise that, although according to TEM and diffraction data the absence of dislocations and microdistortions has been noted in 20–40 nm TiN particles,[118] the question of the defectiveness of ultradisperse refractory compound powder particles requires a more wide-ranging study.

b. The content of impurities and gases. Chemical properties

In terms of the level of impurities and gas content, ultradisperse powders are in most cases inferior to the usual powders let alone single crystals and other highly pure substances. This is associated with, on the one hand, the characteristics of their preparation and, on the other, with their extremely high surface area and the conditions in their storage. Nevertheless, as mentioned previously, it has been possible to synthesise β-SiC which was extremely pure as regards cationic impurities.[48] However, only the use of a special condensation technique[19,20,86,87] creates conditions for the preparation of refractory compound powders with a high purity, including purity as regards oxygen admixtures. However, this method, like, incidentally, others, is not universal.

We shall analyse data on the content of impurities in ultradisperse powders with different dispersities in relation to silicon nitride powders, which have been studied in detail.[132] Analysis of the data in Table 5 permits the following conclusions.

1. There is no correlation whatsoever between the overall chemical composition and the particle size of the powders in the experimental range of values of d_s.

2. The surface of the particles is greatly enriched in oxygen and especially carbon, which is indicated by X-ray photoelectron spectroscopic (XPS) data for a layer 2.3–4.6 nm thick. With the exception of the powder in the R2 batch, the difference between the nitrogen contents on the surface and in the bulk of the particles is not very great—the ratio [N]/[Si] = 0.665 for the stoichiometric Si_3N_4. We may note that the enrichment in carbon of the plasmochemical Si_3N_4 ultradisperse powder (S = 42 $m^2\ g^{-1}$) has been noted also in another study.[133] It is attributed to the formation of carbonate and carboxy-compounds.

The independence of the composition of the particles on their size (Table 5) can be due to the different methods of preparation and storage of the powders. The enrichment of the surface layers in oxygen and carbon is likewise weakly correlated with the overall content of these impurities. Whereas the increased content of oxygen on the surface can be naturally attributed to oxidation, in order to elucidate the causes of the enrichment of the surface in

Table 5. Chemical composition of Si_3N_4 powders of different origin in the bulk phase (I) and on the surface (II) of the particles.[132]

Type of powder	Method of preparation	Composition (mass %)				d_s/nm	[O]/[Si]		[C]/[Si]		[N]/[Si]

carbon it is useful to turn to the results of the study of gas evolution during the vacuum heat treatment of ultradisperse powders.[4,126,134]

Fig. 5 illustrates the influence of the heat treatment temperature on the rate of gas evolution from TiN powders with the usual grain size ($d_s \approx 8$ μm) and from the ultradisperse powders ($d_s \approx 0.07$ μm).[126] There are two gas evolution peaks ($T_1 = 250-300$ and $600-700$ °C), carbon monoxide predominating appreciably in the evolving gases. The overall content of the gases correlates with the particle size: the values of S for the usual ultradisperse powder were 0.15 and 16 $m^2\ g^{-1}$, while the total amounts of gases were 1 and 7 $cm^3\ g^{-1}$ respectively under normal conditions. X-Ray photoelectron and Auger spectroscopic studies on these powders showed that the surface layers of the particles contain oxide nitride phases and carbon-containing components, the amount of the latter being appreciably reduced after vacuum annealing. The enrichment of the surface of nitride powders (Si_3N_4 [132,133] and TiN [126]) in carbon-containing components is associated with the selective adsorption of CO_2 from the ambient medium, but the mechanism of the subsequent formation of CO under these conditions requires additional detailed study. The predominance of carbon monoxide in the gases evolved during vacuum annealing has been noted also in the study of Si_3N_4 powders with different dispersities.[135] Naturally, mainly components with mass numbers of 28 (CO) and 44 (CO_2) are evolved into the gas phase from ultradisperse powders of boron, silicon, and titanium carbides.[134] The possible chemical reactions during the heat treatment of ultradisperse powders of β-sialon ($Si_{6-z}Al_zO_zN_{8-z}$) and, in particular, the formation of ammonia as a result of hydrolysis and its subsequent catalytic decomposition have been discussed.[136]

Thus the distribution of impurities in the particles of ultradisperse powders is usually nonuniform. Different fine effects, associated with the possibility of estimating the surface segregation of atoms in small two-component particles, have been analysed.[85,137] XPS and Auger spectroscopic methods have proved to be very useful experimentally in this connection. Ultradisperse powders of refractory compounds began to be investigated by XPS methods about twenty years ago. It is necessary to differentiate between the studies[138-141] devoted to these methods. In an early investigation,[139] attention had already been drawn to the different forms in which oxygen exists in an ultradisperse TiN powder (dissolution in the nitride, the formation of individual oxide nitride phases, and adsorption in the form of CO, CO_2, and H_2O on the surface of the particles) and an attempt was made to estimate their amounts. Niobium nitrides and carbide nitrides, silicon nitride and carbide, and other ultradisperse refractory compound powders were also investigated. It was discovered that the F, Cl, Fe, Al, Ca, and Na impurities are present on the surfaces of the SiC and Si_3N_4 powders.[142] The chlorine and sodium impurities may influence significantly the stability of the cubic and tetragonal phases during the annealing of the ultradisperse ZrO_2 powders.[143]

The chemical properties of ultradisperse powders (interaction with acids and alkalis, thermo-oxidative stability, etc.) have also been the subject of study in many investigations (see, for example, the relevant reviews[44,122,125]). Comparative study of the decomposition of an ultradisperse TiN powder ($S = 12.4\ m^2\ g^{-1}$) as well as coarser TiN powders, obtained by self-propagating high-temperature synthesis ($S = 0.1\ m^2\ g^{-1}$) in solutions in sulfuric and nitric acids, showed that the absence of an induction period is characteristic of substances with a larger surface area. Their entire surface is involved simultaneously in the reaction, which occurs in dilute acids and at lower temperatures than in the case of coarse-grained powders.[144] The specific rate of decomposition of the ultradisperse TiN powder in sulfuric acid in the concentration range 9.5–12.6 M and in the temperature range 130–150 °C is $(0.4-3.3) \times 10^{-6}$ mol $min^{-1}\ m^{-2}$. The kinetics of the decomposition of the powder in solutions in the $H_2SO_4-H_2O_2$ system have been investigated.[145]

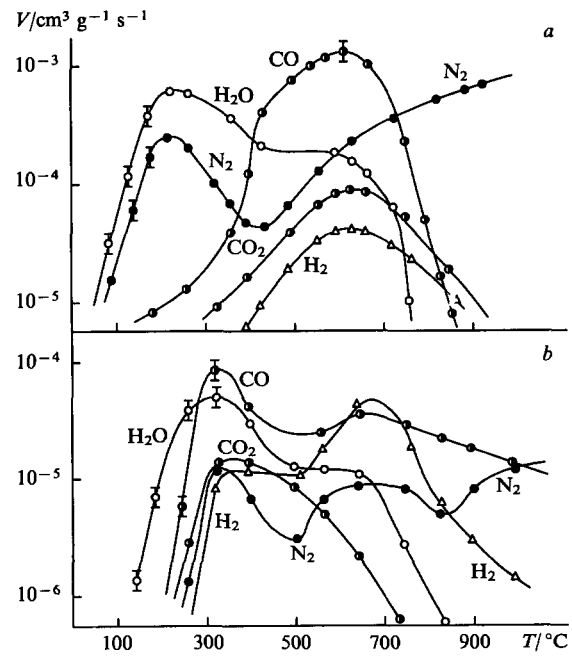

Figure 5. Temperature dependence of the rate of gas evolution from an ultradisperse (*a*) and an ordinary (*b*) TiN powder.[126]

For the temperature of the onset of oxidation of TiN powders, differing in S by five orders of magnitude, the following empirical equation has been proposed:

$$\frac{T}{T_m} = \left(\frac{S}{S_m}\right)^{-n}, \quad (11)$$

where the subscript m refers to the massive material (T_m = 1120 K; S_m = specific surface of ~1 mm particles); n = 0.064.[122]

Many investigators have noted that, when ultradisperse powders are stored in air, hydrolysis takes place. The acid–base properties of the surfaces of ultradisperse powders have been investigated in greatest detail for titanium and silicon nitrides.[146] The position of the zero-charge point in these substances corresponds to a highly acid medium, while the zero electrokinetic potential corresponds to an acid or weakly acid medium. This means that there are uncompensated positive centres. It has been suggested that these comprise coordinated ammonia molecules capable of combining with protons:

$$-NH_3 + H^+ \longrightarrow -NH_4^+. \quad (12)$$

Contact with water leads to the creation of a weakly alkaline medium and to the appearance of uncompensated negative groups.

The high sensitivity of ultradisperse powders to the ambient medium has given rise to an increased interest in methods for their storage; a hermetically sealed container filled with dry argon is usually employed in practice. Thermochemical methods for the treatment of ultradisperse powders with different reagents, which form a protectic shell on the surface of the particles and prevent both oxidation in air and hydration in water and can be removed on heating, have been analysed.[147] It has been suggested that solutions of organofluorine compounds (epilemmas) in Freon-113 be employed as reagents of this kind.

c. Physicochemical and physical properties

The fraction of surface atoms in particles of ultradisperse powders may reach several tens per cent and this exerts a significant influence on the lattice and electronic properties of the substance. The characteristic correlation size (or the characteristic length of the transfer process) for a particular phenomenon in solids may range from several tenths of a nanometer to several tens of nanometers.[148] Two factors which are largely responsible for the differences between the properties of small particles (d < 10 nm) and massive bodies have been noted. The characteristics of the spectral density of vibrations, anomalies in the heat capacity, and the specific features of electronic states and electrical, thermophysical, optical, and magnetic properties of small particles, mainly metallic particles, have been analysed.[5,85,128,148–150] Questions concerning the thermodynamics of small particles have been discussed in the same studies: the minimum size to which the concepts of 'phase' and 'surface energy' are applicable; the possible transformation in relation to small particles of the familiar Thompson formula for the vapour pressure as a function of the radius of curvature, fusion and other phase transitions in small particles, etc. (see also Refs 151–154). Without dwelling on these topics in detail, we shall only note that there exists little reliable experimental information on the dimensional effect for ultradisperse powders of refractory compounds.

The critical magnetic field (H_{C_2}) increases with decrease in the particle size of transition metal nitrides (NbN, VN, TiN, NbNC).[155,156] The increase in H_{C_2} was ~200% when d changed from ~75 to ~15 nm. Comparative study by XPS and the spectroscopy of characteristic energy losses of a well crystallised hexagonal BN and an ultradisperse BN powder showed that a lower atomic ratio [N]/[B] and a lower concentration of valence electrons per unit volume are characteristic of the latter.[140] A study of the IR spectra of an ultradisperse BN powder with different dispersities (d_s = 5–66 nm), which were regulated by annealing at 800–1800 °C, revealed an appreciable deformation of the basal planes of the lattice of the unannealed small particles, which was also confirmed by X-ray diffraction data.[157]

The band structure of ultradisperse powders of superconducting niobium carbide nitrides (NbC_xN_{1-x}, x = 0.06 to 0.09) was investigated by Auger spectroscopy.[141] It was shown that the effective energies of the hole interaction in the valence band for the metallic and nonmetallic positions are significantly different. Analysis of the IR and fluorescence emission spectra in the ultraviolet region for an ultradisperse powder of amorphous Si_3N_4 led to the conclusion that the width of the forbidden gap is greater for nanoparticles than for massive objects.[158]

III. Consolidated powdered nanocrystalline materials

1. Principal characteristic features of the consolidation of ultradisperse powders

Virtually all the consolidation methods known in powder technology—pressing and sintering, different versions of hot pressing, etc.[4]—are applicable also to ultradisperse powders. However, if one is dealing with the preparation of compact materials with a nanocrystalline structure, i.e. largely with retention of the grain size characteristic of ultradisperse powders, then the usual sintering and hot pressing temperatures are inapplicable because vigorous recrystallisation processes occur. In essence, in the vast majority of cases only high-energy consolidation methods, involving the use of static and dynamic high pressures, electric pulse influences, etc. are suitable for the maintenance of the above conditions.

Certain features of the pressing, sintering, and hot pressing of ultradisperse powders of refractory compounds, including such procedures at high pressures, were described in our earlier communication[13] and here we shall confine ourselves to stating the most important factors. Figs 6 and 7 illustrate the variation of the relative densities of ultradisperse powders of Si_3N_4 and TiN over a wide pressure range.[4,159] Data referring to coarser Si_3N_4 powders are also presented (the experiments were performed under different conditions). It is clearly seen from these results that the susceptibility to compaction on pressing diminishes significantly with decrease in dispersity and that it is impossible to attain or even approach the theoretical density at pressures up to 7–9 GPa. The low susceptibility to compaction of ultradisperse BN, SiC, and Si_3N_4 powders has also been noted in other investigations.[48,160,161]

The low susceptibility to compaction of such powders is associated with a high level of the interparticle friction characteristic of powders with a high surface area.[4] Hence it is understandable why it has not been possible to prepare compact

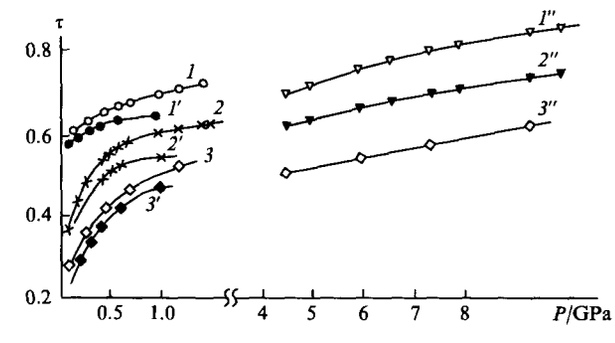

Figure 6. The influence of the pressing pressure on the relative densities (τ) of silicon nitride powders:[4] (*1*)–(*3*) pressing in a hydrostat; (*1'*)–(*3'*) pressing in the usual press-moulds; (*1''*)–(*3''*) pressing in high-pressure apparatus; (*1*), (*1'*), and (*1''*) $d_s \approx 1$ μm; (*2*), (*2'*), and (*2''*) $d_s \approx 0.05$ μm; (*3*), (*3'*), and (*3''*) $d_s \approx 0.017$ μm.

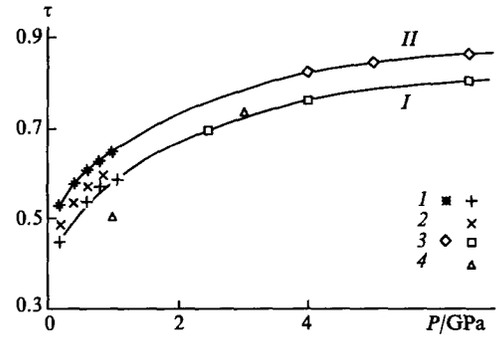

Figure 7. The influence of the pressing pressure on the relative density of an ultradisperse TiN powder:[159] (*I*) $d_s \approx 0.07$ μm; (*II*) $d_s \approx 0.08$ μm; (*1*) usual pressing, specimen diameter 10 mm, height 5 mm; (*2*) ditto, specimen dimensions 15 × 15 × 15 mm; (*3*) pressing at high pressure, specimen diameter 8 mm, height 5 mm; (*4*) magnetopulse pressing, specimen diameter 7 mm, height 15 mm.

specimens from ultradisperse powders obtained by the condensation method:[86,87] the porosity of even metallic pellets in such experiments has rarely been less than 10%. High pressures combined with heating to temperatures not inducing intense crystallisation can lead to appreciable compaction with retention of the nanocrystalline structure.

Unfortunately insufficient data have been accumulated hitherto concerning the preparation of such specimens. As an illustration of the possibilities of hot pressing, we shall quote the results of a study[162] for ultradisperse $ZrO_2-3\%\ Y_2O_3$ powders ($d_s = 40-60$ nm) (Table 6). The sintering and hot pressing temperatures for ultradisperse zirconium oxide powders are low as a consequence of the increased reactivity of these powders, but, despite the short duration of the process, it is impossible to achieve a sufficient compaction and to prevent the growth in grain size at a pressure of 1.6 GPa. By reducing the temperature and by increasing the duration of the sintering ($T = 1050$ °C, $t = 5$ h), it is possible to obtain partially stabilised zirconium dioxide with a relative density of ~99.9% and a grain size of ~85 nm at low heating rates (5 K min^{-1}).[163] Similar data have been obtained in another study.[164] The deagglomeration of ultradisperse powders is also important for active compaction during sintering.[165]

Table 6. Variation of the relative density (τ) and grain size (L) during the sintering and hot pressing of ultradisperse ZrO_2-3 mol % Y_2O_3 powders.

T/°C	Sintering		Hot pressing	
	τ	L/nm	τ	L/nm
1100	0.72	120	0.87	130
1200	0.83	150	0.93	170
1300	0.94	170	0.97	250

Note. In all cases, the pressure was 1.6 GPa and the duration of treatment at the temperatures indicated was 10 s.

Attention should be drawn to possible methods of preparation of nanocrystalline materials from refractory compounds such as dynamic recrystallisation at high pressures[166] and crystallisation from the amorphous state.[167] The temperature conditions, which again should not lead to vigorous growth in grain size, are fundamentally important in both cases. Studies on these lines are only just beginning.[168]

An interesting combination of the pyrolysis of a precursor—polysilazane (Table 2)—with pressing and sintering methods at comparatively low temperatures (1100–1600 °C) made it possible to obtain a Si_3N_4+SiC nanocrystalline composition (overall composition $Si_{1.73}N_{1.56}C_1$) with a relative density of 92%–93%.[169]

2. Properties

Hardness is one of the most thoroughly investigated characteristics of nanocrystalline materials based on refractory compounds. Table 7 shows that the main information about hardness refers to specimens prepared using high dynamic and static pressures. However, even under these conditions it is in many cases impossible to suppress recrystallisation and the grain size increases. An appreciable scatter of the results is characteristic of specimens obtained by explosive methods, which is manifested particularly clearly in the case of ultrahard materials (for comparison, the table includes data for diamond), although other methods also lead to some nonuniformity of the results.

The data[64] obtained for the WC + 10 mass % CO solid alloy, which has been thoroughly investigated, are of great interest. As a result of the application of the thoroughly developed technology for the preparation of ultradisperse powders and their low-temperature consolidation, it has been possible to attain hardness parameters exceeding the corresponding characteristics of standard solid alloys by a factor of 1.5–2.

The overall level of hardness is also affected by the residual porosity, which amounted to several per cent for the majority of the specimens presented in Table 7. According to data of Averback et al.[179] a decrease in τ from 0.94 to 0.89 (i.e. an increase in porosity by 5%) for nanocrystalline titanium oxide leads to a decrease in hardness by more than 30%.

However, even if this fact is taken into account, the hardness of Al_2O_3, SiC, MgO, TiN, ZrO_2, and Si_3N_4 specimens is nevertheless low and does not exceed greatly the hardness of the usual polycrystalline and single crystal refractory compounds or is actually approximately the same.[9] This finding appears strange from at least two points of view. Firstly, measurements have shown that the hardness of nanocrystalline metals and intermetallic compounds (Cu, Ni, Ag, Fe, Pb, TiAl, $NbAl_3$; see, for example, Refs 6–8, 12, and 180–185) can exceed the hardness of the usual polycrystalline materials by a factor of 3–6. Secondly, as will be seen from the consideration below of the refractory compound-based films, the hardness of these substances is appreciably greater than that of the usual massive refractory compounds.

The familiar Hall–Petch relation between hardness (critical splitting shear stress) and grain size:

$$H = H_0 + kL^{-1/2}, \qquad (13)$$

where k and H_0 are constants [L is average grain diameter (Ed. of Translation)], holds for the majority of the nano-crystalline metals and intermetallic compounds mentioned above. Admittedly inversion relations of type (13) (for example, for TiAl [182]) and nonmonotonic relations $H = f(L)$ (for example, for Cu [181] and $NbAl_3$ [183]) are observed fairly frequently. This can be explained by the influence of impurities, residual stresses, sliding along boundaries, etc. One cannot rule out the possibility that the low level of hardness of the materials presented in Table 7 is due to the limited amount of available information: none of the existing publications contain data obtained for a wide range of values of L. It may be that the results in Table 7 were found for an unfavourable range of values of L and that the determination of the purities of the test specimens left something to be desired.

The physicomechanical properties of two-phase nanocrystalline materials based on refractory compounds have been studied.[186–192]. Certain characteristics of percolation effects have been investigated in ultradisperse TiN + AlN, Si_3N_4 + SiC, and ZrO_2 + Ni compositions.[186–189] The critical point for the last system, corresponding to a sharp increase in electrical conductivity of the compositions, is in the range 25 vol.% – 30 vol % Ni,[186] while for the Si_3N_4 + SiC composition it is at the level predicted by percolation theory (~17 vol.% SiC).[187] Special interfaces with a reduced resistance to phonon scattering have been discovered in the TiN + AlN system.[189]

A nonmonotonic variation of the high-temperature and decomposition strengths in the SiC + Si_3N_4 system has been noted.[190] A higher temperature of the degradation of hardness and

Table 7. The hardness (H_v) of nanocrystalline refractory compounds.[13,170]

Compound	Method of consolidation	Characteristics of specimen		H_v/GPa	Ref.

of the modulus of elasticity as well as a greater strength compared with aluminium oxide without additives have been observed in the $Al_2O_3 + SiC$ nanocomposites.[191,192] Nanocrystalline ZrO_2–Al_2O_3 specimens are also distinguished by a high decomposition strength and ordinary strength.[193]

The present authors have shown[194] that the use of a plasmochemical ultradisperse Si_3N_4 powder in the $TiB_2 + Si_3N_4$ composition hot-pressed at high pressures is accompanied by a sharp increase in the rate of creep, which may be attributed to the manifestation of superplasticity (Fig. 8). The values of L for these specimens were ~0.5 μm for Si_3N_4 and ~2–4 μm for TiB_2 (the grain size in the usual Si_3N_4 powders was 2–4 μm).

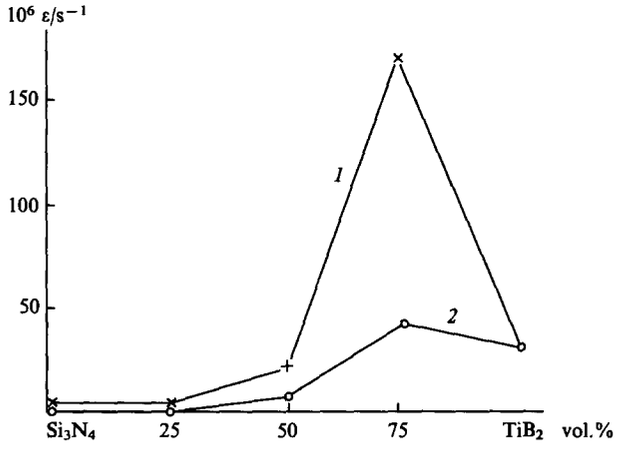

Figure 8. Variation of the rate of creep with the composition of the TiB_2–Si_3N_4 system (T = 1600 °C, tension 20 MPa, t = 30 min):[194] (*1*) Si_3N_4 ($L \approx 0.5$ μm); (*2*) Si_3N_4 ($L \approx 2-4$ μm). The TiB_2 grain size was ~2 μm in both cases.

The superplasticity in the deformation of nanocrystalline sialon at 1500–1600 °C (L = 100–200 nm) has been described.[195] High rates of creep at 1100 °C are also characteristic of zirconium dioxide (L = 100–140 nm), specimens of which (τ = 0.93–0.97) were obtained by the hot forging method.[196]

The optical properties of nanocrystalline silicon nitride obtained by pressing ultradisperse powders at high pressures (up to 5 GPa) and at the temperature of liquid nitrogen with subsequent low-temperature sintering (T = 1400 °C), have been described.[161]

The role of dimensional effects in the establishment of ferromagnetic, ferroelectric, and elastic characteristics on transition from multidomain to single-domain and nanodomain structures has been discussed in a review.[197]

Owing to the presence of an excess surface free energy, specific phase equilibria may be observed in multiphase systems containing ultradisperse particles. Several computational studies, in which the influence of dispersity on the equilibrium in the Zr + C,[198] TiC(TiN) + TiB_2,[12] and TiN + AlN [199] systems was estimated, have been carried out hitherto. Table 8 presents estimates of the influence of dispersity on the eutectic temperature in the TiC + TiB_2 and TiN + TiB_2 systems. These calculations were performed in the simplest regular solution approximations and their results may be regarded as estimates. Nevertheless, they indicate the necessity to take into account the displacement of phase equilibria on passing to multiphase nanocrystalline materials. The desirability of setting up the corresponding experimental studies is likewise quite evident.

Table 8. The influence of the particle size of one of the components in the TiC + TiB_2 and TiN + TiB_2 systems on the eutectic temperature (T_e = 2790 K in the $TiC_{0.9}$ + TiB_2 system, and T_e = 2870 K in the $TiN_{0.9}$ + TiB_2 system).[9,12]

Particle radius/nm	$-\Delta T_e$/K	
	TiC(TiN) + TiB_2	TiB_2 + TiC(TiN)
100	~45	~35
50	~90	~70
10	~450	~350
5	~900	~700

To conclude the description of the properties of consolidated powdered nanocrystalline materials, one should note that the available data are limited, which has a lot to do with the difficulties in the preparation of representative thoroughly authenticated nanocrystalline specimens. As noted in our earlier publications,[13,70] studies concerning titanium dioxide, carried out mainly by American and German investigators, contain somewhat more information (see, for example, Refs 6, 7, 86, 87, and 179). These workers used the condensation method in combination with the preparation of the specimens at high pressures. However, as a consequence of the porosity of the specimens, these data are not always sufficiently representative. Therefore progress in nanocrystalline materials science depends in many respects on the level of the technology for the preparation of test specimens.

IV. Nanocrystalline films

1. Characteristics of the preparation

Available information about films and coatings based on refractory compounds is extremely extensive (see, for example, Refs 200–205) and we shall therefore confine ourselves merely to a description of information on multilayer films as well as films with a specified grain size.

The principal methods for the preparation of refractory compound-based films are presented in Table 9. It is easy to see the similarity between Tables 1 and 9: with a few exceptions, the methods of preparation of ultradisperse powders and films are virtually identical and in many instances differ only in the conditions determining the formation and growth of nuclei in the bulk phase or on the surface. The arbitrary nature of the subdivision of preparative methods into chemical and physical, noted above, applies to an even greater extent to the preparation of films. The existing terms Chemical Vapour Deposition (CVD) and Physical Vapour Deposition (PVD) are mainly of historical significance. In many instances, chemical refractory compound formation reactions are decisive factors in the formation of the structure and properties of films on thermal vaporisation, in atomisation processes, and in the plasma methods. Methods for the modification of the surface such as ion implantation should be added to this list. Plasma (the so called plasma-accelerated or plasma-accompanied processes) and lasers are being used increasingly to activate, for example, processes involving the reduction of halides and the pyrolysis of silazanes and hydroborates.[202,206]

Table 9. The principal methods of preparation of films based on refractory compounds[a].

Method	Compound
Physical	
Thermal vaporisation	
electron beam	Oxides, borides, nitrides
laser	Oxides, nitrides
Ionic atomisation	
ionic-plasma	Nitrides, carbides
magnetron	Nitrides, carbides, borides, oxides
Chemical	
Synthesis	
deposition from gas phase	Nitrides, carbides, borides oxides
Sol–gel technology	Oxides
Thermal decomposition	
condensed precursors	Carbides, oxides, nitrides
gaseous precursors	Borides, oxides

[a] See also Table 1, monographs,[202,204] and a review[203].

The thermal vaporisation methods, used to obtain nanocrystalline films based on refractory compounds, are less universal compared with the plasma and magnetron methods, although they have come to be used to some extent in the formation of oxide films. For example, the preparation of ZrO_2–10 mol.% Y_2O_3 films by the laser pulse vaporisation of metals in a beam of oxygen ions has been described.[207] In the range of deposition temperatures 100–400 °C, the size of crystallites was 10–30 nm.

In the course of the study of wear-resistant instrumental coatings, extensive experimental data have accumulated on the ionic-plasma and magnetron films based on titanium and other transition metal nitrides and carbides (see, for example, Refs 202–204 and 208). Mainly metallic targets, atomised in nitrogen- and carbon-containing media, are used for the preparation, although the magnetron technique in fact makes it unnecessary to resort to reactive methods involving directly refractory compound targets. Such a procedure has been used successfully, for example, in the synthesis of borides. The employment of a relatively low temperature of the support (approximately 200–500 °C) makes it possible to avoid appreciable recrystallisation when physical deposition methods are resorted to, and in many cases a nanocrystalline structure can be formed. Multilayer and two-phase films as well as films with complex alloying are preferable in this respect.[209–212]

The rate of deposition of magnetron films under direct current conditions usually amounts to several tenths of a micrometer per minute; high-frequency devices, which make it possible to atomise dielectric targets, ensure rates approximately an order of magnitude lower. In ionic-plasma devices (of the 'Bulat' type), the rates of deposition are also high, but it is not always possible to avoid the appearance in the films of the so called drop phase as a consequence of the incorporation in the plasma of drops from the fused cathodic crater.

The size of the crystallites in the films obtained by the traditional deposition methods from the gas phase (CVD) is usually several micrometers and a temperature not less than 850–900 °C is then usually developed. Only in the case of multilayer or multiphase films is it possible to achieve nanostructures. In particular, this applies to the TiB_2+TiC composition obtained by deposition at 1000 °C from a $TiCl_4+n\text{-}C_7H_{16}+BCl_3+H_2$ mixture at atmospheric pressure ($L < 100$ nm).[213] The use of the laser technique also makes it possible in many instances to reduce the temperature and to synthesise nanocrystalline films. Thus the formation of silicon carbide films ($L < 50$ nm), deposited from a $Si_2H_8+C_2H_2+Ar$ mixture with exposure to the excimer ArF laser ($T = 518$ K), has been reported; this is the so called photo-CVD process.[214]

Sol-gel technology, involving the preparation of a solution, immersion, drying, and annealing and requiring simple apparatus, is becoming an increasingly popular method of preparation of oxide films (in particular, lead titanates and zirconates as ferroelectric materials). According to Tohye et al.,[215] the physical properties of these films are not inferior to those of magnetron films. The preparation of zirconium oxide films by the sol-gel method has been described.[216]

Thermolysis of organometallic compounds in order to obtain thin films has long attracted the attention of a wide range of investigators (see, for example, Refs 200 and 201). The characteristics of formation of the structure and the properties of thin Al_2O_3 films (~100 nm), arising in the oxidative pyrolysis of aluminium tris(acetylacetonate) $Al(Acac)_3$, have been described.[217] The authors suggest that the molecules of the initial compound in the adsorption layer do not decompose fully and that organic fragments are removed from the upper layers of the film formed. The reason for the instability of the charge in these films is the migration of OH^- and H^+ ions produced by the electrolysis of the water of crystallisation present in the film. Thin ZrO_2 films with Y_2O_3 as the stabilising additive (3–8 mol. %) are obtained by pyrolysing the acetates.[218] The preparation of an ultradisperse Si_3N_4+SiC powder by the thermal decomposition of organosilicon precursors on exposure to a CO_2 laser as well as the formation of films of similar composition have been described.[81] In exactly the same way, the decomposition of Group IV transition metal hydroborates leads to the formation of not only ultradisperse powders but also of films.[82,83]

Comparative results of the analysis of zirconium diboride powders and films, formed in the pyrolysis of the hydroborate $Zr(BH_4)_4$, are presented in Table 10. The characteristic features of the films are evidently crystallinity (the parameters of the structure are close to the tabulated data) and slight deviation from stoichiometry. The powdered deposits are amorphous and contain an appreciable excess of free boron, the origin of which has already been considered in connection with the discussion of reaction (9).

The superstoichiometric content of the nonmetallic component in films is characteristic also of other refractory compounds, for example the nitrides obtained by the ionic-plasma, magnetron, and other methods. Thus zirconium nitride films acquire a superstoichiometric composition at a nitrogen pressure in excess of ~10^{-3} Torr under the conditions of high-frequency magnetron atomisation.[219] The appearance of superstoichiometric zirconium

Table 10. Characteristics of films prepared from zirconium diboride powders obtained by the decomposition of zirconium hydroborate.[83]

T/°C	Deposit	[B]/[Zr]	Lattice period/nm		S/m^2 g^{-1}	$[H_2]/[B_2H_6]$ in gas phase
			a	c		
250		No decomposition				
300	Amorphous powder	2.76			27.7	9
	Film	2.03	0.3167	0.3528	–	9
350	Amorphous powder	3.74			26.2	12
	Film	2.15	0.3165	0.3534	–	12

Note. The duration of treatment at the temperatures indicated was 5 h in all cases.

nitride has also been detected in the electron beam vaporisation of zirconium accompanied by bombardment with nitrogen ions having energies in the range 400–700 eV.[220] The mechanism of their formation (the appearance of vacancies in the metallic sublattice, the presence of phases of the Zr_3N_4 type, etc.) is still not entirely clear and is the subject of lively discussion in the literature.

2. Properties

Although the number of publications on the properties of thin films is fairly large, only some of them refer to nanocrystalline refractory compound-based films. Furthermore, not all these data are accompanied by a more or less detailed specification of the size of crystallites in the film. It appears that the study of the characteristic features of the formation and growth of refractory compound films, obtained by many and varied methods (Table 9), is in the initial stage. The overall scheme describing the crystallisation of coatings and films, proposed in the familiar study of Movchan and Demchishin[221] and then amplified by Thornton,[222] should be made significantly more specific in relation to refractory compounds.

For example, there is an interesting approach to the estimation of the stability of polycrystalline thin films obtained by the pyrolysis of zirconium acetate and yttrium nitrate solutions.[218] Heat treatment at 1200 °C is accompanied by the formation of ~25 nm crystallites, but, after annealing at 1400 °C, the continuous film is disrupted and converted into isolated fragments. The latter phenomenon can be described in terms of the hypothesis of the etching of grain boundaries using the energy approach and estimating the critical dihedral angle between the grains. Certain problems of the recrystallisation of thin films, including those based on nitrides, have been examined.[212,223]

Among the properties of films, their hardness has been studied to the greatest extent (as for powdered nanocrystalline materials). It has been demonstrated convincingly in a review[203] that the increased hardness of TiN films can be explained mainly by the small grain size (20–70 nm). Measurement of the hardness of thin films has its characteristic features. It is preferable to use small and even ultrasmall loads (the so called nanoindentation) in order to avoid the influence of the support. Fig. 9 illustrates the influence of the load applied to the indentor on the hardness of Ti–B, Ti–B–N, Ti–B–C, and Ti–B–N–C films obtained by magnetron atomisation (film thickness 3–5 μm; support—solid alloy).[210] Evidently, the hardness remains most stable for loads up to ~0.5 N. The Ti–B–N system has the best parameter. The presence of a phase of the $TiB_{1.6}N_{0.6}$ type has been discovered with the aid of X-ray powder diffraction and Auguer spectroscopy. The hardness of boride films alone is also fairly high, surpassing that of TiB_2 (in the form of the usual polycrystalline material or single crystals) by a factor of approximately 1.5–2. This has also been noted in other investigations.[211,224]

Particularly interesting results have been obtained in the study of multilayer refractory compound-based films.[209,212,225] Fig. 10 illustrates the influence of the number of layers on the hardness of TiN + ZrN, TiN + NbN, and TiN + CrN films (the film thickness was 2 μm in all cases). An appreciable increase in the hardness of

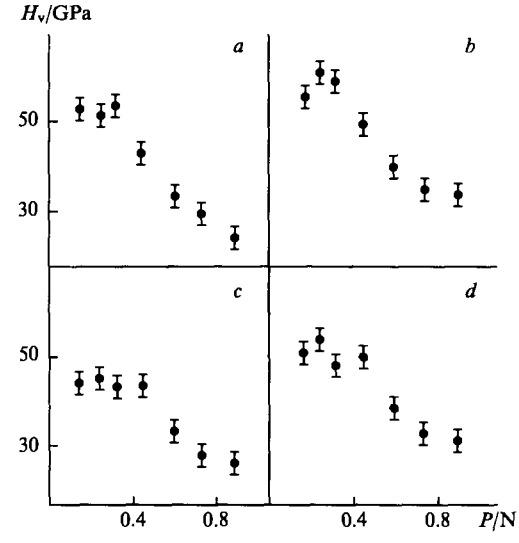

Figure 9. The influence of the load on the hardness of different films: (*a*) Ti–B; (*b*) Ti–B–N; (*c*) Ti–B–C; (*d*) Ti–B–C–N.[210]

the films of the first two systems and its nonmonotonic variation in the TiN–CrN system have been observed. X-Ray powder diffraction revealed the formation of a (Ti,Cr)N solid solution in the latter case, which had not been observed (or had been detected only in the initial stage) for multilayer films of the first two types. Thus the appearance of the solid solution and hence the disappearance of the interfaces with increase in grain size is accompanied by a decrease in the hardness parameters. The strengthening effect due to formation of the solid solution is less significant than the influence of the interfaces on the recrystallisation and the retention of the nanocrystalline structure.

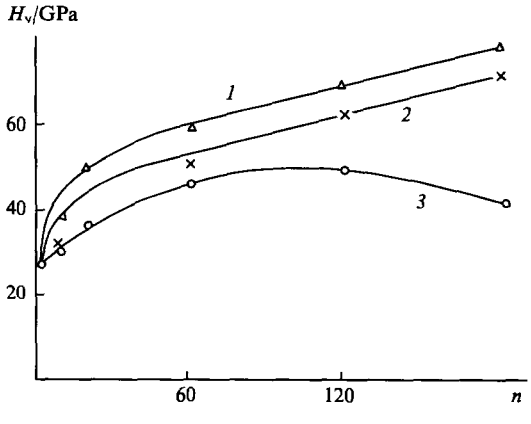

Figure 10. The influence of the number of layers (n) on the hardness of the films:[225] (*1*) TiN–NbN; (*2*) TiN–ZrN; (*3*) TiN–CrN.

Available information about other properties of films based on nanocrystalline refractory compounds is limited to data on the electrical resistance[203] and elastic characteristics[226] of mainly nitride films. In particular, the considerable influence of oxygen on the electrical resistance of TiN, which may vary in the range from 10^4 to ~ 20 $\mu\Omega$ cm, has been noted. In this connection, the precise identification of the role of grain boundaries as one of the factors governing the scattering of carriers (together with structural vacancies, lattice distortions, etc.) is by no means a trivial problem. The deviations from stoichiometry also greatly influence the modulus of elasticity.[226] Several studies using scanning and transmission electron miscroscopy combined with microdiffraction have been devoted to the morphological features and the dislocational structure of W–C–(Co),[227] Ti–N and Ti–B–N,[228] TiN, NbN, VN, and (Ti, Nb)N,[229] TiC + TiB_2,[230] etc. films. However, it is thought that this is only the beginning and systematic studies are still a matter for the future.

V. Conclusion

It is seen from the foregoing that only the first steps have been taken in the study of the properties of nanocrystalline refractory compounds in powder and film form. The amount of information obtained is much smaller than that on nanocrystalline metals.[6–8] It is also smaller than the amount of information available on ultradisperse powders.

The possible applications of nanocrystalline refractory compounds, apart from the materials of the hexanit type based on boron nitride and ultradisperse powders added to the usual powders (see, for example, Refs 231–233), include the technology of the preparation of nanocrystalline WC + Co solid alloys[64] with a high hardness and wear resistance (Table 7) for the manufacture of microtomes and other suitable devices. On the one hand, bearing in mind the high hardness parameters of nanocrystalline metals and intermetallic compounds as well as films, one may hope for the creation of new ultrahard materials based on nanocrystalline refractory compounds. On the other hand, the small grain size of these materials increases significantly their capacity for deformation and the development of ultraplastic compositions based on brittle refractory compounds becomes entirely realistic. The possible temperature of the hot pressing of such materials (1200–1400 °C) is technically entirely acceptable.

Promising applications of nanocrystalline refractory compounds such as preparation of highly selective filters (with fine 5–20 nm filtration apertures) and ion-conducting membranes (in fuel cells and oxygen sensors), the formation of solid-phase junctions between ceramic components, and finally their use for a significant reduction of the sintering temperature have been noted in a review.[165] New possible applications of nanocrystalline refractory compounds in catalysis must be added to the above list.

There is no doubt that the effectiveness of the above materials for particular applied purposes depends significantly on further progress in the study of the methods of preparation of nanocrystalline materials and of the establishment of their properties.

This review has been written with financial support by the International Scientific Fund (ISF, grant No. MTF 000) and the Russian State Scientific-Technical Program 'New Principles and Methods of Preparation of Chemical Substances and Materials' (project No. 3.5.15.93).

Abstract. A wide range of inorganic crystal hydrates possessing proton conductivity is analysed. The possible mechanisms of defect formation and proton transfer are considered, including those for a series of specific compounds. The main directions in the search of compounds having high proton conductivity at room temperature are outlined. The bibliography includes 65 references.

I. Introduction

One of the priority aspects of the development of modern chemistry is the elaboration of materials possessing special electrical properties; in particular, the search for solid electrolytes having proton conductivity. The prospects for their application are exceedingly wide. For example, they have been used to create high-performance fuel cells (with an efficiency approaching 100%) based on the oxidation of hydrogen,[1,2] water vapour electrolysers, devices for the extraction of hydrogen from water gas,[3] and highly sensitive sensors for hydrogen, carbon monoxide, and several other gases.[4,5] Recently a new field of application of proton-conducting materials was discovered: their use for the non-faradaic electrochemical modification of the catalytic activity (EMCA) of metal catalysts, resulting in a manifold increase in their activity and selectivity, e.g., in the 'catalytic cross-linking' of methane.[6] It should also be noted that the same requirements must be met for a compound to possess proton conductivity as those for the existence of acid–base catalytic activity in organic syntheses.[7] These properties are therefore directly correlated for many compounds,[8] and proton conductivity is used in several scientific centres as the primary test for screening proposed catalysts. The above factors led to a broad development of the search for and study of new solid proton-conducting electrolytes. Not only electrical conductivity but also other properties of the material, such as thermal stability, solubility, dispersity, etc., appear to be of primary importance.

If one considers the list of compounds possessing a high proton conductivity at the usual, relatively low temperatures, it is easy to see that virtually all of them, including all 'record holders', are hydrates of bases, acids, acid salts, or oxides with distinct acidic properties. For example, the highest proton conductivity at room temperature (0.17 S cm^{-1}) is exhibited by highly hydrated heteropolyacids.[9,10] The following compounds have conductivities lower by two orders of magnitude: uranyl phosphate,[11] some hydrated acid sulfates,[12] hydrates of sulfonic acids,[13] hydrated tetramethylammonium,[14] and certain finely dispersed materials, such as acid phosphates of zirconium, tin, antimony,[15–17] polyantimonic acid,[18] etc. Taking this into consideration, we shall devote most attention in this review to the proton conductivity of inorganic hydrates of acids, acid salts, and bases.

We shall present here several known general relations for ionic conductivity which will be used below. In the general case, electrical conductivity is defined by the following equation:

$$\sigma = \sum n_i q_i \mu_i, \quad (1)$$

where n_i is the number of the charge carriers, q_i is their charge, and μ_i is their mobility.

Temperature dependence of the number of carriers is expressed by the equation:

$$n_d = N\exp(-\Delta G_d/2kT), \quad (2)$$

where N is the overall number of possible sites for the formation of the carriers (most frequently proton defects in the case under consideration), ΔG_d is the free energy for defect formation, and k is the Boltzmann constant.

In its turn, the mobility of the charge carriers also depends on temperature:

$$\mu = (a^2 q/kT)\, v_0 \exp(-E_m/kT), \quad (3)$$

where a is the distance between the neighbouring positions in the structure, q is the proton charge, v_0 is the frequency of proton vibrations near the equilibrium position ($\sim 10^{14}$ s^{-1}), and E_m is the energy barrier to migration.

Thus the temperature dependence of the overall conductivity is defined by the equation

$$\sigma = (a^2 q/kT)\exp[-(\Delta G_d/2 + E_m)/kT]. \quad (4)$$

In practice, this equation is used in an abbreviated form adjusted to molar values and is known as the Frenkel equation:

$$\sigma T = A\exp(-E/RT). \quad (5)$$

To understand the essential nature of the proton conduction process, it is important to formulate the mechanisms for the formation of defects and their transfer in the structure of the substance.

II. Formation of charge carriers

As a rule, the formation of charge carriers reduces to proton transfer from the ground state to an excited state characterised by a higher energy. Most often, this can be described by reactions of the following types:[19,21]

$$2HSO_4^- \rightleftharpoons H_2SO_4 + SO_4^{2-}, \quad (6)$$

or

$$O_3SO^{2-} - HOH_2^+ \rightleftharpoons O_3SOH^- - OH_2 . \quad (7)$$

The concentration of charge carriers for reaction (6) at room temperature can be estimated easily from the equilibrium constant, which is equal to the ratio of the successive dissociation constants of the corresponding acids in solution. This concentration is normally of the order $10^{-10}-10^{-6}$, although, strictly speaking, the corresponding values for a solid can differ significantly. The concentration for reaction (7) is determined by the difference between the proton-accepting capacities of water molecules and the anion. It can vary within very wide limits, reaching values close to 1 when the above capacities are equal. The proton transfer can occur along a chain of successively linked water molecules and oxonium ions, as in the case of highly hydrated molybdo- and tungsto-phosphoric acids. Since for the latter even the identification of the H_3O^+ ions in the structure is problematical, it can be assumed that all the acid protons act as charge carriers. Their absolute concentration, calculated from the unit cell volume, is 1.9×10^{21} cm^{-3} (or 3.2×10^{-3} mol cm^{-3}). If one takes the above considerations into account, the concentration of carriers in the hydrates of weaker acids is usually lower and can reach 10^{11} cm^{-3} or even less. For example, Chandra[20] suggests that the boundary between compounds with low and high concentrations of carriers lies at 10^{18} cm^{-3}. If the proton mobility is high, the former are assigned to the class of the so-called superionic conductors. However, the boundary between these and the usual ionic electrolytes is very arbitrary. Furthermore, proton defects can be formed due to the interaction of the compound with the molecules of water of hydration. A characteristic example is given by salts of heteropolyacids, in which the processes described by the reactions

$$PW_{12}O_{40}^{3-} + 7H_2O \rightleftharpoons PW_{11}O_{39}^{7-} + H_2WO_4 + 4H_3O^+, \quad (8a)$$

or

$$-W-O-W- + 3H_2O \rightleftharpoons 2-W-O^- + 2H_3O^+, \quad (8b)$$

result in a high effective concentration of the carriers even in the case of neutral salts.[21] Evidently, the same processes result in the existence of excess protons in the highly hydrated heteropolyacids, found by Ukshe et al.[22]

In addition, the concentration of defects is affected very strongly by various admixtures that can be present in solid proton-conducting electrolytes owing to various reasons. On the one hand, these materials normally exhibit ion-exchange properties. As a result, a portion of the protons can be replaced by various cations with a much lower mobility, which decreases the concentration of the carriers. This results in a decrease in the electrical conductivity of these compounds, as in the case of acid zirconium phosphate, even though the degree of hydration can increase.[23-27] On the other hand, doping the solid electrolytes with heterovalent cations can 'force' the generation of an excess concentration of the carriers correlated with the concentration of the admixture. A typical example of such doping is presented by oxygen-conducting materials based on the cubic modification of zirconium dioxide, stabilised with yttrium or calcium, as well as by halides. In this case Eqn (4) transforms into

$$\sigma = [N_0 + N \exp(-\Delta G_d/2kT)](a^2 q \nu_0/kT) \exp(-E_m/kT), \quad (9)$$

where N_0 is the number of admixture-generated defects. In contrast to individual compounds, the logarithmic conductivity plot for such a material consists of two straight lines intersecting at the point where the concentrations of the admixture- and thermally-generated charge carriers are equal. The effective activation energy is higher for the high-temperature branch. Unfortunately, the specific procedures used for the preparation of hydrates of inorganic acids and acid salts and their specific structure make it difficult to introduce doping ions into some materials and result in a high surface defectiveness of other materials. This makes it very difficult to investigate correctly the effect of doping with various admixtures on the electrical conductivity of these compounds.

III. Proton transfer

Like many other cations that can act as carriers in solid electrolytes, the proton is singly charged. However, it is distinguished by an exceedingly small radius, mass, small coordination number, and the absence of an electronic shell. It follows from these facts that the presence of large channels in the structure is not obligatory for the existence of proton conductivity. On the other hand, the activation energy for the transfer of charged species in structures with ionic conductivity passes through a minimum for cations with a radius of about 1 Å, as in β-alumina. The transfer of large cations encounters steric hindrance, whereas small cations 'stick' to the channel 'walls' forming fairly strong bonds. Therefore, proton transport is characterised by several specific features:

over a reasonable temperature range, the proton is always bound covalently to one of the electronegative atoms;

the hydrogen bond is always directed;

the proton can be effectively 'delocalised' between two electronegative atoms, and its oscillation along the H-bond, $O-H\cdots O \leftrightharpoons O\cdots H-O$, is an important step in the transfer reaction and can proceed by the tunnelling mechanism.

1. The 'carriage' mechanism

At present, the most common view is that a proton in a solid can move either by the 'relay' mechanism, i.e. by transfer from one electronegative atom to another, or by the so-called 'carriage' mechanism. The latter was suggested on the basis of the fact that the maximum proton conductivity at low temperatures is shown by compounds containing water or ammonia molecules together with protons. In this case, the formation of H_3O^+, NH_4^+, and other ions becomes possible. The authors of this theory suggest that these ions can migrate through the structure as a single whole structure, thus ensuring proton transfer.[28]

This view is fairly common and is supported by a number of facts. For example, the 'carriage' mechanism has been ascribed to uranyl phosphate tetrahydrate on the basis of the similarity of the activation energies for electrical conduction and the migration of oxygen atoms.[29] Although this view is popular, the existence of solid proton-conducting electrolytes with the 'carriage' transfer mechanism seems questionable, primarily because the actual time for a proton jump in uranyl phosphate is no more than 10^{-9} s,[30-32] whereas the lifetime of the oxonium ion is 10^{-12} s.[33] Furthermore, the environment of the H_3O^+ and $H_5O_2^+$ ions in the crystals is not restricted to oxygen atoms forming hydrogen bonds directly with these ions, but also includes at least one additional atom. The law governing this phenomenon can be readily understood from the fact that the energy of the dipole–charge interaction is inversely proportional to the cube of the distance between them, whereas that of the charge–charge interaction is inversely proportional to the distance. Hence, if the O^{2-} ion moves farther from the oxonium ion oriented towards it with its oxygen atom, then, starting from a certain distance, the attraction between them as oppositely charged species becomes the dominant effect. Moreover, in terms of the close-packed spheres structure, the oxonium ions are often located in tetrahedral cavities and more rarely in octahedral cavities with a somewhat distorted environment. This also implies that these ions are surrounded by more than three electronegative atoms.

The existence of such additional bonds in several real hydrates of acid salts has been demonstrated.[34] Assuming that the lengths of the three main H-bonds are 2.6, 2.8, and 2.8 Å (which is most typical for the hydrated oxonium ions) and that the mean statistical angles between them are 114°, one can find that the radius of an inscribed circle for the cross-sections formed by three oxygen atoms, through which the oxonium ion should pass, is 2.63–2.69 Å (less than the sum of two ionic radii of oxygen). Clearly, the diffusion process will involve substantial steric hindrance. When calculating the channel radius in real compounds, one has to take more atoms into account; hence this value can become even less. For example, the radii are 2.52 and 2.12 Å for the tetra- and monohydrates of indium bisulfate respectively.

Finally, there is also a direct method permitting an experimental choice between the 'carriage' and 'relay' proton transfer mechanisms. The replacement of oxonium ions or H_2O-H^+ fragments by NH_4^+ should result, in the case of the 'carriage' mechanism, in an increase in the concentration of carriers owing to the higher stability of the latter cation, and in an increase in their mobility owing to lower strength of the hydrogen bonds. On the other hand, in the case of the 'relay' mechanism, this change complicates the proton transfer owing to the high activation energy for its transfer from the ammonium cation to the anion. It has been shown, using this method, that the transfer in $D_3OZr_2(PO_4)_3$,[35] $Sn(HPO_4)_2.2H_2O$,[16] $H_3OM(SO_4)_2$[12] (where M = Al, Ga, In, Tl, Ti, V, Mn, or Fe), and some other compounds occurs by proton jumps. A degree of probability of the carriage transfer mechanism can perhaps be retained only for the ammonium salts formed by acids in which the proton-accepting capacity of the anion is exceedingly low. This assumption is based on the fact that the electrical conductivities of ammonium, rubidium, and caesium perchlorates are similar. However, it is noteworthy that the analogous value for oxonium perchlorate is nine orders of magnitude higher.

2. The 'relay' mechanism

Unlike the situation with other ions, the transfer of the proton never occurs in one step, but normally consists of a series of jumps along the hydrogen bond and of rotations of proton-containing groups. It should be noted that a prerequisite condition for the transfer is an excess of potential hydrogen bonds in comparison with the number of protons present in the system. As was shown above, this condition should almost always be fulfilled for hydrates of inorganic salts and acid salts. 'Hydrogen bonds' of this type involving no proton are called the Bjerrum L-defects. In its turn, a Bjerrum D-defect is a hydrogen bond involving two protons. Their formation can be easily imagined if one rotates a water molecule in the structure of ice by 120° relative to any of the hydrogen bonds. The D-defects should have extraordinarily high energies. For this reason, some authors consider that their existence is, in principle, impossible. However, a hydrogen bond with a length of 1.91 Å has been found in $H_{3.33}Fe(CN)_6.2.7H_2O$.[36] The exceedingly short length of this bond is thought to be due to the fact that it incorporates two protons. Note that this ambiguous finding has not been supported by any other evidence.

Consider a hypothetical system containing oxonium ions and XO_4^{n-}, and assume that it already contains defects consisting of water molecules formed by the dissociation of oxonium. The transfer process in such a system can be represented by the scheme

$$\begin{aligned} &H_2O-H^+\cdots O_a\cdots OH_2 \overset{a}{\rightleftharpoons} \\ &\rightleftharpoons H_2O\cdots H^+-O_a\cdots OH_2 \overset{b}{\rightleftharpoons} \\ &\rightleftharpoons H_2O\cdots O_a-H^+\cdots OH_2 \overset{c}{\rightleftharpoons} \\ &\rightleftharpoons H_2O\cdots O_a\cdots H^+-OH_2. \end{aligned} \qquad (10)$$

The process with the maximum activation energy should be the rate-determining step. The activation energy for proton transfer along the hydrogen bond (steps *a* and *c*) increases abruptly with increasing bond length,[33] whereas the activation energy for the rotation of the $X-O\diagup H$ moiety relative to the X–O bond (step *b*) actually decreases.[34] It follows that there exists an optimum length for hydrogen bonds, which should maximise the proton mobility. Using the data in Refs 33 and 34, one can conclude that, provided that the proton-accepting capacities of the oxygen atoms participating in the transfer are close, the systems with ~2.8 Å hydrogen bonds should have the lowest activation energies (of the order of 15–20 kJ mol^{-1}).

An example of proton transfer by this mechanism is provided by acid indium and thallium sulfate monohydrates $H_3OM(SO_4)_2$ (Fig. 1) described by us previously.[12] The *a*, *b*, *c*, and *d* indices refer to the states which the system adopts successively. The arrows indicate the directions of the movement of hydrogen ions resulting in these transformations (proton jumps and rotation of proton-containing groups). The environment of each oxonium ion incorporates six equivalent oxygen atoms of the anion, but only three of these can form hydrogen bonds with the oxonium ion simultaneously.[37] Thus the system initially contains three Bjerrum L-defects for three actually existing hydrogen bonds. The proton defects are formed by reaction (7). Judging from the equilibrium constant of this reaction, which can be easily estimated from NMR spectra at 77 K, ΔG for this process is close to 1.5 kJ mol^{-1}. The activation energy for the oxonium ion rotation in these compounds is only 18 kJ mol^{-1}; an excess of hydrogen bond acceptors plays an important role in decreasing this activation energy.[34] The rotation of the S–O–H moiety proceeds even more readily, since it requires the breaking of only one hydrogen bond and rotation around a S–O single bond. On the other hand, the proton transfer along hydrogen bonds with a length of 2.87 Å, formed by oxygen atoms possessing similar proton-accepting capacities, should be characterised[33] by an activation energy of ~ 33 kJ mol^{-1}, which determines the overall proton mobility in this case. Thus, the activation energy $E \sim 33 + 0.7 = 33.7$ kJ mol^{-1} can be obtained from Eqns (4) and (5) (cf. the experimental values of 30–34 kJ mol^{-1}).

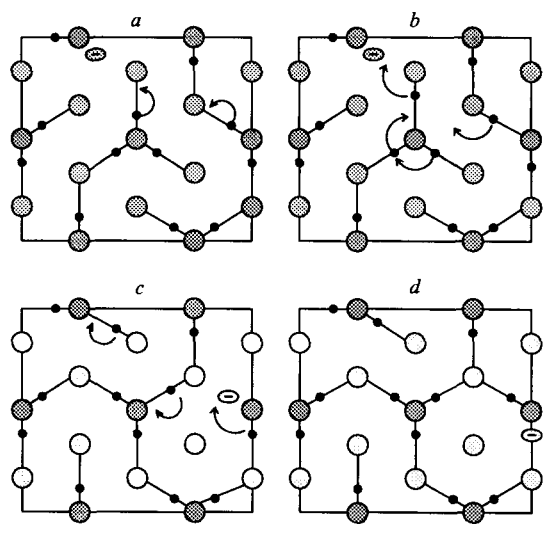

Figure 1. Schematic illustration of proton transfer in $H_3OM(SO_4)_2$: (*a*)–(*d*), consecutive conformations of the system; ◎ – oxonium oxygen; ○ – anion oxygen.

The proton transfer in a number of other hydrates of acids and acid salts, including oxonium perchlorate, occurs similarly.[38,39] The electrical conductivity of the latter compound increases abruptly in the first-order phase transition at 250 K,[33,38] after which the oxonium ions pass to the isotropic rotation state[40] and are surrounded by seven oxygen atoms at a distance of 2.86–3.40 Å.[41] It should be noted that the occurrence of phase

transitions resulting in an increase in proton conductivity is quite typical for these compounds.[19,39]

Usually, as in the above examples, the mobility of the proton is limited by the step involving its transfer along the hydrogen bond. However, the rotation of the proton-containing moieties is strictly necessary for the existence of proton conductivity. A typical example of a compound having an exceedingly low proton conductivity due to the hindered rotation of the proton-containing groups is provided by sulfuric acid octahydrate. The infinite planar networks $(H_9O_4)_n^{n+}$ in this compound are built up on the basis of the $H_5O_2^+$ ions with R(O—O) = 2.447 Å and with equivalent oxygen atoms. Each OH_2 moiety in these ions is a donor in hydrogen bonds with the anion and with a water molecule characterised by equal lengths of 2.654 Å. In turn, the water molecules form H-bonds with the anion (2.735 Å) and with similar molecules (2.762 and 2.765 Å). In the latter two bonds, each participant can act with equal probability as a proton donor or acceptor.[42] The proximity of a further two H_2O molecules not bonded directly is noteworthy. Thus the structure of $H_2SO_4.8H_2O$ seems to be ideal for proton conductors. However, the formation of numerous strong hydrogen bonds hinders the rotation of the proton-containing moieties. This inhibits in its turn the transfer of protons, which, according to our data,[43] do not pass to the mobile state below the melting point.

A number of solid proton-conducting electrolytes, whose conductivity is limited by different proton transfer steps, have been reported in the literature. Unfortunately, this assignment was not sufficiently well founded in most of the studies and was based merely on the activation energies for proton transfer (which is not always unreasonable). Some typical frequencies and activation energies for the elementary proton transfer steps reported in the literature are given in Table 1.

Table 1. Some typical frequencies and activation energies for the elementary proton transfer steps.

Process	Frequency/Hz	E_a/kJ mol^{-1}	Ref.
Reorientation of polyatomic ions	$10^{11}-10^{12}$	< 10	44
Reorientation of interlayer water molecules or 'zeolite'-type water	$10^{7}-10^{12}$	20–30	30, 32, 44
Reorientation of coordinated water	10^{9}	20–30	44
Proton jumps	$10^{8}-10^{10}$	20	30, 32, 44
Oxygen diffusion	10^{9}	80	30

In our opinion, these data can be used for a preliminary comparison of the energetic and frequency parameters of conductivity-determining processes. For example, it follows from these data that the transfer process can normally be limited by the rotation of polyatomic ions such as HPO_4^{2-}, $HSeO_4^-$, etc. On the other hand, the parameters of these tabulated processes may be outside these limits for some compounds.[16]

In real structures, the proton should be transferred by ~3 Å in one step. By substituting this value, together with the previously estimated minimum activation energy of 15 kJ mol^{-1}, in Eqn (3), it is possible to obtain a proton mobility of 8×10^{-3} cm^{2}V^{-1}s^{-1}. On combining this with the maximum concentration of carriers, we obtain from the Frenkel equation (5) $A_{max} = 3.3$ S cm^{-1} and $\sigma = 2.5 \times 10^{-5}$ S cm^{-1} for the 'relay' mechanism.

3. The Grotthus mechanism

The structures of many solid proton-conducting electrolytes are characterised by a large number of virtually equivalent oxygen atoms, which nevertheless form different proton-containing groups (H_3O^+ and H_2O, OH^- and H_2O). The conditions for proton transfer are most favourable in such systems—ice might be an ideal proton conductor. However, the main obstacles to this are the low concentration of charge carriers (10^{-7}) and the low rotational mobility of water molecules in ice. The situation changes completely if oxonium ions or hydroxide ions are introduced into an ice-like structure. This results in the concentration of carriers and the proton mobility increasing abruptly; the rotational mobility of the proton-containing moieties is stimulated very strongly.[45,46] However, the combination of the above factors does not explain the anomalously high proton mobility, which is at least an order of magnitude higher than that of other ions in aqueous solutions and in a number of other compounds. It is also difficult to explain the difference between the maximum electrical conductivity for the 'relay' mechanism quoted in the previous section (2.5×10^{-5} S cm^{-1}) and the electrical conductivity of highly hydrated heteropolyacids (0.17 S cm^{-1}). One explanation for these facts is the equivalence of protons in H_3O^+ and H_2O. According to Haggins[47] and Zundel,[48] the transfer in these systems can be represented as structural migration of $H_5O_2^+$ ions (Fig. 2). This model is reminiscent of the familiar fairy tale about a race between a hedgehog and a hare, where a twin hedgehog awaited the exhausted hare at the finish. Zundel remarks that the proton jump occurs against the background of the vibration of the system of oxygen atoms, which leads to a shift of the shortest bond (the change from Fig. 2*b* to Fig. 2*c*). Undoubtedly, this condition favours proton migration,[48,49] although it is not essential.

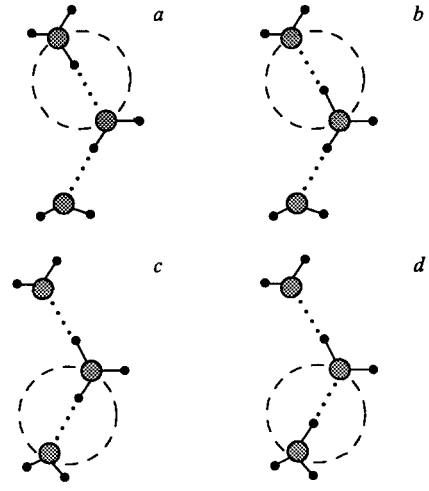

Figure 2. Schematic illustration of proton transfer by the Grotthus mechanism (the circles indicate the short hydrogen bond);[48] (*a*)–(*d*), consecutive conformations of the system.

Strictly speaking, the above scheme describes only the polarisation of the system, whereas proton conductivity requires, in addition, reorientation of the newly-formed proton-containing groups. It is easily seen that the rotation of any of these groups would result in a Bjerrum D-defect. Therefore, the view exists that such rotations occur in a concerted manner, i.e. the rotation of one water molecule initiates the rotation of a second molecule, then a third, etc., with a small phase lag. As a result, the D-defect migrates cooperatively in a wave-like manner (this is also called the soliton mechanism). The rapid overall proton transfer consisting of jumps between equivalent proton-containing groups alternating with their rotations was called the Grotthus mechanism. Combination of the above factors results in a

cooperative proton jump over an enormous distance, which in this case should be called more appropriately 'the length of the free path'. For example, this length for heteropolyacids estimated by Eqn (4) is 100 Å.

This mechanism is quite common not only for hydrates of acid salts[50,51] but also for bases.[14,52] The proton transfer in $CsOH.H_2O$ takes place in this way. This process is quite instructive and has been studied thoroughly, and so it seems reasonable to discuss it although formally this is beyond the scope of this review. Below 229 K, the compound crystallises in the monoclinic system with the structurally nonequivalent OH^- groups and H_2O forming a planar network (Fig. 3). This conclusion is also confirmed by ^2D NMR data.[52] However, above this temperature a phase transition occurs, which is accompanied by the transformation of the monoclinic crystal lattice into the hexagonal form with structurally equivalent oxygen atoms. The symmetrical hydrogen bond with $R(O-O) = 2.64$ Å is characterised by two possible positions of the proton 1 Å apart. The transfer between these positions is characterised by a frequency of 8×10^{10} Hz. When combined with the rotation of the proton-containing groups at a frequency of 2.8×10^9 Hz, this leads to the occurrence of two-dimensional proton diffusion in $CsOH.H_2O$, via the Grotthus mechanism.[52] Similar disordering is observed in $RbOH.2H_2O$, in which the hydroxyl groups participate in the formation of four hydrogen bonds with water molecules.[53]

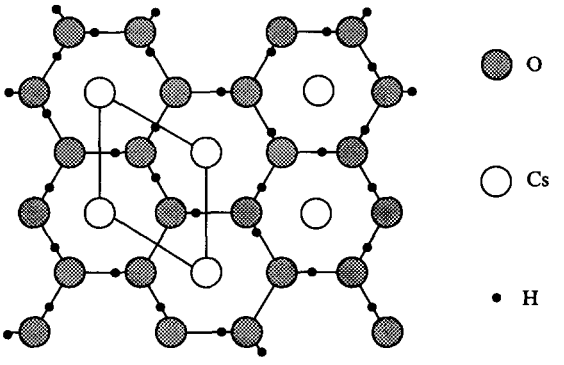

Figure 3. The structure of $CsOH.H_2O$.

A proton hydrate sublattice having the composition $H(H_2O)_n^+$ with a three-dimensional framework of hydrogen bonds is also formed in highly hydrated heteropolyacids. The existence of several variants of proton transfer ensures the extremely high electrical conductivity of these compounds, which decreases as the degree of hydration decreases.[9-11]

IV. Proton transfer on the surface of particles

Since in most cases the surface layer of particles of a compound constitutes a small proportion of the bulk, its contribution to the electrical conductivity is low. However, the situation changes completely when compounds such as hydrated oxides of polyvalent elements are considered. X-Ray microanalysis often indicates the presence of lines resembling those of the corresponding lines of oxides but differing mainly in having larger widths. This allows the assumption that the compounds have the globular structures[54,55] shown in Fig. 4 for tin hydroxide.

The composition inside the globules is close to that of the corresponding metal oxide. However, the surface of the globules incorporates fairly numerous OH groups, water molecules, and, possibly, anions trapped from the solution. The charged species located on the surface are highly reactive and can be readily exchanged when in contact with the solution.[54,55] A fraction of the water molecules are located in the intergranular space and,

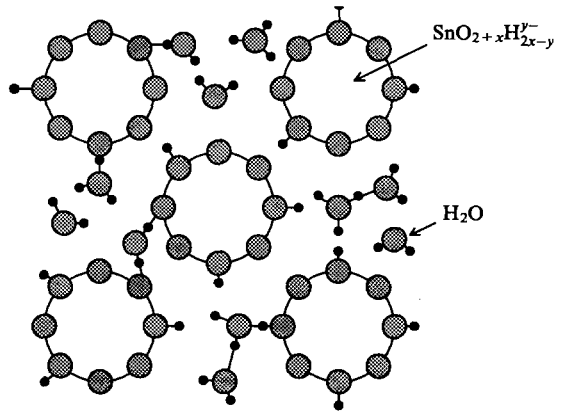

Figure 4. The structure of $SnO_2 . nH_2O$.

being retained only by hydrogen bonds, are highly mobile.[55,56] The overall composition of tin hydroxide may be represented by the formula $SnO_{2-x}(OH)_{2x}.nH_2O$. In this composition there are $2+x$ oxygen atoms per tin atom. For 25 Å particles, $x = 0.6$, while for 100 Å particles $x = 0.15$.[54] There is a special term for these compounds in the English language literature, namely, 'particle hydrates'; in the Russian-language literature they are sometimes called 'globular hydrates', although this name is not generally accepted. The acidic nature of the hydroxyl groups in $SnO_2.nH_2O$ brings about their partial dissociation via the mechanism:

$$SnO_{2+x}H_{2x} + yH_2O \rightleftharpoons SnO_{2+x}H^{y-}_{2x-y} + yH_3O^+. \quad (11)$$

Thus the intergranular space contains a highly mobile solution with the composition $yH^+ . nH_2O$ ensuring the high electrical conductivity of this compound, which reaches 3×10^{-4} S cm^{-1} at room temperature. Obviously the transfer itself occurs via the Grotthus mechanism.

The highly hydrated heteropolyacids are a prominent example of compounds with this type of proton transfer mechanism. In these, the heteropolyanions, in which all three OH groups are completely dissociated, act as globules whose radii are about 12 Å. Evidently this is why these compounds have the highest electrical conductivities.[9] Insoluble alkali metal tungsto-phosphates possessing cation-exchanging properties and a proton conductivity up to 10^{-2} S cm^{-1} form larger particles.[57] Ice doped with strong acids can be regarded as a system of this kind with a minimal core of particles (these are anions).

Hydrated acid zirconium phosphate is one of the best known proton conductors. Depending on the degree of crystallinity and atmospheric humidity, its electrical conductivity varies over five orders of magnitude, which indicates that the intercrystallite component plays the major role. The mobility of surface protons is four orders of magnitude higher than that of the bulk-phase protons.[58,59] The replacement of the OH groups by the $-C_xH_ySO_3H$ or $-C_xH_yCOOH$ fragments, or the sorption of bulky amines on some of them, significantly increases the interplanar distance in lamellar phosphates such as $Zr(HPO_4)_2 . nH_2O$. In the opinion of some authors,[60-64] this might lead to the properties of the surface being acquired by almost the whole material. Unfortunately, this idea has not found practical confirmation. The maximum electrical conductivity of such compounds, which reaches 10^{-2} S cm^{-1} at room temperature and 90% humidity, is apparently also due to the surface component.[60-64] Furthermore, the authors postulated that proton transfer in compounds containing acid groups at the end of a flexible hydrocarbon moiety ($-C_xH_{2x}COOH$) can occur when the latter come closest together during their vibrations.

V. Some features of solid proton-containing electrolytes

Undoubtedly the presence and magnitude of proton conductivity in a compound depend primarily on its structural features. For example, the existence of a continuous network of hydrogen bonds, or the possibility of one being formed due to the rotation of hydrogen-containing groups, is a prerequisite. Furthermore, as shown above and by Potier,[39] the hydrogen bonds should have an optimum length, etc.

Despite these requirements, one can outline fairly confidently the range of hydrates and acid salts among which materials with a high proton conductivity should be sought at comparatively low temperatures. It is convenient to use the classification proposed by us,[65] based on the proton-accepting capacity of the acid residue and its spatial structure in the compound. For example, both the formation of carriers and their transfer are hindered in the salts of weak acids (class I, $pK_a > 3$).

The class II compounds ($-3 \leqslant pK_a \leqslant 3$) are much more suitable for this purpose, since the proton transfer from the anion to water molecules and vice versa occurs comparatively easily. The behaviour of the class IIa compounds (where the proton is localised on the oxygen atom of the anion in the ground state) is often restricted by the low degree of hydration. Therefore, these compounds usually exhibit a high electrical conductivity only in a finely dispersed state [$Zr(HPO_4)_2 . nH_2O$]. In the class IIc compounds with isolated anions, the latter form fairly strong hydrogen bonds with the hydrated proton, which significantly restricts its mobility. The class IIb compounds with a bulky anion forming skeletal structures are good proton electrolytes. The majority of these compounds have layered structures ($MH(SO_4)_2 . nH_2O$, $MH(PO_4)_2 . nH_2O$, $UO_2HPO_4 . 4H_2O$).

The hydrates of strong acids ($pK_a < -3$) tend to form hydrogen bonds between the H_3O^+ or $H_5O_2^+$ ions and water molecules and hence to exhibit a high degree of hydration.[65] Consequently, despite some hindrance to proton transfer from the proton-hydrate sublattice to the anion (which, incidentally occurs comparatively easily, for example, in oxonium perchlorate), proton transfer by the Grotthus mechanism is most probable in this case ($H_3PW_{12}O_{40} . nH_2O$). This is why compounds possessing the maximum proton conductivity have been found among these compounds. The search for proton-conducting electrolytes among highly hydrated class III compounds is especially advisable. However, their tendency to change their hydrate composition (dehydration in air or absorption of moisture) can be a limiting factor in their employment.[65]

Abstract. The synthesis of thiophene and alkylthiophenes by the reaction of acetylene, C_4-C_8 alkanes, and C_4-C_6 alkenes and alkadienes with hydrogen sulfide in the presence of metal oxides and sulfides as well as their mixtures is examined. The conditions for the testing of catalysts in flow type apparatus in stationary and fluidised catalyst beds are presented. The calculated equilibrium yields of thiophenes from C_4-C_6 hydrocarbons and hydrogen sulfide are compared with experimental data. Together with the heterocyclisation reaction, the interaction of C_6-C_8 hydrocarbons with hydrogen sulfide involves dehydrocyclisation with formation of aromatic hydrocarbons. The mechanism of the interaction of C_4-C_5 hydrocarbons with hydrogen sulfide, investigated by the isotope-kinetic method, is discussed. Certain physicochemical properties of active chromium-containing oxide heterocyclisation catalysts and industrial methods of synthesis of thiophene are described. The bibliography includes 63 references.

I. Introduction

During the 1960s, information concerning the selection of effective catalysts for the synthesis of thiophene and alkylthiophenes by the heterocyclisation reaction was available, with some exceptions, only in the patent literature. Transition metal oxides and sulfides were used as the catalysts.

A review of catalytic methods of synthesis of thiophene and alkylthiophenes from petroleum processing products and organic sulfur-containing compounds was published in 1971.[1] Analysis of the review data leads to the conclusion that it is most useful to obtain thiophenes from readily available starting materials — hydrocarbons and hydrogen sulfide. The selection of an effective catalyst capable of being regenerated would make such a process promising. The use of sulfur-containing organic compounds is difficult in practice because dialkyl sulfides, mercaptans, and thiophane are not yet produced on an industrial scale.

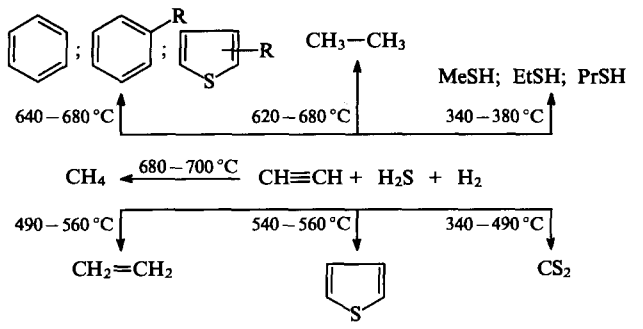
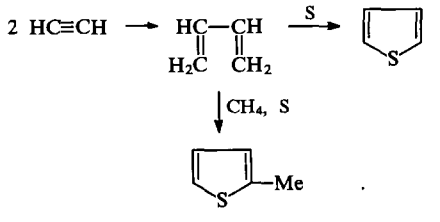
By virtue of their high reactivity, thiophene and its homologues are a potential starting material for the synthesis of a wide variety of both aliphatic and alicyclic compounds. Methods of synthesis of certain polyorganosiloxanes, herbicides, physiologically active substances, and perfumes from thiophene have been developed. The successful development of thiophene chemistry, especially during the last ten years, has made it possible to develop a series of valuable medicinal preparations, including antibiotics. Like benzene, thiophene is known to possess biological activity but it is less toxic. Compounds containing thiophene and its derivatives can be used in the treatment of diseases of the central nervous system and also as anti-inflammatory, cardiovascular, antihistamine, and other agents.



The literature data on thiophene and its derivatives published up to 1982 have been surveyed in a monograph[2] which was published in 1985. The methods of synthesis of thiophene by a cyclisation reaction and from other cyclic systems are described in the monograph and the pharmacological activity of thiophene and its derivatives have also been considered.[3,4]

II. Interaction of acetylene with hydrogen sulfide



Thiophene was first obtained from acetylene and hydrogen sulfide by Chichibabin in 1915.[5] The reaction was carried out in the presence of aluminium oxide at 425–450 °C. The studies on the catalytic synthesis of thiophene from hydrogen sulfide and acetylene up to 1952 have been surveyed in a monograph.[6]

Interesting results have been obtained[7,8] in experiments on γ-Al_2O_3 in the study of the interaction of hydrogen sulfide and an acetylene-containing gas from the electrocracking of petroleum products, the gas having the following composition (vol.%): 29.0 C_2H_2, 7.8 C_2H_4, 0.6 C_2H_6, 5.6 CH_4, and 57.0 H_2. The yield of thiophene proved to be higher than in the case where pure acetylene was used and amounted to 50%–52% relative to the acetylene passed through the system instead of 38%. The high activity at γ-Al_2O_3 is probably associated with the presence of hydrogen in the initial mixture, which promotes hydrogenation and the removal of carbonaceous deposits — the condensation products on the surface of alumina.

Depending on the temperature, the following products are obtained in the interaction of the acetylene-containing electrocracking gas with hydrogen sulfide on γ-Al_2O_3:

The introduction of transition metal (Cr, La) oxides as well as K_2O intensifies the hydrogenating function of the catalyst — the yield of ethylene and ethane increases by a factor of 1.5, but the yield of thiophene does not increase. These data, as well as the results of experiments in which a mixture of 30% of ethylene with H_2S was used, show that thiophene is not formed via hydrogenation products. It is most likely that the formation of thiophenes and alkylthiophenes involves the intermediate formation of dimerisation and alkylation products in accordance with the mechanism[9]

The yield of thiophene on γ-Al_2O_3 did not change with increase in the rate of supply of acetylene.[10] The size of the catalyst grains also did not affect the yield of thiophene. The concentration of the helium-diluted hydrogen sulfide was varied from 0 to 87.5 mass% at an acetylene concentration of 12.5 mass%. The activation energy for the synthesis of thiophene from hydrogen sulfide and acetylene at 300–400 °C was 153 kJ mol^{-1}.[10] The reaction is influenced by the surface acidity of γ-Al_2O_3. The presence on the catalyst surface of weak acid centres, probably electron-accepting, is necessary for the formation of thiophene. Strong proton centres promote appreciable coke formation, which results in a rapid loss of activity by the catalyst.[11]

In the search for a possible increase in the activity of γ-Al_2O_3 in the temperature range 350–450 °C, a study was made of the influence of La, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, and Zn oxides.[12] Catalysts containing 0.5–2.5 mass% of Cr, Co, and Ni oxides showed the highest activity. In terms of their activity in the formation of thiophene from acetylene and hydrogen sulfide, the catalysts can be arranged in the sequence Cr_2O_3, Al_2O_3 > Co_3O_4, Al_2O_3 > NiO, Al_2O_3 > Al_2O_3. An increase in the content of the additives leads to an increase in the rate of formation of side products, in particular of the condensation of acetylene. The introduction of promoting oxides increases the activity of γ-Al_2O_3 in reactions involving the elimination of hydrogen from ethanethiol and the redistribution of hydrogen, the catalyst with added Cr_2O_3 showing the highest activity.

The dependence of the activity of a two-component catalyst on the structure of the *d* electron shell of the constituent ions has two peaks.[12] The Al, Cr and Al, Co catalysts show the maximum activity, their ions having the d^3, d^6, and d^7 electronic configurations. The introduction of ions with the d^8, d^9, and d^{10} electron shells probably hinders the activation of hydrogen sulfide molecules, which do not tend to form a dative bond, and enhances the activation of acetylene molecules, which increases the rate of formation of high-molecular-mass products on the catalyst surface. The low activity of the catalyst containing Ti^{4+} and Fe^{3+} has been explained[12] in terms of the zero stabilisation energy of ions with d^0 and d^5 configurations.

When the acetylene–hydrogen mixture containing 30 vol.% of acetylene was used (490–500 °C, space velocity v_{sp} = 300 to 320 h^{-1} with respect to acetylene, and H_2S : C_2H_2 = 1), thiophene was obtained on γ-Al_2O_3 in 16.4% yield.[13] The introduction of chromium oxide into aluminium oxide increased the rate of heterocyclisation: the yield of thiophene increased by a factor of 1.6. At the same time, the content of acetylene rose by a factor of 10 and that of ethane by a factor of 2. Under these conditions, the amount of coke diminished by a factor of 2. The dimerising effect of the aluminium oxide–chromium oxide catalyst was manifested by an increase in the yield of C_4 hydrocarbons by a factor of almost 2. The addition of lanthanum and potassium oxides to the aluminium oxide–chromium oxide catalyst increased the hydrogenating activity and diminished coke formation. The highest yield (26.3%) of thiophene from the acetylene–hydrogen mixture was obtained in the presence of the 5% Cr_2O_3–95% γ-Al_2O_3 catalyst.[13]

III. Interaction of C_4 hydrocarbons with hydrogen sulfide

Thiophene has been obtained mainly from C_4 olefins and hydrogen sulfide over various catalysts containing chromium or molybdenum oxides on aluminium oxide, bauxite, or silica gel.[1] The reaction is slightly endothermic and can be carried out in a flow system. However, the catalyst requires periodic regeneration with air. Since this entails a large exothermic effect and an increase in temperature, it is more convenient to employ a catalyst in a fluidised bed. This diminishes the temperature rise during regeneration.

Thiophene has been obtained in a high yield from hydrogen sulfide and n-C_4 hydrocarbons.[14] The yield of thiophene from butenes is higher than from n-butane. Thus the yields of thiophene were 31.2%, 52.9%, and 55.4% from butane, but-1-ene, and but-2-ene respectively in the presence of the 5% SiO_2–10% MoO_3–85% Al_2O_3 catalyst (590 °C, H_2S : hydrocarbon = 1.6:1.8, v_{sp} = 1.5–1.7 h^{-1}).

An effective aluminium oxide–chromium oxide catalyst with oxide additives was selected for the reaction of butane, butene, or butadiene with hydrogen sulfide.[16] It was shown[15,16] that the γ-Al_2O_3 carrier exhibits mainly a cracking activity and a weak heterocyclising activity, whereas chromium oxide exhibits dehydrogenating, hydrogenating, heterocyclising, and cracking properties. The following reactions take place on the aluminium oxide–chromium oxide catalyst when butane interacts with hydrogen sulfide: heterocyclisation with formation of thiophene, dehydrogenation with formation of alkenes and alkadienes, cracking with formation of C_1–C_3 hydrocarbons, and coke formation. By introducing the lanthanum oxide[15] and potassium oxide[16] additives into the aluminium oxide–chromium oxide catalyst, it is possible to increase its heterocyclising and dehydrogenating activities and to weaken its cracking and coke forming functions. Potassium oxide also increases the stability of the catalyst. By selecting the concentrations of the components, the optimum composition of the polyfunctional catalyst (mass%) was found: 5 Cr_2O_3, 5 La_2O_3, 1 K_2O, and 89 γ-Al_2O_3.[16] The introduction of lanthanum and potassium oxides into the aluminium oxide–chromium oxide catalyst increased the yield of thiophene by a factor of 1.4–1.75 and diminished the formation of C_1–C_3 hydrocarbons by a factor of 1.2–1.5 and the deposition of coke by a factor of 1.5–2.8 (Table 1).

It has been shown that the heterocyclisation, dehydrogenation, and cracking reactions proceed on the same catalyst active centres. The cracking functions can be suppressed to a slight extent by introducing alkaline additives.[17] Under optimum conditions in the interaction of C_4 hydrocarbons with hydrogen sulfide in the presence of the catalyst comprising chromium, lanthanum, potassium, and aluminium oxides, thiophene was formed in

Table 1. The interaction of hydrogen sulfide with C_4 hydrocarbons in the presence of chromium-containing catalysts (according to the data of Ryashentseva et al.[18]).

Initial hydrocarbon	Catalyst mass%	T/°C	Yield relative to C_4 passed through system (%)				
			of thiophene (rel to theoretical)	C_1-C_3	C_4H_8	C_4H_{10}	coke
Butane	5 Cr_2O_3, 95 Al_2O_3	580	12.5	45.7	8.3	–	3.3
	5 Cr_2O_3, 5 La_2O_3, 1 K_2O, 89 Al_2O_3	580	21.8	39.7	11.0	–	1.3
But-1-ene	5 Cr_2O_3, 95 Al_2O_3	500	21.7	31.2	–	6.0	6.5
	5 Cr_2O_3, 5 La_2O_3, 1 K_2O, 89 Al_2O_3	500	37.9	20.4	–	8.0	2.3
Butadiene	5 Cr_2O_3, 95 Al_2O_3	500	21.9	13.9	27.1	9.2	6.4
	5 Cr_2O_3, 5 La_2O_3, 1 K_2O, 89 Al_2O_3	500	30.6	9.2	27.1	8.9	4.2

40%–55% yield relative to the hydrocarbon passed through the system. Under conditions where this catalyst was used continuously, the yield of thiophene from butane and hydrogen sulfide fell from 37%–40% in the first 2–3 h to 23% in the next 7 h. The conditions for the regeneration of the catalyst after its use for 1, 2, and 3 h were found; the regeneration time is equal to the contact time.[17,18]

Thermodynamic calculations for the reactions involving the formation of thiophene from n-butane, but-1-ene, *cis*- and *trans*-but-2-enes, buta-1,3-diene, and hydrogen sulfide, taking into account the extent of side reactions,[19] made it possible to determine the equilibrium constants for these reactions in the temperature range 300–1000 K and also to calculate the equilibrium yields of thiophene for the stoichiometric and excess amounts of hydrogen sulfide relative to the hydrocarbon at 700–900 K. In order to compare the experimental and calculated equilibrium yields of thiophene in the presence of the Cr, La, K, Al catalyst, experiments were performed with [the determination] of the material balance of the products of the interaction of C_4 hydrocarbons and hydrogen sulfide. The experimental yields of thiophene obtained by the reaction of butane, but-1-ene, and buta-1,3-diene with hydrogen sulfide were 60%, 70%, and 90% respectively relative to the calculated equilibrium yield (taking into account side reactions).[19]

Certain data concerning the synthesis of thiophene from alkenes and alkadienes have been published in Japanese patents.[20,21] In the presence of the 12 Cr_2O_3–5 K_2O–83 Al_2O_3 catalyst (compositions in mass%) at 500 °C and for a contact time of 8.8 s, 26% of thiophene was formed from but-1-ene and hydrogen sulfide in the presence of nitrogen (molar ratios 1 : 2 : 4).[20] In the presence of the V_2O_5–Al_2O_3 catalyst at 410 °C, 49.7% of thiophene was obtained from buta-1,3-diene and hydrogen sulfide.[21]

The interaction of hydrogen sulfide with a butane–butene fraction (BBF) having the composition (mass%) 0.9 C_2-C_3, 11.3 iso-C_4H_8, 22.9 n-C_4H_8, 40.5 iso-C_4H_{10}, 23.2 n-C_4H_{10}, and 1.2 C_5 hydrocarbons has been investigated.[22] The reaction was carried out in a reactor with a vibrofluidised bed of a catalyst comprising Cr, La, K, and Al oxides (Cr, La, K, Al catalyst) at temperatures in the range 400–600 °C, with v_{sp} = 100–700 h^{-1}, and for the component ratio H_2S : BBF = (0.5–5.0) : 1. The yield of thiophene was higher than in the reactor with a stationary catalyst bed. The use of a gradient-free reactor with forced fluidisation facilitates the measurement of the rate of reaction in the initial instants of the employment of the catalyst, which is particularly important when catalysts with a variable activity are used.[22]

The synthesis of thiophene in the presence of a catalyst in which lanthanum oxide has been replaced by a mixture of lanthanide oxides may be of interest from the practical point of view. In the presence of the catalyst having the composition (mass%) 5 Cr_2O_3, 1 K_2O, 5 Ln (2.7 CeO_2, 1.3 La_2O_3, 0.75 Nd_2O_3, and 0.25 Pr_6O_{11}), and 89 Al_2O_3, the interaction of hydrogen sulfide with BBF was investigated and it was shown that the effectiveness of the reaction in a vibrofluidised bed is higher than in a stationary bed.[23,24] The corresponding data are presented in Table 2.

Table 2. The interaction of hydrogen sulfide with the butane–butene fraction (BBF) over the Cr, Ln, K, Al catalyst (according to the data of Abramovich et al.[24]).

T/°C	v_{sp}/h^{-1}	H_2S : BBF (mol.%)	Yield of thiophene[a] relative to			
			n-butane		BBF	
			A	B	A	B
520	200	1.4	–	41.6	32.5	55.4
545	243	2.2	27.7[b]	75.0	–	–
562	128	1.7	–	84.1	44.8	71.7
565	123	2.7	–	88.1	–	–
580	153	2.7	66.8	–	46.2	76.8
595	216	2.2	49.7[b]	91.2	57.7	89.1
610	152	1.7	38.0	–	46.2	76.8
614	145	3.0	–	83.7	–	–

[a] A—in a stationary bed, B—in a vibrofluidised bed.
[b] For v_{sp} = 229 h^{-1}.

The best yield of thiophene (66.8% relative to the hydrocarbon passed through the system) in a stationary catalyst bed was achieved at 580 °C for v_{sp} = 153 h^{-1} and H_2S : BBF = 2.7. The yield of thiophene falls with increase in temperature. In a reactor with a vibrofluidised bed under similar conditions (595 °C, v_{sp} = 216–228 h^{-1}, H_2S : BBF = 2–2.2), the yield of thiophene reached 91.2% relative to n-butane passed through the system or 89.1% relative to BBF. Above 600 °C, the yield of thiophene in both stationary and vibrofluidised beds diminishes, which is apparently associated with the decomposition of the initial hydrocarbon. Gradient-free conditions with respect to temperature are achieved in a reactor with a vibrofluidised bed; the reaction takes place under isothermal conditions, where a higher equilibrium degree of conversion and lower equilibrium concentrations of the initial hydrocarbons than under adiabatic conditions are attained.[24]

The influence of modifying additives on the heterocyclising activity of the aluminium oxide–chromium oxide catalyst has been investigated in the reaction of BBF with hydrogen sulfide. Li, K, Rb, Cs, Sr, Cd, Be, Se, Ti, and Mo oxides were used as additives.[25] The content of butane and butene in the industrial BBF was 40%–50%. The reaction was carried out at 570–590 °C, at a space velocity of 100–500 h^{-1}, for a molar ratio H_2S : BBF = (1.5–3.0) : 1, and with a duration of the experiment of 60 min. The replacement of potassium oxide by lithium, rubidium and caesium oxides proved ineffective: the yield

of thiophene was appreciably lower than in the presence of the Cr, K, Al catalyst. The yield of thiophene relative to the n-C_4 hydrocarbon passed through the system in the presence of the Cr, K, Al catalyst promoted with selenium dioxide was 85.4%. Among lanthanide oxides, those of scandium, praseodymium, and gadolinium as well as that of indium proved to be the most effective promoting agents. Catalysts with added samarium and cerium oxides are of special interest, the yield of thiophene in the presence of the latter attaining 85%–90%. In order to carry out the reaction in a fluidised catalyst bed, the mechanically strong γ-Al_2O_3 in the form of spherical pellets was employed. In the presence of the catalysts (the compositions are in mass%), $15.5\,Cr_2O_3-1.9\,K_2O-4.5\,In_2O_3-78.1\,\gamma$-$Al_2O_3$ and $14.8\,Cr_2O_3-2.0\,K_2O-4.9\,Sm_2O_3-78.3\,Al_2O_3$, the yields of thiophene (relative to the n-C_4 hydrocarbon passed through the system) were 71.6% and 66.0% respectively. However, the activity of these catalysts was not higher than that of the Cr, K, Ln, Al catalyst.[24]

When a zeolite was used as a carrier, the chromium catalysts had a low activity in the reaction of BBF with H_2S.[25] Catalysts based on type A zeolites in both the sodium- and calcium-forms proved to be completely inactive. The low activity of the chromium oxide–zeolite catalyst can be accounted for by the discrepancy between the dimensions of the window-channels and the dimensions of the molecules of the initial compounds and products.

Thiophene has also been obtained on sulfide catalysts. The properties of the aluminorhenium sulfide [aluminium sulfide–rhenium sulfide?] catalysts have been investigated in relation to the reaction of n-butane with hydrogen sulfide.[26] Rhenium sulfide Re_2S_7 has a high catalytic activity, for example in the hydrogenation of sulfur- and nitrogen-containing heterocyclic compounds.[27] In contrast to the chromium-containing Cr, La, K, Al and Cr, Ln, K, Al catalysts, carbon disulfide (12%) was obtained together with thiophene (14%) in the presence of a H_2S-treated catalyst comprising 11% Re and 89% γ-Al_2O_3 [580 °C, $v_{sp} = 250\ h^{-1}$, H_2S : n-C_4 = (3–5) : 1]. The formation of carbon disulfide can be explained by the interaction of sulfur with the carbon produced as a result of the cracking of the hydrocarbons on the catalyst. The source of sulfur may be both the surface of the sulfided catalyst and the decomposition of hydrogen sulfide under the catalytic conditions. This is confirmed by the increase to 24% of the yield of carbon disulfide with increase in the molar ratio of H_2S and n-butane to 9. The yield of thiophene also increases under these conditions (to 21%). These data indicate indirectly the formation of thiophene and carbon disulfide on the same catalyst active centres.

A multistage mechanism has been proposed for the formation of thiophene from butadiene and hydrogen sulfide in the presence of sulfide catalysts.[28] It is postulated that butadiene interacts with the surface sulfur in the slow stage. This is followed by the resulfidation of the catalyst by the sulfur from the reaction medium and the restoration of the stationary composition of the surface. Sulfided Cr and Mo oxides as well as Re_2S_7 were used as the catalyst. The activity of the catalyst was determined by a pulse method at 400–500 °C for a contact time of 1.2–3 s using helium as the diluent gas. It was postulated that the surface becomes coated with sulfur as a result of the treatment of the catalyst with hydrogen sulfide before the start of the experiment. The resulfidation stage is not rate-limiting, the removal of sulfur from the surface by butadiene with formation of thiophene occurring most slowly. The most active catalysts contain sulfur weakly bound to the surface.[28]

IV. Interaction of C_5 hydrocarbons with hydrogen sulfide

There exist patent data concerning the synthesis of alkylthiophenes by the reaction of C_5 alkadienes with hydrogen sulfide in the presence of aluminium oxide–chromium oxide catalysts.[5] Various multicomponent catalysts have been compared in the synthesis of 2-methylthiophene by the reaction of piperylene with hydrogen sulfide.[29] Under optimum conditions [480–500 °C, $v_{sp} = 0.5-0.7\ h^{-1}$, $H_2S:C_5 = (2-4):1$], the yield of 2-methylthiophene in the presence of the Cr, K, Al catalyst was 35 to 40 mass%. The catalyst was regenerated with a 1 : 1 air–nitrogen mixture in order to remove coke, after which it was exposed to a stream of hydrogen.[30] The catalytic activity increases with increase in the temperature of the preliminary treatment of the catalyst with hydrogen up to 600 °C and at a space velocity up to 200 h^{-1}. The effect obtained has been explained by the enhancement of the desorption of water formed as a result of the reduction of Cr^{6+} by hydrogen.[31]

Preliminary treatment of the Cr, K, Al catalyst with hydrogen sulfide increases its activity and selectivity as a consequence of the interaction of sulfur with the surface.[32] In order to elucidate the nature of the bond between sulfur and the catalyst [Cat(S)], the latter was treated with hydrogen sulfide for 5–90 min at 200–500 °C and a space velocity of 600–700 h^{-1}. The influence of this treatment on the activity of the catalyst was estimated from the yield of 2-methylthiophene from H_2S and piperylene at 500 °C, $v_{sp} = 2.7\ h^{-1}$, and $H_2S:C_5 = 2.1-2.2$.[33] The kinetic model of the process can be described by the equations presented in Scheme 1.

Scheme 1

$$H_2S \rightleftharpoons H_2 + S \quad (1)$$

$$Cat(S)S + C_5H_8 \longrightarrow C_5H_6S + H_2 + CatS \quad (2)$$

$$C_5H_8 \longrightarrow \text{coke} \quad (3)$$

$$C_5H_6S \longrightarrow \text{coke} \quad (4)$$

$$C_5H_8 \longrightarrow \text{gas} \quad (5)$$

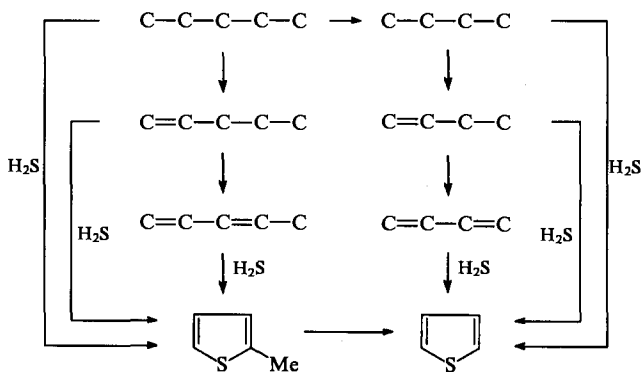
Hydrogen sulfide dissociates in the first stage at a temperature above 400 °C. This is confirmed by the fact that treatment of the catalyst surface with hydrogen sulfide at lower temperatures does not increase the activity of the catalyst. Thiophene is formed mainly as a result of the interaction of piperylene with the sulfur chemisorbed on the sulfided catalyst.[33]

In the presence of an effective catalyst having the composition (mass%)[34] 18 Cr_2O_3, 4 K_2O, and 78 Al_2O_3 under optimum conditions [470–500 °C, $v_{sp} = 0.5-0.7\ h^{-1}$, $H_2S:C_5 = (2-1):1$], 2-methylthiophene was obtained from hydrogen sulfide and piperylene in 62% yield, while 3-methylthiophene was obtained from 2-methylbut-2-ene and hydrogen sulfide in 75% yield.[29–33] 3-Methylthiophene was obtained in 53% yield from isoprene and hydrogen sulfide at 500 °C and a gas flow rate $v_{mass} = 0.34\ h^{-1}$ [$H_2S:C_5 = (4-5):1$] in the presence of a catalyst having the composition (mass%) 5 Cr_2O_3, 5 La_2O_3, 1 K_2O, and 89 Al_2O_3.[16] 2-Methylthiophene was obtained in 43.2% yield from piperylene and hydrogen sulfide under the same conditions.[17] It has been stated that aluminium oxide (77.5 mass%–78.5 mass%) with a specific surface of 150 to 170 $m^2\ g^{-1}$ is used to increase the activity and mechanical strength of the catalyst the composition of which includes Cr_2O_3 (14.5 mass%–15.5 mass%), K_2O (2 mass%–2.5 mass%), and lanthanides (4.5 mass%–5 mass%).[35]

The principal disadvantage of the synthesis of 2-methylthiophene from piperylene and hydrogen sulfide is the comparatively short operating lifetime of chromium-containing catalysts. For example, the catalysts (compositions in mass%) $18\,Cr_2O_3-4\,K_2O-78\,Al_2O_3$ (Cr, K, Al) and $5\,Cr_2O_3-1\,K_2O-5\,La_2O_3-89\,Al_2O_3$ (Cr, K, La, Al) have a high initial activity: the yields of 2-methylthiophene in their presence are respectively 60 mass% and 40 mass% relative to the piperylene passed through the system.[36] However, after they have been used for only 3–4 h, their activity begins to fall and after 6–7 h the yields diminish to 12 mass% and 22 mass% respectively. The less marked decrease in the activity of the Cr, K, La, Al catalyst is apparently associated with the presence of lanthanum oxide in

the latter. The experiments were performed at 500 °C, v_{sp} = 0.3 to 0.5 h^{-1}, and $H_2S:C_5$ = (2–4):1. These catalysts have a running-in period of 1.5–2 h. Their activity is fully restored after regeneration with an air–nitrogen mixture containing 10 vol.%–11 vol.% of oxygen at 550–580 °C for 5–7 h. After 8–10 regeneration cycles, the activity of the catalyst diminishes somewhat and then stabilises. Preliminary treatment of the catalyst with hydrogen makes it possible to increase its operating lifetime to 150 cycles at a constant activity and to increase the yield of 2-methylthiophene by a factor of 1.5–2 (35%–50%).[36]

The formation of thiophenes from diene hydrocarbons (butadiene, isoprene, and piperylene) and hydrogen sulfide has been investigated in the presence of the sulfided oxides and sulfides of metals in Periods 3–6 in the absence of a carrier. The experiments were performed at 200–550 °C, for a contact time of 1.2–6 s, and for a 1:1 molar ratio of the diene and hydrogen sulfide in the presence of sulfided Fe, V, Mo, Co, Cr, Mn, Ni, Cu, Ti, Zr, Mg, Si, and Al oxides as well as Re, Pd, Pt, and W sulfides. Catalysts containing reactive sulfur weakly bound to the catalyst surface were the most active. It has been suggested that thiophenes are formed by a multistage mechanism. This is confirmed by the fact that thiophene can be obtained both from a diene–hydrogen mixture and when only the diene is passed over the sulfided catalyst surface. In the latter case, thiophene cannot be formed without the participation of the sulfur in the catalyst. The rates of interaction of the diene with the catalyst sulfur and of the synthesis of thiophene from the diene–hydrogen sulfide mixture are similar. Consequently hydrogen sulfide does not participate directly in the formation of thiophene and is required to maintain a stationary state of the sulfide catalyst surface. The yields of 2- and 3-methylthiophenes from piperylene and isoprene were respectively 55.0 mol% and 45.0 mol% (relative to the C_5 hydrocarbon passed through the system) in the presence of sulfided vanadium oxide at 420 °C and for a contact time of 3 s. The activity of the catalyst was estimated from the specific rate of formation of thiophenes, which was calculated in accordance with a first order equation and was referred to the unit catalyst surface. The most active catalysts are Re, V, Fe, Mo, and platinum metal sulfides. The activation energies for the formation of thiophenes from various dienes are similar.[37,38]



In order to estimate the activity of C_5 hydrocarbons of different structure in heterocyclisation processes, the interaction of n-pentane, pent-1-yne, isopentane, 2-methylbut-2-ene, and isopentenes with hydrogen sulfide in the presence of a Cr, K, Ln, Al catalyst was investigated.[39–42] The comparison was carried out at 550 °C, v_{sp} = 0.3–0.9 h^{-1}, and $H_2S:C_5$ = 2. The presence of CO_2 and N_2 in the reaction medium influences the selectivity of the catalyst. Under a CO_2 atmosphere, the yield of the heterocyclisation products increases and the cracking function of the catalyst is weakened. Under these conditions, the yield of liquid products increases from 60% to 98%. In terms of their capacity to undergo heterocyclisation in the presence of the Cr, K, Ln, Al catalyst, C_5 hydrocarbons can be arranged in the sequence n-pentane < pent-1-yne < isopentenes < isopentane < 2-methylbut-2-ene. Hydrocarbons with the iso-structure exhibit a higher reactivity in the formation of methylthiophenes than hydrocarbons with the normal structure. The yield of 2-methylthiophene from n-pentane and hydrogen sulfide is 55.3%, while the yields of 3-methylthiophene from isopentane and 2-methylbut-2-ene are 74.9 mass% and 79.5 mass% (relative to the hydrocarbon passed through the system) respectively. The heterocyclising properties of rhenium oxides and sulfides deposited on aluminium oxide are manifested in the interaction of n-pentane with hydrogen sulfide.[41–43] The yield of 2-methylthiophene at 550 °C, v_{sp} = 0.8–0.9 h^{-1}, and H_2S: n-C_5 = 2 in the presence of 5% of rhenium in the catalyst did not exceed 8%.

Under the same conditions, thiophene and 3-methylthiophene are formed respectively in yields of 19.2% and 12.1% (relative to the n-pentane passed through the system) together with 18.8% of 2-methylthiophene in the presence of the catalyst (composition in mass%) 2 Re_2O_7–2 Cr_2O_3–5 Ln–81 Al_2O_3. The catalytic reaction mixture contains also up to 10% of CS_2. Carbon dioxide and nitrogen have different effects on the selectivity of the reaction. In nitrogen, 2–3 times more of methylthiophene is formed than under a CO_2 atmosphere. 3-Methylthiophene can be produced as a result of the interaction of carbon disulfide with isopentane, which is obtained as a result of the isomerisation of n-pentane.[41]

V. The mechanism of the formation of thiophenes from C_4–C_5 hydrocarbons and hydrogen sulfide

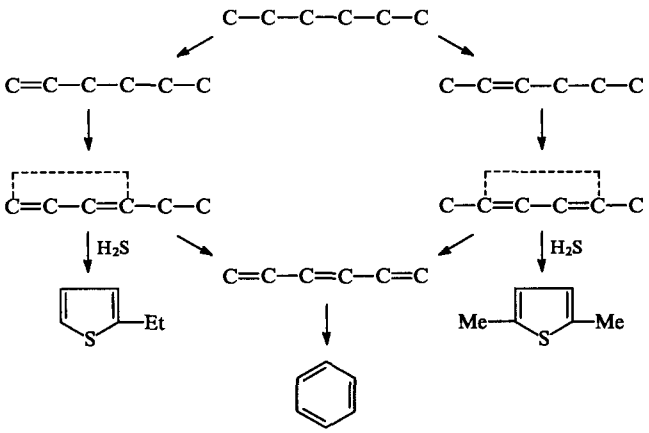
The mechanism of the formation of 2-methylthiophene and thiophene in the presence of the Cr, La, K, Al catalyst has been investigated by the isotope-kinetic method using ^{14}C-labelled molecules.[44,45] Measurement of the concentration and of the molar radioactivity of the reaction products when n-pentane is supplied together with a small amount of added n-pentane labelled with ^{14}C makes it possible to determine the rates of individual stages of the reaction in which both pentane and pentene participate. As a rule, these rates are calculated from the dependence of the molar radioactivity on the contact time. The proposed mechanism is presented in Scheme 2.

Scheme 2

2-Methylthiophene is mainly formed consecutively from hydrogen sulfide and n-pentane via dehydrogenation products—pentenes and pentadiene. Thiophene is also formed via the hydrogenation products—butene and butadiene, with subsequent ring closure at the sulfur atom. Butane is obtained by the cleavage of a C–C bond in n-pentane. A small proportion of 2-methylthiophene is a product of the interaction of n-pentane and pentene with hydrogen sulfide, while thiophene is also partly formed by the reaction of hydrogen sulfide with n-butane or butene and by the demethylation of 2-methylthiophene.

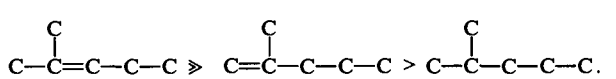
VI. Interaction of C_6–C_8 hydrocarbons with hydrogen sulfide

In the interaction of C_6 hydrocarbons with hydrogen sulfide in the presence of chromium oxide catalysts, the heterocyclisation is accompanied by the dehydrocyclisation reaction with formation of benzene.[46] The dehydrocyclisation of n-hexane to benzene in the presence of chromium oxide catalysts has been investigated very widely. The reaction proceeds via the intermediate formation of hexenes, hexadienes, and trienes.[47] However, one cannot rule out the possibility that the dehydrocyclisation is suppressed by the hydrogen sulfide present in the system. Thus the interaction of 2,3-dimethylbuta-1,3-diene with hydrogen sulfide in the presence of the Cr, K, Al catalyst leads to the formation of only 3,4-dimethylthiophene, while dehydrocyclisation hardly occurs.[34] At 500 °C, v_{mass} = 0.2–0.3 h^{-1} and $H_2S:C_6$ = 2–1 for a reaction time of 1.25 h, the yield of 3,4-dimethylthiophene is 56%–60%.[48] The interaction of n-hexane, 2-methylpentane, hex-1-ene, hex-2-ene, hex-1-yne,



2-methylpent-1-ene, 2-methylpent-2-ene, 4-methylpent-1-ene, 4-methylpent-2-ene, and 2,3-dimethyl butane with hydrogen sulfide has been investigated in the presence of a Cr, Ln, K, Al catalyst under comparable conditions (550 °C, v_{mass} = 0.8 h^{-1}, and $H_2S:C_6$ = 4:1).[43,46] The heterocyclisation of normal C_6 hydrocarbons proceeds with formation of 2-ethylthiophene and 2,5-dimethylthiophene. In terms of their reactivity, C_6 alkanes, alkenes, and alkynes can be rearranged in the following sequence:

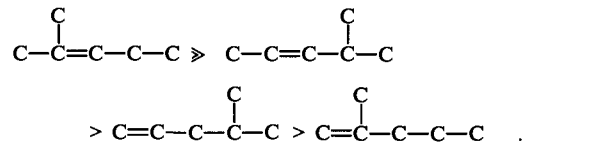
$$C-C-C-C-C-C \leqslant C-C=C-C-C-C$$
$$\simeq C=C-C-C-C-C < C\equiv C-C-C-C-C\ .$$



Alkynes show the highest reactivity in the heterocyclisation reaction and are followed by alkenes and alkanes. With increase in the reactivity of the hydrocarbon, the fraction of 2,5-dimethylthiophene in the reaction products increases compared with 2-ethylthiophene, i.e. ring closure at the sulfur atom involves the 2–5 carbon atoms to a greater extent than the 1–4 carbon atoms. It is noteworthy that, on raising the reaction temperature to 475 °C, n-hexane undergoes dehydrocyclisation with formation of benzene, together with heterocyclisation.

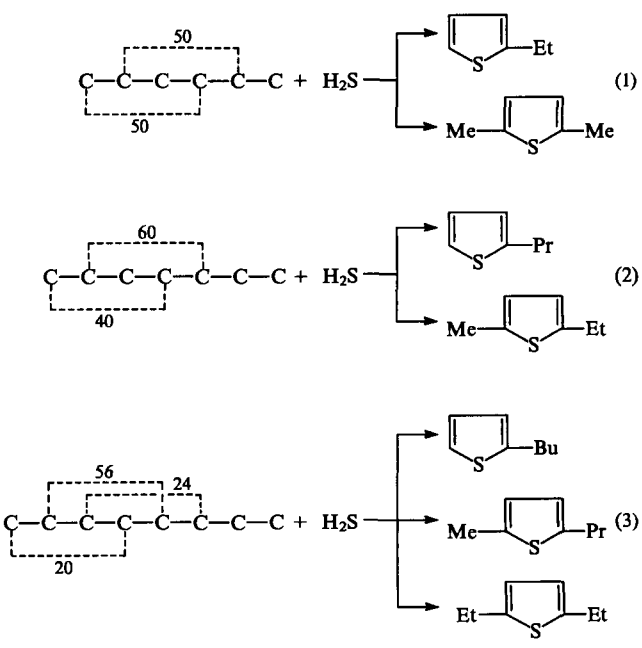
On the basis of data concerning the mechanism of the formation of 2-methylthiophene from hydrogen sulfide and n-pentane, according to which the reaction proceeds via alkenes and alkadienes,[44,45] one can postulate that 2,5-dimethylthiophene and 2-ethylthiophene are formed by a similar mechanism (Scheme 3).

Scheme 3



In the synthesis of dialkylthiophenes by the reaction of C_6 hydrocarbons having the iso-structure with hydrogen sulfide, there is virtually no dehydrocyclisation. In terms of their tendency to undergo heterocyclisation, the C_6 iso-hydrocarbons investigated can be arranged in the sequence

The yields of 2,4-dimethylthiophene from the above compounds are 40.2%, 23.4%, and 11.8% respectively (relative to the hydrocarbon passed through the system).



The position of the methyl group in α-alkenes hardly affects the yield of 2,4-dimethylthiophene and influences only the yield of 2-methylthiophene. The latter is a product of the interaction of hydrogen sulfide with pentane, which is formed owing to the dissociation of a C–C bond in the alkene. Thus the yield of 2-methylthiophene in the interaction of hydrogen sulfide with 4-methylpent-1-ene is twice as great as in the interaction with 2-methylpent-1-ene. The presence of a methyl group in β-alkenes promotes heterocyclisation. The yield of 2,4-dimethylthiophene is 40.2% from 2-methyl-pent-2-ene and 26.4% from 4-methylpent-2-ene.[43,46]

Thus, C_6 α- and β-isoalkenes with a methyl group in different positions in the hydrocarbon chain can be arranged in the following sequence in terms of their tendency to undergo the heterocyclisation reaction (the yields of 2,4-dimethylthiophene are 40.2%, 26.4%, 23.4%, and 22.4% respectively):

Thermodynamic analysis showed that experimental yields of the products of the heterocyclisation and dehydrocyclisation of n-hexane at 820 K are 82.8% (alkylthiophenes) and 81% (benzene), while at 750 K the corresponding yields are 24.4% and 10% respectively relative to the equilibrium yields.[49] In the interaction of C_6 normal alkenes and isoalkenes with hydrogen sulfide at 820 K, the heterocyclisation reaction virtually reaches equilibrium and the yields of ethyl- and dimethylthiophenes are 81.7%–97.8% of the equilibrium values (taking into account side reactions). The reactivity of n-alkanes, which give rise to alkylthiophenes and aromatic hydrocarbons on interaction with hydrogen sulfide, depends on their chain length.[50] In the presence of a Cr, Ln, K, Al catalyst at 450 °C, v_{mass} = 0.8 h^{-1}, and H_2S : n-C_6(n-C_7, n-C_8) = 2 under a nitrogen atmosphere, mainly 2-ethylthiophene and 2,5-dimethylthiophene are obtained from n-hexane, 2-propylthiophene and 2-methyl-5-propylthiophene are obtained from n-heptane and 2-butylthiophene, 2,5-diethylthiophene, and 2-methyl-5-propylthiophene are obtained from n-octane [reactions (1)–(3), Scheme 4]. Dehydrocyclisation results in the formation of benzene and toluene respectively from normal hexane and heptane, while ethylbenzene and *o*-xylene are formed from n-octane. The numerals in Eqns (1)–(3) (Scheme 4) represent the percentage contributions of the ring closure reactions at the sulfur atom involving the 1–4, 2–5, and 3–6 carbon atoms. Heterocyclisation with formation of the thiophene ring, proceeds as shown in relation to n-hexane, with ring closure at the sulfur atom involving the carbon atoms in the 1- and 4-positions or the 2- and 5-positions. With increase in the chain length of the alkane from C_6 to C_7, the fraction of alkylthiophenes formed via ring closure at the sulfur atom involving the carbon atoms in the 2- and 5-positions increases. In the case of n-octane, the 1–4 and 2–5 heterocyclisations are accompanied also by ring closure at the sulfur atom involving the carbon atoms in the 3- and

Scheme 4

6-positions. With increase in the chain length of the n-alkane, the yield of the heterocyclisation product diminishes, while the yield of the dehydrocyclisation product increases. The molar ratios of alkylthiophenes and aromatic hydrocarbons formed in the interaction of hydrogen sulfide with n-hexane, n-heptane, and n-octane are respectively 5.5, 1.25, and 0.7.

As shown for the interaction of hydrogen sulfide with n-hexane, the alkylthiophene and benzene formation reactions probably include a common stage involving the dehydrogenation of alkanes to unsaturated hydrocarbons. The longer the n-alkane chain, the more readily the unsaturated hydrocarbons obtained undergo closure to an aromatic ring compared with ring closure at the sulfur atom with formation of the thiophene ring.[50] The different abilities of n-alkanes (depending on the chain length) to enter into heterocyclisation or dehydrocyclisation reactions in the presence of chromium oxide catalysts may have to be taken into account in considering the genesis of petroleum containing both aromatic and thiophene oxide compounds.

VII. Physicochemical properties of chromium-containing oxide catalysts

The active chromium-containing heterocyclisation catalysts have been investigated by various physicochemical methods.[51–53] X-Ray diffraction analysis of the Cr, La, K, Al catalyst after the heterocyclisation reaction has been carried out in its presence (560 °C, v_{mass} = 225 h^{-1}, $H_2S:C_n$ = 2.0, yield of thiophene 33.2% after 3 h) demonstrated the presence of the crystalline γ-Al_2O_3 phase. The addition of potassium and lanthanum oxides does not affect the phase composition of the aluminium oxide–chromium oxide catalyst.[51] The formation during the heterocyclisation process of a solid solution of Cr_2O_3 in Al_2O_3, accompanied by an increase in the unit cell parameter from 7.90 to 7.95 Å, is influenced by the Cr_2O_3 content and the reaction conditions.

In order to account for the effect of added potassium and lanthanum oxides on the heterocyclising properties of the aluminium oxide–chromium oxide catalyst, the optical and EPR spectra of the oxidised and reduced specimens were analysed.[53–55] The catalysts were reduced at a pressure of 200–300 Torr and a temperature of 580 °C for 1 h. The optical and EPR spectra were obtained for the same specimens. After the catalysts had been treated at 500–700 °C in air or under a helium atmosphere, Cr^{6+}, Cr^{5+}, and Cr^{3+} ions were detected in them. The optical spectra of the reduced catalyst contain three absorption maxima: at 22 300, 16 200, and 10 200 cm^{-1}. The absorption maxima at 22 300 and 16 200 cm^{-1} are typical for aluminium oxide–chromium oxide catalysts. Octahedrally coordinated Cr^{3+} ions are responsible for them. The 10 200 cm^{-1} maximum is due to square-pyramidal Cr^{3+} ions. This maximum vanishes after the adsorption of water and hydrogen sulfide molecules. Hence it follows that these ions are in fact the centres for the adsorption of H_2O and H_2S. The adsorbed molecules enter the first coordination spheres of the above ions, increasing their coordination to octahedral.

It follows from analysis of the optical spectra of the reduced specimens that the nature of the spectra is independent of the lanthanum and potassium oxides added to the aluminium oxide–chromium oxide catalyst. On the other hand, the EPR spectra of the reduced catalysts do depend on these additives. They contain in all cases a broad asymmetric band, which results from superposition of signals due to the magnetically concentrated phase (β-phase) and the magnetically dilute phase (δ-phase) of the Cr^{3+} ions. In the spectra of the specimens containing added lanthanum and potassium oxides, the width of the band due to the β-phase (ΔH = 900 Oe) is much smaller than in the spectrum of the aluminium oxide–chromium oxide catalyst (ΔH = 1150 Oe). The additives influence the state of the Cr^{3+} ions in the catalyst.

Preliminary heat treatment of the specimens at 700 °C (the last stage of the preparation of the catalyst) increases the amount of chromium ions responsible for the appearance of the absorption maximum at 10 200 cm^{-1}, i.e. the surface square-pyramidal coordinated Cr^{3+} ions.

The above spectroscopic data for the Cr, La, K, Al catalysts agree with the results obtained for the aluminium oxide–chromium oxide catalyst for the dehydrogenation of alkanes.[53–55] The Cr, Ln, K, Al catalyst is active both in the heterocyclisation of hexane in the reaction with hydrogen sulfide and in the dehydrocyclisation of n-hexane to benzene. Both reactions proceed via common stages involving the dehydrogenation of alkanes to alkenes and alkadienes.[46]

The content of the lowest-valence chromium and lanthanide ions in the above catalyst was determined from the chemisorption of oxygen at 20 °C.[56] The Cr^{2+} ions are formed in the aluminium oxide–chromium oxide catalyst only on reduction above 300 °C, while at 500 °C their amount reaches a maximum.[57] The compositions of the dehydrogenating centres of the aluminium oxide–chromium oxide dehydrogenation and dehydrocyclisation catalysts include Cr^{2+} ions.[58] After the reduced catalysts have come into contact with O_2 at 20 °C, oxygen is first chemisorbed on the Cr^{2+} ions, but there is also a possibility of its chemisorption on the coordinatively unsaturated Cr^{3+} ions. In a reducing medium, under the conditions of the synthesis of 2-methylthiophene at 550 °C, the aluminium oxide–chromium oxide catalyst, without additives and with added potassium and lanthanum oxides, contains Cr^{2+} ions on which the dehydrogenation stages, common to heterocyclisation and dehydrocyclisation, most probably occur. Indeed, we find that (a) in the absence of Cr^{2+} ions the above reactions do not occur on the catalyst, (b) the number of active dehydrogenation centres, found from the curves for the poisoning of the catalyst with oxygen during the dehydrogenation of isopentane, agrees with the number of Cr^{2+} ions determined by titration with iron ammonium alum, and (c) the dehydrogenating and dehydrocyclising activities of the aluminium oxide–chromium oxide, aluminium oxide–chromium oxide–potassium oxide, and aluminium oxide–chromium oxide–calcium oxide catalysts increase in proportion to their Cr^{2+} content.

As in the dehydrocyclisation catalysts, in the heterocyclisation catalysts potassium oxide influences the productivity of the active centres because it alters the environment of the Cr^{2+} ion and its energetic characteristics. The lanthanum oxides in the aluminium oxide–chromium oxide catalyst also play the role of a promoting agent and not of the main active dehydrogenation component, although their amount is the same (5 mass%) as that of chromium oxide. Lanthanide ions in a low-valence state, with very powerful electron-donating properties and capable of functioning as dehydrogenation active centres, have been detected in the Cr, Ln, K, Al catalyst.[56]

It has been shown by X-ray photoelectron spectroscopy that the surface concentration of chromium on the 5% Cr_2O_3–95% Al_2O_3 catalyst decreases by a factor of two after the heterocyclisation reaction, whereas no change in the chromium concentration was observed after the addition of potassium and lanthanide oxides.[43] During the reaction, Cr^{6+} and Cr^{5+} are reduced mainly to Cr^{3+}.

It follows from the data obtained that the aluminium oxide–chromium oxide heterocyclisation catalysts promoted by potassium and lanthanide oxides contain low-valence chromium and lanthanide cations, which may form part of the composition of the catalyst active centres.[56] A study of the properties of the chromium ions in different oxidation states on the surfaces of chromium-containing catalysts by optical and EPR spectroscopy has been described in a review.[59]

Table 3. Catalytic synthesis of thiophenes by the reaction of C_2 and C_4-C_6 hydrocarbons with hydrogen sulfide in the presence of oxide catalysts.

VIII. Industrial methods of synthesis of thiophenes

The Pennwalt Corporation in the USA and the Croda Synthetic Chemicals, Ltd and Pennwalts Holland B.V in Europe are known to produce various thiophenes.[60] The requirement by the world market for thiophene in 1982 amounted to 1000–1400 tonnes.

The synthesis is based on the interaction of butene and butadiene with carbon disulfide (as a source of sulfur) in contact with methane or CO_2 at 500 °C in the presence of an 11% chromium oxide catalyst promoted by alkali metals (6% K_2CO_3). The catalyst is regenerated periodically to remove the coke deposit. This process can also be used to obtain 2- and 3-alkyl-thiophenes from C_6 hydrocarbons.[61]

A plant in which thiophene was produced from C_4 hydrocarbons and fused sulfur — the Socony-Vacuum process — began operating in the USA in the 1950s.[6] The process is carried out at temperatures up to 700 °C and atmospheric pressure. Apart from the high temperature, a disadvantage of this procedure is appreciable tar formation, etc.

Thiophene is obtained also from a mixture of butane, gaseous sulfur, and hydrogen sulfide in the presence of 19% Cr_2O_3–81% Al_2O_3 catalyst at 500 °C (yield: 49% after 168 h). The maximum conversion into thiophene is attained for a ratio H_2S : n-C_4H_{10} = 15 : 1. The temperature in the reactor is maintained by the reaction between sulfur and side products. The hydrogen evolved on dehydrogenation of n-butane reacts with sulfur to form hydrogen sulfide; this highly exothermic reaction compensates for lack of external heating. Corrosion of the reactor is thereby greatly reduced. The catalyst is regenerated periodically. The method makes it possible to increase the yield of thiophene compared with the Socony-Vacuum process, to reduce corrosion, and to diminish tar formation. By this procedure, one can obtain 2- and 3-methylthiophenes from the corresponding hydrocarbons.

There is a possibility of synthesising thiophenes from the gases generated in the semicoking of shale.[63] Apart from C_1–C_5 hydrocarbons, the semicoking gases contain also CO, CO_2, and hydrogen sulfide, the content of which can reach 5%–12%. At 650 °C in the presence of the hydrogen sulfide-treated Cr, La, K, Al catalyst, the yield of the liquid catalytic reaction mixture containing 71.3% of thiophene is 85%. This method of synthesis may prove promising in countries possessing deposits of shale raw material containing sulfur compounds.

* * *

One of the main tasks in modern petroleum processing is rational use of the hydrocarbon raw material and hydrogen sulfide. The employment of oxide catalysts makes it possible to obtain thiophene and alkylthiophenes by the heterocyclisation of C_2 and C_4–C_8 hydrocarbons with participation of hydrogen sulfide. Table 3 indicates the optimum conditions and compositions of the active heterocyclisation catalysts. The reaction of hydrogen sulfide with the acetylene-containing gas generated in electrocracking on γ-Al_2O_3 may be of practical interest. Thiophenes can be obtained in appreciable yields by the reaction of C_4–C_6 hydrocarbons with hydrogen sulfide in the presence of chromium-containing oxide catalysts. In order to increase the yield of thiophenes, it is useful to employ the butane–butene fraction and hydrogen sulfide and to carry out the reaction in a vibrofluidised bed. 2-Methylthiophene may be obtained (in a yield up to 68%) from hydrogen sulfide and piperylene, while 3-methylthiophene may be obtained (in 75% yield) from hydrogen sulfide and isopentane. The results obtained in the study of the interaction of hydrogen sulfide with C_6 hydrocarbons having the iso-structure also merit attention: 3,4- and 2,4-dimethylthiophenes have been synthesised in this way from 2,3-dimethylbutane and 2-methylpent-2-ene respectively. Thus processes involving the catalytic synthesis of thiophenes from a petrochemical raw material — hydrocarbons and hydrogen sulfide — can be used successfully to satisfy the increasing need for these heterocycles.

Spiro[2.4]hepta-4,6-dienes: synthesis and chemical reactions

L G Menchikov, O M Nefedov

Contents

I. Introduction	449
II. Methods of synthesis of spiro[2.4]hepta-4,6-dienes	449
III. Chemical reactions of spiro[2.4]hepta-4,6-dienes	458
IV. Conclusion	467

Abstract. Data on the chemistry of compounds of the spiro[2.4]hepta-4,6-diene series are surveyed and described systematically. The methods of their synthesis, the characteristic features of their reactivity, and their principal chemical reactions are examined. The applications of spiro[2.4]hepta-4,6-dienes in specific organic synthesis are noted. The bibliography includes 230 references.

I. Introduction

Compounds of the spiro[2.4]hepta-4,6-diene (SHD) series, the first representatives of which were synthesised only 40 years ago, have now become a class of chemical substances the interest in which is manifested from a wide variety of directions. Highly effective insecticides of the pyrethroid series[1–10] and new medicinal preparations[11,12] have been synthesised from these compounds. Methods have been proposed for the synthesis of a series of natural and biologically active compounds, in particular prostaglandins,[13] and polymeric materials of practical value have been obtained.[14–24] Furthermore, SHDs are interesting objects for the study of important problems in model organic chemistry such as that of spiroconjugation and complex formation.

SHD has a high degree of symmetry which, together with spiroconjugation, is responsible for a series of unusual chemical and physical properties. These have been investigated by means of a wide variety of instrumental[25–32] and quantum-chemical methods.[33–36]

Extensive data have now accumulated in the literature both on the synthesis of SHDs and on their chemical reactions and use in specific organic synthesis. However, there are no reviews in this field. The principal methods of synthesis of SHD and its derivatives and some of their chemical reactions of greatest synthetic interest are described systematically and examined below.

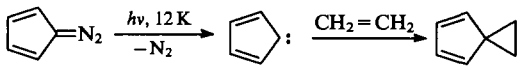
II. Methods of synthesis of spiro[2.4]hepta-4,6-dienes

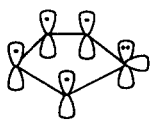
Spiro[2.4]hepta-4,6-diene was synthesised by Levina et al.[37] as early as 1955 by the reaction of cyclopentadiene with 1,2-dibromoethane on treatment with sodium in liquid ammonia, but its first derivatives were obtained only later in 1965 by Moss,[38] who developed the first method of synthesis of compounds of the SHD series. Moss's method, which is based on the reaction of diazocyclopentadiene (DACPD) with unsaturated compounds, led to the possibility of synthesising a wide variety of SHD derivatives, and initiated the vigorous study of these compounds. Since then, numerous SHD derivatives have been obtained and new methods of their synthesis have been developed.

The methods of synthesis of compounds of the SHD series described in the literature hitherto can be divided arbitrarily into two groups. The first includes methods for the construction of the SHD skeleton by the cyclomethylenation of double bonds (reaction of DACPD and its derivatives with olefins) and also the cyclomethylenation of the exocyclic double bond in fulvenes. The second group includes methods based on nucleophilic substitution (in particular alkylation and cyclialkylation†) and nucleophilic addition (addition of carbanions to Michael acceptors) reactions of the cyclopentadienyl anion generated as an intermediate. In addition, the formation of compounds of the SHD series, usually in the form of minor products, has been observed in certain photochemical and carbene reactions.

1. Interaction of diazocyclopentadienes with unsaturated compounds



DACPD and its derivatives are highly reactive compounds, which decompose photochemically with formation of free cyclopentadienylidene (CPDI).[39–41]

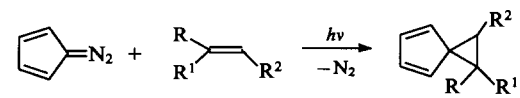


†Cyclialkylation is alkylation with formation of a new ring [see G L Mishchenko, K V Vatsuro *Sinteticheskie Metody Organicheskoi Khimii* (Synthetic Methods in Organic Chemistry) (Moscow: Khimiya, 1982) pp 400, 404].

An example of the catalytic decomposition of a substituted DACPD is also known.[42] The CPDI formed and its derivatives enter into reactions characteristic of carbenes, in particular they add to the C=C double bonds of unsaturated compounds, affording compounds of the SHD series in 10%–60% yields.

The reaction of free CPDI with ethylene, leading to SHD, has been detected in an $Ar-N_2O$ matrix at low temperatures (between 12 and 45 K).[43,44]

Since CPDI is an electrophilic carbene,[40,41,45–47] the rate of its addition, like that of other electrophilic carbenes,[40,41] to multiple bonds is retarded by electron-withdrawing substituents at the multiple bonds and is facilitated by electron-releasing substituents.[45,46] It is also noteworthy that, although CPDI has a triplet ground state,[40,41] nevertheless it reacts in an excited singlet state,[48] especially when it is generated photochemically, which also explains the stereoselectivity of its reactions involving addition to multiple bonds.[40,41,49]



The availability of DACPD, which can be readily obtained[50] in 70%–80% yields from cyclopentadiene (CPD) and toluene-*p*-sulfonyl azide in the presence of diethylamine at 0 °C, as well as the simplicity of its carbene decomposition, promoted the synthesis of an appreciable proportion of the SHD derivatives known at the present time precisely by this method (Table 1).

Table 1. The yields of SHD derivatives **1** in the reactions of diazocyclopentadiene with olefins.

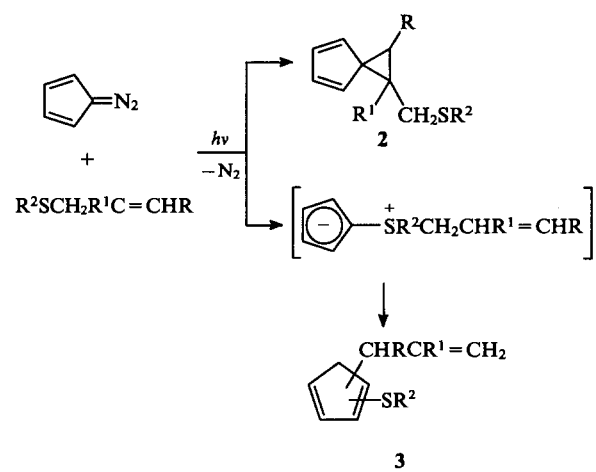
[a] In the reaction with tetramethylethylene, the yield of SHD is 35%.[38,51]
[b] The yield of SHD derivatives is not indicated.

The reaction is usually carried out in the presence of a (30–40)-fold molar excess of the initial unsaturated compound, its mixture with the DACPD being irradiated for several hours at 0–30 °C.

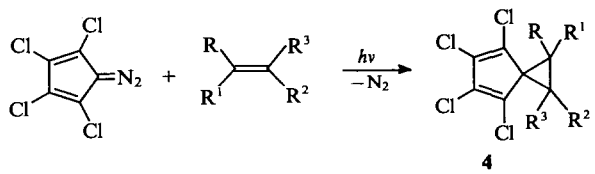


1

It is noteworthy that such reactions involve a side process in which the intermediate CPDI is inserted in different single bonds of the initial unsaturated acceptor.[55,59] For example, the insertion of CPDI in a C–H bond in the initial olefins leads to substituted cyclopentadienes.[59]

1 : 0.14–0.29

However, in the reaction of DACPD with allyl sulfides under similar conditions, the usual addition of CPDI to the double bonds is accompanied by the formation of unstable S ylides, which are subsequently converted into disubstituted cyclopentadienes (Table 2).[55]



3

Table 2. The yields of SHD derivatives **2** and disubstituted cyclopentadienes **3** in the reaction of diazocyclopentadiene with allyl sulfides.

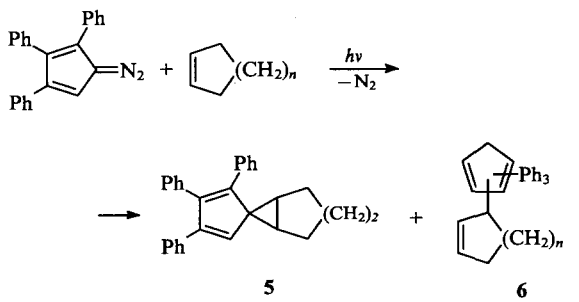
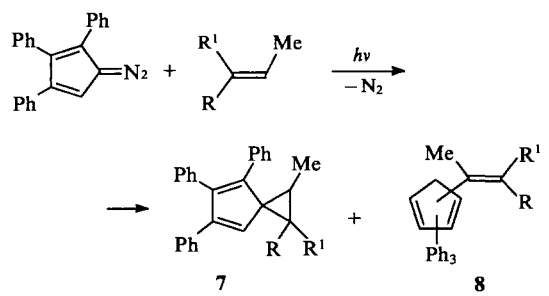
H	Me	Me	18	28



The reactions of substituted DACPD with unsaturated compounds, leading to SHD derivatives, have been studied only occasionally. Thus photolysis of tetrachlorodiazocyclopentadiene in the presence of a (30–40)-fold excess of the unsaturated compound afforded a series of 4,5,6,7-tetrachlorospiro[2.4]hepta-4,6-dienes (Table 3).[53,65,66]

4



On the whole, the same behaviour has been observed for tetrachlorodiazocyclopentadiene as for the unsubstituted DACPD: first, the presence of electron-withdrawing groups (for example, COOMe) at the double bond of the unsaturated acceptor lowers significantly the yield of SHD derivatives and, second, the addition of the tetrachlorodiazocyclopentadiene takes place stereoselectively (Table 3).

The reactions of 2,3,4-triphenyldiazocyclopentadiene with cyclic and acyclic olefins,[42] leading to the formation, together with compounds of the SHD series, of the products of the insertion of the corresponding carbene into a C–H bond in the initial olefin, have also been described.

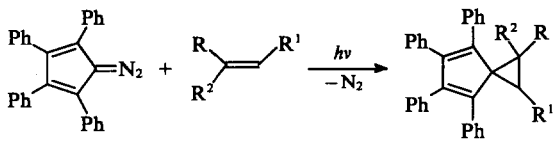
The catalytic decomposition of 2,3,4-triphenyldiazocyclopentadiene in the presence of cyclooctene also led to the formation of the corresponding substituted SHD **9**.[42]

9 (24%)



Although in the catalytic decomposition of triphenyldiazocyclopentadiene the yield of SHD derivatives is lower than on photolysis, nevertheless this example indicates the possibility of using the more convenient and simpler catalytic methods, in comparison with photolytic methods, for the generation of the corresponding carbenes from DACPD and its derivatives.

Tetraphenyldiazocyclopentadiene interacts with cyclic and acyclic olefins under the conditions of photolytic decomposition [(20–30)-fold excess of the initial unsaturated compound], which leads to the corresponding SHD derivatives **10** and **11**.[65, 67, 68]

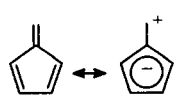
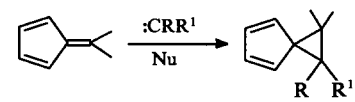
Finally there is an instance of the formation of the corresponding derivative **13** from tetrakis(trifluoromethyl)-diazocyclopentadiene under the conditions of photolytic decomposition.[69]

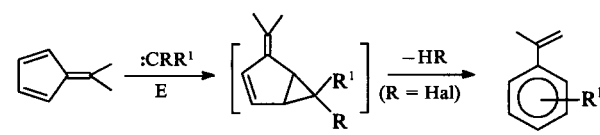


13



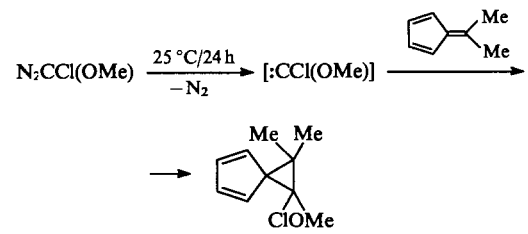
It follows from the data presented that the method of synthesis of compounds of the SHD series by the addition of cyclopentadienylidenes, generated photolytically from DACPD and its derivatives, to the double bonds of unsaturated compounds is fairly universal. At the same time, it suffers from a series of significant limitations. These are, in the first place, the low yields of the cycloaddition products and also the large number of side processes, in particular the insertion of the intermediate CPDI and its derivatives into the single bonds of the initial unsaturated compounds, especially when these contain heteroatoms (for example, sulfur and oxygen atoms). Furthermore, by virtue of the electrophilic nature of the cyclopentadienylidenes, electron-withdrawing functional groups in the initial unsaturated compounds lower significantly the rate of their addition to the double bonds, which increases the amount of side products, in particular the products of insertion in single bonds, and, since the majority of the known functional groups are electron accepting, the method may be relatively unsuitable for the synthesis of SHD with such functional-group substituents. Finally, the method is experimentally complex and has no preparative value because DACPD and its derivatives are extremely explosive, which necessitates the use of only small amounts of these substances (only 50–200 mg of DACPD are normally employed in the experiments). Nevertheless, the method is convenient for the synthesis of many complex SHD derivatives.

2. Cyclomethylenation of the exocyclic double bond in fulvenes

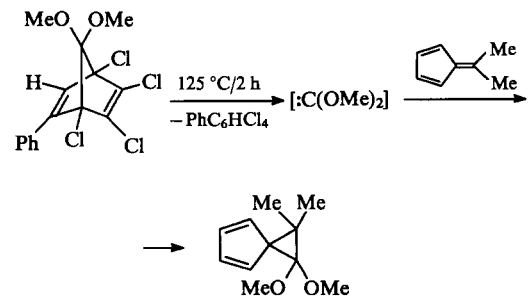


The high polarity of fulvene, which is responsible for the difference between the chemical properties of its double bonds, is generally known.[70–72]

The exocyclic double bond in fulvene is electrophilic, whereas the endocyclic double bond is nucleophilic. Therefore, as shown by Moss et al.,[73] electrophilic and nucleophilic carbenes react differently with fulvenes. Nucleophilic carbenes (Nu) add to the exocyclic double bond of the fulvene, affording SHD derivatives, but the range of such carbenes is extremely small, since it is restricted by the small number of electron-releasing substituents at the carbene centre (R = OAlk, OCOAlk).

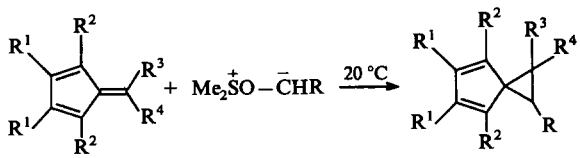


On the other hand, electrophilic carbenes, which constitute the vast majority of the known carbenes, add to the endocyclic nucleophilic double bonds, the product of such an addition usually being unstable and isomerising under the reaction conditions to aromatic derivatives.[73,74]

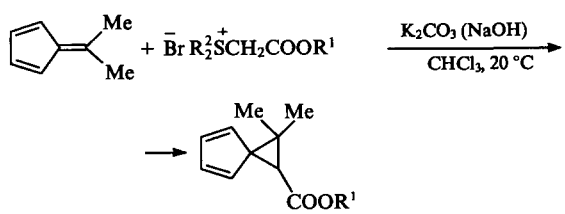


R, R^1 = Hal, COOMe, COMe, CN, etc.

Thus the addition of nucleophilic carbenes to the exocyclic double bond in fulvenes can be used to synthesise compounds of the SHD series containing electron-releasing groups in the cyclopropane ring. For example, nucleophilic carbenes such as chloromethoxycarbene and dimethoxycarbene, generated by the decomposition of chloromethoxyazirine and 1,2,3,4-tetrachloro-7,7-dimethoxy-5-phenylbicyclo[2.2.1]hepta-2,5-diene,[73] afford derivatives **14** and **15** respectively in their reaction with fulvene.



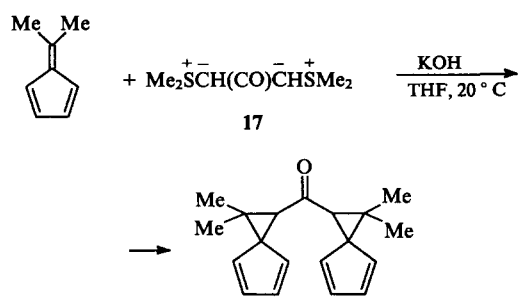
14 (35%)



15 (8%)

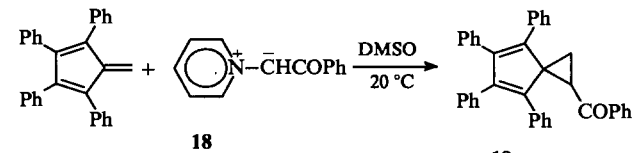
Like nucleophilic carbenes, sulfur ylides, in which the reaction centre (the carbon atom linked to sulfur) has a negative charge, convert the exocyclic double bond in fulvenes into a cyclopropane group.[75,76] A series of derivatives **16** have been obtained in this way (Table 4).[77,78]

16



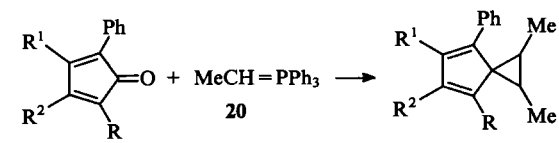
Special mention should be made of the use of the ylide method for the synthesis of a number of highly effective insecticides of the pyrethroid series (in 40%–80% yield); their toxicity to warm blooded animals is low.[1–8]

R^1 = CH_2—(OPh),[7] CH_2—(O)—CH_2Ph,[6]



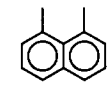
R^1 = —$CHRC_6H_4OPh$-*m*, where R = H, CN,[2–5]
R^2 = Me, R^2_2 = —$(CH_2)_4$—.[4]

The use of the diylide **17** in this reaction made it possible to obtain a compound with two SHD systems in 50% yield.[79]



17

Nitrogen and phosphorus ylides (X^+-C^-, X = P, N) convert the exocyclic double bond of fulvenes into a cyclopropane group similarly to sulfur ylides. Thus the substituted SHD **19** has been obtained in 75% yield from the N ylide **18**.[77]



18 **19**

When the phosphorus ylide **20** was used, the corresponding substituted SHD **21** were obtained in 15%–30% yields from cyclopentadienones by the Wittig reaction with a subsequent secondary reaction involving the conversion of fulvenes into cyclopropane derivatives by reaction with the same phosphorane.[80]

21a: R = R^1 = R^2 = Ph
21b: R = Ph, $R^1 + R^2$ = 
21c: R = Me, R^1 = R^2 = Ph

However, the attempt to synthesise SHD derivatives unsubstituted in the three-carbon ring from triphenylmethylenephosphorane was unsuccessful—the reaction stopped at the fulvene formation stage.[80]

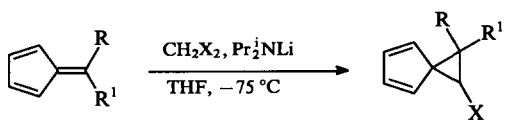
A series of reactions are known in which the carbanions generated with the aid of highly basic agents and containing a halogen atom at the carbanionic centre ($-CHalRR^1$) add to the electrophilic exocyclic bond of fulvenes, forming the anion **22**, the intramolecular cyclisation (S_N) of which leads to compounds of the SHD series.



22

The interaction of fulvenes with equimolar amounts of an organolithium derivative $Li^+CHX_2^-$, generated in different ways, also leads to compounds of the SHD series.[54]

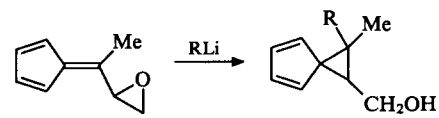
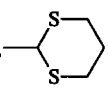
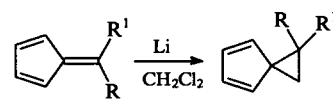
Pr^i	H	33	30
Bu^t	H	90	72
Me	Me	80	92
Ph	Ph	0	0

The carbanion generated from ethyl chloroacetate reacts similarly with dimethylfulvene, affording the corresponding SHD in 13% yield.[9,10] A series of pyrethroids have been obtained in this way.

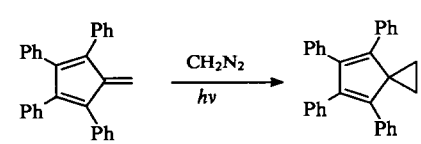




An alternative mechanism for the synthesis of compounds of the SHD series, involving the formation of monohalocarbenes or alkoxycarbonylcarbenes, is unlikely because in this case the nucleophilic endocyclic double bond of fulvene should be converted into a cyclopropane group by virtue of the electrophilic nature of these carbenes.[40,41,46] Thus it has been shown[54] that the monochlorocarbene, generated at −20 °C from CH_2Cl_2 by treatment with MeLi, does indeed add to the endocyclic double bond of fulvene, but the product of such addition is unstable and readily isomerises to methylstyrene under the reaction conditions.

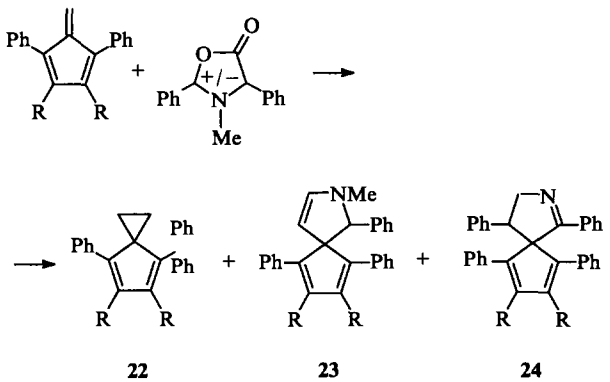


The rearrangements of the cyclopentadienyl anion, generated from alkyllithium and fulvene, constitute the basis of the synthesis of hydroxymethyl-substituted SHD (in 31%–55% yield).[81,82]



R = Me, Bu, CHMeEt, $CH=CH_2$, 

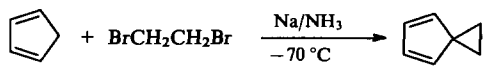
Finally, the anion of 6,6-diarylfulvenes enters into a nucleophilic substitution reaction with CH_2Cl_2, affording 1,1-diaryl-substituted SHD.[83]



R = Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4;
R^1 = Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4, 2-C_5H_4N.

Among other reactions of fulvenes, mention should be made of the synthesis of the tetraphenyl derivative of SHD in a quantitative yield (99%) by the photolysis of the pyrazoline formed as a result of the 1,3-dipolar addition of a fourfold excess of diazomethane to tetraphenylfulvene.[77]

Finally, the synthesis of SHD derivatives (in 17%–27% yield) from fulvenes and 3-methyl-2,4-diphenyl-1,3-oxazolidinium-5-olate has been described.[84]



22 **23** **24**

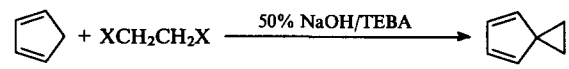
R	Yield (%)		
	22	**23**	**24**
Ph	27	30	11
4-MeC_6H_4	24	22	19
4-$MeOC_6H_4$	17	30	17

Thus the methods of synthesis of compounds of the SHD series by the cyclomethylenation of the exocyclic double bonds in fulvenes, which have been examined above, have a number of characteristic features. In speaking of the carbene methods, one should emphasise that the formation of SHD derivatives is characteristic only of nucleophilic carbenes, which have an extremely limited range, while the methods of their generation are rather complex for wide-scale use in the synthesis of SHD derivatives. However, such methods do in fact make it possible to obtain most effectively derivatives of SHD with electron-releasing groups. Similar reactions are also characteristic of sulfur ylides, but the number of the latter is likewise small [75,76] and the syntheses of compounds of the SHD series from them involve multiple stages. In addition, it has to be mentioned that reactive ylides enter readily also into side reactions. For example, when the initial compounds or the products contain carbonyl groups, epoxidation side reactions take place to a significant extent. [75,76] Nevertheless, ylides have been used successfully in the synthesis of aryl- and carboxy-substituted SHD.

3. Cyclialkylation of cyclopentadiene by 1,2-dibromo derivatives and similar 1,2-difunctional compounds

As mentioned above, SHD was first obtained in 25% yield [37] by the cyclialkylation of cyclopentadiene (CPD) by 1,2-dibromoethane on treatment with sodium in liquid ammonia.

This method of synthesis of SHD still remains the most convenient preparative procedure, its improvement involving mainly the simplification of the method and an increase in the SHD yield (Table 5).



The appearance of a new method in organic synthesis—phase transfer catalysis (PTC) [100,101]—also made it possible to simplify significantly the cyclialkylation of cyclopentadiene, leading to the formation of SHD and its derivatives. [95–99,102,103] The advantages of the PTC method are not only its simplicity and the high yield of SHD but also the possibility of using ordinary NaOH instead of expensive bases and of carrying out the reaction in the absence of a solvent, which facilitates in its turn the isolation of SHD.

Under the conditions of phase-transfer catalysis, SHD can be obtained by the reaction of cyclopentadiene with 1,2-dichloroethane or ethylene glycol di(benzenesulfonate). [102–104]

Table 5. Conditions in the cyclialkylation of cyclopentadiene by 1,2-dibromoethane and the yield of SHD.

Base	*T*/°C	*t*/h	Yield of SHD (%)	Ref.
Na/NH_3	−70–35	3–5	18–75	37, 85–88
Na/THF	0	–	[c]	89

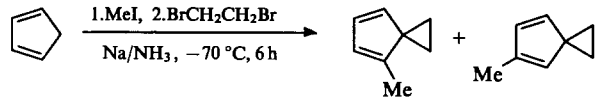
KOH (solid), TEBA	0–20	3	80	97
K_2CO_3/DMSO	20	8	70	99

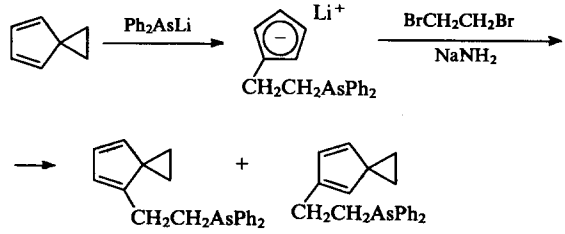
[a] TEBA = triethylbenzylammonium chloride. [b] PEG = poly(ethylene glycol). [c] The yield of SHD is not indicated.



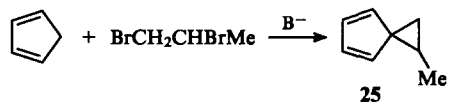
X = Cl, OSO_2Ph.

The reaction with dichloroethane can be carried out also on treatment with NaH as the base (THF, 20 °C, yield 83%). [105]

The use of the more readily available and cheaper 1,2-dichloroethane instead of 1,2-dibromoethane opens up new prospects for investigators. The possibility of using di(benzenesulfonate) in this reaction is of special interest in its turn, because di(benzenesulfonates) (together with ditosylates) are intermediates in the synthesis of the corresponding dihalo-derivatives.



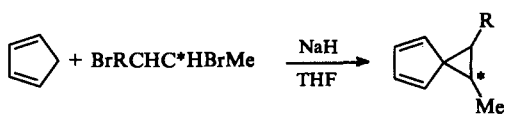
The use of substituted cyclopentadienes in the reaction with 1,2-dibromoethane makes it possible to obtain the corresponding SHD derivatives. Thus a mixture of 4- and 5-methyl-substituted SHD is formed in 30%–55% overall yield on successive alkylation of cyclopentadiene by methyl iodide and 1,2-dibromoethane. [87,106]



2.8 : 1

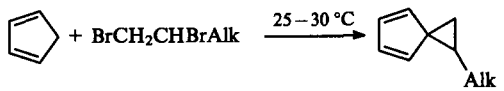
This evidently involves the initial formation of a mixture of isomeric methylcyclopentadienes in which the thermodynamically most stable 1- and 2-methyl derivatives predominate. [107] These are subsequently cyclialkylated by 1,2-dibromoethane.

Similar cyclialkylation by 1,2-dibromoethane of an arsenic derivative of cyclopentadiene has been described. [108] In this case, a mixture of the 4- and 5-substituted SHD is likewise formed.



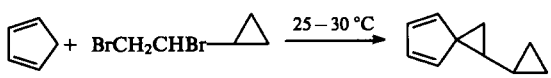
Apart from 1,2-dibromoethane, 1,2-dibromopropane, its closest homologue, is used in the cyclialkylation of cyclopentadiene.

25



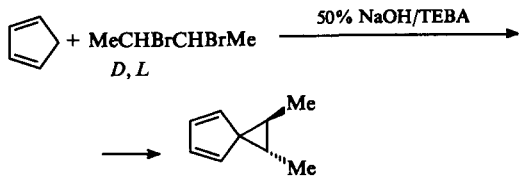
Base	Yield of **25** (%)	Ref.
Na/NH_3, −35 °C	54	57, 109
$NaNH_2/NH_3$	–	110
NaH/THF	–	111
NaOH (50%), TEBA	76–85	96, 97

The use of the optically active 1,2-dibromopropane in this reaction makes it possible to obtain the optically active 1-methyl-substituted SHD.[111]

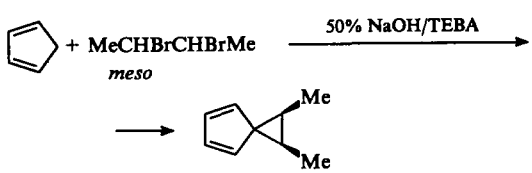


R = H, D.

Under the conditions of phase transfer catalysis, the cyclialkylation of cyclopentadiene by 1,2-dibromo-n-alkanes, in which one bromine atom is at a primary carbon atom and the other at a secondary carbon atom, proceeds just as smoothly as the reaction with 1,2-dibromoethane itself and leads to the corresponding 1-alkylspiro[2.4]hepta-4,6-dienes (in 65%–75% yield).[96, 97, 102, 103]

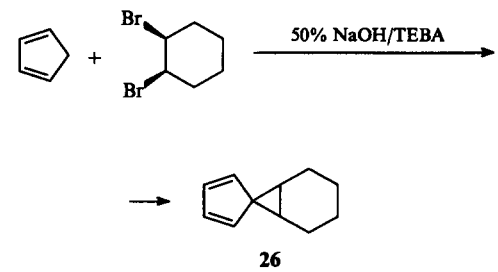


Alk = Me, Pr, Bu, Pe.



1-Cyclopropylspiro[2.4]hepta-4,6-diene has been obtained in 80% yield from 1,2-dibromo-1-cyclopropylethane under similar conditions.[96]

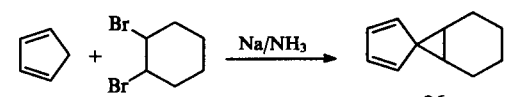
The possibility of using 1,2-dibromo-derivatives with the two bromine atoms at secondary carbon atoms in this reaction under PTC conditions has also been demonstrated. Thus the interaction of cyclopentadiene with *D,L*-2,3-dibromobutane readily affords *trans*-1,2-dimethylspiro-[2,4]hepta-4,6-diene in 70% yield.[96, 102, 103]



On the other hand, the reaction of cyclopentadiene with *meso*-2,3-dibromobutane leads to the corresponding *cis*-isomer in 60% yield.[96, 102, 103]

The formation of only one isomer of 1,2-dimethyl-SHD on reaction of cyclopentadiene with *meso*- or *D,L*-2,3-dibromobutane is evidence in support of the S_N2 mechanism of cyclialkylation of cyclopentadiene under PTC conditions and leads to the possibility of obtaining optically active derivatives of SHD in this way.[102, 103]

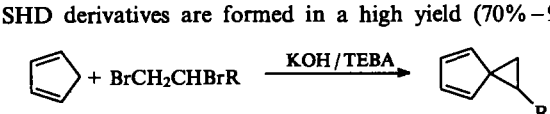
Under the same conditions, another dibromo-derivative — *cis*-1,2-dibromocyclohexane — reacts similarly with cyclopentadiene under the same conditions and leads to spiro(bicyclo-[4.1.0]heptane-7,5′-cyclopentadiene) **26**.[102, 103]



26

On the other hand, the reaction of cyclopentadiene with *trans*-1,2-dibromocyclohexane affords, instead of the corresponding SHD derivative, isomeric bromocyclohexylcyclopentadienes (the products of the monoalkylation of cyclopentadiene) as well as the products of the dehydrobromination of the latter and of the initial dibromocyclohexane.[97]

Thus the difference between the reactivities of *cis*- and *trans*-1,2-dibromocyclohexanes confirms the S_N2 mechanism of the cyclialkylation reaction.[102, 103]

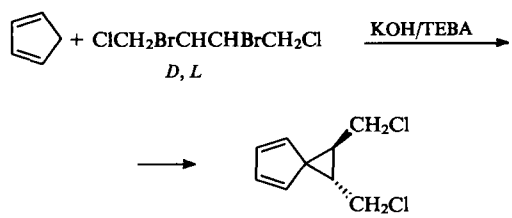


The cyclialkylation of cyclopentadiene by 1,2-dibromocyclohexane takes place also when the Na/NH_3 system is used as the base, which results in the formation of the corresponding tricyclic derivatives of SHD **26** in 10% yield.[86]

26

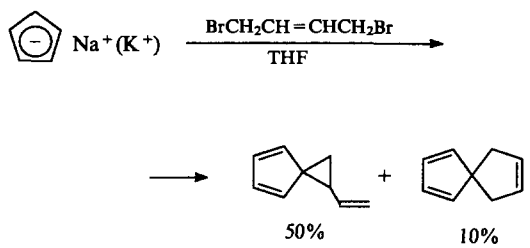
In contrast to primary and secondary dibromo- derivatives, dibromoalkanes containing at least one bromine atom at a tertiary carbon atom do not form SHD derivatives under the conditions of phase transfer catalysis because of the ease of their dehydrobromination.[96, 102, 103]

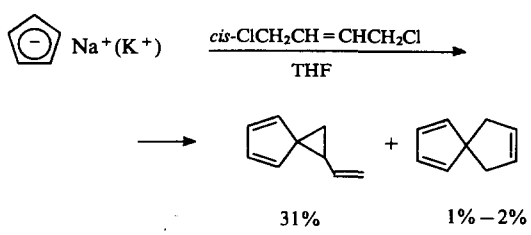
The cyclialkylation of cyclopentadiene under conditions of phase transfer catalysis by 1,2-dibromoethane with functional group substituents makes it possible to obtain various SHD derivatives.[102, 103, 112] The use of powdered KOH in CH_2Cl_2 in the presence of TEBA under these conditions fully rules out side reactions involving functional groups, for example hydrolysis. The yields of SHD derivatives depend significantly on the electronic properties of the functional group R in the initial 1,2-dibromoethane. Thus, when the group R linked directly to the reaction centre is an aryl substituent or possesses electron-withdrawing properties (COOMe, COMe, CN, Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-BrC_6H_4, 4-$NO_2C_6H_4$, Cl), then the corresponding SHD derivatives are formed in a high yield (70%–95%).[112]



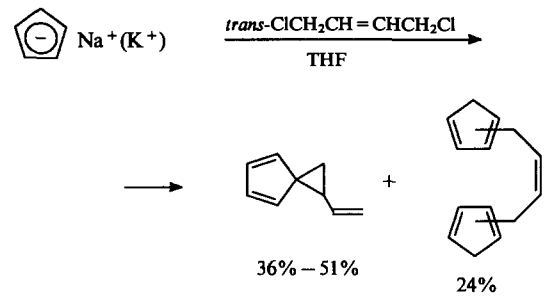
On the other hand, if the functional group in the initial 1,2-dibromoethane is markedly electron-releasing (R = OAc, OEt), then the yields of the SHD derivatives are significantly lower (25%–50%).[112]

However, if the functional group is separated from the reaction centre by a methylene unit, its electronic properties hardly affect the yields of the SHD derivatives, which in this case are 60%–80% for 1,2-dibromopropanes containing functional group substituents in the 3-position with both electron-withdrawing (R = CN, Cl) and electron-donating (R = OMe, OAc) properties.[112]

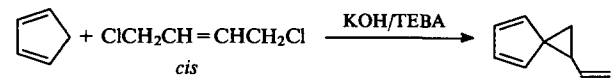




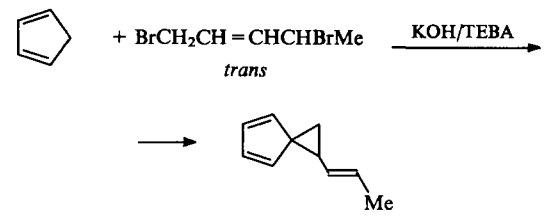
The possibility of synthesising SHD disubstituted in the 1,2-positions by functional groups has been demonstrated for the reaction of cyclopentadiene with *D,L*-2,3-di-bromo-1,4-dichlorobutane. The main product obtained in this case in 55% yield was *trans*-1,2-di(chloromethyl)spiro[2.4]hepta-4,6-diene.[112]



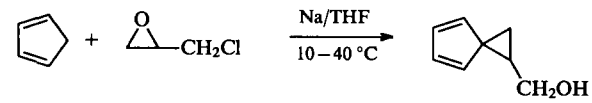
The exclusive formation of *trans*-1,2-bis(chloromethyl)-SHD is fully consistent with the S_N2 mechanism of cyclialkylation of cyclopentadiene under phase transfer catalysis conditions and at the same time indicates a higher reactivity of the bromo-derivatives compared with the chloro-derivatives, although bromine is attached to a secondary carbon atom whereas chlorine is attached to a primary carbon atom.[102,103,112]



Among other alkylating agents used to obtain SHD derivatives by the cyclialkylation of cyclopentadiene, mention should be made of 1,4-dihalobut-2-enes and epichlorohydrin. Thus the interaction of cyclopentadiene with 1,4-dihalobut-2-enes is accompanied by the allyl rearrangement and leads mainly to 1-vinyl-substituted SHD.[60,113,114]



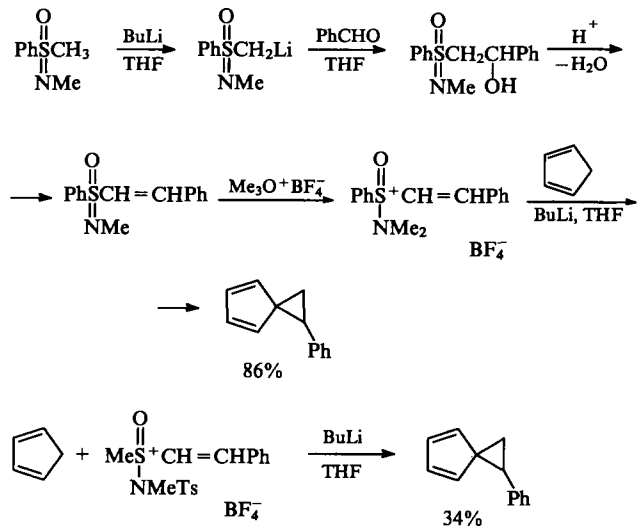
Under PTC conditions, the interaction of cyclopentadiene with *cis*-1,4-dichlorobut-2-ene on treatment with solid KOH in CH_2Cl_2 proceeds similarly, leading to 1-vinylspiro-[2.4]hepta-4,6-diene in 60% yield.[115]



The cyclialkylation of cyclopentadiene by *trans*-1,4-dibromopent-2-ene also proceeds similarly, leading to the formation of propen-1-ylspiro[2.4]hepta-4,6-diene in 55% yield.[115]

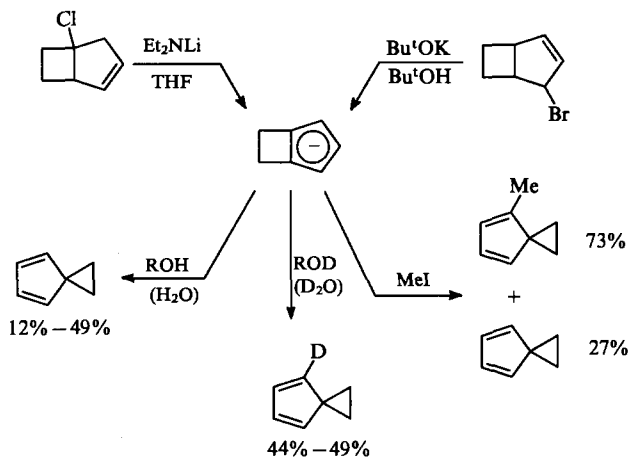
The formation of vinyl-substituted SHD in these reactions indicates the possibility of using derivatives of 1,4-dihaloalk-2-enes for the synthesis of alken-1-ylspiro[2.4]hepta-4,6-dienes.[102,103]

Finally, the cyclialkylation of cyclopentadiene by epichlorohydrin leads to 1-hydroxymethylspiro[2.4]hepta-4,6-diene in 64%–77% yields.[116–118]



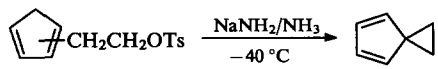
Thus the method involving the cyclialkylation of cyclopentadiene is universal and makes it possible to obtain easily and in high yield SHD derivatives with various functional groups, which renders these compounds readily available synthons for wide scale employment in specific organic synthesis. This method of preparation of SHD and its derivatives is the simplest and most effective compared with other procedures examined in previous sections of the review. The cyclialkylation of cyclopentadiene under the conditions of phase transfer catalysis with formation of compounds of the SHD series proceeds via an S_N2 mechanism,[102,103] which can be used in the synthesis of optically active SHD derivatives. The method is ineffective in the synthesis of SHD with electron-releasing substituents and of *gem*-disubstituted SHD.

4. Other methods of synthesis of spiro[2.4]hepta-4,6-dienes



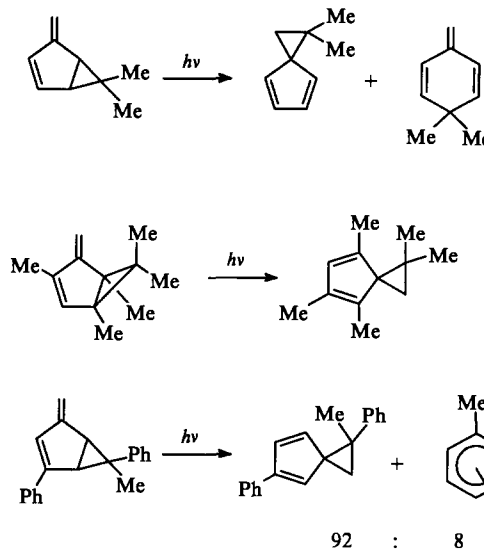
Certain further examples of the construction of the SHD system are considered below. They are frequently random in character and as a rule have no preparative value.

Thus the synthesis of the 1-phenyl derivative of SHD by the reaction of cyclopentadiene with derivatives of vinylsulfoxyimines on treatment with butyllithium has been described.[119]

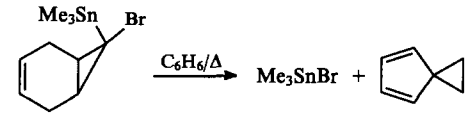


Apparently the mechanism of this reaction is similar to that of the addition of a nucleophile to a Michael acceptor,[119] the cyclopentadienyl anion, formed as an intermediate from cyclopentadiene on treatment with BuLi, acting as the nucleophile.

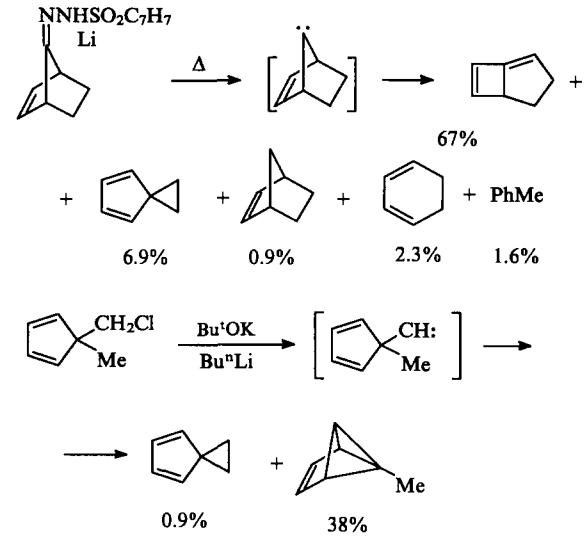
Several examples of the synthesis of SHD and its derivatives as a result of intramolecular reactions have been described. Thus halo-derivatives of bicyclo[3.2.0]hept-2-ene readily give up a hydrogen halide molecule on treatment with strong bases, affording the corresponding bicyclo[3.2.0]hepta-1,3-dienyl carbanion, which combines with a proton or a methyl group and rearranges to SHD and its derivatives.[120, 121]



Furthermore, intramolecular alkylation of the β-tosylethyl derivative of cyclopentadiene also results in the formation of SHD.[122]



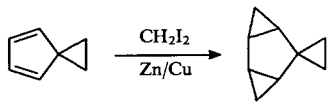
This reaction is very similar to those described in the previous Section.



Examples also exist of the formation of compounds of the SHD series as a result of the photochemical isomerisation of derivatives of 4-methylenebicyclo[3.1.0]hex-2-ene.[56, 58, 123–126]

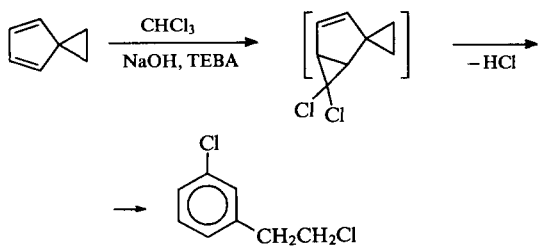
Spiro[2.4]hepta-2,6-diene has been synthesised in 76%–86% yield by the thermolysis (101–162 °C) of a derivative of norcarene[127] (degree of conversion 75%–85%). It has been suggested that the reaction proceeds via the intermediate formation of carbene.

Finally, the formation of SHD has been observed, although only as a side product, in the following carbene reactions.[128–131]



Whereas in the first case[128–131] the mechanism of the formation of SHD is not altogether clear, in the second reaction[131] SHD is apparently obtained as a result of the insertion of the intermediate carbene in a C–H bond of the methyl group.[128, 129, 131]

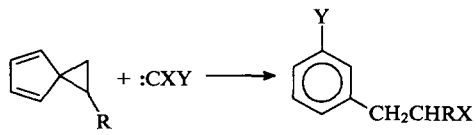
III. Chemical reactions of spiro[2.4]hepta-4,6-dienes



The [2 + 1]-, [2 + 2]-, [2 + 3]-, and [2 + 4]-cycloaddition reactions involving compounds of the SHD series as well as oxidation, reduction, and thermal isomerisation reactions will be considered in this Section. The review does not include the numerous thoroughly investigated complex formation[92, 132–151] (only

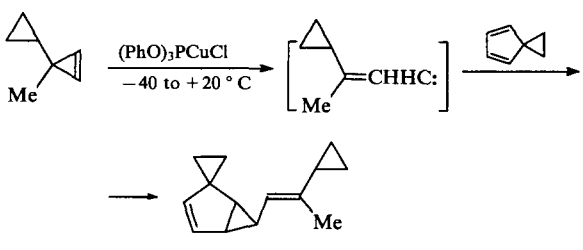
studies published during the last ten years are quoted), polymerisation,[14–24] and dehydrochlorination[152] reactions as well as the reactions of SHD and its derivatives with organolithium compounds of arsenic and other elements.[153]

In the [2 + 1]-cycloaddition reactions, i.e. in the reactions with carbenes, SHD yields the products of conversion into one or two cyclopropane groups. Thus the product resulting from the conversion of both double bonds of SHD into cyclopropane groups is formed from the latter in 50% yield under the conditions of the Simmons–Smith reaction.[154]



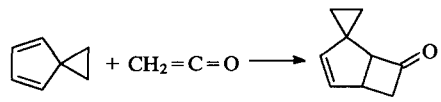
In the reaction of SHD with dichlorocarbene, generated under the conditions of phase transfer catalysis, the intermediate product of conversion of one of the double bonds of SHD into a dichlorocyclomethylene group is unstable, like the analogous monoadduct of dichlorocarbene and cyclopentadiene, and rearranges to the *meta*-derivative of benzene under the existing reaction conditions.[155,156]

50%



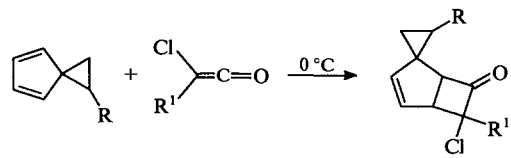
SHD and its substituted derivatives react similarly with other halocarbenes generated under of PTC conditions.[157,158]

X = Y = Cl, Br; X = Cl, Br, Y = F;
R = H, Ph, 3-ClC_6H_4, 4-ClC_6H_4, 4-MeC_6H_4.



The exclusive formation of *meta*-substituted benzenes in these reactions is very important, since it opens up prospects for the creation of new convenient methods of synthesis of *meta*-substituted benzenes, which are of great practical value, from SHD derivatives (*meta*-substituted benzenes are usually obtained as a result of multistage synthesis). This demonstrates that compounds of the SHD series are likely to be useful as synthons in organic synthesis.

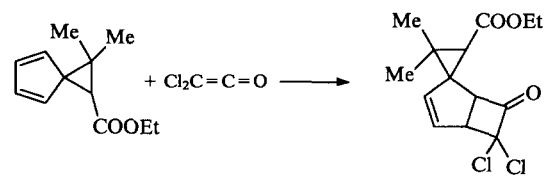
The reaction of SHD with vinylcarbene, generated from methylcyclopropylcyclopropene, leads to the formation of the stable product of the conversion of one of the double bonds of SHD into a cyclopropane group.[159]



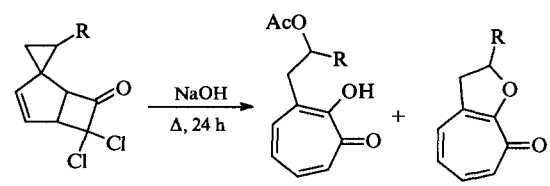
65%

The [2 + 2]-cycloaddition of SHD to ketene affords the corresponding cyclobutanone **27**, which may serve as a convenient intermediate for the synthesis of a series of analogues of natural icosanoids, for example thromboxane A_2 and prostaglandin D_2.[160]

27

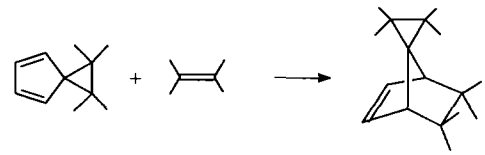


The reactions of SHD and 1-methyl-SHD with chloroketenes, obtained from dichloroacetic acid chloride on treatment with a (3–5)-fold excess of triethylamine, proceed similarly.[161–163]



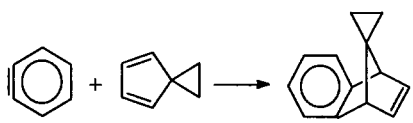
28

R	R^1	Yield of **28** (%)
H	Me	88
H	Pr^i	82
H	Ph	95
H	Cl	85
Me	Cl	92.5



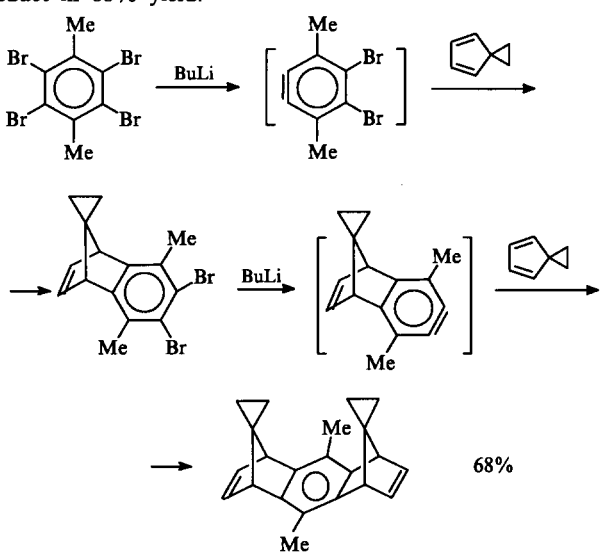
The addition of dichloroketene to trisubstituted SHD also proceeds in this way.[164]

The cyclobutanone derivatives obtained in the [2 + 2]-cycloaddition reaction isomerise with the opening of the four-membered carbon ring on treatment with alkali. The tropolones formed in 35%–40% yield are convenient intermediates for the synthesis of a series of important biologically active compounds and natural products.[162]



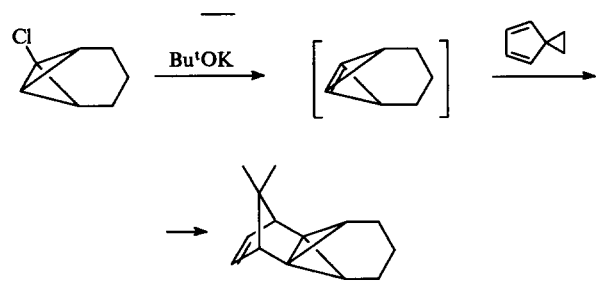
The majority of the reactions investigated, proceeding with participation of compounds of the SHD series, are [2 + 4]-cycloaddition reactions in which SHD and its derivatives usually react as the diene component, affording derivatives of spiro-(bicyclo[2.2.1]hept-2-ene-7,1′-cyclopropane).

The vast majority of reactions of this type have been achieved for SHD itself and its 1-hydroxymethyl derivative. Reactions involving 1-vinyl-substituted SHD and certain other SHD derivatives are also known. The available literature data concerning the involvement of SHD itself in the [2 + 4]-cycloaddition reaction, summarised in Table 6, indicate its high reactivity. This opens up extensive prospects for the employment of SHD in the synthesis of skeletal structures.

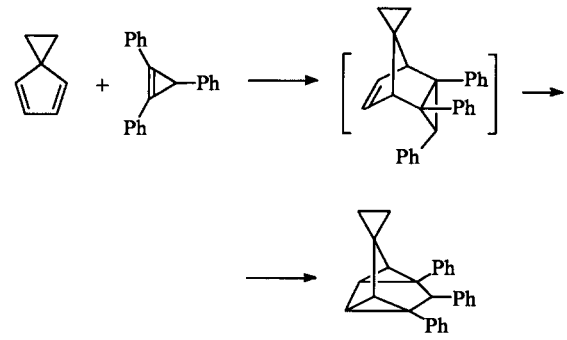


The Diels–Alder reaction involving SHD can proceed both via the usual thermal pathway and catalytically. For example, SHD and 1-methyl-SHD form exclusively cyclic *endo*-[2 + 4]-adducts (in 70%–75% yield) with 1,4-benzoquinone and 1,4-naphthoquinone under the conditions of micellar catalysis (an analogue of phase transfer catalysis) in an aqueous medium in the presence of cetyltrimethylammonium bromide as the micelle forming agent.[175–177] SHD may dimerise in the presence of Lewis acids[165] and on photoinduced electron transfer.[31,32]

SHD readily gives rise to cyclic [2 + 4]-adducts **28** on reaction with dehydrobenzene and its derivatives.[88,164,187]



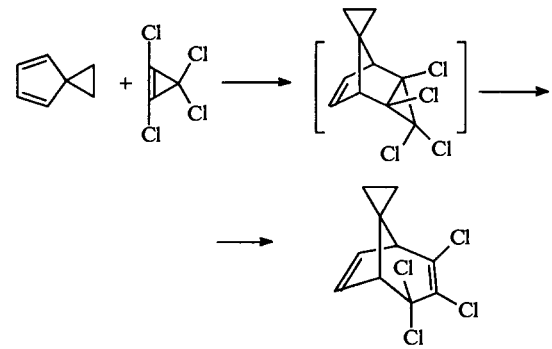
28 (50%–70%)



SHD reacts similarly with 1,2,4,5-tetrabromo-3,6-dimethylbenzene, affording the corresponding double cyclic [2 + 4]-adduct in 68% yield.[190]

The reactions of SHD with 1,2,4,5-tetrabromobenzene and 2,3,6,7-tetrabromonaphthalene proceed similarly, affording both mono- and di-adducts of dehydrobenzene derivatives.[191]

SHD is an effective 'trap' for highly reactive unstable unsaturated molecules, for example cyclopropenes. The intermediate unstable strained molecules, containing a double bond, readily afford in this case cyclic [2 + 4]-adducts with SHD. Similar products are also formed in the reactions with stable cyclopropenes. This is illustrated by the following examples.[192,193]



A series of highly strained polycyclic hydrocarbons have been obtained from SHD and its dimer (see, for example, Khusnutdinov et al.[165] and de Meijere et al.[194]).

In many cases, the primary adducts formed are labile and rearrange to thermodynamically stable products under the reaction conditions. Thus the product of reaction of SHD with tetra-chlorocyclopropene derives from the opening of the three-carbon ring of the intermediate chlorocyclopropane.[195]

Derivatives of SHD enter into the Diels–Alder reaction similarly to SHD itself (Table 7, see page 464)).

It is interesting to note that the adduct formed in the Diels–Alder reaction of tetracyanoethylene with dicyclopropyl-substituted SHD undergoes an unusual isomerisation under the conditions of its formation, in contrast to SHD itself and its other alkyl-substituted (methyl- and propyl-substituted) derivatives.[197,198]

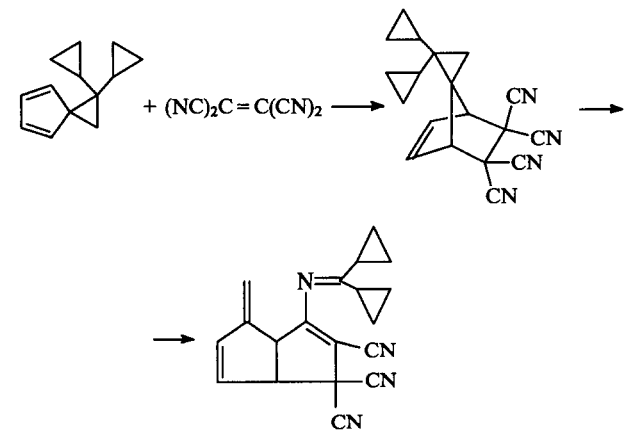


Table 6. The yields of the products of the [2 + 4]-cycloaddition reaction (the Diels–Alder reaction) of dienophiles with SHD.

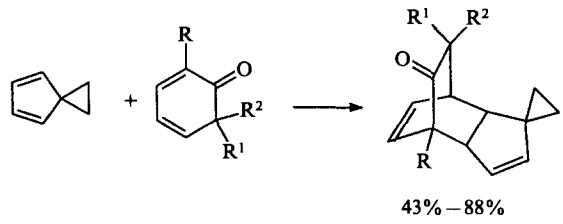
In speaking of useful practical properties of compounds of the SHD series, one should note that some of the Diels–Alder adducts of SHD possess physiological activity,[11,12] including insecticidal properties.[183] Interesting polymers have been obtained from the adducts of SHD with fluoroolefins.[16,17] The diene adducts of 1-hydroxymethyl-substituted SHD are of great interest as chemical intermediates. The simplest and most effective methods of synthesis of prostaglandins, for example prostaglandin A_2 (compound **29**) (overall yield 9%)[13] and their analogues,[199] as well as certain natural products such as cinularene **30**[118,200–202] and longifolene **31**,[118,202–204] have been proposed on the basis of the chemical reactions of such adducts.

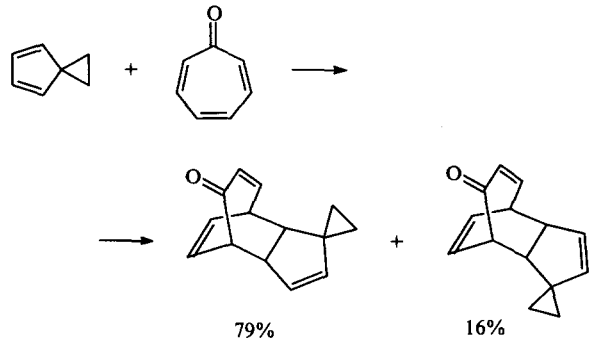


29

30 **31**

Such products are also convenient intermediates in the synthesis of norbornenes disubstituted by functional groups in the 7,7-positions.[205]

SHD and its derivatives can also enter into [2 + 4]-cycloaddition reactions as the dienophile, especially in reactions with highly reactive dienes such as 2,4-cyclohexadienones that are generated in situ.[206–210]



43%–88%

R = H, Me; R^1 = OH, OAc; R^2 = Me, CH_2Cl; $R^1+R^2 = CH_2O$.

The adducts of SHD with 6-hydroxymethylenecyclohexa-2,4-dienone are convenient intermediates in the stereoselective synthesis of natural polyquinane products[210] and compounds of the sesquiterpene series.[209]

SHD also reacts as the dienophile with tropone.[211]

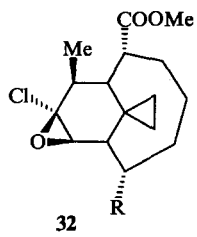
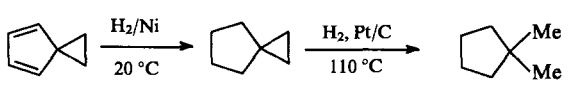
SHD again assumes the role of the dienophile in a series of reactions with simple dienes. Thus its reaction with butadiene leads to the exclusive formation of spiro(bicyclo[4.3.0]nona-3,7-diene-9,1′-cyclopropane) (in 40% yield).[165]



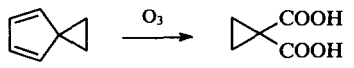
The reaction with cyclopentadiene proceeds similarly.[165]

The reactions involving the dipolar [3 + 4]-cycloaddition of propen-2-oxides, generated in situ, to SHD are also known; for example:[212–214]

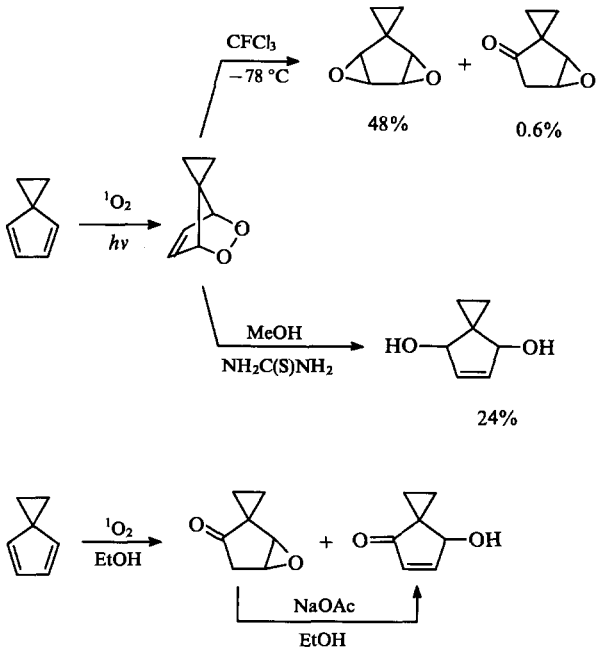


R = Cl, Me; R+R = CH_2CH_2.

The adducts obtained in this way are convenient intermediates in the synthesis of various natural products, for example taxane diterpenes **32**.[215]

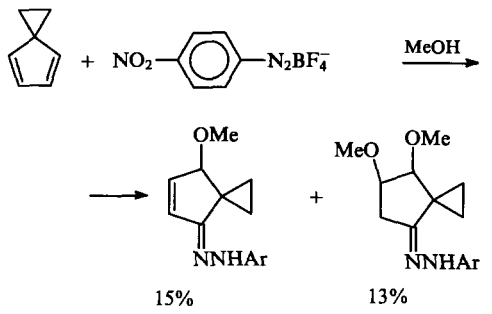


32

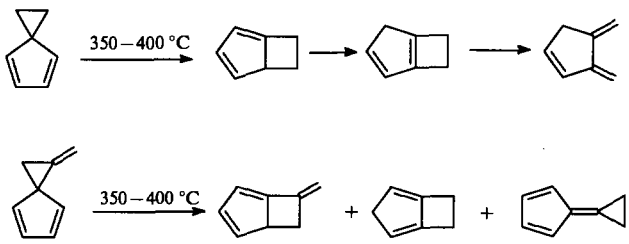


Among other reactions involving SHD, mention should be made of its catalytic hydrogenation, which, in the presence of Raney nickel at 20 °C, leads to the reaction of only the double bonds and yields the associated products, whereas at higher temperature the hydrogenolysis of the three-carbon ring also occurs.[86,216]

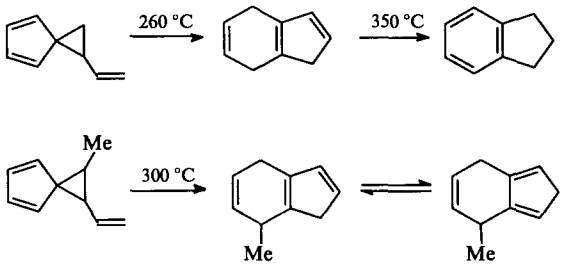
The ozonolysis of SHD involves both double bonds of the cyclopentadiene ring and leads to the formation of cyclopropane-1,1-dicarboxylic acid.[85]



On the other hand, oxidation of SHD by singlet oxygen leads initially to the product of the 1,4-addition of oxygen to the diene system of SHD, which then undergoes further transformations under the reaction conditions.[217,218,219]



These reactions constitute the basis of the synthesis of natural pederol.[219]



The reaction of SHD with 4-nitrobenzenediazonium fluoroborate in methanol likewise leads to 1,4-adducts.[220]

Finally, certain thermal reactions of compounds of the SHD series have been investigated. At 300–400 °C, SHD and its derivatives undergo irreversible isomerisation, similarly to 5,5-disubstituted cyclopentadienes, as a result of the 1,2-shift of the methylene unit of the three-carbon ring accompanied by 1,2-hydride transfer. Isomerisation leads to the thermodynamically more stable isomeric bicyclo[3.2.0]hepta-1,3-dienes, which may be subsequently trapped by reactive dienophiles in the Diels–Alder reaction.[64,151,220–225]

On the other hand, the thermal reactions of vinyl-substituted SHD are accompanied by the allyl rearrangement, which results in the formation of derivatives of bicyclo[4.3.0]nonatriene.[61]

These bicyclo[3.2.0]heptadienes formed in thermal reactions of SHD can participate subsequently in various [2 + 4]-cycloaddition reactions.[224,225]

The thermolysis of 1-substituted and 1,2-disubstituted SHD at temperatures above 200 °C can also entail their epimerisation.[111]

IV. Conclusion

As can be seen from the literature data examined in the present review, compounds of the SHD series constitute an extremely interesting class of chemical substances with considerable potential synthetic possibilities, both as such and as intermediates in the synthesis of physiologically active and other products of practical value. SHD derivatives have found applications in the synthesis of polyfunctional compounds[226,227] and skeletal structures. Furthermore, such compounds have been arousing an unflagging interest in connection with the problem of spiroconjugation[228–230] and complex formation.

The development of the chemistry of compounds of the SHD series depends to a large extent on the availability of effective methods for their synthesis. The methods of synthesis of SHD and its derivatives developed hitherto, principally the cyclialkylation of cyclopentadiene under the conditions of phase transfer catalysis, have made mono- and 1,2-disubstituted SHD derivatives readily available. It may be expected that further studies in this field will be directed to the development of new preparative methods of synthesis of such compounds by means of reactions involving the cyclomethylenation of the exocyclic double bond of fulvenes.

Finally, the above survey of literature data demonstrates that the chemical reactions of SHD and its derivatives have been studied mainly in relation to the most readily available compounds. Evidently the high availability of these interesting compounds will also stimulate a comprehensive study of their properties, including their chemical properties.

Abstract. The homogeneous and heterogeneous mechanisms of antifoam action are examined. The homogeneous mechanism involves the adsorption displacement of the molecules of the foam-forming agent from the surface layers of foam films with formation of mixed layers of the foam-forming agent and the antifoam; in this case, the foam films are in a nonequilibrium state. The heterogeneous mechanism of the destruction of the foam consists in the formation of unstable asymmetric aqueous films and the subsequent appearance, after their disruption, of 'bridges' consisting of drops or solid particles of the antifoam passing through the foam film. It is shown that the most important factors governing the instability of the asymmetric film are the low degree of adsorption of the foam-forming agent on the interface between the films and the drops of the antifoam and the solid particles, as well as the presence of rough regions on the solid particles. The antifoam action of solid particles or drops forming the 'bridges' is determined by the wetting angles. The foam film is ruptured when the establishment of an equilibrium three-phase foam film – antifoam – gas contact is impossible. In many systems, both mechanisms of the destruction of the foam operate simultaneously. The bibliography includes 66 references.

I. Introduction

Many industrial processes are accompanied by the formation of a foam, which creates serious difficulties in the technological process or spoils the product. The formation of a foam in the cellulose and paper industries, in the enzymic synthesis of antibiotics and other medicinal preparations, in the electroplating industry, in the dyeing of fabrics, in the preparation of food yeast, baker's yeast, and tomato juice, in blood transfusion, and in the pumping and treatment of bore hole, boiler, industrial, and domestic waste water is a list of only some examples of undesirable foam formation.[1,2]

In order to diminish foam formation, various measures are undertaken. Technological procedures (diminution of the entrainment of air, change in the composition of the solutions or their pH) are usually insufficient and it is necessary to resort to various physical (usually mechanical) and chemical methods to combat foam formation (antifoam action).

Mechanical antifoam equipment includes various rotating devices (stirrers, discs, blades, centrifuges, separators, etc.); in air, steam, or liquid streams, the foam is disrupted by the critical stresses and deformations in the film or as a consequence of the acceleration of the syneresis (drying) of the foam. A rational classification of these procedures for the destruction of the foam and the methods used in the design calculations for mechanical antifoam devices have been examined in detail by Vetoshkin.[3]

The physical procedures include the disruption of the foam by thermal action (heating, treatment with hot steam, freezing), by an electric current, by acoustic waves (mainly ultrasound), by vibration, by exposure to α-particles, by the creation of a high capillary pressure in the foam, etc.[1,2,4]

The most widely used procedure in the fight against foam involves the introduction into the foam-forming solution (or into the foam) of special substances — antifoams (chemical antifoam action). Fats, oils, waxes, aliphatic alcohols, acids, amines, ethers, organophosphorus compounds (in particular, tributyl phosphate), organosilicon compounds (silicone oils), nonionogenic surfactants with a low hydrophilic – lipophilic balance (HLB) [with a HLB number less than 6 (usually 1 – 3)], solid hydrophobic particles, as well as numerous types of waste containing the above and other components†.

'Filled' antifoams (hydrophobic particles, usually hydrophobic silica, dispersed in an oil), which can be emulsified in an aqueous medium, are regarded as some of the most promising.

Hitherto antifoams have been selected mainly empirically taking into account the purposes and nature of the industry. The mechanism of the action of antifoams, especially in the form of a separate phase (drops or hydrophobic particles), remains in many respects obscure.[2]

In terms of the principle governing their action, antifoams can be divided into two groups. The first includes substances that interact chemically with the foam-forming agent, which leads to the formation of insoluble or sparingly soluble compounds. Thus, when soluble aluminium or calcium salts are added to a foam or a foam-forming solution of the sodium or potassium salts of aliphatic acids or when cationic surfactants are added to a solution

† A detailed list of antifoams and their applications may be found in the relevant books.[1,5].

of anionic surfactants, insoluble compounds are obtained, whereupon the foam is disrupted or ceases to form. The effectiveness of the antifoam is determined in this case by its ability to bind the foam-forming agent, converting it into a precipitate.

A procedure intensifying the disruption of an existing foam involves the supply of antifoams in the form of a foam.[2] For example, a foam produced from a solution of a cationic surfactant with added calcium and aluminium salts is supplied to a foam produced from a solution of anionic surfactants which it is proposed to destroy. The disadvantages of antifoams of this group are the large consumption of the substance and contamination of the working solution by the insoluble compounds formed. For this reason such antifoams are used very rarely.

The second, more common group of antifoams includes substances which do not interact chemically with the foam-forming agent. They disrupt the foam or prevent foam formation as a result of various physicochemical processes, so that they should probably not be referred to as chemical antifoams.

The mechanism of the action of the antifoams of the second group is more complex: it depends not only on the nature of the substance (composition, structure, etc.) and its concentration, but also on the state in which it exists in the foam-forming solution (in the form of molecules or ions or as a separate phase) and many other factors.

The mechanism of the antifoam action of dissolved antifoams will be referred to henceforth as homogeneous (or adsorption) and that of antifoams forming a separate phase will be called heterogeneous. The mechanism of the heterogeneous antifoam action operates in a pure form when liquid, nonpolar, and water-insoluble hydrocarbons or solid hydrophobic particles (Teflon, hydrophobic glass, or silica) are used. When diphilic sparingly soluble compounds are used, the foam may be destroyed as a result of the joint operation of the homogeneous and heterogeneous mechanisms of the antifoam action.

Antifoams in the form of a separate phase (such as drops of a pure substance, solutions in organic solvents, or emulsions) have long been used.[6] There exist various treatments of the mechanisms of the antifoam action including a homogeneous treatment involving the monolayer spreading of the antifoam on the surfaces of foam films and the adsorption displacement of the molecules of the foam-forming agent from their surfaces. The drops can then be regarded (like surfactant micelles) merely as an absorber (or 'reservoir') of the antifoam.

Various qualitative ideas concerning the operation of a special heterogeneous mechanism of antifoam action have been put forward in discussing the role of the spreading of drops in antifoam processes and in the prevention of the formation of optically black spots in microscopic foam films.[7,8]

An explanation of the heterogeneous mechanism of the antifoam action of drops, based on the conversion of stable foam films into unstable aqueous films on an antifoam support owing to the sharp decrease in the degree of adsorption of the foam-forming agent on one of the surfaces of the asymmetric film, was first put forward by Kruglyakov and coworkers.[9,10]

Another mechanism of the heterogeneous antifoam action has been proposed for hydrophobic solid particles.[11,12] Subsequently it was developed in detail in many other investigations.[13–16] This treatment came to be used also in relation to liquid drops.[13,15,16] Different mechanisms of antifoam action have not so far been compared.

The problem of the stability of foams (like that of other disperse systems) and of its regulation (increase in some systems and decrease in others) is crucial in colloid chemistry. Many aspects of this problem have not yet been elucidated.[2,17]

As a consequence of the excess surface energy, a foam is as a whole in a state of thermodynamic nonequilibrium. A consequence of this is spontaneous processes involving the segregation of the liquid from the foam (syneresis of the foam), diffusional transport of gas from small bubbles into larger ones, rupture of films with local coalescence, and the destruction of the foam as a whole, i.e. the separation of the disperse system into a liquid and a gas. However, individual constituents of the foam, in particular films and Plato–Gibbs channels, may be in equilibrium and may possess true stability (metastability).

Analysis of these processes and equilibrium states is outside the framework of this review (although it is important for the understanding of the mechanism of the action of antifoams). Individual questions concerning directly the influence of antifoams on the equilibrium in films or on the kinetics of the syneresis and disruption of the foam will be considered in the analysis of the mechanisms of the antifoam action.

The rate of syneresis of the foam as a function of time or simpler parameters, for example, the time required for the segregation of half of the initial volume of liquid, are used as characteristics of stability in relation to the segregation of the liquid.

The main parameter characterising the rate of internal disruption (aggregative instability) is the rate of decrease in the specific surface of the film and the parameter characterising the disruption of the foam as a whole is the rate of decrease in its volume or of the height of its column (provided that the cross-section of the column is identical along its height). The corresponding characteristics of the stability may be the reciprocals of the rates of the internal disruption and of the disruption of the foam as a whole. The simplest integral characteristic of the stability of a foam is the lifetime of the entire foam or of part of it.

The equilibrium in foam films and hence the prolonged existence of a foam are ensured, on the one hand, by the molecular, electrostatic, and short-range (adsorption or structural) components of the disjoining pressure (Π). On the other hand, various kinetic factors exert a significant influence on the rate of equilibration, the rate of the internal disruption of the foam (as a consequence of diffusion and coalescence), and on the response to the effect of various external perturbations (compressive and stretching deformations, changes in temperature, local changes in surfactant concentrations, etc.). These factors are determined by the stabilising effect of the surfact adsorption layers and by the volume properties of the solution[2]—the equilibrium and dynamic elasticity, the retardation of the rate of flow of the liquid along the films and the Plato–Gibbs channels with different mobilities of the adsorption layers, the volume and surface viscosities, and the electroosmotic pressure—as well as other properties combined in the concept of the structural-mechanical barrier.[18]

External physical influences (a change in temperature, an increase in capillary pressure, irradiation by a stream of α-particles, etc.) alter the rates of the above processes and lead to the breakdown of equilibria. The study of the mechanisms of certain influences helps to achieve a better understanding of the nature of the kinetic processes and equilibrium states and a specific regulation of the stability of the foam.

The method involving the creation of large pressure drops in the liquid phase of the foam and of the corresponding capillary (P_σ) and disjoining pressures in the foam films proved very effective in the study of various physicochemical processes and equilibria in a foam.[2,19,20] In this method, the foam is brought into contact with a porous hydrophilic partition under which a reduced pressure (relative to the atmospheric pressure), not exceeding the capillary pressure in the pores of the partition, is established. Only the liquid but not the gas flows out of the foam under these conditions. This form of external action is most 'natural' for a foam, since a reduced pressure in the Plato–Gibbs channels is an essential condition for the formation of any polyhedral foam. By regulating the pressure drop, it is possible to reduce the positive component of the disjoining pressure by $\Pi - P_\sigma$.

Comparison of the properties of microscopic foam films and the films in a real foam showed that the behaviour of the films in a foam and their response to external influences are more complex than in model films. This is associated both with the difference between the kinetics of various processes in the foam and with the

influence of the dimensions of the films, on the one hand, and with the existence of 'collective effects', arising as a result of the transmission of perturbations due to the rupture of individual films by neighbouring films and bubbles, on the other.[19,20] Various factors stabilising a real foam have been surveyed in a monograph.[2]

II. Methods for the investigation and estimation of the antifoam activities of substances

Various ways of using antifoams are known. They can be introduced beforehand into the working medium (foaming solution) in a pure form or as solutions and dispersions of solid particles in organic solvents (kerosene, turpentine, liquid paraffin) and also as emulsions of different composition in order to prevent the undesirable foam formation. Antifoams are sometimes introduced directly into the foam. The efficiency of antifoams is not the same under these conditions.[1,2]

In view of this, in estimating the antifoam activities of antifoams it is essential to distinguish their effectiveness in disrupting a foam which has already been formed (antifoam action proper) and in preventing foam formation in the foaming process. Substances which are effective in preventing foam formation usually effectively disrupt an existing foam at the same time. On the other hand, many antifoams which effectively disrupt a foam become relatively ineffective in preventing the formation of a foam when introduced into a solution. For example, when drops of butanol and silicone oil are added to a 0.024% solution of saponin, the foam is rapidly destroyed.[21,22] However, when the solution is subsequently shaken with butanol, abundant foam formation again takes place and the resulting foam is stable. On the other hand, the shaking of a solution containing a drop of the silicone antifoam does not induce foam formation.

Various methods are used to estimate the antifoam activities of substances. In the study of the mechanism of antifoam action and of the prevention of foam formation, a comprehensive qualitative assessment of the antifoam activity is very important. This is done in the first place by observing the behaviour of a model foam film (usually macroscopic) when a drop of the antifoam is deposited on it.[23,24] It can involve the observation of the characteristics of the behaviour of the foam or the foam film after the introduction of the antifoam (the nature and rate of attenuation, the lifetime, etc.) and of the behaviour of the antifoam (the form of spreading, fragmentation, the formation of 'bridges', etc.). The film is obtained by withdrawing frames of different size (for example 2 × 1.5 cm) or rings (6–10 mm in diameter). A drop of the test substance or a hydrophobic particle is deposited on the film or the latter is touched with a needle wetted with the antifoam. The film is also obtained from a solution containing the antifoam[13,14] and the nature and rate of its attenuation and disruption are observed.

Similar observations are also carried out when a drop of the antifoam is added directly to the foam investigated immediately after its formation or after a certain time (for example, after 2 or 20 min) or to a solution on the surface of which 'islands' of foam bubbles have been obtained.[7] This permits conclusions concerning the mechanisms of the antifoam action (homogeneous or heterogeneous), the rate of disruption of the foam, the role of the spreading of the antifoams, the influence of solvents on the antifoam activity, etc.

Yet another method for the investigation of the antifoam activity, useful in elucidating the mechanism of the antifoam action, involves the study of the suppression of the formation of optically black spots in microscopic foam films and the influence of the added antifoam.[8,9] This method is based on the fact that a sharp transition to films with a high stability with increase in the concentration of the antifoam is associated with the appearance of black spots in microscopic foam films.[2]

For the film to remain stable after the addition of the antifoams, i.e. in order to ensure the appearance of black spots, it is necessary to increase the concentration of the foam-forming agent. Conversely, with increase in the concentration of the foam-forming agent, the concentration of the antifoam necessary to suppress the formation of black spots must also be increased. Comparison of the ratio of the concentrations of the antifoam and of the agent producing black spots makes it possible to find a measure of the antifoam activity. Such a method for the estimation of the effectiveness of antifoams was first proposed by Ekserova and Buleva.[25]

A direct or indirect determination of the decrease in the stability (lifetime) of the foam or of the decrease in its volume under the influence of a definite dose of the antifoam are used to obtain quantitative characteristics of the antifoam activity. These are usually determined from the average lifetime of the foam or of the relative (compared with the foam without additives) lifetime of the foam in the presence of the antifoam.[1,2] The effectiveness of substances in preventing foam formation is frequently estimated from the decrease in the rate of foam formation for a constant supply of the gas, from the decrease in the height of a column of the foam compared with the height of the foam without the antifoam, etc.[1,2]

For industrial purposes, the antifoam activity (for example, the decrease in the volume of the foam) is referred to a unit volume or mass of the antifoam and sometimes the consumption of the antifoam is compared with the consumption of a standard substance.[1,2] The most complete estimate of the antifoam activity must take into account not only the effectiveness of the substance for different ways of its application but also the influence of the duration of its action (since the effectiveness usually diminishes greatly on contact with the solution) as well as the influence of the solvent and the form and concentration of the foam-forming agent.

III. The homogeneous (adsorption) mechanism of the antifoam action

Any decrease in the lifetime of a foam as the composition of the solution is altered may be regarded as the manifestation of antifoam activity and in this sense the process can be regarded as part of the problem of the stability of foams. However, antifoam action has come to be regarded as the rapid disruption of the foam by special additives and such a process and the mechanisms inducing it constitute a special theoretical and applied problem in colloid chemistry. It is at present difficult to predict theoretically the rate of disruption of a foam even in the simplest systems, for example, in foams for which the type of foam films and the internal structure and capillary (disjoining) pressure, determining the thickness of the films in the absence of an antifoam, are known. One of the main reasons why the mechanisms of the antifoam activity have not yet been fully elucidated is associated with this factor. Furthermore, antifoam activity is caused by many factors on which the effectiveness of antifoams also depends.

One of the possible mechanisms of the action of antifoams involves the adsorption displacement (complete or partial) of the molecules of the foam-forming agent from the interfaces of the foam films and the formation of mixed adsorption layers, which exhibit a poor stabilising activity.

The idea of the adsorption mechanism of the antifoam action was put forward in early studies by Quinke to account for the disruption of the foam on beer by ether vapour.[1] This idea is extremely widespread and is used to explain antifoam activity and de-emulsification,[1,4,26,27] although special studies designed to confirm and determine the details of the adsorption mechanism have been scarcely carried out.

As mentioned above, the disruption of a foam by antifoams introduced into the foam or the foam-forming solution as drops of the pure antifoam or its solutions in organic solvents immiscible with water or directly in the form of emulsions has been investigated in most of the studies. The spreading of the antifoam on the foam-forming solution (for a positive spreading coefficient

or a positive spreading pressure) does not permit an unambiguous conclusion concerning the mechanism of the antifoam action: it can be both homogeneous and heterogeneous.

The only reliable indication of a homogeneous mechanism of the antifoam action is provided by the results of a direct study of the decrease in the stability of foams in foam-forming systems containing an antifoam in an amount not exceeding its solubility (the true solubility or the colloidal solubility in the form of a solubilised system).

The disruption of foams by ethanol was already known to Plato. However, the antifoam activity of alcohol is low: the complete prevention of foam formation requires a concentration of about 25%. The properties of the solvent (mixture of water and alcohol) are markedly altered at such a high concentration.

The prevention of foam formation and the disruption of a foam obtained from a solution of sodium dodecyl sulfate (DDSNa) has been investigated under conditions where after the introduction of the antifoams (19 kinds in all) it was known exactly whether the system was homogeneous or heterogeneous.[28] When certain homogeneous systems (ethyl acetate, oleic acid) were used to prevent foam formation, virtually no decrease in the volume and stability of the foam was observed, but when the system became heterogeneous an appreciable suppression of foam formation was noted.

An almost complete prevention of foam formation in the homogeneous region is characteristic of other homogeneous systems (phenol, pentyl and butyl alcohols, butyric acid, ethyl ether, and triethyl phosphate)—when the antifoam was introduced, the height of the foam after 10 min did not exceed 0.4–0.5 cm, while the height of the foam in an aqueous DDSNa solution without additives was 10 cm. This confirms unambiguously the homogeneous mechanism of the antifoam action.

The antifoam activities of readily soluble antifoams—lower saturated alcohols—have been compared[29] over a wide range of concentrations, including the region of the transition from the homogeneous to the heterogeneous system. The effectiveness of the antifoams was estimated from their ability to prevent foam formation. The dependence of the decrease in the lifetime of the foam on the concentration of the antifoam is illustrated in Fig. 1 for certain foam-forming agents.

Comparison of the stabilities of foams in the homogeneous region showed that, in order to decrease the lifetime of the foam to the same value, for example to 20 min, the amount of butyl alcohol required is ~10–30 times greater than that of hexyl alcohol (depending on the nature and concentration of the foam-forming agent). This means that the antifoam activity of the lower homologous alcohols is approximately directly proportional to the surface activity of the alcohol. According to Traube's rule, the surface activity increases by a factor of 12 on passing from butyl to hexyl alcohol.[30] The most effective suppression of foam formation in the homogeneous region has been observed in a solution of saponin, which is probably associated with the fact that it has the lowest surface activity and with the poor stabilising activity of mixed adsorption layers. These results confirm, at least qualitatively, the fact that in the given homogeneous system the antifoam activity of the antifoam is determined by its adsorption capacity and that in a number of systems (DDSNa–isovaleric acid, OP-10‡–butyl alcohol) virtually complete suppression of foam formation is observed after the attainment of the concentration corresponding to the solubility limit (saturation). However, in other systems, for example DDSNa–hexyl alcohol and OP-10 (0.1%)–tributyl phosphate (TBP) and in all cases where higher homologues of alcohols are used,[29,31] an appreciable stability of the foam is retained (the lifetime is 10–25 min) up to the instant of saturation, but the subsequent increase in the concentration of the alcohols and transition to the heterogeneous region lead to the complete disruption of the foam and prevention of foam formation.

Convincing evidence for the inadequacy of the adsorption displacement of the foam-forming agent in antifoam action has also been obtained in studies of the suppression of the formation of black spots in microscopic foam films by the addition of aliphatic alcohols and acids.[8,9] It was shown experimentally[8,9] that this effect (i.e. the conversion of foam films into an unstable form) occurred in all the systems investigated only after the attainment of the limiting solubility of the antifoam in the solution of the foam-forming agent. These and the results mentioned previously[23,28] indicate the possible operation of two mechanisms of the antifoam action different from the adsorption-displacement mechanism and associated with the appearance of a new phase. In a number of systems (for example, in a mixture of saponin and soap), the antifoam action can be accounted for within the framework of the homogeneous mechanism but in a more complex specific form[32] with allowance for chemical interaction.[2]

In the homogeneous mechanism of the antifoam action, the effect of the antifoam reduces mainly to the alteration of the properties of the adsorption layers of the foam film, the rate of adsorption,[26,33] the elasticity, the surface viscosity,[26,34] and the positive component of the disjoining pressure. Antifoams sometimes influence indirectly the surface properties of foam films by altering the solubility of the foam-forming agent or its critical concentration for micelle formation (CCM). Thus it has been established[35,36] that the addition of 2-ethylhexanol, TBP, and tetradecanol increased the CCM of the foam-forming agent (sodium oleate, DDSNa, etc.) and hence reduced the surface activity.

Ross and Young[37] divided all antifoams into two groups: the first (for example, TBP) mainly accelerate the syneresis of foams by decreasing the surface viscosity and elasticity, while others (for example, isobutylcarbinol) increase the critical thickness of the films or more precisely convert the metastable foam films into unstable ones, which are ruptured at a certain critical thickness (in conformity with theory§; for further details, see Kruglyakov and Ekserova[2]).

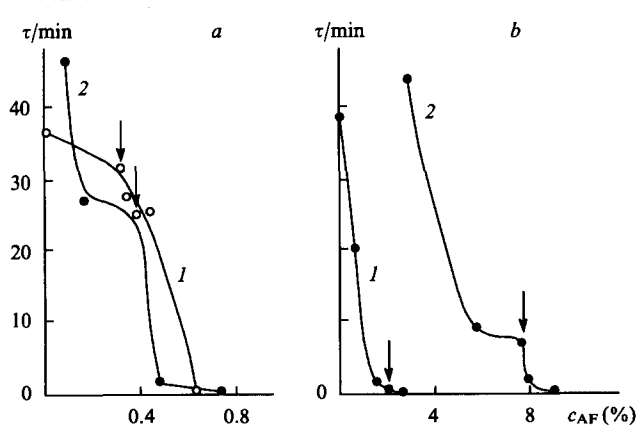

Figure 1. Dependence of the lifetime of the foam on the antifoam concentration. Antifoam: (*a*) 5 × 10^{-1} M DDSNa + 0.4 M NaCl + hexyl alcohol (curve *1*); 0.1% OP-10 + 0.1 M KCl + hexyl alcohol (curve *2*); (*b*) 5 × 10^{-5} M DDSNa + 0.4 M NaCl + isovaleric acid (curve *1*); 2.5 × 10^{-4} M DDSNa + 0.4 M NaCl + butyl alcohol (curve *2*). The limiting solubilities of the antifoams are indicated by arrows.

IV. The spreading of antifoams and the effectiveness of the antifoam action

Antifoams frequently spread on the surface of the foam-forming solution (and foam films produced from this solution), destroying foam thereby, and for this reason many investigators explain the antifoam activity as being due to spreading.[2,21,25] Leviton and Leighton[38] were among the first investigators to relate the effectiveness of an antifoam to the spreading pressure. Ross and coworkers,[35,37,39] who investigated the influence of spreading on the antifoam action in greatest detail, concluded that there are several types of effects by the spreading substance on the stability of foam films.

The first type of effect involves the formation of a polymolecular spreading film. A condition for polymolecular spreading is a positive value of the initial spreading coefficient ($S_{B/A}$)¶:

$$S_{B/A} = \sigma_A - \sigma_{AB} - \sigma_B \ , \qquad (1)$$

where σ_A and σ_B are the surface tensions of the foam-forming solution A and of the antifoam B, while σ_{AB} is the interfacial tension between A and B.

Rapid spreading of an organic film on the surface of water is usually observed when this liquid has low surface and interfacial tensions. The coefficients $S_{B/A}$, calculated by Eqn (1) for several typical antifoams with a positive initial value of $S_{B/A}$ on the surface of foam-forming solutions, are listed in Table 1.

Table 1. Initial spreading coefficients.[7,31]

Antifoam	Surface tension of antifoam/mN m^{-1}	Foam-forming solution	
		I	II
Alcohols			
Butyl alcohol	24.6	3.0	4.7
Hexyl alcohol	25.3	1.1	1.7
Organosilicon compounds			
Polymethylsiloxane PMS-200	20.4	4.8	3.5
Polyhydrosiloxane liquid PGZh-891	20.2	6.3	6.9

Note. (I) σ_A = 28.5 mN m^{-1}; 1% solution of sulfonol (technical alkyl arenesulfonate) + 0.1% carboxymethylcellulose; (II) σ_A = 31.0 mN m^{-1}; 1% OP-10 solution.

Some time after the addition of the antifoam, the liquids are mutually saturated (at least in a thin layer) and the tensions σ_A and σ_{AB} vary up to the equilibrium values (σ'_A and σ'_{AB}), while the equilibrium spreading coefficient $S''_{B/A}$ becomes negative. Thus, for positive coefficient $S_{B/A}$, the liquid spreads in the form of a polymolecular film and soon after saturation the main bulk of the substance assumes the form of a lens, while the remainder exists in the form of a saturated monolayer.

The characteristic form of the lens is presented in Fig. 2. The shapes of such lenses and the equilibrium condition have been investigated in a number of studies (see, for example, Adamson[40]).

According to the Neuman equation, we have at equilibrium

$$\sigma'_A \cos\gamma = \sigma'_B \cos\beta + \sigma'_{AB} \cos\alpha \ . \qquad (2)$$

¶ A similar condition was used for a hypothetical film of condensed ether vapour in an early study by Quinke as a condition governing the displacement of the foam-forming agent by the antifoam.[4]

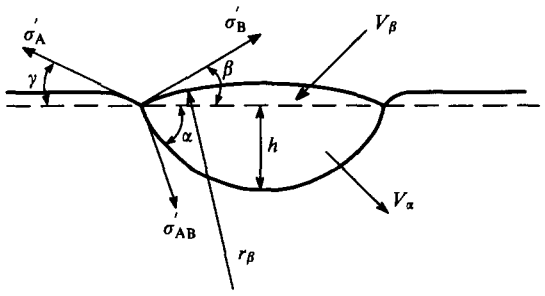

Figure 2. Profile of the organic liquid lens on water (for explanation, see text).

The angle γ is usually small and may be neglected in calculations of equilibria. The lens may be represented in the form of two spherical segments with volumes V_α and V_β. The volume of a segment is

$$V = \pi\left(r - \frac{h}{3}\right)h^2 \ , \qquad (3)$$

where h is the height of the segment and r the radius of curvature.

Furthermore, the radii of curvature of the upper (r_β) and lower (r_α) segments are related by the Laplace equation

$$r_\beta = r_\alpha \frac{\sigma'_B}{\sigma'_{AB}} \ . \qquad (4)$$

Table 2 presents the angles α and β for lenses floating on the surface of water.[41,42]

Table 2. The surface and interfacial tensions as well as the wetting angles for the lenses floating on the surface of water.

Substance	σ'_A/ mN m^{-1}	σ'_B/ mN m^{-1}	σ'_{AB}/ mN m^{-1}	α/ deg	β/ deg
Benzene	62.3	28.8	35	6	7.3
Chloroform	59.4	27.1	32.6	4.7	5.7
Heptyl alcohol	28.5	26.8	7.7	67	16
Octyl alcohol	28.8	26.2	8	70.5	16.7

Comparison of the data in Tables 1 and 2 shows that the tensions σ'_A and σ'_B in alcoholic systems are similar. Thus the angles α and β in typical antifoam systems (Table 1) are the same as for alcohols on the surface of water (Table 2). These angles may be used to predict the behaviour of the film (rupture or equilibrium) with a lens which covers the film.

The second type of effect is monomolecular spreading equivalent to the adsorption penetration by the molecules of the antifoam into the surface layer of the foam-forming agent. A necessary condition for monomolecular spreading is a positive surface pressure[40]

$$\pi^0_{BA} = \sigma_A - \sigma'_A = RT \int_{P(\Gamma=0)}^{P_0(\Gamma_\infty)} \Gamma \ln p \ , \qquad (5)$$

where Γ is the degree of adsorption of substance B, Γ_∞ the limiting degree of adsorption of substance B, and p the saturated vapour pressure of substance B for a negative initial spreading coefficient $S_{B/A} < 0$.

The surface pressure can also be determined from the difference between the initial ($S'_{B/A}$) and final (equilibrium $S''_{B/A}$) spreading coefficients:[40]

$$\pi^0_{B/A} = S'_{B/A} - S''_{B/A} \quad (6)$$

According to Ross's data, polymolecular spreading is most effective for the disruption of a foam, although Ross did not discover the mechanism of the action of such a film. Among the numerous systems investigated by Ross and coworkers,[21,37,39] Robinson and Woods,[43] and Pattle,[44] very many of those for which the conditions $S_{B/A} < 0$ and $\pi^0_{B/A} < 0$ hold proved to be effective antifoams (see, for example, Tables 3, 1, and 6 in the papers of Ross and Young,[37] Ross,[39] and Robinson and Woods[43] respectively). The effective disruption of a foam for $S_{B/A} < 0$ was also noted in later investigations.[7,13,45]

The possibility of the direct preparation of stable aqueous films on a support comprising certain antifoams[9] demonstrates that the condition for polymolecular spreading is not by itself either necessary or sufficient for the antifoam activity. Nevertheless, in a later study Ross[46] and a number of other investigators (see, for example, Pletnev[47] and Kozhanov et al.[48]) continued to assume that the antifoam activity in heterogeneous systems is a consequence of polymolecular spreading and suggested that the condition $S_{B/A} > 0$ be used as the principal criterion for the selection of effective antifoams. It is therefore useful to consider in greater detail the role of the spreading of antifoams in the prevention of the formation of foams and in the destruction of foams.

A study has been made[7] of the antifoam activity of aliphatic alcohols, acids, and polysiloxanes in two foam-forming systems with a high surfactant concentration (0.1% of OP-10 and 1% of sulfonol) with exact monitoring of the spreading. The antifoam activity was estimated both from the rate of disruption of the foam and from the ability to prevent its formation. The condition $S_{B/A} > 0$ served as the criterion of polymolecular spreading, while $\pi^0_{B/A} > 0$ combined with $S_{B/A} < 0$ served as the criterion of monomolecular spreading. In addition, the Wilhelmy balance was used to monitor the spreading directly.

An effective antifoam activity has been observed also for polymolecular (hexyl alcohol, PGZh-891) and monomolecular (heptyl and decyl alcohol in both systems, oenanthic and caprylic acids in solution in sulfonol) spreading and also in the absence of any spreading (caprylic and pelargonic acids). The nonpolar polysiloxane PMS-200 (without filler), having a high positive spreading coefficient, exhibits a very low antifoam activity.

In other experiments, the influence of antifoam drops on the disruption of foam 'islands' on the surface of the solution was observed.[7] It was established that only direct contact between the antifoam drops and the bubbles leads to the effective disruption of the foam. It was noted that polymolecular spreading of the polysiloxane PGZh-891 is completed by the fragmentation of its film into small droplets, which is an important factor, increasing the effectiveness of the antifoam.

It has also been shown that the antifoam activity of dispersions of solid stearic and palmitic acids[13] and of trialkylmelamine[49] is not due to spreading.

The results of a series of investigations[7,13,45,49] permit the conclusion that the effective action of antifoams in heterogeneous systems is not associated with any particular form of spreading and that an explanation of the partial association of positive values of $S_{B/A}$ and $\pi^0_{B/A}$ with effective antifoam activity can probably be found by comparing these conditions with the condition governing the instability of asymmetric aqueous films.

Yet another condition necessary for the manifestation of antifoam properties is believed to be a positive value of the so called disruption coefficient R,[26,43] for which the drops of the antifoam are believed[43] to penetrate the foam film between the bubbles. The positive disruption coefficient is given by[43]

$$R = \sigma_A - \sigma_B + \sigma_{AB} = -(\sigma_B - \sigma_A - \sigma_{AB}) > 0. \quad (7)$$

Evidently R is a negative coefficient for the spreading of the foam-forming solution on the antifoam, i.e. condition (7) is the condition for the nonwetting of B by a solution of A ($S_{A/B} < 0$). Condition (7), in the form of the negative spreading coefficient $S_{A/B}$, describes[50] yet another possible mechanism of the antifoam action, in which nonwetting is considered as a condition for the instability of the aqueous film.

However, it is known from the analysis of the stability of asymmetric films[51] that the fulfillment of the thermodynamic condition (7) is sufficient for the instability of an aqueous film on an antifoam support. It is then possible to obtain long-lived metastable aqueous films on an antifoam support stabilised by surfactant adsorption layers (similarly to stable foam films). The possibility of effective antifoam action should therefore be sought in the conditions for the instability of metastable films.

V. The antifoam effect of drops of organic liquids

Various organic liquids, sparingly soluble in water, appreciably diminish the stability of a foam on coming into contact with the latter.[28,45,48,50,52]

When a foam is formed in the presence of drops of an organic phase immiscible with the aqueous solution, there is a possibility of the formation of asymmetric aqueous films bounded by the gaseous medium on one side and by the antifoam phase on the other. Such aqueous films on an antifoam support can be obtained in the course of the attenuation of foam films if the solution of the foam-forming agent contains drops of an antifoam in the form of an emulsion (Fig. 3) and also when a solution of the antifoam is atomised in the form of an aerosol over the foam or when it spreads on the surface of the films and when the films containing drops of the antifoam are ruptured. The formation of an asymmetric film from a foam film containing drops of an organic liquid is promoted to a large extent by the absence of a charge on the drops, by a high concentration of the disperse phase, and by other conditions influencing heterocoagulation.

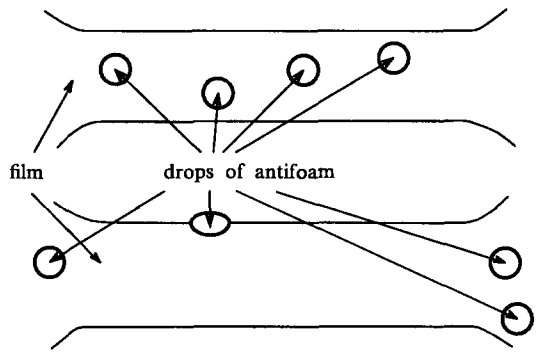

Figure 3. Schematic explanation of the formation of asymmetric films.

The asymmetric film (film on an antifoam support) can be part of the foam film or it can be fully bounded on one side by the organic phase, as in the polymolecular spreading of an antifoam on a film. If the asymmetric film formed is in a state of non-equilibrium for all thicknesses and is ruptured following the attainment of a critical thickness, its rupture leads to the disruption of the entire foam film of which it was a component. On the other hand, if the asymmetric film reaches equilibrium at a certain thickness (h), its influence on the stability of the foam film will depend on the height of the barrier on the disjoining pressure isotherm $\Pi(h)$. For the same height of the barrier, the lifetime of the foam film will evidently remain virtually unaltered. However, in the presence of antifoam drops the concentration of the foam-forming agent usually decreases in the aqueous phase as a consequence of its extraction by the drops of the organic liquid

and the additional adsorption on the drops. The adsorption of the surfactant on the water–antifoam interface is as a rule much smaller than on the water–gas interface, so that the energy repulsion barrier, generated by the interaction of the adsorption layers of the foam-forming agent on the water–antifoam and water–gas interfaces is significantly reduced compared with that in a two-sided film with adsorption layers on the water–air interface. Thus in this case too the antifoam exhibits a definite foam destroying capacity.

Analysis of the stability conditions shows that aqueous films on a support consisting of an organic phase are thermodynamically unstable.[4,51] Metastable asymmetric aqueous films can be obtained under certain conditions when the adsorption (Π_{ads}) or electrostatic (Π_{es}) components of the disjoining pressure, arising in the course of the attenuation of the film, exceed the molecular attraction Π_{vw} within a certain range of thicknesses:[51]

$$\Pi_{es}+\Pi_{ads} > \Pi_{vw}.$$

Model films of this type were first obtained from a solution of a nonionogenic surfactant—20-hydroxyethylated nonylphenol [NP-20, concentration $(1-5) \times 10^{-2}$%] with added magnesium sulfate on a cyclohexane support.[53] As in the case of foam and emulsion films, two types of equilibrium films were obtained in this case depending on the electrolyte concentration: the usual films and Newtonian black films.

In such films, the minimum surfactant concentration (c_{st}), necessary to obtain stable films (with a lifetime in excess of 10 min), depends greatly on the polarity of the organic phase (Table 3).

Table 3. Surfactant concentrations ensuring the formation of stable aqueous films on the surfaces of organic liquids.[9]

Organic phase	Surfactant concentration × 10^3 (%)	
	OP-10	Saponin
n-Decane	–	4
Benzene	3	3
Decyl alcohol	4	2
Heptyl alcohol	7	8
Butyl alcohol	Unstable films	

Note. The minimum surfactant concentrations for which thin (grey) films with a lifetime not less than 10 min were obtained.

In the case of a nonpolar organic phase, c_{st} does not differ greatly from the minimum concentration required to obtain a stable foam film, i.e. the concentration for the formation of black spots c_{bl} ($c_{bl} \approx c_{st}$). For example, $c_{bl} = 7 \times 10^{-4}$ % for a saponin solution and $c_{bl} = 1.2 \times 10^{-4}$ % for an OP-10 solution. This means that the effective disruption of the foam by nonpolar hydrocarbons due to the formation of unstable films is possible only at very low concentrations of the foam-forming agent (less than 0.003%–0.004% for saponin and OP-10). At higher concentrations of the foam-forming agent, the foam destroying capacity of the antifoam is determined by the slight decrease in the energy barrier and certain kinetic factors (for example, by additional adsorption).

The lifetime of a foam on an organic support diminishes greatly following the establishment of a reduced pressure in the Plato–Gibbs channels as a consequence of the decrease in the repulsion forces barrier by the amount $\Pi-\Delta P$ (where ΔP is the decrease in the pressure within the channels).[2,54] For alcohols, the difference between c_{bl} for foam films without and with added antifoam becomes significant and, on a support comprising lower alcohols, it is altogether impossible to obtain stable aqueous films as a consequence of the sharp decrease in the adsorption of the foam-forming agent on the water–antifoam interface (Table 3).

The simplest mechanism of the action of an antifoam (with barrier-free rupture whereupon the asymmetric film is in a state of nonequilibrium for all thicknesses) operates when highly polar organic liquids with a high affinity W_A for the aqueous medium are employed:

$$W_A = \sigma_A+\sigma_B-\sigma_{AB}.$$

In this case, the adsorption of the foam-forming agent at the water–antifoam interface is impossible (or its extent is very low) over the entire range of concentrations up to and including the CCM, because in such systems

$$\sigma^0_{AB} \approx \sigma_{AB} \approx 0, \quad (8)$$

where σ^0_{AB} is the interfacial tension on the antifoam–water interface and σ_{AB} is the interfacial tension on the interface with the aqueous solution of the foam-forming agent.

A low degree of adsorption of the foam-forming agent on the water–antifoam interface occurs in various foam-forming systems,[10] where lower alcohols (propyl and butyl) are used as antifoams at concentrations which exceed their solubility, and $\sigma^0_{AB} \sim 0$.

The same heterogeneous mechanism of the disruption of the foam with formation of unstable films on a support operates when the foam is introduced into highly polar liquids (partially or fully soluble in water): lower alcohols and acids, ketones, ethers, etc.[45] The rate-limiting stage in the disruption of the foam may be determined in this instance by various kinetic factors (the suction of the organic liquid into the foam, the rate of its dissolution in water, etc.), but the instability of the films is due to the sharp decrease or complete loss of the surface activity of the foam-forming agent on the water–antifoam interface.[45]

A heterogeneous mechanism of the antifoam action of drops has been described.[2,9,10,55] The second stage of the disruption of the foam film after the rupture of the asymmetric film and the appearance of a two-sided (symmetrical) antifoam lens within the foam film was not considered because the instability of such a system was regarded as evident.

Fig. 4 illustrates the possible behaviour of the antifoam lens after the rupture of the asymmetric film. It is seen that, when the lens shape is retained, the drop is continuously extended as a consequence of the inequality

$$\sigma'_B\cos\beta < \sigma'_A+\sigma'_{AB}\cos\alpha,$$

and is converted into a planar film of the substance. Without attaining mechanical equilibrium, the film of substance B and the foam film will be ruptured. On the other hand, if the drop rapidly assumes a shape close to spherical after the rupture of the asymmetric film, then, under the conditions of a temporary local mechanical drop–film equilibrium, the foam film forms a convex meniscus with an increased capillary pressure within it. The outflow of the liquid from the meniscus leads to a further rapid approach of the surfaces of the foam film and the drop until they touch and the foam film is then separated from the drop (slips off) and is destroyed. The instability of liquid drop 'bridges' within the foam film has also been indicated by Garrett.[12]

The disruption of a foam by diphilic antifoams as a consequence of the surface activity on the water–air interface takes place with the joint operation of two mechanisms–homogeneous (adsorption displacement) and heterogeneous. This is yet another of the causes of the greater effectiveness of diphilic antifoams compared with nonpolar liquids.

The contribution of the heterogeneous mechanism in the disruption of the foam in such systems can be isolated and estimated only in a quantitative study of the dependence of the foam destroying capacity of the antifoam on its concentration when passing from a homogeneous to a heterogeneous system.[29] The contribution of the heterogeneous mechanism usually increases at high surfactant concentrations, whereupon the homogeneous mechanism proves to be relatively ineffective.

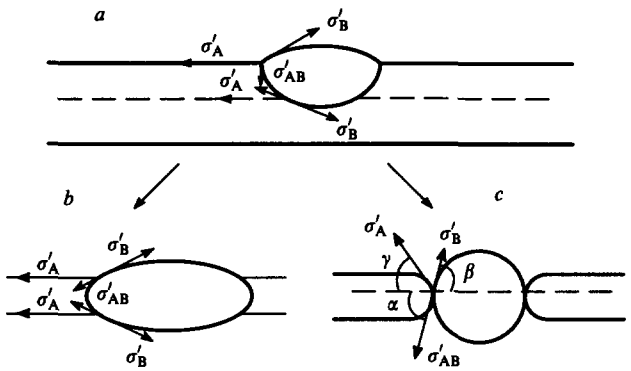

Figure 4. Schematic illustration of the behaviour of the antifoam lens on formation of a 'bridge' in the foam film: (*a*) initial stage after the rupture of the asymmetric film (the second side of the film is shown dashed); (*b*) extension of the lens with retention of the initial shape; (*c*) formation of a convex spherical meniscus near the antifoam drop.

A series of important features of foam formation and destruction in heterogeneous systems have been explained on the basis of the mechanism of the heterogeneous antifoam action:[2,55,56] the temperature dependence of the stability of foams produced from solutions of nonionogenic surfactants in the region of their turbidity temperature, the influence of solvents on the foam-destroying capacity of antifoams when they are used in the form of solutions, and, especially, the inversion of the antifoam activity in the series of aliphatic alcohols.[10]

VI. The antifoam effect of solid hydrophobic particles

Kurzendorfer[49] reported that, when particles of solid trialkylmelamine in suspension in alkyl benzenesulfonate fall on the surfaces of films, they cause their rapid rupture, which is not associated with the formation of mixed layers comprising trialkylmelamine and sulfonate molecules (with the adsorption displacement mechanism).

It has also been reported[57] that, when atomised silica particles which have been rendered hydrophobic enter a foam, they lead to the rapid disruption of the films in those bubbles which are in contact with the particles. Garrett later showed[11] that the chemically inert 5–40 μm particles of dispersed Teflon act as an effective antifoam on contact with a foam. He explained their antifoam properties by the appearance of hydrophobic 'bridges' made up of such particles and passing through the film and by their nonwettability. The formation of 'bridges' with subsequent rupture of the film near the hydrophobic particles (glass beads which have been rendered hydrophobic, lead sulfide, etc.) was demonstrated by Dippenaar[58] using a high speed filming technique.

The studies of the influence of hydrophobic particles on the stability of foams generated from aqueous surfactant solutions were later continued by other investigators.[12–16] The influence of the method used to form the foam and of the state of aggregation of the particles and of their shape on the effectiveness of the disruption of the foam was examined and the joint action of solid and liquid particles was investigated. In Garrett's experiments,[11] the foam was obtained from solutions of surfactants of different types (6-hydroxyethylated tetradecyl alcohol, tetradecyltrimethylammonium bromide, and DDSNa) by shaking in a 250 ml cylinder for 15 s. The three-phase contact wetting angles θ, measured on a plate wetted with water, were $\theta = 108° \pm 5°$ (incoming flow angle) and $\theta = 97° \pm 5°$ (outgoing flow angle). The volume of the foam in the presence of Teflon particles (40 mg per 50 ml of the solution) diminished by a factor of 2 and at low surfactant concentrations the foam was not obtained at all.

Garrett[11] deduced a thermodynamic justification of the critical value of the wetting angle at which the film ruptures spontaneously as a consequence of the formation of the hydrophobic particle 'bridge' between both surfaces of the foam film and the subsequent 'slipping off' (separation) of the menisci from the particles.

Garrett's analysis was based on the calculation of the change in the Helmholtz free energy when the particle passes from the incompletely or completely wetted state (immersion in the liquid) to a state where the foam film does not wet the elliptical particle at all, forming a point contact with the particle. An improved more realistic model of the rupture as a consequence of the nonwetting of the particle was developed by Frye and Berg.[14]

The mechanism of the rupture of the foam film by hydrophobic particles is explained by the scheme presented in Fig. 5. If the surfactant solution contains poorly wettable particles, then one (or several) may find itself on the surface (flotation by the surface), where it is rapidly oriented, occupying an equilibrium position. After the rupture of the asymmetric film under the particle, the latter moves, as shown by Dippenaar's direct measurements,[58] and occupies a symmetrical position relative to the film, so that the wetting angles on either side of the film are closer to the equilibrium values. the subsequent behaviour of the film around the particle depends on the equilibrium wetting angle. If $\theta < 90°$ (for a sphere), then the initially convex meniscus around the particle is converted, after the attainment of the equilibrium wetting angle, into a concave meniscus with a reduced pressure, which prevents further attenuation. If $\theta > 90°$, then after the formation of a 'bridge', a convex meniscus with an increased pressure $\Delta p = 2\sigma/R$, where R is the radius of curvature of the surface of the meniscus, appears. The increased pressure expels the liquid from the menisci and, since equilibrium is not attained under these conditions, the mutual approach of the surfaces around the particles continues until they come into full contact. This leads to the 'slipping off' (separation) of the meniscus, the 'liberation' of the particle, and the rupture of the film. This model has been used by Frye and Berg[14] to calculate the time required to disrupt such films. This time is made up of the attenuation time until the formation of a 'bridge' and the time required for the dewetting of the particle (direct rupture of the film). According to the authors,[14] the rupture time must be sufficiently short for the particle to behave as an effective antifoam. The attenuation time (τ) up to the formation of a 'bridge' was determined from the

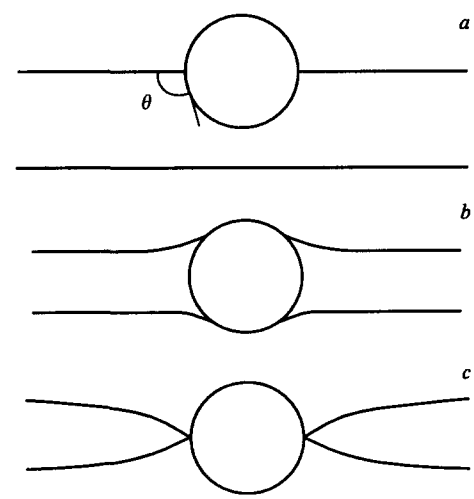

Figure 5. The influence of a solid hydrophobic spherical particle on the behaviour of the foam film: (*a*) equilibrium position on the surface; (*b*) local thickening of the film near the particle for $\theta < 90°$; (*c*) local attenuation of the film near the particle, inducing the rupture of the latter, for $\theta > 90°$.

Reynolds equation [2, 14] on the assumption that the surface of the film is fully retarded (immobile):

$$\tau = \frac{3\mu R}{2\Delta p h^2}, \quad (9)$$

where R is the radius of the circular film, μ the dynamic viscosity, Δp the capillary pressure, and h the thickness of the film at the instant of the appearance of the 'bridge'.

In the calculation of the rupture time (the time required for contact between the surfaces of the two menisci), it is assumed that the particle occupies a symmetrical position relative to the surfaces of the film. Fig. 6 illustrates the region of contact between the film and the particle and presents the designations of the quantities used to calculate the rupture time.

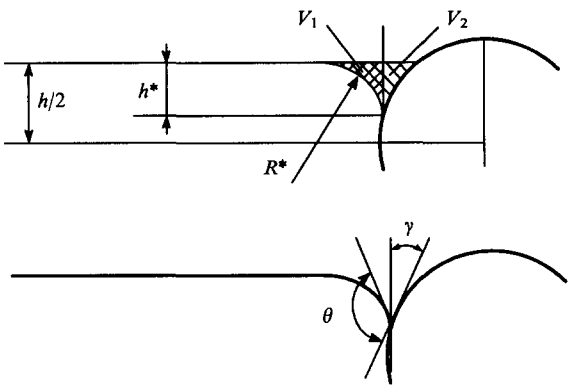

Figure 6. Schematic explanation of the significance of the parameters used to calculate the film rupture time.

In the initial state, the surface of the film is planar until there is contact with the solid particle; while at the instant of rupture, at which point the edges of the menisci come into contact, the thickness of the film becomes $h = 2h^*$. The rate of the mutual approach of the menisci depends on the volume rate of attenuation of the film and on the excess volume of the liquid ($V_1 + V_2$).

The calculation was based on Eqn (9) with substitution of the capillary pressure given by

$$\Delta p = \frac{\sigma}{R^*} = \frac{\sigma[1 - \sin(\theta + \gamma)]}{h^*}, \quad (10)$$

where γ is the angle between the vertical and the tangent at the point of contact between the surfaces of the solid and liquid phases. In this calculation, it is assumed that the excess liquid flows from the meniscus through the entire film, although Dippenaar's observations have shown [58] that the liquid flows only a short distance away from the particle at the instant of rupture. For particles with smooth surfaces without sharp angles (spheres, discs, ellipsoids, and rods oriented at right angles to the surface of the film), the calculation predicts the rupture of the film at $\theta > 90°$. A strong antifoam activity (a rupture time of the order of milliseconds) should be observed already for $\theta = 95° - 100°$.

Among particles of all shapes (to simplify the calculation, only figures of rotation are considered), conical particles alone are effective for $\theta < 90°$. The rupture time for conical particles depends both on the wetting angle θ and on the angle at the apex of the cone (β) and it is essential that $\beta < \theta$. The influence of the initial thickness of the film, the particle size, and other parameters on the film rupture time has also been considered. [14]

The results of the calculation agree well with experiment. The experiments involving the rupture of films obtained on a frame, by piercing the films with thin rods (d = 1 mm) of different materials, are especially instructive. In these experiments, only the shape, size, and orientation of the particles were known. The wetting angle could be measured accurately and it was an incoming flow angle. Furthermore, the problem of the probability of the penetration (entry) of particles onto the surface, which is not entirely evident in the disruption of a foam obtained from a suspension of particles, was in this instance solved unambiguously.

The results of such experiments are presented in Fig. 7. Despite some scatter in the range of angles 95° – 105°, it is readily seen, that for $\theta < 95°$, none of the films is ruptured and, for $\theta > 105°$, all the films are ruptured. Experiments with suspensions of solid particles (Teflon, glass beads which have been made hydrophobic, and ground glass) showed that in the case of 'smooth' particles, the antifoam activity begins to be manifested for $\theta = 35° - 45°$ and complete prevention of the formation of foam occurs for $\theta = 85°$. In the case of rough ground glass particles, effective antifoam action occurs already for 25° – 30° and, when $\theta = 50° - 55°$, a foam is not formed. The quantitative treatment of experiments with suspensions is more complex as a consequence of some uncertainty in the determination of the wetting angle during the rupture of films (owing to its uncertainty as the angle approaches the outflow value), the adsorption kinetics, and other factors.

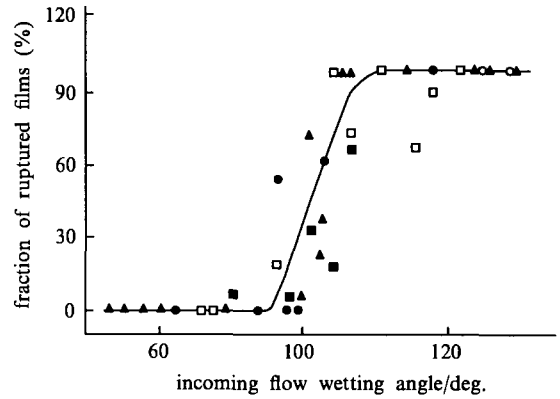

Figure 7. Dependence of the proportion of ruptured films on the incoming flow wetting angle. Antifoam: (*1*) hexadecyltrimethylammonium bromide; (*2*) sodium dodecylbenzenesulfonate; (*3*) Triton X-100. Open symbols — Teflon; filled symbols — glass which has been made hydrophobic.

The influence of the state of aggregation of the particles on the antifoam activity has been investigated by Aronson. [13] It was shown that, regardless of the type of solid particles (hydrocarbon or saturated aliphatic acids), the antifoam activity falls sharply with increase in temperature over a narrow range corresponding to the melting point.

Aronson believes that the most important cause of the large difference between the antifoam activities of liquids and solid particles is the influence of roughness on the stability of asymmetric films. Regardless of their shape, solid particles always have rough regions, which make it possible to overcome the energy barrier hindering the rupture of asymmetric films. However, the heights of the barriers are no less important for the wetting films on solid and liquid supports.

Various synergistic effects in the joint action of solid and liquid hydrophobic particles have been examined on the basis of the model of antifoam action described above. [15, 16] In particular, it has been shown [16] that an increase in the effectiveness of the antifoam action by solid particles in the presence of dodecane is associated with the decrease in the wetting angle θ required to disrupt the foam, while the decrease in the effectiveness of antifoams with increase in the concentration of the foam-forming agent is a consequence of the adsorption of the surfactant on the solid particles and the acquisition of hydrophilic properties by their surfaces.

Comparison of the two mechanisms of the antifoam action in heterogeneous systems permits the following conclusions. A necessary condition for the rupture of foam films in the model of drop antifoams is the instability of the film on the support as the drop approaches the interface. The cause of the instability may be a change in any of the components of the disjoining pressure. The simplest and clearest case of instability occurs when the energy barrier disappears due to the complete loss of surface activity at the water–polar antifoam (aliphatic alcohol or acid) interface.

The rupture stage after the formation of the drop 'bridge'-lens through the foam film is assumed to be evident in this case in view of the instability of the system produced for both lens-shaped and spherical initial drops (Fig. 4).

The second attenuation stage—extending from the formation of the hydrophobic 'bridge' up to equilibrium or rupture—is decisive for the mechanism of the antifoam action by solid particles. The first stage—the rupture of asymmetric films—is assumed to be evident at least for films on solid hydrophobic supports as a consequence of the influence of rough regions, although it has been shown experimentally [13] that, in the absence of such regions, films may be thermodynamically stable (metastable).

In the theory of the rupture of films by hydrophobic particles, the question of the influence of the particle size on the effectiveness of the antifoam action for $r < 1$ μm is not entirely clear. It follows from calculation [15] that the time required to attain rupture shortens with decrease in the particle size (from $r = 10^3$ to $r =$ 1 μm) as a consequence of the decrease in the volume of the meniscus and of the thickness of the film at the instant of formation of the 'bridges'. The experiments in which large particles ($r > 1$ μm) were separated by filtration demonstrated a sharp (almost complete) fall in the antifoam activity in systems without these particles. [13] Furthermore, when very small hydrophobic particles were used ($r = 20-1000$ nm), their pronounced stabilising action was observed and, according to data of Tang et al., [59] such particles behave to some extent like molecules, diminishing the surface tension.

VII. Concentration effects in antifoam processes

The effectiveness of antifoams in preventing foam formation diminishes sharply with increase in the concentration of foam-forming agents. However, as noted above, at high surfactant concentrations many substances effective in destroying foam lose this capacity fully or partially on entering the solution. These changes in antifoam activity, which are frequently extremely significant, may be a consequence of various physicochemical processes.

The mechanisms of antifoam action examined make it possible to explain, at least qualitatively, the various concentration effects in the prevention of foam formation and in the disruption of a foam by the addition of antifoams.

We shall consider certain characteristic instances of changes in antifoam activity following a change in the composition of the foam-forming agent and in the methods used to apply antifoams.

In the development of foam-forming compositions, used to extinguish fires arising on inflammation of liquids which are miscible with water, experiments are carried out on the disruption of the foam by these 'corrosive' liquids, the foam being supplied on to the surface of the liquid. The rate of such contact antifoam action is extremely high, but at the same time, when comparatively large amounts of these liquids (5%–10%) are added to aqueous solutions of surfactants, they cause a comparatively small decrease in the stability of the foam. A marked decrease in stability is observed only with increase in the concentration of the liquids to 20%–30%. The cause of the significant difference between the antifoam activities of these liquids in their contact interaction with the foam and when they are added to an aqueous solution in the given systems is evident: when a foam comes into contact with such liquids, unstable asymmetric films arise in the heterogeneous antifoam process [owing to the complete loss of surface activity by the foam-forming agent on the water–alcohol (ether, acetone) interface]. Furthermore, the surface is 'unstable' as a consequence of the complete miscibility of the phases in contact.

When such solvents are added to water, the stability of the foam does not change, owing to the low surface activity, until the foam-forming agents cease to be surface-active on the liquid–gas interface at very high concentrations owing to the marked change in the composition of the mixture (solvent). For this reason, the foam becomes completely unstable under these conditions.

Another example is the characteristic case involving the use of sparingly soluble diphilic additives (for example, aliphatic alcohols—pentyl, hexyl, heptyl, etc. [31]) as antifoams. With increase in the concentration of the foam-forming agent in systems [10, 31, 60] containing added antifoams in a molecular or drop form, the lifetime of the foam increases and the time required for the formation of its specified volume (Fig. 8), necessary to suppress the formation of black spots in foam films, achieving thereby the complete prevention of foam formation (Fig. 9), diminishes (or the amount of the antifoam increases). For low-molecular-mass diphilic antifoams (alcohols, acids, ethers, etc.), the loss of effectiveness is largely a consequence of the solubilisation of large volumes of the antifoam [31] which decreases the thermodynamic activity (for the dissolved component) and the number of drops, while for initial concentrations of the antifoam less than its colloidal solubility, it is a consequence of the change in the mechanism of the antifoam action (from the joint homogeneous and heterogeneous mechanism in the presence of drops to the homogeneous mechanism after dissolution).

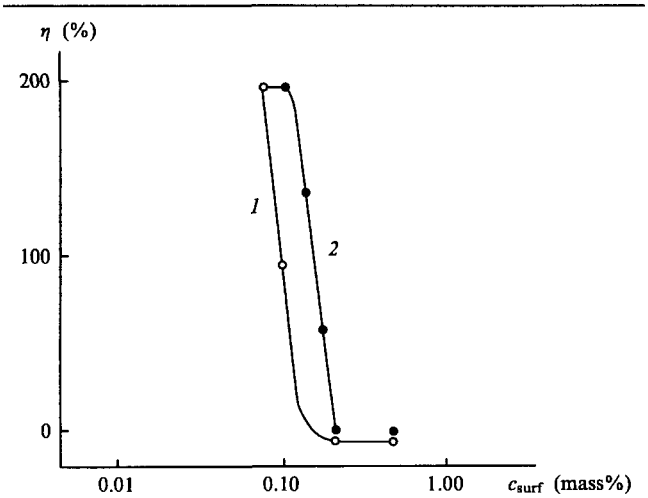

Figure 8. Dependence of the effectiveness of the antifoam action (η) on the concentration of the foam-forming agent (η is the ratio of the rate of foam formation without the antifoam to the rate in the presence of 0.016 vol.% of a 10% emulsion of polydimethylsiloxane as the antifoam): (*1*) 1% DDSNa solution; (*2*) 1% dodecylammonium chloride solution.

Another cause of the decrease in the antifoam activity may be an increase in the stability of the asymmetric films at high surfactant concentrations owing to the increase in the degree of adsorption on the interface between the solution of the foam-forming agent and the antifoam drops. [9, 10]

Yet another important cause of the loss of antifoam activity with increase in the concentration of ionogenic foam-forming agents, particularly when nonpolar (for example siloxane) antifoams are employed, is the appearance of a charge on the drops. Such a case has been studied in detail. [60]

The antifoam activity and the ζ-potential change markedly in the region of the 0.1% concentration of DDSNa, which corresponds approximately to the CCM (Fig. 10). Similar results have been obtained also for a solution of a cationic surfactant. The appearance of a charge stabilises the asymmetric film, the

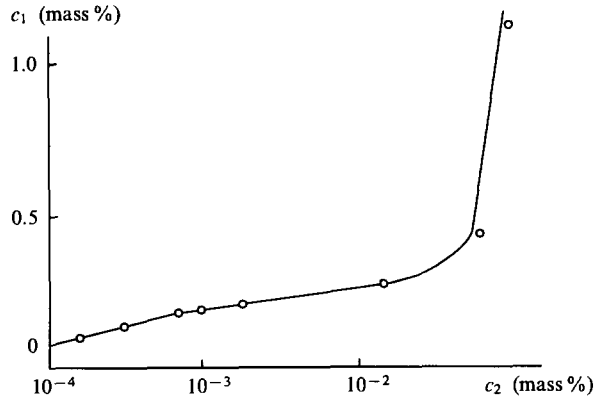

Figure 9. Dependence of the concentration of heptyl alcohol required to prevent foam formation (c_1) on the concentration of the OP-10 foam-forming agent (c_2).

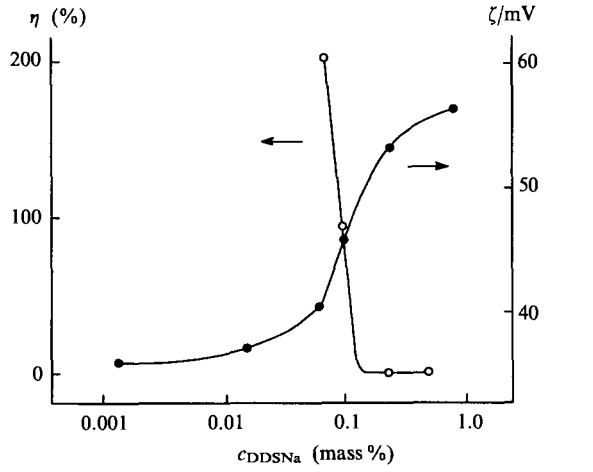

Figure 10. Dependence of the electrokinetic potential ζ and of the antifoam activity η on the DDSNa concentration (amount of added antifoam 0.016 vol.%).

drops cease to fall onto the surface, and the heterogeneous mechanism of the antifoam action becomes relatively ineffective.

The inversion of the antifoam activity in the series of aliphatic alcohols is associated with concentration effects. Systematic studies on higher aliphatic alcohols have shown that, at low concentrations of the foam-forming agents (OP-10, DDSNa, etc.), the effectiveness of the antifoam activity, estimated from the amount of alcohol required for the complete prevention of foam formation, increases along the homologous series with increase in the molecular mass of the alcohol (from butyl to undecyl).[9,10,55] With increase in the concentration of foam-forming agent, the maximum in the antifoam activity begins to shift towards lower homologues and finally, at the very highest concentrations, the lowest member of the series (butyl alcohol), which is fully insoluble in aqueous solution, becomes most effective.

The inversion of the antifoam activity of alcohols and the maximum in the antifoam activity corresponding to the middle homologues at 'medium' concentrations have been explained within the framework of the heterogeneous drop mechanism of the antifoam action.[10]

The effectiveness of the heterogeneous antifoam action is largely determined by two factors: the solubility of the antifoam (the lower the solubility, the sooner the heterogeneous mechanism is 'switched on') and the ability to prevent the adsorption of the foam-forming agent on the interface between the foam film and the antifoam and to destabilise thereby the asymmetric aqueous films.

The solubility of alcohols in the aqueous phase diminishes with increase in their molecular mass and the ability of the alcohols to prevent the adsorption of surfactants, which is determined by the interfacial tension on the interface between the aqueous solution of the foam-forming agent and the alcohol, decreases in the same direction.

At low concentrations of the foam-forming agent, when a minimal excess of any alcohol (relative to its solubility) is sufficient to destabilise foam films, the higher homologues are most effective. Conversely, at high concentrations of the foam-forming agent, the degree of its adsorption on the interface between the film and the alcohol drops is a maximum for the higher homologues, and it is sufficient to stabilise the asymmetric films, so that only films on supports comprising lower alcohols, for which the degree of adsorption of the surfactant is low, are unstable. This is precisely the reason why lower alcohols are the most effective. The inversion of the antifoam activity has been discussed in detail by the present author.[10,55]

In aqueous solutions with a high content of a solubilised organic phase, a marked influence of the amount of the oil on the solubility of foams is observed. By regulating the hydrophilic–lipophilic balance for the foam-forming agent by adding hydrophobic surfactants (for example, the esters of aliphatic acids and anhydrosorbitol, xylitol, and glycerol, aliphatic alcohols, acids, and amines) and also by varying the number of hydroxyethylene groups in the surfactant molecule and the electrolyte concentration, it is possible to obtain a water–oil–surfactant phase three-phase system in such solutions with high water and oil contents.[61,62] A significant increase in the stability of the foam with increase in the concentration of the oil is observed in systems of this kind already in the homogeneous micellar region. For example, the stability of the foam in a 15% solution of DDSNa with added butyl alcohol (up to 16%) decreased greatly on solubilisation of xylene: for a 20%–25% content of xylene, the foam became completely unstable.[63]

Similarly, in a foam formed from a solution of a mixture of technical alkylphenols (OP-10 and alfapol-4)[61] with an average number of hydroxyethyl groups $n = 7.8$ in the absence of an oil (kerosene), the lifetime of the foam exceeded two days, while for a kerosene content of ~20% (still in the homogeneous region) it was only 3 min. In another system,[61] water–kerosene–mixture of volgonate† and FM emulsifier‡ (concentration 30%), the lifetime of the foam fell from tens of hours when the volgonate : emulsifier concentration ratio was 4 : 1 and the kerosene content was 3.5% to 6 h for a concentration ratio of 2 : 3 and a kerosene content of 27%.

With increase in the concentration of pentyl alcohol in the system containing 1% of DDSNa, 1.75% of NaCl, and kerosene, the volume and stability of the foam fell sharply in the region of the hydrophilic–lipophilic balance close to the region corresponding to the appearance of the micellar phase of the surfactant, falling to zero on formation of this phase. The stability of the foam diminished similarly in a number of other systems on formation of the micellar phase.[62]

It is noteworthy that, also in the absence of oils, the stability of the foam is appreciably lower in this region of the hydrophilic–lipophilic balance compared with neighbouring regions. This means that not only the formation of the surfactant phase and the associated significant depletion of the aqueous solution in the surfactant, but also radical changes in the properties of the adsorption layers of the foam films are the causes of the instability of foams (and emulsions). As in many of the other cases considered above, in this instance the foam is disrupted via a mixed mechanism. The instability of asymmetric films is determined by the behaviour of the multilayer metastable foam films formed in these systems.

† Technical alkyl sulfate.
‡ Ester of oleic acid and triethanolamine.

The attenuation of the multilayer films does not take place continuously but with a discrete separation of the layers (stratification) with a thickness which is equal to (or is a multiple of) two surfactant bilayers containing a certain amount of a solubilised oil. [64] In conformity with this, the $\Pi(h)$ isotherm has an oscillating form. [65]

In nonaqueous nonpolar solutions, highly stable foams are usually obtained only in the presence of liquid crystals. [66] In such systems, water and certain other phases may be effective antifoams. The mechanism of the action of such antifoams is unknown.

IV. Conclusion 488

Abstract. The use of hydride forming metals and alloys as hydrogen acceptors in order to overcome the thermodynamic limitations in catalytic reactions involving the evolution of hydrogen is examined. The high effectiveness of intermetallic hydrogen acceptors in reactions involving the dehydrogenation of cycloalkanes, isobutane, and alcohols (C_1-C_3) and the aromatisation of alkanes (C_2-C_3) is noted. The bibliography includes 36 references.

I. Introduction

A unique feature of many transition metals and alloys based on them is the ability to absorb reversibly significant amounts of hydrogen at fairly high rates of absorption and desorption. This particular feature is in fact responsible for the wide scale application of metal hydrides in power and atomic engineering for the storage and purification of hydrogen.[1-3]

The incorporation of hydrogen in the metal or alloy lattice is preceded by dissociative chemisorption with formation of atomic hydrogen, while the evolution of hydrogen from the bulk of the hydride involves the recombination of atoms with subsequent desorption of H_2 molecules into the gas phase. The heterophase exchange of hydrogen between the hydride lattice and the hydrogen in the gas phase takes place continuously. The high activity of the surface centres as regards the dissociation of H_2 and the constant presence of activated hydrogen on the surfaces of hydrides makes it possible to employ compounds of this kind as highly effective hydrogenation catalysts in petrochemistry and petroleum processing.[4-6] The formation of hydrogenation products of hydrocarbons in the presence of hydrides of intermetallic compounds depleted in hydrogen was first observed more than 20 years ago by Lunin et al.[7]

In 1985, the absorption capacity of hydride forming metals and intermetallic compounds was used successfully to overcome thermodynamic limitations in catalytic dehydrogenation processes.[8,9] The reactions involving the dehydrogenation of alkanes, alkenes, and alcohols are known to be thermodynamically unfavourable at moderate temperatures. For example, the dehydrogenation of alkanes C_nH_{2n+2} to alkenes C_nH_{2n} at 298 K is accompanied by an increase in the standard Gibbs free energy.

$$C_nH_{2n+2} \longrightarrow C_nH_{2n} + H_2, \quad \Delta G^0 > 0 \qquad (1)$$

It was found that the introduction of a suitable metal or intermetallic compound (M) into the system displaces the equilibrium appreciably towards dehydrogenation, since the formation of the hydride (MH_2) entails the evolution of energy necessary to effect reaction (1).

$$M + H_2 \longrightarrow MH_2, \quad \Delta G^0 < 0 \qquad (2)$$

The absorption capacity of the initial alloy may be restored in the subsequent regeneration cycle. The combination of reactions (1) and (2) together with the regeneration of the initial alloy can be represented in the following form:

$$C_nH_{2n+2} + M \longrightarrow C_nH_{2n} + MH_2$$
$$\uparrow \qquad\qquad\qquad\qquad \downarrow$$
$$-H_2$$

Consequently the role of the hydride-forming alloy consists in binding the hydrogen evolved on dehydrogenation with the formation of a thermodynamically more favourable compound. This process is in many respects analogous to oxidative dehydrogenation:

$$C_nH_{2n+2} + O_2 \longrightarrow C_nH_{2n} + H_2O,$$

with the sole difference that in the former case a hydride is formed and may be regenerated to the initial alloy with evolution of hydrogen, while in the oxidative version water is formed as a side product.

The first studies using hydride forming metals and alloys as hydrogen acceptors were carried out in relation to the catalytic dehydrogenation of isobutane[8] and cyclohexane.[9] Subsequent investigations made it possible to discover a positive effect, which is attained when the hydrogenation of metals and intermetallic compounds is coupled with a whole series of thermodynamically restricted catalytic reactions proceeding with evolution of hydrogen. The principal results of such investigations are summarised in the present review and the characteristic features of the reactions in the presence of intermetallic hydrogen acceptors are considered.

II. Catalytic reactions using intermetallic hydrogen acceptors

Tables 1 and 2 present the literature data on the application of hydride forming metals and alloys as hydrogen acceptors in catalytic reactions of various organic compounds. Intermetallic hydrogen acceptors have been tested mainly in the dehydrogenation reactions of alkanes and alcohols. Both oxide and zeolite systems with deposited metals and the activated surfaces of the intermetallic compounds themselves have been used as dehydrogenation catalysts. We shall examine in greater detail the reaction conditions and the principal results achieved.

1. Reactions of hydrocarbons

The first reaction in which a hydride forming metal (Ti) was used successfully to remove the hydrogen evolved was the dehydrogenation of isobutane to isobutene.[8] The reaction was carried out in a flow system on a platinum/alumina catalyst (5 mass% Pt) mixed mechanically with titanium powder at 641 K. The mass ratio of the catalyst and the acceptor was 1 : 1.5. As a result of the removal of 60 vol.% of the hydrogen formed, the ratio iso-C_4H_{10} : iso-C_4H_8 in the reaction product was 12.5 : 1, which corresponds to 7.4% conversion of isobutane into isobutene. Under these conditions but without the removal of hydrogen, the equilibrium ratio iso-C_4H_{10} : iso-C_4H_8, calculated from thermodynamic data is 19 : 1 and corresponds to 5.3% conversion. In a repeated dehydrogenation cycle after the regeneration of titanium, the conversion reached 10.4%. Thus, by carrying out the hydrogenation of the titanium powder jointly with the dehydrogenation of isobutane, it was possible to increase by a factor of 1.5 – 2 the yield of the alkene compared with the equilibrium value (without removing hydrogen).

The use under the same conditions of the intermetallic compound $Ti_{0.63}V_{0.27}Fe_{0.1}$, which functions simultaneously as a hydrogen acceptor and as a dehydrogenation catalyst, did not yield a positive result owing to the low catalytic activity of the intermetallic compound. The conversion to isobutane did not exceed 1% in this case although the hydrogen formed was fully absorbed by the acceptor.

The dehydrogenation of isobutane to isobutene has also been investigated in the presence of the ZrNi and ZrCo hydrogen acceptors on the Pt/Al_2O_3 and Pt/SiO_2 catalysts for a catalyst : acceptor mass ratio of 1 : 3.[10] The reaction was carried out at 300 and 350 °C. The calculated equilibrium yield of isobutene under these conditions, without the removal of hydrogen, was 1.5% and 4.2% respectively, while in the presence of the intermetallic compound ZrNi it reached 4.3% and 11.5%, i.e. exceeded the equilibrium yield by a factor of 2.5 – 3. The intermetallic compound ZrCo and the Pt/SiO_2 catalyst proved to be less effective in this reaction.

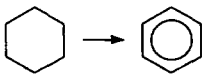
The highest yield of isobutene from isobutane, amounting to 45%, which exceeds by a factor of 2 the equilibrium yield under the same conditions without the removal of H_2, was achieved at 470 °C in the presence of the Cr_2O_3/ZrO_2 catalyst mixed with the intermetallic compounds Zr_2Fe.[10]

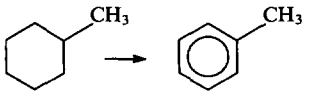
The effect of hydride-forming intermetallic compounds on the dehydrogenation of cycloalkanes to the corresponding aromatic hydrocarbons has been considered in a number of studies.[9,12–14] In the series of intermetallic compounds tested,[9,12] $CaNi_5$ proved to be the most effective hydrogen acceptor. In its presence, the yield of benzene from cyclohexane on the Pt/Al_2O_3 catalyst at 150 °C increased by a factor of 3.5 compared with the equilibrium yield (without the removal of hydrogen) and reached 32.2% (the equilibrium yield is 9.1%). The use of the intermetallic compound ZrNi as the hydrogen acceptor in a similar system made it possible to exceed by a factor of 5 the equilibrium yield of benzene from cyclohexane and of toluene from methylcyclohexane at 190 °C.[13,14] Under these conditions, 100% conversion of cycloalkanes into the corresponding aromatic products was observed (the equilibrium yield is about 20%).

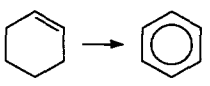
The positive effect of the lanthanide intermetallic compounds Nd_2Co_7 and Sm_2Co_7, used simultaneously as catalysts and hydrogen acceptors, has been noted in the dehydrogenation of cyclohexene to benzene and of n-heptane to methylcyclohexane.[15] The latter reaction occurred at 398 K and only traces of the n-heptane cyclisation product were observed.

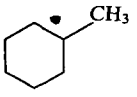
The intermetallic compound Zr_2Fe proved to be an effective hydrogen acceptor in the significantly more complex multistage aromatisation of C_2–C_3 hydrocarbons.[16–20] The reaction was studied in the temperature range 450 – 550 °C in the presence of catalysts based on the high-silica TsVM zeolite modified by zinc, gallium, or platinum cations. When the hydrogen evolved in the reaction was bound by the intermetallic acceptor, the yield of aromatic hydrocarbons from ethane was higher by a factor of 4 – 6 than in the absence of the intermetallic compound, and the selectivity of the aromatisation increased by a factor of 2 – 2.5 as a result of the suppression of the methane-forming side reaction.[16–18] In the aromatisation of propane in the presence of hydrogen acceptors, the yield of aromatic hydrocarbons increased by a factor of 2 – 5 and the sensitivity of the aromatisation increased by a factor of 1.5 – 3.5.[19,20]

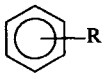
An attempt was also made to influence the equilibrium in reactions involving the direct conversion of methane into C_2 hydrocarbons, which is thermodynamically least favourable but is of extremely great practical importance.[21] The reaction was carried out at 400 K with the use of Ti and TiFe as the hydrogen acceptor and deposited metallic catalysts containing Pt, Rh, or Ni. However, the only reaction product, for a very low conversion of methane (above 1%), was coke.

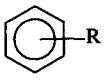












2. Reactions of alcohols

A large group of studies[15,22–27] has been devoted to the reactions of alcohols in the presence of intermetallic compounds of various compositions. In contrast to the reactions of hydrocarbons, hydride forming metals and alloys play the role of acceptors of the evolved hydrogen and of catalysts simultaneously in these processes. In certain cases, the surface of the alloys was modified by platinum, ruthenium, copper,[26] or rhodium[23] salts in order to increase the catalytic activity. The reactions were carried out in flow[24,25] and circulation systems[15,22,23,26] or in an auto-clave.[27] A direct quantitative estimate of the effect of hydride formation on the dehydrogenation of an alcohol is difficult and it can be inferred only indirectly from the decrease in the reaction temperature and the increase in the process selectivity.

In the presence of intermetallic compounds of different composition, methanol was dehydrogenated selectively under mild conditions (356 – 443 K) to CO and hydrogen, the latter forming part of the composition of the hydride.[15,22,23] The activity of the intermetallic compounds fell in the series $Zr_2Ni > M_2Co_7 > MFe_2$, where M is a lanthanide element. The authors explain this by the possible decrease in the catalytic activity of metals in the sequence Ni > Co > Fe. On the other hand, in terms of their absorption capacity the lanthanide intermetallic compounds were superior to Zr_2Ni: in their presence, complete removal of hydrogen from the reaction mixture was observed, whereas in the case where Zr_2Ni had been used, hydrogen was present in the gas phase from the very start and throughout the entire experiment. After the deposition of platinum or rhodium salts on the surfaces of the least active intermetallic compounds MFe_2, their properties were appreciably improved.[23] Thus the deposition of $RhCl_3$ on $DyFe_2$ increased the activity of the latter in the decomposition of methanol by a factor of 18.

Depending on the composition of the hydride-forming intermetallic compound used, the formation of various products was observed in the dehydrogenation of methanol at 523 K.[24,25] Thus the main product was formaldehyde in the presence of FeTi and $(Fe_{0.9}Mn_{0.1})Ti$. On nickel-containing alloys, methanol was con-verted into CO, while on Mg_2Cu methyl formate was also found among the reaction products in addition to CO.

The selective dehydrogenation of ethanol to acetaldehyde and hydride hydrogen occurred at 423 K [22] and 523 K [24] on all the intermetallic compounds tested by the authors with the exception of Mg_2Cu, in the presence of which a small amount of ethyl acetate was formed (the ethyl acetate : acetaldehyde ratio was 0.0047). The activities of the intermetallic catalysts in the reactions of ethanol and methanol depended to almost equal extents on the composition of the alloys, which indicates, according to the authors,[22,24] the similarity of the mechanisms of these reactions.

The dehydrogenation of isopropyl alcohol in the presence of the intermetallic compounds M_2Co_7 (where M = Pr, Nd, Sm) was quantitative and the selectivity in the formation of the corresponding hydride and acetone was close to 100% even at 317 K.[15,26] The rates of dehydrogenation of isopropyl alcohol on $Nd_2Co_7H_{0.1}$, $Nd_2Co_7H_{2.7}$, and $Nd_2Co_7H_{5.1}$ were respectively 1.1×10^{-3}, 6.0×10^{-4}, and 3.5×10^{-4} mmol min^{-1} per gram of the alloy. According to the authors,[15,26] this means that the formation of the hydride is the driving force of the dehydrogenation reaction. On the other hand, as in the case of methanol, modification of the surfaces of the alloys with platinum increases significantly their activity. For example, treatment of Pr_2Co_7 suspension with an aqueous solution of H_2PtCl_6 increased its activity in the dehydrogenation of isopropyl alcohol by a factor of 10.[26]

The effect of the hydride forming alloy $Mg_{2.4}Ni$ on the dehydrogenation of isopropyl alcohol in the presence of the Cu/CuO catalyst has been investigated[27] in a static system in an autoclave at 473 K and a pressure of 0.1–1.0 MPa. The absorption of hydrogen by the alloy altered appreciably the hydrogen balance in the system. However, as a consequence of the catalytic activity of the hydride in condensation reactions, the selectivity of the dehydrogenation reaction fell greatly.

Analysis shows that, in the vast majority of cases, the formation of the hydrides of transition metals and alloys under the conditions of catalytic dehydrogenation has a positive effect on the yields of the target products and on the selectivity of the dehydrogenation process.

III. Characteristic features of catalytic dehydrogenation coupled with hydride formation

Despite the wide variety of the initial organic reagents, the catalysts and the intermetallic compounds employed, and the experimental conditions, certain general features are characteristic of all the dehydrogenation reactions using intermetallic hydrogen acceptors.

1. Thermodynamics

It follows from Eqns (1) and (2) that the thermodynamic features of coupled dehydrogenation and hydride formation processes are equally important for the attainment of a positive effect.

For hydrogen to be absorbed, it is essential that its partial pressure in the gas phase should exceed the equilibrium dissociation pressure (p_{eq}) of the hydride. The pressure p_{eq} for a given metal or alloy is determined by the thermodynamics of the absorption–desorption equilibrium and tends to increase with increasing temperature.[28] The partial pressure of hydrogen in the reaction mixture is determined by the dehydrogenation equilibrium. When the temperature is reduced, thermodynamic

limitations to the dehydrogenation reactions arise (Fig. 1). In the dehydrogenation of alcohols, $\Delta G°$ shifts to the positive region at significantly lower temperatures than in the dehydrogenation of hydrocarbons, with the exception of the aromatisation of cycloalkanes (Table 3). Thus the equilibrium pressure p_{eq} and the temperature at which the free energies $\Delta G°$ for the dehydrogenation reactions shift to the positive region impose certain limitations on the choice of metals and intermetallic compounds as hydrogen acceptors. For example, the equilibrium dissociation pressure of the hydride of $Mg_{2.4}Ni$ [27] is such that this alloy can be used to remove the H_2 evolved in the dehydrogenation of ethanol or isopropyl alcohol but not propane or methanol.

The majority of binary and ternary metal hydrides have been synthesised and investigated in order to use them as hydrogen accumulators.[28] One of the main requirements which must be met by such systems is a low equilibrium dissociation pressure at room temperature. This restricts the search for intermetallic hydrogen acceptors suitable for the dehydrogenation of saturated hydrocarbons. Intermetallic compounds having the composition M(IV)$_2$M(VIII), the equilibrium dissociation pressures of the hydrides of which at 500 °C are much lower than 1 atm, appeared to be the most promising.

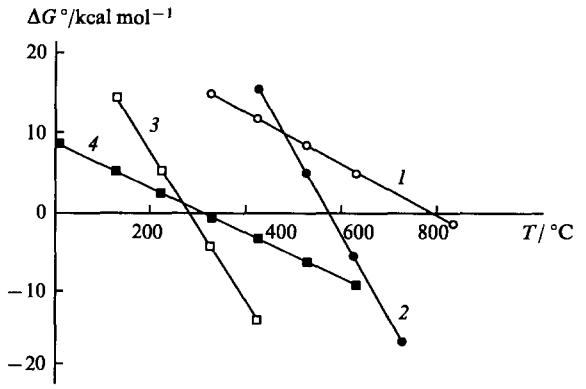

Figure 1. Temperature dependence of the change in the standard Gibbs free energy in the reactions involving the conversion of ethane into ethylene (line *1*), of ethane into benzene (line *2*), of cyclohexane into benzene (line *3*), and of ethanol into acetaldehyde (line *4*).

2. Absorption by metals and alloys of the hydrogen evolved in the dehydrogenation reaction

Evidently, for hydride formation to have a positive effect on the dehydrogenation reaction it is essential that the rate of absorption of hydrogen by the intermetallic acceptor should be equal to or greater than the rate of its formation as a result of the reaction. Indeed, in the dehydrogenation of isobutane,[10] cycloalkanes,[9,14] and alcohols[22] the rate of absorption of hydrogen by intermetallic compounds was one of the factors determining the effectiveness of their application.

The interaction of metals and alloys with hydrogen is a complex process including stages involving the dissociative adsorption of H_2, surface migration, transition from the adsorbed to the absorbed state, and finally bulk-phase diffusion.[28] Kinetic studies have shown that below 400 °C the rate of absorption is as a rule limited by the dissociation of H_2 molecules or the passage of H atoms through the surface oxide film,[30] which is formed when metals and intermetallic compounds come into contact with air under normal conditions.[31] This could have hindered the use of intermetallic hydrogen acceptors in low-temperature cycloalkane and alcohol dehydrogenation reactions. However, the presence on the surface of intermetallic compounds of Group VIII metals reduces appreciably the activation energy for the dissociative chemisorption of hydrogen, which facilitates absorption significantly even at room temperature.

The absorption of hydrogen may be promoted by sputtering isolated regions or monolayers of Ni, Pd, or Fe on to the surface of the intermetallic compound.[30,31] The introduction of Group VIII metals into intermetallic compounds at the stage where the metals are fused together does not always activate the absorption processes, since the surface oxide film is formed preferentially

Table 3. Thermodynamics of the dehydrogenation reactions of hydrocarbons and alcohols.

Reactant	Product	Temperature/ °C at which $\Delta G° = 0$ [a]
Ethane	ethylene	800
Ethane	benzene	580
Propane	propene	660
Butane	butene	540
Cyclohexane	benzene	260
Methanol	formaldehyde	430
Ethanol	acetaldehyde	330
Isopropyl alcohol	acetone	150

[a] Determined from thermodynamic data.[29]

from elements with a higher affinity for oxygen, so that the concentration of the Group VIII metal on the surface proves to be inadequate. In order to enrich the surface in the Group VIII metal, it is necessary to subject the intermetallic compound to a preliminary oxidation-reduction treatment under specific conditions[32] or to repeat the absorption-desorption cycles.[8,27]

One of the fairly important factors which determines the possibility of using particular intermetallic compounds as hydrogen acceptors is the retention of the ability to sorb H_2 under dehydrogenation conditions and after carrying out the desorption cycles. It was found that intermetallic hydrogen acceptors effectively retained their absorption properties under the conditions of catalytic reactions. In reactions involving hydrocarbons, this is probably associated with the catalytic inertness of the metals and alloys employed. In the reactions of alcohols, the dehydrogenation and H_2 absorption reactions take place at different active centres,[22,27] so that deactivation of the surface by the reaction products (observed in some cases) does not affect the absorption capacity of the acceptor.

As mentioned above, the repetition of the absorption-desorption cycles may increase the absorption capacity of the metals and alloys by activating their surfaces. For example, the acceptor properties of titanium are improved on repeating the isobutane dehydrogenation reaction after the desorption of hydrogen from the hydride.[8] On the other hand, the thermal desorption of hydrogen from the hydride of the intermetallic compound Zr_2Fe leads to an irreversible decrease in its absorption capacity as a consequence of the bulk-phase decomposition to $ZrFe_2$ and ZrH_2, which occurs at temperatures above 400 °C. However, the introduction of oxygen in the stage where the metals are fused together prevents the bulk phase decomposition of this intermetallic compound even at 850 °C.[33]

3. The activity of dehydrogenation catalysts and the change in the selectivity of catalytic processes

The yield of the products of dehydrogenation coupled with hydride formation is virtually unrestricted by the thermodynamic equilibrium and is therefore determined primarily by the rate of the reaction, i.e. by the activity of the hydrogenation catalyst. This was clearly demonstrated for the dehydrogenation of isobutane using Pt/Al_2O_3, $Ti_{0.63}V_{0.27}Fe_{0.1}$, or $Ti_{0.63}V_{0.225}Fe_{0.1}Pt_{0.045}$ as the catalyst.[8] In the aromatisation of cyclohexane,[14] the difference between the dehydrogenation activities of the Pt/Al_2O_3 and Pd/Al_2O_3 catalysts, which is not manifested in the absence of the hydrogen acceptor for thermodynamic reasons (the conversions of cyclohexane into benzene in the presence of these catalysts are respectively 19% and 21%), becomes very distinct if the product is removed by the intermetallic compound ZrNi (the conversions are 100% and 42% respectively). The yields of the dehydrogenation products of methanol[23] and isopropyl alcohol[26] increased by a large factor after deposition on the surfaces of intermetallic compounds of metals, such as platinum or rhodium, which are highly active in the dehydrogenation reactions.

The removal of hydrogen from the reaction mixture may exert a positive effect on reactions occurring with evolution of hydrogen, whereas reactions in which hydrogen is actually one of the reactants may be to a large extent suppressed in the presence of the intermetallic acceptor. The composition of the products of complex catalytic processes, in particular of the aromatisation of hydrocarbon gases, which includes several dehydrogenation stage as well as parallel hydrocracking, dealkylation, and hydrogen redistribution reactions, changes significantly in the presence of intermetallic compounds. For example, the selectivity of the aromatisation of ethane in the presence of pentasils modified by platinum increases by a factor of 2 in the presence of the intermetallic compound Zr_2Fe [18] as a result of the suppression of the methane formation side reaction and the displacement of the thermodynamic equilibrium in the rate-limiting stage involving the dehydrogenation of ethane to ethylene. The effect of the hydrogen acceptor on the secondary stage of the aromatisation reaction (the oligomerisation of ethylene) promotes the preferential formation of bicyclic aromatic products from ethane on Zn- and Ga-containing zeolites.[17]

The positive effect of the removal of hydrogen on the oligomerisation process was confirmed by the present authors in relation to the aromatisation of ethylene on the HTsVM zeolite (Table 4). In contrast to ethane, ethylene is readily activated on the acid centres of the H-form of pentasil, where rapid oligomerisation and aromatisation takes place. In the presence of Zr_2Fe, there is an appreciable increase in the yield of the aromatic products and of their content of bicyclic hydrocarbons for only a slight increase in the conversion of ethylene, but coke formation is not intensified. Evidently the removal of hydrogen has a positive effect on the stage involving the dehydrogenation of oligomers. On the other hand, the content of C_2-C_3 hydrocarbons in the gaseous reaction products diminishes. Consequently, as in the aromatisation of ethane, the removal of the hydrogen formed prevents the cracking of the intermediate and final reaction products. The slight increase in the yield of methane in the presence of the hydrogen acceptor is probably due to the demethylation of xylenes, the yield of which is reduced with a simultaneous increase in the yield of benzene.

Table 4. Aromatisation of ethylene on HTsVM (450 °C, 3600 h^{-1}) in the absence and presence of Zr_2Fe.

Parameter	Without acceptor	With acceptor
Conversion (mass%)	96.6	98.4
Yield of aromatic hydrocarbons (mass%)	38.2	44.9
Proportions of products (%):		
CH_4	1.4	3.7
C_2H_6	6.4	5.2
$C_3H_6+C_3H_8$	44.6	35.5
$C_4H_8+C_4H_{10}$	7.4	9.4
C_{5+}	0.6	0.6
Aromatic hydrocarbons	39.6	45.6
Proportions of aromatic hydrocarbons (%):		
Benzene	12.3	14.2
Toluene	39.5	40.1
Xylenes + ethylbenzene	43.7	37.6
C_{9+}	4.5	8.1
Content of coke on catalyst (mass%)	4.4	3.5
Content of hydrogen in the reaction stream (mol%)	11.8	0.2

Contrary to expectations, the removal of hydrogen by the hydrogen acceptors suppressed the dehydrogenation of ethane on oxide and on platinum-containing catalysts, both of which are inactive in the aromatisation reaction (Table 5), and at the same time no appreciable coke formation was observed.[18] This result shows that hydrogen plays a definite role in the dehydrogenation of ethane. One can postulate that it reduces to the acceleration of the desorption of the alkene from the surface of the catalyst. It has been shown[34] that the dehydrogenation of propane on gallium and zinc oxides is limited by the propene desorption stage, which is accelerated appreciably in the presence of the HZSM-5 zeolite as a result of the migration of $C_3H_7^+$ from gallium oxide to the acid centres of the zeolite, where a proton is fairly readily abstracted with the formation of propene. When H^+ is replaced by Na^+ in ZSM-5, the rate of dehydrogenation of propane diminishes by a factor of 100. It may be that this bifunctional mechanism operates in the dehydrogenation of ethane as well.

The change in the mode of reaction in the presence of hydrogen acceptors as a function of its mechanism and the catalyst composition has been observed in the aromatisation of

Table 5. The influence of the hydrogen acceptor Zr_2Fe on the dehydrogenation of ethane.

Catalyst	T/ °C	Reaction time/min	Yield of ethylene (mass %)	
			without acceptor	with acceptor
Ga_2O_3/SiO_2	550	6	5.1	5.7
	550	15	5.0	0.3
Cr_2O_3/ZrO_2	600	5	9.7	13.6
	600	22	9.8	1.9
Pt/SiO_2	550	7	7.9	1.2
	550	22	7.4	1.9
Pt/NaTsVM	550	5	7.2	1.0
	550	15	7.8	0.04

propane.[19,20] The authors suggest that, owing to the high activity of Ga/HTsVM in the dehydrogenation and oligomerisation processes, the displacement of the dehydrogenation equilibrium, occurring in the presence of the Zr_2Fe hydrogen acceptor, virtually precludes competition between the side reaction involving the hydrocracking of the intermediates and the aromatisation reaction, and the selectivity in the formation of aromatic hydrocarbons increases almost by a factor of 2. In the presence of the HTsVM and Pt/HTsVM catalysts, the removal of hydrogen from the reaction mixture activates the hydrogen redistribution processes, which increases the yield of aromatic products from propane but does not lower the amount of C_1-C_2 alkanes in the reaction products.

The dehydrogenation of methanol on intermetallic catalysts of different composition takes place with the formation of CO, formaldehyde, or methyl formate.[24,25]

Thus the activity and selectivity of the dehydrogenation catalyst as well as the process mechanism are of primary importance for the attainment of high yields of the target products when intermetallic hydrogen acceptors are used.

4. The spill-over of hydrogen

When the dehydrogenation and hydride formation reactions take place simultaneously, the catalytically active centres and hydrogen absorption centres are separated from one another by large distances. Presumably the hydrogen evolved migrates to the acceptor through the gas phase in the molecular state or it migrates on the surface in the atomic form. i.e. via spill-over.

The spill-over of hydrogen is more likely when the intermetallic compound functions simultaneously as a dehydrogenation catalyst and a hydrogen acceptor, since in this case the catalytic and absorption centres are close to one another and the transfer of hydrogen through the gas phase is energetically less favourable. The view exists[22,23,27] that the dehydrogenation of alcohols on hydride-forming intermetallic compounds is a pure example of the spill-over of hydrogen when the alcohol serves as the source of hydrogen atoms and the intermetallic compound is a solid acceptor. The activation of the surface of the intermetallic compound accelerates, according to the authors' view, not only dehydrogenation but also the spill-over of hydrogen to the absorption centres.

The ability to initiate the spill-over of hydrogen is characteristic of all hydride forming metals and alloys, because the H_2 absorption process involves the migration of the hydrogen dissociated on the surface into the bulk of the intermetallic phase. However, only some of them are active in dehydrogenation and this frequently requires a special treatment of the surface. Studies on the spill-over of hydrogen in various catalytic systems using different organic molecules as the hydrogen donors have shown that the ability of the catalysts to initiate this process depends on their activity in dehydrogenation.[35] In other words, the spill-over of hydrogen is closely related to dehydrogenation and apparently does really occur in the systems considered.

In the case where the intermetallic compound performs only the function of a hydrogen acceptor and the dehydrogenation reaction proceeds on an oxide, a deposited metal, or a zeolite catalyst, the involvement of spill-over in hydrogen transfer from the catalyst to the acceptor is less likely, but it cannot be ruled out on the basis of available data.

The appearance of molecular hydrogen in the reaction medium from the first minutes of the dehydrogenation of isobutane on Pt/Al_2O_3 in the presence of titanium presupposes, according to the authors,[8] that the transport of hydrogen takes place through the gas phase or in competition with the spill-over. The occurrence of the spill-over of hydrogen has been demonstrated indirectly in the dehydrogenation of cyclohexane in the presence of the intermetallic compound ZrNi and deposited platinum catalysts.[14] On Pt/Al_2O_3 and Pt/SiO_2 without a hydrogen acceptor, the yield of benzene was 19 mass% and 15 mass% respectively. After the removal of hydrogen, the maximum yield of benzene on the platinum/alumina catalyst reached 100%, while on Pt/SiO_2 it did not exceed 16 mass%, hydrogen being fully absent from the gas phase at the beginning of the experiment in the former case whilst in the latter it was present. This fact can be attributed to the different abilities of the Al_2O_3 and SiO_2 carriers to transfer the activated hydrogen along the surface.[36] Furthermore, for different proportions of Pt/Al_2O_3 and ZrNi in a mechanical mixture, the effectiveness of the hydrogen acceptor in the dehydrogenation of cyclohexane depends on the area of contact between the catalyst and the acceptor,[14] which can also be associated with the spill-over of hydrogen. Thus the maximum effect of hydride formation on the dehydrogenation reaction is probably attained when these processes are coupled, i.e. when the hydrogen acceptor reacts with the active hydrogen species formed as a result of dehydrogenation.

IV. Conclusion

The results examined in the present review reveal a new application of hydride-forming metals and intermetallic compounds as hydrogen acceptors for the displacement of the equilibrium in thermodynamically restricted catalytic reactions occurring with the evolution of H_2. The results indicate a high effectiveness of intermetallic hydrogen acceptors in the dehydrogenation reactions of cycloalkanes, isobutane, and C_1-C_3 alcohols and also in the aromatisation of C_2-C_3 hydrocarbon gases. This is manifested by the increase by a large factor in the yields of the target products, by the reduction of the reaction temperature by 100–150 °C, and by an increase in the selectivity of the processes.

In order to couple hydride formation with dehydrogenation, the hydrogen acceptor and the catalyst must satisfy certain requirements. It is essential that the metal or the intermetallic compound should be characterised by a low equilibrium dissociation pressure of the hydride at elevated temperatures, that the rate of absorption by the metal or the intermetallic compound should be high, and that it should retain its absorption capacity under dehydrogenation conditions and on repetition of the desorption cycles. The catalyst must have a high dehydrogenating activity and ability to initiate the spill-over of hydrogen. The process mechanism, which depends on the composition and properties of the catalyst, also affects the results of the dehydrogenation reaction occurring in the presence of an intermetallic hydrogen acceptor. All these factors create certain difficulties in the practical realisation of the processes and require additional search for new intermetallic compounds with the necessary properties and also the study of the reaction mechanisms under the conditions of hydrogen removal by the acceptor.

Abstract. The mechanism of cryochemical chain reactions is examined in relation to polymerisation. The study of such processes in crystals has led to the discovery of a low-temperature limit to the rates of chemical reactions. Polymerisation occurring under the conditions of a sharp change (by 5–6 orders of magnitude) in the molecular mobility of the medium in the region of the devitrification of the matrix has been investigated in vitreous systems. Unusual mechanoenergetic chains of chemical reactions have been observed in the study of systems immersed in liquid helium. The chemical reaction is initiated by a local brittle fracture and is propagated along the specimen in the form of an autowave. Auto-oscillations of the rate of cryopolymerisation have been observed under certain conditions. The bibliography includes 132 references.

I. Introduction

It is difficult to imagine an effective chemical reaction in a solid without a significant mass transfer of the reactants and products. At first sight it might turn out that chemical reactions in a solid occur in nature only on the geological time scale and even then not without the participation of liquid and gas phases, mechanical breakdown, and high pressures and temperatures.

Indeed, the classical picture of the elementary step in a chemical reaction is based on the following postulates: (1) an activation barrier must be overcome for the interaction reactions to be initiated; (2) reactants receive the energy required to overcome the activation barrier as a result of intermolecular interactions; (3) the time necessary for the reactions to accumulate this energy (the characteristic time of the elementary step) is determined by the temperature of the medium. It is easy to show that these postulates exclude the possibility of a chemical process in the vicinity of the absolute zero of temperature.

In the 1930s, communications were published in which the polymerisation of crystalline monomers was reported. It was found that crystalline trioxane polymerises in the presence of formaldehyde vapour with formation of polyoxymethylene fibres oriented along one of the crystallographic axes. The formation of rubber-like polymers of acetaldehyde was observed at the same time at the instant of its freezing (crystallisation) and fusion. The latter processes occur at low temperatures. Thus it was found that chain reactions can take place in a solid also at low temperatures.

Later investigators found new ways of initiating chemical reactions in the solid. One of them is based on the use of γ-radiation. Initiation of active centres, more or less uniform throughout the volume of the solid phase, takes place under these conditions and all the complications associated with the diffusion of the initiator molecules within the crystals are fully eliminated. However, the main advantage of radiation initiation is that its effectiveness is independent of temperature (in contrast to chemical initiation). The latter factor made it possible to proceed to the study of the polymerisation of solid monomers at low and ultralow temperatures.

All this led in the 1960s to a vigorous development of studies on solid-phase polymerisation. However, at the time most of the investigations were phenomenological in nature and theoretical generalisations and hypotheses were novel rather than experimentally well-founded.

It was found initially that the rigorous orientation of the monomer molecules in space, which is characteristic of crystals, may be reflected in the regularity of the macromolecules formed. Furthermore, hopes arose that the 'ordered military ranks' of the reactants in the crystal would promote the rapid occurrence of the process. In 1960, Semenov [1] proposed the energy chain mechanism for solid-phase polymerisation. The idea was that the energy evolved in each elementary chain propagation step is not scattered by being converted into heat, but, by virtue of the collective interaction of the monomeric 'precursors' in the crystal, ensures that the activation barrier is overcome in the next such step. One of the variants of the collective interaction may involve the movement of an exciton along the 'precursor'. In this case, the polymer chain may grow at the rate of propagation of the exciton. (The exciton chain model has been examined in detail by Adirovich [2].)

Here we shall not dwell on the analysis of the extensive factual data, with which the reader may become acquainted in the relevant communications, [1,3–8] and only the principal conclusions will be quoted. The formation of a polymer in a crystal of the initial monomer alters the average distances between the individual

fragments, whereupon the spatial orientation of the monomer units may be changed. There is a wide variety of numerous systems in which these geometrical factors play a significant role. The transfer of classical ideas about the reaction mechanisms in the gas and liquid phases to solid-phase reactions proved fruitless; new ideas were needed.

In view of the extremely restricted translational displacements in a crystal, it is difficult to imagine the destruction of growing macroradicals as a result of recombination or disproportionation. In this case, the polymer chain gradually ceases to grow owing to progressive difficulties in the supply of the monomer to the growing active centre — a kinetic arrest of the process ('setting and revival' of the polymer chain) is observed.[9] This served as a basis for the development of the theory of 'polychronic kinetics'.[10]

The idea that chemical reactions are impossible near the absolute zero changed after *the low temperature limit to the rates of chemical reactions had been established* experimentally. This phenomenon was observed in the study of the mechanism of the polymerisation of solid formaldehyde in the temperature range 4–100 K.[11] The existence of the low-temperature limit to the rate was subsequently confirmed for a series of chain and nonchain chemical reactions.[12] Systems in which the chemical reaction takes place even at the temperature of liquid helium were found experimentally. Although the rate of such a reaction is low, it is nevertheless measureable and is independent of temperature.

Immediately after the discovery of the phenomenon of the low-temperature limit to the rate, it was suggested that its mechanism be interpreted within the framework of the concept of molecular tunnelling. This idea was subsequently developed taking into account the role of intermolecular vibrations.[12–15]

The present review describes only a small portion of the enormous amount of data concerning the mechanisms of solid-phase reactions.

II. Crystals

1. Formaldehyde

The possibility of the radiation polymerisation of solid formaldehyde at temperatures close to that of liquid nitrogen has been reported.[16–18] However, these studies were qualitative. Indeed, the yield of the polymer was determined only after the heating and fusion of the irradiated solid monomer (the rate of the process was determined by dividing the mass of the polymer isolated by the irradiation time of the system). This naturally did not allow the determination of the true rates of polymerisation at 77 K. Subsequently, it was found that, when the irradiated polycrystalline formaldehyde is heated, effective postpolymerisation takes place, masking completely the effect occurring directly during the radiolysis of the specimen at 77 K. Only the use of kinetic calorimetry made it possible to investigate these processes separately. The principal results of investigations of the solid-phase polymerisation of formaldehyde in the temperature range 5–150 K are presented below.[11,19–26]

The method for the purification and drying of gaseous formaldehyde, which has been thoroughly elaborated, made it possible to eliminate the problem of the reproducibility of kinetic measurements.[27] Calorimetric analysis showed that frozen formaldehyde forms a polycrystalline mass rapidly (~200 K min^{-1}) or slowly (~0.3 K min^{-1}) and undergoes no phase transitions of any kind in the temperature range 4.2–155 K. It melts at 155 K and its heat of fusion is $\Delta H = 1.80 \pm 0.05$ kcal mol^{-1}. The enthalpy of the polymerisation of solid formaldehyde was found to be 8.5 ± 1.0 kcal mol^{-1} and this value was used subsequently to calculate the rate of polymerisation.

The radiation polymerisation of formaldehyde proceeds extremely effectively, so that thermal explosion is observed when heat is removed inadequately.[16,17] For this reason, all the kinetic measurements were performed under conditions as close to isothermal conditions as possible, which was achieved by increasing the heat exchange area and by reducing the γ-radiation dose rate. After exposure to γ-radiation, the rate of heat evolution associated with polymerisation reaches a steady value during a period equal to the characteristic time of the calorimetric apparatus used in the experiments (Fig. 1).

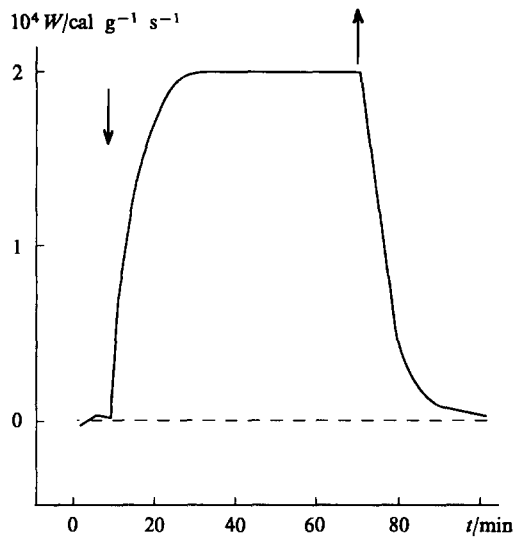

Figure 1. Variation of the rate of heat evolution in the polymerisation of formaldehyde in the field of γ-radiation. Temperature 100 K; dose rate 1.4×10^{-4} Gy s^{-1}. The arrows indicate the instants when γ-radiation was switched on and off. The dashed line represents the analogous experiment with polyformaldehyde.

However, the steady rate of polymerisation does not persist for a long time and an appreciable decrease in the rate is observed already for degrees of conversion of ~0.5%. The reason for the decrease can be only the kinetic arrest of the process when the access of the monomer to the growing polymer centre is hindered.

Experimental proof that the kinetic chain termination reaction is first order in the polymerisation process has been obtained. It is natural to attribute linear termination to the kinetic arrest of the growth of the polymer chain ('setting') and not to the destruction of active centres, because, when the temperature rises outside the radiation zone, effective postpolymerisation is observed, i.e. the chains which have set are 'revived'.

The radiation-chemical yield of the polymer is $G(-M) \geqslant 10^6$ molecules per 100 eV of the absorbed energy of the γ-radiation in the early stages of the process. One may assume that this is the highest recorded quantity for radiation polymerisation.

The temperature dependence of the steady rate in the range 80–150 K is described satisfactorily by the Arrhenius equation (the activation energy is 2.0 ± 0.6 kcal mol^{-1}). At temperatures above 140 K, the rate of polymerisation falls, apparently owing to the increase in the chain termination rate constant near the melting point of the monomer crystals. A negative activation energy for the polymerisation of formaldehyde ($E = -0.5$ kcal mol^{-1}) has been reported.[16,17] This value is clearly erroneous if only because the authors of the above communications observed the phenomenon of thermal explosion, which is impossible for a negative temperature dependence of the rate of polymerisation.

The following expression for the chain propagation rate constant has been obtained in the temperature range 8–140 K:

$$k_p \approx 0.03 \exp\left(-\frac{2000 \pm 100}{RT}\right).$$

On passing to the liquid phase, the steady rate of polymerisation of formaldehyde falls sharply (almost by a factor of 10). This is naturally associated with the significant increase in the rate of termination of polymer chains in the liquid phase compared with that in the crystal lattice.

The high radiation yield of the polymerisation of solid formaldehyde at the temperature of liquid nitrogen made it possible to proceed to the investigation of its polymerisation at still lower temperatures (5–80 K). The temperature dependence of the rate of polymerisation was studied. With decrease in temperature (below 80 K), the temperature dependence of the rate of polymerisation diminishes and then ceases altogether. A more marked deviation of the rate from the Arrhenius law is observed. However, even at 5 K polymerisation still occurs with a radiation yield $G(-M) \approx 1000$, which is characteristic of chain processes. Thus, the occurrence of a chain reaction at such low temperatures was observed for the first time by a direct method for the given process.

The characteristic chain propagation times in solid formaldehyde have also been measured in the temperature range 5–80 K. Two identical calorimetric experiments were performed: one with solid formaldehyde and another with polyoxymethylene. In the experiment with polyoxymethylene, the evolution of heat is associated solely with the heating of the system owing to the absorption of γ-radiation. Since γ-radiation is absorbed equally by the polymer and the monomer, in the experiments with the monomer the overall heat evolution due to the absorption of γ-radiation and the polymerisation reaction was detected.

Figure 2 presents the results of these measurements. The characteristic time of the process τ (the average kinetic chain propagation time) was determined by fitting the following relation to the rate of increase in the rate of polymerisation after exposure to initiating radiation:

$$W = W_{st}\left[1 - \exp\left(-\frac{t}{\tau}\right)\right].$$

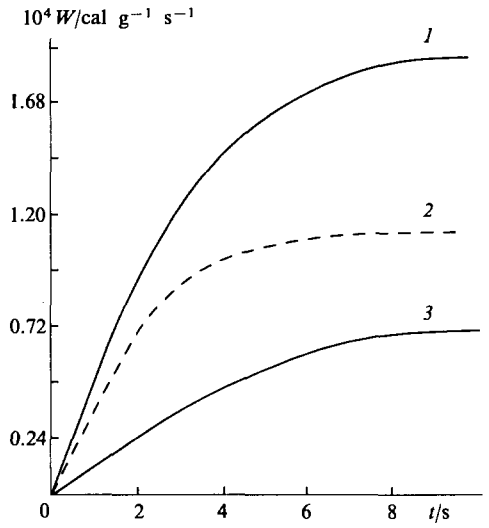

Figure 2. Time variation of the rate of heat evolution in the field of γ-radiation for formaldehyde (curve *1*) and polyformaldehyde (curve *2*) and variation of the rate of polymerisation of formaldehyde (curve *3*) (difference between the rates represented by curves *1* and *2*). Polymer sample 0.25 g; dose rate 0.45 Gy s^{-1}; temperature 5 K.

The intrinsic chain propagation characteristic time at temperatures below 10 K approached 10 s. The temperature dependence of the chain propagation time was obtained from the results of a series of similar experiments carried out at different temperatures. From the measured chain propagation characteristic times, one can proceed to the time required for the step involving an increment by one monomer unit:

$$\tau_o = \frac{\tau g}{G(-M)},$$

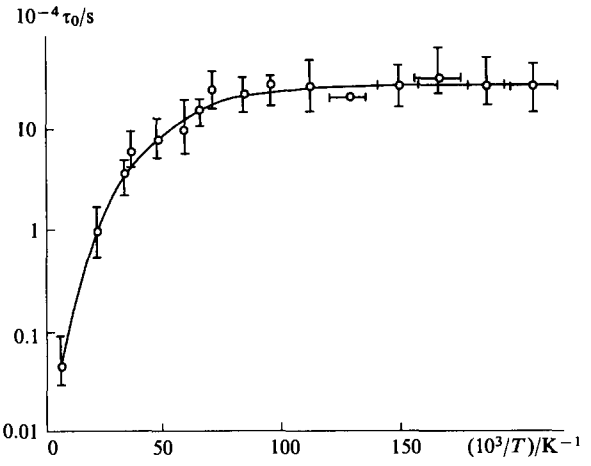

Figure 3. Temperature variation of the time required for the addition of one monomer unit in the polymerisation of formaldehyde.

where g is the radiation yield of the active centres initiating the polymerisation (usually $g \approx 1$). With decrease in temperature, a more marked deviation of the rate of polymerisation from the Arrhenius law is observed — the time required for the addition of one unit tends to the constant value $\tau_0 = 0.01$ s (Fig. 3), while extrapolation of the data for 80–140 K on the basis of the Arrhenius law would yield a value at 5 K, which would be much too high ($\tau_0 \approx 10^{100}$ years!).

A low-inertia calorimetric apparatus was used to investigate the possibility of polymerising formaldehyde at 5 K in the absence of radiation, but the reaction was carried out in this case under conditions where γ-radiation was switched off rapidly. After γ-radiation has been stopped, a decrease in the rate of polymerisation is observed with a characteristic time $\tau \approx 15$ s, which is significantly longer than the time corresponding to the inertia of the calorimeter (Fig. 4).

Thus it was shown clearly that the polymerisation chain continues to be propagated at helium temperatures also in the absence of a radiation field. Therefore the hypothesis that the

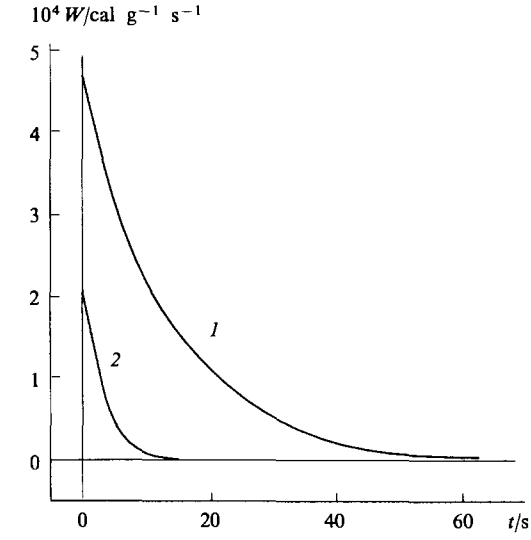

Figure 4. The postpolymerisation of formaldehyde after switching off γ-radiation: (*1*) monomer in the calorimetric cell; (*2*) analogous experiment with the polymer. Formaldehyde sample 0.25 g; temperature 5 K; dose rate 6 Gy s^{-1}.

radiant energy is used to activate each elementary addition step is incorrect. At the same time the hypotheses postulating that chain propagation takes place as a result of the transfer of short-lived excited states, that polymerisation takes place in tracks, etc. have to be abandoned. This significantly narrows the range of the possible hypotheses concerning the mechanism of the observed phenomenon.

The polyformaldehyde obtained by the radiation polymerisation of formaldehyde at 77 K has a supermolecular structure comprising monolithic crystalline domains.[28] The formation of this morphological type was not observed either on crystallisation of this polymer from solutions or melts or on crystallisation during synthesis.[29-31] Analysis of the IR spectra in the range 800–1300 cm^{-1}, where the vibration bands sensitive to changes in the angles of internal rotation of the CHO chain are located, demonstrated an unusual conformation of the chains in the polymer obtained by solid-phase polymerisation.

The known modifications of polyformaldehyde, named in accordance with the type of crystal lattice — hexagonal (I) and orthorhombic (II) — are characterised by a sequence of monomer units having the *gauche, gauche*-conformation with internal rotation angles of 77° (I) and 63° (II).[32] Such differences between the angles of internal rotation of the polymer chains do not lead to significant differences between the IR spectra. On the other hand, the spectrum of the polymer specimen obtained by solid-phase polymerisation contains bands additional to the absorption bands of the known modifications (I) and (II).[28] This finding shows that some of the monomer units of the polymer chains in the specimen are in a conformation different from the *gauche, gauche*-conformation. This can be only the uncoiled *trans*-conformation, since the coiled *cis*-conformation is prohibited by steric hindrance. One can therefore postulate that the chains in the new structural modification of the polymer are characterised by sequences of monomer units with the *gauche, trans*-conformation.

The new structural modification of the polymer, obtained by the solid-phase polymerisation of formaldehyde, proved to be metastable. Judging from the changes in the IR spectra, it passes to the known modification I on recrystallisation from melts and solutions and also under the influence of pressure. We may also note that a stable modification is formed in the radiation polymerisation of liquid formaldehyde.

The polymerisation of a monomer crystal entails a change in both the average distances between individual fragments (the intermolecular distances are replaced by chemical bond lengths) and in the spatial orientation of the monomer units. We may note two extreme cases: (1) the structure of the monomer crystal determines to a large extent the structure of the polymer (derivatives of conjugated diacetylenes, trioxane); (2) the polymer arises as an independent phase in the extended lattice defects, which leads to further fracture of the monomer crystal; the polymer phase is amorphous (acrylamide). There is a large number of intermediate cases between these extremes.

The polymerisation of crystalline acrylamide begins in the region of the extended defects and proceeds on the interface between the amorphous polymer and the crystalline monomer.[33] A decrease in the size of the crystals facilitates the polymerisation process. The average rates of polymerisation in fine defective acrylamide crystals are higher than in large perfect crystals.

An example of the first of the extreme cases listed above is the so called topochemical polymerisation.[34] A polymer phase, the crystallographic directions of the axes of which are determined by the directions of the axes of the initial crystal, is formed in such processes. The polymerisation in large crystals of monomers of this kind is faster than in small crystals, while the presence of noncrystallising additives reduces the rate of the process.

In this connection, it appeared important to elucidate the influence of the size of the formaldehyde crystals and of their defectiveness on the kinetics of the low-temperature radiation polymerisation. It was found[35] that the kinetics of the radiation polymerisation of formaldehyde depend significantly on their crystal size. The rate of polymerisation in small defective crystals is almost 20 times lower than in slowly grown large crystals. It is natural to assume that the decrease in the yield of the polymer on passing to highly defective formaldehyde crystals is associated with the decrease in the length of the kinetic chains in the polymerisation process, i.e. that the solid-phase polymerisation of formaldehyde takes place at a high rate only within large and perfect crystals.

Photoinitiation has also been used in the study of the low-temperature solid-phase polymerisation of formaldehyde. Thus the polymerisation of crystalline and amorphous formaldehyde at temperatures above 20 K on photoexcitation of added β-naphthol has been reported.[36,37] Such initiation entails the transfer of a proton from β-naphthol to formaldehyde with formation of a cation as the chain-transfer agent.

The low-temperature reactions of formaldehyde in amorphous formaldehyde–chlorine mixtures have been investigated.[38-40] Chlorine was photolysed by using an excimer laser (λ = 308 nm) or a mercury arc lamp (λ = 365 nm). The formation of oligomers with a chain length corresponding to 5–7 units was observed in the temperature range 10–77 K, whilst at temperatures $\geqslant$90 K the chain length increased by a factor of 2. The molecular mass of the polymer obtained in this way is much lower than that of the polymer formed in the crystal (chain length 10^3–10^6). This is caused by the molecular disorder in the amorphous state.

In order to account for the low-temperature limit to the rate of chain propagation, the concept of molecular tunnelling was introduced.[23,24] These investigations stimulated many studies on the theoretical development of ideas concerning the elementary chemical step in a solid†.

2. Acetaldehyde

Acetaldehyde is the closest homologue of formaldehyde. Rubber-like acetaldehyde polymers were first obtained by Travers[41] and Letort.[42] Pshezhetskii et al.[43] observed with the aid of thermographic and cine-film techniques the propagation of the polymerisation front in solid radiolysed acetaldehyde at relatively high temperatures (117–147 K) close to the melting point of the monomer (T_m = 150 K). Having made a series of assumptions and having restricted the treatment to one thermal conductivity equation, the authors[43] obtained an extremely short time for the addition of one monomer unit to the polymer chain (10^{-8} s). Such high rates stimulated further investigations of this system by the calorimetric method under slow temperature scanning conditions and directly in the field of γ-radiation under isothermal conditions.[44]

Even at the maximum rate of cooling of the liquid monomer to 77 K (~100 K min^{-1}), the latter does not form a vitreous state. As in formaldehyde, in polycrystalline acetaldehyde there are no phase transitions of any kind, the compound melting at 150 K (ΔH = 1.40 ± 0.07 kcal mol^{-1}).

Figure 5 presents the typical time dependence of the rate of polymerisation (rate of heat evolution) of solid acetaldehyde in the field of γ-radiation, indicating a distinct autoacceleration of the polymerisation process. Evidently, the autoacceleration is associated with the accumulation of active centres during the radiolysis of the solid monomer, i.e. with the increase in the rate of initiation. The expression for the time variation of the rate of the process is

$$W = -\frac{d[M]}{d[t]} = k_p g I t [M]_0 \exp(-0.5 k_p g I t^2),$$

where k_p is the polymer chain propagation rate constant, I the intensity of the radiation, and $[M]_0$ the initial monomer concentration. Two corollaries arise from this: (1) the experimental

† For further details, see the monograph of Gol'danskii et al.[12]

relation $W = f(t)$ (Fig. 5) should become linear in terms of the $\ln(W/t)$ against t coordinates; (2) the time required for the attainment of the maximum rate t_{max} is $k_p g I^{-0.5}$, which makes it possible to calculate k_p. This kinetic scheme does not take into account the possibility of the kinetic arrest of the growing chains, but it describes satisfactorily the relation obtained. Indeed, the function illustrated in Fig. 5 becomes satisfactorily linear in the appropriate coordinates.

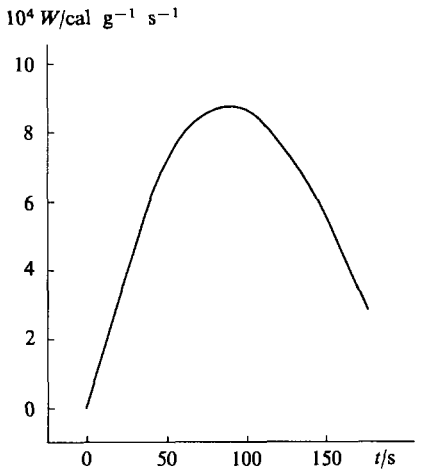

Figure 5. Time variation of the rate of heat evolution (polymerisation) in solid acetaldehyde in the field of γ-radiation. Dose rate 0.6 Gy s^{-1}; temperature 136 K.

A series of experiments, analogous to that described above, were then carried out at different temperatures, which made it possible to determine the chain propagation rate constant. The temperature variation of k_p in the range 130 – 144 K is described by an expression of the type

$$k_p = 5 \times 10^{-4} \exp\left(-\frac{11000}{RT}\right),$$

i.e. the average time required for the addition of the monomer unit in this temperature range is 0.1 – 0.001 s.

It is noteworthy that the activation energy (11 kcal mol^{-1}) is much higher for acetaldehyde than for formaldehyde (2 kcal mol^{-1}) in the same temperature range. However, we are apparently dealing here with an effective activation energy because its high values are compensated by the high values of the pre-exponential factor, which is characteristic of reactions occurring near the melting point.

Thus, in contrast to its nearest homologue, acetaldehyde hardly polymerises even at 77 K. An intense thermoactivated post-effect is characteristic of solid acetaldehyde, as for formaldehyde.

3. Glyoxal and tricarbon dioxide

We shall consider the polymerisation of crystalline glyoxal $(HCO)_2$.[45] In contrast to formaldehyde, the mechanism of the polymerisation of this monomer has been little investigated.[46] Calorimetric analysis showed that phase transitions of any kind do not occur in solid glyoxal in the temperature range 80 – 288 K. Glyoxal melts at 288 K and its heat of fusion is ΔH = 3.0 kcal mol^{-1}. The slightest traces of moisture lead to spontaneous polymerisation near the melting point of the monomer, which is clearly recorded on the calorimetric heating curve.

The rate of polymerisation of solid glyoxal in the field of γ-radiation slowly reaches a steady value and, with the initiating radiation switched off, it decreases with the characteristic time τ = 1300 s.

The heat of polymerisation of glyoxal is 5 ± 1 kcal mol^{-1}. This quantity is the mean of the heats of polymerisation of formaldehyde (8.5 kcal mol^{-1}) and acetaldehyde (2.5 kcal mol^{-1}). A series of measurements of the process dynamics at different temperatures made it possible, as in the case of other monomers, to determine the principal kinetic parameters. The chain propagation rate constant for the solid-phase polymerisation of glyoxal is different from that for formaldehyde.

$$k_p \approx 10^{-17} \exp\left(-\frac{4000}{RT}\right).$$

At 170 K, the rate of polymerisation of glyoxal becomes negligible. However, the postpolymerisation of this monomer can be observed even at temperatures slightly above 100 K. The supermolecular and molecular structures of the polymer formed depend significantly on the temperature at which glyoxal is polymerised. The particles of the polymer obtained at 100 – 170 K have a polygonal shape and exhibit double refraction, which indicates oriented growth of the polymer chains. The polymers obtained at higher temperatures (200 – 280 K) do not have this property. In both cases, the polymer is amorphous, because the formation of a three-dimensional network prevents crystallisation.

At low temperatures, predominantly one aldehyde group participates in the polymerisation of glyoxal. The IR spectrum contains an intense band due to the aldehyde group (1740 cm^{-1}). The spectrum of the polymer obtained at higher temperatures contains an absorption band due to hydroxy-groups in the range 3200 – 3400 cm^{-1}. Apparently, the polymerisation of the simplest dialdehyde proceeds via the mechanism of aldol condensation with formation of $-[CH(CHO)-CH(OH)]_n-$ chains. Since aldol condensation is characterised by a large volume of activation for chain propagation (compared with the formation of a polyacetal chain), this reaction becomes possible at high temperatures. Thus the closest analogues of the formaldehyde — glyoxal and acetaldehyde — polymerise in the crystalline state at comparatively high temperatures, the rate of their polymerisation decreases in conformity with the Arrhenius law, and a low-temperature plateau is not observed.

Continuing the search for monomers capable of chain polymerisation in the vicinity of the absolute zero of temperature, we considered a fairly exotic monomer — tricarbon dioxide O=C=C=C=O. The polymerisation of this monomer on thermal[47] and radiation[48] initiation as well as photoinitiation[49] has been reported in the literature. In all the studies, the investigators dealt with a complex set of reactions occurring in parallel, which hindered significantly the understanding of the polymerisation mechanism. When this reaction is carried out at low temperatures, the set of possible reaction pathways becomes significantly smaller. We shall consider the results of these investigations.[50,51]

The phase state of solid C_3O_2 has been subjected to calorimetric analysis. At 130 – 135 K a phase transition, apparently of the crystal – crystal type, takes place with ΔH = 1.4 ± 0.2 cal g^{-1}. Tricarbon dioxide melts at 160 K with the heat of fusion ΔH = 20.3 ± 1.7 cal g^{-1}. The enthalpy of polymerisation of C_3O_2 has been determined for the temperature range 160 – 310 K in a series of experiments; ΔH was 35 ± 5 kcal mol^{-1}.

The calorimetric experiments showed that the occurrence of the radiation polymerisation of C_3O_2 with measureable yields cannot be detected in the solid phase over the entire temperature range. This means that the radiation yield of the polymerisation reaction does not exceed $G(-M) \approx 100$ molecules per 100 eV of the absorbed energy.

The postpolymerisation of C_3O_2 specimens irradiated with different doses was investigated at 77 K. Evolution of heat due to the polymerisation of C_3O_2 begins to be observed on the calorimetric heating curve for the radiolysed specimen starting from the melting point of the monomer. In the temperature range 180 – 260 K, the polymerisation takes place at a low rate.

On further heating, the rate of polymerisation rises sharply, reaches a maximum, and then falls owing to the consumption of the monomer. The monomer specimen was heated in the experiments to 310 K, whereupon the overall yield of the polymer was 80% – 100%.[50]

The postpolymerisation was studied calorimetrically at a constant temperature of 297 ± 1 K (Fig. 6). It was found that the rate of the process initially increases with time, autoacceleration is observed, and then falls to zero owing to the exhaustion of the monomer. These experiments show that the active centres stored during the low-temperature radiolysis are retained in the postpolymerisation of not only solid but also liquid C_3O_2.

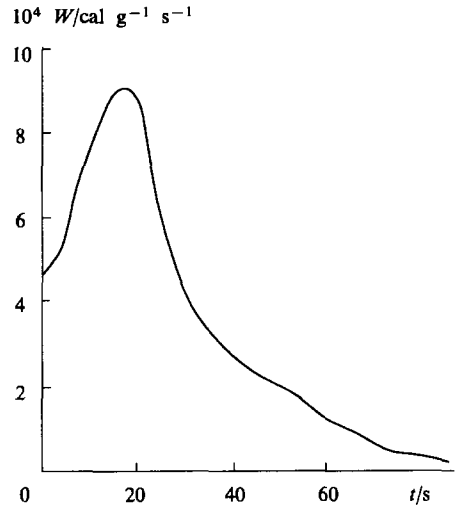

Figure 6. Time variation of the rate of heat evolution (postpolymerisation) in C_3O_2 at 297 K. Preliminary irradiation dose 10 kGy.

Unfortunately there are no experimental data of any kind concerning the nature of the active centres propagating the polymerisation. However, one can postulate that, as in the gas phase,[48] the polymerisation is propagated by ions. Apparently the long lifetime of the active centres, which are retained even in the liquid, is due to the following causes. The primary centres stabilised during the solid-phase radiolysis initiate the polymerisation of the monomer in its melting temperature range, forming oligomeric growing centres. The lifetime of such centres rises sharply owing to the appearance of steric hindrance, so that even in the liquid phase their concentration is sufficiently high to ensure effective polymerisation.

Another interesting feature of the postpolymerisation of C_3O_2 is the autoacceleration of the process at a constant temperature (Fig. 6). This phenomenon is unusual if only because the number of active centres generated during the preliminary irradiation can only decrease. The most probable cause of the autoacceleration is the increase in the rate of initiation apparently as a consequence of the branching of the chain reaction in the elementary monomer addition step. Without specifying in detail the branching mechanism, we may note that one may consider both material and energy branching. In one way or another, the question of the mechanism of the autoacceleration still remains open.

Thus the search for cryochemical chain polymerisation processes among the closest analogues of formaldehyde proved unsuccessful. The only example of a chain process occurring in the vicinity of the absolute zero of temperature and demonstrating the existence of a low-temperature limit to the rate still remains the polymerisation of formaldehyde. The next logical step was to switch the search to the chain reactions of compounds of other classes.

4. Hydrogen cyanide

It has been suggested that liquid hydrocyanic acid polymerises via an anionic mechanism under the influence of γ-radiation, affording a complex mixture of nitrogen compounds.[52] Furthermore, HCN is an extremely common molecular formation in the giant clouds of interstellar dust, in comets, and in other galactic structures. In general, the HCN molecule has come to be regarded as the basis of the prebiological chemical evolution, since its reactions constitute a direct pathway to the formation of purines, pyrimidines, and aminoacids.[53–57] It has been suggested[58] that the chain length of the cyanopolyene macromolecules arising on condensation of HCN be employed as an internal clock for the determination of the age of interstellar clouds. Other astrophysical aspects of the chemical reactions of hydrogen cyanide are developing vigorously.[59,60]

The chemical behaviour of this simple molecule under conditions approaching those in cosmic space (low temperatures and radiation) and its role in the 'cold' chemical evolution of the universe are of interest. The principal results of a series of experiments carried out on these lines recently are presented below.[61,62]

When hydrocyanic acid is cooled to 77 K, it passes to a crystalline state and, when it is heated, a phase transition of the crystal – crystal type (248 K) and fusion at 260 K (ΔH = 2.1 ± 0.1 kcal mol^{-1}) take place.

Calorimetric measurements directly in the field of γ-radiation at 77 K demonstrated the absence of appreciable heat evolution associated with a chain polymerisation reaction. When hydrocyanic acid radiolysed at 77 K is heated to room temperature, the formation of a polymer is observed. The heat change associated with the polymerisation of hydrocyanic acid is detected only in the fusion region. The yield of the polymer formed on heating to room temperature HCN specimens irradiated at 77 K increases with the preliminary irradiation dose and reaches 2.5% for a dose of 725 kGy. It is of interest that the radiation polymerisation of liquid HCN at 273 K proceeds significantly less effectively.

Prolonged maintenance of hydrocyanic acid in evacuated sealed tubes at room temperature does not lead to any changes in its colour or to the formation of polymeric products. But storage at room temperature of HCN specimens radiolysed at 77 K alters the colour (from pale-brown to almost black) and leads to the formation of polymeric products. The yield of polymer increases with increase in storage time, reaching 33.5% after 750 h.

Analysis of the IR absorption spectra of the freshly prepared polymer showed that, together with the absorption bands due to the stretching vibrations of the C≡N bond (2100–2200 cm^{-1}), which are also observed in the spectrum of monomeric HCN, absorption bands in the ranges 1600–1700 and 1200–1250 cm^{-1} appear in the spectrum. They are apparently due to the stretching vibrations of the C=N and C–N bonds respectively. When the system is maintained at room temperature, structure formation in the polymeric product together with an increase in its amount take place. A redistribution of the band intensities in the regions of 1250 and 2200 cm^{-1} is observed in the IR spectrum and the background in the range 1700–2200 cm^{-1} intensifies, but all the principal absorption bands are retained.

The polymer gives rise to a singlet EPR spectrum, characteristic of polyconjugated systems. The electrical conductivity of the polymer is typical for the majority of dielectric materials: $\sigma = 3 \times 10^6 \Omega^{-1}$ cm^{-1}. The appearance of colour in the polymeric product and its variation (up to black) during the radical reaction can be accounted for as a consequence of the formation of the –C=N–C=N– conjugation chain.

The appearance of the acicular crystals of the tetrameric hydrocyanic acid may be associated[63] with the formation of an intermediate biradical — aminocyanocarbene, the dimerisation of which actually leads to the appearance of the tetramer — 1,2-diaminomaleic acid dinitrile:

$$\begin{matrix} N{\equiv}C\text{-}C\text{-}NH_2 \\ \quad\quad\quad\

Indeed, photolysis of a vitreous solution of the lithium salt of the toluene-*p*-sulfonylhydrazone of 1-cyanoformamide in 2-methyltetrahydrofuran at 77 K led to the formation of a yellow product — aminocyanocarbene.[64] The biradical

$$H_2N-\overset{\delta+}{\ddot{C}}-C\equiv\overset{\delta-}{N},$$

exists in the singlet state.

The formation of appreciable amounts of the tetramer in our experiments on radiation polymerisation suggests the operation of the mechanism described above. Aminocyanocarbene apparently initiates further propagation of the hydrogen cyanide polymerisation chain, which leads to the formation of the polymeric product.

In the first place, it was necessary to discover when the tetramer crystals are formed: during the heating of the hydrocyanic acid radiolysed at 77 K, in the solid phase, or after its fusion. The radiolysed solid HCN specimen was therefore placed in vacuo and the unreacted monomer was sublimed at a temperature below the melting point (260 K). The residue obtained after such prolonged sublimation (2.5% of the initial mass) consisted of a mixture of the polymer and the crystalline tetramer. A noteworthy feature of fundamental importance is that these products were formed in the solid phase.

X-Ray diffraction analysis of the crystals selected from the residue obtained after the sublimation of the unreacted monomer described above showed that the crystals belonged to the monoclinic system.[65] The bond lengths and bond angles in the $(HCN)_4$ molecule have the standard values. The molecule is planar with localised triple $C\equiv N$ and double $C=C$ bonds and possesses an intrinsic plane of symmetry. Shortened intermolecular contacts or other specific interactions are absent from the crystal.

Thus it has been shown experimentally that crystals of 1,2-diaminomaleic acid dinitrile are formed together with a conjugated polymer of the type $-C=N-C=N-$ during the sublimation of the solid hydrocyanic acid matrix radiolysed at 77 K. These crystals are formed on recombination of biradicals of the aminocyanocarbene type, which are stabilised in the matrix during the low-temperature radiolysis. When the matrix sublimes in the vicinity of its melting point, these biradicals acquire molecular mobility and recombine.

In our experiments, 1,2-diaminomaleic acid dinitrile was formed with a radiation yield $G \approx 2$ molecules per gram per 100 eV of the absorbed energy. Such a yield is typical for the products of a primary radiation-induced reaction (for example, of the radicals). Consequently, 1,2-diaminomaleic acid dinitrile cannot be formed as a result of consecutive radiation-induced reactions. We suggest that dimers are formed in the solid HCN matrix via $C\equiv N\cdots H$ hydrogen bonds. The primary radiation excitation of these dimers actually leads to aminocyanocarbene. In one way or another, the formation of 1,2-diaminomaleic acid dinitrile under conditions approaching those in cosmic space appears to us to be extremely important because this compound may play a key role in prebiological organic synthesis, since the hydrolysis of 1,2-diaminomaleic acid dinitrile leads to the formation of an aminoacid.

From the standpoint of the problem of the cold chemical evolution of matter in cosmic space and the formation of complex polymeric macromolecules, the polymerisation of the closest analogue of HCN — cyanogen $(CN)_2$ — is of no less interest. It was found that the low-temperature radiation polymerisation of $(CN)_2$ proceeds less effectively than that of hydrogen cyanide. After $(CN)_2$ had been irradiated at 77 K with doses up to 10^3 kGy and was subsequently heated, the yield of the polymer was only 0.1%. However, polymerisation of this monomer in various solvents (alcohol, butyl chloride) leads to a severalfold increase in the yield. A significant increase in the yield of the polymer was also observed in the polymerisation of HCN in the presence of acetylene.

III. Glasses

Amorphous bodies are characterised by the presence of short-range order alone. Owing to the absence of long-range order, the macroscopic properties of amorphous bodies are independent of direction. However, on sufficiently rapid cooling, it is possible to obtain the state of a nonequilibrium supercooled liquid. Further cooling of the substance in this state below the glass point T_g leads to the formation of a nonequilibrium solid amorphous state frequently referred to as a glass. In reality, the transition from the supercooled liquid to the vitreous state usually occurs over a narrow temperature range. The glass point is not a thermodynamic characteristic of the substance and, depending on the conditions in the preparation of the specimen and the method of measurement employed, it can vary within a fairly wide range. In the vitreous state, the species comprising the substance are capable of only vibrational and small-scale rotational motions. The translational mobility, characteristic of the liquid state is almost completely lost in the vitreous state.

The fact that transitions from the supercooled liquid to the glass state and conversely (devitrification) are accompanied by a sharp alteration in properties is extremely important: the viscosity changes by 10–15 orders of magnitude, the modulus of elasticity changes by a factor of 10–1000, the coefficient of thermal expansion changes by a factor of 10–100, etc. The gigantic jump in viscosity over the narrow vitrification temperature range is naturally the most impressive. For the chemist, this means that the molecular mobility, which determines the dynamics of the chemical reaction, changes sharply in this region. The nature of the chemical process should change on passage through the glass softening region owing to the extremely sharp alteration of the mobilities of the reactants. The mobility of molecules changes very markedly following a very slight alteration in temperature (by only a few degrees).

Reactive radical and ionic species are formed on radiolysis of vitreous matrices, are stabilised in deeper or shallower traps, and can retain their reactivity for a very long time. The absence of molecular mobility in the glass prevents the mutual recombination of such stabilised radicals. When the matrix is heated and devitrified, the translational mobility increases sharply, which entails the recombination of the accumulated radicals.

Thus, following a sharp increase in translational mobility, which occurs over the narrow temperature range in the transition from the glass to the supercooled liquid, relatively small radicals undergo effective recombination. It is more accurate to say that those radicals recombine whose mobility is sufficient to ensure their encounter in a viscous supercooled liquid. In systems where radicals liberated on devitrification are capable of initiating a chain reaction, a chemical chain process does occur effectively, as will be shown below.

1. Radical polymerisation

Vinyl acetate can be obtained in both vitreous and crystalline states. The rate of polymerisation of vitreous vinyl acetate is an order of magnitude higher than that of the crystalline substance under identical conditions.[66] High rates of post-radiation polymerisation have been noted for a series of vitreous solutions of monomers in liquid paraffin and other glass-forming solvents.[67,68]

The use of the calorimetric method of measurement established that the polymerisation process in many radiolysed vitreous systems occurs when they are heated in the temperature range corresponding to the devitrification of the matrix.[69–71] We shall consider in greater detail the study of polymerisation in the acrylic acid–ethanol vitreous system.[72]

It has been established that, on cooling to 77 K, a 17% solution of acrylic acid in ethanol passes to the vitreous state. During the heating of the glass in the calorimeter, a transition of the system from the vitreous to the supercooled liquid state ($T_g \approx 103$ K) is observed. On further heating, the supercooled

liquid passes to the region of a thermodynamically stable liquid (without crystallisation and subsequent fusion). Direct calorimetric measurements in the field of γ-radiation showed that there is hardly any polymerisation in this system at $T \leqslant T_g$. Immediately after the devitrification step, intense heat evolution, associated with the polymerisation of acrylic acid, is observed on the calorimetric curve. The overall yield of the polymer then reaches 80%. EPR spectra recorded at 108 K indicate the conversion of the monomeric radicals and the radicals of the alcohol matrix, formed during radiolysis, into the radicals of the growing polymer chain.

The EPR spectra of these radicals and their conformational transformations have been analysed in detail.[73] Together with the initiation of the polymer chain, some of the monomeric radicals recombine and only half of them are converted into polymeric radicals. On further heating in the temperature range where acrylic acid polymerises vigorously, the concentration of the growing polymeric radicals remains unchanged. Later studies of the polymerisation dynamics in this system with the aid of Mössbauer spectroscopy confirmed the validity of the principal conclusions.[74]

It follows from the foregoing that the polymerisation process proceeds virtually without chain termination over a comparatively narrow temperature range in the region corresponding to the devitrification of the matrix. The radicals stabilised in the glass during radiolysis acquire translational mobility on passage through the devitrification region and begin to recombine. They also add simultaneously to the double bond of the monomer. *n*-Meric growing radicals, the mobility of which is so low in a viscous supercooled liquid that their encounters and recombination are hardly noticeable, are produced. Furthermore, the small monomer molecules are readily supplied to such *n*-meric growing centres and their termination-free propagation is observed. This unique situation has been widely used in various polymerisation processes.

The method involving polymerisation on devitrification of the matrix has been applied to the determination of the principal kinetic parameters (rate of chain propagation, activation energy) of the low-temperature polymerisation of tetrafluoroethylene.[75] Perfluoro-3-ethyl-2,4-dimethylpent-2-ene served as the vitrifying matrix. Solutions of tetrafluoroethylene in this solvent pass fully to the vitreous state on cooling. With increase in the tetrafluoroethylene concentration in the solution, the glass point shifts monotonically into the region of lower temperatures with a corresponding decrease in the temperature range of the polymerisation process.

It has been shown that chain termination occurs when the growing macroradical adds to the double bond of the solvent, whereupon a relatively inactive stable radical, incapable of further chain propagation, is produced.[76]

We may note that the method involving postpolymerisation on devitrification was subsequently used widely in the study of the kinetics and mechanisms of low-temperature polymerisation processes (see, for example, Barkalov[77] and Barkalov and Kiryukhin[78] and the literature quoted therein, as well as other communications by Barkalov and coworkers[79–81]). It would seem that the polymerisation process carried out on devitrification of the matrix should lead to the formation of polymers with an extremely high molecular mass. In reality this is not observed. Presumably even at such low temperatures chain transfer through the monomer or the solvent plays an appreciable role in limiting the length of the polymer chain owing to the long time of the mutual contact of the reactants. Here chain transfer is understood, for example, as the reaction involving the abstraction of hydrogen from the monomer or the solvent by the growing macroradical with formation of an inert macroradical and a radical which initiates the propagation of a new polymer chain.

Indeed, the results of a study of the polymerisation of acrylamide in a vitreous solution of acrylamide in glycerol have been published.[82] Kinetic chains with a length $\geqslant 10^7$ occur in this system. Effective polymerisation during heating takes place in the temperature range 220–260 K immediately after the softening of the glass. The initiation of polymerisation in this system requires an extremely low radiation dose—only 0.3 Gy. The number of growing polymeric radicals was measured by the EPR method and their radiation-chemical yield was calculated. It was found that a single chain initiation step leads to the reaction of more than ten million monomer molecules.

During polymerisation on devitrification of alcohol solutions, the reactivities of acrylic and methacrylic derivatives differ sharply.[83] Whereas the yield of the polymer reaches 80% in the polymerisation during the vitrification of alcohol solutions of acrylic acid, its amide, and its methyl ester, the yield of the polymer for methacrylic acid and its analogous derivatives does not exceed 3%–5% under identical conditions. Bearing in mind that the relative concentrations of the growing polymeric radicals proved to be similar for all the monomers investigated, one may conclude that the sharp difference between the rates of polymerisation of acrylic and methacrylic derivatives is not associated with the difference between the initiation efficiencies.

Figure 7 presents the temperature dependences of the relative concentrations of the radicals during the heating of radiolysed vitreous solutions. Evidently the concentration of the growing polymeric radicals for acrylic acid and its derivatives is constant within a certain temperature range. In this temperature range, acrylic acid undergoes effective polymerisation. In the case of methacrylic acid and its derivatives, a completely different picture is observed. The *n*-meric radicals initiated possess sufficient translational mobility, are not stabilised, and recombine rapidly.

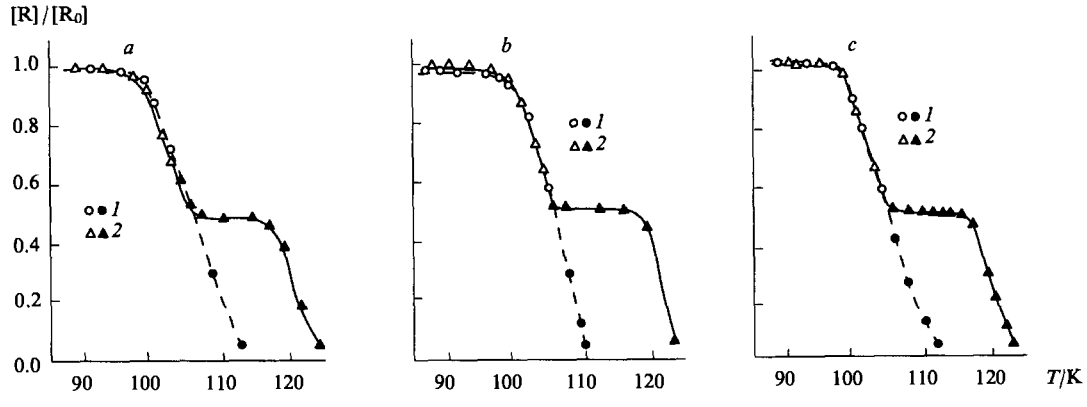

Figure 7. Variation of the relative concentration of radicals during the heating of radiolysed vitreous solutions: (*a*) methacrylic (*1*) and acrylic (*2*) acids; (*b*) methacrylamide (*1*) and acrylamide (*2*); (*c*) methyl methacrylate (*1*) and methyl acrylate (*2*). Filled symbols—growing *n*-meric radicals; initial radical concentration 1×10^{18} cm^{-3}.

In order to elucidate the causes of such a sharp difference between the rates of chain termination in the polymerisation reactions of acrylic and methacrylic acids, a study was made of the structure of the EPR spectra and the conformation of the growing terminal macroradicals was determined from the hyperfine splitting of the β-proton. The main factor responsible for the low translational mobility of macroradicals in a supercooled liquid is known to be their interaction with the alcohol molecules, which is indicated by the specific nonequilibrium conformation of the growing centre.[72,73] It was found that the presence of the CH_3 group near the reaction centre in the case of methacrylic acid prevents the interaction of the growing macroradical with the alcohol matrix, thereby preserving its mobility. This is apparently the main cause of the sharp difference between the rates of polymerisation of acrylic and methacrylic monomers on devitrification of their alcohol solution.

Thus, in contrast to the usual liquid-phase polymerisation, a sharp difference between the capacities of acrylic and methacrylic monomers for polymerisation is observed in polymerisation on devitrification, which is associated with the stronger interaction of the growing acrylic macroradicals with the medium. This difference between the reactivities of acrylic and methacrylic monomers is manifested only at fairly low temperatures.

2. Ionic polymerisation

The change in the physical properties of the matrix on passage through the devitrification region cannot fail to be reflected also in the dynamics of the propagation of the polymer chain via a cationic or anionic mechanism, since not only radicals but also trapped electrons and holes are stabilised during low-temperature radiolysis in glasses, i.e. the occurrence of the polymerisation process via an ionic mechanism is just as likely as its occurrence via a radical mechanism. The lifetime of the ions increases in the low-temperature region, while impurity water is segregated as its own crystalline phase and does not inhibit the polymerisation. Thus one may postulate that special methods for the drying of the monomer and the solvent are not needed under the conditions of postpolymerisation on devitrification of the matrix.

Cyclopentadiene was selected as the object for the study of low-temperature ionic polymerisation. The choice of cyclopentadiene was dictated by the fact that it had been earlier observed[84] that it undergoes cationic polymerisation on exposure to γ-radiation. Butyl chloride served as the vitrifying matrix in which the cationic centres arising on radiolysis are satisfactorily stabilised. On rapid cooling, solutions of cyclopentadiene in butyl chloride pass fully to the vitreous state. At 97 K, the glass is converted into a viscous supercooled liquid, which crystallises on heating and then melts at 140 K. Heating of a vitreous solution of cyclopentadiene in butyl chloride, γ-irradiated at 77 K, leads to the effective polymerisation of the monomer.[85,86] The heat evolution associated with the polymerisation of cyclopentadiene is observed over a narrow temperature range immediately after the transition of the system from the vitreous to the supercooled liquid state. On crystallisation and fusion of the system, polymerisation does not occur. The yield of the polymer increases with increasing preliminary irradiation dose and reaches a limiting value for extremely low doses (~30 kGy), which is characteristic of the accumulation of stabilised ionic centres in the course of the low-temperature radiolysis.

Epoxyethane is known to polymerise readily with the opening of the epoxide ring via a cationic or ionic mechanism in the presence of a large number of different catalysts. However, the epoxide ring proved to be extremely resistant to the action of high-energy radiation. The attempts to carry out the radiation polymerisation of epoxyethane in the solid and liquid phases were unsuccessful.[87] The effective polymerisation of epoxyethane with radiation initiation was achieved only by employing the post-polymerisation regime on devitrification of a butyl chloride matrix.[86,88] In contrast to the crystalline monomer, heating of vitreous solutions of epoxyethane in butyl chloride γ-irradiated at 77 K leads to effective polymerisation. The heat evolution associated with the postpolymerisation of epoxyethane is observed in the temperature range corresponding to the softening of the glass (~96 K).

The following evidence has been obtained for a cationic mechanism of the polymerisation of epoxyethane on devitrification of the matrix: (1) optical bleaching of the radiolysed specimens leads to a marked suppression of the postpolymerisation process; (2) the addition of small amounts of ethanol or pyridine (typical cationic inhibitors) fully inhibits the post-polymerisation; (3) the addition of hydroquinone (a typical inhibitor of radical polymerisation) to the initial solution does not affect the post-polymerisation reaction on devitrification.

Thus the use of the method of postpolymerisation on devitrification of the matrix makes it possible to achieve effective cationic polymerisation. A characteristic feature of this process is the lack of any special requirements as regards the drying of the monomer and the solvent.

3. Copolymerisation

On copolymerisation in the liquid and gas phases, the composition of the copolymer is determined by the reactivities of the comonomers (a homogeneous copolymer is obtained only in the initial stage of the polymerisation reaction). As the more reactive monomer is consumed, the resulting copolymer begins to be enriched, as a rule, in the less reactive monomer and the polymer chains acquire an inhomogeneous composition.

A characteristic feature of the supercooled liquid state obtained after the devitrification of the matrix is its comparatively high viscosity. In a highly viscous system of this kind, the duration of mutual contact between the reacting species is much longer than in the gas and liquid phases. It was therefore to be expected that the composition of the copolymer obtained under such conditions could be regulated by varying the composition of the initial mixture of monomers and that a homogeneous copolymer could be obtained for any degree of conversion.

Copolymerisation on devitrification in monomer–complex-forming agent systems has been investigated by Zubov and coworkers,[89–93] while similar copolymerisation in the absence of a complex-forming agent has been investigated by Bol'shakov et al.[94] It has been shown experimentally that copolymerisation in a supercooled viscous liquid makes it possible to obtain homogeneous copolymers and to regulate their composition.

It may be hoped that an increase in the time of contact between the reactants in the supercooled liquid will make it possible to involve compounds in copolymerisation which are not usually regarded as comonomers. In this connection, it is of interest to consider the copolymerisation of acetone with acrylic acid.[95] Heat evolution associated with copolymerisation was observed immediately after the transition of the system to a supercooled liquid state (110 K) on slow heating in a calorimeter of a vitreous solution of acrylic acid irradiated at 77 K.

In dilute acetone solutions of acrylic acid, the yield of the polymer isolated reached 250% relative to acrylic acid. Consequently the polymeric product contained two acetone molecules per acrylic acid molecule. Analysis of various mechanisms for the incorporation of acetone in the polymeric product showed that the copolymerisation of acrylic acid with the enolic form of acetone is most probable.

Thus the specific features of the supercooled liquid state, manifested by a significant increase in the contact time between the reactants, lead to a radical alteration of ideas concerning the reactivity of comonomers.

4. Graft polymerisation

Not only low-molecular-mass compounds but also polymers can be used as the vitrifying matrix. The use of the grafting method with devitrification of a polymer matrix proved effective for readily polymerising monomers such as tetrafluoroethylene.[96,97] The usual methods for the joint radiolysis of the monomer and

polymer in order to achieve graft polymerisation are difficult to use because the homopolymerisation of the monomer becomes the dominant process under these conditions.

IV. Other metastable systems

A large series of studies have been carried out also for other metastable solid systems. The low-temperature polymerisation of various monomers by condensing the monomer and the initiator onto a cooled surface (the molecular beam method) was achieved in 1959.[98-100] The initiators employed were metal couples (magnesium, potassium, sodium) and certain oxides and salts. In their presence, acrylamide, styrene, acrylonitrile, methyl methacrylate, and a series of other monomers polymerised at high rates. The low-temperature polymerisation occurred mainly in the vicinity of phase transitions, where the necessary mobility of the molecules was attained. The results of these studies have been surveyed in a review.[100]

Recently, the molecular beam method has been applied successfully in the low-temperature (77 K) polymerisation of frozen cocondensates initiated by a local mechanical action.[101-109] The polymerisation of cyclopentadiene and styrene in the presence of $TiCl_4$ has been investigated. The local mechanical action on the molecular mixtures of the monomer and the initiator involved impact by a steel needle with the aid of an electromagnetic gun. After the application of the mechanical impact, a rapid propagation of the polymerisation reaction through the specimen was observed at low temperatures. The dependence of the mechanical stresses in the low-temperature cocondensates of the monomer and the initiator on the conditions in the formation of the specimens and their role in the initiation of rapid polymerisation were demonstrated. These phenomena will be examined below in greater detail.

Photoinitiation has been used in a series of studies[105-109] of polymerisation and polycondensation at low temperatures. This procedure generally requires the application of photosensitisers; the systems obtained under these conditions are usually heterogeneous. It has been shown that in certain systems (with cinnamic acid derivatives and anthracene as sensitisers), the rate of addition at low temperatures ceases to depend on temperature and the polymerisation proceeds without activation as far as 4.2 K.

The photosensitised chain polymerisation reactions of acrylonitrile, formaldehyde, and xylene at low temperatures have been investigated. The sensitisers employed were *N,N'*-tetramethyl-*p*-phenylenediamine and β-naphthol and the specimens were prepared by the joint vacuum condensation of the monomer and the sensitiser onto an optical support. These reactions proceed as a result of the direct transformation of part of the radiant energy into the energy of the motion of the species along the reaction coordinate. Furthermore, it has been suggested that a proportion of the chemical energy is converted into mechanical stresses, which, for a certain structure of the solid system, induce the mutual approach of the reacting species and chain propagation at the very low temperatures employed.

Communications of this series report polymerisation at temperatures much lower than the glass point and the reactions are distinguished by a high yield of the polymer.

V. Autowaves

The mechanical energy of the elastic deformation of a solid at the instant of its disruption is concentrated in the region directly adjoining the newly formed surface. This energy transformation process is known to give rise to significant changes in the physicochemical properties of the substance on the freshly formed surface compared with the bulk-phase properties.[110]

Brittle breakdown is accompanied by phenomena such as the emission of electrons and ions, luminescence, the formation of radicals, and a sharp acceleration of transport processes on the cleavage surfaces. It appeared likely that the transition of the process from a homogeneous to a significantly heterogeneous regime via the brittle fracture of the specimen would include a nonequilibrium mechanism of energy transfer to the active centres previously stabilised in the solid matrix and would initiate the chemical reaction at low temperatures.

The ideas described above stimulated the study of the sensitivity of solid-phase processes to local perturbations which have been either introduced or have arisen spontaneously. These investigations led to the observation of highly intense autowave regimes in low-temperature solid-phase reactions. The principal conclusions have been surveyed in reviews.[111,112] The logic of the development of these studies will be traced below.

The objects of study were systems in which the spontaneous development of reaction chains is impossible in the solid state at radiolysis temperatures of 77 and 4.2 K, and the first task was to elucidate the activating role of the brittle fracture of the system. It was possible to show that the formation of the primary crack plays the role of an initiating device which switches on the positive feedback mechanism ensuring a self-supporting process regime. The following self-activation mechanism has been proposed. The chemical reaction arising on the cleavage planes and in the adjoining regions disturbs the monolithic nature of the sections of the solid matrix not involved in the reaction, thereby preparing the next layer for the reaction to take place. Such breakdown of monolithic structure can occur, for example, as a consequence of the appearance of temperature or density gradients during the reaction, which create stresses disrupting the specimen.

Autowave phenomena are known to be characteristic of systems described by nonlinear branched-chain models. Autowave reaction regimes should arise in sufficiently long specimens in response to a locally introduced perturbation. In the first experiments,[113] it was already possible to initiate the spontaneous propagation of the reaction wave throughout the specimen on formation of a local cleavage plane. The structure of the travelling front of the cryochemical reaction proved to be completely atypical for classical thermal self-propagation processes.

The qualitative picture of the propagation of the wave involved the concept of the movement in the solid specimen of a narrow zone highly truncated by an extensive network of freshly formed cracks. The chemical reaction arises in precisely this zone on the surface of the cracks (or close to it) and creates in its turn conditions for continuation of the breakdown in the adjoining layer of the solid matrix. Such layer-by-layer dispersion of the specimen is referred to as the travelling stress field. A stress of this kind may be caused, as already stated, either by the difference between the densities of the starting materials and the final products (isothermal mechanism) or by the appearance in the specimen of 'steep' temperature gradients as a result of the exothermicity of the reaction (nonisothermal mechanism). Naturally both factors can also operate simultaneously.

The studies carried out indicate the wide occurrence of autowave phenomena in cryochemical solid state reactions and the identity of their physical mechanism in a wide range of chemical systems. This gave grounds for the assumption that autowave reaction regimes can prove useful in the creation of new nontraditional chemical technologies. Indeed, the principal technological tasks (activation of the chemical system, supply of energy, and mixing of the reactants) are performed jointly by employing the energy of the autowave chemical proceses. The occurrence of very high rates of the chemical reaction in the autowave regime at low temperatures is also extremely attractive.

1. Acetaldehyde

The autowave polymerisation regime arises in polycrystalline acetaldehyde already at 4.2–77 K. Its principal characteristics have been investigated.[114] The polymerisation wave in the crystalline monomer was observed in massive (cylindrical) and thin-walled specimens immersed in both nitrogen and helium baths. The reaction wave was excited in response to the local brittle fracture of the frozen acetaldehyde.

Propagation of the polymerisation front in solid radiolysed acetaldehyde at relatively high temperatures (117 – 147 K), close to the melting point of the monomer (150 K), was observed with the aid of thermography and cine-filming.[43] This phenomenon was interpreted within the framework of the classical thermal combustion mechanism. The rate of propagation of the reaction front at these temperatures was 1 – 3 cm s^{-1} for preliminary irradiation doses of 5 – 100 kGy.

The development of ideas concerning autowave processes made it possible to analyse the characteristics of the polymerisation of acetaldehyde at a new qualitative level. Acetaldehyde is of special interest in connection with two factors. First, the autowave regime in the polymerisation of acetaldehyde is an example of the appearance of a cryochemical wave in a one-component system. Second, the heat of this reaction is almost an order of magnitude lower than for the systems investigated previously. This created preconditions for the development of ideas concerning the role of the isothermal and nonisothermal mechanisms and their inter-action in the autowave process.

When the autowave passed through the specimen in the helium bath, the maximum temperature in the front did not exceed 130 K, i.e. was significantly lower than the melting point of the monomer (Fig. 8). Thus here there are all the conditions for the analysis of the changes in the structure and phase state of the crystalline specimen induced by the passage of the mechanochemical cryo-wave through it. According to the ideas developed, the chemical reaction front represents a mechanical dispersion zone moving through the solid reactant. One may postulate that the passage of such a wave through the specimen results in its dispersion.

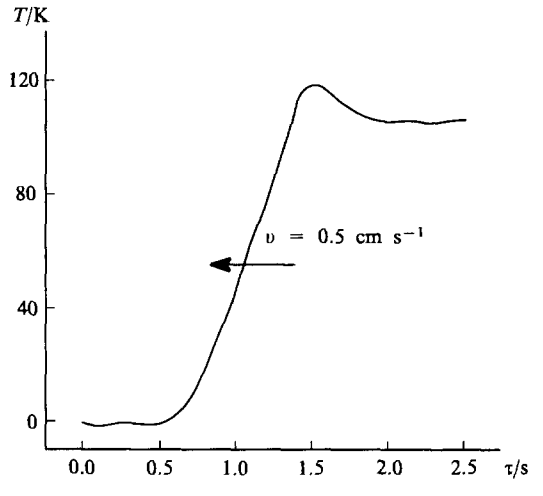

Figure 8. Time variation of the temperature profile of the acetaldehyde polymerisation travelling wave at 4.2 K. Preliminary γ-irradiation dose 700 kGy.

This hypothesis was tested by calorimetric analysis. To carry out such an analysis, the acetaldehyde specimen was transferred to a bath of liquid nitrogen after the passage of the auto-wave through it (in liquid helium) and was then cut up into several portions. Each of these was placed separately in a calorimeter at 77 K and the calorimetric heating curve was recorded. It was found that after the passage of the wave there was no crystalline phase in the specimen. Only a heat capacity jump, accompanying devitrification, was detected in the calorimetric experiments, and the signal corresponding to the heat of fusion was absent. When the process was carried out not in the autowave regime but in a regime involving the slow heating of the entire specimen in the calorimeter (without the brittle fracture initiating the autowave), the unreacted monomer retained its crystallinity. Thus the passage of the mechanochemical wave through the crystalline specimen does indeed lead to its conversion into an amorphous form.

The rate of propagation of the autowave depends on the preliminary γ-irradiation dose. As in the systems investigated previously,[111] there is a critical dose necessary for the attainment of the autowave regime. The magnitude of this dose increases with decrease in the thermostat temperature from 77 to 4.2 K. For specimens immersed in liquid nitrogen, the rate of propagation of the polymerisation wave increases linearly with the irradiation dose. It is logical to postulate that the increase in the rate of propagation of the wave with increasing irradiation dose is associated with the increased concentration of the active centres. However, the accumulation of paramagnetic centres (radical-ions and radicals) during the radiolysis of polycrystalline acetaldehyde at 77 K takes place linearly only in the region of small doses (only up to ~50 kGy) and then slows down. After the attainment of ~650 kGy, the stabilised active centres altogether cease to accumulate.

Even on rapid cooling, pure acetaldehyde cannot be converted into a vitreous state and its polymerisation in such a state has not therefore been investigated. A study has been made[115] of the polymerisation of a solid vitreous solution of acetaldehyde in butyl chloride. Local brittle fracture initiated the autowave polymerisation regime. The principal parameters of the autowave polymerisation process in the polycrystalline and vitreous matrices agreed only qualitatively. On the other hand, in quantitative terms, the critical dose of the preliminary γ-irradiation, above which it is possible to generate an autowave in glass, is 60 kGy, while in crystalline acetaldehyde it exceeds 300 kGy.

2. Cyclopentadiene

In the phenomenological description of the autowave processes considered above, the nature of the active centres arising on brittle fracture of the system were not specified in concrete terms. Since the majority of the cryochemical autowaves have been observed for typical radical chain reactions, it was of interest to establish the autowave regime for a typical ionic chain reaction.

Cyclopentadiene polymerises only via an ionic mechanism and this is why it was selected for the investigation of the characteristics of the autowave regimes in cryochemical reactions of this type.[116] It is noteworthy that the 'explosive' polymerisation reaction of cyclopentadiene was observed in films obtained by freezing them from molecular beams comprising the monomer and the catalyst ($TiCl_4$) and then pricking the film with a metallic needle at 77 K.[101]

On rapid cooling to 77 K, a solution of cyclopentadiene in butyl chloride passes to the vitreous state. On local brittle fracture of the radiolysed specimen immersed in liquid nitrogen, the polymerisation reaction, propagated through the specimen in the form of an autowave, begins. The velocity of the polymerisation wave and the form of its temperature profile depend significantly on the preliminary irradiation dose. The velocity of the wave increases with increasing dose, while the temperature profile of the wave becomes increasingly sharp.

The velocity of the polymerisation wave increases linearly with increasing preliminary irradiation dose up to 1200 kGy. This type of dependence of the velocity of the wave is evidently not associated with the dynamics of the accumulation of the cationic active centres, because such accumulation ceases for significantly lower doses.

The molecular mass and the yield of the polycyclopentadiene obtained in the autowave regime are higher than in thermo-activated postpolymerisation. The latter factor may prove useful in the development of technological regimes for the synthesis of polymers.

VI. Oscillations in the rate of reaction

Oscillations in the rate of reaction is an unusual phenomenon as regards the classical ideas concerning the nature of a chemical process. Many investigators are engaged nowadays in the study of its mechanism.[117-122]

The present authors encountered auto-oscillations in the rates of cryochemical reactions for the first time in a study of the solid-phase radiation-induced hydrobromination of ethylene.[123] The post-radiation process (for example, polymerisation), occurring under conditions where the temperature of the thermostat is scanned, is initiated by the active centres gradually liberated with increase in the temperature of the matrix. A definite number of active centres stabilised in the matrix are generated on γ-irradiation. The irradiation takes place at a fairly low temperature, the centres formed are stabilised in the matrix, and the reaction is not initiated. Only on raising the temperature of the medium are the active centres liberated and initiate the chemical reaction.

We shall consider the establishment of auto-oscillatory regimes in low-temperature radiation-induced thermokinetic chemical chain reactions.[123-128] For reactions occurring under isothermal conditions, the negative feedback necessary for the occurrence of oscillations in the reaction rate can be brought into operation only by chemical autocatalysis. For exothermic chain reactions, the heat evolved may play the role of the negative feedback under certain conditions. The evolution of heat can increase the temperature of the medium and hence the rate of the chemical reaction. Thus the evolution of heat can perform a function analogous to autocatalysis.

Cryochemical reactions are responsible for the appearance of thermokinetic oscillations: the defectiveness of solid matrices and their low heat capacities promote the appearance of non-uniformities in the temperature field. Thermokinetic models of the auto-oscillations in the rates of chemical reactions have been considered by Sal'nikov[129,130] and a detailed description of such reaction conditions may be found in monographs.[117,121,122] We shall consider certain examples of the auto-oscillatory regimes in cryochemical reactions in vitreous and crystalline matrices.

As an illustration, we may quote the results of a study of the polymerisation of crystalline heptyl acrylate. The process takes place during the heating of specimens γ-radiolysed at 77 K in both auto-oscillatory and the usual regimes. On rapid cooling of heptyl acrylate to 77 K, the monomer passes to the vitreous state. Heating of such specimens in a calorimeter makes it possible to observe the transition from the vitreous to the supercooled liquid (~138 K) state and then the crystallisation of the supercooled liquid in the temperature range 140–205 K and fusion of the monomer crystals at 205–210 K. If, however, the monomer is initially annealed at 205 K and then cooled to 77 K, then it passes fully to the crystalline state. The calorimetric heating curve for such specimens shows only the endothermic peak due to the fusion of the monomer at 208 K (Fig. 9). The postpolymerisation process was in fact investigated in precisely such specimens.

In order to accumulate the polymerisation active centres, the monomer was γ-irradiated at 77 K with a dose of 5–100 kGy. The calorimetric heating curves of the specimens subjected to preliminary irradiation are presented in Fig. 9 (curves *2–4*). The polymerisation reaction, recorded from the evolution of heat, begins at temperatures 15–20 K below the melting point of the monomer, where the molecules acquire translational mobility.

The rate of polymerisation exhibits a marked temperature dependence along the initial section and rapidly attains a maximum. After this, a sharp decrease and a further increase in the rate of the process are observed. Ultimately, several acceleration and retardation periods occur. The oscillations in the rate of reaction have a decaying amplitude. An increase in the preliminary irradiation dose shifts the onset of the process into the region of lower temperatures and increases the amplitude of the oscillations in the rate (cf. curves *2* and *3* in Fig. 9). When the preliminary

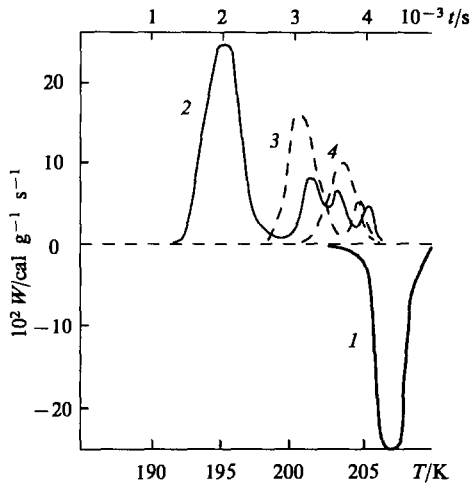

Figure 9. Calorimetric heating curve for nonirradiated heptyl acrylate (curve *1*) and variation of the rate of heat evolution on heating heptyl acrylate γ-irradiated at 77 K using different doses (kGy): (*2*) 100; (*3*) 17.5; (*4*) 5.

irradiation dose is sufficiently low, oscillations in the rate of post-polymerisation are no longer observed (curve *4*). The mathematical model of the postpolymerisation process proposed by Nefedov et al.[125] permits a qualitative explanation of the observed features of the polymerisation reaction of crystalline heptyl acrylate.

Oscillatory regimes in low-temperature radiation-initiated chain reactions have been observed also for polymerisation on devitrification of the matrix. As an example, we shall consider various regimes in the post-radiation polymerisation of acetaldehyde in a vitreous butyl chloride matrix.

On cooling to 77 K, a solution of acetaldehyde in butyl chloride passes fully to the vitreous state. When such a system is heated in a calorimeter in the temperature range 94–97 K, a transition from the vitreous to the supercooled liquid state is observed. This is followed by crystallisation (112–115 K) and then fusion (145 K). When the same system, subjected to preliminary γ-irradiation at 77 K, is heated, heat evolution due to the post-polymerisation of acetaldehyde is observed in the devitrification region. Various process regimes are possible depending on the conditions in the transfer of heat from the calorimetric cell.

Polymerisation can occur in the absence of appreciable superheating of the test substance in the cell relative to the calorimeter block (stationary conditions). For this regime to be achieved, it is necessary to establish a fairly rapid removal of heat from the cell. This can be done experimentally by altering a series of parameters. It is essential to decrease the rate of heating of the specimen, to improve the heat removal conditions by increasing the ratio of the surface of the specimen to its volume (by reducing the mass of the initial sample), and to reduce the preliminary irradiation dose, which leads to a diminution of the concentration of the active centres stabilised in the system, i.e. to a decrease in the rate of heat evolution due to the polymerisation reaction.

During the heating of the specimen in the absence of appreciable superheating of the latter in the cell, the rate of post-polymerisation of acetaldehyde increases with increasing temperature, reaches a maximum, and diminishes smoothly owing to the consumption of the monomer and the active centres for the reaction stored during the preliminary radiolysis (Fig. 10, curve *1*). The initial section of the calorimetric curve can be expressed satisfactorily in a linear form in terms of the Arrhenius variables under these conditions (the activation energy is 6 kcal mol^{-1}).

Another extreme case is the thermal explosion regime. It is observed when the conditions in the elimination of heat from the cell are impaired: an increase in the mass of the substance in the

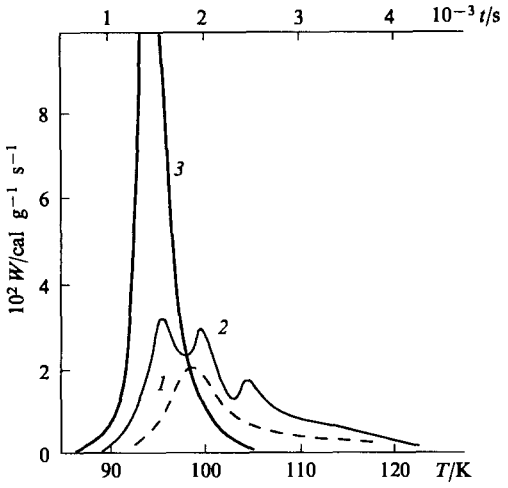

Figure 10. Variation of the rate of heat evolution in the devitrification region during the postpolymerisation of acetaldehyde (AA) in a butyl chloride (BC) matrix in different specimens: (*1*) 0.097 g of AA + 0.367 g of BC; (*2*) 0.138 g of AA + 0.549 g of BC; (*3*) 0.175 g of AA + 0.672 g of BC. Preliminary γ-irradiation dose at 77 K 120 kGy (curves *1* and *2*) and 300 kGy (curve *3*); *T*—temperature of the calorimeter block.

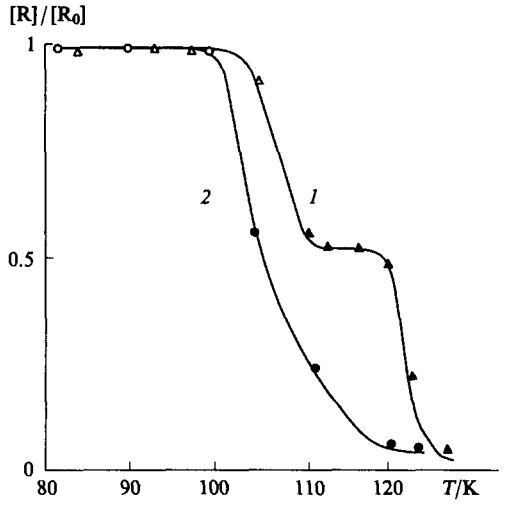

Figure 11. Variation of the relative concentration of radicals during the heating of 17% solutions of acrylic acid in ethanol irradiated at 77 K using doses of 20 kGy (curve *1*) and 50 kGy (curve *2*). Heating rate of the specimens 0.2 K min^{-1} (curve *1*) and 0.5 K min^{-1} (curve *2*). The filled symbols refer to the concentration of the growing polymer chain.

cell, in the rate of heating of the specimen, and in the preliminary irradiation dose (Fig. 10, curve *3*). Under the conditions of moderate heat removal, an oscillatory process regime has been recorded—several cycles involving an increase and a decrease in the rate of reaction were observed during the experiment (Fig. 10, curve *2*).

Thus, depending on the reaction conditions, different process regimes are realised: the stationary regime (in the absence of appreciable superheating of the test substance in the specimen), thermal explosion, and the oscillatory regime. Analysis of experimental data leads to the conclusion that the oscillations in rate in the acetaldehyde–butyl chloride system are associated with the thermokinetic mechanism described above. The following estimates of the limits of the existence of oscillatory regimes may be quoted: (1) $T_{th} < T_c < T_{th} + \Delta T$, where T_c is the temperature to which the reaction mixture has been superheated in the oscillatory regime in the cell relative to the thermostat temperature T_{th}, and ΔT represents the pre-explosion heating ($\Delta T = RT^2/E$); (2) $\tau > n\tau_{os}$, where τ is the average lifetime of the active centres ($\tau = 1/k$ in the case of unimolecular chain termination, $\tau = 1/k_t R_t$ in the case of bimolecular termination, k_t is the termination reaction rate constant, and R_t is the initial concentration of the polymerisation active centres), τ_{os} is the period of the oscillations, and n is the number of oscillation cycles. When the reaction takes place under stationary conditions (in the absence of appreciable superheating in the specimen), the growing macroradicals do not recombine in the temperature range 110–120 K; only the propagation of the polymer chain takes place (Fig. 11, curve *1*). When the quasi-isothermal regime is infringed and oscillations arise in the rate of postpolymerisation, the growing macroradicals are destroyed (Fig. 11, curve *2*). At high rates of heating of the system (~600 K min^{-1}), the growing polymer chains are not formed at all owing to the destruction of the active centres at an early stage in the process.

The different chemical reaction regimes are of interest in connection with the possibility of increasing the selectivity of complex processes and of expanding the technological procedures for controlling cryochemical synthesis. The thermal instability arising in the operation of chemical reactors is usually an undesirable phenomenon leading to a decrease in the quality of the production and possible breakdowns. The understanding of the process mechanism makes it possible to suppress the auto-oscillations and to maintain a stationary regime. However, oscillatory regimes may also prove convenient—they afford a significantly greater average yield of the product than stationary regimes. Such advantages are manifested particularly strikingly when the target product is an intermediate in a complex chemical chain reaction.[131]

As an example of the influence of various reaction regimes on the properties of the final product, we shall consider the low-temperature radiation polymerisation of 1,3-bis(dimethylamino)-isopropyl methacrylate.[132] Depending on the conditions in the removal of heat from the reaction volume, different polymerisation process regimes were realised on devitrification of the matrix: stationary, oscillatory, and thermal explosion.

In the case of the auto-oscillatory postpolymerisation regime, the mass-average molecular mass of the polymer diminishes from 2.8×10^6 to 1.4×10^6 with increase in the preliminary irradiation dose from 10 to 118 kGy. In the stationary regime, the molecular mass diminishes from 1.5×10^6 to 0.3×10^6. The high molecular mass of the polymer obtained in the oscillatory regime is evidently due to the fact that local superheating results in an increase in the mobility of the growing polymer chains, so that their bimolecular termination predominates.

Polymers with a different supermolecular structure, characterised by the presence of microheterogeneities, are obtained in the thermal explosion regime.[132] A more detailed analysis of the polymeric products obtained in this series of studies showed that the appearance of nonstationary conditions in the low-temperature polymerisation process (oscillatory regime and thermal explosion) leads to the broadening of the polymer molecular mass distribution in the direction of higher molecular masses.

VI. Conclusion	516

Abstract. The results of studies on the influence of the nature of the solvent on the kinetics of the radical polymerisation of water-soluble monomers are surveyed. It is noted that the rate of the process and the chain propagation rate constant in the polymerisation of monomers of this kind change sharply on passing from organic solvents to aqueous solutions. Comparative analysis of the kinetic data and the results of spectroscopic and viscometric studies made it possible to put forward a mechanism for the polymerisation of water-soluble monomers in various solvents. A distinctive feature of the polymerisation of water-soluble monomers is the hydrophobic interactions arising in aqueous solutions of the polymers and leading to a sharp difference between the kinetic parameters of the polymerisation of monomers of this class in water and organic solvents. The bibliography includes 76 references.

I. Introduction

The development of the classical theory of the radical polymerisation of vinyl monomers was completed towards the end of the 1950s. It was formulated in final form in the monographs of Bamford et al.[1] and Bagdasar'yan,[2] which appeared almost simultaneously. The theory is based mainly on the results of studies of the polymerisation of weakly polar hydrocarbon monomers (for example, styrene). The principal postulate of this theory is that the reactivity of the monomers and of the polymeric radicals formed from them, and hence the rate constant for the propagation of polymer chains (k_p), are determined solely by the chemical structure of the compounds and do not depend on the nature of the solvent in which the polymerisation takes place.

However, by the beginning of the 1960s studies had already been carried out in which it was established that the nature of the solvent affects not only the chain termination rate constant (k_t), as a consequence of a change in the viscosity of the reaction system, but also the propagation constant k_p in the polymerisation of monomers such as styrene, methyl methacrylate, and certain others.

Subsequently studies on the influence of the solvent and of various added compounds on the polymerisation of vinyl monomers were developed in a number of investigations (see, for example, Refs 3 – 15). They led to the establishment of new aspects of the field of radical polymerisation, in particular complex-radical polymerisation.[16] Studies on the influence of the nature of the solvent on the radical polymerisation of vinyl monomers published up to 1978 were examined in an earlier review.[17] The results of these investigations demonstrate that the influence of the solvent on the polymerisation of weakly polar monomers is associated with the formation of a donor – acceptor complex between the polymeric radicals and the solvent molecules, which alters the reactivity of the polymeric radicals. It is noteworthy, however, that the change in the overall rate of polymerisation and of the constant k_p for nonpolar monomers such as styrene is small (it does not usually exceed 30% – 50%). A more significant influence of the nature of the solvent is observed in the polymerisation of monomers containing functional groups capable of participating in a specific interaction with the solvent molecules. Such compounds include the esters of acrylic and methacrylic acids, vinyl acetate, and others. According to a series of data,[13–15] the overall rate of polymerisation of such monomers and the constant k_p may vary severalfold depending on the nature of the solvent.

The solvent exerts a much greater influence in the polymerisation of monomers containing atoms with a lone pair and functional groups capable of being involved in the formation of stronger complexes, in particular in the formation of hydrogen bonds. Such monomers include primarily water-soluble monomers incorporating amide, carboxy-, and carbonyl groups. In the polymerisation of these monomers, the replacement of the solvent may be accompanied by a change in the overall rate of polymerisation by a factor of several tens, an especially sharp change being observed on passing from an organic solvent to an aqueous solution.

The study of the influence of the nature of the solvent on the radical polymerisation of water-soluble monomers was initiated in the 1960s. Since then, numerous investigations of this problem have been published. The objects of study have been usually acrylamide, acrylic acid, *N*-vinylpyrrolidone, and the salts of the aminoesters of methacrylic and acrylic acids.

Apart from the elucidation of purely theoretical problems concerning the mechanism of the polymerisation of water-soluble

monomers, the interest in this problem is also due to the fact that water-soluble anionic and cationic polymers, primarily acrylamide polymers and copolymers, have found extensive application in various branches of the economy as flocculants, for the purification of drinking and waste waters, in increasing the extraction of petroleum, in reducing the hydrodynamic resistance to friction, etc.

The fact that, for the monomers investigated above, the influence of the nature of the solvent not only on the overall rate of the process but also on the rate constants for the elementary polymer chain propagation and termination has been determined is especially important for the determination of the mechanism by which the nature of the solvent influences radical polymerisation. Studies on these lines, carried out up to 1980, were devoted mainly to the investigation of polymerisation in various individual solvents.[16–20] In the present review, we shall deal only briefly with the results of these studies, attention being concentrated on later studies, and an attempt will be made to formulate the principal characteristic features of the radical polymerisation of water-soluble monomers and the causes responsible for these features.

II. Kinetics of the polymerisation of water-soluble monomers in various solvents

According to the nature of the solvent, the overall rate of polymerisation of water-soluble monomers varies by 1.5–2 orders of magnitude. These effects were first observed and then studied in detail for acrylamide, acrylic acid, and their derivatives, as well as for the salts of the aminoesters of methacrylic and acrylic acids.[17,19]

In terms of the influence on the overall rate of polymerisation of acrylamide, the above solvents can be arranged in the sequence water > formamide > dimethylsulfoxide(DMSO) > tetrahydrofuran (THF). In the polymerisation of acrylamide in aqueous solution at 40 °C, the quantity $k_p/k_t^{1/2}$ is 12 times greater than in DMSO and 50 times greater than in THF. The decrease in the rate of polymerisation on passing from water to DMSO and THF is accompanied by a decrease in the molecular mass of the polymers.

A similar effect of the nature of the solvent has been established also in the polymerisation of methacrylamide.[17]

In order to elucidate the causes responsible for the observed kinetic effect, the absolute values of k_p and k_t were determined for the polymerisation of acrylamide under homogeneous conditions.[17] These data show that the change in the overall rate of polymerisation of acrylamide on passing from an aqueous solution to a solution in an organic solvent is caused mainly by the change in k_p. The chain termination constant changes in the same direction (albeit to a much lesser extent) and thus diminishes the influence of k_p on the overall rate.

An appreciable influence of the nature of the solvent on the overall rate of reaction and the constant k_p has also been established in the polymerisation of *N*-vinylpyrrolidinone. The solvents investigated can be arranged in the following sequence: tetrahydrofuran ≈ dichloroethane < methanol < *N*-vinylpyrrolidinone < water, the change from polymerisation in THF to polymerisation in an aqueous solution entailing a change in k_p by a factor of ~50.[21–23]

Qualitatively the same results have been obtained in the study of the homogeneous polymerisation of acrylic acid and its derivatives in various solvents (Table 1). In this case too, the polymerisation is fastest in aqueous solution, the overall rates as well as the constant k_p decreasing significantly on passing to polymerisation in formamide and DMSO. However, the data in Table 1 indicate a significant difference between the behaviour of the acids investigated in the polymerisation in different solvent. Whereas in the case of acrylic acid the sharp dependence of the overall rate of polymerisation and of the constant k_p on the nature of the solvent is observed, in the case of methacrylic and especially fluoroacrylic acid this dependence is much less pronounced. Nevertheless, in all the systems investigated the overall rate of polymerisation increases in the series of solvents DMSO < formamide < water. The increase in the rate of polymerisation in the above sequence is almost wholly determined, as in the case of acrylamide, by the increase in k_p, which is in its turn associated with the decrease in the activation energy for the chain propagation reaction.

According to the classical theory of radical polymerisation,[1,2] the rate of chain propagation is determined by the reactivity of the polymeric radical. Comparison of the data presented in Table 1 shows that the change in the nature of the solvent in the polymerisation of the acids investigated makes the reactive radical formed in the polymerisation of acrylic acid in water (the reactivity of this radical is characterised by the constant k_p) less reactive than the radicals derived from fluoroacrylic and methacrylic acids in DMSO. The different degrees of dissociation of these acids in water and DMSO as well as the ability of the acid polymeric radicals to participate in the formation of complexes with DMSO (which has basic properties) probably play a definite role in such alteration of the reactivity of polymeric radicals.

The homogeneous polymerisation of the aminoesters of acrylic or methacrylic acid and of their tertiary and quaternary salts is also much faster in water than in organic solvents (Table 2). As in the radical polymerisation of other water-soluble polymers, the increase in the overall rate of polymerisation in water is also caused by the increase in the chain propagation rate constant. Thus the constant k_p in the polymerisation of acetate salts of diethylaminoethyl methacrylate in water (72 000 litre mol^{-1} s^{-1}) is 240 times greater than k_p in the polymerisation of dioxane.[26] Furthermore, a very considerable change in k_t was established in this system on passing from an organic solvent to an aqueous solution: the constants k_t in water and dioxane are 65 × 10^7 and 0.1 × 10^7 litre mol^{-1} s^{-1} respectively.

There is no doubt that the polymerisation of ionogenic monomers such as acrylic and methacrylic acids and their salts or the salts of their aminoesters is influenced significantly by the degree of ionisation, which depends on the nature of the solvent.[18] Nevertheless, the principal features of the polymerisation of water-soluble ionogenic anionic and cationic monomers do not

differ from those of the radical polymerisation of nonionogenic water-soluble monomers of the type of acrylamide or *N*-vinylpyrrolidinone and are determined mainly by the same factors.

Analysis of the results obtained in the study of the polymerisation of water-soluble monomers in solvent mixtures of different composition is very important in elucidating the causes of the influence of the nature of the solvent on the polymerisation of such monomers. In our view, the study of the reaction in mixtures of water with organic solvents is especially important. Such investigations have been carried out in greatest detail for acrylamide.

The addition of even small amounts of an organic solvent in the homogeneous polymerisation of acrylamide in water–DMSO mixtures diminishes k_p significantly. A similar effect is exerted by the addition of dioxane or THF.[27,28] The addition of small amounts of benzene to a DMSO–H_2O mixture, which do not alter the homogeneity of the process, is also accompanied by a decrease in the overall rate of the process and in the constant k_p (Table 3).

Fig. 1 presents the dependence of the constants k_p and k_t and also of the relative viscosity of the reaction mixture on the water content in the solvent in the polymerisation of acrylamide in water–DMSO mixtures. Evidently there is no relation of any kind

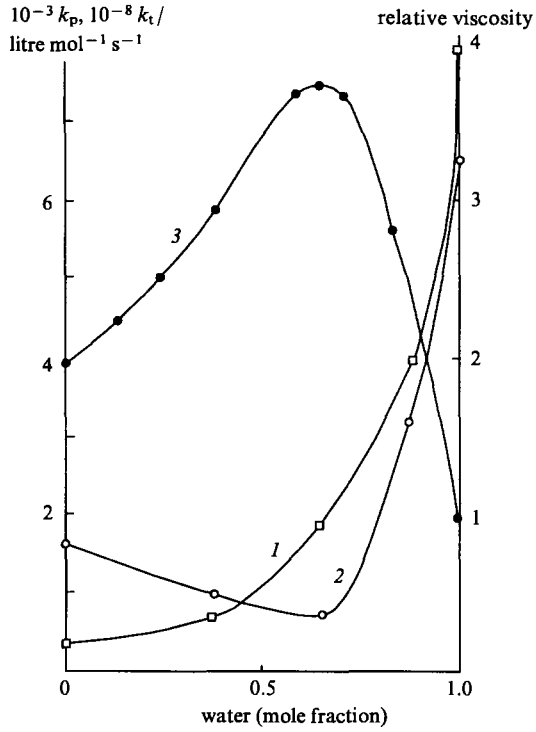

Figure 1. Dependence of k_p (curve *1*), k_t (curve *2*), and the viscosity of the initial reaction mixture (curve *3*) on the water content in the polymerisation of acrylamide in water–DMSO mixtures.[31] Monomer concentration 0.38 M.

between k_p and the viscosity of the reaction system: while k_p diminishes continuously on passing from water to DMSO, the viscosity of the reaction mixture passes through a maximum. The constant k_t also decreases with increase in the DMSO content in the solvent mixture, reaches a minimum for the water:DMSO = 65:35 molar ratio corresponding to the maximum viscosity of the reaction mixture, and then again increases somewhat. However, comparison of the data obtained in the polymerisation of acrylamide in individual and mixed solvents (Fig. 2) demonstrates the absence of a linear relation

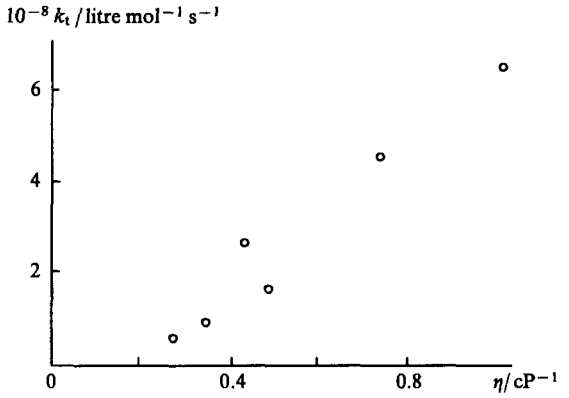

Figure 2. Dependence of k_t for the polymerisation of acrylamide in different solvents on the fluidity of the reaction mixture.[27]

between k_t and the fluidity of the initial polymerisation solution. Such a relation is characteristic of a diffusion-controlled chain termination reaction, for example, in the polymerisation of styrene and methyl methacrylate in various solvents.[1] The deviation from linearity shows that k_t for the polymerisation of acrylamide in the solvents investigated is not determined solely by diffusion. A similar relation has also been observed[29,30] in the polymerisation of vinyl benzoate and vinyl acetate in various solvents.

In the polymerisation of acrylamide in individual and mixed solvents, there is no definite relation between k_p and the relative permittivity of the solvent (ε). In particular, there is no linear correlation between the logarithm of k_p and the polarity parameter $(\varepsilon - 1)/(2\varepsilon + 1)$. This result shows that the solvent polarity is not in this case a factor which determines the reactivity of the reacting species.[31]

The addition of water to individual and mixed organic solvents (ethanol, ethanol–dioxane, DMSO) also increases significantly the overall rate of polymerisation of methacrylic acid and of the molecular masses of the polymers.[32] In this case too, the rate of reaction is almost independent of the relative permittivity of the reaction mixture and is determined by the amount of water present in it. The same pattern has been observed also in the polymerisation of diethylaminoethyl methacrylate and its salts. The addition of even 5 mol.% of water to methanol or dioxane is accompanied by an appreciable increase in the overall rate of polymerisation and also in the rate constant k_p both for the aminoester itself and for its acetate and chloride salts (Table 4).

Table 4. The influence of the nature of the solvent on the chain propagation and termination rate constants in the radical polymerisation of diethylaminoethyl methacrylate (DE) and its acetate (DE.HAc) and chloride (DE.HCl) salts.[26,33]

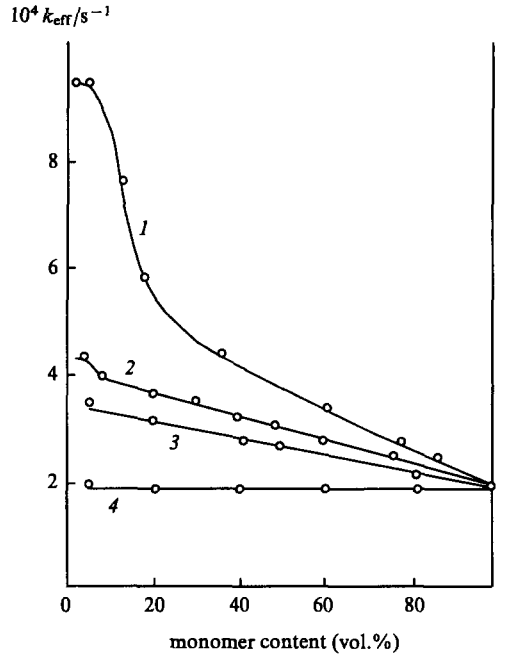

Figure 3. Dependence of k_{eff} on the *N*-vinylpyrrolidinone concentration in polymerisation in water (curve *1*), ethanol (curve *2*), 2-pyrrolidinone (curve *3*), and 2-methylpyrrolidinone (curve *4*) at 60 °C; concentration of azobisisobutyronitrile 1×10^{-3} M (data of Kirsh et al.[35]).

The influence of the composition of the reaction mixture on the effective overall rate of polymerisation constant $k_{eff} = V_o/[M]$, where V_o is the overall rate of polymerisation and [M] the monomer concentration, was established also in the polymerisation of *N*-vinylpyrrolidinone.[23,34,35] In the homogeneous polymerisation of this monomer in protic solvents such as water, ethanol, and 2-pyrrolidinone, the effective reaction rate constant decreases with decrease in the monomer concentration in solution. This effect is manifested to the greatest extent for aqueous solutions (Fig. 3). When the polymerisation is carried out in 2-methylpyrrolidinone, which is, as it were, a saturated analogue of the monomer, the constant k_{eff} remains unchanged over a wide range of monomer concentrations.

It is possible to distinguish three *N*-vinylpyrrolidinone concentration ranges depending on their influence on the rate of polymerisation in water: (1) the range from 100 to 30 vol.% of the monomer, where k_{eff} increases only slightly; (2) the range from 30 to 10 vol.% of *N*-vinylpyrrolidinone (in this range, a sharp rise in k_{eff} is observed with increase in the concentration of the monomer); (3) the range from 10 to 2 vol.% of the monomer, where the rate constant hardly changes.

Thus a sharp increase in k_{eff} in the polymerisation of *N*-vinylpyrrolidinone in aqueous solution is observed in the range of monomer mole fractions in the solution from 0.1 to 0.018, i.e. in the range where the number of water molecules per monomer molecule increases from 10 to ~60. For a higher water content in the reaction mixture, k_{eff} does not change. The ratio 60:1, established as a result of a kinetic study of the polymerisation, corresponds to the maximum number (55) of water molecules in the hydration shell of *N*-vinylpyrrolidinone in a dilute aqueous solution, i.e. to the maximum degree of solvation of the monomer by water molecules.[35] It is noteworthy that the maximum effective rate of polymerisation is observed in a medium with a minimal viscosity, which rules out the possible influence of the rate of the chain termination reaction on the overall rate of the process. The change in k_{eff} on passing from polymerisation in bulk to polymerisation in aqueous solution containing 10 vol. % of the monomer (~1 M) is wholly determined, as in the polymerisation of acrylamide, by the change in the constant k_p.

Thus k_p = 1200 litre mol^{-1} s^{-1} for the polymerisation of *N*-vinylpyrrolidinone in bulk,[22] while in the polymerisation in 10% aqueous solution $k_p = 2.2 \times 10^4$ litre mol^{-1} s^{-1}.[23]

The addition of small amounts of water to a solution of 1-vinyl-1,2,4-triazole in dimethylformamide or dimethylacetamide is accompanied by an appreciable increase in the molecular mass of the polymer obtained under the influence of radical initiators.[36]

Thus a distinctive feature of the polymerisation of water-soluble monomers is the marked dependence of the overall rate of polymerisation and also of the chain propagation rate constant and the molecular mass of the polymer on the nature of the solvent. The reaction proceeds at the highest rate and with formation of polymers having the maximum molecular mass in aqueous solution. The addition of even small amounts of an organic solvent to an aqueous solution of the monomer diminishes appreciably both the rate of polymerisation and the molecular mass of the polymers.

III. The role of solvation effects in the radical polymerisation of water-soluble monomers

The change in the kinetic parameters of the polymerisation of water-soluble monomers in various solvents may be influenced, as in the case of weakly polar monomers, by complex formation between the growing radicals and the solvent and also by the solvation of the monomers and radicals by the solvent. The role of the second factor is much more pronounced. This is associated with the fact that the water-soluble monomers, and especially amides and carboxylic acids, can exist in a self-associated form as a result of the formation of intermolecular hydrogen bonds even in dilute solutions,[37] the degree of association depending on the ability of the solvents to form hydrogen bonds. Cryoscopic studies have shown[27,28] that, at an acrylamide concentration of 1.0 M in water, acrylamide exists in the monomeric form, whereas in formamide and DMSO it is 15% or 30% dimerised respectively. The degree of dimerisation of acrylic acid in DMSO is ~10%, while fluoroacrylic acid exists exclusively in the monomeric form in both water and in solution in DMSO.[38] Different degrees of interaction with the solvent are also indicated by the heats of solution of acrylamide and acrylic acids in different solvents and by ^{1}H NMR spectroscopic data.[28] The difference between the degrees of self-association of the monomer molecules may be the cause of the observed difference between the activation energies for the chain propagation reaction and between the heats of polymerisation of water-soluble monomers.[38]

The formation of complexes between the polymeric radicals and solvent molecules can exert only an insignificant influence, as in the case of nonpolar vinyl monomers, on the kinetic parameters in the polymerisation of water-soluble monomers. Firstly, the energy of such interaction in not very great (thus it amounts to ~1 kcal mol^{-1} in the interaction of aromatic solvents with radicals). Secondly, the formation of a complex with an active centre is accompanied by the appearance of a compensation effect,[39] which should diminish the overall effect of the solvent on the overall rate of the process. Therefore, even when a complex is formed between the solvent and the unpaired electron of the radical via a hydrogen bond, the energy of which is higher than the energy of the donor–acceptor bond, the overall influence of the solvent should not be very great, particularly if one takes into account the fact that only a certain proportion of polymeric radicals are involved in the formation of the complex.

The solvation of the monomer by solvent molecules and especially the formation of hydrogen bonds between the monomer and the solvent can alter the electronic structure of the monomers and hence their reactivity. A distinctive feature of water-soluble monomers such as acrylamide, acrylic acids, and the salts of the aminoesters of methacrylic acid is conjugation between the C=C and C=O groups, which has been established experimentally for a series of water-soluble monomers by various spectroscopic methods.[26,40–43] Therefore the change in electron density at the carbon atom of the carbonyl group as a consequence of the formation of a hydrogen bond between the C=O group and the proton-donating solvents should naturally be accompanied by a change in electron density in the C=C double bond and hence by a change in the reactivity of the monomer.

According to IR spectroscopic data, the frequency $\nu_{C=O}$ in the spectra of the acetate salt of diethylaminoethyl methacrylate increases on passing from dioxane and acetonitrile to the dioxane–water mixed solvent and further to water, a linear relation being observed between the rates of polymerisation of this monomer and the frequency $\nu_{C=O}$ in the corresponding solvent.[26] A linear correlation between $k_p/k_t^{1/2}$ and $\nu_{C=O}$ for the monomer is observed in the polymerisation of certain other salts of the aminoesters of methacrylic acid, acrylamide, and *N*-vinylpyrrolidinone in various solvents.[26] The formation of a hydrogen bond between the monomer and the solvent diminishes the electron density on the protons and carbon nuclei of the CH_2 group of the monomer. This is indicated by the increase in the chemical shift of the proton and the carbon atom in the given group on passing from solutions of the monomers in an aprotic solvent (dioxane) to aqueous solutions. The decrease in electron density on the CH_2 group of the salt of the aminoester of methacrylic acid and hence the increase in the polarisation of the double bond of the monomer increases the rate of interaction between the monomer and the radical. As a consequence of the nucleophilic properties of alkyl radicals,[44] this leads to an increase in the rate of polymerisation on passing from a solution in dioxane to aqueous solutions, i.e. on formation of a hydrogen bond between the C=O group of the monomer and the solvent.

It is noteworthy that the formation of a hydrogen bond with the proton-donating solvent leads to some increase in the overall rate of polymerisation and in the constant k_p in the homogeneous polymerisation of a series of monomers which do not dissolve in water but contain the carbonyl group. Thus k_p for the polymerisation of methyl methacrylate in acetic acid is somewhat higher than in the polymerisation of the monomer in bulk.[45]

In the case of ionogenic monomers, a change in the nature of the solvent exerts a significant influence also on the degree of ionisation of the monomers and the polymeric radicals in the reaction system. The different degrees of ionisation as well as the presence of monomers in solution in the form of free ions or ion pairs lead in their turn to a change in the kinetic parameters of polymerisation of monomers such as methacrylic and acrylic acids or the salts of their aminoesters. The influence of ionisation on the polymerisation of ionogenic monomers has been examined in detail by Kabanov and Topchiev[18] and Bune et al.[19]

Valuable information for the determination of the mechanism of the polymerisation of water-soluble monomers in water–organic solvent mixtures of different composition has been obtained by comparing kinetic and spectroscopic data. A detailed study of the influence of the composition of the water–DMSO mixed solvent on the NMR spectra of acrylamide has been carried out[46] and it has been established that an increase in the concentration of water in the solvent mixture leads to an appreciable downfield displacement of the ^{13}C chemical shift of the C=O group of acrylamide ($\delta_{C=O}$). The comparatively slight alteration of the chemical shifts of the protons of the NH_2 group observed under these conditions shows that the strength of the intermolecular hydrogen bond between the NH_2 group of acrylamide and the solvent does not change very greatly on passing from DMSO to water and cannot be the cause of such a significant alteration of $\delta_{C=O}$. The change in $\delta_{C=O}$ is apparently caused mainly by the formation of a hydrogen bond between the carbonyl group of acrylamide and water molecules. An increase in the concentration of water in the acrylamide–DMSO system is not only accompanied by a change in $\delta_{C=O}$

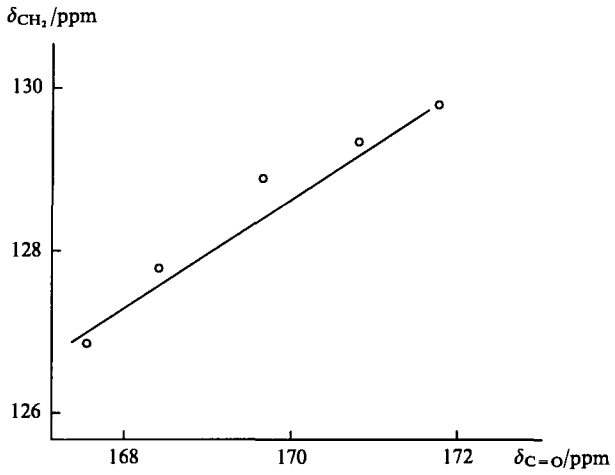

Figure 4. Relation between the ^{13}C chemical shifts of the CH_2 and C=O groups of acrylamide.[46] The measurements were performed in water–DMSO mixtures of different composition.

but also leads to an alteration of the chemical shifts of the hydrogen and carbon atoms involved in the double bond of acrylamide. There is a linear relation between the chemical shifts δ_{CH_2} and $\delta_{C=O}$ (Fig. 4), showing that the change in the electronic state of the C=O group as a consequence of the formation of a hydrogen bond between the groups and water alters the electronic state of the C=C group.

Indeed the formation of the C=O...H hydrogen bond between acrylamide and water is responsible for the enhancement of the electron-accepting properties of the amide group, the conjugation of which with the C=C double bond diminishes the electron density on the carbon atom of the CH_2 group. This conclusion follows from the correlation established[47–49] between the chemical shifts of the carbon atoms of the double bond and the elecron density in this bond. The change in the electron density in the C=C bond of the monomer should naturally alter its reactivity.

Assuming that both free acrylamide molecules and such molecules bound in a complex are present in the water–DMSO mixture and are characterised by different chain propagation rate constants, it was shown[46] that the effective chain propagation rate constant k_p^{eff} in the polymerisation of acrylamide in the water–DMSO mixture should vary linearly with $\delta_{C=O}$ or δ_{CH_2}. However, as can be seen from Fig. 5, this relation has a sharp break in the region of high concentrations of water in the mixed solvent. This type of curve indicates the existence of additional factors determining the reactivity of acrylamide in its polymerisation in the presence of water. The dependence of k_{eff} in the polymerisation of *N*-vinylpyrrolidinone in an aqueous solution on the ^{13}C chemical shift of the CH_2 group of this monomer is similar.

The relative contribution of the change in the electronic structure of the monomer as a consequence of its solvation by the solvent to the alteration of the reactivity of vinyl monomers and their radicals in radical polymerisation can be estimated approximately from the data of Sutyagin et al.[50] According to these data, a linear correlation is observed between the activation energy for chain propagation E_p in the polymerisation of vinyl monomers and the chemical shift of the β-carbon atom of the monomer in the ^{13}C NMR spectrum. The change in δ_{C_β} by ~25 ppm (transition from styrene to acrylonitrile) is accompanied by a change in E_p by 2.4 kcal mol^{-1} (Table 5). The maximum change in δ_{C_β} for acrylamide when the water content in the mixture with DMSO varies from 0% to 100% is 4.4 ppm.[46] Therefore, if account is taken only of the difference between the conditions in the solvation of acrylamide in water and DMSO, one may expect that E_p for the polymerisation of acrylamide in water should be lower by ~0.5 kcal mol^{-1} than in DMSO. On the other hand, the real difference between the values of E_p in these systems is more than 3 kcal mol^{-1}.[51] A similar situation is observed in the polymerisation of acrylic acid (the experimental change in E_p on passing from water to DMSO is ~5 kcal mol^{-1} [51]) and *N*-vinylpyrrolidinone in different solvents.[34,35]

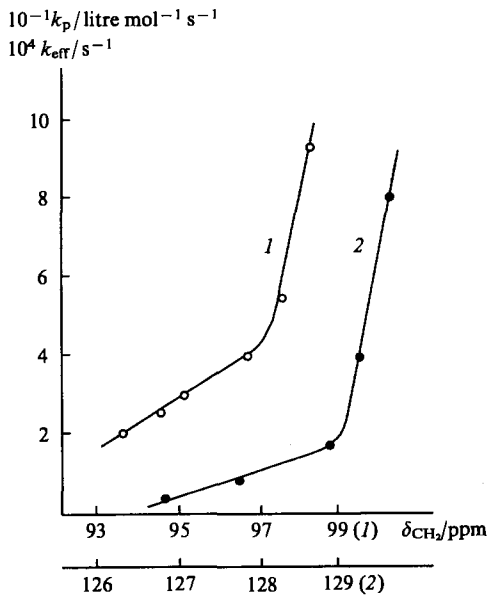

Figure 5. Dependence of k_p for the polymerisation of acrylamide (curve *1*) and k_{eff} for the polymerisation of *N*-vinylpyrrolidinone (curve *2*) on the ^{13}C chemical shift of the CH_2 group of the monomer.[55,56] Acrylamide was polymerised in water–DMSO mixtures of different composition; *N*-vinylpyrrolidinone was polymerised in aqueous solution at different monomer concentrations.

Table 5. Chemical shifts of the C_β atoms in the ^{13}C NMR spectra of vinyl monomers and certain parameters characterising their reactivity in radical polymerisation.[50]

Monomer	δ_{C_β}/ppm	Relative localisation energy of		E_p/kcal mol^{-1}

Thus the solvation of the monomer and the resulting change in its reactivity have a much greater influence on the overall rate of polymerisation and k_p than the formation of donor–acceptor complexes between the polymeric radical and the solvent. Nevertheless, this factor cannot fully explain the observed influence of the solvent on the radical polymerisation of water-soluble monomers.

IV. The influence of the solvent on the conformational characteristics of water-soluble polymers

The data presented above show that the hypotheses postulating different solvation conditions in water and organic solvents as well as the formation of complexes between polymeric radicals and the solvent cannot fully explain the results obtained in polymerisation in the presence of small amounts of added organic solvent. Indeed, it is difficult to postulate that such small amounts of the additive (up to 10 mol. %) can lower significantly the degree of dimerisation of acrylamide in solution. Nevertheless, as can be seen from Table 3, they appreciably diminish k_p. One can postulate that the change in the rate of chain propagation in such systems is partly caused by the change in the conformation of the polymer chains. This hypothesis is based on a comparison of the size of the polymer coil with the constant k_p for the polymerisation of acrylamide in various solvents.[52] It is seen from the data presented in Table 6 that the intrinsic viscosity of the same polymer and hence the size of the polymer coil in solution diminishes on passing from water to its mixtures with DMSO, dioxane, and THF containing 10 mol. % of the organic solvent.

It was found that the nature of the change in the size of the polymer coil as a function of the solvent is the same as for k_p (Fig. 6). An increase in temperature from 25 to 50 °C hardly affects the intrinsic viscosity of the polymer in aqueous solution (Table 6). On the other hand, in mixtures of water with organic solvents the viscosity $[\eta]$ increases somewhat as the temperature is raised. Consequently the size of the polymer coil formed in mixed solvents increases with increase in temperature relative to the size of the macromolecular coil formed on polymerisation in aqueous solution. Such a change in the morphology of the polymer coil as the temperature is altered may be one of the factors responsible for the marked temperature dependence of the overall rate of reaction and of the rate of chain propagation in mixtures of water with an organic solvent compared with the polymerisation of acrylamide in aqueous solution (Table 3).

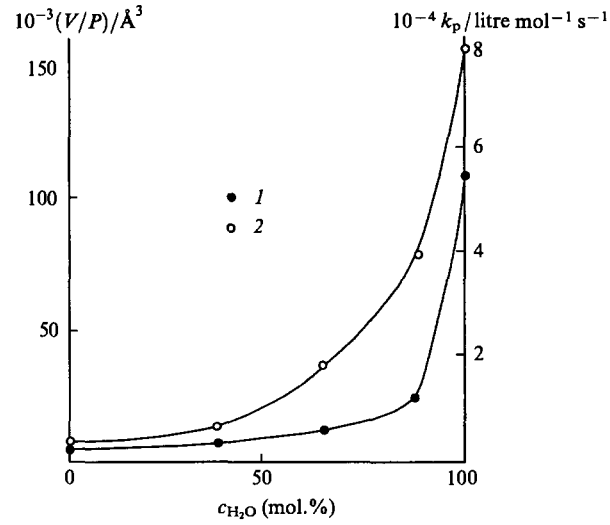

Figure 6. Dependence of the relative size of the polymer coil (curve *1*) and of the constant k_p (curve *2*) on the water content in the polymerisation of acrylamide in water–DMSO mixtures.[56] V = volume of polymer coil; P = degree of polymerisation.

An increase in the size of the polymer coil on passing from an organic solvent to water has also been observed for polymers of the tertiary salts of the aminoesters of methacrylic acid.[26,53] It is striking that in this case there is a sharp decrease in the size of the coil following the addition to water of even small amounts of an organic solvent. Thus the intrinsic viscosity of the solution of the acetate salt of poly(diethylaminoethyl methacrylate) (and hence also the volume of the polymer coil) diminishes from 1.3 in aqueous solution to 1.1 in the water–dioxane mixture containing 20 mol. % of dioxane and to 1.05 in dioxane.[33]

Calculations have shown that the density of the polyacrylamide coil synthesised in an organic solvent or in an aqueous organic medium exceeds by a factor of 30–40 the density of the polymer coil formed in aqueous solution.[27] A similar result has been obtained in a study[54] where it was shown that the addition of even small amounts of precipitants such as acetone or methanol to dilute aqueous solutions of high-molecular-mass polyacrylamide [$M_W = (2 - 3) \times 10^7$] diminishes the volume of the polymer coil by a factor greater than 100. The change in the density of the polyacrylamide coil on impairment of the quality of the solvent (the same picture has been observed also for other water-soluble polymers, in particular the polymers of the salts of dimethylaminoethyl methacrylate) indicates a possible conformational transition of the coil–globule type and may lead to the appearance of steric hindrance in the interaction between macroradicals and monomers.

The change in the conformation of polymer coils depends on the rigidity of the polymer chain. The introduction of a fluorine atom into the acrylic acid molecule increases the rigidity of polyfluoroacrylic acid compared with polyacrylic acid. Therefore the influence of the nature of the solvent on the conformational characteristics of the polymer and the kinetic parameters of the polymerisation of fluoroacrylic acid is much more pronounced than in the case of acrylic acid.

It is noteworthy that some influence by the conformational characteristics of the polymers on the constant k_p and k_t has been observed also in the polymerisation of butyl acrylate in different solvents.[14]

Thus the change in the overall rate of polymerisation of water-soluble monomers and of the rates of the elementary polymer chain propagation and termination reactions on passing from aqueous solutions to solutions in aqueous organic mixtures and organic solvents is caused both by a complex formation reaction of the solvent with the monomer molecules and growing

radicals as well as a number of physical factors, including the solvation of the monomeric and polymeric molecules, the change in the conformational characteristics of the macromolecules, etc. Ultimately all these factors lead to a change in the effective rates of chain propagation and termination.

V. Ideas concerning the mechanism of the influence of the solvent on the radical polymerisation of water-soluble monomers

Analysis of the kinetics of the polymerisation of acrylamide in water–DMSO mixtures, NMR spectroscopic data characterising the state of the monomer in these mixtures, as well as data on the conformational state of the polymer in solution permits a more accurate estimation of the role of various factors in the polymerisation of water-soluble monomers in different solvents.

It follows from the results in a number of investigations [27, 55, 56] that, on the one hand, a sharp increase in the overall rate of polymerisation of acrylamide, in the constant k_p, and in the volume of the polymer coil was observed after the addition of a large amount of water to DMSO (the water content in the solvent mixture was ~80–85 mol. %). On the other hand, the chemical shift δ_{CH_2} increased almost linearly with increase in the amount of water in the water–DMSO mixture up to 100%. In order to elucidate the causes of such discrepancy, the solvation of a number of water-soluble monomers and polymers in water, organic solvents, and water–organic solvent mixtures was investigated by NMR spectroscopy. [43, 56] It follows from the data presented in Tables 7 and 8 that the signals due to the carbon atoms of the C=O and CH_2 groups of the monomers are displaced downfield on passing from solutions in organic solvents to water–organic solvent mixtures and aqueous solutions, which is due to the formation of a hydrogen bond between the C=O group and water. Qualitatively the same picture has been observed also for $\delta_{C=O}$ for the polymers. However, whereas for acrylamide and *N*-vinylpyrrolidinone the change in $\delta_{C=O}$ is 4.4 and 5.0 ppm respectively on passing from a solution of the monomers in DMSO, which does not form a hydrogen bond with the carbonyl group, to an aqueous solution, for the polymers the replacement of DMSO by water is accompanied by a change in $\delta_{C=O}$ by only 2.3 and 3.6 ppm respectively. In the case of acrylic and polyacrylic acids, $\delta_{C=O}$ changes to almost the same extent on passing from DMSO to water (2.9 and 3.1 ppm respectively).

Analysis of the NMR spectroscopic data for a large number of low-molecular-mass compounds of the type RCOX (where X = OR', OH, NH_2) in solvents of different nature made it possible to establish [43, 57] that, regardless of the nature of the substituent R, the formation of a hydrogen bond between the carbonyl group and the solvent leads to a downfield displacement of the chemical shift $\delta_{C=O}$, which is rigorously defined for each type of compound. For different carboxylic acids, as well as their esters and amides, such displacements are 4.0, 4.0, and 5.0 ppm respectively. The results presented in Tables 7 and 8 show that the carbonyl groups of acrylamide, *N*-vinylpyrrolidinone, and dimethylaminoethyl methacrylate are almost fully linked by hydrogen bonds to water molecules, but in the case of the corresponding polymers only some of the carbonyl groups are involved in the formation of bonds of this kind.

A similar conclusion was reached for acrylic acid and its polymer. It is noteworthy that in this case analysis of the NMR spectroscopic data took into account the influence of the degree of ionisation of the ionogenic monomers and polymers on $\delta_{C=O}$. [43, 58] An estimate showed that, regardless of the nature of the polymer, ~70% of the carbonyl groups of the water-soluble polymers are involved in the formation of hydrogen bonds with water molecules in the aqueous solution. This difference between the numbers of carbonyl groups participating in the formation of hydrogen bonds with water molecules is due to the fact that the interactions of the monomer and polymer molecules with water are determined not only by the ability to form hydrogen bonds but also by the accessibility of the carbonyl groups for such interaction. Water-soluble monomers form a homogeneous solution in water, which is the reason for the ready accessibility of water for interaction with all the carbonyl groups of the monomer.

Another situation probably arises in the case of polymer solutions, where hydrophobic interactions begin to play a significant role. The unique properties of water-soluble polymers (in particular, polyacrylamide), which permit the use of these polymers as agents modifying the viscous and rheological properties of aqueous solutions, are apparently actually determined by the hydrophobic interactions, which lead to the formation of organised hydrophobic microdomains in the system. [59–63]

Table 7. The ^{13}C chemical shifts ($\delta_{C=O}$) of the monomers and polymers in different solvents and the increments in the influence of the hydrogen bond (Δ_{hb}). [43, 57]

Compound	Solvent	$\delta_{C=O}$	Δ_{hb}
MMA	dioxane	167.5	
	water	171.5	4.0
PMMA	dioxane	178.0	
DM	–	166.6	
	water	170.3	3.7

Water-soluble polymers containing a long main hydrocarbon chain and short hydrophilic side groups of the type of COX (where X = OH, NH_2, etc.) may be regarded to some extent as compounds exhibiting surface activity. In view of this, in aqueous solution they should tend to form microaggregates of the type of micelles containing the hydrophobic hydrocarbon chain of the polymer in their interior, while the hydrophilic groups are located on the outside as far as possible. The entry of water into the interior regions of these microaggregates is difficult because of their hydrophobic properties, so that only the carbonyl groups located in the aqueous phase participate in the formation of hydrogen bonds with water molecules. The appearance of aggregates of this kind in aqueous solutions has been established experimentally in the study of the fluorescence spectra of acrylamide polymers containing very small amounts of added (<0.5 mol. %) hydrophobically modified units, in particular acrylamide units with long alkyl substituents (C_8 and longer) or other hydrophobic substituents at the nitrogen atom of the amide group.[64-69]

The formation of micelle-like clusters has also been observed in aqueous solutions of hydrophobically modified poly(ethylene oxide).[70] The hydrophobic microaggregates are present in solution even at very low polymer concentrations. An attempt has been made[66] to determine experimentally the concentration of the polymers below which they do not aggregate but form monomolecular polymer solutions. Although the exact values of this 'critical concentration for aggregation' have not been determined for different hydrophobically modified acrylamide polymers, it has been established that hydrophobic microdomains exist in these systems at a very high dilution of the polymer solutions. Thus, in the case of the hydrophobically modified polyisopropylacrylamide, the presence of hydrophobic microdomains in aqueous solution has been observed at a polymer concentration of 10^{-3}%. The formation of interchain associated species of this kind depends on the extent to which the polymers are hydrophobic. Presumably in the case of unmodified water-soluble polymers the same situation occurs, while in aqueous solutions of these polymers different microaggregates of the type of micelles arise (albeit to a lesser extent). For example, the fact that only four polymer chains are sufficient for the formation of interchain associated species may serve as a basis for such a hypothesis.[71] Associated species of this kind can catalyse the reactions occurring within them and in particular the chain propagation reaction, i.e. a kind of micellar catalysis, capable of increasing the rates of various processes to a consider-able extent, may be observed.[72]

The associated species formed as a result of hydrophobic interactions solubilise the molecules of organic compounds, in particular those of the monomer, which may alter its local concentration in the vicinity of active centres — the growing polymeric radicals within the associated species. The preferential sorption of organic compounds by polymer chains is indicated by the results obtained in a study of the dissolution of polyisopropylacrylamide in water–methanol mixtures.[73] The favourable spatial disposition of the groups participating in the chain propagation reaction within their associated species evidently decreases the activation energy for this reaction in polymerisation in water. At the same time, association as a result of hydrophobic interactions should diminish the entropy of the system. Indeed the pre-exponential factor in the Arrhenius equation for the chain propagation reaction in the polymerisation of acrylamide and acrylic acid in aqueous solution is smaller than in other solvents investigated (Table 3).

The addition of even small amounts of an organic solvent to water should apparently lead to a decrease and then to a complete disappearance of the hydrophobic effect and hence to a decrease in the rate of chain propagation and in the overall rate of polymerisation. Precisely such a situation is observed in the polymerisation of acrylamide in mixtures of water with DMSO, dioxane, and THF, in the polymerisation of *N*-vinylpyrrolidinone in water at different monomer concentrations, and also in the polymerisation of salts of diethylaminothiomethacrylate [diethylaminoethyl methacrylate?] in mixtures of water with methanol or other organic solvents.

The ideas described above concerning the hydrophobic interaction in aqueous solutions of polymers combined with kinetic data, as well as the results of spectroscopic and viscometric studies, made it possible to put forward the following mechanism for the influence of the nature of the solvent on the radical polymerisation of water-soluble monomers.[52,56]

In the polymerisation of water-soluble monomers in various organic solvents and also in water–organic solvent mixtures containing up to ~70%–80% of water, the change in the overall rate of polymerisation and its k_p is caused mainly by the change in the reactivity of the monomer as a consequence of the alteration of the electron density in the C=C bond on formation of a hydrogen bond between the carbonyl group of the monomer and the solvent. This is confirmed by the linear dependence of the rate of polymerisation on δ_{CH_2} for many of the systems investigated.

The influence of the solvent on the kinetic parameters of the polymerisation of water-soluble monomers in such systems does not differ quantitatively from that in the polymerisation of acrylic acid esters, which, for example k_p, may vary by a factor of 3–4 depending on the nature of the solvent.[13-15,29,30] Approximately the same change in the rate of the process has been observed in the polymerisation of acrylamide in water–DMSO mixtures, where the water content increases to 60–70 mol. %[52,56] and also in the polymerisation of *N*-vinylpyrrolidinone, where the concentration of water in the reaction mixture does not exceed 70 mol. %.[34,35] A further increase in the amount of water in the reaction mixture leads, not withstanding the linear relation between the water content and δ_{CH_2}, to a sharp increase in the rate of polymerisation and in k_p, which is due to the hydrophobic interactions. The increase in the rate of copolymerisation of the hydrophobically modified salts of dimethylaminoethyl methacrylate with methyl methacrylate or styrene on passing from dimethylformamide to an aqueous solution has been explained[74] by the influence of the hydrophobic interaction in the aqueous systems.

Even at high water concentrations in the organic solvent–water mixture the organic solvent enters preferentially the microaggregates and the composition of the solvent within these microaggregates, i.e. in the vicinity of the active centres, remains almost constant. Therefore the solvation of the polymer, even at a relatively high concentration of water in the reaction mixture, and also the constant k_t (adjusted to the same viscosity of the reaction mixture) should remain unchanged. Indeed $\delta_{C=O}$ for polyacrylamide, characterising the formation of hydrogen bonds between the carbonyl group and water, as well as the constant k_t remain virtually unchanged when the water content in the mixture with DMSO is altered from 0 to 50 mol. % (Fig. 7). For a higher content of water in the mixture, the latter begins to penetrate into the polymer coil; the composition of the solvent in the coil, where the chain termination reaction takes place, begins to change, which is the reason for the experimentally observed change in the quantities $\delta_{C=O}$ and k_t.[55,56]

The characteristic features of the copolymerisation of water-soluble monomers which have been established comparatively recently are apparently also determined by the hydrophobic interactions in aqueous solutions of polymers. The study of the copolymerisation of acrylamide with water-soluble anionic and cationic monomers (ethylenesulfonic acid and the sulfate salts of dimethylaminoethyl methacrylate) in water established that the composition of the copolymers formed remains almost constant as the conversion increases up to a 70%–80% yield of the polymer.[75,76] Such behaviour can be explained by assuming that the compositions of the copolymerising monomer mixture within the active polymerisation zone (in the polymer coil) and outside it are different and that a constant ratio of the concentrations of the comonomers is maintained in the active zone.

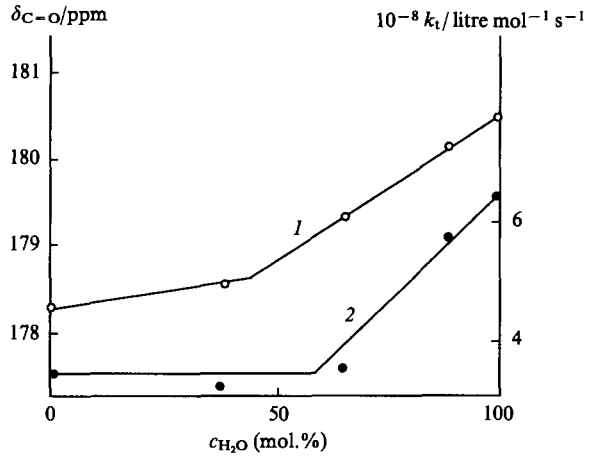

Figure 7. Dependence of the ^{13}C chemical shift of the C=O group of polyacrylamide (curve *1*) and of the constant k_t (curve *2*), adjusted to the same viscosity of the reaction system, on the water content in the polymerisation of acrylamide in a water–DMSO mixture.[55]

Such behaviour is probably a specific feature of the copolymerisation of water-soluble monomers in aqueous solutions and is associated with the formation of different interchain associated species resembling micelles, which solubilise preferentially the hydrophobic groups. A difference between the average composition of the initial monomer mixture and its composition in the active zone has been demonstrated in the emulsion copolymerisation of styrene and methyl methacrylate with long-chain alkyl salts of dimethylaminoethyl methacrylate,[74] which confirms the important role of the micellar structures in water in determining the distribution of the monomers in the reaction system.

Depending on the nature of the ionogenic comonomers, their copolymers with acrylamide are enriched either in the acrylamide units or in the units of the second comonomer. In the acrylamide–sulfate salt of dimethylaminoethyl methacrylate system, the copolymer is enriched in the cationic comonomer units, while in the copolymerisation of acrylamide with sodium ethylenesulfonate the enrichment of the copolymer in acrylamide units is observed. The rate of copolymerisation diminishes with increase in the content of the ionogenic comonomer in the initial monomer mixture regardless of the nature of the ionogenic monomer. This difference can be accounted for as follows. In the copolymerisation in an aqueous solution of monomers having different hydrophobic properties, a particular type of hydrophobic associated species is formed, depending on the composition of the copolymer, and determines the incorporation into the latter of definite amounts of the comonomers. Evidently the more hydrophobic (compared with acrylamide) cationic comonomer (the sulfate salt of dimethylaminoethyl methacrylate) enters the hydrophobic associated species more readily than acrylamide. Its local concentration in the vicinity of the active centre is therefore higher than in the initial monomer mixture. With increase in the amount of the polymer in solution, the role of the hydrophobic associated species should increase, which in fact probably leads to the observed constancy of the composition of the copolymer as the conversion is varied.

A somewhat different situation occurs in the acrylamide–sodium ethylenesulfonate system.[76] Since the hydrophilic properties of these comonomers are similar, one can postulate that, in contrast to the first system with a cationic comonomer, in this case the composition of the monomer mixture in the polymer coil differs little from the average composition of the mixture. Here one should bear in mind that sodium ethylenesulfonate was fully ionised under the copolymerisation conditions in the above study[76] and was present in the form of free ions solvated by water molecules. This factor probably hinders the incorporation of charged ethylenesulfonate anions in the hydrophobic associated species, so that the monomer mixture in these species is enriched in acrylamide compared with the average composition of the initial monomer mixture.

The independence of the composition of the copolymer of the conversion has also been established in the emulsion copolymerisation of the hydrophobically modified salt of an aminoester of methacrylic acid with styrene or methyl methacrylate. The idea that the compositions of the monomer mixture within and outside the active zone are different as a consequence of the sorption of the more hydrophobic comonomers by the polymer coil was also invoked to account for this finding.[74]

VI. Conclusion

The results presented above demonstrate convincingly that the nature of the solvent is an important factor determining the course of the radical polymerisation of water-soluble monomers. The influence of the solvent is significantly greater in the case of water-soluble monomers than in the case of the radical polymerisation of weakly polar monomers such as, for example, styrene. An especially large change in the overall rate of the reaction and in the constant k_p is observed on passing from polymerisation in organic solvents to polymerisation in an aqueous solution.

The influence of the nature of the solvent may be attributed to a number of causes, among which the following should be noted primariliy:

(1) The formation of donor–acceptor complexes between the polymeric radicals and the solvent molecules, which decreases the reactivity of the radicals.

(2) The solvation of the monomer molecules and the polymeric radicals or the specific interaction of these species with solvent molecules, in particular via the formation of hydrogen bonds, which alter the electron density in the C=C bond of the monomer or the unpaired electron density in the radical and hence alter the reactivity of the reacting species.

(3) The changes in the conformational characteristics of the polymer molecules in solvents possessing different solvent powers in relation to the polymer.

However, in our view, a distinctive feature of the polymerisation of water-soluble monomers is the hydrophobic interaction arising in aqueous solutions of the polymers. It leads to a sharp difference between the kinetic parameters of the polymerisation of monomers of this class in water and in solutions in organic solvents. The hydrophobic interaction is also responsible for the appreciable decrease in the rate of polymerisation and in the constant k_p following the addition of even small amounts of an organic solvent to water as a consequence of the preferential sorption of the organic solvent by the polymer coil.

Naturally, the formation of interchain associated species as a result of the hydrophobic interactions and hence their "catalytic" effect must depend on the hydrophobic properties of the monomers employed.

A fairly large number of studies devoted to the rheological properties of aqueous solutions of hydrophobically modified polymers have been published recently. However, there are virtually no data on the kinetics of the polymerisation of water-soluble monomers containing hydrophobic groups. At the same time, we believe that, in order to confirm the influence of the hydrophobic effect on the radical polymerisation of water-soluble monomers, it is necessary to expand the range of systems investigated, especially water-soluble monomers containing hydrophobic groups. The study of the polymerisation of monomers of this kind in water, organic solvents, and water–organic solvent mixtures of different composition will yield additional information about the role of hydrophobic interactions in radical polymerisation in aqueous solutions.

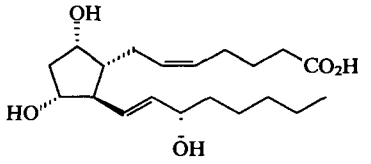
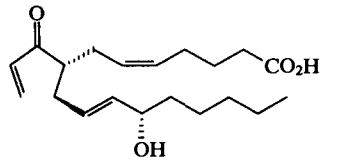
III. Chemical syntheses of marine prostanoids	523
IV. Analogues of marine prostanoids	528
V. Biological properties of marine prostanoids	529



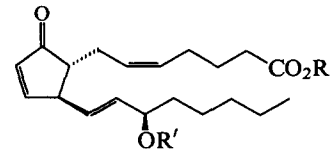
Abstract. The review describes the stages involving the isolation and the determination of the structures of marine prostanoids and their analogues, the problems of their biosynthesis, and their biological properties. The bibliography includes 76 references.

I. Introduction



Prostaglandins (PG) were first discovered in the human seminal fluid by Kurzrok and Lieb[1] in 1930, but it was not until the beginning of the 1960s that Bergstrom and his coworkers[2–4] were able to isolate and identify a series of the main representatives of compounds of this class on the basis of the researches by Euler, who was Bergstrom's teacher. The structural formulae of the commonest series 2 prostaglandins are presented below.

PGE_2



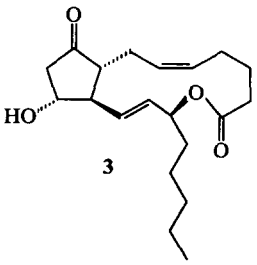
$PGF_{2\alpha}$

PGA_2

We may note that the content of total prostaglandins (more than ten prostaglandins of different types) in a rich source such as the plasma of human seminal fluid is only 300 μg ml^{-1}.[5] After the development of effective methods for the detection, isolation, and the determination of their structure, prostaglandins of different types and series as well as their derivatives were found at extremely low concentrations in virtually all mammalian organs and tissues and then in insects, plants, etc. (see the relevant reviews [6–10]).

Marine organisms, which are promising in this respect, did not prove an exception either. A major achievement of the period was the communication by Weinheimer and Sparings concerning the isolation of (15*R*)-PGA_2 (derivatives **1** and **2**) in 0.2% and 1.3% yields respectively from the coral *Plexaura homomalla*, which is common in the Caribbean Sea.[11] As can be seen from their structures, compounds **1** and **2** are the epimers of PGA_2 with respect to the allylic–alcoholic centre [C(15)] and they therefore lack the powerful hypotensive effects characteristic of PGA_2. Other workers[12] also isolated from corals of this species (15*R*)-PGE_2 and its ethyl ether in 0.1% – 0.2% yields. On the other hand, certain colonies of *Plexaura homomalla* contained only (15*S*)-prostaglandins identical to those isolated from mammals, while others contained approximately equal amounts of (15*R*)- and (15*S*)-PG.[13] Reasonable explanations of the lack of selectivity in the production of (15*R*)- and (15*S*)-PG by the coral were not proposed. Analysis of the lipids from both (15*R*)- and (15*S*)-prostaglandin-containing variants of *Plexaura homomalla* showed that 97% of the $C_{20:4}$ acid component comprises arachidonic acid. Therefore the formation of the (15*R*)-prostaglandins in some colonies of *Plexaura homomalla* and of (15*S*)-prostaglandins in other taxonomically identical colonies cannot be accounted for by the stereochemical differences between the initial $C_{20:4}$ acids.[14]

1, R = R′ = H
2, R = Me, R′ = Ac



Schneider and coworkers[15,16] found 0.06% of PGE_2, traces of $PGF_{2\alpha}$, 13,14-dihydro-PGA_2, 5-*trans*-PGA_2, and other substances in Caribbean corals. Only insignificant amounts of (15*S*)-PG were discovered in specimens of *Plexaura homomalla* collected in the sea around Florida.[12] It was found that PGE_2 and $PGF_{2\alpha}$ are the most frequently encountered prostanoids in the marine organisms—coral, molluscs, seaweed, etc. Thus prostaglandin $F_{2\alpha}$, the 11-acetate of the methyl ester of $PGF_{2\alpha}$, and its 18-acetoxy-derivative were isolated from the soft

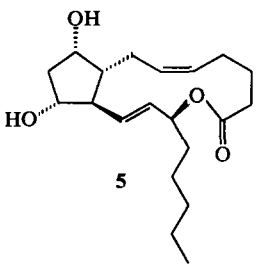
coral *Lobophyton depressum*[17] and from the tissues of the molluscs *Tethys timbria* and *Aglisia californica*.[10] The content of PGE_2 in the Australian red seaweed *Gracularia lichenoides* is 0.05%–0.07% of the dry mass.[18] $PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$ were isolated together with PGE_2 from the aqueous extracts of the sea sponge *Teprios zeteki*.[19]



The 1,15-lactones of prostaglandins E_2, A_2, and $F_{2\alpha}$ (compounds **3**–**5**) and a series of their acyl derivatives, isolated from the tissues of the mollusc *Tethys timbria*, are of interest.[20] An unusual lactone **6**, related to prostanoids and called hybridalactone, was isolated from the red seaweed *Laurencia hybrida*. A mechanism of its biosynthesis from eicosapentaenoic acid has been postulated.[21] The structure of hybridalactone was confirmed by spectroscopic data and unambiguous synthesis.[22]

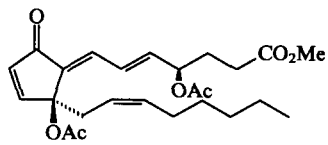
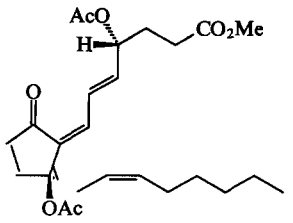
6

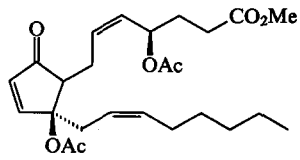


In order to identify the prostaglandins in the extracts from marine organisms, use was made of methods for their biological testing and their comparison with authentic specimens, immunochromatography and radioimmunology, thin-layer chromatography combined with biological testing for prostaglandin-like activity, etc.[10]

On the whole, it appears important that the above prostaglandins were detected and isolated in relatively large amounts from primitive nonmammalian sources (in contrast to mammals, in the tissues of which the content of prostaglandin does not exceed 1–2 ng g^{-1}, marine organisms are able to accumulate prostaglandins). The (15*R*)- and (15*S*)-PGA_2 substances produced by coral can be readily transformed chemically into prostaglandins of types E and F, which were used in its turn for the industrial manufacture of prostaglandins.[23] Several hypotheses concerning the biological functions of coral prostaglandins, including regulation of the ion and water transport in the coral as well as its protection against predators and parasites, have been put forward.

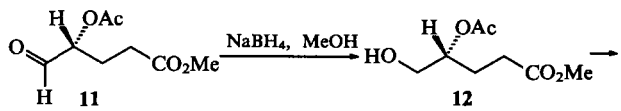


A group of Japanese scientists[24,25] published almost simultaneously in 1982 the results of studies devoted to the isolation from marine organisms and the determination of the structures of new prostanoids, which attracted attention because of their unusual structure and their antitumour activity. The prostanoids of this type detected in the corals of the Stolonifer *Clavularia virides* species were called clavulones by Yamada and coworkers.[24] Numerals ranging from I to IV were assigned, in order of decreasing polarity, to the related compounds **7**–**10** differing by the configuration of the double bonds at the C(5) and C(7) atoms. The names claviridenones D, C, B, and A, proposed for these structures by Kitagawa and coworkers[25] have not been widely used. Anticipating, we may note that clavulones and a series of similar structures — halovulones and punaglandins have been combined under the term marine prostanoids† in view of the unusual nature and uniqueness of their structures and this term also indicates the sources where they have been found and from which they have been isolated.

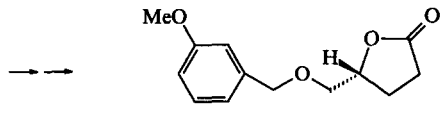


7, clavulone I

8, clavulone II



9, clavulone III

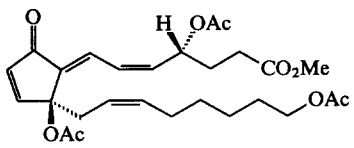


10, clavulone IV

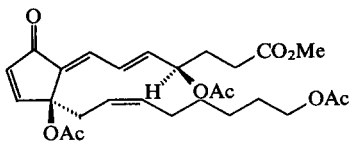
The structure of the clavulones was established by thorough investigation of IR, UV, and ^1H and ^{13}C NMR spectroscopic data for these compounds, as well as of their chemical reactions. Additional evidence that compounds **7**–**10** are geometrical isomers was provided by the formation of the 1 : 6 : 12 : 2 mixture of all four compounds on UV irradiation of a benzene solution of any of these substances.[25] A similar result was achieved when one of the isomers was treated with a solution of oxalic acid in methanol (20 °C, 20 days).[26]

The absolute (*R*)-configuration of the C(4) chiral centre of clavulones was established by converting the aldehyde **11**, obtained by the ozonolytic cleavage of clavulone I, into the alcohol **12** and then into the lactone **13**, the enantiomer of which was obtained from the acetonide of D-glyceraldehyde.[26]

11 **12**

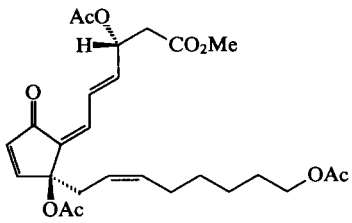


13



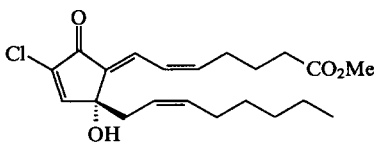
The study of ^1H NMR and circular dichroism spectra of the 9-(*p*-bromobenzoate) of clavulone I and its 12-deacetoxy-derivative established the (*S*)-configuration of the C(12) chiral centre.[26,27]

Subsequently three new C_{20}-acetoxyprostanoids **14**–**16** were isolated from the coral *Clavularia virides*.[28,29] Previously the C_{20}-hydroxyprostanoids were known as unstable prostaglandin metabolites detectable by gas–liquid chromatography or mass-spectrometrically. With the exception of the additional signal due to the CH_2OAc fragment, the spectroscopic characteristics of compounds **14**–**16** are identical with those of clavulones I–III, the absolute configuration of the chiral centres also remaining unchanged.

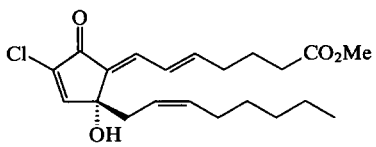


† As a consequence of a lack of appreciable structural differences from the classical prostaglandins isolated from mammals, it would be incorrect to combine the (15*R*)-PGA_2 and other prostaglandins (metabolites of C_{20} eicosapolyenoic acids) described previously with 'marine prostanoids' in terms of features defining this class. We shall therefore consider them only in terms of the historical aspect.

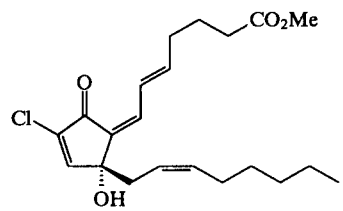
14



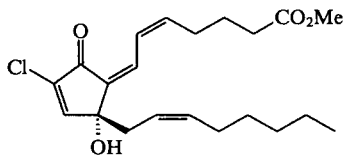
15



16

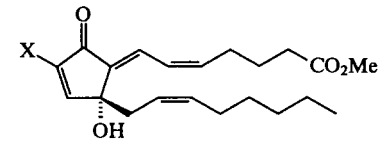


The next important stage of the studies on these lines was described in the communication published in 1985 concerning the isolation from *Clavularia virides* of 10-haloprostanoids exhibiting an anticancer activity—chlorovulones I–IV (compounds **17–20**).[30]

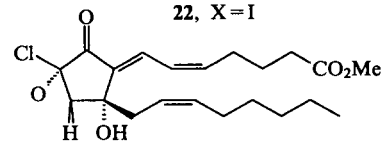


17, chlorovulone I

18, chlorovulone II



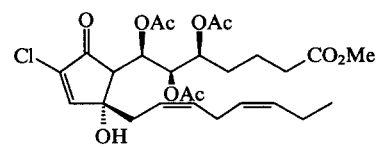
19, chlorovulone III



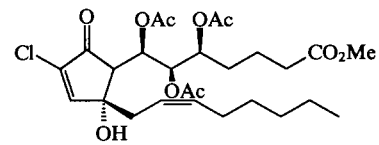
20, chlorovulone IV

The absolute configuration of the C(12) chiral centre in chlorovulones, determined from circular dichroism data of their derivatives and by comparing the spectroscopic characteristics as well as the specific angles of rotation of the natural chlorovulone II (compound **18**) and (−)-chlorovulone II obtained by enantioselective synthesis, was found to be the opposite of the configuration of the C(12) stereocentre of clavulones.[27]

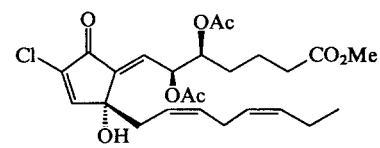
In addition, prostanoids related to chlorovulones and containing Br and I atoms, which were called bromovulone I (compound **21**) and iodovulone I (compound **22**),[31,32] as well as the C(10,11)-epoxy-analogue **23**[33] were also identified among the series of compounds isolated from marine organisms. Like the parent chlorovulone I and clavulone I, they have the (5*Z*, 7*E*, 14*Z*)-configuration of the double bonds in the side chains.



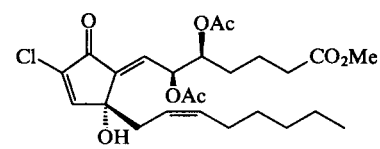
21, X = Br
22, X = I



23



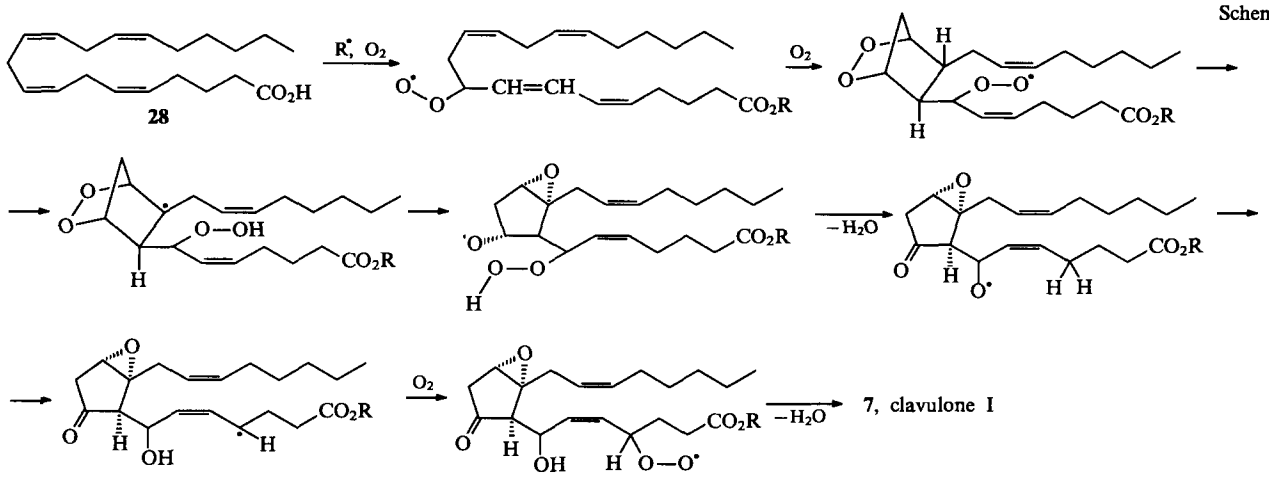
Representatives of halogenated eicosanoids with a more complex structure were isolated from the octocorals of the *Telesto riisei* species.[34,35] They have been called punaglandins I–IV (compounds **24–27**). The presence of vicinal acetate groups at the C(5) and C(6) atoms is characteristic of these compounds. The (*R*)-configuration of the C(12) chiral centre, refined by means of enantioselective synthesis, proved to be the opposite of that proposed initially and characteristic of clavulones.[35,36]



24, punaglandin I

25, punaglandin II

26, punaglandin III



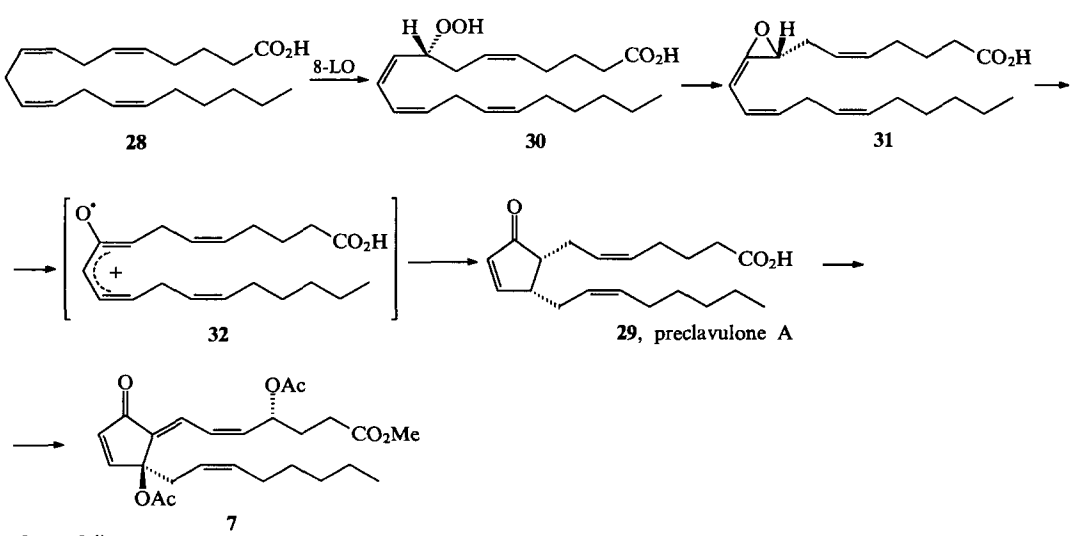
27, punaglandin IV

II. Biosynthesis of marine prostanoids

Arachidonic acid **28** is known to be synthesised by the 'endoperoxide pathway'. Initially Corey et al.[38] put forward the hypothesis that the biosynthesis of clavulones proceeds via a similar mechanism and that the key stage in this process is the ready transformation of the β-peroxyl radicals into cyclopentane epoxyketo-derivatives, which are formed as a result of the intramolecular attack by the radical on the nearest peroxide oxygen atom (Scheme 1, see over).

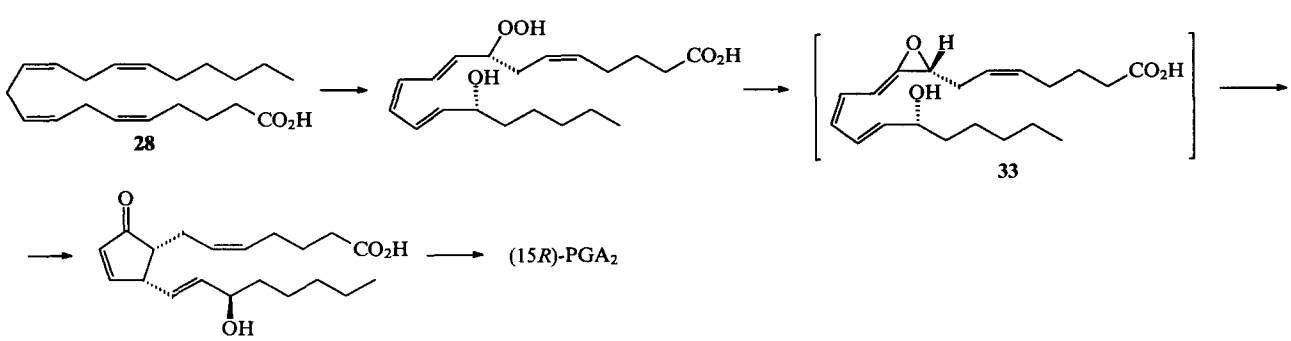
Somewhat later it was observed that, when arachidonic acid is treated with a homogenate of the coral of the *Clavularia virides* or *Pseudoplexaura porosa* species, the habitats of which are extremely remote from one another, a new eicosanoid **29**, called preclavulone A (PC-A), is formed.[35,39,40] Its structural similarity to 12-oxophytodienoic and *cis*-jasmonic acids suggested the similarity of the pathways leading to their biosynthesis, probably via a cationic mechanism through 8-hydroperoxyeicosatetraenoic acid [(8*R*)-HPETE] **30**, the allene oxide **31**, and the oxypentadienyl

Scheme 1



cation **32**.[40-42] Next, as a result of the successive enzymic hydroxylation of the C(4), C(7), and C(11) atoms, exhaustive acylation, and the elimination of the AcO group to the C(7) atom, preclavulone A is converted into clavulones (Scheme 2).

The formation of preclavulone A when the coral homogenate is kept in contact with tritium-labelled (8*R*)-HPETE confirms that the acid **30** is an intermediate in the biosynthesis of PC-A from arachidonic acid (radiochemical yield up to 13%).[42] The biosynthesis of PGA_2 in corals of the *Plexaura homomalla* species, which is known to be the richest source of prostaglandins (up to 2% of the dry residue), can take place via a similar chain of reactions (Scheme 3) from the acid **28** via the allene oxide **33**.[43] Thus, from the evolutionary point of view, the possibility of the biosynthesis of protanoids in mammals and marine organisms via different pathways is surprising.



As already mentioned, the biomimetic synthesis of PC-A achieved by Corey[40] confirms the possibility, in principle, of the 'marine' pathway to the biosynthesis of prostanoids. The absolute configuration of the chiral centres of PC-A was established by the enantioselective synthesis of the methyl ester of (−)-preclavulone A.[44] The Cope rearrangement of the trimethylsilyl ether of the enone **34** undoubtedly constitutes a rational way of constructing the structures of the *cis*-joined tetrahydroindenes **35** and of achieving the synthesis of the key cyclopentanone derivative **36** with the required orientation and chemodifferentiation of the side substituents. The subsequent operations are standard and are well known from the chemistry of prostaglandins (Scheme 4).

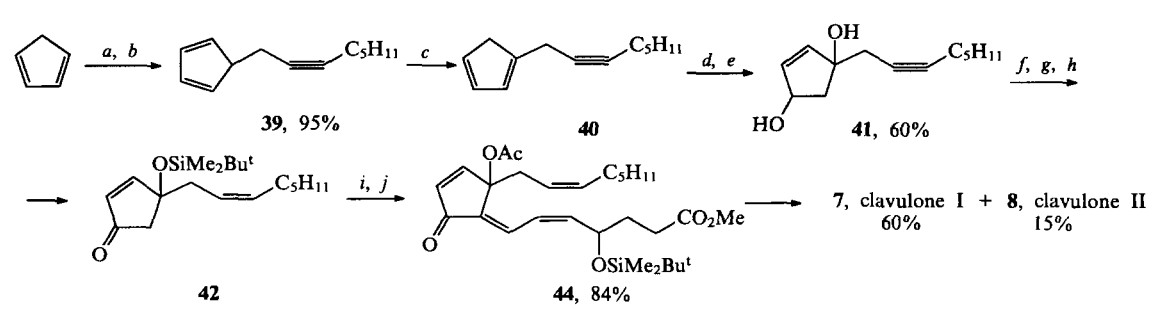
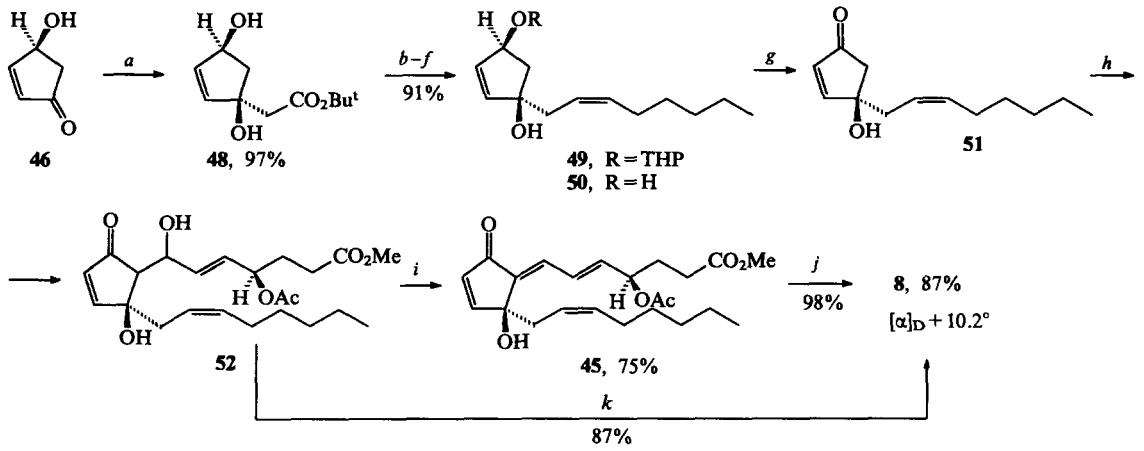
III. Chemical syntheses of marine prostanoids

The stages involving the formation of the tertiary alcohol cyclopentane unit with a lower chain and the introduction of the polyoxygenated α-chain with an *exo*-methylene bond via the condensation of the enolate of the ketone **37** with the aldehyde **38** having the required structure are the most characteristic in the syntheses of marine prostanoids.



37, X = H, Cl **38**

Corey and coworkers[45] were the first to achieve the total synthesis of the racemic clavulone I. A synthetic scheme starting from cyclopentadiene is presented below.



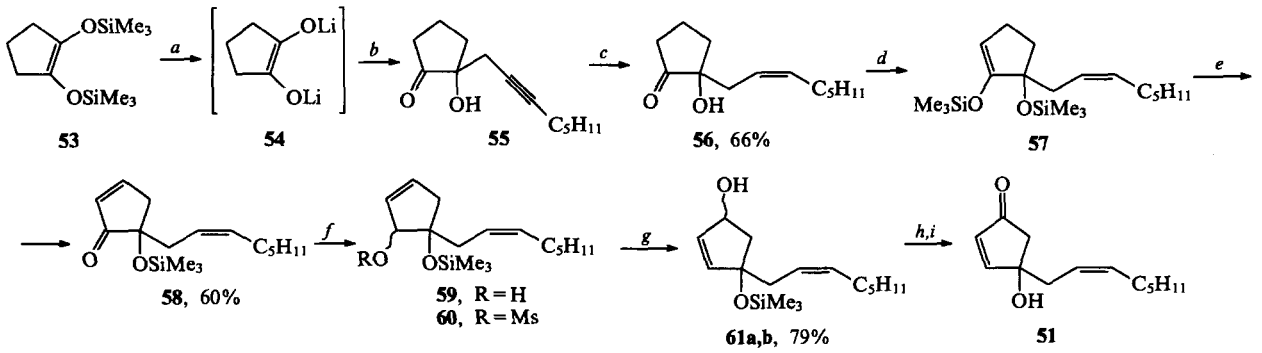
2-Alkylcyclopentadiene **40** was obtained by alkylating cyclopentadienyllithium with 1-iodooct-2-yne and subsequent 1,5-sigmatropic isomerisation of compound **39** under mild conditions. The key stage — photochemical oxidation of the diene **40** and the reduction of the intermediate endoperoxide by treatment with $NaBH_4$ — led to the diol **41**, which was converted by standard procedures into the synthon **42**. The second important stage — the condensation of the ketone enolate **42** with the aldehydoester **43** and the selective replacement of the Bu^tMe_2Si group protecting the tertiary hydroxyl by Ac — led to a mixture of the diastereoisomers **44** in proportions of 1 : 1, which was separated by column chromatography on SiO_2. The ^1H NMR spectrum confirmed the complete absence of the (7,8-*Z*) isomer. The less polar isomer was then smoothly transformed into a mixture of clavulones I and II, which were isolated by column chromatography on silica gel in 60% and 15% yields respectively and were identical as regards spectroscopic and chromatographic characteristics with the natural specimens.

The first enantioselective and stereoselective synthesis of clavulone II and of its 12-*O*-deacetyl derivative **45** has been described by Nagaoka et al.[46] The strategy of the synthesis is analogous to that presented above and consists in the successive introduction of the α-chain and of the chiral α,β-unsaturated aldehyde **47**, obtained from D-(+)-mannitol, into the structure of the optically active cyclopentenone **46** (Scheme 5).

The *cis*-diol **48** has been obtained with a high stereoselectivity by the interaction of (4*S*)-hydroxycyclopentenone **46** with the lithium enolate of *tert*-butyl acetate. The subsequent stages involving the blocking of the alcoholic groups, the conversion of the ester group into an aldehyde group, and the Wittig reaction, led to the alkene **49** in high yields. The oxidation of the diol **50** by Corey's reagent and condensation of the lithium enolate of the enone **51** with the aldehyde **47** afforded a diastereoisomeric

(*a*) BuLi, C_5H_{12}–THF; (*b*) 1.1 equiv. of $ICH_2C{\equiv}CC_5H_{11}$, from −78 to 30 °C, 3 h; (*c*) 23 °C, 4 h; (*d*) 0 °C, *hv*, MeOH, −40 °C, 2 h; (*e*) $NaBH_4$, MeOH; (*f*) pyridinium chlorochromate (PCC), CH_2Cl_2, 23 °C, 2 h; (*g*) H_2, $Pd/CaCO_3$, EtOAc–Py (9 : 1); (*h*) 2 equiv. of Bu^tMe_2SiCl, 3.5 equiv. of 2.6-lutidine, CH_2Cl_2, from 0 to 23 °C, 2.5 h; (*i*) LDA, THF, −78 °C, 5 min; (*j*) HOCCH=CHCH[OSi(Me$_2$)Bu^t]$CH_2CH_2CO_2Me$ **43**, from −78 to 10 °C, 6 h; (*k*) 5 equiv. of Bu_4^nNF, 20 equiv. of Ac_2O, 3 equiv. of 4-dimethylaminopyridine (4-DMAP), from 0 to 23 °C, 30 min; (*l*) column chromatography on SiO_2, Et_2O–C_6H_6 (6 : 4).

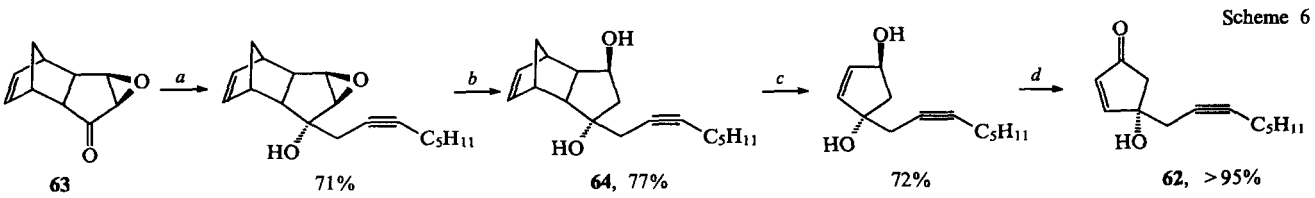
Scheme 5



(*a*) $MeCO_2Bu^t$, LDA, THF, −78 °C; (*b*) dihydropyran (DHP), camphorsulfonic acid, Et_2O, 0 °C; (*c*) $LiAlH_4$, Et_2O, 20 °C; (*d*) DMSO–$(COCl)_2$, CH_2Cl_2, −78 °C, NEt_3; (*e*) $Ph_3PC_6H_{13}Br$, Bu^nLi, THF–HMPTA (hexamethylphosphoramide), −40 °C; (*f*) AcOH–H_2O (4 : 1); (*g*) PCC, molecular sieves (3 Å), CH_2Cl_2, 20 °C; (*h*) LDA, THF, −78 °C, HOCCH=CHCH(OAc)$CH_2CH_2CO_2Me$ **47**; (*i*) MsCl [Ms = methanesulfonyl (Translator)], NEt_3, CH_2Cl_2; (*j*) Ac_2O, Py, 30 °C; (*k*) Ac_2O, Py, 50 °C.

mixture of the alcohols **52**, the methanesulfonates of which are converted into 12-*O*-deacetylclavulone **45** on treatment with NEt_3. Standard acetylation of the latter afforded (+)-clavulone II, all the characteristics of which were identical with those of an authentic specimen of the natural product.

A fundamentally different pathway leading to the synthon **51** from the disilyl ether **53** has been proposed.[47] The key stage in this scheme—the interaction of the dilithium derivative of the 1,2-enediol **54** with 1-bromooct-2-yne, leading to a satisfactory yield of the hydroxyketone **55**, merits attention. Next, the ketoalcohol **56**, obtained by partial hydrogenation, is converted into the silyl ether of the enol **57**, which is oxidised by treatment with $Pd(OAc)_2$ in acetonitrile to the enone **58**. The boron hydride reduction of the latter, the methanesulfonation of the resulting allyl alcohol **59**, and subsequent hydrolysis of the methanesulfonate **60** afford a diastereoisomeric mixture of allyl alcohols **61a, b** in proportions of 1 : 1. The transformation of the enone **58** into an alcohol, formally regarded as 1,3-transfer of the oxygen-containing functional group, is possible as a consequence of the unidirectionality of the stages involving the hydrolysis and inversion of the sterically hindered allyl methanesulfonate **60**. The Collins oxidation of the alcohol **61** with subsequent hydrolysis of the protecting groups completes the synthesis of the enone **51**.



The acetylenic enone **62** described above, which is the equivalent of the synthon **51**, was obtained from the epoxyketone **63**, which is formed readily in its turn from *endo*-dicyclopentadiene.[48] The key stage in this scheme is the vacuum flash pyrolysis of the norbornene derivative **64** (Scheme 6).

The effective stereospecific synthesis of clavulones from Corey's lactone—a synthon popular in the synthesis of prostaglandins—is of special interest.[49] The polyfunctionalised cyclopentane synthon **65** is an extremely rational starting compound for the construction of the of clavulone structure. The main problem in work involving this compound is the stereoselective introduction of the C(12)-hydroxy-group. For this purpose, Corey's lactone was converted via the α,β-unsaturated lactone **66** into the allyl alcohol **67** and then into the epoxide **68**

(Scheme 7). On treatment with sodium bis(2-methoxyethoxy)-aluminium hydride (Red-Al), the epoxide afforded the tertiary alcohol **69** in 60% yield. The construction of the ω-chain from the triol **69** via the aldehyde **70** by the Wittig reaction does not present difficulties. Manipulation of the protecting groups in the resulting unit made it possible to arrive at compound **71**, the Collins oxidation of which led to the corresponding aldehyde **72**, which was then condensed with the dilithium intermediate **73**. By performing on the intermediate aldol the operations: acylation, hydrolysis of the protecting groups, the Jones oxidation, and methylation, the ketoester **74** was obtained. During the slow filtration of the latter through a layer of silica gel, the labile C(7)- and C(12)-acetoxy-groups were smoothly split off, which led to the thermodynamically favourable conjugated polyene structure **75** in the form of a mixture of isomers. Acylation of the tertiary alcoholic functional group at the C(12) atom in compound **75** gave rise to a mixture of clavulones I and II in proportions of 2 : 1, which were separated by high-pressure liquid chromatography (HPLC).

The initial compound in another effective scheme for the stereospecific synthesis of clavulones is the readily available *gem*-dichlorolactone **76**.[50,51] The key synthon **77** with a tertiary alcoholic group was obtained by a ten-stage sequence of reactions including the selective dechlorination of the lactone **76**, the preparation of the iodohydrin **78**, dehydroiodination with formation of a double bond, reduction to the lactol, the Jones oxidation, introduction of the ω-chain, and the selective hydrogenation of the triple bond (Scheme 8). In order to form the α-chain, the lactol **77** was converted into the corresponding aldehyde and was subjected

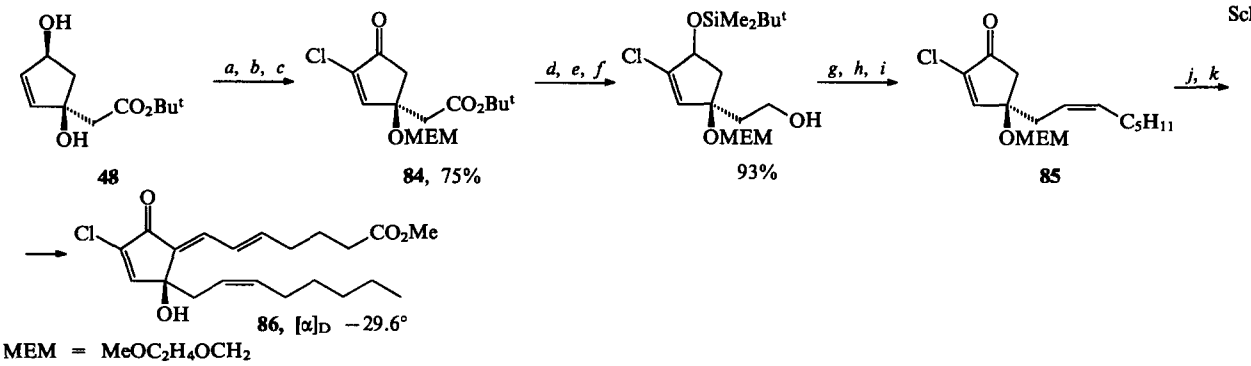
to Wittig condensation with dimethyl 4-methoxycarbonyl-2-oxobutylphosphonate. In conclusion, the diketone **79** obtained was converted into a mixture of clavulones **80** by dehydrochlorination, selective reduction of the keto-group in the α-chain, and exhaustive acylation.

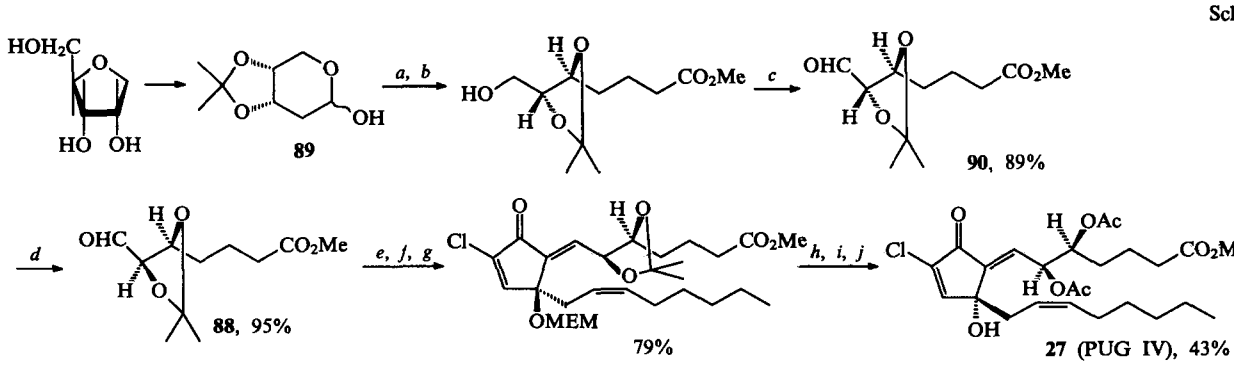
A convergent approach to the synthesis of clavulone-like compounds **81a–d** and **82a–d**, fundamentally different from those described above, has been proposed by Tolstikov et al.[52] The scheme is based on the initial construction of a new synthon — cyclopentene-1,3-dione **83a,b** with an exocyclic double bond in the side chain — and the subsequent introduction of the ω-chain with the simultaneous generation of a tertiary hydroxy-group via the condensation of the enone with the corresponding organometallic reagents.



The enantioselective synthesis of (−)-chlorovulone II was undertaken by Yamada and coworkers[27] in order to establish the absolute configuration of the chiral centres in this natural product. The scheme for the synthesis reflects to an appreciable extent the strategy used by the same workers in the synthesis of clavulones.[46] The initial compound in this case is the optically active diol **48** obtained from (4*S*)-hydroxycyclopenten-2-one, which was converted in three stages into α-chlorocyclopentenone **84** and further into the key intermediate **85**. The subsequent transformation of this synthon led to (−)-chlorovulone II (compound **86**), identical in terms of all its spectroscopic characteristics, except for the sign of the angle of rotation, with a specimen of the natural product (Scheme 9).

Punaglandins II and IV have been obtained mainly in accordance with schemes similar to those described above for clavulones and chlorovulones.[27,46]

Thus, according to Nagaoka et al.,[35] the lithium enolate of the chiral cyclopentenone **87** is condensed with the chiral aldehyde **88**, synthesised from 2-deoxy-D-ribose via the acetonide **89** and the (*S*)-aldehyde **90**, which readily isomerises to compound **88** on treatment with catalytic amounts of K_2CO_3 in methanol (Scheme 10). The key condensation reaction and the subsequent standard transformations yielded a set of clavulones with different configurations of the chiral centres. The structures of punaglandins III and IV, which have the (5*S*, 6*S*, 12*R*)-configuration, were refined by comparing the spectroscopic (^{1}H NMR, IR, UV, and CD) as well as optical rotation data and the chromatographic characteristics of the synthetic and natural specimens.



Another scheme for the preparation of punaglandins (IV) is based on the use of 1,2-bistrimethylsilylcyclopentene **53**, which was used earlier in the synthesis of clavulones.[53] The intermediate **91**, obtained by chlorinating the synthon **56**, was reduced after

dehydrochlorination to the diol **92**, which was converted into a secondary methanesulfonate and solvolysed in 80% aqueous DMSO (Scheme 11). The solvolysis of methanesulfonate proceeds with the allyl rearrangement and affords the alcohol **93** [a 1 : 1 mixture of the epimers at C(9)]. Oxidation of the crude mixture yielded a cyclopentanone derivative, which was converted into the corresponding methoxymethyl-blocked ketone **94**. The lithium enolate of the latter was treated with the aldehyde **95** and a mixture of the four diastereoisomers **96**–**99** obtained in equal amounts was separated by column chromatography. Their absolute configurations were determined by comparing the spectroscopic and optical rotation characteristics with those for authentic specimens. Selective hydrolysis of the isopropylidene protecting group in each of the products followed by acylation and acid hydrolysis afforded compounds **27** and **100**–**102** in 30%–40% yields, compound **27** being identical with the natural punaglandin IV.

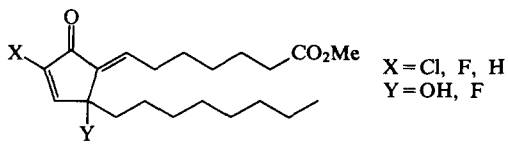
A similar strategy (introduction of the ω-chain into the corresponding cyclopentenones, chlorination of the cyclopentane ring, and addition of a chiral aldehyde — the equivalent of the α-chain — by means of aldol condensation) has been used in the synthesis of 6-*epi*-14,15-dihydropunaglandin IV.[54]

Noyori's group[36] described a convergent synthesis of the natural (7*E*)- and (7*Z*)-punaglandins IV by means of the successive introduction of precursors of the ω-chain (compound **103**) and the α-chain (compound **104**) into (4*S*)-cyclopentenone **105**.

Scheme 12

(*a*) 1 equiv. of $H_2C{=}C{=}C(C_5H_{11})SnBu^n_3$ **103**, BuLi, THF, −78 °C; (*b*) Bu_4NF; (*c*) the Lindlar catalyst, MeOH; (*d*) Py.$2CrO_3$, DMF; (*e*) $MeSO_3SiMe_3$, Pr^i_2NH, CH_2Cl_2; (*f*) **104**, LDA, THF, −78 °C; (*g*) Ac_2O, 4-DMAP, CH_2Cl_2; (*h*) AcOH–THF–H_2O (6 : 3 : 1).

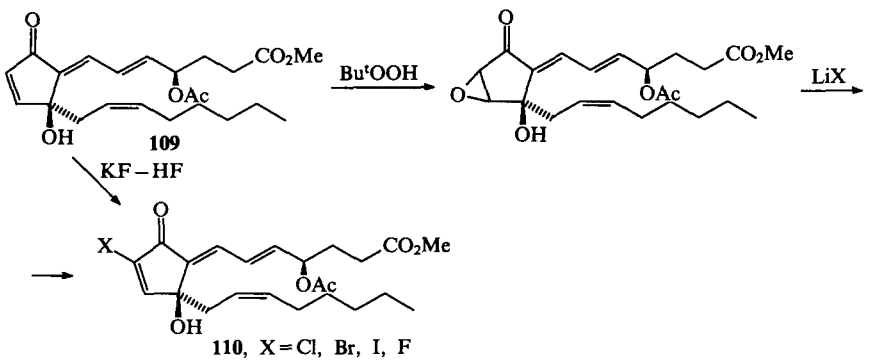
Tributylstannylallene **103** was obtained by the S_N2 reaction of 3-chloro-1-tributylstannylpropyne with tributylphosphine-pentylcopper at −78 °C in solution in THF. The chiral aldehydoester **104** was synthesised by the enantioselective Sharpless epoxidation of the unsaturated alcohol **106**. In the concluding stage of the synthesis, the crystalline diol **107** was obtained by condensing the stannyl derivative **103** with the enolate of the ketone **105**. The structure of the diol was confirmed by X-ray diffraction. The sequence of selective hydrogenation, oxidation and silylation reactions led to a satisfactory yield of the synthon **98**, in which the α-chain **104** was formed by standard methods (Scheme 12).



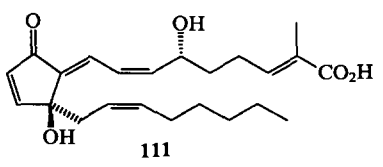
Overall, all the possible diastereoisomers with different configurations of the C(5), C(6), and C(12) chiral centres were obtained from the set of synthons **103**–**105** and their enantiomers. The involvement of the enantiomer **105** and compounds **103** and **104** in the above sequence of reactions led to a product all the characteristics of which (NMR, CD) agreed with those of the natural punaglandin IV having the (5*S*, 6*S*, 12*R*)-configuration. Thus the configuration of the C(12) chiral centre in punaglandins is identical with that in chlorovulones and is the opposite of the configuration of the C(12) centre in clavulones.

IV. Analogues of marine prostanoids

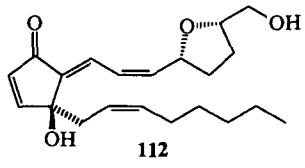
Immediately after the discovery of this class of prostanoids, studies were published on the synthesis and biological activity of their modified derivatives. Thus a group of Japanese investigators took out a series of patents[55–58] describing the isolation from *Clavularia virides* of clavulones and related compounds exhibiting anti-inflammatory and antitumour activities.

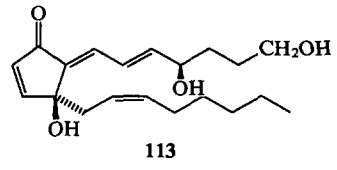


A patent[59] described the synthesis of analogues of clavulones by means of elimination reactions of sulfo-derivatives of 7-hydroxy-PGE_2. They exhibit anticancer and antiviral properties (IC_{50} = 0.4–1 μg ml^{-1}). The same workers[60] used the 7,8-dehydro-analogues of PGA to obtain the corresponding 1-chloro-derivatives, which can be regarded as modified clavulones. The compounds synthesised possessed antitumour, antibacterial and antiherpes activities.

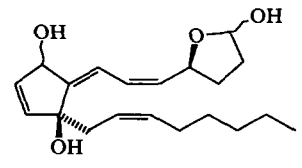


Derivatives of punaglandins have been patented[61] as effective anticancer and antiviral compounds. An attempt has been made[62] to modify the cyclopentane ring in prostaglandins by introducing powerful electronegative substituents—fluorine atoms—in the C(10) and C(12) positions. Unfortunately, comparative data on the biological activities of these compounds are not presented.

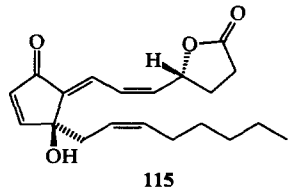


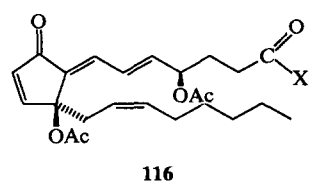


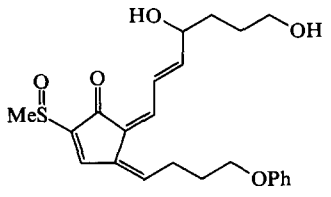
10-Haloclavulones **110** have been obtained from the cross-conjugated trienone **109**.[63]

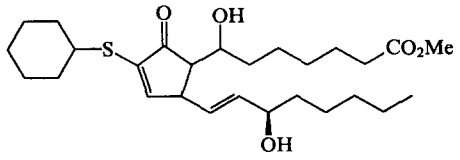


Modifications of the natural clavulones have been achieved.[64,65] Thus α-homologues of type **111**, γ-lactols **112**, the triols **113** and **114**, the lactone **115**, and derivatives **116** involving the modification of the carboxy-group have been synthesised from clavulone II.[64]









X = OH, OCH_2Ph, Bu^tO, Bu^iNH

Considerable attention has been devoted to the synthesis of the 10-thio-analogues of marine prostanoids.[66,67] In vitro experiments designed to test the activity against L-1210 cells demonstrated that the 10-methanesulfonyl derivative **117** had IC_{50} = 0.1 mg ml^{-1}, while compound **118** had IC_{50} = 0.02–2.30 mg ml^{-1}.

117

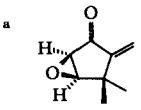
118

A series of other modifications have been achieved in order to investigate in detail the 'structure–activity' relation for this series of compounds.[68] This will be considered in detail in the next Section.

V. Biological properties of marine prostanoids

The antitumour activity of prostaglandins of types A and E was discovered as early as 1972. Subsequently, Suzuki et al.[62] found that the growth of cancer cells is also inhibited by PGD_2 and PGI_2 (9-deoxy-Δ^9-PGD_2), the activity of the latter exceeding by a factor of 3 that of PGA and PGE. Among the known prostaglandins, the most powerful antitumour agents are Δ^7-PGA_1 and Δ^{12}-PGI_2 and their derivatives. It was shown that the cyclopentane ring containing the α,β-unsaturated ketone fragment is responsible for this type of biological activity. Thus a promising field of study of prostaglandins concerns prostanoids with an alkylidenecyclopentane ring, which exhibit specific cytotoxic and antitumour activities. Clavulones (acetoxy-derivatives of Δ^7-PGA_2), discovered in 1982, and then the related punaglandins proved to be the most striking representatives of this class of prostaglandins. Tests on fertilised chicken eggs (30 μg ml^{-1}) showed that clavulones I–III possess anti-inflammatory properties.[69]

Clavulone I exhibited a distinctive antiproliferation activity in relation to HL-60 cells (ED_{50} = 0.4 μmol $litre^{-1}$), it is cytotoxic[70] at concentrations in excess of 1 μM, and it inhibits the synthesis of DNA.[71] Clavulone II manifested effective cytotoxic properties on L-1210 cells (IC_{50} = 0.6 μmol $litre^{-1}$)[71] and exhibited an antiviral activity in relation to the vesicular stomatitis virus in mice (IC_{50} = 1–1.5 μmol $litre^{-1}$).[72] Depending on the dose, punaglandins inhibit the growth of L-1210 cells in vitro (0.01–0.2 mg ml^{-1}), for which IC_{50} = 0.02 mg ml^{-1}; this is less than for vincristine and doxorubicin—the most powerful anticancer agents.[63,73,74] For clavulones, IC_{50} = 0.3 mg ml^{-1}, which is close to data for Δ^7-PGA_1.



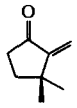
In vitro experiments showed[73] that, when mice infected with the L-1210 strain are administered punaglandins III and IV for five days using a dose of 5 mg per kilogram per day, their survival time increases by 50.5% and 78.9% respectively, while for clavulone II (10 mg per kilogram per day) the increase is by 50.8%; similar results are attained for Δ^7-PGA_1 using a dose of 20 mg per kilogram per day. Overall, the relative activities of the prostanoids in vitro and in vivo are correlated. It was also found that these compounds inhibit the synthesis of macromolecules containing leucine or thymidine: punaglandin IV causes 90% inhibition at a concentration of 5 mg ml^{-1} (L-1210), while clavulone II gives rise to a similar result at a concentration which is five times greater. It may be that these processes lead to the inhibition of the growth of tumours. The facts obtained also permit the hypothesis that one of the functions of eicosanoids in the vital activity of marine organisms may be the regulation of the growth of corals and other organisms growing in the immediate vicinity.

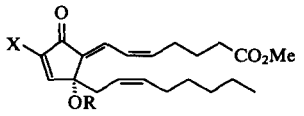
Yamada and coworkers[75,76] reported the results of biotests and elucidated certain features of the 'structure–activity' relation for a series of marine eicosanoids.

The decisive factor, necessary for the compounds to possess cytotoxic and antitumour (anti-HL-60 cells) activities, is the presence of an alkylidenecyclopentenone fragment in the structure. Comparison of the data in Table 1 for clavulone II and of its 10,11-dihydro-analogue shows that the presence of the C(10)–C(11) double bond is essential for the manifestation of cytotoxic activity. An exception to this rule is epoxyclavulone, which has no cross-conjugated cyclopentene system but which does exhibit a high activity. The epoxyketone fragment is probably a biological isostere of the enone system in this case (Table 1).

Table 1. The inhibiting effect of prostanoids of the clavulone type on the growth of HL-60 cells.[76]

Compound	X	R^1	R^2	IC_{50}/μmol $litre^{-1}$ (μg ml^{-1})	Cytotoxic effect/μmol $litre^{-1}$ (μg ml^{-1})
Clavulone II	H	MeCO	MeCO	0.40 (0.2)	>1.0 (0.5)
4-*O*-Deacetylclavulone II	H	MeCO	H	0.24 (0.1)	>1.2 (0.5)
12-*O*-Deacetylclavulone II[36]	H	H	MeCO	0.15 (0.06)	>0.5 (0.2)
4,12-*O*-Deacetylclavulone II	H	H	H	0.07 (0.025)	>0.3 (0.1)
10-Chloro-12-*O*-deacetylclavulone II	Cl	H	MeCO	0.03 (0.015)	>0.3 (0.15)
10,11-Epoxyclavulone II[a]	—	MeCO	MeCO	0.43 (0.2)	>1.08 (0.5)
10,11-Dihydroclavulone II[b]	—	MeCO	MeCO	2.23 (1.0)	>11.2 (5.0)
12-*O*-Methoxymethylclavulone II	H	$MeOCH_2$	MeCO	2.00 (0.90)	>4.5 (2.0)





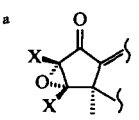


Table 2. The inhibiting effect of prostanoids of the chlorovulone type on the growth of HL-60 cells.

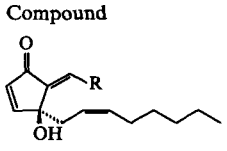
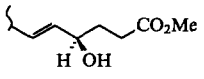
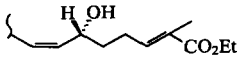
Compound	X	R	IC_{50}/ μmol litre^{-1} (μg ml^{-1})	Cytotoxic effect/ μmol litre^{-1} (μg ml^{-1})
Chlorovulone I	Cl	H	0.03 (0.01)	>0.3 (0.1)
Bromovulone I	Br	H	0.06 (0.025)	>0.9 (0.4)
Iodovulone I	I	H	0.06 (0.03)	>0.9 (0.4)
12-*O*-Acetyl-chlorovulone I	Cl	Bu^{t}O	0.19 (0.08)	>1.18 (0.5)
10,11-Epoxy-chlorovulone I[a]	Cl	H	0.10 (0.04)	>0.76 (0.3)

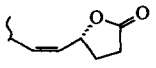
[a] 

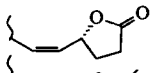
The introduction of a halogen atom in the C(10) position increases the biological activity (Cl = F > Br = I > H) (Table 2).

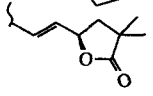












The introduction of a hydroxy-group at the C(12) atom increases the activity and the stereochemistry of the hydroxy-group does not exert an appreciable influence on the latter. The 12-hydroxy-group greatly increases the antiproliferation and cytotoxic activities. Thus the weak antiproliferation activity of PGA_2, Δ^7-PGA, PGI, and Δ^{12}-PGI has been explained precisely by the absence of the C(12)–OH group. When it is replaced by an acetyl group, the cytotoxic effect is diminished. Epoxidation decreases the activity compared with chlorovulone I, although it is nevertheless higher than that of clavulone II.

The introduction of groups blocking the β-oxidation of the α-chain does not induce an appreciable increase in activity. As shown in Table 3, the introduction of a cyclic γ-lactone or a hemiacetal group (d, e, f) does not have much influence on the β-oxidation process. On the basis of the data presented, one may note that the activity diminishes with increase in the length of the α-chain (chlorovulone I > a > b > c). The presence of eight carbon atoms is probably optimal, since the shortening of the chain also diminishes the activity.

The presence of the dienone fragment [C(5,6), C(7,8)] leads to an increase in activity.

Overall, the observed features of the 'structure–activity' relation in the series of marine prostanoids are undoubtedly important and necessary for studies directed specifically to the creation of a new class of anticancer medicinal preparations.

Table 3. The inhibiting effect of clavulones with a modified α-chain.

Compound 	R	IC_{50}/μmol litre^{-1} (μg ml^{-1})	Cytotoxic effect/μmol litre^{-1} (μg ml^{-1})
4,12-Deacetylclavulone II		0.07 (0.025)	>0.3 (0.1)
a		0.10 (0.033)	>0.6 (0.2)
b		0.11 (0.04)	>0.6 (0.2)
c		0.36 (0.15)	>1.2 (0.5)
d		0.09 (0.03)	>0.3 (0.1)
e		0.12 (0.04)	>0.6 (0.2)
f		0.11 (0.04)	>0.6 (0.2)

Abstract. The results of studies on the structures of more than 50 new crystals of germanates, gallates, borogermanates, borates, and silicates, possessing laser, piezoelectric, ferroelectric, and ion-conducting properties, are presented. The structure–property relations are considered. The bibliography includes 71 references.

I. Introduction

The needs of modern engineering for new materials, which are promising by virtue of their unusual physical properties, are increasing with each year. Inorganic single crystals occupy an important place among such materials. The interest in them has been aroused by the developing modern technologies. Thus the enormous possibilities arising in the application of the new optical properties of crystals have been demonstrated in a communication [1] reviewing the results of studies involving the search for new nonlinear optical materials of the $KTiOPO_4$ structural type. The large band widths available in the optical transmission of data make it possible to move and store specimens with an information density in excess of 10^8 bits cm^{-2}. The generation of the third harmonic can be used to improve significantly the density of optical discs. The fibre optics used in telecommunications permits a relatively free transmission of signals subject to a minimal noise due to the external electromagnetic field. This also means that the modulations of the light wave carriers are nontrivial and that chemists specialising in materials science should play an important role in the creation of an optical system (crystal) with a predetermined amplitude and response time.

In a study [2] of the relation between the structures of new crystalline phases and their ferroelectric properties, the structure–properties problem was designated as crucial in chemistry and structural crystallography. Ferroelectrics, i.e. crystals capable of spontaneous polarisation, are materials in which structure–property relations are clearly manifested and are being actively investigated. Such materials frequently also possess ionic conductivity.

Studies in recent years have shown that solid electrolytes or superionic crystals have a specific structure — they contain large channel-cavities in which cations migrate. This has led to the specific search for and synthesis of such compounds.

Compounds in which, for example, luminescent, piezoelectric, and nonlinear optical properties are combined with a high mechanical and thermochemical stability are especially valuable. This review is devoted to the consideration of the characteristics of the steric structures of such compounds which have been obtained and whose structures have been investigated during the last 10–15 years. For example, in the case of solid state lasers, the search for compounds has been governed by problems involving the adoption of new spectral ranges and expansion of the stimulated radiation frequency ranges. Problems associated with the improvement of the effectiveness of energy conversion and of thermal stability are of current interest for piezoelectric single crystals.

The problem of the preparation of large and perfect single crystals for their subsequent study (in particular of their optical properties) and use is extremely important in such investigations. For this purpose, it is essential to know the conditions for the crystallisation of the corresponding phases. The determination of the regions of stability of structural types make it possible to achieve optimum compositions for the manifestation of the given physical properties by means of isomorphous substitution of atoms at different sites.

In the present review, attention is concentrated on the question of the relation between the structural characteristics of the new phases and physical properties. Mainly studies by Russian investigators, who have contributed greatly to the preparation and study of the properties and structures of new laser, piezoelectric, ferroelectric, and ion-conducting crystals, will be considered.

The majority of the germanate, gallate, and borogermanate crystals were obtained by B V Mill' in the Faculty of Physics at Moscow State University, the germanate-zeolites were obtained by L N Dem'yanets at the Institute of Crystallography of the Russian Academy of Sciences, and lanthanide borates were

prepared by L I Leonyuk in the Faculty of Geology at Moscow State University. The optical, piezoelectric, and mechanical properties were measured by A A Kaminskii and coworkers at the Institute of Crystallography of the Russian Academy of Sciences, while the measurements concerned with second harmonic generation and measurements of the electrical and ion-conducting properties were performed by S Yu Stefanovich of the Physicochemical Institute.

II. Brief characteristics of the methods for the preparation and study of the new compounds

The majority of the compounds, the crystals of which will be considered below, belong to the class of germanates and the related gallates. Crystallisation has been investigated for the $A_2O(AO)-M_2O_3(MO_2)-GeO_2(Ga_2O_3, SiO_2)$ systems, where A are alkali, alkaline earth, or lanthanide elements, i.e. large cations, and M are predominantly trivalent cations (Ga, Al, In, Fe, Sb, Ta), smaller in size and with higher electronegativities. The crystals were obtained by solid-phase synthesis,[3] i.e. by sintering in air-pressed mixtures of the oxides at 1100–1500 °C for 3–5 h (the temperatures used in the preparation of the single-phase specimens will be given below on the basis of the literature quoted in describing the data). The single crystals of a number of congruently melting compounds were grown by Czochralski's method. The boules were 8–9 cm long and 3 cm thick. The germanate-zeolites were obtained by hydrothermal synthesis[4] in autoclaves from alkaline solutions in the $NaAlO_2-GeO_2-Na_2CO_3-NaOH-H_2O$ systems at 300–500 °C. The lanthanide borates were synthesised by the solution-melt method in the $Ln_2O_3-Al_2O_3-B_2O_3-K_2Mo_3O_{10}$ systems by spontaneous crystallisation on cooling from 1500 °C.[5]

Crystalline elements in the form of rods up to 70 mm long and up to 5 mm in diameter with plane-parallel (5") end-faces were prepared for the investigation of the optical properties from the boules obtained by Czochralski's method.[6] The crystals were pumped by the pulsed radiation from neodymium (LaF_3, $Y_3Al_5O_{12}-Nd^{3+}$) and praseodymium ($Y_3Al_5O_{12}-Pr^{3+}$) laser crystals and also using Xe lamps. The spectral-lasing characteristics of the stimulated radiation, the optical transmission, absorption, and Raman spectra and the optical activity were investigated for the specimen synthesised, and measurements were also made of their elastic, dielectric, and piezoelectric characteristics. The measurements concerned with second harmonic generation and the measurements of the electrical and ion-conducting properties were performed by means of a specially developed method (see, for example, Belokoneva and Timchenko[5]).

Full X-ray diffraction studies of the single crystals of the new compounds were carried out in order to investigate their crystal structures. A correct allowance for the absorption of X-rays is extremely important in the study of objects containing germanium, gallium, the lanthanides, barium, strontium, and other heavy elements. In most cases, the single crystal specimens were prepared in the form of spheres with radii determined by the linear absorption coefficient ($\mu r \leqslant 4$).

The compounds will be considered in accordance with their structural types, most of which are known. New, previously unknown structural types or their modifications were also obtained and investigated in the course of the structural studies.

III. The garnet structural type

Many compounds with valuable properties crystallise with a garnet-type structure, for example, the garnet-ferrites $M_3Fe_5O_{12}$ with lanthanide elements at the dodecahedral M sites[8] or the familiar $Y_3Al_5O_{12}:Nd^{3+}$ laser crystal.[9] Isomorphous substitutions in the crystals can lead to the formation of new promising compounds.

By analogy with the work of Gibbs and Novak[10] on silicate garnets, in which the crystal-chemical characteristics and the region of stability were characterised as a function of the size of the ion at the dodecahedral (*c*) and octahedral (*a*) structural sites, the corresponding germanate analogues were investigated.[11] The garnet-germanate crystals were grown by Czochralski's method. The X-ray diffraction characteristics of the representatives of this series investigated are presented in Table 1. In the diffraction experiments, only the reflections for which the contribution of the cations is small or zero were scanned, this yielded from 58 to 86 observed independent reflections. The positional and thermal parameters of the O atom were refined on their basis, after which the interatomic distances in the polyhedra of the cations, located at the specific 24*c*, 16*a*, and 24*d* sites in the cubic lattice (the dodecahedron, octahedron, and tetrahedron) and their distortions were calculated. The quantities obtained from the structural data made it possible to deduce the region of stability of the germanium garnets (Fig. 1), i.e. to determine the combinations of ions in conformity with their ionic radii at the 24*c* and 16*a* sites of the *Ia*3*d* group when the germanium atoms are located at the 24*d* sites. These characteristics were deduced on the basis of the existence of common edges in the garnet structure between the tetrahedron and the octahedron, on the one hand, and the dodecahedra on the other.

Table 1. X-Ray diffraction characteristics of the phases investigated with the structure of the garnet type (space group *Ia*3*d*).

Compound	*a*/Å	μr	N_{refl}	R_{hkl} (%)
$Mn_3Al_2Ge_3O_{12}$	11.891(3)	2.5	84	7.8
$Ca_3Al_2Ge_3O_{12}$	12.116(3)	1.3	86	5.2
$Ca_3Ga_2Ge_3O_{12}$	12.247(3)	2.5	79	5.7

$Sr_3Sc_2Ge_3O_{12}$	12.750(4)	4.0	31	11.8

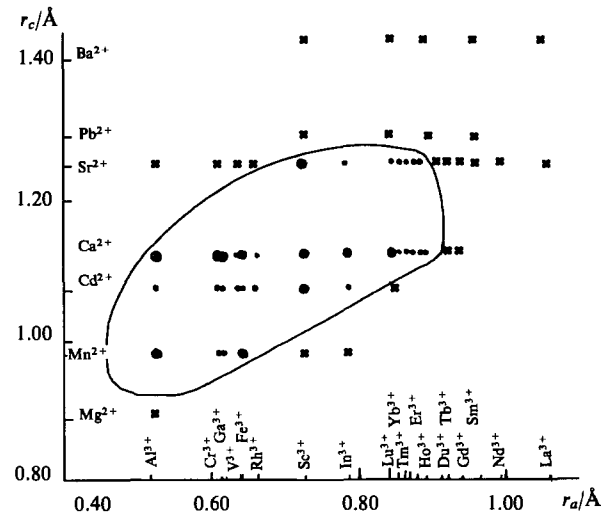

Figure 1. The region of stability of germanium garnets.

As regards practical applications (for the production of stimulated radiation), the $Ca_3Ga_2Ge_3O_{12}$ crystal activated by Nd^{3+} at concentrations from 0.05 to 16 at.% proved to be most promising. The position of the Nd^{3+}-activated ion was unambiguously determined as 24*c*, while that of the Cr^{3+} sensitiser ion was determined as 16*a*. The luminescence spectra of

this specimen have been analysed.[12] The question of the usefulness of polycationic garnets with heterovalent isomorphism for the formation of disordered Nd^{3+}-containing laser garnet crystals of the type $\{Ca_{1-x}Nd_x\}_3[Ga_2](Ge_{1-x}Ga_x)_3O_{12}$ was discussed in the same communication.

As a development of the possibilities of the heterovalent isomorphism discussed previously,[12] the cation-deficient garnet $Ca_{3.02}Nb_{1.67}Ga_{3.2}O_{12}$ (space group $Ia3d$, a = 12.507 Å) was synthesised and its structure was investigated.[13] The initial nonstoichiometry of the specimen compared with the standard $A_3B_2T_3O_{12}$ stoichiometry and also the unusually pronounced broadening of the lines in the luminescence spectra indicated a complex isomorphism and the presence of unoccupied cationic sites. Partial incorporation of Ca at the octahedral sites occupied predominantly by Nb and the excess Ga as well as the inclusion of a small proportion of Nb at Ga tetrahedral sites have been postulated. The ionic radii of the elements permit isomorphous mixing of this kind. In addition it was found that all the cationic sites in the structure are unoccupied. Successive refinement of various structural models of the crystal for different compositions (with specification of mixed atomic scattering curves) and populations of the atomic sites made it possible to obtain satisfactory thermal corrections for the atoms and the optimum divergence factor (R = 0.020) for the structural formula $\{\square_{0.05}.Ca_{2.95}\}[\square_{0.025}Ca_{0.07}Nb_{1.62}Ga_{0.275}](\square_{0.025}Nb_{0.05}Ga_{2.925})O_{12}$.

The existence of cationic vacancies was also established for V-garnets, but the Ca, Nb, Ga-garnet investigated by Kaminskii et al.[13] is the first disordered crystal with the garnet structure used to excite stimulated radiation. The statistical nature of the distribution of the heterovalent Ca^{2+}, Ga^{3+}, and Nb^{5+} ions among crystallographic sites, obtained as a result of X-ray diffraction study, was fully confirmed by the results of the study of the Raman spectra (Fig. 2), the luminescent properties, and the stimulated emission from this crystal containing Nd^{3+} ions. The high quality of experimental X-ray diffraction data and the reliability of the results for this crystal were confirmed by the investigation of the electron density distribution[14] and $\delta\rho$ maps, which proved to be comparable to those obtained for other garnets.

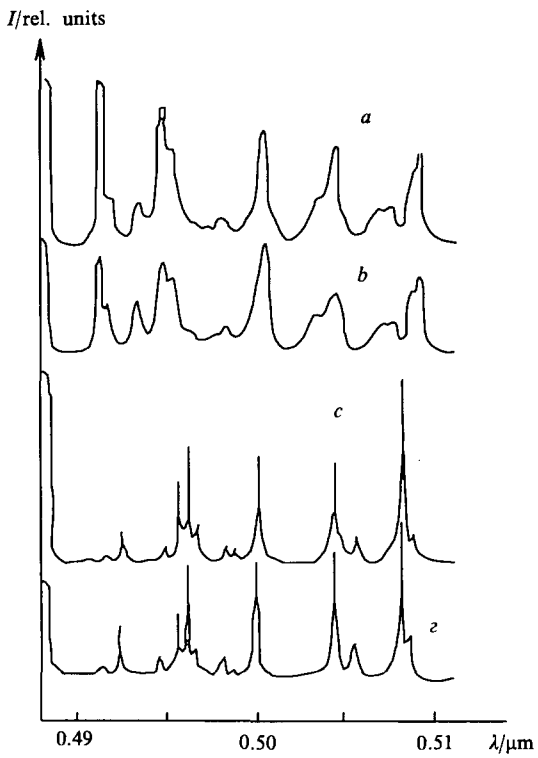

Figure 2. Raman spectra of the $Ca_{3.02}Nb_{1.67}Ga_{3.2}O_{12}$ garnets[13] with a disordered structure (a, b) and the $Ca_3Ga_2Ge_3O_{12}$ garnet with an ordered structure (c, d).

IV. The $A_3M_xT_{6-x}O_{14}$ structural type

In the study of the crystallisation of the $Ca_3Ga_2Ge_3O_{12}$ garnet, the compound $Ca_3Ga_2Ge_4O_{14}$ was obtained and subsequently became the parent compound of a series of compounds of a new structural type. The small amount of added oxides of certain tetravalent and pentavalent elements stabilises this new structural type for different compositions.[3] In the main, the compounds were obtained by solid-phase synthesis and those which melt congruently were synthesised by Czochralski's method. In all, more than 50 compounds were synthesised. The phase diagrams for the $CaO-Ga_2O_3-GeO_2$, $SrO-Ga_2O_3-GeO_2$, $Ln_2O_3-Ga_2O_3-SiO_2(GeO_2)$ (Ln = La, Nd), and $La_2O_3-Ga_2O_3-Nb_2O_5$ systems have been described.[15] The structures of seven compounds were investigated, the relevant data being presented in Table 2. In the acentric trigonal Fedorov group $P321$, which is characteristic of these phases, the cations are distributed among four regular point systems a, d, e, and f with different symmetries and with coordination to the oxygen atoms: a—octahedron with 32 symmetry; e—Thompson cube with 2 symmetry, and d and f—tetrahedra with 3 and 2 symmetry respectively (Table 2, Fig. 3). The true diffraction symmetry of $A_3M_xT_{6-x}O_{14}$ is trigonal ($P\bar{3}1m$), and the diffraction pseudosymmetry is hexagonal ($P6/mmm$). In the crystal structure, the Ge tetrahedra on the threefold and twofold axes form layers (Figs 3 and 4) perpendicular to the c axis. The Ge octahedra, strengthening the tetrahedra by forming a mixed framework, are distributed among them. The unshared ('hanging') apex of the d tetrahedron, viewed from above or downwards along the 3 axis (Fig. 3), makes it necessary to assign such a framework to the class of pseudoframeworks; the formula of the framework is $[M_1T_5O_{14}]$. The 'double-decker' structure of the framework is clearly seen in side projection (Fig. 4). The large A cations, the coordination polyhedra of which are the so called Thompson cubes in which the two square bases have been rotated relative to one another approximately by an angle of 45°, are located in the large cavities between the tetrahedral layers (Fig. 3). The most characteristic detail of the pseudoframework of the structural type considered is the group with 32 symmetry made up of the a octahedron and the three apices of the f tetrahedra linked to it.

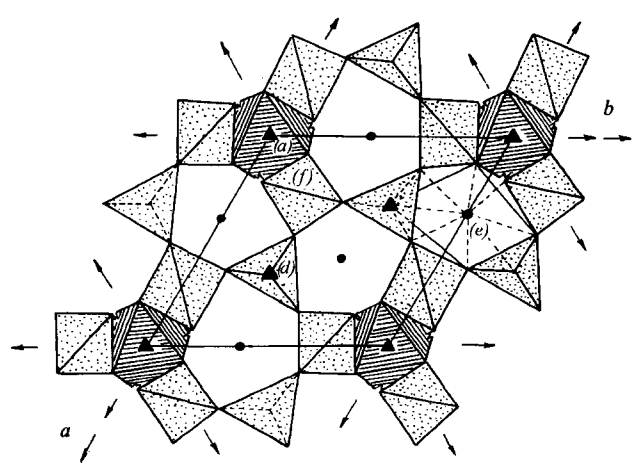

Figure 3. Projection of the crystal structure of the $A_3M_xT_{6-x}O_{14}$ type onto the ab plane. The regular systems of points for the positions of the cations and the symmetry elements are indicated.

Table 2. X-Ray diffraction characteristics of the phases investigated with structures of the $A_3M_xT_{6-x}O_{14}$ type.

[a]The mean interatomic cation–oxygen distance (in Å) in the polyhedron is given in brackets.

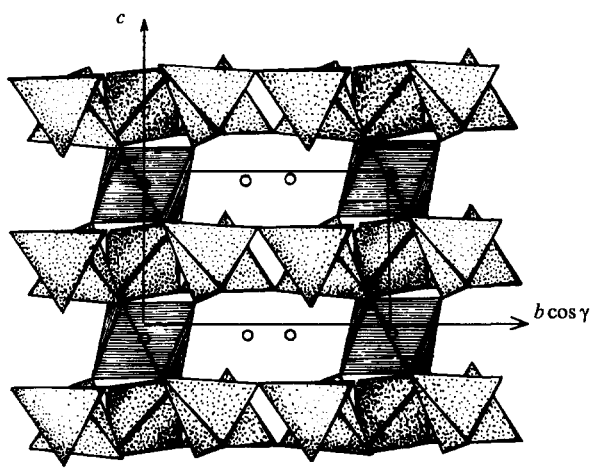

Figure 4. Projection of the crystal structure of the $A_3M_xT_{6-x}O_{14}$ type onto the *bc* plane.

Similar structural blocks are fundamental for mixed frameworks and pseudoframeworks of a large group of compounds with Ge atoms in octahedral and tetrahedral coordination such as $Li_2Ge_4O_9$, $LiNaGe_4O_9$, $Li_2Ge_7O_{16}$, $Li_4Ge_9O_{20}$, $Cd_2Ge_7O_{16}$, $BaGe_4O_9$, $K_2Ba(Ge_4O_9)_2$, and $Ba_3Ge_9O_{20}(OH)_2$.[16] The symmetry of the microblocks may be varied: 32, $\bar{3}m$, $3m$, $\bar{3}$, i.e. they may or may not have a centre of symmetry.

A similar structure, involving the existence of layered tetrahedral elements and different combinations of tetrahedra and octahedra, is characteristic of a large group of germanates, which nevertheless differ in the symmetry of their structures (the tetragonal Cd germanate, the trigonal Ca, Ga and K, Ge germanates, the orthorhombic $Li_2Ge_4O_9$ and $Li_2Ge_7O_{15}$, and the monoclinic $Li_4Ge_9O_{20}$) and in the topology of the tetrahedral layer. The axes perpendicular to the layered elements have the same dimensions in all the structures as that of the c = 4.7 Å axis of the structural type investigated or are a multiple of it (Fig. 5).

All these phases contain large interlayer cavities which can be filled by cations. Such cavities constitute convenient sites for activator ions. This can lead to the appearance of laser properties in the crystal. One can also postulate that phases such as $Cd_2Ge_7O_{16}$ (sp. gp $P\bar{4}b2$), $BaGe_4O_9$ (sp. gp $P31m$),

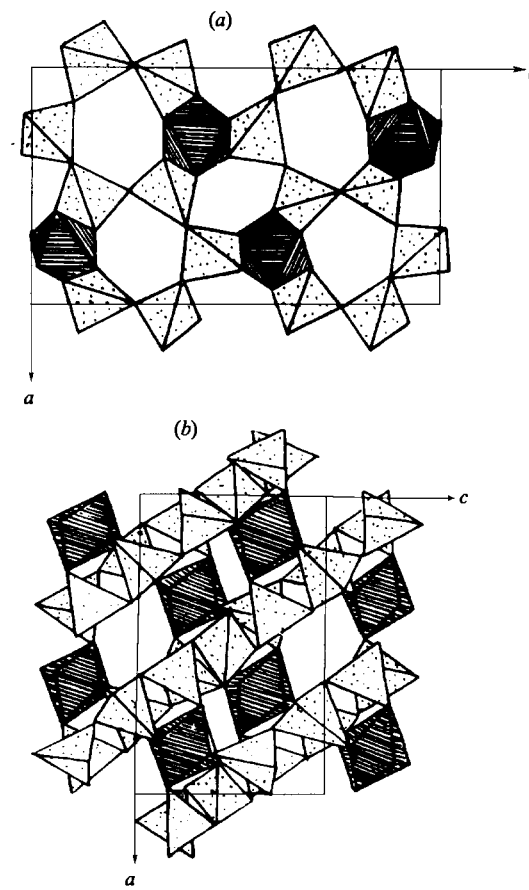

Figure 5. The crystal structures of $Li_2Ge_4O_9$ (*a*) and $Li_4Ge_9O_{20}$ (*b*). The anionic framework is illustrated.

and $Li_4Ge_9O_{20}$ (sp. gp $C2_1$) are promising as regards possible ferroelectric (for polar crystals) properties. Thus it has been established[17] that the compound $Li_2Ge_7O_{15}$ in this group undergoes a phase transition at 283.5 K ($Pbcn$—$Pbc2_1$) to a polar ferroelectric modification, which is accompanied by spontaneous polarisation along the c axis of the structure.

The synthesis and X-ray diffraction structural studies established that in crystals of the $A_3M_xT_{6-x}O_{14}$ structural type there is a possibility of extensive isovalent and heterovalent isomorphism which would enhance the laser and piezoelectric properties of those crystals which possess them.

The region corresponding to the stability of the compounds has been constructed in accordance with the crystal-chemical results in terms of the radii of ions with C.N. = 8 and the average radii of the ions of the framework as variables (Fig. 6).[16] Table 2 shows that isomorphic substitutions take place at all the cationic structural sites: (Na + Ca), Ca, Sr, Ba, and La for *e*; Ge, (Ge + Ga), Fe, and (Ga + Nb) for *a*; Ge, (Ga + Si), and Ga for *d*; Ge, (Ge + Ga), (Fe + Ge), and Ga for *f*. In the presence of isomorphism, the charge on the framework varies from −4 to −9: $[Ge_6O_{14}]^{4-}$, $[Ga_2Ge_4O_{14}]^{6-}$ and $[Fe_2Ge_4O_{14}]^{6-}$, $[Ga_5SiO_{14}]^{9-}$. One of the two independent tetrahedra, the *f* tetrahedron on the twofold axis, forming a microblock with the octahedron, is larger than the *d* tetrahedron on the threefold axis. In the *f* tetrahedron, the average interatomic distance varies from 1.766 Å (Ge) to 1.861 Å (Ga) with a possible inclusion at this site of up to 30% of the Fe atoms ($Ba_3Fe_2Ge_4O_{14}$). (In the structurally similar tetragonal gehlenites, which will be considered below, there is also a difference between the sizes of the two independent tetrahedra.) The tetrahedron on the threefold axis represents a cell for the smallest cations in the given structural type, in particular for Si^{4+} in $La_3Ga_5SiO_{14}$.

Octahedra with a mixed framework are also distinguished by 'flexibility' as regards size [the mean cation–oxygen distance varies from 1.893 Å (Ga) to 2.015 Å (Fe)] and, as already noted, can be occupied by germanium, gallium, niobium (to the extent of 50%), and iron cations. The fairly loose framework which is susceptible to isomorphism is readily distorted, and this may be the reason for the appearance of polarity in the structure and of the spontaneous polarisation vector P_s. The introduction of the Nd^{3+} activator ion at sites with lanthanide elements makes it possible to obtain satisfactory lasing characteristics.[18] The compound $La_3Ga_5SiO_{14}$ proved to have the best spectroscopic characteristics and piezoelectric properties among all those investigated.[3,15] $La_3Ga_5SiO_{14}$ single crytals are nowadays grown by a number of western and Russian firms. In accordance with the structural results, these crystals have been assigned to the class of materials with a disordered structure and a single activation quasi-centre. The fully substituted (La^{3+}–Nd^{3+}) compound $Nd_3Ga_5SiO_{14}$, i.e. a compound with a very high Nd^{3+} concentration, has been obtained from $La_3Ga_5SiO_{14}$.[6] Crystals of lanthanum gallate containing niobium (Table 2), which is incorporated in the *a* octahedron, are promising as regards the manifestation of nonlinear optical properties.

All the crystals of this group exhibit a piezoactivity higher by a factor of 3–8 than that of quartz.[15] The acoustic Q-factor of the crystals is also higher. Although the symmetry space groups of the new phases ($P321$) and quartz ($P3_121$) differ, they are both acentric and belong to the same 32 point group.

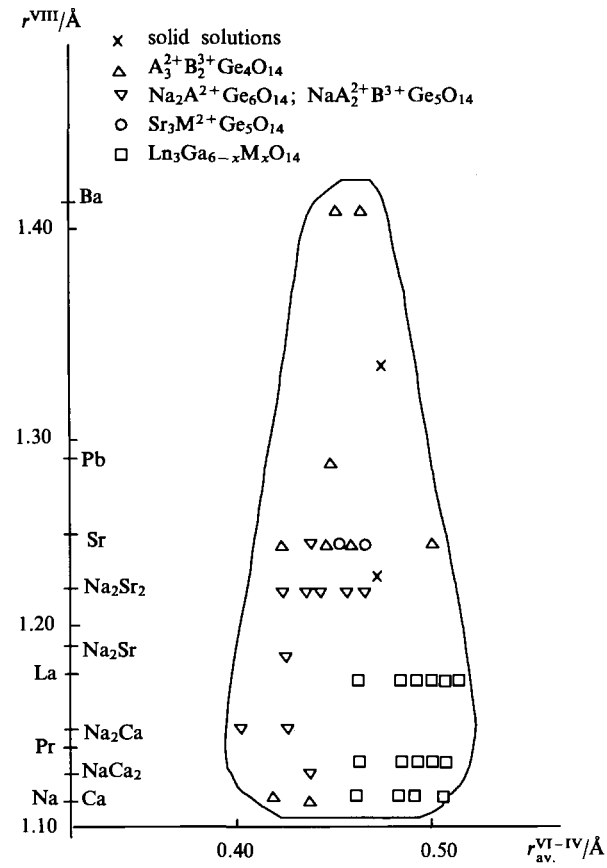

Figure 6. The region of stability of the compound $A_3M_xT_{6-x}O_{14}$.

The unique combination of physical properties (luminescent, laser, nonlinear optical, piezoelectric, and elastic) in this structural type of germanates makes it possible to regard them as multifunctional elements for technological purposes.

V. The melilite structural type

In the study of the $CaO–Ga_2O_3–GeO_2$ ternary system, crystals of the Ca, Ga, Ge-gehlenite $Ca_2Ga_2GeO_7$, belonging to the melilite structural type, were obtained. The interest in compounds with the melilite structure is due to the fact that stimulated emission from Ba,Zn and Ba,Mn germanates with the melilite structure and containing Nd^{3+} ions has been excited. A structural study of $Ca_2Ga_2GeO_7$ confirmed[19] that it belongs to the melilite structural type with the $P\bar{4}2_1m$ group. Apart from this compound, two further representatives of this structural type have been

Table 3. X-Ray diffraction characteristics of the phases investigated with structures of the gehlenite type.

Compound	*a*/Å	*c*/Å	Positions of cations[a]			μr	N_{refl}	R_{hkl} (%)
			e Thompson cube	*a* tetrahedron	*e* tetrahedron			
$Ca_2Ga_2GeO_7$	7.896(4)	5.207(2)	Ca (2.58)	Ga (1.85)	Ga + Ge = 1 : 1 (1.80)	0.9	392	5.5

$CaNdGa_3O_7$	7.903(3)	5.231(2)	Ca + Nd = 1 : 1 (2.591)	Ga (1.816)	Ga (1.824)	2.35	842	5.2

[a]The mean interatomic cation–oxygen distance in the polyhedron (in Å) is given in brackets.

synthesised and their structures have been investigated—$Ca_2Ga_2SiO_7$ and $CaNdGa_3O_7$ (Table 3)[20] (the low accuracy of the structural data obtained previously[21] for $Ca_2Ga_2SiO_7$ precluded a complete interpretation of the physical properties). The calcium or calcium + neodymium cations in the compounds synthesised are accommodated in Thompson cubes with the *m* symmetry. The larger *a* tetrahedra on the inversion axes, filled in the given structures with gallium atoms, are occupied by magnesium atoms in melilites and by iron atoms in åkermanites. The smallest *e* tetrahedra with *m* symmetry are occupied by Ga, Ga + Ge, and Ga + Si. The cationic polyhedra of gehlenites and $A_3M_xT_{6-x}O_{14}$ are identical (Tables 2 and 3). Despite the significant difference between symmetries (trigonal and tetragonal), the two structural types of Ca gallogermanates have features in common as regards coordination polyhedra, isomorphous relations (Tables 2 and 3), and the alternation along the *c* axes of layers of tetrahedra and A polyhedra in the large interlayer cavities.

The increased germanium content in the trigonal phase revealed, as mentioned previously by many investigators, its amphoteric nature, cationic character, and the manifestation of the octahedral as well as tetrahedral environments. The tetrahedral layers of both gallogermanates also have similar structures. The tetrahedral melilite layer can be described as made up of translationally identical bands extended along the *a*(*b*) axis (Fig. 7*a*). Five-membered tetrahedral rings can be distinguished in each band. The tetrahedral layer in the trigonal phase is made up of similar bands twisted in succession around the 2 axes (Fig. 7*b*). As a result of the presence of germanium atoms in the octahedra in this structure, the tetrahedral five-membered rings are ruptured and the band is converted into a chain. One of the melilite tetrahedra has rotated and occupies a position on the 2 axis (Fig. 7*b*). The relative dimensions of both *a*(*b*) axes and the *c* axis in both structures are in full agreement.

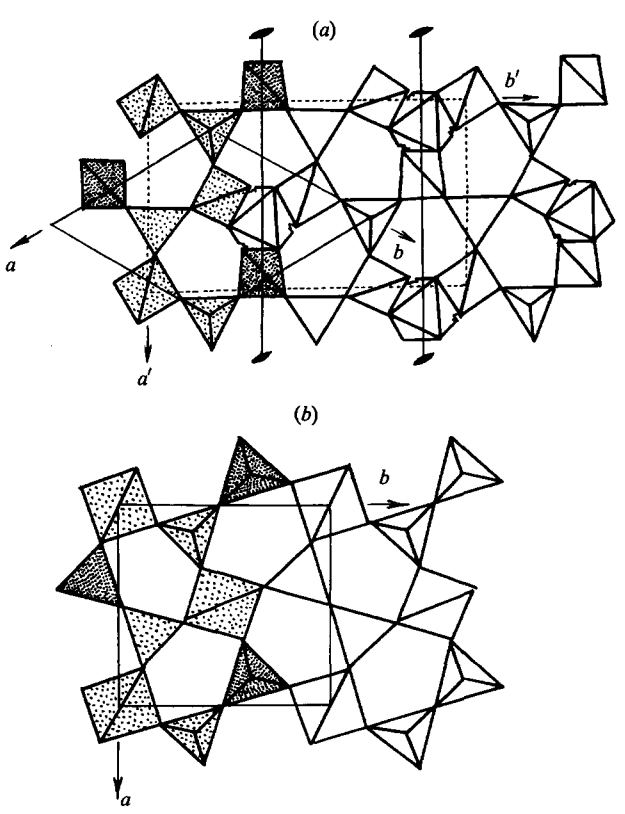

Figure 7. Comparison of the structures of $Ca_3Ga_2Ge_4O_{14}$ (*a*) and $Ca_2Ga_2GeO_7$ (*b*).

Thus the similar crystal structures involving the presence of layered elements and large cavities between them—the positions of the cations A and the impurity activator ions Nd^{3+}—made it possible to use the crystals of both structural types in lasers. Stimulated emission has been investigated.[20] According to X-ray diffraction data, crystalline $Ca_3Ga_2Ge_4O_{14}$ and $Ca_2Ga_2GeO_7$ are disordered compounds with a single activation quasi-centre.

VI. The $Pb_3GeAl_{10}O_{20}$ and $NdAlGe_2O_7$ structural types

The compound $LaSr_2Ga_{11}O_{20}$ crystallises in the $SrO-La_2O_3-Ga_2O_3$ system and its structure is similar to that of $Pb_3GeAl_{10}O_{20}$ (Table 4).[22] The results of an X-ray diffraction study showed that the Ga atoms, like the Ge and Al atoms in the structure of the prototype phase, form a mixed framework. It is made up of Ga octahedra joined into bands and Ga tetrahedra forming a highly puckered three-dimensional double-decker layer with large cavities (Fig. 8). In the tetrahedral layer, it is possible to distinguish vinogradovite bands linked in pairs by the mirror *m* planes (Fig. 8). In the cavities of the mixed framework, which has many features in common with the vinogradovite structure, there are two sites for the large La and Sr cations: sites *a* (2/*m* symmetry) at which Sr atoms are located and *i* sites (*m* symmetry) occupied isomorphously by the La and Sr atoms in proportions of 1 : 1. Calculation of the mean interatomic distances showed that a Sr–O distance of 2.691 Å is characteristic of the larger *a* cavity (distorted octahedron), whereas in the heptagon of the *i* site the mean (La, Sr)–O distance is 2.628 Å. It follows from X-ray diffraction data that the Nd^{3+} activator ion occupies the 4*i* site. The La–Sr disorder is manifested also in spectroscopic data.[22] Analysis of the parameters of the anisotropic thermal vibrations shows that the Sr atoms vibrate more freely in the *bc* plane in the intertetrahedral layer, whereas the Sr, La atoms vibrate in the direction of the *c* axis in the communicating open-network cavities (Fig. 8). The La,Sr gallate, which appears promising for use in lasers, has structural features in common with $A_3M_xT_{6-x}O_{14}$—a mixed framework made up of octahedra and tetrahedra with large cavities for identical large cations.

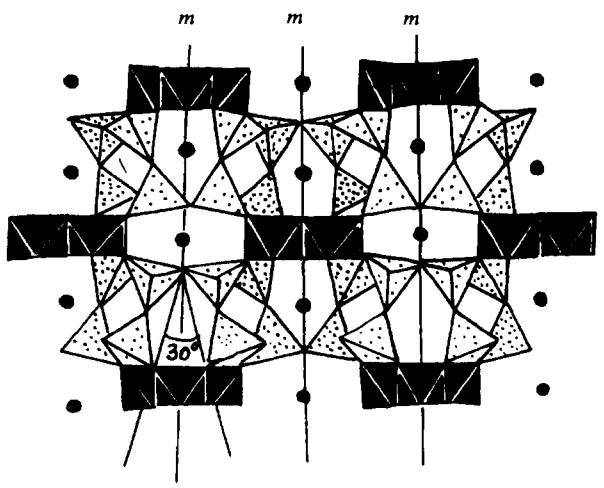

Figure 8. The crystal structure of La,Sr gallate.

Crystals of $LaGaGe_2O_7$ have been obtained in the study of the conditions for the crystallisation of $La_3Ga_5GeO_{14}$ in the $La_2O_3-Ga_2O_3-GeO_2$ system. X-Ray phase analysis[23] showed that they belong to the $NdAlGe_2O_7$ structural type. X-Ray structural study of the single crystals (Table 4) confirmed this similarity. Apart from the La gallogermanate, the Gd gallogermanate was obtained and its structure was investigated (Table 4). In the

Compound	a/Å	b/Å	c/Å	β	Space group	μr	N_{refl}	R_{hkl} (%)
$LaSr_2Ga_{11}O_{20}$	14.576(5)	11.637(3)	5.070(1)	91.27	$I2/m$	2.4	2319	4.3
$LaGaGe_2O_7$	7.307(2)	6.635(1)	12.962(4)	117.41	$P2_1/c$	2.9	3419	7.3
$GdGaGe_2O_7$	7.160(3)	6.571(2)	12.763(4)	117.5	$P2_1/c$	2.0	3212	3.8

crystal structures of both phases, the Ge tetrahedra, combined into diortho-groups, and the Ga pentagons (distorted trigonal bipyramids) form a mixed framework as in the phases investigated previously. It is possible to distinguish in them six-sided window-rings made up of two Ga pyramids and two diortho-groups $[Ge_2O_7]$ as well as four-sided window-rings made up of two tetrahedra and two Ga pyramids (Fig. 9). The lanthanide cations (La, Gd), C.N. = 9, coordinated to O atoms are accommodated in the large cavities. The interatomic distances are La–O = 2.558 Å and Gd–O = 2.481 Å. When the crystals were activated by Nd^{3+} ions, occupying the sites for the lanthanide element, stimulated emission was obtained.[23,24]

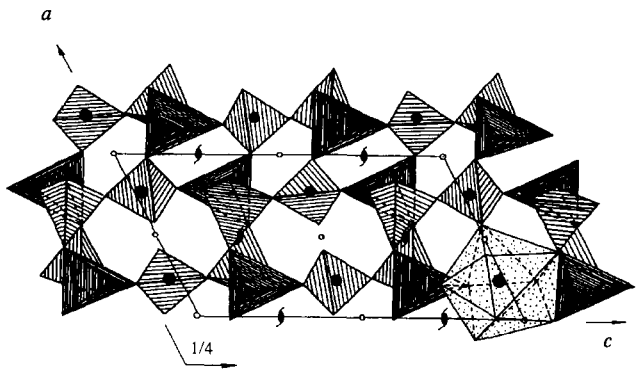

Figure 9. Projection of the crystal structure of $LaGaGe_2O_7$ onto the *ac* plane.

VII. The stillvellite–datolite structural type in the $LnBGeO_5$ series

In terms of their structures, the compounds $LnBGeO_5$ are divided into two groups: compounds with Ln = La–Pr (at low temperatures also with Nd and Eu), which crystallise with the structure of the type of the mineral stillvellite $CeBSiO_5$; the compounds with Ln = Nd–Er and Y (with Nd–Eu in the high-temperature form) have a monoclinic structure, which was assumed similar to that of stillvellite before a structural study had been carried out.

The crystal structures of $LaBGeO_5$ and $NdBGeO_5$ have been investigated.[25] The stillvellite structural type with the $P3_1$ polar space group has been confirmed for $LaBGeO_5$ (Table 5). In a study of the structure of stillvellite, it had been noted earlier[26] that it has a pseudosymmetry corresponding to the space group $P3_121$ but photographic experimental data and extremely limited diffractometer data cast doubts on the correctness of the choice of the space group $P3_1$ and precluded the determination of the deviations from the pseudosymmetry. The determination of the crystal structure of $LaBGeO_5$ made it possible to achieve this.

The positions of the heavy La and Ge atoms are very similar to the specific positions on the twofold axes in the space group $P3_121$,[24] in which the O(1, 2) and O(3, 4) atoms are linked in pairs by the twofold axes. The B and O(5) atoms are furthest away from the postulated specific positions on the twofold axes of the space group $P3_121$ and remain independent (Fig. 10). According to the literature,[27–29] the phase transition observed at T_c = 530 °C may correspond to the phase transition from the space group $P3_1$ to the space group $P3_121$ with loss of polarity by the crystals but with retention of acentricity. We may note that deviations from pseudosymmetry are significant for all the atoms in the $LaBGeO_5$ structure at room temperature and appreciably exceed the errors.[25]

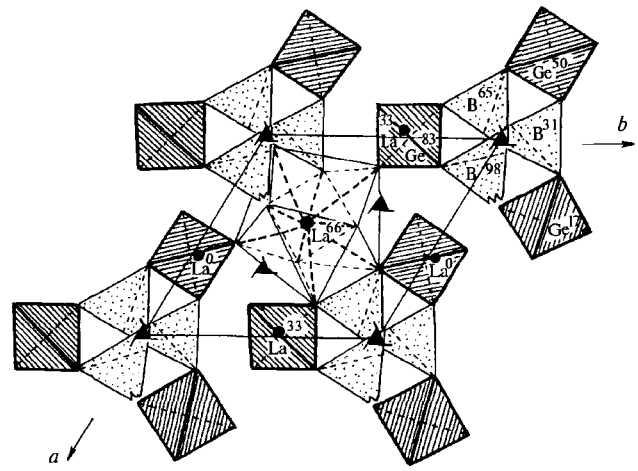

Figure 10. Projection of the crystal structure of $LaBGeO_5$-stillvellite onto the *ac* plane.

The $P3_1$–$P3_121$ phase transition belongs to the class of second-order phase transitions of the displacement type. The $LaBGeO_5$ structure can be described as made up of columns of La nonagons and Ge tetrahedra (Fig. 10) extended along the c axis. Chains made up of $[BO_4]$ tetrahedra, forming together with the Ge tetrahedra the $[BGeO_5]$ chain radical, are extended between the columns in the same direction along the c axis.[26] In an independent accurate study of the crystal structure of stillvellite,[30] difficulties were noted in refining the positional and thermal parameters of the O(5) atom and additional electron density peaks in the vicinity of this atom were observed. The authors[30]

Table 5. X-Ray diffraction characteristics of the $LaBGeO_5$ phases investigated with structures of the stillvellite and datolite types.

Compound	a/Å	b/Å	c/Å	β	Space group	μr	N_{refl}	R_{hkl} (%)
$LaBGeO_5$	7.020(5)	–	6.879(4)	–	$P3_1$	0.95	1407	2.9
$NdBGeO_5$	10.048(20)	7.610(10)	4.964(7)	92.0	$P2_1/a$	3.00	2367	3.0

concluded that the crystal investigated is twinned and is obtained as a result of rotation about an axis along the [110] direction. The polar individuals are linked in opposite directions along the c axis, their volumes amounting to 0.605 and 0.395 respectively.

Numerous studies of the physical properties of the $LaBGeO_5$ crystal, in particular the laser, nonlinear optical,[31] and ferroelectric[28,29] properties, have shown that this material possesses all three properties. For example, the intensity of the generation of the second harmonic in this crystal exceeds by a factor of 50 the intensity in $La_3Ga_{5.5}Nb_{0.5}O_{14}$ (see above). The possibility of obtaining large high-quality single crystals from the melt constitutes an advantage of $LaBGeO_5$ over, for example, other likely materials for the creation of effective lasers with self-multiplication of the lasing frequency, such as $LiNbO_3$ and $YAl_3(BO_3)_4$ with Nd^{3+}. Structural data make it possible to explain the occurrence of the spontaneous polarisation P_s in the given crystal and its ferroelectric properties.

The crystal structure of $NdBGeO_5$ differs from that of stillvellite[25] but is close to the structure of another natural borosilicate—datolite $CaBSiO_4(OH)$ and it involves the replacement in the latter of Ca by Nd, of Si by Ge, and of OH^- by O^{2-}. It can be described as a layered structure (Fig. 11) in which the large-cation layers alternate with tetrahedral layers along the c axis. Tetrahedral layers, the structure of which is similar to that of the datolite layers, are also present in melilite, the structural type of which was described above. A similarity between the melilite and $A_3M_xT_{6-x}O_{14}$ layers was noted at the same time (Fig. 7). The Nd and Ca coordination polyhedra are identical—they are all the same Thompson cubes. As regards the manifestation of physical properties, the presence of the centrosymmetrical space group for members of the lanthanide series ranging from Nd and beyond rules out the nonlinear optical and ferroelectric properties, but the possibility of the manifestation of laser properties is retained.

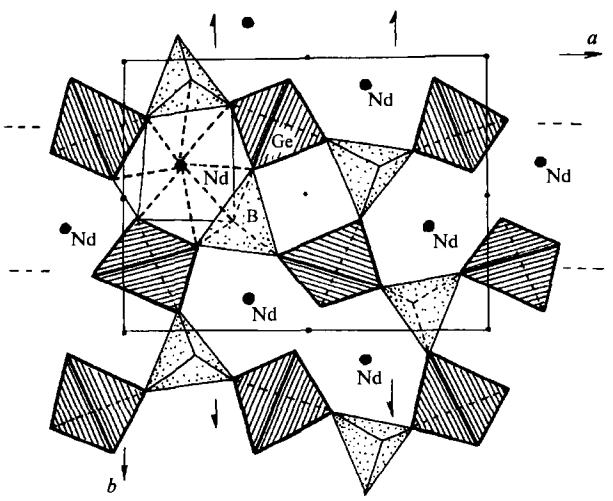

Figure 11. Projection of the crystal structure of $NdBGeO_5$-datolite onto the *ab* plane.

Two polymorphic modifications of $LnBGeO_5$—the chain (stillvellite) and layered (datolite) modifications—have significantly different structures. The polymorphism of $LaBGeO_5$ is associated with the variation of the sizes of the Ln^{3+} ions (the lanthanide contraction). The stillvellite structure is characteristic of compounds with large ions accommodated in coordination polyhedra (nonagons), whereas for members of the series with smaller ions, the stability of the stillvellite structure diminishes and in the datolite structure the coordination polyhedra are octagons—Thompson cubes. Both structures obtain for cations of average size ($Nd^{3+}-Eu^{3+}$).

The sharp difference between the structures of the two polymorphic modifications of $LnBGeO_5$ is manifested in absorption luminescence spectra.[25] In both structures, the Nd^{3+} ions form activator centres of the same type. On the other hand, the coordination numbers, coordination polyhedra, and the symmetries of sites differ markedly in the structures of these centres. In conformity with the structural results, the spectroscopic data show that both phases belong to the class of simple crystals with an ordered structure.

VIII. Lanthanide borates with the huntite structure and their polytypic derivatives

The compound $YAl_3(BO_3)_4:Nd^{3+}$ with the huntite $CaMg_3(BO_3)_4$ structure already attracted the attention of investigators a long time ago—since the beginning of the 1960s. The crystals of Y,Al-huntite possess a combination of laser and nonlinear optical properties.

Studies on the solution-melt crystallisation of the Y, Al borate made it possible to obtain crystals of this compound of satisfactory quality; structural studies have been carried out for the compounds $NdAl_3(BO_3)_4$[32] and $GdAl_3(BO_3)_4$,[33] directly for $YAl_3(BO_3)_4$,[34] and also for $NdGa_3(BO_3)_4$[35] and $(Nd,Bi)Fe_3(BO_3)_4$.[36] It was observed that, apart from the huntite modification,[34–36] further monoclinic high-temperature modifications[32,33] are characteristic of $LnAl_3(BO_3)_4$. They were investigated in relation to $NdAl_3(BO_3)_4$ and $GdAl_3(BO_3)_4$. The crystallisation regions of the high-temperature modifications of the neodymium and gadolinium borates differ appreciably. The high-temperature monoclinic modification of the Nd,Al borate is stable over a wide temperature range (from 870 to 1150 °C). The high-temperature monoclinic modification of Gd,Al borate was noted in the crystallisation of highly supersaturated solution-melts at a temperature above 1060 °C. It was shown[5] that the two monoclinic modifications of Nd,Al and Gd,Al borates are different polytypic modifications having the same parameters a and b but different parameters c, structures, and space groups (Table 6).

In the rhombohedral cell of huntite, it is possible to select the monoclinic C cell in accordance with familiar rules. One of the $a(b)$ axes of the trigonal cell then becomes the monoclinic axis, one of the R translations becomes a C translation, and the a and c axes with the corresponding angle β may be selected on the basis of the R lattice sites in the plane perpendicular to b. In both monoclinic borates, it is possible to select cells with the same monoclinic angle β in which the parameters c'_2 and c'_3 are greater by factors of 2 and 3 respectively than the parameters c'_1 of the huntite modification ($c'_1 = 5.9$ Å) considered in the monoclinic aspect.

Dornberger-Schiff[37] devised a theory of OD structures the symmetry relations of which have been applied widely and clearly for the description of the characteristics of polytypic structures with differentiation of one or more types of layers and consideration of different kinds of neighbours. Thus it is possible to differentiate layers of two types (L_{2n} and L_{2n+1}; Fig. 12) in the monoclinic cells of three modifications of lanthanide borates (huntite, Nd,Al and Gd,Al borates). The layers of the first type (L_{2n}) are made up of pairs of edge-linked Al octahedra combined by B triangles into a layer. The formula of the layer is $[Al_2B_2O_{10}]$ and its symmetry is higher than that of each structure and can be described in terms of the $C2/m$ symmetry group. Layers of the second type (L_{2n+1}) are made up of Ln trigonal prisms and Al octahedra linked via their apices into columns extended along the a axis; the columns are also bound by the B triangles. The formula of the layer is $[LnAlB_2O_{10}]$ and its symmetry is $C2$. When two layers are combined in the structure, sixteen oxygen atoms are shared and a compound with the formula $LnAl_3B_4O_{12}$ is obtained. The subsequent odd L_{2n+1} layers are obtained from the initial layer by multiplication involving symmetry operations on the even L_{2n} layers: by the twofold axes in the case of huntite, by the centres of symmetry $\bar{1}$ in the case of Nd,Al borate, and by the twofold axes and the centres of symmetry $\bar{1}$ simultaneously with the

Table 6. X-Ray diffraction characteristics of the $LnAl_3(BO_3)_4$ phases investigated.

Compound	a/Å	b/Å	c/Å	β	Space group	μr	N_{refl}	R_{hkl} (%)
$YAl_3(BO_3)_4$	9.295(3)	–	7.243(2)		$R32$	0.8	450	3.7
$NdGa_3(BO_3)_4$	9.500(1)	–	7.502(2)		$R32$	2.0	464	3.0
$(Nd_{0.5}Bi_{0.5})Fe_3(BO_3)_4$	9.587(3)	–	7.608(2)		$R32$	2.4	654	3.9
$NdAl_3(BO_3)_4$	7.262(3)	9.365(3)	11.138(7)	103.41	$C2/c$	1.4	3641	5.0
$GdAl_3(BO_3)_4$	7.262(3)	9.315(3)	16.184(4)	90.37	$C2$	1.5	5063	5.2

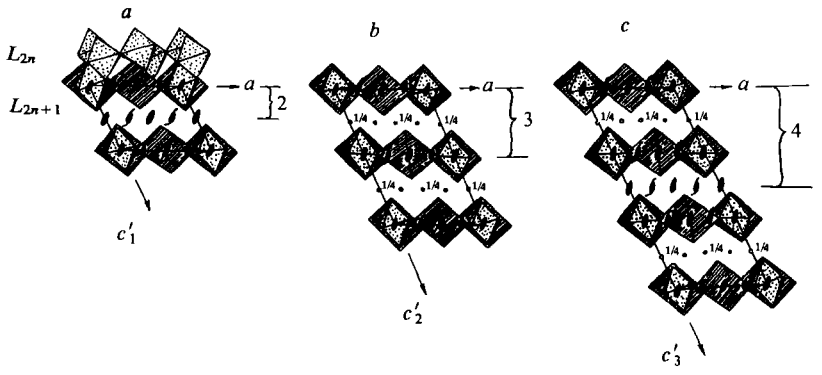

Figure 12. Polytypic diversity in the family of Ln,Al borates: (*a*) huntite (222...); (*b*) the Nd,Al modification ($\bar{1}\bar{1}\bar{1}$...); (*c*) the Gd,Al modification ($\bar{1}\bar{1}2\bar{1}\bar{1}2$...).

$\bar{1},\bar{1},2,\bar{1},\bar{1}$... alternation in the case of Gd,Al borate. Thus the odd layers in the structures with the C_2 symmetry are multiplied by the $C2$ and $C\bar{1}$, subgroups belonging to the $C2/m$ group of the even layer.

L_{2n}	L_{2n+1}
$[Al_2B_2O_{10}]$	$[LnAlB_2O_{10}]$
C 1 2/m (1)	C 1 2 (1)
[P 1 2 (1)]	[C 1 2/$\bar{1}$ (1)]

The result obtained expresses the operation of the familiar Dornberger-Schiff theorem, according to which the number of combinations of two layers Z is equal to the ratio of the multiplicity of the symmetry group of the initial layer N and the multiplicity F of the symmetry group of a pair of layers, i.e. $Z = N/F$. In the given case, $Z_{2(1)} = 4/2 = 2$. The sequence 222... corresponds to a structure with a period c in one pair of layers (Fig. 12, braces) — this is the huntite structure, which can be described in terms of the rhombohedral setting. The sequence $\bar{1}\bar{1}\bar{1}$... corresponds to a structure with a period c in two pairs of layers — this is the high-temperature $NdAl_3(BO_3)_4$ modification. The sequence $T\,\bar{1}\bar{1}2\bar{1}\bar{1}2$... corresponds to the third, $GdAl_3(BO_3)_4$ structure and has a period in three pairs of layers.

The different sequences of operations afford hypothetical structures with different periods and symmetries. The possible variants for 10-layer polytypes with a symbolic-literal description have been specified by Zvyagin and Belokoneva.[38]

The Laue diffraction patterns for Nd huntite, obtained (in contrast to the remaining lanthanide borates) by rapid quenching, showed, together with point reflections also distinct diffuse reflections. Out of the three equally legitimate a axes in the trigonal cell, one axis, which possesses a plane of symmetry according to the diffuse reflections, was selected. The $h0l$ and $h1l$ layer lines, corresponding to the monoclinic setting of the trigonal phase, were recorded along this axis. Distinct diffuse lines, along which the index l varies continuously, were observed on the Weissenberg diffraction pattern. Point reflections, corresponding to integral values of l for c in the huntite structure were distinguished against their background. This type of picture indicates the breakdown of a rigorous order in the alternation of layers and the existence of a disorder superimposed on the ordered structure.

It is seen from the foregoing that the decisive factors in the formation of borate polytypes and in the breakdowns of order in the latter are the crystallisation temperatures and the rate of cooling of the melt. The higher the crystallisation temperature, the more complex the polytypes. Polytypes even more complex than those established hitherto may be found among them. Strictly ordered polytypes are formed on slow cooling, while at a high cooling rate a nonordered structure also arises against the background of the simplest ordered structure (as in trigonal huntite)

The nature of the lanthanide element also plays a definite role in polytypicism. It has been noted[39] that the statistics of the morphotropic transitions in tetrahedral compounds (silicates, germanates, phosphates) with lanthanide elements makes it possible to differentiate a single common region around Nd (in the case of germanates this also applies to Gd). The $LnBGeO_5$ and $LnAl(BO_3)_4$ series provide a good illustration of the empirical rule noted above. The reason for it is the magnitudes of the ionic radii of the lanthanide elements.

The phase transitions between the polytypic modifications examined above, which occur at different temperatures and sometimes coexist (for example, in the case of Pr, Al borate[40]) are second-order phase transitions of the 'order–disorder' type and are accompanied by very slight changes in structure.

Structural studies made it possible to account for the absence of nonlinear optical properties in $NdAl_3(BO_3)_4$, unlike $YAl_3(BO_3)_4$, and also for the impairment of their laser properties†. The former is associated with the presence in the Nd,Al borate crystals of the monoclinic centrosymmetric space group $C2/c$, while the latter is associated with the polytypic nature of the phases, which entails a tendency towards disorder and inhomogeneity in the crystal, particularly with increase in the crystallisation temperature.

IX. The $KTiOPO_4$ structural type

Potassium titanyl phosphate $KTiOPO_4$ (PTP) is nowadays one of the most effective nonlinear optical crystals.[1] The germanate and silicate analogues of $KTiOPO_4$ having the general formula

† In all the crystals, the positions of the activator ions correspond to the positions of Ln or Y.

Table 7. X-Ray diffraction characteristics of the phases investigated with structures of the $KTiOPO_4$ type.

Compound	a/Å	b/Å	c/Å	Space group	μr	N_{refl}	R_{hkl} (%)

$AMOXO_4$ (A = Na, K, Rb, Tl, Ag; M = Sb, Ta; X = Ge, Si) have been obtained recently and their structures have been investigated.[41,42] On the basis of results of measurements of the temperature dependence of the generation of the second harmonic of laser radiation[7] (Fig. 13), as well as dielectric and microcalorimetric studies,[43] the phase transitions were assigned to the class of second-order transitions. The possibility of a weak first-order transition has also been considered for $TlSbOGeO_4$ and $AgSbOSiO_4$.[44,45] The Curie points T_c, determined by various methods, agree satisfactorily and the entire group of compounds has as a whole significantly lower T_c than the phosphates and arsenates known up to that time.

The study of the phase transitions in new compounds of the $KTiOPO_4$ structural type makes it possible to discover the structural features responsible for the ferroelectric and nonlinear optical properties. According to the results of measurements of second harmonic generation (SHG), the crystal structures of K,Sb germanate, Rb,Sb germanate, K,Ta germanate, and also $NaSbOGeO_4$ obtained from $KSbOGeO_4$ by ion exchange in a $NaNO_3$ melt (the sold-phase synthesis affords a sphene structure) proved to be polar (Table 7) like that of $KTiOPO_4$.[41,45–47] According to the results of French investigators,[48,49] Na, Sb and K, Sb silicates are also polar at room temperature with the space group $Pna2_1$.

The study of the crystal structures of $KFeFPO_4$ and $KSnOPO_4$ showed that the mixed framework made up of Fe(Sn) octahedra and P tetrahedra possesses a pseudosymmetry corresponding to the space group *Pnan* (Fig. 14).[50,51] It follows from this that there is a possibility that a highly symmetrical prototype phase may exist. SHG measurements have shown[7] that Tl, Sb germanate should have the structure of the centrosymmetric modification at room temperature, since T_c = 272 K for this compound.

The structure of $TlSbOGeO_4$ at room temperature has been investigated by Belokoneva and Mill'[52] and then reinvestigated by Belokoneva et al.[53] Within the framework of the *Pnan* group, the position of the Tl atom was found to be split (the Tl – Tl′ distance is 0.6 Å for populations of 0.65 and 0.35 respectively). The splitting of the positions of the cations in the large cavities of the mixed framework made up of M octahedra and P tetrahedra was first established for $KFeFPO_4$ and $KTiOPO_4$, where additional split positions were noted for the K(1) and K(2) atoms but with significantly smaller populations: 0.1 (in the additional position) compared with 0.9 (in the main position).[50] Crystal-chemical analysis showed that the splitting originates from the main positions along the direction of two additional pseudosymmetrical positions (Fig. 14).[52]

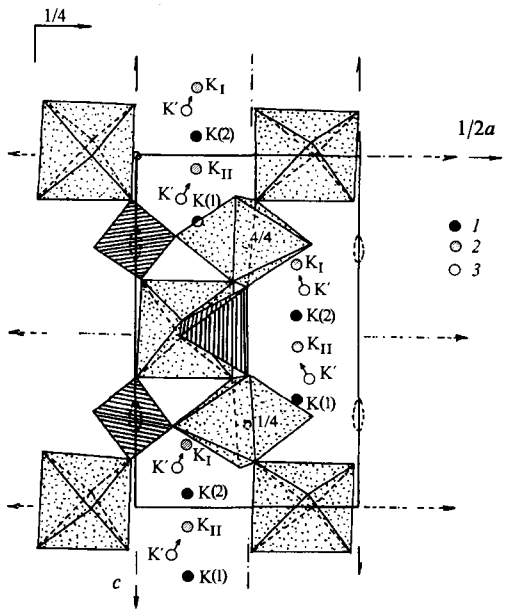

Figure 14. The pseudosymmetry of the framework in $KTiOPO_4$-like phases. The continuous lines represent the true symmetry elements of the space group $Pna2_1$, while the dashed lines represent the symmetry pseudoelements of the space group *Pnan*: (*1*) principal positions of K atoms; (*2*) additional positions; (*3*) unoccupied pseudosymmetrical positions.

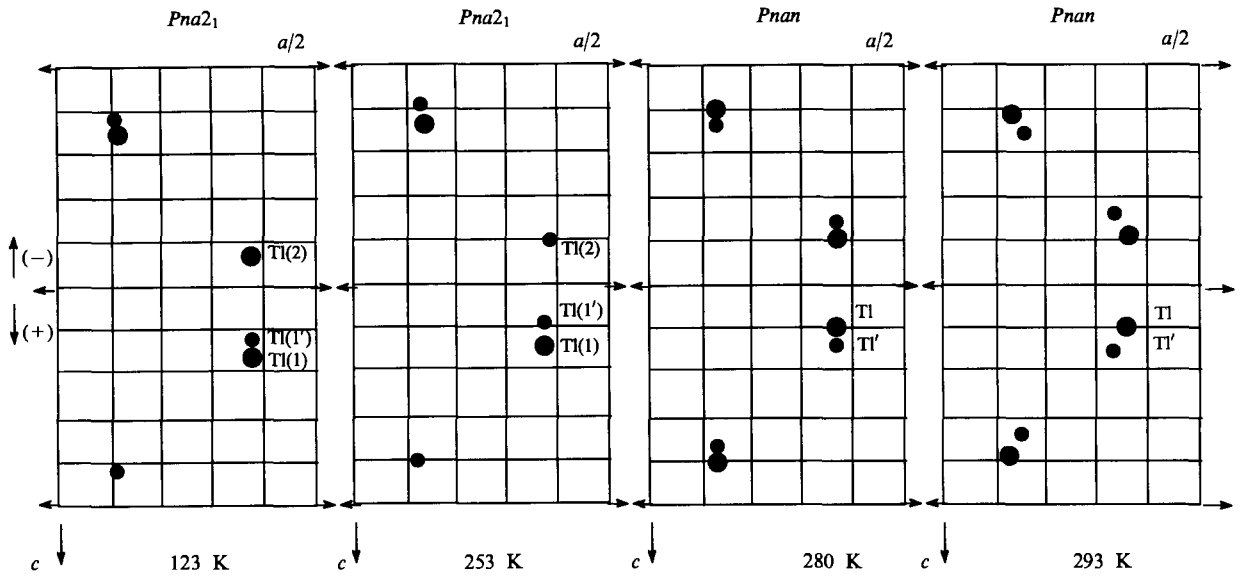

Figure 15. Disposition of Tl atoms at four temperatures in the $TlSbOGeO_4$ structure. The true axes in the space group *Pnan* and the twofold pseudoaxes in the space group $Pna2_1$ are shown at the 1/2 level on the *c* axis (at 123 and 253 K).

For the $TlSbOGeO_4$ crystal structure, the polar modification should exist also at a low temperature. It was expected that the Tl atoms would then be displaced from their positions in the structure to form an acentric modification. In order to determine the polar modification of the Tl, Sb germanate, low-temperature studies were carried out. At 123 K, the structure did indeed prove to be acentric[53] and the maximum displacement [to a greater extent for Tl(2) than for Tl(1)] was ~0.8 Å.

It was of interest to follow the dynamics of the phase transformation in the vicinity of the Curie point (272 K). For this purpose, a low-temperature X-ray diffraction experiment was carried out at 253 K. A study was also made of the structural state at 280 K, corresponding to an intermediate point between T_c and a second extremum at 286 K, observed in measurements of the relative permitivity and the electrical conductivity of $TlSbOGeO_4$ single crystals.[44] The results of the measurements and structural calculations at the above four temperatures are presented in Fig. 15 and Table 7.[53,54] The positions of the Tl atoms and the positions symmetrical to them in the two modifications are linked by either a true twofold axis or a twofold pseudoaxis. The distances from the ½ level along the *c* axis, (+) and (−), are given in Table 8. It is seen from the data in Table 8 that, compared with room temperature, the populations of the positions at 280 K remain unchanged, the atoms being slightly displaced towards the twofold axis. Overall, the structure determined from the system of sharp reflections (diffuse ring reflections with a texture similar to that of metals were also observed on the rocking X-ray diffraction pattern) retains the centrosymmetric space group and its principal characteristics. At 253 K, after passage through T_c = 272 K, the space group changes and becomes acentric, one of the Tl positions (−) is no longer split and the (+) and (−) distances are not strictly equal (Table 8), although they are in fact similar to one another [Tl(2) and Tl(1′)] and to the distances for the Tl and Tl′ positions at 280 K. The populations of the Tl−Tl′ positions (280 K) and Tl(1′)−Tl(1) positions (253 K) also change. With decrease in temperature, the polarity of the *c* axis increases owing to further displacement of the Tl atoms. The difference between the (+) and (−) distances increases and is now appreciably different from that in the initial (293 K) state (Table 8). As mentioned above, the overall shift is ~0.8 Å. The thermal corrections for the Tl and O atoms at 253 K indicate the instability of the structure near the phase transition.

One may conclude that the thallium atoms are most responsible for the paraelectric⇆ferroelectric phase transitions. The calculated displacements of the remaining atoms of the structure are an order or two orders of magnitude smaller.[54] The phase transitions are most probably mixed second-order phase transitions, being simultaneously of the displacement and order–disorder type, since not only are the thallium atoms displaced but there is a change in the splitting of the positions and their populations [Tl(1) ⇆ Tl(1′)]. The appearance of structural polarity along the *c* axis is directly responsible for the occurrence of the spontaneous polarisation P_s in the same direction, which has been attributed to the manifestation of ferroelectric and nonlinear optical properties. We may note that a high ionic conductivity is characteristic of $TlSbOGeO_4$.

Such treatment of the structural transformations is consistent with the approaches developed by Abrahams[2] in order to account for the structure–ferroelectric properties relation. The Abrahams–Kurtz–Jamieson (AKJ) criterion relates the square of the maximum displacement of the atom along the polar direction from the position with zero spontaneous polarisation to the

Table 8. The distances between the Tl atoms in $TlSbOGeO_4$ and the true twofold axis or twofold pseudoaxis.

Atom	Space group $Pna2_1$		Atom	Space group *Pnan*

Tl(1)	+0.1562 (1.68)	+0.1464 (1.58)	Tl′	+0.1441 (1.55)	+0.1502 (1.62)

Note. Values expressed as fractions of the cell are quoted, the same values in Ångstroms being given in brackets.

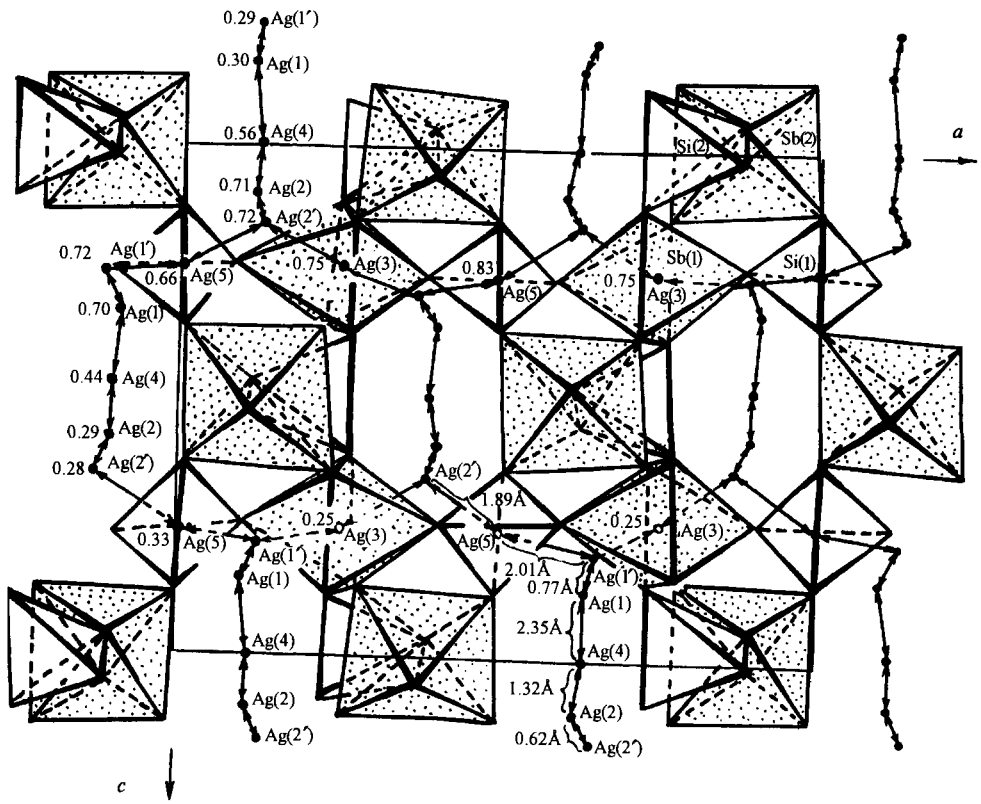

Figure 16. The cation migration pathways in $AgSbOSiO_4$ (projection onto the *ac* plane). The heights of the atoms and the distances between the positions in the independent increment are shown.

Curie point T_c.[2] According to this criterion, the group of germanates investigated, belonging to the $KTiOPO_4$ structural type and having in the polar state a higher pseudosymmetry than $KTiOPO_4$ and other phosphates and arsenates, should be distinguished by smaller atomic displacements in phase transitions and should have a correspondingly lower Curie point T_c, which has in fact been observed in measurements.

The higher pseudosymmetry and the very slight distortion of the octahedra in the germanates investigated (with which the non-linear optical properties are traditionally associated) compared with the Ti octahedra in $KTiOPO_4$ are responsible for the significantly lower intensity of the SHG signal in these compounds than in 'record holders' such as $KTiOPO_4$ and $KTiOAsO_4$.

The results of the study of the $AgSbOSiO_4$ structure (Table 7) constitutes an extremely remarkable example confirming that the cations in compounds of the given structural type are responsible for the course of the phase transitions and the ionic conductivity. Like $NaSbOGeO_4$ crystals, those of $AgSbOSiO_4$ have been obtained by ion exchange in a nitrate melt.[45] Despite the clear acentricity of the structure at room temperature, both positions, Ag(1) and Ag(2), are split, the components having similar populations, as in the case of $TlSbOGeO_4$, i.e. the Ag atoms occupy virtually all four possible positions[50,55] for cations in the cavities. The electron density difference maps unexpectedly show peaks at positions corresponding to cavities joining the large cavities within the skeleton, i.e. to passages between the tetrahedra and octahedra and also at the centres of the largest cavities between the four positions occupied by cations. This made it possible to discover the real ion-exchange channels. Previously their existence in structures of the $KTiOPO_4$ type was merely postulated in view of the manifestation of ion-exchange properties by the latter.[56]

Fig. 16 illustrates the ion-exchange channels in the $AgSbOSiO_4$ structure. The Ag(5) position, located in the widest passages between the tetrahedra, is populated to the greatest extent in the structure (population coefficient $f = 0.07$). Some of the silver atoms have 'settled' at the centres of the cavities at the Ag(4) position ($f = 0.04$). Traces of silver have been detected also at the Ag(3) position ($f = 0.01$) in the narrower passages between the more bulky octahedra (compared with tetrahedra). Accordingly, the populations of the three principal positions of the Ag atoms in the structure are found to be deficient.

The schematic representation of the potential relief profile in Fig. 17 for the principal conductivity channel along the *c* axis

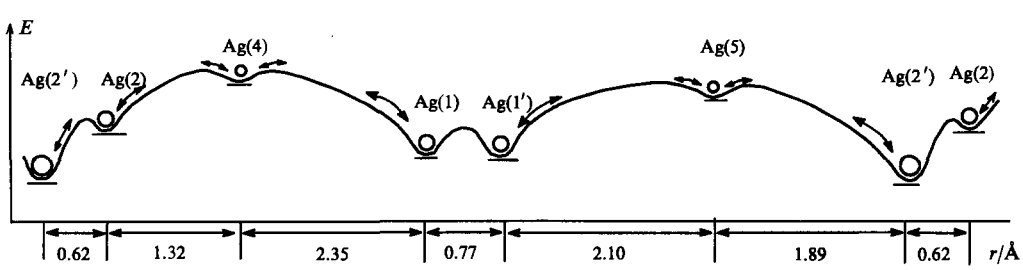

Figure 17. Schematic profile of the potential relief of the main ion-exchange channel in the $AgSbOSiO_4$ structure.

(a second possible path is along the *a* axis; there is no path along the *b* axis) illustrates the jumps of Ag atoms during ion migration. This state is unstable and one may expect that, for example on heat treatment of the crystals, the Ag(3, 4, 5) positions will be vacated.

Annealing of the specimens with subsequent quenching and slow cooling yielded interesting results. Slow cooling from 973 K leads to the same polar structure but with vacated Ag(3, 4, 5) positions and with some redistribution of the silver atoms relative to the initial ion exchange state at the main positions.

Fixation by quenching at 673 K afforded the high-temperature centrosymmetric modification. In contrast to the positions of the Tl atoms in $TlSbOGeO_4$, the positions of the Ag atoms in $AgSbOSiO_4$ (space group *Pnan*) are hardly split (f = 0.02) (Fig. 18). The population of the position corresponding to the tetrahedral passage diminished appreciably and the positions at the centre of the cavity and between the octahedra were vacated.

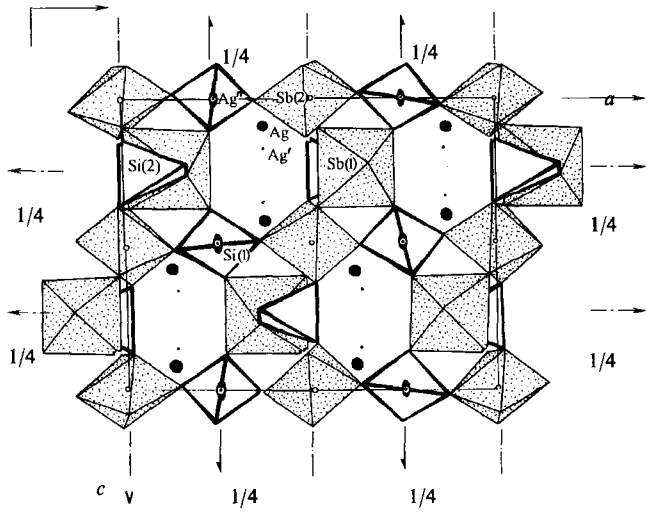

Figure 18. Projection of the centrosymmetric modification of $AgSbO.SiO_4$ onto the *ac* plane after annealing at 673 K and quenching. The positions of the Ag atoms and the symmetry elements of the space group *Pnan* are shown.

The course of the phase transformations in $AgSbOSiO_4$ is also reflected in Fig. 19, where the state at 293 K and that quenched at 673 K are the extreme possible states, while the state obtained on slow cooling from 973 K is intermediate. The Ag(2′)–Ag(2′)–Ag positions populated to the maximum extent are retained together with the Ag(1)–Ag(1)–Ag positions. The Ag(1) position (973 K) begins to split only on cooling, but does not return to the initial state Ag(1′) at 293 K. The pseudosymmetry of the crystal annealed at 973 K is much higher than the pseudosymmetry of the crystal cooled to 293 K. This is also seen from the comparison of the coordinates of the (+) and (−) positions of the Ag atoms, as for the Tl atoms in the case of $TlSbOGeO_4$.

This confirms the conclusion reached previously for the Tl compound that the disposition of the cations in the cavities of structures of the $KTiOPO_4$ type is the principal determinant of their symmetry and hence of their properties. X-Ray diffraction studies[55] made it possible for the first time to locate the pathways followed in the migration of the cations in structures of the $KTiOPO_4$ type and to explain the preferred conduction along the *c* axis, the weak conduction along the *a* axis, and its absence along the *b* axis.

A tetragonal pseudosymmetry is also characteristic of $KTiOPO_4$, which had been noted already by Tordjman et al.[57] The tetragonal modification has also been detected[58] for the compound $K(Mg_{1/3}Nb_{2/3})PO_5$. The results make it possible to conclude that the isomorphous substitutions play an important role in the manifestation of nonlinear optical properties, in particular that they are sharply impaired when Mg atoms are incorporated in the structure.

X. The sphene (titanite) structural type

As already mentioned above, the solid-phase synthesis of $NaSbOGeO_4$ leads to the sphene structure. This indicates a similarity of the regions corresponding to the existence of these two structural types. Among the four crystalline sphene structures (Table 9), only one has the $P2_1/c$ space group characteristic of the low-temperature modification. Note that $LiTaGeO_5$ has in addition a strongly pseudohexagonal symmetry[59] ($KTiOPO_4$-like phases have a pseudotetragonal symmetry). The formation of high-pressure modifications at

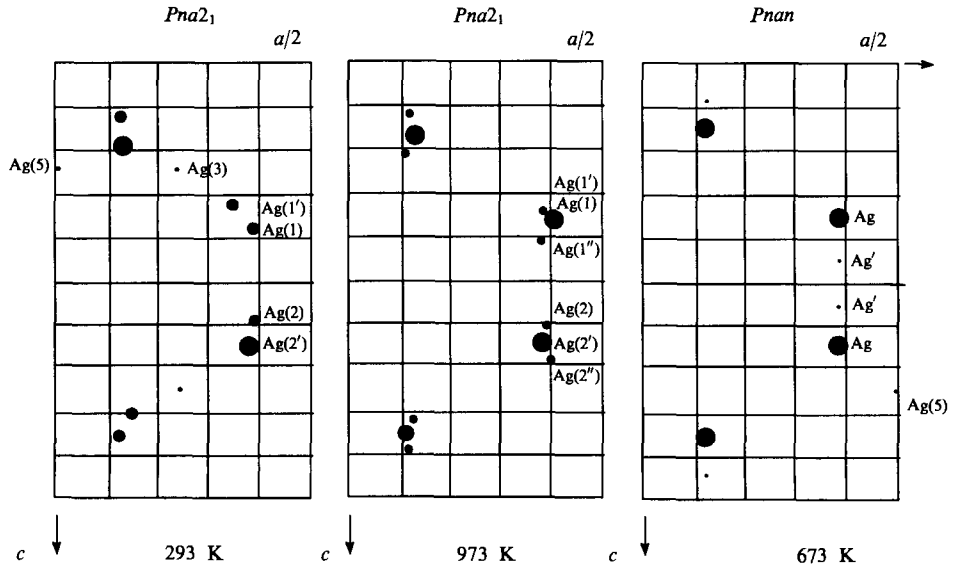

Figure 19. Disposition of the Ag atoms in the $AgSbOSiO_4$ structure at three temperatures.

Table 9. X-Ray diffraction characteristics of the phases investigated with structures of the sphene and sillimanite types.

Compound	a/Å	b/Å	c/Å	β	Space group	μr	N_{refl}	R_{hkl} (%)
$NaNbGeO_5$	6.798(4)	8.913(3)	7.523(2)	115.42	$P2_1/c$	0.7	2445	2.6

pressures significantly lower than for silicates is characteristic of germanates. The high-temperature modifications are formed with a $KTiOPO_4$ type of structure at much lower temperatures than, for example, those of phosphates. The sphene germanates also crystallise preferentially with the space group $C2/c$ (the high-temperature modification). The reason for this is the unusual crystal-chemical properties of the Ge atoms (large ionic radius, smaller electronegativity compared with Si), which are manifested, in particular, by the much greater ease of the formation of compounds with Ge atoms in the octahedra.

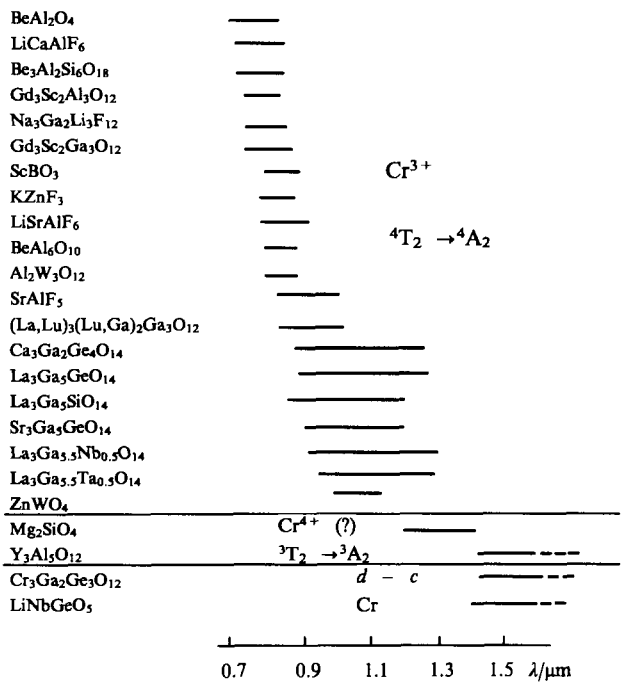

Figure 20. The spectral ranges corresponding to the retuning of the lasing wavelength for chromium-containing laser crystals.[61]

In the study of niobium-containing compounds, it was observed that the compound $LiNbGeO_5$ crystallises in the fairly unexpected sillimanite (Al_2SiO_5) type structure. The two structures are similar, when account is taken of the replacement of Li by Al, of Nb by Al, and of Ge by Si and of the change in the symmetry space group. Chains of Nb, Sb, and Ta octahedra, equivalent to the Ti octahedra in natural sphene, are differentiated in the $LiNbGeO_5$ structure, as in the sphene structure. According to the spectroscopic data of Dutch investigators[60] as well as our own data,[61] stimulated emission can be excited from $LiNbGeO_5$, especially in the presence of a Cr^{3+} admixture. Consequently, this crystal can be used in lasers. The spectroscopic characteristics of 24 chromium-containing compounds (Fig. 20) and of well known laser crystals (Y,Al and Gd, Sc garnets, fluorides, and oxides) and of the new phases examined in the present review have been compiled and compared.[61]

XI. Germanate-zeolites and zeolite-like germanates

In a study of compounds which are potential ferroelectric materials, Abrahams[2] considered also the crystal structure of natural cancrinite (space group $P6_3$). The germanium analogue of cancrinite was obtained by hydrothermal synthesis. Whilst retaining the size of the unit cell and the space group (Table 10), the synthetic Ge-cancrinite contains the octahedral $Ge(OH)_6^{2-}$ group instead of CO_3 (Fig. 21).[4] The positions occupied in the lattice by the Ge, Al, O(1, 2, 3, 4) as well as Na(1, 2) atoms are completely filled while the Ge^{VI} position is half-filled. The change in coordination from plane-trigonal for the C atom to octahedral for the Ge atom following the replacement of CO_3 by $Ge(OH)_6^{2-}$ induces a slight shift of the Ge atom from the position occupied by the C atom on the c axis. The positions of the water molecules in the structure have also been determined. It was found that the large cavity-channels along the c axis ensure the ion-exchange properties of the synthetic cancrinite. In natural cancrinite, these cavities are blocked by OH groups, while in the synthetic Ge-cancrinite the cavity is occupied by the $[Ge(OH)_6]^{2-}$ groups, which are, as it were, trapped by the structure—the $Ge(OH)_6$ octahedra had been observed earlier in the mineral stottite $Fe[Ge(OH)_6]$. Thus the synthetic germanium cancrinite possesses ion-exchange properties and is a potential ferroelectric material.

Table 10. X-Ray diffraction characteristics of the zeolite-germanates and zeolite-like germanates investigated.

Compound	a/Å	b/Å	c/Å	Space group	μr	N_{refl}	R_{hkl} (%)

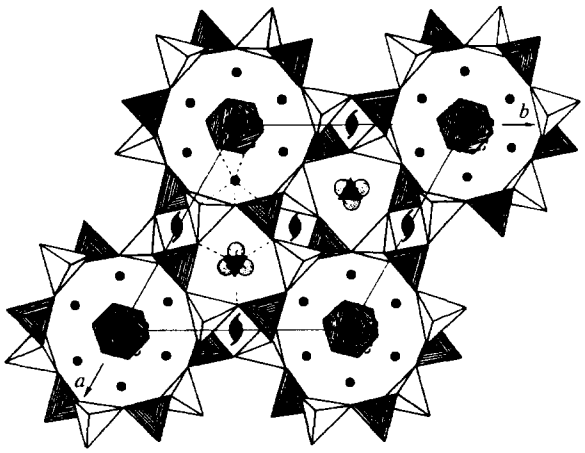

Figure 21. Projection of the structure of Ge-cancrinite onto the *ab* plane.

Sodalite also has germanium analogues (Table 10)[62,63] in which the positions of the Al, Na, and O (1, 2) atoms are retained while the Si atom is replaced by Ge. In the Ge-hydrosodalite, the OH groups of the natural mineral have been displaced from the 2*a*(000) positions of the Cl atoms to the 8*e*(*xxx*) positions and, for a statistical distribution, there is one OH group per cavity. The positions of the Br atoms are identical with those of the Cl atoms. Isomorphous substitutions in the anionic component makes it possible to improve the cathodochromic properties. Sodalites may prove promising for use where crystals with electrooptical and piezoelectric properties are required.[63]

Zeolites having the composition $M_3HGe_7O_{16} \cdot 4H_2O$ were described by Novotnyi[64] as early as 1958. It was noted that the combination of Ge octahedra and tetrahedra leaves room for large channels in the direction of coordinate axes, while the alkali metal cations are distributed statistically. This accounts for the zeolitic properties of these phases. The Ge-zeolite investigated (Table 10) contains the atoms of potassium as the metal, the deficiency of K atoms being compensated by the excess number of H atoms (or H_3O^+ groups).[65] The structural type of the Ge-zeolite belongs to the leucophosphite–pharmacosiderite group. Thus the crystal structure of $Cs_3Mo_4P_3O_{16}$ in this family[66] may be compared with the structure of $K_3Ge_7O_{16} \cdot 4H_2O$ (investigated by Sturua et al.[65]), where the positions of the Ge(2) atoms in the octahedron have been occupied by Mo atoms, while those of the Ge(1) atoms in the tetrahedron have been occupied by P atoms. The Cs atom is at the centre of the large channels. The diameters of the channels are ~5 Å in the $Cs_3Mo_4P_3O_{16}$ zeolite, exceed 6 Å in cancrinite, and are ~4 Å in sodalites.

We shall examine a further three structures of germanates and a silicate having the general formula $AMTO_5$ with the alkali metals A = K, Rb or Cs, M = Nb or Sb, and T = Ge or Si. Whilst differing in symmetry (Table 10), all three crystals have one feature in common, namely the large cavities in which the A atoms are accommodated. These cavities communicate with one another via channels which facilitate the ion-exchange in these compounds.

In the orthorhombic $RbNbSiO_5$[67] containing the chain radical $[Si_3O_9]_\infty$, the mixed framework $\{Nb_3[Si_3O_9]\}^{6-}$ was obtained by combining the three-dimensional bands of Nb octahedra with Si chains (Fig. 22). The crystal contains tubular cavities, where Rb atoms are accommodated.

In the tetragonal $CsSbGeO_5$,[63] the pattern of the cross-junction of the octahedra (Fig. 23) is close to that in $RbNbSiO_5$. The difference is that in $CsSbGeO_5$ one series of apex-linked octahedra, located below the main rod, has been omitted. Furthermore, the octahedra in this compound form a framework and no longer a band. In this framework, joined to the four-membered $[Ge_4O_9]$ rings, there are large communicating cavities in which Cs atoms are accommodated (Fig. 24), and it is possible to

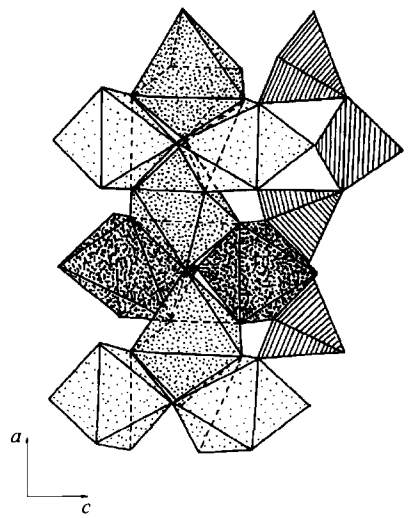

Figure 22. A band of Nb octahedra in the $RbNbSiO_5$ structure. The dot density reflects the height of the Nb octahedra along the *b* axis; the Si tetrahedra in the $[Si_3O_9]_\infty$ chain are shown shaded.

differentiate fragments close to the $KTiOPO_4$-like phases and sphenes. The crystal structure of $CsSbGeO_5$ was also solved in another study,[69] where the likely usefulness of this compound as an ion exchanger was likewise noted.

The crystal structure of the orthorhombic '$KNbGeO_5$'[70] with a slight deficiency of potassium and oxygen atoms (Table 10) proved to be derived from the structure of hexagonal $Cs_8Nb_{10}.Si_6O_{41}$.[71] In both structures, the tetrahedral radical is a three-membered $[T_3O_9]$ (T = Si, Ge) ring. In the structures, it is possible to differentiate the benitoite and pyrochlore fragments. The reason for the distortion of the '$KNbGeO_5$' structure and for the decrease in its symmetry from hexagonal to orthorhombic is the replacement of the Si atom by the large Ge atom in the tetrahedral position. To maintain the structure, the $[Ge_3O_9]$ ring in '$KNbGeO_5$' must be greatly distorted compared with $[Si_3O_9]$ in $Cs_8Nb_{10}Si_6O_{41}$ in order fit in the framework which has also been 'compressed' by replacement of Cs the by K. Like the two phases described above, K,Nb silicate should exhibit ion-exchange properties, i.e. it is possible to identify channels for the migration of cations along the *b* and *c* axes of the crystal.

* * *

More than 50 structures of germanates, gallates, borates, and silicates have been examined in the present review. The class of germanates (gallates), which predominates, provides analogues of the known structures of the silicate type such as garnet, melilite, sphene, cancrinite, and sodalite. Borogermanates are analogues of the borosilicates stillvellite and datolite. The tendency of germanium to be involved in octahedral coordination, particularly when it is present in excess in the initial systems, is responsible for the wide variety of germanates and their ability to form new structural types such as $A_3M_xT_{6-x}O_{14}$. An important factor is that the formation of high-temperature modifications at lower temperatures than, for example, in the case of phosphates, is typical for germanates. This makes it possible to investigate successfully the phase transitions in $KTiOPO_4$-like phases.

The study of the structures of the new phases is extremely important for the interpretation of their physical properties and for the understanding of their nature and hence in the search for phases having these properties and for the improvement of the already existing physical characteristics, for example by means of isomorphism.

The crystals of germanates, gallates, borates, and silicates investigated have a wide range of physical properties and can serve as multifunctional elements in engineering.

V. Conclusion 556

Abstract. The role of certain hydrogen adsorption complexes in the dehydrogenation and hydrocracking of hydrocarbons on low-percentage one-component, (Pt, Pd/Al_2O_3) and bimetallic (Pd – Co, Pd – Ce, Pt – Co, $Pt-Sn/Al_2O_3$) catalysts is discussed. It is shown that the combination of metals in reduced forms and forms oxidised to different extents on the catalyst surfaces is responsible for their high capacity for the chemisorption of hydrogen, the wide range of its energetic inhomogeneity, and the high activity of the catalysts in the conversion of saturated hydrocarbons. Catalysts containing on the surface mainly sites for the type $H^{\delta-}$ chemisorption are the most active in the dehydrogenation of hydrocarbons, whereas specimens chemisorbing hydrogen mainly in the $H^{\delta+}$ form are the most active in the hydrocracking of hydrocarbons. It is concluded that the strongly bound atomic hydrogen $H^{\delta+}$ plays a dual role, since it not only participates directly in the dehydrogenation reaction but also promotes the reduction of the electron-deficient surface centres, which optimises the number of centres for the activation of C – H bonds. The bibliography includes 75 references.

I. Introduction

Hydrogen strongly affects the course of the processes involved in the heterogeneous catalytic conversion of saturated hydrocarbons. It alters the capacity of hydrocarbons for adsorption, participates in the hydrogenation of highly dehydrogenated molecules, enters into the composition of intermediate adsorption complexes, etc.[1-3]

In the present review, attention is concentrated on the role of hydrogen in the dehydrogenation and hydrocracking of hydrocarbons on supported metal catalysts. Mainly platinum catalysts, including those modified by doping with other elements, containing both zerovalent and oxidised metals are used as dehydrogenation catalysts.[1] The participation of adsorbed hydrogen in dehydrogenation and hydrocracking and also the nature of the adsorbed state, which is determined by the composition and structure of the active centres on the catalyst surface, have been scarcely investigated hitherto.

II. The mechanism of the activation of H – H, C – H, and C – C bonds in molecules of hydrogen and hydrocarbons

The mechanism of the chemisorption of hydrogen on the surfaces of Group VIII metals has been discussed in detail in a number of communications, in particular in reviews.[4,5]

In considering the mechanism of the activation of hydrogen on metal oxides, one should bear in mind that experimental estimation of the sorption state of hydrogen is possible only in the case of metal oxides which are difficult to reduce — those of molybdenum, zirconium, strontium, barium, and cerium.

As a consequence of the highly ionic character of such metal oxides, the interaction of hydrogen with the latter leads to the polarisation of the hydrogen molecule:

$$\begin{matrix} H^{\delta-} & \cdots & H^{\delta+} \\ \vdots & & \vdots \\ H^{\delta+} & \cdots & H^{\delta-} \end{matrix}$$

This is followed by heterolysis.[6-11] The existence of the $M^{m+}-O^{n-}$ pairs on the surfaces of the oxides of the metals indicated above[12-18] with different coordinative unsaturation of the metal and oxygen (surface defects) is responsible for the presence of several types of pairs of active centres differing in the strength of bonding of the chemisorbed hydrogen.[7,18]

The chemisorption of hydrogen on readily reducible metal oxides (including Group VIII metal oxides) and its energy characteristics have been investigated mainly by theoretical methods.[7,12,19-22]

Quantum-chemical calculations for the chemisorption of a hydrogen molecule on the (001) face of NiO indicate that the binding of hydrogen to Ni^{2+} ions is very weak in a perfect lattice (E_b = 0.65 eV).[19,22] Only a positively charged molecular form of chemisorbed hydrogen arises on a positively charged iron ion in the hematite (Fe_2O_3) lattice.[20] The presence of defects — cationic or anionic vacancies — on the oxide surface leads to strong binding of hydrogen (E_b = 4.5 – 7.7 eV).[7,19,22]

Calculations for the chemisorption of a hydrogen molecule on an oxygen ion of the Fe_2O_3 cluster showed that the H–H bond energy diminishes greatly on interaction with an O^{n-} anion.[20] When the hydrogen molecule is oriented parallel to the metal–oxygen bond, the interaction is repulsive, i.e. there is no chemisorption of hydrogen on Fe_2O_3 via a heterolytic mechanism.

Analysis of the H–H and C–H bond activation processes on metallic surfaces and on transition metal complexes showed that these processes proceed via similar mechanisms.[6,18,23,24] The activation of hydrocarbon molecules, like that of hydrogen molecules, involves electron transfer from the bonding σ_g orbitals of the H–H and C–H bonds to the metal and the reverse electron transfer from the occupied orbitals of the metals to the antibonding unoccupied σ_u^* orbitals of the molecule of hydrogen or the saturated hydrocarbon.[23] The electron-donating or electron-accepting nature of the interaction of metals with hydrogen or hydrocarbons is determined by the oxidation states of the metals, i.e. by the position of the Fermi level of the metal relative to the highest occupied or lowest unoccupied level of the reactant molecule, which is in fact the reason for the preferential charge transfer either to the adsorbed molecule or to the transition metal.[23]

In the case of zerovalent metals, the high energies of the highest occupied molecular orbitals (HOMO) of their surface atoms give rise to interaction involving mainly electron transfer from the metal to the σ_u^* levels of the hydrogen or saturated hydrocarbon molecule. Quantum-chemical calculations of the heats of chemisorption of saturated hydrocarbons (CH_4, C_2H_6) on 3*d* transition metals showed[24] that the difference between the energies of the Fermi level of the metal and the σ_g levels of the hydrocarbon molecules are fairly large for the majority of these metals. It is therefore evident that the electron-accepting properties of saturated hydrocarbons will predominate in the interaction with metals.

In oxides and metal complexes (in contrast to heterogeneous metal catalysts), the metal ions exhibit a higher coordinative unsaturation and the energies of their frontier orbitals are higher.[23,24] Thus the typical Fermi energies, established from the electron work functions of the reduced transition metals, range from −4.5 to −5.5 eV, while the ionisation potentials of the atomic *d* orbitals in complexes range from −8 to −12 eV.[23] As a consequence of the lower HOMO energies of the metals in complexes or oxides compared with H–H and C–H bonds, electron transfer from the σ_g orbitals of the H–H and C–H orbitals to the metal predominates in the early stages.[25,26]

The dominant role of electron-donating properties of saturated hydrocarbons in their interaction with metals in a high oxidation state, for example, with organometallic clusters, has been demonstrated.[24] The author[24] calculated a critical point $\varepsilon_d \approx -9.1$ eV on the energy scale. He showed that, when the HOMO energy of the metal is greater than this quantity, then the molecule, for example of CH_4, is an electron acceptor, whilst if it is lower than the critical point the molecule is an electron donor. Since the HOMO energies of the majority of transition metals are above −9.1 eV, the methane molecule is an electron acceptor in relation to them.

The frontier orbital energies of the molecules of hydrogen and the hydrocarbons involved in the chemisorption on the surface metal atoms determine the difference between the activations of the H–H and C–H bonds: the CH_4 molecule is a better electron donor, since its HOMO lies 2 eV higher than in hydrogen. The electron-accepting properties of hydrogen and methane molecules are similar, since the energy of the bonding σ_g hydrogen orbital is −17.56 eV, while that of the antibonding σ_u^* orbital is +4.17 eV; the energies of the corresponding orbitals in CH_4 are −15.4 and +3.6 eV.[23]

The deposition of the metal on a carrier exerts a significant influence on the donor–acceptor character of the interaction of the metal with hydrogen and hydrocarbons. According to Beran et al.,[27] the C–H bond dissociation energy in the CH_4 molecule on supported nickel catalysts diminishes with increase in the electronegativity of the carrier. The transfer of electrons from the carrier to the metal is hindered by the higher electron density in the latter (for example 10^{23} cm^{-3} in platinum and 10^{20} cm^{-3} in titanium dioxide).[28] However, in the case of highly dispersed particles of the deposited metal, which are electron-deficient,[29–31] paraffinic hydrocarbons exhibit electron-donating properties, coordinating very strongly to these particles, reducing catalytic activity in their reactions.[29,31,32]

In the reactions of hydrocarbons on the surfaces of heterogeneous catalysts, the C–C bond is activated together with C–H, which leads to a nonselective course of the reaction in the dehydrogenation of hydrocarbons. The ratio of the dehydrogenation and hydrocracking products is determined by the ratio of the energies of the bonds formed (M^+–H, M^+–C) and dissociated (C–C, C–H).[33]

It has been shown in a study of the hydrogenolysis kinetics of C_2–C_5 alkanes on supported rhodium and nickel catalysts and also on the surface of single crystal iridium[34–36] that the activation of the C–C bond is a structure-sensitive reaction. According to Dorfman,[37] because of symmetry considerations the dissociation of the C–C bond takes place on pairs of coordinatively unsaturated atoms of *d* metals located at the apices, on the edges, and in high-index planes of small crystallites.

Systematic data on the ability of metals to break the C–C bond as a function of their position in the Periodic System are not to be found in the literature; only isolated results have been published. Thus it has been shown[38] that the C–C and C–H bond dissociation energies decrease in the sequence Pt > Ni > Fe/W. The strength of the bond between the metal and carbon increases on passing from Pt to Ir and Os; the frequency of the C–C bond increases in the same direction.[34] It has been established for fission exchange involving deuteriated methane that cobalt and iridium preferentially form multiple bonds to a carbon atom, whereas on platinum the formation of single M–H bonds is preferred.[39,40] The ability of cobalt and iridium to form multicentre bonds explains their high activity in the hydrogenolysis processes.

Certain ideas about the mechanism of the fission of C–C bonds have arisen in the study of the high-temperature activation of saturated hydrocarbons by metal complexes.[33] Several C–C bond activation pathways are possible on coordinatively unsaturated transition metal (metals in the zerovalent or a low oxidation state) complexes. For example, activation takes place on direct insertion of the metal in the C–C bond via the oxidative addition mechanism or in the initial oxidative addition of a C–H bond to the metal complex and the subsequent cleavage of the C–C bond in the σ-alkylmetal hydride complex.

Thus the activation of hydrogen and hydrocarbon molecules on the surfaces of supported catalysts proceeds either via oxidative addition (the formation of negatively charged complexes) or via a donor–acceptor mechanism with charge transfer from the molecule to the metal (the formation of positively charged complexes) predominating depending on the degree of reduction of the metals on the surface.

III. The role of hydrogen in the reactions of hydrocarbons

In the numerous studies of the reactions of saturated hydrocarbons in the presence of hydrogen (dehydrogenation, dehydrocyclisation, hydrogenolysis, hydrocracking, etc.) published hitherto, it has merely been shown that hydrogen, without being a stoichiometric reactant, has a positive effect at certain concentrations both on the rate and selectivity of the process. Thus it has been observed[2,41] that the addition of hydrogen to the reaction medium suppresses the dissociative chemisorption of hydrocarbons on the surfaces of metals, which prevents self-poisoning of the catalyst surfaces and the deposition of carbon on the latter. On the other hand, at relatively high concentrations of the gas phase,

hydrogen promotes both the hydrogenation of the alkenes formed and the cleavage of the C–M bond, reducing thereby the fraction of the surface involved in the reaction of the hydrocarbons and lowering the overall degree of conversion.[2,41,42] The forms of hydrogen firmly retained on the catalyst surface insulate the surface metal atoms from direct contact with the reactant molecules,[43] which can alter the mechanism of their interaction.

The change in the size of the working metal assemblies, induced by the change in the amount of carbonaceous deposits, has also been explained[44] by the involvement of hydrogen in the reactions of alkanes on the surfaces of platinum catalysts. In the presence of a deficiency of hydrogen, the catalyst surface is largely covered by hydrocarbons, retained mainly on the platinum centres. The H–Pt–C system formed under these conditions breaks up the large platinum assemblies and the centres active in the dissociation of the C–C bond are blocked. In the presence of an excess of hydrogen in the mixture, whereupon the surface coverage by the hydrocarbons is low (the H–Pt system), the main reaction path involves the fragmentation of the alkane molecules.[44,45]

It has been established[46] that the reaction of n-hexane on the surface of a platinum–tin catalyst freed from adsorbed hydrogen proceeds nonselectively with formation of light saturated hydrocarbons. If the catalyst surface has been covered with hydrogen, then the selectivity with respect to alkenes increases.

The role of the energy characteristics of hydrogen, which influence the rate and mode of the reactions of hydrocarbons, have been discussed in a number of publications. Thus Volter and coworkers[47,48] observed a satisfactory correlation between the activity of platinum and platinum–tin catalysts in the dehydrogenation of cyclohexane and their content of hydrogen retained on the surface in the temperature range 0–300 °C.

The hydrogen initially adsorbed on the platinum/alumina catalyst can participate directly in the reactions of cyclohexane, effecting the hydrogenation of its extensively dehydrogenated strongly bound molecules with formation of a high-temperature form of benzene.[49] The chemisorbed hydrogen does not participate directly in the formation of the low-temperature form of benzene, but in the absence of hydrogen from the catalyst surface this form of benzene is not formed and the thermoprogrammed desorption (TPD) spectrum shows only the peaks of the strongly bound form of benzene.[49]

The direct involvement of atomic forms of hydrogen in the dehydrogenation of cyclohexane adsorbed on the surfaces of palladium or nickel catalysts has been demonstrated.[50] As a result of the study of the dehydrogenation of cyclohexane on specimens with preadsorbed deuterium, a reaction mechanism was proposed in which the adsorbed hydrogen and the hydrogen in the chemisorbed cyclohexane molecule recombine with elimination of a hydrogen molecule. Analysis of the activation energy for the reaction involving the deposition of carbonaceous deposits led Masai et al.[50] to conclude that the forms of hydrogen which can increase the activity of catalysts in the dehydrogenation of cyclohexane are also responsible for the high degree of carbon deposition on the surface.

The C_5-dehydrocyclisation reaction proceeds via a similar mechanism, presupposing the recombination of a hydrogen atom belonging to a hydrocarbon transition complex with a hydrogen atom adsorbed on the surface.[2]

It has been suggested in a number of investigations[51–53] that the C–H bonds in the cyclohexane molecule are activated on the centres for the adsorption of weakly bound hydrogen because the dehydrogenation reaction on the Pt/Al_2O_3 and $Pt–Sn/Al_2O_3$ catalysts begins at temperatures at which the surface of the specimens is freed from hydrogen (T_{des} < 350 °C).

A correlation between the content in the catalyst of the hydrogen desorbed in the temperature range 320–480 °C and the catalyst activity has been observed in a study of the dehydrogenation of n-dodecane on platinum catalysts promoted with indium and gallium.[54] The observed relation can be explained by the fact that the centres for the activation of the dissociatively chemisorbed hydrogen serve simultaneously as the sites for the adsorption of intermediate products formed on dissociation of a C–H bond.

Comparison of the reactivity of hydrogen in the dehydrogenation of cyclohexane and its thermodesorption characteristics in low-percentage promoted Pt and Pd catalysts on Al_2O_3 showed[55,56] that the most active specimens chemisorb two energetically different atomic forms of hydrogen—with T_{des} = 160–480 °C and 480–900 °C respectively. The weakly active catalysts are characterised by the absence from the surface of the form of hydrogen with a lower bond energy.

Thus analysis of the available literature data shows that hydrogen is an obligatory participant in the catalytic reactions of saturated hydrocarbons. However, as a consequence of the nonuniformity of the energy characteristics of the hydrogen chemisorbed on the surfaces of catalysts, it is necessary to discover the role of each form of hydrogen in the catalytic reactions of unsaturated hydrocarbons.

The nature of the adsorption complexes of hydrogen, determined by the state of the active centres of the catalyst surface, can be discovered from the relation between the oxidation state of the metals in supported low-percentage catalysts and the adsorption characteristics of the hydrogen on their surfaces.

IV. Relation between the adsorption characteristics of hydrogen, the state of the metals, and catalyst activity in the reactions of saturated hydrocarbons

It is essential to note that towards the beginning of the 1980s there had been virtually no experimental studies on the chemisorption of hydrogen and its energy characteristics on Group VIII metal oxides. The reason for this was the relative ease of the reduction of the oxidised metals in hydrogen.

The metals can retain their oxidation state during the reduction process if the oxides are part of the composition of low-percentage supported catalysts [in the presence of a strong metal–carrier interaction (SMCI)]. The H–H bond is activated via the heterolytic mechanism for high oxidation states or via the donor–acceptor mechanism for low oxidation states of the metal in the oxide and for chemisorption on highly dispersed electron-deficient particles of the metal on a carrier.[23,33,37]

It has been shown[1,57–61] that metals deposited on a carrier at low concentrations (0.02–0.1 mass% Pd; 0.5–1.0 mass% Co; 0.05–0.1 mass% Pt; 2.1 mass% Ce), corresponding to the SMCI region, are mainly in the oxidised state (Pt^{2+}, Co^{2+}, Pd^{2+}, Ce^{4+}) and in the case of Pd/Al_2O_3 partially in the atomically disperse[58,60] state after high-temperature (400–500 °C) treatment in hydrogen. The highly dispersed particles of the deposited metals with an increased concentration of the active phase are also electron-deficient.[29–31,62,63] In the above catalyst, virtually all the atoms of the deposited metal are on the surface and are accessible for chemisorption. Thus, according to data obtained by the paramagnetic probe method (PPM), after the deposition of 0.02–0.1 mass% Pd, 0.6×10^{13} palladium atoms cover 2×10^{13} Al^{3+} centres,[57] whereupon a sharp decrease (up to 50%) in the number of coordinatively unsaturated Al^{3+} atoms on the surface is observed (Fig. 1*a*, curve *1*).

The degree of coverage of the active phase of the catalysts by hydrogen in the SMCI region, determined by the TPD method,[57,58] is negligible: the ratio H : M $\leqslant$ 0.01 (M = Co, Ce, Pt) with the exception of Pd/Al_2O_3, for which H : Pd is somewhat higher—H : Pd = 0.01–0.2 (Fig. 1*a*, curve *2*; Fig. 2*a*, curve *1*). This is evidently induced by the presence on the catalyst surface of palladium in the atomically dispersed electron-deficient state.[58]

In catalysts with an active phase concentration higher than in the SMCI region (Pd $\geqslant$ 0.01–0.3 mass%; Pt > 0.1 mass%; Co > 1.0 mass%; Ce $\geqslant$ 2.1 mass%), the deposited metal is adsorbed on the previously occupied parts of the surface, because the number of coordinatively unsaturated Al^{3+} centres does not

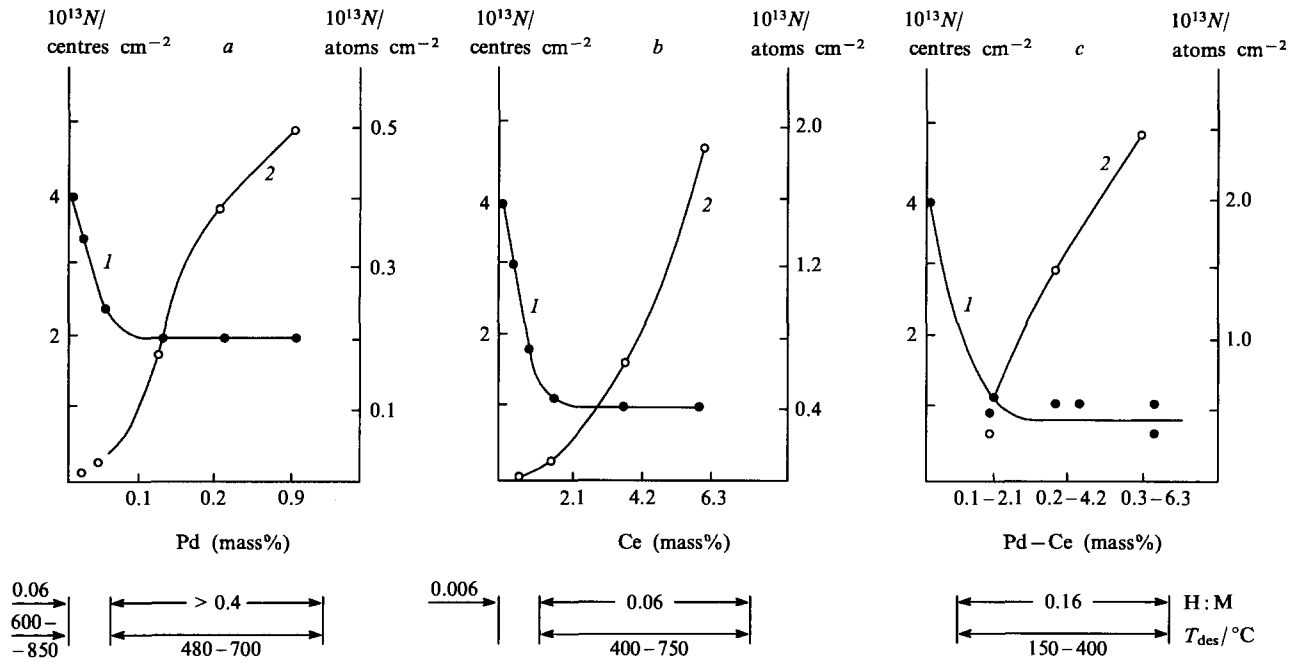

Figure 1. Effect of concentration of deposited Pd (*a*), Ce (*b*), and Pd–Ce (*c*) on the number of Al^{3+} acceptor centres on the Al_2O_3 surface (curves *1*) and on the overall content of the hydrogen adsorbed by the catalyst (curves *2*). The H : M ratios and the temperature ranges in which hydrogen is desorbed, corresponding to regions of strong and weak interaction of the metal with the carrier, are indicated on the scale parallel to the abscissa axis.

diminish with increase in the metal content, according to PPM data (Figs 1*a* and 1*b*, curves *1*).[57] After high-temperature reduction in hydrogen, metals in a more reduced form as well as highly dispersed metallic particles are detected in such specimens.[58,61,64–67] For example, it has been demonstrated by X-ray photoelectron spectroscopy (XPES) that in the 6% Co/Al_2O_3 and 0.35% Pt/Al_2O_3 catalysts 37% and 20% of the metal atoms relative to the overall content exist on the surface in the reduced form.[67,68] Catalysts of this type interact with H_2 and produce mainly strongly bound forms of the chemisorbed hydrogen ($T_{des} \geqslant 480-500$ °C; Fig. 2*a*, curves *2* and *3*), the ability of the specimens to chemisorb hydrogen increasing significantly with increase in the concentration of the deposited metal (from 0.1–0.3 mass% Pd, from 1.7–4.3 mass% Co, and $\geqslant$ 4.2 mass% Ce): the ratio H : M increases by a factor of 8–10 (Figs 1*a* and 1*b*, curves *2*; Fig. 2*a*, curves *1–4*; Fig. 3*a*, curves *1–3*) and hydrogen less strongly bound to the catalyst surface appears (Fig. 2*a*, curve *4*).[57–59]

For bimetallic catalysts, there is a mutual facilitation of the reduction of the metals.[56,58,64–72] Therefore in the platinum/alumina and palladium/alumina catalysts with the noble metal concentrations corresponding to the SMCI region ($\leqslant$ 0.1%) and promoted by the oxides of cobalt (1.0–1.7 mass%),[55,56] cerium (1.0–2.5 mass%; Fig. 1*c*, curve *1*),[56,57,59] and tin (2.0 mass%),[68] the degree of reduction of the metals is higher than in the corresponding monometallic catalyst. For example, the fraction of Pt^0 rises to 40% in $Pt-Sn/Al_2O_3$ compared with 20% in Pt/Al_2O_3. A characteristic feature is also an appreciable increase in the overall capacity for the chemisorption of hydrogen and the appearance of the form of hydrogen weakly bound to the surface (Fig. 1*c*, curve *2*; Fig. 2*a*, curve *5*; Fig. 4*a*, curves *2* and *3*).

Thus there is virtually no chemisorption of hydrogen on oxides of transition metals in a high oxidation state incorporated in the carrier matrix (in the SMCI region). Following the appearance in the specimens of weakly oxidised forms of the metal (highly dispersed electron-deficient metallic particles and the oxides of metals in a low oxidation state), the chemisorption of H_2 is observed with the formation of atomically adsorbed forms firmly bound to the surface (T_{des} > 480–500 °C). When the supported catalysts contain metallic bulk phases, the chemisorption of relatively weakly bound forms of hydrogen with $T_{des} \gtrsim 300$ °C is observed together with the chemisorption of the strongly bound forms.[56,58] This means that, as increasingly more reduced forms and bulk phases of the reduced metal appear in the catalysts, the energetic nonuniformity of the adsorbed hydrogen complexes increases as a result of the formation of the weakly bound $H^{\delta-}$ forms.

The absence of chemisorbed hydrogen from catalysts with the concentration of the active phase corresponding to the SMCI region, in which the oxidised forms of the metals are retained after the high-temperature treatment in hydrogen, may be a consequence of both thermodynamic difficulties induced by the greater difference between the energy levels of the oxidised metals and hydrogen and by the coordinative saturation of the metal oxides in the carrier matrix (Al_2O_3). The chemisorption of hydrogen on the more reduced metals can be regarded[23,33,37] as a result of the activation of hydrogen via the mechanism involving the donor–acceptor interaction with transfer of electron density in both directions $H \rightleftarrows M^{n+}$.

Analysis of the oxidation states of the metals and of the thermodesorption characteristics of the chemisorbed hydrogen permits a conclusion concerning the charge distribution in the adsorbed forms of hydrogen. Thus the chemisorption of hydrogen in the strongly bound atomic form (the $H^{\delta+}$ form with T_{des} > 480 °C), which occurs on electron-deficient metallic particles and on oxides of metals in a low oxidation state, may be associated with the activation of hydrogen via the donor–acceptor mechanism with the preferential transfer of electron density from the hydrogen molecule to the unoccupied *d* orbitals of the metal.[23,37] The presence of relatively weakly bound forms of hydrogen (the $H^{\delta-}$ form with $T_{des} \geqslant 300$ °C), which are characteristic of monometallic catalysts with a high metal concentration and of bimetallic systems containing bulk phases of the reduced metal, is due to the activation of hydrogen via a mechanism involving oxidative addition with electron transfer

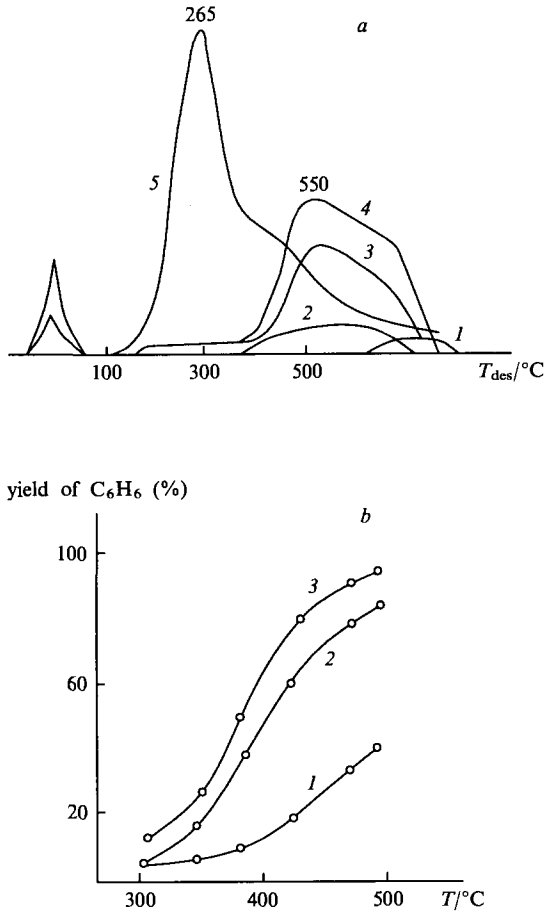

Figure 2. Spectra of the thermodesorption of hydrogen from catalysts on Al_2O_3 (*a*) and the activity of hydrogen in the dehydrogenation of cyclohexane when different catalysts are used (*b*). Metal concentration (mass%): (*a*) 0.04 Pd (curve *1*), 0.3 Pd (curve *2*), 4.2 Ce (curve *3*), 6.3 Ce (curve *4*), and Pd–Ce (curve *5*); (*b*) 0.05 Pd (curve *1*), Pd–Ce/Al_2O_3 (curve *2*); Ce content 1.0 mass% (curves *2*) and 2.5 mass% (curves *3*).

from the metal to the antibonding σ_u^* orbital of the hydrogen molecule.[23,27] The different degrees of dispersion of the reduced metallic particles create in their turn a set of energetically different desorption centres on the surface. Thus it has been shown [73] that, depending on their size, the monodisperse platinum particles on Al_2O_3 (23, 45, or 90 Å) chemisorb hydrogen with different bond energies (E_{des} = 204, 113.4, or 96.6 kJ mol^{-1}).

We shall consider the influence of the state of the metals and of the associated characteristics of the adsorption complexes of hydrogen on the activity of the catalyst in the hydrocracking and dehydrogenation reactions of hydrocarbons (cyclohexane [55,56] and n-propane [68]). In the cobalt/alumina catalyst with a low concentration of the deposited metal (1.7 mass%), containing cobalt mainly in the oxidised state (the SMCI region) and partly in the atomically disperse form, the amount of chemisorbed relatively strongly bound hydrogen in the $H^{\delta+}$ form is small. This catalyst exhibits a low activity in the hydrocracking of cyclohexane [~10% of C_1-C_5 hydrocarbons can be detected in the products (Fig. 3*b*, curve *1*)] and the parallel dehydrogenation reaction (~6% of benzene). The ratio of the yields of the hydrocracking and dehydrogenation products is 1.7. With increase in the cobalt content in the catalyst to 3.0 mass% – 4.3 mass% accompanied by a sharp increase, not proportional to the increase in the concentration of the deposited metal, in the amount of strongly bound hydrogen chemisorbed on weakly oxidised and finely dispersed particles of reduced cobalt, the hydrocracking of cyclohexane proceeds very readily (the yield of C_1-C_5 hydrocarbons is 95% – 99%; see Fig. 3*b*, curves *2* and *3*), while dehydrogenation is almost completely suppressed (the yield of benzene is 3.0% – 0.4%); the ratio of the yields of the hydrocracking and dehydrogenation products increases by a factor of 32 – 246 respectively.

The experimental data presented show that the hydrocracking reaction requires the presence of weakly oxidised forms of the metals on which hydrogen is chemisorbed with formation of strongly bound $H^{\delta+}$ complexes (E_{des} > 250 kJ mol^{-1}; Fig. 3*a* and 4*a*). With increase in E_{des} for the chemisorbed hydrogen, the ability of the catalyst to cleave the hydrocarbon molecule increases and the temperature corresponding to complete conversion diminishes (Fig. 3*b*, curves *2* and *3*; Fig. 4*c*).

While analysing the relation between the state of the chemisorbed hydrogen and the activity of the catalysts investigated, it is essential to note that at 500 °C, where saturated hydrocarbons such as cyclohexane and n-propane react, only hydrogen with T_{des} > 500 °C remains on the surface according to data obtained by the stepwise thermodesorption method (Figs 2*a*, 3*a*, and 4*a*). The $H^{\delta+}$ form of hydrogen cannot evidently be displaced from the catalyst surface during the reaction by the organic component of the reaction mixture (H_2 + saturated hydrocarbon) as a consequence of the lower reactivity of the C–C and C–H bonds compared with the H–H bond. [33] Retained on the surface in this form, hydrogen promotes an increase in the degree of reduction of the weakly oxidised highly dispersed metallic particles, i.e. it behaves as a modifying additive able to alter the electronic properties of the catalyst surface.

Consequently the catalysts containing on their surface an appreciable amount of strongly bound atomic hydrogen in the $H^{\delta+}$ form exhibit an increased activity in the hydrocracking of cyclohexane. This agrees well with the finding that the structure-sensitive C–C bond dissociation reaction takes place readily on pairs of coordinatively unsaturated metal atoms via the

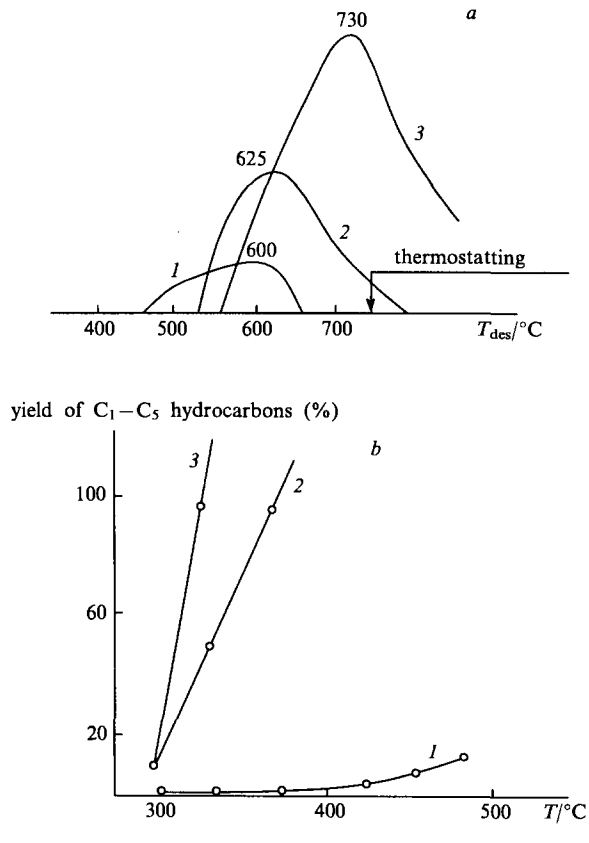

Figure 3. Hydrogen thermodesorption spectra (*a*) and the activity of the Co/Al_2O_3 catalysts in the hydrocracking of cyclohexane (*b*). Cobalt concentration (mass%): (*1*) 1.7; (*2*) 3.0; (*3*) 4.3.

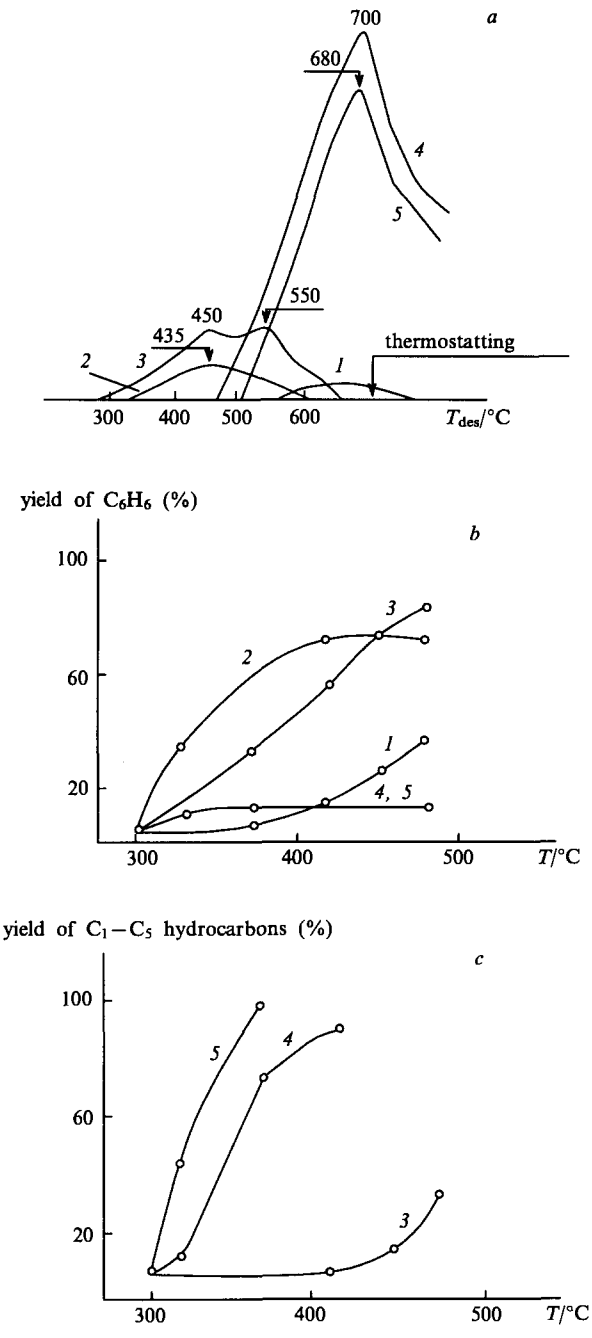

Figure 4. Hydrogen thermodesorption spectra (*a*) and activities in the dehydrogenation (*b*) and hydrocracking (*c*) of cyclohexane of the 0.1 mass% Pd/Al_2O_3 catalyst (curves *1*) and the $Pd-Co/Al_2O_3$ catalysts with various cobalt contents (mass%) [(*2*) 1.0; (*3*) 1.7; (*4*) 3.0; (*5*) 4.3].

oxidative addition mechanism with formation of negatively charged hydrocarbon fragments $(R_3C)^-$.[37] The hydrogen in the $H^{\delta+}$ form also promotes an increase in the degree of reduction of the coordinatively unsaturated electron-deficient metal atoms, accelerating thereby the dissociation of the C–C bonds in the hydrocarbon molecule. Furthermore, it evidently participates in the hydrogenation of the $(R_3C)^-$ fragments that are formed on cleavage of the C–C bonds. The possibility of the simultaneous activation of the H–H and C–C bonds on the same metal atom (centre) has been demonstrated.[37]

In the dehydrogenation reactions of cyclohexane and n-propane, the most active are bimetallic platinum/alumina and palladium/alumina catalysts containing low concentrations of the promoting agent [1.0–1.7 mass% Co (Fig. 4*b*, curves *2* and *3*), 1.0–2.5 mass% Ce (Fig. 2*b*, curve *3*), or 2.0 mass% Sn],[68] in which the degree of reduction of both the noble and nonnoble metals is higher. Their oxidised forms are less electron-deficient than in the corresponding monometallic specimens. These catalysts are characterised by the chemisorption of both the $H^{\delta+}$ form of the hydrogen and of the $H^{\delta-}$ form (Figs 2*a* and 4*a*).

In the dehydrogenation reaction, a significant fraction of the relatively weakly bound atomic hydrogen $H^{\delta-}$ in the modified catalysts is desorbed from the surface of the specimens, liberating the chemisorption centres on which the C–H bonds in the hydrocarbon molecules are activated. This stage is rate-limiting in the dehydrogenation reaction.[74, 75] The concentration of the centres for the activation of C–H bonds can be estimated quantitatively on the basis of the presence and content of the $H^{\delta-}$ form of hydrogen with E_{des} = 125–250 kJ mol^{-1}, which is chemisorbed on the most reduced surface centres of the catalyst, and the activity of the catalyst in the dehydrogenation of hydrocarbons can be inferred.

The hydrogen in the $H^{\delta+}$ form ($T_{des} > T$) chemisorbed on weakly oxidised and highly dispersed metallic particles is retained on the surface of the catalyst at the temperature of the dehydrogenation reaction. Evidently the hyrogen can participate directly in the catalytic dehydrogenation step, recombining with the atomic hydrogen $H^{\delta-}$ formed on dissociation of the C–H bonds as a result of their activation on the reduced surface centres via the oxidative addition mechanism.[37] Furthermore, the degree of reduction of the electron-deficient surface centres increases during the formation of the $H^{\delta+}$ form. Hence, the number of centres for the activation of the C–H bonds is increased.

V. Conclusion

The combination of reduced metals and metals oxidised to different extents in the bimetallic catalysts investigated, which chemisorb hydrogen via different mechanisms, ensures their high capacity for the chemisorption of hydrogen. The degree of reduction of the metals in bimetallic catalysts, which determines the strength of the bonding and the charge state of the different forms of chemisorbed hydrogen and hence the mode of the reactions of saturated hydrocarbons, depends on the chemical nature of the modifying additive (the electron work function, the oxidation-reduction potential, etc.) which weakens or intensifies the electron-donating properties of the noble metal, for example:

Catalysts containing on their surface centres for the chemisorption of complexes of the type $H^{\delta-}$ exhibit a fairly high activity in the dehydrogenation of hydrocarbons ($Pd-Ce/Al_2O_3$ with 2.5 mass% Ce). On catalysts containing centres for the chemisorption of both types, namely $H^{\delta+}$ and $H^{\delta-}$ ($Pd-Co$, $Pt-Sn/Al_2O_3$), alkanes react via two pathways: dehydrogenation and hydrocracking, whereas catalysts which chemisorb hydrogen only in the $H^{\delta+}$ form (Co/Al_2O_3) drive the process mainly along a single path — the hydrocracking of the molecule.

Chemisorbed hydrogen can be regarded not only as a participant in the dehydrogenation or hydrocracking reaction (hydrogenation of fragments of the hydrocarbon molecule in the hydrocracking process or recombination with the hydrogen atom formed on dissociation of a C–H bond) but also as a modifying agent, which gives rise to a definite degree of oxidation or reduction of the metals on the catalyst surface.

Abstract. The structures of the intermediate surface compounds in heterogeneous-catalytic reactions of hydrocarbons, alcohols, and acids, established by spectroscopic (mainly IR spectroscopic) measurements, are examined. The evidence obtained concerning the role of particular structures in catalysis is differentiated: from spectroscopic data obtained before or after catalysis; from spectroscopic data obtained in situ but without kinetic measurements; from spectroscopic data obtained in situ by comparing the kinetics of the heterogeneous-catalytic reactions with the kinetics of the changes in the concentrations of the surface compounds. The mechanisms of heterogeneous catalytic reactions obtained on the basis of the available information about the surface complexes are presented. The bibliography includes 89 references.

I. Introduction

In order to understand the mechanism of heterogeneous catalysis, it is necessary to know the sequence of the elementary stages through which the catalytic reaction proceeds. For this purpose, information on the structures and reactivities of the intermediates is first needed.

In the general case, a large set of complexes may exist on the catalyst surface. For example, in the reaction $A \rightleftharpoons B$, occurring on a catalyst K in accordance with the mechanism

$$\begin{array}{l} \quad\quad\quad\

the catalytic reaction. Therefore they cannot be regarded as proven. Furthermore, the majority of investigators confined themselves merely to stating that a particular compound is formed (it was later referred to as the intermediate) under the catalytic conditions without studying the rate of its formation and consumption.

Nevertheless, it is precisely by measuring the rates of formation and consumption of the different compounds in the reaction medium and by comparing them with the rates of the catalytic reaction proper that one can demonstrate whether a particular compound, found under the catalytic conditions, is an intermediate. In heterogeneous catalysis most of the stages of the overall processes occur on the surface. The concentration of the reactive species on the surface, calculated per unit volume, is much lower than in homogeneous reactions. Therefore sensitive spectroscopic methods must be resorted to in order to detect the intermediates on the surface.

The high resolving power of spectroscopic methods as regards time is also very important. Under stationary conditions in catalytic reactions, direct comparison of the concentration of complexes of any kind with the rate of the overall reaction cannot provide a direct answer to the question whether such complexes are intermediate or 'dead-end'. This can be done by carrying out the reaction under non-stationary conditions using methods involving the pulsed introduction of the reactants, a sharp variation of the reactant concentrations (the 'response method'), a jump in temperature, irradiation, etc. The turnover number of a catalytic reaction (i.e. the number of reaction steps occurring on a single active catalyst centre per second) is known[2] to be as a rule $10^{-2}-10^{2}$ s^{-1}†. The characteristic times of a catalytic reaction are correspondingly in the range from 10^{-2} to 10^{2} s. Evidently the resolving power of the spectroscopic methods employed in situ as regards time must not be less than this. However, in the majority of cases spectroscopic measurements are performed with interruption of the catalytic reaction, the interruption time greatly exceeding the characteristic time of the catalytic reaction.

This review presents data (mainly from communications published after 1980) concerning the intermediates in catalysis obtained by spectroscopic methods, mainly by IR spectroscopy. UV spectroscopy, spectroscopy in the visible region, X-ray photoelectron spectroscopy, low-energy electron scattering spectroscopy, NMR, and EPR have been used in individual investigations. Unfortunately, in the vast majority of studies, the above criterion, based on the correspondence between the kinetic characteristics of the concentration variation of a possible intermediate and the kinetics of the catalytic reaction itself, was not considered. Therefore the conclusions reached in them concerning the structure of the intermediates and the sequence of their reactions must be regarded as tentative and not proven.

Apart from spectroscopic methods, other procedures also exist for the investigation of the catalytic reaction mechanism: temperature-programmed desorption (TPD) and temperature-programmed reaction (TPR), isotopic methods (exchange of isotopes under catalytic conditions, kinetic isotopic effect), kinetic transient response methods, the so called 'time analysis of the products' (TAP-reactor), and others. Without dwelling especially on the description of these methods and the results obtained with their assistance, we shall use these data as well in a number of cases.

The present review presents data concerning intermediates in the simplest heterogeneous-catalytic polymerisation and oligomerisation reactions, the metathesis of hydrocarbons, and the decomposition of alcohols and acids. The single starting material in these reactions is converted into one or several reaction products. More complex oxidation–reduction reactions will be considered in future reviews.

† These figures refer to reactions occurring under flow or static conditions at pressures not too remote from atmospheric. At ultralow and high pressures, smaller and larger turnover numbers are obtained respectively.

We shall not deal with the spectroscopic proof of the existence of a particular intermediate and so the numerical vibration frequencies will not therefore be quoted as a rule.

II. Certain problems concerning the methods for the study of processes on the surfaces of solids

IR spectroscopy in the frequency range 400–5000 cm^{-1} is usually employed to investigate the nature of the complexes arising on the surfaces of the catalysts. This is associated not only with the fact that molecular IR spectroscopy yields information directly concerning the structure of surface compounds but also with the fact that, in contrast to the majority of other physical methods, it permits a wide scale variation of the temperature and pressure in the spectrometer cell.

The amount of information derivable from IR spectroscopy may actually increase in the study of complexes on the surfaces of solids (compared with molecules in the gas phase). The point is that a fairly large number of vibrations are inactive in the IR spectrum and are manifested only in the Raman spectrum. When molecules interact with the surface, their symmetry is reduced, so that virtually all the vibrations become active in the IR spectrum. Adsorbed nitrogen, hydrogen, oxygen, etc. molecules may be successfully detected on the surfaces of solids by IR spectroscopy.

Transmission spectroscopy, reflectance spectroscopy, emission spectroscopy, and diffuse reflectance spectroscopy are used nowadays to a greater or lesser extent in the study of processes on the surface.

Massive metals are one of the commonest types of catalyst. The surface processes on such objects cannot be investigated by the traditional transmission spectroscopic methods. Emission spectroscopy is promising in this instance.

The measurement of the transmission spectra of surface compounds is frequently hindered by the intrinsic absorption of the catalyst. Difficulties of this kind can be overcome by applying the diffuse reflectance method in the IR region of the spectrum.We shall consider briefly the principal features of each of the methods listed above.

1. Infrared transmission spectroscopy

The principles of this method have been described in detail in numerous monographs (see, for example, Refs 3–5). Spectrophotometers record the transmittance T:

$$T = \frac{I}{I_0} = \exp(-kl), \tag{1}$$

where I and I_0 are the intensities of the transmitted and incident light, k is the linear absorption coefficient, and l the thickness of the absorbing layer. According to the Beer–Lambert–Bouguer law, the optical density is given by

$$D = \ln\frac{1}{T} = \ln\frac{I_0}{I} = \varepsilon c l, \tag{2}$$

where ε is the extinction coefficient and c the concentration of the absorbing layer. Eqn (2) constitutes the basis of quantitative analysis by means of spectroscopy.

The sensitivity of the method is determined both by the characteristics of the radiation detector and by the absorption coefficient of the medium. It is possible to estimate the number of absorbing molecules necessary to obtain sufficiently intense absorption bands on tranditional instruments. For example, a reliable determination requires $\sim 10^{17}$ CO molecules in the sample or 10^{12} molecules cm^{-2} for a specific surface of the specimen of 100 $m^2 g^{-1}$. Since other vibrations (C–H, C–C, etc.) are characterised by lower (by two–three orders of magnitude) absorption coefficients, the sensitivity with respect to them is significantly lower.

The appearance of the Fourier technique improved somewhat the situation in this field. Calculations have shown[5] that the use of

an interferometer instead of a dispersing element should result in an approximately 100-fold gain in sensitivity. In practice, however, the use of an interferometer with Fourier transformation yields a gain in sensitivity by a factor of only 10. The intrinsic noise of the detector precludes the attainment of the calculated gain in sensitivity.

A significant obstacle to the application of transmission spectroscopy under the conditions of a catalytic reaction is the intrinsic emission by the specimen. As a result of this, instead of the true absorption spectrum, one records a resultant spectrum due to the superposition of absorption and emission spectra. Emission can be excluded by modulating the emission in front of the specimen.

It is noteworthy that Fourier spectrometers permit measurements at high temperatures. Distortions of the spectra are possible only due to the fact that the emission by the heated specimen can alter the glow bar temperature. A very important advantage of Fourier spectroscopy is the possibility of working with low radiant energies. This means that the surface compounds can be investigated even on catalysts with a high intrinsic absorption.

Since spectroscopic measurements are performed under stationary and nonstationary conditions, the question arises of the characteristic times of the processes which can be investigated by this method. Processes with characteristic times $> 1\ s^{-1}$, which constitutes the upper limit to the range of characteristic times of catalytic reactions, are accessible to study by spectroscopic methods.

The same time constant applies also to Fourier spectroscopy (the time of a single scan is ~ 1 s). In studying specimens with a high intrinsic absorption, a large number of scans is necessary in order to obtain a high quality spectrum of the surface compounds (the signal to noise ratio increases in proportion to the square root of the number of scans). In this case, the time of the measurement of one spectrum may reach 1 h. Clearly, such systems can be investigated only under stationary conditions. A Fourier spectrometer capable of performing 25 scans per second has been described recently.[6] With the aid of such instruments, it is possible to investigate reactions with characteristic times significantly less than 1 s.

It is noteworthy that the application of transmission spectroscopy has made it possible hitherto to accumulate an enormous amount of information about the structures and properties of surface compounds. However, the question of their role in the catalytic reaction remains open.

2. Infrared diffuse reflectance spectroscopy

In experiments using infrared transmission spectroscopy, it is essential to employ sufficiently thin (from the standpoint of transmission) discs of the test substance. Very often success depends precisely on the possibility of preparing such a disc (the formation of discs is necessary to suppress scattering). Furthermore, in the spectral range above 2000 cm^{-1} the transmittance is fairly low owing to the fairly considerable intrinsic absorption by the catalyst. Finally, as a result of the large optical path length in the cell, the absorption bands of the molecules in the gas phase and on the surface compounds are superimposed.

Diffuse reflectance spectroscopy is free from the above disadvantages.[7,8] Its essential feature is that the detector detects the light scattered by a powdered specimen.

The Kubelka–Munk formula,[7] which relates the fraction of the light reflected by an infinitely thick medium to the absorption and scattering coefficients, is used for the quantitative description of diffuse reflectance spectra.

$$\frac{K}{S} = \frac{(1 - R_\infty)^2}{2R_\infty}, \tag{3}$$

where K is the absorption coefficient of the specimen, S its scattering coefficient, and R_∞ the fraction of the light reflected by the infinitely thick medium.

For the adsorption of molecules on an infinitely thick specimen, the Kubelka–Munk formula assumes the form

$$\frac{K + \varepsilon c}{S} = \frac{(1 - R)^2}{2R}, \tag{4}$$

where ε is the extinction coefficient of the adsorbed substance, c its concentration, and R the fraction of the light reflected by the infinitely thick specimen with the adsorbed layer. The quantities R and R_∞ are determined from the spectrum.

The line intensity is found from the formula

$$I = \frac{R_\infty - R}{R_\infty}. \tag{5}$$

After obtaining the difference between Eqns (4) and (3) and taking into account Eqn (5), we obtain the relation between the intensity of the band due to the adsorbed substance and its concentration (the Kubelka–Munk function):

$$F(R) = I\left(\frac{1}{R - R_\infty}\right) = \frac{2\varepsilon c}{S}. \tag{6}$$

The optical path length for the light in the material of the catalyst can be estimated from this formula.

It has been shown[8] that the optical path length is 2–3 mm when this method is used, which is much greater than in the transmission method. The greater path traversed by light in the specimen is apparently in fact one of the causes of the high sensitivity of diffuse reflectance spectroscopy. Theoretical estimates indicate that, when effectively scattering specimens are investigated, diffuse reflectance spectroscopy is more sensitive (by more than an order of magnitude) than the traditional transmission spectroscopy.

Under real conditions, the sensitivity relation is less favourable owing to the difference between the scattering capacities of the powders (scattering spectra) and the discs (transmission spectra). Furthermore, the attachments used to measure the diffuse reflectance spectra are nonideal and are incapable of collecting all the light scattered by the specimen. However, despite this, even when only a few per cent of the scattered light reaches the detector, in the analysis of effectively scattering substances ($R_\infty \sim 1$) diffuse reflectance spectroscopy has an advantage, as regards sensitivity, over transmission spectroscopy.

It follows from the Kubelka–Munk function (3) that quantitative measurements require the determination of the scattering coefficient. However, it has been shown[8] that in the case of low-intensity bands the concentration of the absorbing substance and the intensity of the corresponding band in the spectrum are linked by a relation analogous to the Beer–Lambert–Bouguer law:

$$-\varepsilon c l_{ef} = \ln\left(\frac{R}{R_\infty}\right), \tag{7}$$

where l_{ef} is the optical path length for the light in the specimen. Eqn (7) is valid when

$$\frac{R_\infty - R}{R_\infty} \ll \frac{2(1 - R_\infty)}{(R_\infty)^{1/2}}.$$

In the analysis of intense bands for the determination of concentration characteristics, it is essential to know the scattering coefficient. The procedures for the independent determination of S have been examined.[8]

The characteristic times of the processes which may be investigated with the aid of diffuse reflectance spectroscopy are the same as in measurements involving the use of transmission spectroscopy.

3. Emission spectroscopy

A large proportion of the early studies on energy emission processes were devoted to blackbody emission. The frequency distribution of the energy emitted on heating a blackbody depends on temperature but is independent of the material of the body itself, i.e. information about the substance cannot be obtained from the emission spectrum of a blackbody. However, real materials are not blackbodies. For example, the emission spectrum of a gas at a low pressure consists of a set of lines which carry information about the nature of the gas.

The expression for the distribution of the radiant energy on a non-blackbody can be obtained with the aid of the Kirchhoff–Planck laws. The emittance of a grey medium (ε_ν) at a temperature T and a frequency ν is defined as the ratio of the radiant intensities of the emission by the grey medium [$I(\nu, T)$] and blackbody [$I_B(\nu, T)$]:[9,10]

$$\varepsilon_\nu = \frac{I(\nu, T)}{I_B(\nu, T)}. \quad (8)$$

The Kirchhoff law establishes the fact that $\varepsilon_\nu = a_\nu$, where a_ν is the absorptance of the substance.

The simplest case is that of emission by a gas whose molecules are distributed uniformly in a certain volume. We shall calculate the emittance from a thin layer of molecules located at a distance d from the boundary of the emitting volume. If $I_0(\nu, T)$ is the emittance from this layer, then the emittance which has reached the boundary is $I(\nu, T) = I_0 \exp[-K(\nu, T)d]$, where $K(\nu, T)$ is the absorption coefficient of the medium. The fraction of the energy transmitted through the layer d is equal to the ratio I/I_0, so that $a = 1 - I/I_0$.

Using the Kirchhoff law and eliminating I_0, we obtain the expression

$$I(\nu, T, d) = I_B(\nu, T)\{1 - \exp[-K(\nu, T)d]\}, \quad (9)$$

which describes the emittance from a layer of gas parallel to the boundary and at a distance d from the latter. There is a possibility that I may depend on the pressure because the quantity $K(\nu, T)$ may change owing to an intermolecular interaction.

Calculation of the emittance from liquids or solids constitutes a more difficult task, because it is essential to take into account the reflection of the radiation emitted in the direction towards the boundary of the substance.

Catalytic systems partly transmit IR radiation. According to the theory of emission by semitransparent substances,[9,10] the sum of the emittance (ε_ν), reflectance (r), and transmittance (T) is approximately unity:

$$\varepsilon_\nu + r + T \approx 1. \quad (10)$$

Eqn (10), which can be derived thermodynamically, is at present the principal expression for quantitative measurements. Emission spectroscopy is much more rarely used than transmission and diffuse reflectance spectroscopy. The reason for this is the difficulty of measuring low-intensity emittances with the aid of dispersion spectrometers. The possibilities of emission spectroscopy have increased significantly only recently following the development of the Fourier technique.

If the reflectance of the specimen is low, then, according to Eqn (10), the following expression is sufficiently accurate:

$$\varepsilon_\nu(\nu) = 1 - T(\nu).$$

The absorptance of the specimen $a(\nu)$ is related to the concentration of the absorbing substance by the Beer–Lambert law:

$$a(\nu) = -\lg T(\nu) = Kcl. \quad (11)$$

In this case, the emittance from the specimen may be related to the concentration of the absorbing substance as follows:

$$c = \frac{\lg[1 - \varepsilon_\nu(\nu)]}{Kl}. \quad (12)$$

This relation holds satisfactorily for gases and semitransparent bodies.[10]

Analogous expressions exist for the calculation of emittance when the emitting substance is on the surface of a metal.[11] Certain characteristics of various IR spectroscopic methods are presented in Table 1. For a comparative assessment of the sensitivities of the dispersion and Fourier spectroscopic methods, we may recall that a reliable determination of CO requires the presence in the sample of 10^{17} and 10^{16} molecules of this substance respectively.

Table 1. Comparative characteristics of the IR methods for the study of catalytic processes.

Characteristics	Spectral range/cm^{-1}	Time resolution/s^{-1}	Equation for quantitative treatment
Transmittance	400–5000	> 1	$D = \varepsilon cl$
Diffuse reflectance	1800–5000	> 1	$F = \frac{2\varepsilon}{S}c$
Emittance	400–2500	> 1	$F = \frac{2\varepsilon}{S}c$ (for highly reflecting objects) $D = \varepsilon cl$ (for weakly reflecting objects)

4. Raman spectroscopy

The radiation scattered by the specimen is investigated in Raman spectroscopy. Suppose that the specimen is irradiated by light at a frequency ν_0. Then most of it undergoes Rayleigh scattering in which the frequency of the scattered light is also ν_0. However, the frequency of a small proportion of the scattered light changes and assumes a new value ν such that the quantity $h(\nu_0 - \nu)$ is exactly equal to the energy of the vibrational or rotational transition. The frequency shifts $\Delta\nu$ give rise to the vibrational–rotational spectra of the specimen. However, the selection rules in Raman spectroscopy differ from those in IR spectroscopy. The main requirement is that the polarisability of the molecule should change during the vibration. Vibrations active in the IR spectrum may be active or inactive in the Raman spectrum and conversely. IR and Raman spectra supplement each other, so that their joint employment makes it possible to obtain virtually complete information about the objects investigated.

The Raman spectra of many molecules adsorbed on oxide systems have now been described. The application of this method at elevated temperatures encounters a series of technical difficulties associated with the emission of light from the heated walls. This is apparently the reason why Raman spectroscopy has so far been used in catalysis to investigate the state of the catalyst itself but not of the adsorbed phase.[12] For example, the reduction of deposited molybdenum oxide catalysts has been investigated from the variation of the intensity of the Mo=O absorption band. Studies[13,14] in which it was claimed that adsorbed CH_3 and CH_2 groups are formed on oxide catalysts during high-temperature oxidative condensation of methane are an exception. This observation is apparently an artefact and is associated with the intense heating and decomposition of the organic molecules in the light beam.

An appreciable increase in the sensitivity of Raman spectroscopy has been achieved with the use of laser sources. Hence the name of the method—laser Raman spectroscopy. Its sensitivity reaches 10^{18} molecules in the specimen, which is as a rule much greater than the number of molecules in the monolayer. A further increase in sensitivity was achieved by the discovery of the SERS (surface-enhanced Raman spectroscopy) or GRS

(giant Raman spectroscopy) effect.[15] Following adsorption on Ag, Au, Cu, and certain other metals, the sensitivity (scattering cross-section) increases by a factor of 10^4-10^6.

5. X-Ray photoelectron spectroscopy, Auger spectroscopy, and electron energy loss spectroscopy

X-Ray photoelectron spectroscopy (XPES) and Auger spectroscopy make it possible, in principle, to investigate the composition of adsorbed compounds and, when the spectral resolution is satisfactory, their structures as well. Electron energy loss spectroscopy (EELS) yields information about the vibrational levels of the absorbed molecule, i.e. in principle the same information as IR spectroscopy. Its advantages are high sensitivity (0.01–0.1 of a monolayer even on smooth surfaces) and the possibility of using it in the low-frequency range of vibrations (10–800 cm^{-1}). At the same time, the EELS method is characterised by a much poorer resolution (at best 25 cm^{-1}, usually 50 cm^{-1}) than IR spectroscopy (1–2 cm^{-1}).

An evident disadvantage of all the varieties of electronic spectroscopy is the impossibility of using them at a high pressure, which usually occurs in catalytic processes. The maximum possible pressure is 10^{-3} Pa (10^{-5} torr). However, even at a pressure below 10^{-3} Pa, the mechanism of the catalytic reaction must be studied on surfaces cleaned in an ultrahigh vacuum. Here one has to bear in mind that the catalytic reaction under the usual conditions, i.e. at higher pressures, can proceed via a different mechanism. The problem of the pressure gap is widely discussed in the literature on catalysis. There are cases where the kinetic data obtained at a low pressure can be referred to high pressures, but the converse cases also occur.

6. Spectroscopy in the visible and ultraviolet regions

The spectroscopy in the visible and ultraviolet regions (UV-VIS) is distinguished by a fairly high sensitivity. In particular, the intensity of the absorption for allowed one-electron $d-d$ transitions is characterised by a molar absorption coefficient of the order of $\sim 10^4$. For this absorption coefficient, it is possible to detect $\sim 10^{16}$ molecules of the test substance in a 1 cm^3 sample. The absorption coefficient for $d-d$ transitions in complexes with a high symmetry is significantly lower and hence the sensitivity is appreciably worse.

The advantage of UV-VIS spectroscopy over IR spectroscopy is the simplicity of the design of the cell-reactors: there is no need to use 'windows' made from special materials and quartz cells can be employed. This method is widely used to determine the electronic state and the coordination of transition metal ions forming part of the composition of the catalysts. It is fairly rarely used to investigate the catalytic reaction intermediates and surface compounds. Organic compounds with C=C, C≡C, C=O, etc. multiple bonds, specially with conjugated bonds, and aromatic compounds are mainly investigated. The electronic transitions in compounds with C–C, C–H, and C–O single bonds occur in the far UV region and are therefore difficult to observe under the conditions of the catalytic reaction. The studies are usually carried out at room temperature, since technical difficulties, associated with light emission from the heated walls, arise at an elevated temperature.

7. Electron paramagnetic resonance

Electron paramagnetic resonance has by a high sensitivity; the presence in the specimen of 10^{11} spins is sufficient for the measurement.

The EPR method is used widely to investigate transition metal ions and other radical centres in catalysts. Its application to the investigation of adsorbed compounds in situ is limited, firstly, by the fact that the lifetime of the free radicals on the surface is as a rule short under catalytic conditions (high temperatures and pressures) and because of this the sensitivity of the method proves to be insufficient. Secondly, the EPR signal from the surface paramagnetic complexes is frequently broadened under catalytic conditions (up to complete disappearance) involving physical adsorption of O_2, H_2O, etc. molecules on the surface due to the dipole–dipole interaction.

The EPR method is frequently employed to observe the radical states of oxygen, NO, and certain other molecules on the surface. For this purpose, the cell-reactor is usually cooled rapidly to low temperatures. Accordingly the time required for the observation of the test molecules increases to ~10 s.

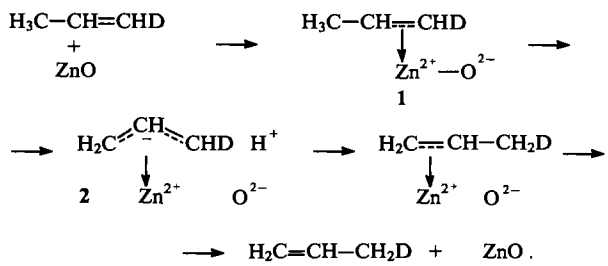
8. Nuclear magnetic resonance

The NMR method has been finding increasing application in catalysis during recent times.[16] The NMR method with a magic angle of rotation is used in the study of solids, especially catalysts.

When applied to catalysis in situ, the NMR method has been used successfully to investigate reactions such as catalytic polarisation under the conditions of an isolated static reactor. However, the technical difficulties associated with the necessity for the continuous introduction of the reactants into a rotating tube-reactor have so far precluded the wide scale employment of NMR.

* * *

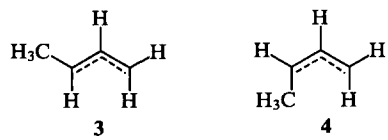
Among all the spectroscopic methods listed above, IR spectroscopy has remained the most widely used procedure since it has been most thoroughly developed. Therefore it is in fact recommended that IR spectroscopy be used to determine the intermediates and to investigate the dynamics of catalytic reactions.[17]



A large proportion of the studies published nowadays concern the measurement of the spectra of adsorbed molecules at room temperature (these investigations were initiated by Terenin and coworkers[18]) and the spectra of surface compounds after 'freezing' the reaction. Evidently, conclusions concerning the role of surface complexes in the reaction, based on such measurements, are to a large extent tentative. The application of IR spectroscopy in the study of the dynamics of heterogeneous catalysis was pioneered by Tamaru,[19,20] who drew attention to the need for the simultaneous measurement of the rate of the catalytic reaction and the rate of reaction of the surface compounds. Together with his coworkers, he investigated the intermediates formed during the decomposition of HCOOH on Al_2O_3, SiO_2, and ZnO and also during the oxidation of methanol on ZnO.

The extents to which the involvement of particular surface compounds as intermediates in catalysis has been demonstrated are differentiated in the present review. In most studies, the conclusion concerning the participation of surface compounds in catalysis is based on spectroscopic measurements before and after the reaction. The reliability of such conclusions will be designated by the letter L (lowest). Measurements of IR spectra in situ are resorted to much more rarely in order to establish the role of the surface compound in the reaction. The reliability of the conclusions reached on the basis of such measurements will be designated by the letter M (moderate). Publications in which the role of the surface complex in the reaction is estimated by comparing the rate of its reaction with the rate of formation of the reaction product are altogether rare. It is quite evident that agreement between these quantities serves as an adequate basis for the claim that the surface compound detected is an intermediate in the reaction. The reliability of such conclusions will be designated by the letter H (highest).

III. Isomerisation of alkenes

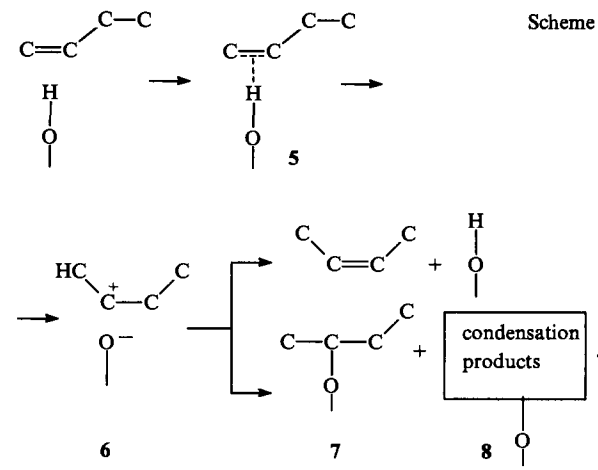


The simplest type of catalytic reaction is A → B, where A and B are substances of similar chemical nature. The isomerisation of alkenes belongs to reactions of this type.

The isomerisation of deuteriopropenes on zinc oxide results in the formation of an equilibrium mixture of $CH_2D-CH=CH_2$, $CH_3-CH=CHD$, and $CH_3-CD=CH_2$.[21] A band corresponding to the vibration of the OH group and five bands corresponding to the formation of the symmetrical π-allyl are observed in the IR spectrum. This indicates that the isomerisation proceeds via dissociative cleavage of a C–H bond. The intermediate (π-allyl) probably exists in the anionic form $C_3H_5^-$:

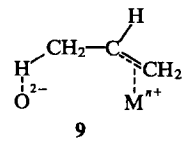
The first stage of the reaction is evidently the formation of the π-complex **1**. Bands corresponding to the formation of π-complexes following the adsorption of alkenes on a series of oxides have indeed been observed in the IR spectra.[22] In chemical terms, one can also imagine the formation of π-complexes of the alkene with the acid OH groups and the subsequent formation of the carbonium ion $C_3H_7^+$. However, the formation of such ions has not been detected in any of the investigations.

In the isomerisation of but-1-ene to but-2-ene on ZnO, bands corresponding to the π-complexes of but-1-ene and *cis*- and *trans*-butenes as well as π-allyl complexes were observed in the IR spectra.[23] Of the two possible methyl-π-allyls



the allyl **3** may be a precursor of *trans*-butene, while the allyl **4** may be a precursor of *cis*-butene. However, only complex **4** was detected on the surface. The most intense absorption bands in the spectra of the π-complexes are those of the *cis*-butene π-complex, although a greater amount of *trans*-butene is formed in the equilibrium gas mixture. Consequently, the form **3** exists only as a short-lived precursor in the reaction **4** ⇌ **3** ⇄ *trans*-butene. Under catalytic conditions, the intensity of the signal due to π-C_4H_8-1 diminishes slowly, while that of the signals of π-*cis*- and π-*trans*-C_4H_7 increases slowly. At the same time, complex **4** is formed initially at a rate close to the overall rate of isomerisation, which then remains constant. Hence one may conclude that π-allyl is a true intermediate.

The formation of a π-complex with acid OH groups was observed in a study of the isomerisation of but-1-ene to *cis*-butene on HY zeolites and other acid silicates at 0–200 °C.[24] The attempts to detect the $C_4H_9^+$ carbonium ions failed in this case too, although a correlation was observed between the rate of reaction and the number of acid OH groups. It is suggested that the reaction proceeds in acordance with scheme 1. According to Paukshtis et al.,[24] the conversion of complex **5** into complex **6** is the rate-limiting stage. In a kinetic study, it was observed that the continuous increase in the intensity of the absorption bands of the saturated complexes **7** and **8** is accompanied by a decrease in the rate of isomerisation. Evidently complexes **7** and **8** are 'dead-end' compounds which deactivate the catalyst.



A band at 1510 cm^{-1}, characteristic of a C=C bond with an OH group, was observed in the IR spectra in the isomerisation of hex-1-ene to hex-2-ene and the subsequent *cis–trans* isomerisation on the HZSM-5 zeolite at 200 °C. At the same

Scheme 1

time, the spectrum of the OH groups changed also. On this basis, the authors[25] concluded that the reaction proceeds via the intermediate formation of a carbonium ion (a reaction of the **5** → **6** type)‡.

The formation of stable carbonium ions of the type $(CH_3)_2C^+CH_2CH_3$ has been postulated in the adsorption of isoalkenes on zeolites.[22] The possibility of the isomerisation of the double bonds via cyclic complexes of the type

9

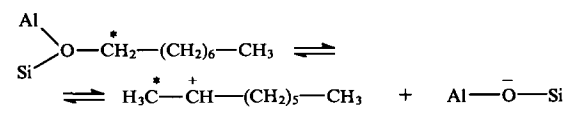
in accordance with an associative, 'concerted' mechanism was considered in the same investigation.

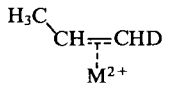
Table 2 presents a compilation of data concerning the intermediates formed in the adsorption of alkenes on heterogeneous catalysts; the reliability of the evidence for the role of a particular complex in the isomerisation reaction, in conformity with the criteria described above, is indicated.

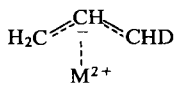
A dissociative isomerisation mechanism, involving the cleavage of a C–H bond with formation of π-allyl anions or carbonium ions, has been postulated in all the studies considered. We may note, however, that virtually no direct spectrokinetic confirmations of such a mechanism exist (apart from the detection of the π-allyl complex itself). The observed changes in the IR spectra of the adsorbed molecules are associated in most cases with dead-end compounds not involved in the main reaction.

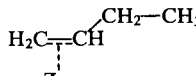
The data presented in table 2 refer to the isomerisation of alkenes involving the double bond. As regards their skeletal isomerisation, there have been virtually no investigations in which intermediates were identified with the aid of IR spectroscopy. The mechanisms of the skeletal isomerisation quoted in individual communications (see, for example, Cuong Pham-Hun et al.[26]) are based on indirect data.

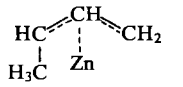
‡The migration of carbon along the chain of carbon atoms in octane at 20–70 °C on the HZSM-5 zeolite has been recently demonstrated by ^1H and ^{13}C NMR methods [A G Stepanov, M V Luzgin, V N Romannikov, K I Zamaraev *Catal. Lett.* **24** 271 (1994)]. The authors believe that this proves the formation of a carbenium ion. The direct spectroscopic detection of this ion is impossible because it is in equilibrium with an alkyl silyl ether.

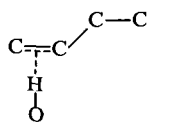


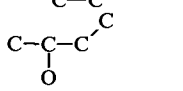












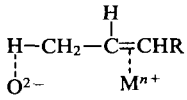


Table 2. Intermediates formed in the isomerisation of alkenes.

Reaction, catalyst	Intermediate complex	Reliability	Ref.
Isomerisation of deuteriopropenes on oxides		M	21, 22
		M	21, 22
Isomerisation of butenes on ZnO		H	23

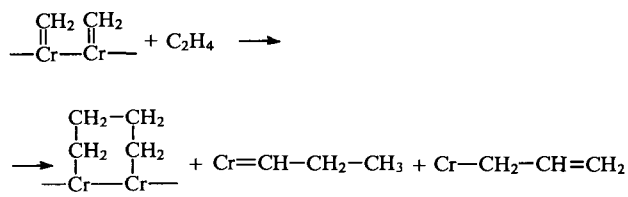
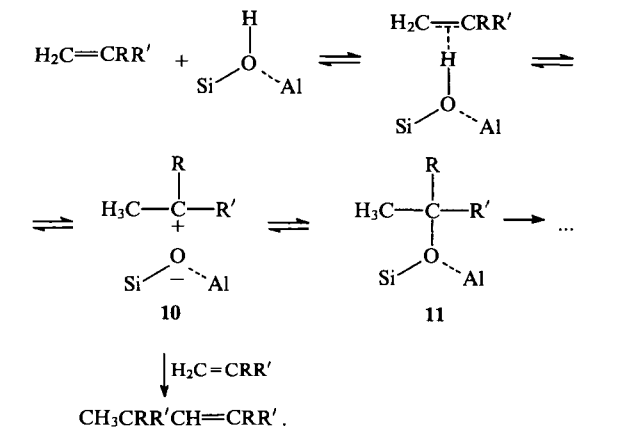
Isomerisation of oct-1-ene on HZSM-5 zeolite		M	



IV. Oligomerisation of alkenes and certain other reactions

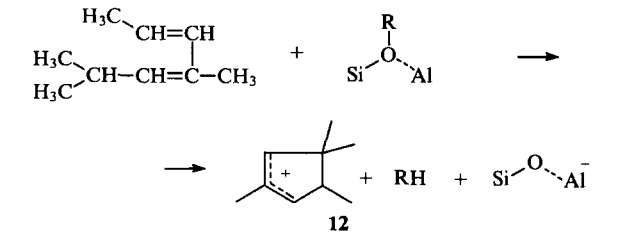
1. Oligomerisation, alkylation, and aromatisation of alkenes



The oligomerisation of alkenes $n\mathrm{A} \rightarrow \mathrm{B}$ formally belongs to the class of reactions of a more complex type than isomerisation. However, the fact that the reaction product—an oligomer or a polymer—is not desorbed into the gas phase facilitates the spectrokinetic investigation and this renders the results more unambiguous. UV-VIS and NMR spectroscopy have been used together with IR spectroscopy to identify the intermediates.

Mainly the stable starting materials and oligomers as well as stable long-lived alkoxy-derivatives have been dectected in situ by IR [25,27–29] and NMR [30–32] spectroscopy in the oligomerisation of C_2H_4, C_3H_6, and C_4H_8 on zeolites at 0–200 °C.

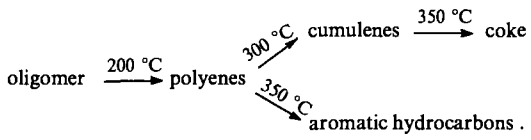
The initial stage of the interaction—the formation of a π-complex with an OH group—was discovered in a study of the NMR spectra of isobutene on the HY and HZSM zeolites at a low temperature (−150 °C). [31] The oligomerisation of propene to 4-methylpentene and hex-1-ene on NiO/SiO_2 involves the formation of a π-complex between C_3H_6 and Ni^{2+}. [33] The nature of the IR spectra, obtained in situ in a study of the polymerisation of C_2H_4 on Cr/SiO_2, [27] indicates the existence of dissociative forms of ethylene adsorption. This provided grounds for the hypothesis that carbenes participate in the reaction, although these intermediates were not detected directly.



The π-complex of the alkene with an OH group can be converted into a carbonium ion. It can be formed as a transition state, but carbonium ions have not been detected in the study of the reactions of alkenes by IR and NMR spectroscopic methods even at low temperatures. [31–32] Apparently they are immediately converted into long-lived alkoxide groups $\equiv Si-OR$ on alumino-silicates. A study of the kinetics of the oligomerisation of C_2H_4 and C_3H_6 on the TsVK zeolite and silicalite [29] from the change in the IR band at 2935 cm^{-1} (due to CH_2 groups in the reaction products) showed that the rate of reaction initially diminishes and then increases. This is due to the fact that the CH_3O groups are relatively unreactive, although the $O(CH_2)CH_3$ groups are reactive in relation to the alkene. The band due to the CH_3O group (2977 cm^{-1}) gradually disappears from the spectrum. The initial stages of the oligomerisation reaction may be represented by the following scheme: [31–33]

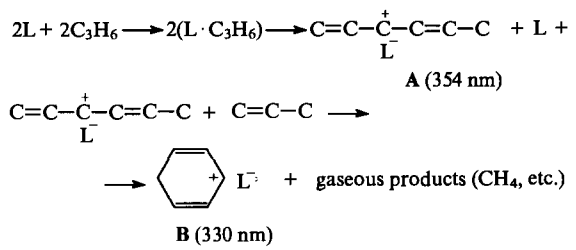
This is followed by the formation of the alkoxide $\equiv Si-O-CH_2-CRR'-CH_2-CHRR'$ and a further increase in the chain length of the oligomer. The rate-limiting stage may be the conversion of the intermediate carbonium ion **10** into a dimer, after which both linear and branched polyalkenes are produced.

Stable cyclic carbonium ions **12**, formed via the scheme



after the consumption of the entire monomer, have been detected in a study of the oligomerisation of C_3H_6 by the NMR method. [32] However, they are not intermediates in the oligomerisation reaction.

The oligomer chain is apparently terminated via β-limination. Peaks corresponding to the products of the interaction of the terminal $-CH=CH_2$ group of the growing oligomer with an OH group of the catalyst have been observed in the IR spectra obtained in the polymerisation of C_2H_4 on 0.5% Cr/SiO_2. [34]



The subsequent stages of the reaction of oligomers at a higher temperature (260–400 °C) were investigated by UV-VIS spectroscopy. [29,35–37] Polyenyl and other condensed structures

were then detected. Starting from 250–300 °C, aromatisation takes place, while at a still higher temperature (350 °C) coke is formed. The overall scheme of the reactions of oligomers on zeolites assumes the following form:[29]

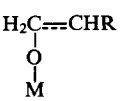
Polyenes are stabilised under catalytic conditions on the same OH groups as oligomers. It has been confirmed by the IR [28] and NMR [38] spectroscopic methods that coke and aromatic hydrocarbons are formed via independent pathways.

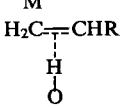
The formation of stable unsaturated cations has also been observed by UV-VIS spectroscopy. It has been shown [35] that C_3H_6 is aromatised on the Lewis acid centres of γ-Al_2O_3 at 180–300 °C via the mechanism

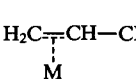
where L is a Lewis acid centre. The rate of formation of compound **B**, characterised by the 330 nm vibration frequency, is proportional to the concentration of compound **A** (354 nm vibration frequency) and the pressure of C_3H_6 in the gas phase. After the reaction has occurred, various condensed compounds are detected on the surface.[23,35,36]

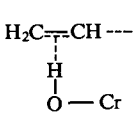
It has also been shown by the EPR method that, when HM, HY, etc. zeolites with adsorbed alkenes are heated, free-radical products are formed. For example, C_3H_6 affords the radicals[39]

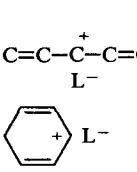
$$CH_2{=}\dot{C}H{=}CH_2 \text{ and } CH_2{=}\dot{C}H{=}CH{-}CH(CH_3)_2.$$

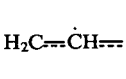


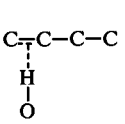












The EPR spectra were recorded after extensive cooling and not under catalytic conditions.

Alkylation on zeolites proceeds via a mechanism analogous to the oligomerisation mechanism. The π-complexes of C_4H_8 and alkoxide compounds were detected in situ in a study of the alkylation of isobutane by butenes on the HNaCaX zeolite by IR spectroscopy. According to the authors,[40] butane can also give rise to the intermediate carbonium ion $(CH_3)_3C^+$, which participates in hydride (H^-) transfer to $C_4H_9^+$ with formation of the alkoxy-group $(CH_3)_3C{-}O{-}$ or a C–C bond in oligomers via an associative mechanism. Isobutane is capable of being adsorbed mainly on the basic (nucleophilic) centres of the zeolite, whereas butenes are adsorbed on the acid centres.

We may note that the oligomerisation examined above probably proceeds via an associative mechanism (for example, by the reaction of the carbonium ion **10** with the alkoxide **11**). Its occurrence apparently requires two active centres: one with the alkoxide chain and the other with the carbonium ion. The lack of a direct relation between the concentration of the alkoxide structure and the rate of oligomerisation indicates the possible existence of equilibria of the type **10** $\rightleftharpoons$ **11**. The main bulk of the surface may serve as a reservoir supplying the reaction when its conditions are varied. It may be that cyclic carbonium ions **12** play the same role.

A compilation of data on the intermediate compounds formed in the oligomerisation of alkenes, aromatisation, and alkylation is presented in Table 3.

Table 3. Intermediates formed in the oligomerisation and certain other reactions of alkenes.

Reaction, catalyst	Intermediate complex	Reliability	Ref.
Oligomerisation of alkenes on zeolites		L	25, 27–33
		M	31
Oligomerisation of propene on NiO/SiO_2		L	33
Polymerisation of ethylene on Cr^{3+}/SiO_2		L	27, 33
Aromatisation of propene on Al_2O_3		H	35
Aromatisation of propene on zeolites		L	39
Alkylation of isobutane by butenes on zeolites		L	40

The polymerisation of alkenes, for example on Ziegler–Natta catalysts, apparently proceeds via a coordination mechanism. The alkene molecule forms a π-complex with the transition metal ion, which simultaneously retains the polymer chain. CH_2 groups, interacting with the catalyst to some extent, have been detected in a high concentration in an IR spectroscopic study of this process.

2. The cracking of hydrocarbons

The cracking of hydrocarbons can be regarded as a reaction which is to some extent the reverse of oligomerisation. It too proceeds on aluminosilicates. However, cracking occurs at much higher temperatures and therefore the intermediates may be different. A generally accepted view is that carbonium ions are formed as intermediate species. The application of spectroscopic methods in situ to investigate the cracking is difficult owing to the high process temperatures. The same intermediates as in oligomerisation have been detected by the NMR method among the cracking products of propene oligomers on HY at 220 °C.[38] Dissociative mechanisms are more probable at higher temperatures.

In the cracking of the methylcyclohexane and 3-methylpentane on H-mordenite above 100 °C, adsorbed free radicals were detected by the EPR method.[41] They are stable up to 100 °C, while at a higher temperature they are converted into the final products, possibly via the formation of intermediate carbonium ions. The EPR signal is not observed at room temperature. The authors suggest that a strong Lewis acid centre abstracts an electron from a tertiary C–H bond in the first stage of the reaction with formation of a radical-cation. The latter loses a H atom and gives rise to a free radical. This is followed by the two-stage elimination of the hydride ion.

The cracking on metals proceeds via a different mechanism. On decomposition of C_2H_6 on Pt/SiO_2, absorption due to ethylidyne structures $CH_3C{\equiv}Pt$ and possibly $PtCH_2-CH_2Pt$ were observed in the IR spectra. At 200–300 °C, these compounds decompose with formation of CH_4 and a carbon residue.[42]

V. Metathesis of alkenes

The metathesis of alkenes

$$2A \rightarrow B + C$$

is formally a reaction of a more complex type than those examined above. However, in reality its mechanism is simple, since all the reactants (A, B, and C) belong to the same class of alkenes (for example A may be propene, B ethylene, and C butene). Therefore the intermediates should also be of the same type. Intermediate carbene complexes have been detected in this reaction.

The present authors investigated the UV-VIS diffuse reflectance spectra of molybdenum, tungsten, and rhenium oxides deposited on Al_2O_3 and SiO_2.[43,44] The mechanisms of the metathesis of propene in the presence of such a catalyst are different at low (50–250 °C) and high (300 °C) temperatures judging from the content of the butene isomers. It was postulated that the metathesis can proceed via quasi-cyclobutane and carbene mechanisms at low and high temperatures respectively.

$$H_3C-CH=CH_2 + 2M \longrightarrow H_3C-CH{:}M + H_2C{:}M$$

$$H_2C{:}M + H_3C-CH=CH_2 \longrightarrow \underset{\text{13}}{H_3C-\underset{\displaystyle CH_2}{\overset{\displaystyle M}{\overset{\diagup\!\diagdown}{CH}}}-CH_2} \longrightarrow$$

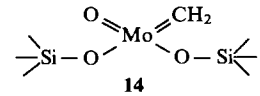
$$\longrightarrow H_3C-\underset{\displaystyle CH_2}{\overset{\displaystyle \diagup\!\diagdown}{CH}}-CH_2 + CH_3CH=CHCH_3 + C_2H_5CH=CH_2$$

$$H_2C{:}M + H_3C-CH=CH_2 \longrightarrow H_3C-CH{:}M + C_2H_4$$

$$H_3C-CH{:}M \longrightarrow M + C_2H_4$$

M = metal

However, conclusions concerning the mechanism were reached on the basis of indirect data, namely by analysing changes in the coordination in the Mo, W, and Re complexes, which are reflected in the nature of the UV-VIS spectra.



UV-VIS spectroscopy has been applied[45,46] directly under the conditions of the propene metathesis reaction. The rate of reaction was determined simultaneously with the measurement of the spectra. Comparison of these data made it possible to establish that the activation of the $Mo(CO)_6/\gamma\text{-}Al_2O_3$ catalyst is associated with the formation and rearrangement of subcarbonyl structures on the surface. The formation of the $Mo_2(CO)_6$ active centre may be represented schematically as follows:

$$Mo(CO)_6 \rightleftharpoons Mo(CO)_4 \underset{-CO}{\overset{L}{\rightleftharpoons}} Mo(CO)_3L \underset{-L}{\rightleftharpoons} Mo_2(CO)_6,$$

where L is the ligand (possibly a surface OH group).

The kinetic parameters of the formation of the active centre in the metathesis reaction have been established as a function of the state of the hydroxyl coating of the surface. The decrease in the activation energy for the formation of $Mo_2(CO)_6$ active centre is associated with the decrease in the energy expenditure on overcoming the hydroxy-group barrier when it arises. The nature of the temperature dependence of the activity of the catalyst is determined by the ratio of the rates of evolution of CO and of the rearrangement of the subcarbonyl surface structures.

The formation of the carbene complex

14

stable in vacuo up to 400–450 °C, has been observed by IR and UV-VIS spectroscopy in the adsorption of cyclopropane on MoO_3/SiO_2, in which Mo^{6+} had been reduced photochemically to Mo^{4+}.[47] Isotope exchange between complex **14** and C_2D_4 is observed at room temperature.

$$Mo{=}CH_2 + C_2D_4 \rightleftharpoons Mo{=}CD_2 + D_2C{=}CH_2.$$

At 0–350 °C, complex **14** interacts with alkenes via the mechanism

$$Mo{=}CH_2 + H_2C{=}CH-CH_3 \rightleftharpoons$$

$$\rightleftharpoons Mo{=}CH-CH_3 + C_2H_4\uparrow \rightleftharpoons \overset{H_2C}{\underset{Mo}{\overset{\|}{\underset{|}{}}}}CH_2.$$

There is also a possibility of the formation of the cyclobutane complex **15**, which has been confirmed by the appearance of new bands in the spectrum.

$$Mo{=}CH_2 + H_2C{=}CH-CH_3 \rightleftharpoons \underset{\text{15}}{\overset{CH_3}{Mo\diagup\!\diagdown}} \rightleftharpoons$$

$$\rightleftharpoons Mo{=}CH-CH_3 + C_2H_4$$

The same bands appear also in the interaction of cyclopropane with the Mo=O bond. The energy of the $Mo{=}CH_2$ bond in complex **14** is 435 kJ mol^{-1}.[48]

It is noteworthy that the catalyst in the study of Vikulov et al.[47] was subjected to photochemical reduction. However, in the usual thermal metathesis of alkenes there is also a possibility of the appearance of carbenes. In the metathesis of propene on Nb/SiO_2, the intermediate carbene complex $Nb{=}CH_2$ was formed.[49] Its structure was investigated by IR spectroscopic and EXAFS methods. It was found that the Nb–C distance in the complex is 0.195 nm, which corresponds to the length of the Nb=C double bond (whereas the length of the normal Nb–C bond is 0.210 nm). The IR bands correspond to vibrations of the CH_2 group.

Data concerning the intermediates formed in the metathesis of alkenes are compiled in Table 4.

The kinetics of the formation and decomposition of the carbene were not compared in the above studies[43,44,47–49] with the kinetics of the overall metathesis reaction.

Table 4. Intermediates formed in the metathesis of alkenes.

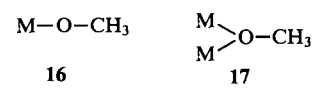
VI. Decomposition of alcohols

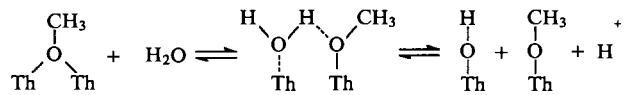


Alcohols decompose via two principal pathways: with dehydration and the formation of an alkene and water or with dehydrogenation and the formation of hydrogen and an aldehyde (or ketone). Both pathways involve reactions of the type

$$A \rightarrow B + C.$$

On dehydration of the first member of the series of aliphatic alcohols (methanol), formaldehyde CH_2O or dimethyl ether $(CH_3)_2O$ may be formed. The dehydration of methanol to CO and H_2 will not be considered here. The conversion of methanol into hydrocarbons will be examined below in Section VIII.

1. Dehydration of alcohols



Surface methoxy-groups were detected in situ by IR spectroscopy in all the studies on the decomposition of methanol on oxides. They are present on α-Fe_2O_3,[50] CeO_2 and ThO_2,[51] Cr_2O_3,[52] ZnO,[53] and ThO_2.[54] Linear (compound **16**) and bridging (compound **17**) methoxy-groups were distinguished on CeO_2 and ThO_2.

16 **17**

The decomposition of complex **16** results in the reformation of methanol, while the decomposition of complex **17**, or more precisely the decomposition of two such complex species next to one another, affords the $CH_3OH + (CH_3)_2O + CO$ mixture.[52]

There is also a possibility of the interconversion of complexes **16** and **17**.[54]

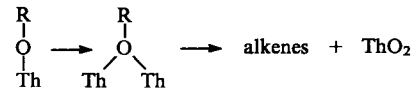
17 **18** **16**

The interconversion of the methoxide complexes **16** and **17** proceeds in essence via the associative catalytic dehydration mechanism.

Methanol bound to the oxide by the CH_3OH ... OM hydrogen bond was also detected at a low temperature (150 °C). It may be a precursor of the methoxide.[50] Heating to high temperatures (> 200 °C) leads to the conversion of the alkoxides into formates and carbonates.[50,53]

Periodic modulation of the free stream of CH_3OH with a 1 s resolution made it possible[55] to distinguish two mechanisms of the dehydration of methanol on γ-Al_2O_3—the dissociative mechanism

$$CH_3OH_{ads} + CH_3O_{ads} \longrightarrow CH_3OCH_3(g) + OH_{ads}$$

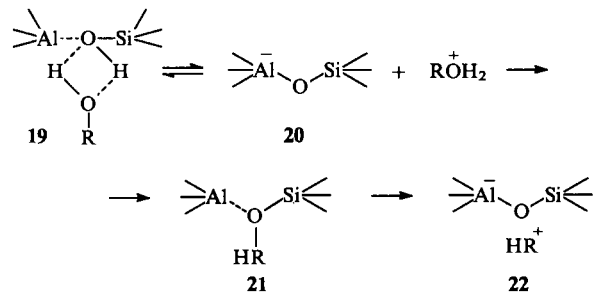


$$2\,OH_{ads} \longrightarrow H_2O(g) + O_{ads},$$

and the associative mechanism

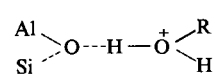
$$CH_3OH_{ads} + O_{ads} \longrightarrow CH_3O_{ads} + OH_{ads} \longrightarrow$$

$$\longrightarrow CH_3OCH_3(g) + H_2 + H_2O.$$



Alkoxy-groups are also formed in the dehydration of higher alcohols: isopropyl alcohol on ThO_2,[54] isobutyl alcohol on Al_2O_3,[56] and various alcohols on the HZSM-5 zeolites.[57] An attempt has been made[54] to correlate the kinetics of the dehydration of *tert*-butyl alcohol and isopropyl alcohol, based on the measurement of the rate of evolution of gaseous products, with the kinetics of the decomposition of linear and bridged alkoxides. The authors proposed the following scheme:

However, bearing in mind that the curves obtained[54] are insufficiently distinct, the reaction may also proceed via a bimolecular mechanism.



The change in the diffuse IR spectra in situ and the kinetics of dehydration of a series of alcohols (C_2H_5OH, iso-C_3H_7OH, *tert*-C_4H_9OH) on Al_2O_3 have been investigated by the response method at 140–280 °C.[56] The removal of alcohol from the gas phase at 260 °C leads immediately to the disappearance of the bands due to the hydrogen-bonded or coordinated alcohol; the bands of the alkoxide vanish somewhat more slowly, while those of the carboxylates remain unchanged. The dehydration rate constants, found from the analysis of the IR spectra and from the yield of the gaseous products, are the same. Hence the authors concluded[56] that the alkoxide is an intermediate.

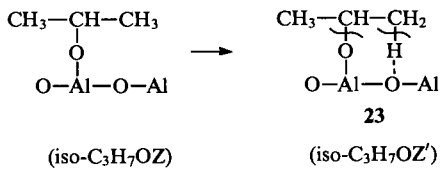
In the adsorption of various alcohols, ranging from C_1 to C_4, on the HZSM-5 zeolite,[57,58] each alcohol molecule is adsorbed near an Al atom, which is indicated by the disappearance from the IR spectrum of the band due to the acid OH group. The results of exchange studies in isopropyl alcohol and *tert*-butyl alcohol, on the one hand, and D_2O, on the other, indicate that the alcohol molecules are dehydrated with formation of a carbonium ion before desorption. However, 1-butanol does not exchange with D_2O, which can be explained, according to the authors,[57] by a bimolecular mechanism in which two alcohol molecules are involved. A hydrogen bond is formed in the first stage of the interaction (complex **19**), after which the oxonium ion **20** and then the carbonium ion **22** appear.

19 **20** **21** **22**

The covalent structure **21** predominates in zeolites with nucleophilic centres, whilst the ionic structure **22** predominates in zeolites with more acid centres. The ionic structures **20** and **22** are not manifested in the IR spectra (at any rate it is difficult to distinguish them from the covalent structures), but the authors[57] assume that they may arise as a result of stabilisation due to interaction with the zeolite lattice, for example with formation of the bridged ions

as in homogeneous catalysis.[58] Such stabilisation helps to overcome the energy barrier in the endothermic stages of the reaction.

We may note that the formation of association complexes in the dehydration of isopropyl alcohol on Al_2O_3 was demonstrated previously by kinetic and calorimetric methods.[59] A four-stage scheme was proposed:



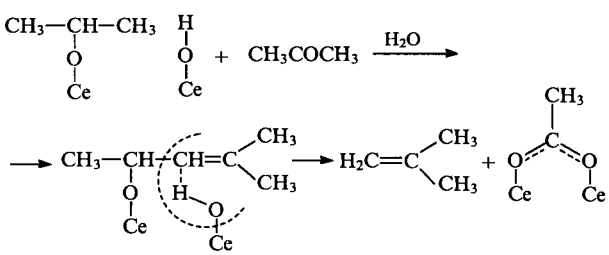
$$\text{iso-}C_3H_7OH + ZOH \rightleftharpoons [\text{iso-}C_3H_7OH \cdot ZOH],$$

$$[\text{iso-}C_3H_7OH \cdot ZOH] \rightleftharpoons \text{iso-}C_3H_7OZ + H_2O,$$

$$\text{iso-}C_3H_7OZ \xrightarrow{Z'} \text{iso-}C_3H_7OZ + Z,$$

$$\text{iso-}C_3H_7OZ' \longrightarrow C_3H_6 + Z'OH.$$

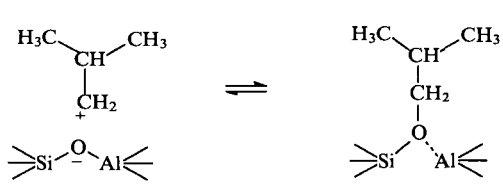
A complex of type **19** is formed in the first stage, whilst the third stage (possibly rate-limiting) represents surface diffusion of the isopropoxide groups to another active centre Z′ incorporating a surface oxygen atom.



(iso-C_3H_7OZ) (iso-C_3H_7OZ')

The activation energy for this stage is 106 kJ mol^{-1}. The measured enthalpy of the first stage (26 kJ mol^{-1}) corresponds approximately to the energy of two hydrogen bonds in the type **19** complex or to a lifetime of the complex of $\sim 10^{-10}$ s.

Consequently the mechanisms proposed[57,60] agree with one another as regards the formation of hydrogen-bonded association complexes and alkoxy-groups, which do in fact largely cover the surface under stationary conditions. On the other hand, the formation of propene (the concluding stage of the reaction) proceeds, according to Aronson et al.,[57] with participation of a carbonium ion, while Sadovnikov and Gefter[60] believe that it proceeds with participation of basic centres. The question whether all the alkoxy-groups (Z centres) or only some of them (Z′ centres) participate in the formation of the final product while the remaining ones serve as a reservoir for the latter remains unresolved.

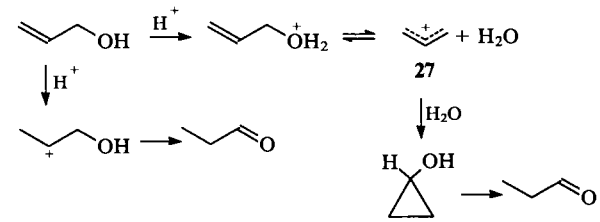


According to the view of Zaki and Sheppard,[61] based on the analysis of the IR spectra recorded after heating CeO_2 in isopropyl alcohol at 150–400 °C, the dehydration also proceeds via an associative mechanism. Apart from the direct dehydration, aldol condensation with the acetone formed on dehydrogenation of the alcohol takes place.

24

At a low temperature, close to room temperature, the aldol condensation proper, with formation of the unsaturated ketone $CH_3COCH=C(CH_3)_2$ from complex **24**, takes place. A similar process involving CH_3CHO on Na/SiO_2 has been investigated by Raman spectroscopy at room temperature.[61] Enolate complexes and complexes retained on the surface by two C–O–M bonds were detected. Physically adsorbed 2,4-dimethyl-1,3-dioxane was also found. On heating to 130 °C, it decomposes, affording crotonaldehyde $CH_3CH=CH-CHO$, acetaldehyde (or the adsorbed enolate $CH_3=CHOH$), and water.

The mechanism of the alcohol dehydration has also been investigated by the NMR method in situ.[63–69] The dehydration of *tert*-butyl alcohol and isobutyl alcohol at 100 °C, proceeds with formation of isobutene, water, and a C_8 oligomer according to the NMR data. The short-lived carbonium ion **25** may be an



25 **26**

intermediate.[64,65] The alcohol molecule is localised at an intersection of the zeolite channels. Under these conditions, the alkoxide **26** (C_4H_9OSi) is an intermediate in the dehydration of isobutyl alcohol but not *tert*-butyl alcohol.§

The stable triphenylmethyl carbonium ion was detected in the dehydration of triphenylcarbinol on acid catalysts.[67]

The formation of the isobutyl carbonium ion, also in the dehydration of *tert*-butyl alcohol on HZSM-5, could not be detected by the NMR method,[62] although the same authors[57] had previously postulated the appearance of complex **22** in this process on the basis of IR spectroscopic data. Only type **21** alkoxide was detected. The same complex was found by these investigators also in the adsorption of methylpropane. The carbonium ion formed as a result of the adsorption of C_3H_8 on the zeolite[68] likewise belongs, according to Stepanov et al.,[64] to the class of ethers Si–O–R. The formation of a carbonium ion on the HY zeolite is more probable than on HZSM-5 owing to its higher relative permittivity and nucleophilicity.

NMR study of the dehydration of allyl alcohol on the HZSM-5 zeolite made it possible to detect the intermediate oxonium and carbonium compounds and to establish the sequence of the reactions.[69]

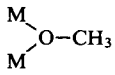
27

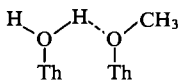
The interaction of the allyl cation **27** with allyl alcohol afforded diallyl ether $(CH_2=CH-CH_2)_2O$.

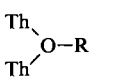
The formation of the isopropoxide was likewise observed in a study of the decomposition of isopropyl alcohol on metallic molybdenum by the EELS method.[70] C_3H_6, C_3H_8, H_2, and H_2O were also found among the reaction products.

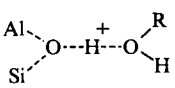
A compilation of data concerning the intermediates formed in the dehydration of alcohols is given in Table 5.

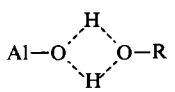
Summarsing the data presented above on the dehydration of alcohols, we may note that the formation of linear and bridged alkoxides is acknowledged in all the investigations and in some of them also the formation of carbonium ions. Spectrokinetic measurements have scarcely been made with the exception of some not very clear-cut data.[54,56] However, on the basis of the combination of a large number of results, one may assume that the above complexes are very probably reaction intermediates.

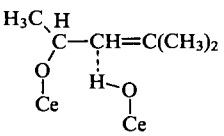


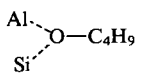


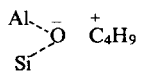




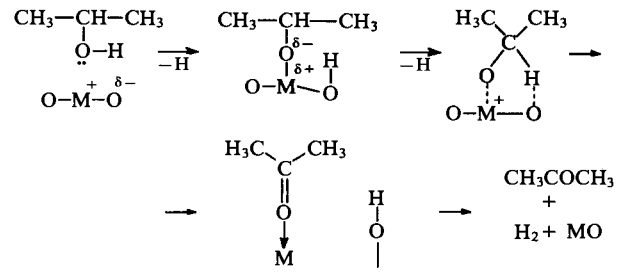








2. Dehydrogenation of alcohols



When alcohols are dehydrogenated on an oxide surface, bands corresponding to alkoxide structures are also observed in the IR spectra,[60,71] but the presence of a strong basic (nucleophilic) centre next to an acid centre is essential for the occurrence of this reaction pathway.

According to Efremov and Davydov,[71] the conversion of isopropyl alcohol occurs only in the absence of the weakly bound alcohol, blocking the neighbouring centres (possibly O^{2-}), i. e. the occurrence of the reaction via an associative mechanism is impossible in this case.

§It has been possible to demonstrate by the NMR method that the decomposition of isobutyl alcohol on the HZSM-5 zeolite involves the transfer of the $^{13}CH_2$ label from isobutyl alcohol to isobutyl silyl ether **26** and a further redistribution of ^{13}C among the C atoms in butane[J Kokes, A L Dent *Adv. Catal.* **22** 1 (1972)]. According to the authors, this demonstrates the occurrence of the transition **26** → **25** and the participation of the carbonium ion **25** in the dehydration of C_4H_9OH.

Table 5. Intermediates formed in the dehydration of alcohols.

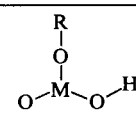
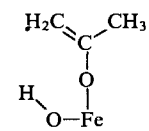
Dehydration of triphenyl-carbinol on acid catalysts	$(C_6H_5)_3C^+$	L	67

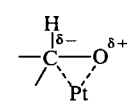
The IR bands at 2910 and 2960 cm^{-1}, observed when isopropyl alcohol was dehydrogenated on Fe_2O_3 at 150 °C,[72] were attributed to the enolate, which is evidently an intermediate between the alkoxide complex and the final product.

The formation of the $C_2H_5O^-$ and the $C_4H_8O^-$ alkoxides as well as acetates and carbonates, which are apparently side products, was noted in a ^{13}C NMR study of the decomposition of C_2H_5OH on MgO.[73]

On dehydrogenation of cyclohexanol to cyclohexanone on Pt/SiO_2, a shift of the C=O vibration bands was observed in the IR spectra and was attributed to the occurrence of the process







The broad bands at 1400 and 1610 cm^{-1} were assigned to the enol group.

Aldehydes and ketones may also be formed in the oxidation of alcohols with participation of the oxygen of the oxide lattice.

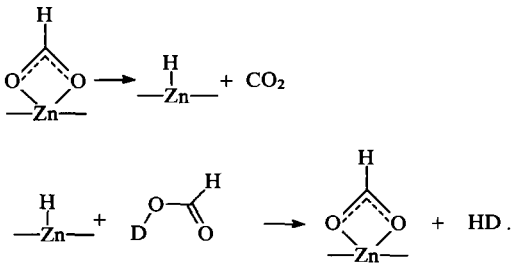
Data on the dehydrogenation of alcohols are compiled in Table 6.

Table 6. Intermediates formed in the dehydrogenation of alcohols.

Reaction, catalyst	Intermediate complex	Reliability	Refs
Dehydrogenation of alcohols on oxides		L	60, 71
Dehydrogenation of isopropyl alcohol on Fe_2O_3		L	72
Dehydrogenation of cyclohexanol on Pt/SiO_2		L	74

Thus the number of reliable data on intermediate compounds participating in the dehydrogenation of alcohols is much smaller than for their dehydration. The formation of enolates or enolate anions is more probable.

VII. Decomposition of acids



Like alcohols, formic acid may decompose via two pathways: dehydration and dehydrogenation. The principal substances formed on the catalyst surface are formates.[19, 20, 50, 75–77]

In the studies by Tamaru and coworkers already mentioned,[19, 20, 77] a catalyst disc was heated in the cell to the reaction temperature and then DCOOD was introduced until the attainment of a steady rate of decomposition. After this,

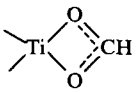
the DCOOD in the gas phase was rapidly replaced by HCOOH and the reaction was continued, observing simultaneously both the behaviour of the chemisorbed species and the rate of the overall reaction. The experiments on the dehydration of formic acid at 150–190 °C on Al_2O_3 showed that most of the adsorbed $DCOO^-$ ions vanish during the reaction, but the corresponding number of molecules appear in the gas phase as HCOOH, i.e. a rapid exchange takes place. A correlation was observed between the rate of dehydration of HCOOH and the number of proton centres on the surface. It was concluded that the $HCOO^-$ groups are not intermediate complexes and that the dehydration of formic acid proceeds when HCOOH molecules interact with the H^+ centres. The adsorption of molecular HCOOH on SiO_2 was observed, but formates were not detected under these conditions. According to the authors,[20] in this case too HCOOH molecules in the gas phase react with OH groups.

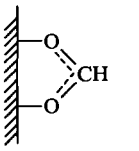
The dehydration of HCOOH on TiO_2 and zeolites has been investigated by ^{13}C NMR.[73] A monodentate formate, bound to an OH group, was detected on TiO_2, while on the zeolite a bidentate formate was found. The rate-limiting stage may be the removal of H_2O from the surface on condensation of the surface OH groups.

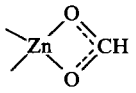
On the other hand, study of the dehydrogenation of HCOOH on ZnO at 145–220 °C confirmed the hypothesis that the reaction proceeds via intermediate formates.[19,20] When HCOOH was removed from the gas phase, evolution of H_2 ceased, but the rate of evolution of CO_2 did not change. On reintroduction of HCOOH into the gas phase, the rate of evolution of H_2 was restored. Almost the entire surface of ZnO was coated by the formate during the reaction. On the basis of these data, the following mechanism of the dehydrogenation of HCOOH on ZnO was proposed:

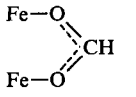
When HCOOH was dehydrogenated on α-Fe_2O_3, vibration bands of the bidentate formates, OH groups, and HCOOH molecules bound to the surface via the O–H and C=O groups were found in the IR spectra.[50] When the reaction was carried out in a closed vessel, a decrease in the intensity of the formate bands was observed.

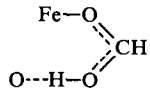
The data on the decomposition of formic acid are compiled in Table 7.





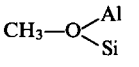






Thus the formates frequently detected under conditions for the decomposition of formic acid are most probably intermediates in the dehydrogenation of HCOOH, which proceeds via an associative mechanism. On dehydration of HCOOH, the protons are such intermediate forms.

VIII. Conversion of methanol into hydrocarbons



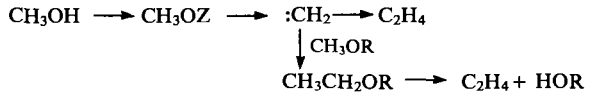
On zeolite catalysts, methanol is dehydrated to dimethyl ether, which is subsequently converted into hdyrocarbons. These reactions are referred to as the Mobil or the MTG (methanol to gasoline) process. The first stage, the formation of the ether $(CH_3)_2O$ on simple oxides, has already been considered in Section VI.

The mechanism of the conversion of methanol into hydrocarbons on the HZSM-5, HY, and SAPO-34 zeolites was investigated by the IR,[78,79] EPR,[80] and NMR[81–84] spectroscopic methods.

Table 7. Intermediates formed in the decomposition of HCOOH.

Reaction, catalyst	Intermediate complex	Reliability	Ref.
Dehydration on Al_2O_3	HCOOH	M	19, 20, 77
Dehydration on TiO_2		L	75
Dehydration on zeolites		L	75
Dehydrogenation on ZnO		M	19, 20
Dehydrogenation on Fe_2O_3		L	50
		L	50

When methanol interacted with the HZSM-5 zeolite in the absence of CH_3OH in the gas phase, the vibration bands due to different methoxy-groups were detected in the IR spectrum, viz.: the zeolite group CH_3O_{Zeol}, the oxygen atom of which is linked to the Al and Si atoms, i.e.



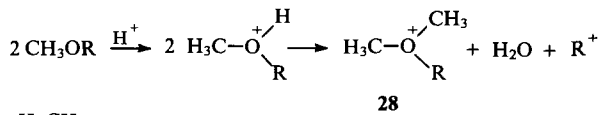
the CH_3O–Al and CH_3O–Si groups, and also weakly coordinated CH_3OH.[78] When CH_3O_{Zeol} is heated, methane and formaldehyde are formed. According to Novakova et al.,[78] this reaction proceeds via the mechanism

$$CH_3O_{Zeol} + (CH_3O-Al)^{n+} \longrightarrow CH_2O + CH_4 + Al^{(n+1)+} + O^-_{Zeol}$$

$$2\,CH_2O_{ads} + O^-_{Zeol} \longrightarrow CH_3OH + COO^-_{ads.\,Zeol}.$$

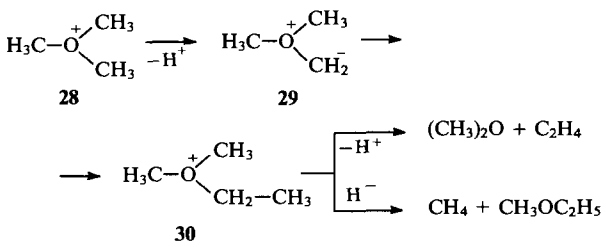
In the presence of methanol in the gas phase, C_2–C_5 hydrocarbons, mainly C_2H_4 and C_3H_6, were detected in the reaction products. Their formation was attributed to the associative interaction of CH_3OH with CH_3OZ, the details of which were not discussed.

The stage involving formation of the C–C bond is the most problematical. According to a hypothesis,[85] it is achieved via the intermediate formation of carbenes.



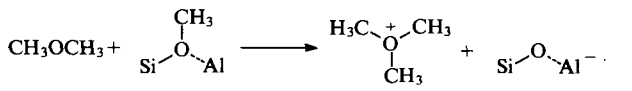
Under the conditions of the interaction of CH_3OH with C_3H_6 on the HTsVK and HY zeolites at 200–240 °C, absorption bands of various substances, attributed to oligomeric alkyl, allyl, and polyenyl cations, were observed in the IR and UV spectra.[79]

The study of the conversion of CH_3OH into hydrocarbons on zeolites by the ^{13}C and ^1H NMR methods in situ with rapid freezing of the reactor at the temperature of liquid nitrogen made it possible to follow the formation of the reaction products.[81–83]



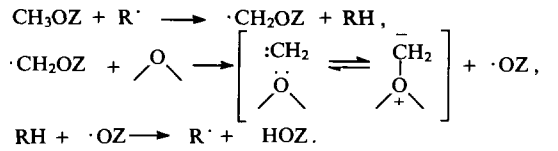
The compositions of the products in the gas phase and within the zeolite cavities were different. When HZSM-5 was used, mainly aromatic hydrocarbons were obtained. Mostly toluene, *m*- and *p*-xylenes, and 1,2,4-trimethylbenzene were found in the reaction products, while the adsorbed phase contained *o*-xylene and 1,2,4,5-tetramethylbenzene. Hence it follows that the molecules within the cavities are formed in equilibrium proportions and their emergence into the gas phase depends on the size of the windows in the zeolite.[82] On the SAPO-34 zeolite, which has even narrower channels, C_1-C_3 hydrocarbons emerge into the gas phase, while branched C_4-C_8 hydrocarbons remain in the intercrystalline space. In contrast to HZSM-5, aromatic products are not formed here.[81]

The hypothesis of the intermediate formation of oxonium ions in the synthesis of hydrocarbons from methanol was first put forward on the basis of isotopic and chemical data and not spectroscopic measurements.[86,87] According to Mole and Whiteside,[86] the oxonium ion **28** is formed in the interaction of methanol or dimethyl ether with the CH_3O^+RH surface group.



R = H, CH_3

This process was investigated using the WO_3/Al_2O_3 bifunctional catalyst with the aid of the ^{13}C carbon label. According to the authors' hypothesis,[87] in the presence of basic centres on the surface the trimethyloxonium ion **28** is converted into methylene-methyloxonium ylide **29** and the latter undergoes intramolecular methylation in the excess of dimethyl ether with formation of dimethylethyloxonium **30**.



This results in the formation of a C–C bond.

The kinetics of the conversion of CH_3OH into hydrocarbons on zeolites at 250 °C were investigated by the NMR method in situ.[84] An induction period was observed initially, after which the rate of reaction attained a steady level. The authors suggest[84] that the induction period is associated with the formation from $(CH_3)_2O$ of trimethyloxonium ion, first discovered by Hunter and Hutchings.[88] However, when ether and CH_3OH were adsorbed jointly, the trimethyloxonium ions were not detected and their kinetic role is therefore not clear. Manson et al.[84] postulated that the trimethyloxonium ion **28** is formed as a result of the activated interaction of $(CH_3)_2O$ with an alkoxide group:

Another, radical mechanism of the formation of the C–C bond has been put forward.[89] Free radicals had been previously detected by the EPR method in the decomposition of $(CH_3)_2O$ on HZSM-5.[80] It had also been shown[89] that the addition of NO inhibits the synthesis of hydrocarbons via a free-radical mechanism. Paramagnetic centres had been found in heat-treated HZSM-5. The following reaction mechanism was proposed:

The radical R· can be an alkyl, alkoxyl, alkoxyalkyl, etc. The reactive carbene species participates in the formation of the C–C bond, possibly via an oxonium ion.

Consequently the formation of the alkoxides ROZ as intermediates in the synthesis of hydrocarbons from CH_3OH may be regarded as more or less demonstrated (degree of reliability M), while the formation of oxonium ions is rather tentative (degree of reliability L). Their real kinetic role has not been elucidated. An associative mechanism, i. e. the participation of two molecules or fragments in the rate-limiting stage, is most likely.

IX. Conclusion

The results of studies of the intermediates in the simplest heterogeneous catalytic reactions of hydrocarbons, alcohols, and acids, obtained by spectroscopic methods during the last 15 years, were described above. We may note that in the vast majority of the studies quoted the reliability is low. The level of sophistication of even recent studies does not exceed that in the fundamental studies by Tamaru,[19,20,76,77] in which a parallel relationship between the rate of a catalytic reaction and the changes in the IR spectra of the adsorbed species under the reaction conditions was first noted.

The most reliable evidence concerning the real role of an intermediate is provided by the agreement between the rate of reaction of the surface complex and the rate of formation of the product.

There have been very few studies in which this approach has been employed. This is associated with the considerable experimental difficulties, among which the following may be noted: (1) the need to construct reactor-cells for the simultaneous study of the spectroscopic and catalytic properties of the system; (2) the need to develop methods for the determination of absorption coefficients; (3) inadequate time resolution in both kinetic and spectroscopic measurements; (4) the presence on the surface of a large number of different surface compounds, some of which are intermediates, whilst others are dead-end complexes.

The majority of the possible intermediate complexes listed above are chemical compounds with a saturated valence; these are alkoxides, formates, acetates, etc. The π-alkene and π-allyl complexes detected in the reactions with participation of alkenes are also fairly stable.

Free radicals were detected by the EPR method only on zeolites at low temperatures, while carbonium ions, which should be more reactive than the saturated intermediates, were found by the NMR method. By resorting to shorter measurement times, at least millisecond times (the lower limit of the characteristic times of catalytic reactions), it is possible to detect short-lived (and hence more reactive) intermediates.

It is also noteworthy that the low reliability of results obtained in the study of the catalytic reactions of hydrocarbons is associated with low intensity (low extinction coefficients) of the C–H and C–C vibrations. The adsorbed substances can be detected in these reactions only when their concentration is fairly high. This explains the small number of data referring to very familiar catalytic reactions such as oligomerisation, isomerisation, and the metathesis of hydrocarbons.

Trivalent phosphorus acid amides as phosphorylating agents for alcohols and amines

E E Nifant'ev, M K Grachev

Contents

I. Introduction	575
II. Phosphorylation of alcohols and phenols	575
III. Phosphorylation of amines	596
IV. Conclusion	602

Abstract. The principal results of studies on trivalent phosphorus acid amides (TPAA) as phosphorylating agents for alcohols, phenols, and amines are summarised and discussed. Problems concerning the catalysis and mechanism of the phosphorylation of proton-donating nucleophiles by TPAA are considered and new possibilities for the development of investigations on these lines are analysed. The preparative advantages of TPAA and the specific prospects for their use in fine organic synthesis and macromolecular chemistry are demonstrated. The bibliography includes 560 references.

I. Introduction

Phosphorylation, i.e. the introduction of a phosphorus-containing functional group in place of hydrogen atoms into a molecule of an organic nucleophile, is one of the most important problems in organophosphorus chemistry. Pentavalent and trivalent phosphorus reagents have been used traditionally in laboratory research and in industry. More attention was devoted initially to pentavalent phosphorus compounds and then in the subsequent period to trivalent phosphorus compounds. There were important reasons for such switching of interest. It was established that the use of trivalent phosphorus compounds ensures the maximum rates of phosphorylation and makes it possible to avoid side processes such as dealkylation and elimination. The usefulness of trivalent phosphorus reagents is also due to the creation of a modern strategy for the synthesis of organophosphorus compounds. According to the latter, in the first stage of the synthetic scheme the trivalent phosphorus reagents interact with nucleophiles to form only the key substances for subsequent reactions. When necessary, in the second stage of the scheme the key substances may be oxidised, iminated, and alkylated and may combine with sulfur, selenium, chlorine, etc. All these features lead to the formation of a large set of target compounds, including those which are inaccessible within the framework of the classical preparative methods based on the use of pentavalent phosphorus reagents.

Uspekhi Khimii **63** (7) 602 – 637 (1994); Translated by A K Grzybowski

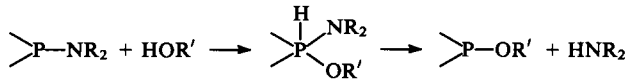
Among the phosphorylating agents which have come to be used vigorously during the last 10 – 15 years, mention should first be made of trivalent phosphorus acid amides (TPAA). Their advantages are ready availability, high reactivity, and the mild conditions in their preparative application. It is very important that the phosphorylating activity of these reagents can be increased significantly by catalysts, for example amine hydrochlorides.

By virtue of these qualities, TPAA are widely used nowadays for the solution of many problems in fine organic synthesis, for example for the preparation of higher oligonucleotides and other phosphorus-containing natural products and their analogues. Furthermore, they are used to obtain valuable high-molecular-mass compounds.

The number of communications describing phosphorylations by phosphoramides runs into thousands. Nevertheless, many important theoretical questions associated with their reactivity have still not been solved, although fairly numerous hypotheses concerning this topic have been put forward in the literature. Thus the phosphorylation mechanism has been elucidated only in broad outline, the relation between the structure and reactivity of the reagents has not been elucidated, and the role of solvation has been poorly investigated. Thus a clear contradiction has arisen between the breadth and depth of the investigation of the problem. In our view, further progress in the study of the phosphorylation of proton-donating nucleophiles by TPAA could be assisted by the writing of an analytical survey of literature data with emphasis on the latest advances. Bearing this in mind, the present review was prepared. In order to differentiate clearly the most important aspects of the problem, we made a selection from the published data and, instead of including data on the phosphorylation of all the proton-donating nucleophiles investigated, only those on the most popular nucleophiles are dealt with: alcohols, phenols, and amines. In the study of precisely these compounds, quantitative measurements have been made of the rates of phosphorylation and reliable results have therefore been obtained concerning both the synthetic aspects of the reactions and their mechanisms.

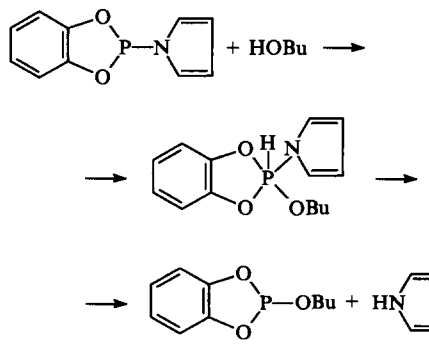
II. Phosphorylation of alcohols and phenols

The reaction of TPAA with alcohols and phenols was discovered at the very end of the 1950s independently in three laboratories simultaneously.[1-3]



$$>P{-}NR_2 + HOR' \longrightarrow >P{-}OR' + HNR_2$$

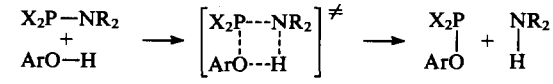
This phosphorylation method has important synthetic advantages (see above), but much time was required for investigators to become 'used to it'. It appears that the new method being chemically unusual had an effect. Indeed, until its discovery it had no evident analogies: the amides of pentavalent phosphorus acids phosphorylate alcohols and phenols with a low effectiveness and only at a high temperature, while the amides of carboxylic acids (and even sulfenic acids[4]) altogether failed to interact with alcohols (on the other hand, the corresponding esters are smoothly converted into amides on treatment with ammonia and primary and secondary amines)†. The new method had not been resorted to for some time also because the synthetic problems in which its best aspect would be manifested had not been clearly formulated and included in the range of those dealt with by chemists concerned with organophosphorus chemistry. Nevertheless, this induction period was not wasted. During this period, studies were carried out which established the catalytic nature of the reaction and its principal features as well as the most promising ways of using it. Ultimately, the TPAA came to be firmly included among organophosphorus reagents and began to be used vigorously for the phosphorylation of labile natural products, in the creation of new types of polymers, and in the solution of other complex scientific problems. Bearing this in mind, the present section of the review has been subdivided into individual subsections devoted to the basic problems and questions in the phosphorylation of alcohols and phenols by TPAA and also in the modern synthetic use of this reaction.



1. The mechanism of the phosphorylation reaction. Catalysis

a. History of the problem

In the first paper devoted to the alcoholysis and phenolysis of the simplest TPAA,[3] certain considerations concerning its mechanism were already put forward. Subsequently, this problem was dealt with by different investigators, but it was discussed only at a speculative level. A version of the mechanism of the 'addition–elimination' type was usually put forward in publications. Thus the intermediate formation of a hydrophosphorane, which decomposes with liberation of an amine, was postulated.[3]



The principal features of this scheme were subsequently confirmed experimentally in a study with cyclic systems,[7–13] for example:[10]

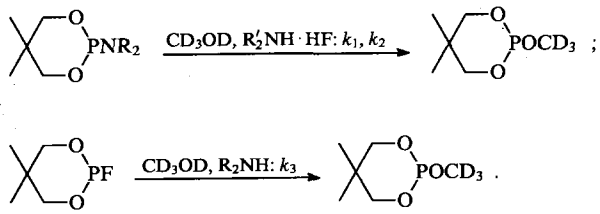
A variant of this scheme is the hypothesis of the P-protonation of the phosphoramide by the alcohol with formation of a quasi-phosphonium adduct, which splits off the amine and is converted into an ester.[3,14–20] An alternative hypothesis is that the TPAA undergoes N-protonation.[3,17,19–23] None of these variants was confirmed experimentally.

At the same time, a view concerning the mechanism of the phenolysis of TPAA has been expressed in the literature according to which a four-centred transition state is formed.[24,25]

This hypothesis is supported by certain thermodynamic data (the activation energies and entropies). Unfortunately experimental errors were made in the relevant studies[25,26] which vitiated the conclusions reached.

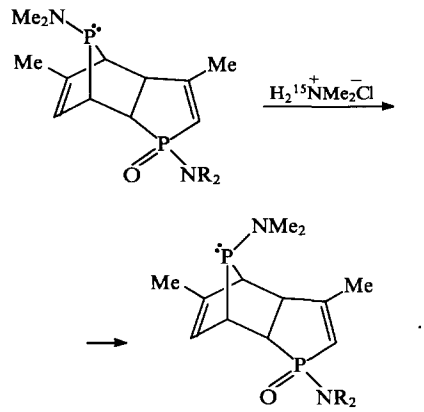
When studies of the rates of phosphorylation were undertaken, it proved possible in a number of investigations to elucidate important problems concerning the chemistry of the reaction. Thus it was confirmed that the process is bimolecular for equimolecular proportions of the reactants[10,25,27–31] and that the medium[10,25,26,31] and temperature[32] influence the reaction. The interesting fact that the phosphorylation is inhibited following the accumulation in the medium of the amine produced in the course of the substitution reaction was established; apparently the inhibition is caused by the complex formation reaction between the amine and the alcohol, which reduces the rate of the main reaction.[10,29,31,33,34]

b. Catalysis of the phosphorylation by amine hydrohalides



The study of the rate of alcoholysis of TPAA made it possible to determine the catalytic character of many reactions of this type. The catalytic effect was observed in 1965 on comparing the rates of phosphorylation of the simplest alcohols by phosphorus(III) acid amides freed from possible impurities and by phosphoramides which were obtained by the usual procedure and were contaminated by a certain amount of amine hydrochlorides (AHC).[35,36] The observed catalytic effect was subsequently confirmed in many laboratories,[10,18,22,25,28,37–41] the concentrations of the initial compounds and of the products of their reactions being usually determined by ^1H and ^{31}P NMR spectroscopy.[10,25,28,37–42]

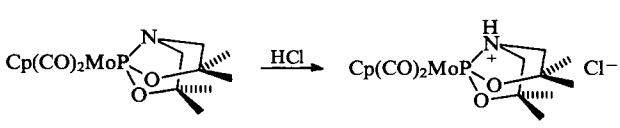
The chemical aspect of the catalysis was the subject of prolonged discussion, the outcome of which has been described by Nifant'ev and Borisov.[43]



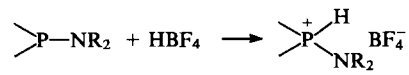
Two hypotheses were discussed. One of them was that acid substances protonate the phosphoramide at the phosphorus or nitrogen atom or at the phosphorus–nitrogen bond. As a result of such protonation, the phosphorus atom of the onium compound becomes more electrophilic and reacts with the alcohol more readily. According to the second hypothesis, the phosphoramide must be protonated at the nitrogen atom. The phosphorammonium cation produced is attacked by an anion (the chloride ion when AHC are used) and is converted into a mixed anhydride, which in fact constitutes the direct phosphorylating agent. The anhydride hypothesis was based on a known fact: on intense heating with diethylamine hydrochloride, phosphorous hexaethyltriamide affords the hydrochloride of *N,N,N',N'*-tetraethylphosphorodiamidite and diethylamine, which is distilled away from the reaction mixture. We may note that, after a lapse of time, the second hypothesis began to be considered by some investigators (see, for example, Refs 44–50) as fully wellfounded. At the same time, it became customary to resort to a speculative description of the mechanisms of the TPAA reaction instead of securing evidence for them. Nevertheless, the anhydride hypothesis was questioned[38,51–54] and was subsequently subjected to a specific criticism. Thus it has been demonstrated experimentally that the cleavage of the phosphoramide linkage in TPAA by amine hydrohalides is not a general phenomenon. For example, phosphorous hexaethyltriamide is cleaved much less effectively than the hexamethyltriamide, while higher amides do not interact

† The unusual character of alcoholysis by TPAA is due to the fact that this reaction had in fact been described twice[5,6] before its 'official discovery', but initially it had not been assessed as a novel and promising phosphorylation method.

preparatively with amine hydrohalides. On the other hand, the effectiveness of catalysis is high for all the amides indicated.[43] An even more interesting result was obtained on comparing the rates of deuteriomethanolysis of the imidazolide (k_1) and *N*-ethylanilide (k_2) of neopentylene phosphite in the presence of amine hydrofluorides and of deuteriomethanolysis of neopentylene phosphorofluoridite (k_3):

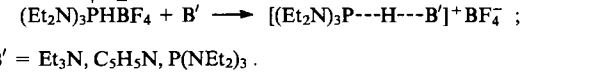


It was found that k_1 and $k_2 \gg k_3$.[55,56] It is significant that the catalytic activities of diethylamine hydrofluoride and other corresponding halides are comparable under standard conditions.[55,56] Such a situation would be impossible if the reaction pathway included a stage involving the formation and alcoholysis of phosphorohalidites. We shall complete the analysis of the hypothesis by quoting the data of Szewczyk and Quin,[57] who investigated the inversion at the phosphorus atom in the presence of dimethylamine hydrochloride enriched in the ^{15}N isotope:



The authors observed the complete inversion of the phosphorus(III) acid amide centre only in the presence of a catalyst (15 h, 25 °C). It was established that the ^{15}N label does not appear in the phosphoramide. Thus the activation of the phosphoramide is associated with some kind of interaction of the substrate and the reagent which does not include an acid chloride formation stage. Otherwise, labelled dimethylamine would have appeared in the medium and its reaction with the acid chloride would have afforded phosphorous [^{15}N]dimethylamide.

The hypothesis of the protonation of TPAA to give onium compounds as a means of their activation for subsequent reaction with alcohols and other nucleophiles was revived at one time and was discussed in the literature. This possibility was specified in detail: the N-protonation pathway was initially considered to be the most probable.[22,23,44] Indeed, in a series of quantum-chemical studies on model >P–N< systems this pathway was specified as energetically preferable.[54,58,59] Nevertheless, convincing evidence for N-protonation in TPAA–AHC–alcohol systems was not obtained. At the same time, data secured in a successful experiment on the N-protonation of a metal complex derivative of one of the bicyclic TPAA were published:[60]



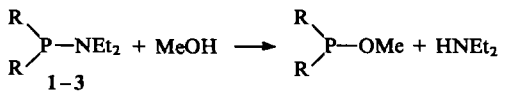
The lone pair of the phosphorus atom in the initial complex formed the phosphorus–molybdenum bond, which fact determines the course of the protonation.

Recently, many investigators indicated the probability of parallel P- and N-protonation[20,47–50] or selective P-protonation.[14,16,30] Evidence for this reaction pathway, obtained by IR[16,61–63] and NMR[20,64–67] spectroscopy, was quoted in the corresponding publications. A group of salts was recently synthesised by the reaction of TPAA with anhydrous fluoroboric acid.[68–72]

These salts are semicrystalline or crystalline. It was of interest that some of them are entirely stable on storage. The interaction of the salts with bases stronger than the initial phosphorus(III) acid amides leads to their deprotonation. By estimating the degree of the latter, it is possible to establish approximately the basicity of the TPAA.[71,72] The structures of certain initial phosphoramides and their quasi-phosphonium salts have been investigated by X-ray diffraction.[70–72] The structural parameters of these substances were determined. Among them, the anomalous shortening of the P–H bonds is striking. Conversely, it was established at the same time that the P–N bond in these salts is anomalously long. For example, its length in the fluoroborate of phosphinous di-*tert*-butylpyrrolide is 1.75 Å.[72] Additional studies demonstrated that treatment of solutions of the quasi-phosphonium salts with bases (B′), including TPAA, leads to the formation of dynamic complexes in which a proton migrates between two donor centres:[71,72]

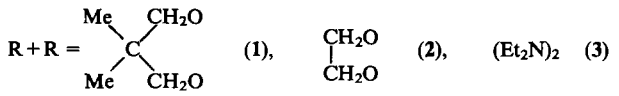
Experiments were carried out on the alcoholysis of the salts and it was established[70–72] that they do not really react with alcohols‡.

Thus the hypothesis that the products of the protonation of TPAA are intermediates in the alcoholysis of phosphoramides is likewise not true. It was of interest to compare the tendencies of the products of the protonation and alkylation of TPAA to undergo alcoholysis, since these salt-like substances are isoelectronic. It was found that they all remain unchanged on treatment with alcohol§.[70,73]



Further study of the alcoholysis of TPAA in the presence of AHC involved investigation of the rates of reaction in the presence of selected concentrations of various catalysts¶.

The quantitative characteristics of the effect of amine salts on the rate of alcoholysis of the amides **1–3** were established in preliminary experiments.[78]



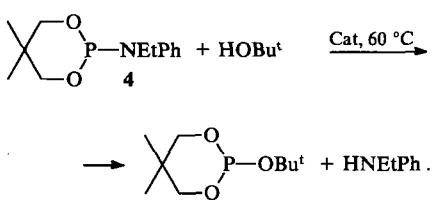
‡ Thus the P(III)–N bond length and the factors influencing it are not decisive criteria of the phosphorylating capacity, which has been occasionally implied.[24,48]

§ In this connection, we may note another important fact, namely that the phosphorammonium salts alkylated at the nitrogen atom undergo alcoholysis at the P–N bond.[74]

¶ For accurate kinetic studies of the acid-catalysed reactions of TPAA, the procedures for the removal of AHC impurities from TPAA already known[75,76] were supplemented by developing a purification procedure using phase transfer principles,[77] which made it possible to achieve a residual concentration of the chloride ions of 0.11×10^{-3} M. The residual content of chloride ions was monitored by potentiometric titration.[70,78] An attempt had been made previously[29] to monitor quantitatively the residual content of AHC and TPAA by a conductimetric method.

1–3

Thus the rate constants for the first stage of methanolysis were determined as a function of the content of the AHC in the ranges of concentrations corresponding to their amounts usually present in TPAA. The quantitative composition of the reaction mixture was determined by NMR spectroscopy — by integrating the ^{31}P signals. The pseudofirst-order rate constants (k_I^{ψ}) were determined from the decrease in the concentration of the initial amide by means of the linear plot of $-\ln([\gtrdot P-NEt_2]/[\gtrdot P-NEt_2]_0) = f(\tau)$, where $[\gtrdot P-NEt]_0$ is the initial concentration of the amide. The second-order rate constant was found from the values of k_I^{ψ} obtained by means of the equations $k_{II} = k_I^{\psi}/[MeOH]$.



The results of the kinetic measurements can be represented by Eqns (1) and (2):[29]

$$-\frac{d\left[\gtrdot P-NEt_2\right]}{d\tau} = k_{II}\left[\gtrdot P-NEt_2\right][MeOH], \quad (1)$$

$$k_{II} = k_0 + k_c[Et_2\overset{+}{N}H_2], \quad (2)$$

where k_0 is the rate constant for the noncatalysed reaction, k_c a catalytic coefficient taking into account the activating effect of diethylamine hydrochloride, and $[Et_2\overset{+}{N}H_2]$ and [MeOH] are the concentrations of the salt and methanol, which remain constant during the reaction. The linearity of the dependence of k_{II} on the salt concentration demonstrated that the reaction is first order with respect to the catalyst. Thus the fundamental importance of the quantitative monitoring of the purity of the amides in the study of the alcoholysis of TPAA was established[70,78] and conditions were selected for the investigation of a crucial feature of the acid-catalysed reactions of TPAA — the nature of the interaction of AHC with TPAA.

For this purpose, a study was made of the influence of the nature of AHC on the catalytic activity in the alcoholysis of TPAA. The experiment was performed in the neopentylene *N*-ethylphosphoroanilidite – *tert*-butyl alcohol system.[70,79]

The catalysts employed were the hydrochlorides of diethylamine (**5**), dimethylamine (**6**), triethylamine (**7**), trimethylamine (**8**), benzyldiethylamine (**9**), benzylmethylamine (**10**), *N*,*N*-diethylaniline (**11**), and imidazole (**12**). The choice of the amide **4** and of the catalysts **5**–**12** was dictated by the fact that the basicity of the amines should be not less than that of the amine produced on alcoholysis, i.e. *N*-ethylaniline. Otherwise the catalyst would change during the reaction.

Graphical treatment of the data in accordance with equations (1) and (2) above showed that there is a linear relation between $\lg k_c$ and the acidity of the salts **5**–**12**. In the case of salts of secondary and tertiary amines, it is expressed by two independent straight lines (Fig. 1). The introduction of the statistical factor *S* (the number of protons bound to the nitrogen atom of the ammonium salt[80]) combines the two lines into one (Fig. 2).

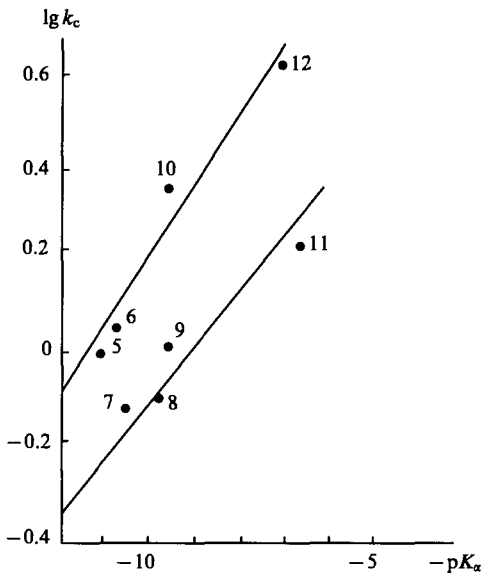


Figure 1. Dependence of $\lg k_c$ on the acidity of catalysts **5**–**12**.

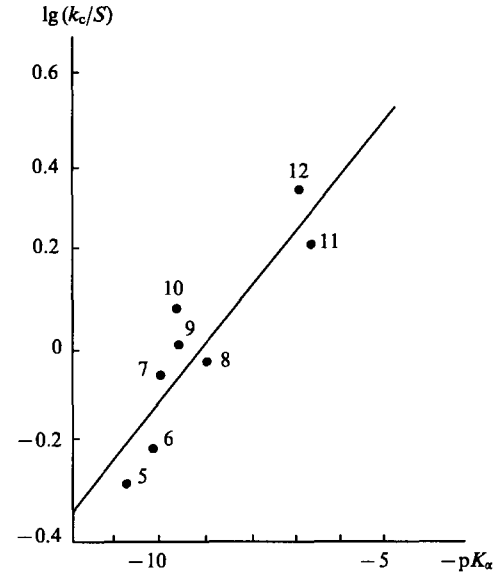

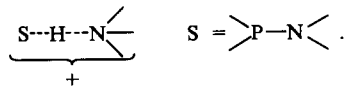

Figure 2. Dependence of $\lg(k_c/S)$ on the acidity of catalysts **5**–**12**.

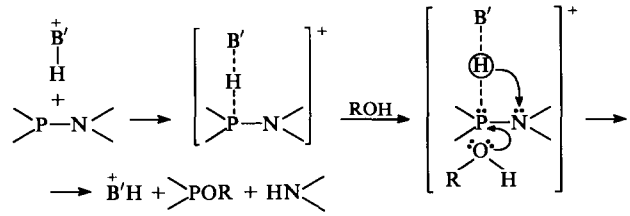
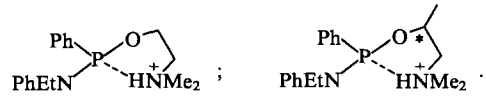
The Brønsted equation (3) was used to analyse the results. For the process investigated, it was expressed in the following form:[81]



$$\lg\left(\frac{k_c}{S}\right) = \lg G_A - \alpha pK_a, \quad (3)$$

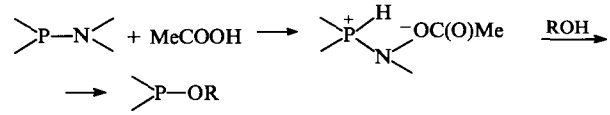
where G_A and α are constants characterising the reaction series. The slope α is a measure of the sensitivity of the reaction to the acid catalyst. It was found that $\alpha = 0.13$ ($r = 0.95$), which indicates *general acid catalysis* of the phosphorylation reaction. In this case, it is best to interpret α as an approximate measure of the change in the charge on the proton-donating or proton-accepting atom in the transition state.[82] Thus the catalytic process proceeds not via the protonation of the phosphoramide substrate (the formation of a phosphonium or phosphorammonium salt postulated previously) but via the formation of the catalytic hydrogen-bonded complex incorporating the substrate (S) and the catalyst as a whole:



In contrast to the onium salts this complex is a proton-labile system, which apparently determines also its tendency to undergo alcoholysis.

Summarising the foregoing, one may conclude that the alcoholysis of TPAA in the presence of AHC includes stages involving the formation of the catalytic hydrogen-bonded complex. In the latter, the proton fulfills two functions: firstly, it activates the phosphorus atom in the electrophilic reaction, for example with an alcohol, and secondly, during the reaction the proton migrates from the phosphorus to the nitrogen atom, thereby assisting the dissociation of the P–N bond.[70–72]

An important stereochemical consequence follows from this: if a chiral catalyst is employed, then the catalytic hydrogen-bonded complex is also chiral. Therefore, when chiral catalysts are used, one may expect the manifestation of stereoselectivity in the phosphorylation reaction. Correspondingly, the interaction of the racemic 1,3-butylene *N*-ethylphosphoranilidite with 1,2;5,6-diisopropylidene-α-D-glucofuranose (in molar proportions of 2 : 1) was carried out in the presence of the racemic hydrochloride of α-phenylethylamine and its (+)- and (−)-enantiomers. It was shown by ^{31}P NMR that, when a racemic catalyst is used, approximately equal amounts of the two diastereoisomers are formed. When the hydrochloride of the laevorotatory amine is employed, 10% more of one of the diastereoisomers is obtained. The dextrorotatory hydrochloride ensures approximately the same preferential formation of the other diastereoisomer. Thus it has been shown[70,79] that the use of optically active catalysts can ensure stereoselectivity in the phosphorylation of TPAA. Subsequently this fact was used to attain a more effective 'contact' between the phosphoramide and the hydrochloride forming part of its composition (compound **13**), which ensured effective intramolecular catalysis resulting in a sharp increase in the rates of phosphorylation and in a significant stereoselectivity of the process following the inclusion of a chiral fragment in the composition of the 'catalytic' component of the phosphorus(III) acid amide **14**:[83]



13 **14**

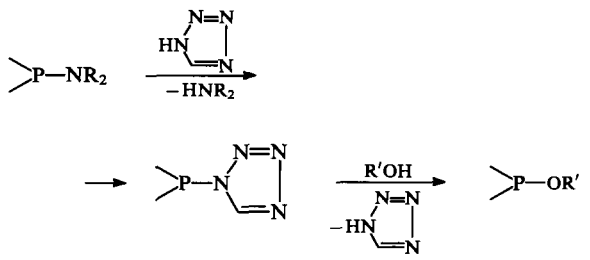
c. Phosphorylation in the presence of carboxylic acids and azoles

The discovery of the catalytic effect of AHC in the alcoholysis of TPAA led to the search for new ways of accelerating this type of phosphorylation. AHC and phenols are known to have comparable acid properties. Taking this into account, successful experiments were carried out on the phosphorylation of alcohols by TPAA in the presence of phenol.[84] The catalysis of the alcoholysis of TPAA by phenol was thus confirmed experimentally. Unfortunately this version of the catalysis is not promising in preparative terms, since the reaction resulted in the formation not only of the compounds sought but also of the corresponding phenyl esters.

The next stage in the development of the acid catalysis involved the study of the alcoholysis of TPAA in the presence of carboxylic acids, acceleration of phosphorylation by acetic acid being observed.[16,25,85] In a number of instances, the acceleration was very significant. Thus it has been shown[16] that phosphorous tripiperidide does not react with ethanol even on refluxing but, when acetic acid is added to the reaction mixture, phosphorylation occurs even at 20 °C. The formation of a quasi-phosphonium cation was initially postulated as the first stage.

Subsequent study of the catalytic effect of acetic acid showed that it not only accelerates but also alters the mode of certain reactions of phosphoramides. Thus the reaction of the amides with aliphatic mercaptans in the presence of acetic acid proceeds with dissociation of the P–N bond[85] and not via the addition of sulfur to the initial amides, noted in experiments without added catalyst.[86]

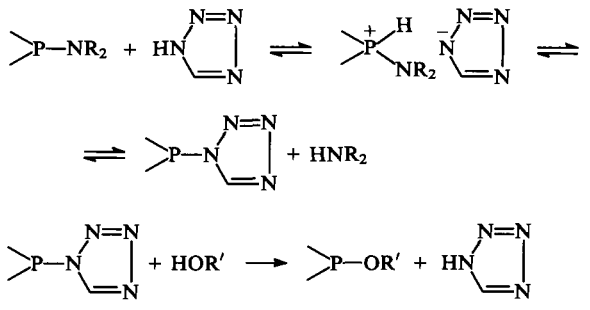
The mechanism of catalysis by carboxylic acids has been investigated only to a first approximation. It may be that the mechanism corresponding to the catalysis by AHC operates under certain conditions, but other variants are also possible. It has been shown[37] that the phenolysis of TPAA in the presence of carboxylic acids involves the formation of acyl phosphites, which were detected by ^{31}P NMR. Apparently the acyl phosphites phosphorylated phenol with formation of phenyl phosphites and carboxylic acids.[87,88] The latter again interact with TPAA, affording acyl phosphites, etc. At the present time, this mechanism is not well founded. We may draw attention to the fact that acyl phosphites can undergo not only phenolysis (alcoholysis) but also aminolysis with formation of carboxylic acid amides and hydrophosphoryl compounds.[87–93] Furthermore, it is essential to take into account also the neutralisation of the carboxylic acid by the secondary amines formed. Yet another important factor may be noted: there are data indicating the catalytic nature of the conversion of TPAA into acyl phosphites.[90,91,94] Hence, in the acyl phosphite variant, there may be two catalytic stages.



The alcoholysis of TPAA can also be catalysed by other acids, for example amidodithiocarbamic acids and also their ammonium salts.[95]

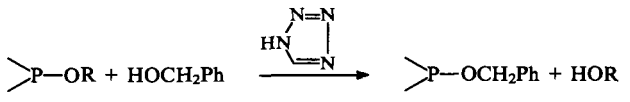
The search for new variants of the phosphorylation reaction led to the investigation of the activation of the alcoholysis with the aid of free azoles, which are weak N–H acids. These are usually 1*H*-tetrazole ($pK_a \approx 4.8$) (see, for example, Refs 96–99) and more rarely 1,2,4-triazole ($pK_a \approx 10$)[100,101] or azoles the acidity of which has been enhanced by the introduction of electronegative substituents into the azole ring (4,5-dichloroimidazole, 3-chloro-1,2,4-triazole,[100,102] 5-*p*-nitrophenyltetrazole, and certain others[103,104])†. The salts of azoles, mainly diisopropylammonium tetrazolide, are used for a similar purpose (see, for example, Refs 106–114). Very satisfactory results — complete phosphorylation in 2–3 min at 20 °C — have been achieved under the optimised conditions for the phosphorylation of complex systems. Because of this, the azolide variant has come to be especially widely used, including its employment in automatic synthesisers for the preparation of important oligonucleotides (see below).

The situation is less satisfactory as regards the understanding of the chemistry of the azolide variant of the phosphorylation reaction. It is significant that the amounts of azoles in relation to TPAA used in the experiments described were not catalytic but equimolar or even greater than equimolar. This makes it difficult to classify the reactions considered as catalytic. In view of the



† The use of the last activator has been criticised.[105]

foregoing, we may note the observation in the ^{31}P NMR spectra of reaction mixtures containing an excess of tetrazole of a signal corresponding to the transamidation product—a phosphorus(III) tetrazolide, which is regarded as an intermediate.[115-117]



The possibility of the formation of phosphorus(III) tetrazolides has been the subject of certain special investigations, in which the role of the acidity of the activators was emphasised. According to the authors of these studies,[100,115,117,118] the activators are capable of protonating the initial TPAA. It is of interest that it has been possible to perform kinetic measurements in the TPAA—tetrazole system and to devise a scheme for the overall alcohol phosphorylation process (Scheme 1).[118]

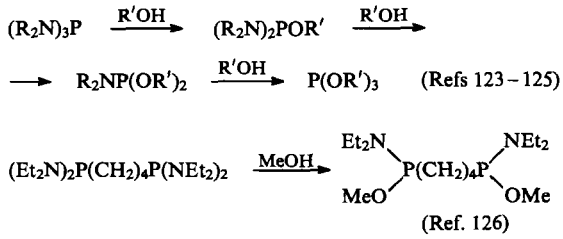
Scheme 1

Unfortunately this scheme has not been analysed in depth. Two comments may be made on this question. The first is that the authors of the scheme do not prove but merely postulate the protonation of TPAA by tetrazole. The second is that the authors have not demonstrated that the phosphorus(III) tetrazolide is an 'on-going' and not a dead-end product in the system of stages involved in the phosphorylation of alcohols using the usual TPAA. The second comment is especially important in connection with the publication of data[119] on the transesterification of neutral phosphites in the presence of tetrazole (Scheme 2). There are also data concerning the activation of the transesterification of neutral phosphites by 1,2,4-triazole.[120]

Scheme 2

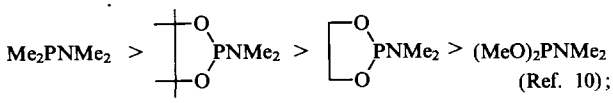
The reaction described is related to that discussed by ourselves because it too involves nucleophilic substitution at the trivalent phosphorus atom in the presence of tetrazole. However, it is difficult to postulate that the stage involving the conversion of the alkyl phosphite ester into the tetrazolide is obligatory, since in fact reactions of the opposite type are well known. Consequently, it is essential to analyse not only the tetrazolide but also other activation procedures. The authors of the present review believe that the most probable form of activation of the alcoholysis of an alkyl phosphite is the formation of a complex between this ester and tetrazole.

We shall return to the question of the phosphorylation of alcohols by TPAA in the presence of tetrazole. Taking into account the foregoing, we suggest that general acid catalysis may operate in this instance in the conversion of the dialkyl amides into the required esters or into tetrazolides. If, on the other hand, the tetrazolides prove to be intermediates in the synthesis of the esters, then they too probably require cooperation from tetrazole. The main factor in the catalysis in all these cases may be the formation and reaction of the corresponding tetrazole complexes. Unfortunately more far reaching kinetic studies with introduction of catalytic amounts of tetrazole into the reaction mixture have not yet been carried out. Nevertheless, a study has been published very recently on the application of triazole, indicating the existence of an acid catalytic stage in this process.[101]



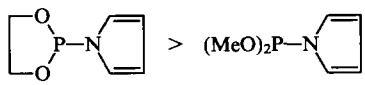
2. General characteristics of the phosphorylation of alcohols and phenols

The dependence of the phosphorylating capacity of TPAA on their structure and certain related problems will be considered in this subsection of the review. The second part of the subsection is devoted to the stereochemical features of the phosphorylation reaction.

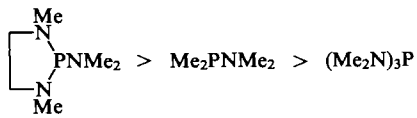


There have been few kinetic studies on the alcoholysis of TPAA and for this reason reliable correlations between the reactivity of phosphoramides and their structure have not so far been established. The situation is complicated also by the fact that in most of the published communications the problem of catalysis was overlooked and for this reason acid admixtures were not specially eliminated from the phosphoramides and a definite amount of a selected catalyst was not added to the substrate. Nevertheless, one can already speak of certain qualitative features, since the phosphoramides most often employed for phosphorylation have been usually obtained by a standard method in different laboratories and they were therefore contaminated by approximately equal amounts of identical activator impurities (these were most often AHC). The range of alcohols employed almost always comprised the most readily available standardised representatives.

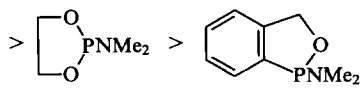
Taking into account these comments, one may note that as a rule branched alcohols had a lesser tendency to undergo phosphorylation than linear alcohols, while secondary alcohols were inferior in this respect to the primary ones.[10,28,84] There exist data indicating a higher reactivity of phenols[10,24,25,28,84] and acid alcohols[84] in phosphorylation compared with the usual alcohols. However, it has been noted that the phosphorylation of phenols in bulk may be complicated by the formation of intermolecular hydrogen bonds, which, however, are ruptured on heating the phenol–TPAA system in aromatic solvents. The use of this procedure makes the phosphorylation of phenols more effective.[121] Intramolecular hydrogen bonds have a smaller inhibiting effect on phosphorylation; however, when these bonds are strengthened, as happens on passing from 8-hydroxyquinoline to 5,7-dibromo-8-hydroxyquinoline, the phosphorylation is impaired.[122]



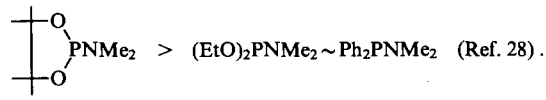
The influence of the TPAA structure on phosphorylation is expressed by more complex relations. It has been established that the amino-groups in phosphorous triamides can be substituted stepwise by alkoxy-groups.[123-126]



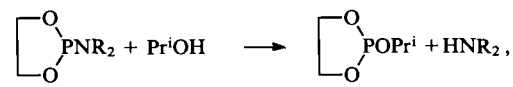
Consequently the full amides are more reactive than the amidoesters. Certain detailed features of the phosphorylation reactions have also been discovered, but these are based on a relatively narrow range of experimental data.[10,28] In terms of reactivity, amines can be arranged in the following sequence:



(Ref. 10);

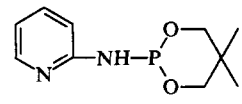


(Ref. 10);



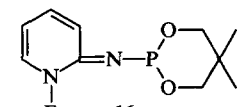
(Ref. 28);

(Ref. 28).

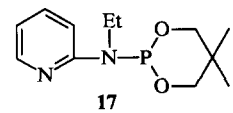


We may draw attention to the fact that the phosphorylating capacity of TPAA is in some way correlated with their basicity. One can apparently now state that the tendency of TPAA to form a complex with the acid catalyst plays a decisive role, i.e. that these substances are ready to form catalytic complexes.

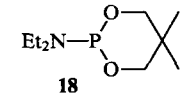
The second aspect of the problem of the reactivity of TPAA, involving the elucidation of the role of substituents at the phosphorus atom, has been examined in greater detail. Thus it has been established for the reaction,



that the phosphorylating activity increases in the following sequence of substituents at the phosphorus atom:[28] $N(Pr^i)_2$ < NMe_2 < NMePh < NPh_2. The high phosphorylating activity of monophenyl- and diphenyl-amides, noted previously,[127] is striking. The phosphopyrrolides, which exhibit an increased resistance to alcoholysis, are an exception.[10,71,127,128] It has been shown[71] that this is associated with the passivity of the lone pair of pyrrole as regards the formation of a hydrogen bond and prototropism. We may note further that data have been published on the high phosphorylating capacity of the vinyl amides of trivalent phosphorus acids.[47] Summarising the foregoing, we may conclude that in phosphorylation there is an inverse relation between the tendency of the amino-group to leave the phosphorus atom and its basicity. It is of interest that, according to the data of Evdakov et al.,[25] the phenolysis of TPAA does not obey the rules presented above. Apparently such data should be subjected to additional analysis.

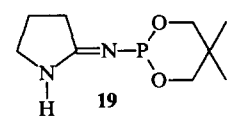


The observation of a high reactivity of anilides in alcoholysis led to the extension of the studies initiated to the field of related heterocyclic phosphoramides.[129,130] Thus phosphorylated 2-aminopyridine **15** and its two derivatives **16** and **17**, ethylated at different nitrogen atoms, have been subjected to methanolysis.[131,132]

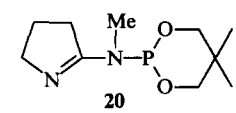


15

16

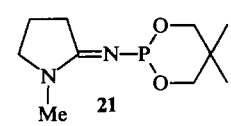


17



18

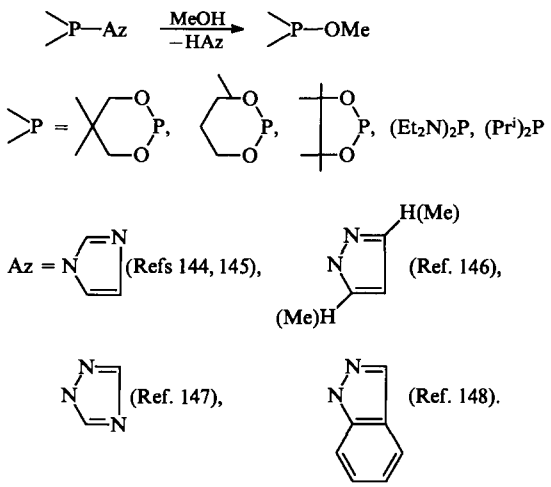
Study of the rates of methanolysis of these compounds made it possible to formulate several important conclusions. (1) The phosphoramides **15** and **17** are more reactive than neopentylene *N,N*-diethylphosphoramidite **18**. Thus the early observation that the reactivity of phosphoranilides is high has been reliably confirmed. (2) The phosphoramides **15** and **17** are more reactive than the phosphorimide **16**, so that the electronic structure in the P–N–C–N fragment is important for the alcoholysis of the P–N bond. (3) The phosphoramide **15**, the molecules of which contain secondary hydrogen atoms, is much more reactive than its *N*-ethyl derivatives **16** and **17**. Furthermore, compound **15** does not require a catalyst in alcoholysis, whilst compounds **16** and **17** do require it. This means that the reactions of compound **15** involve autocatalysis.[132]



Thus it follows from the data presented that the tendency of TPAA to undergo alcoholysis can be effectively regulated by the structural features of these compounds. An even more interesting picture of this phenomenon has been observed in a study of the alcoholysis of phosphorylated 2-aminopyrrolines.[131,133,134] The rates of methanolysis of the three related derivatives **19**–**21** were compared in this instance and it was shown that compound **19** exhibits the greatest susceptibility to substitution.

19

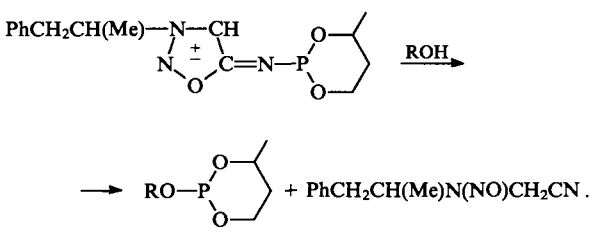
20



21

A distinctive feature of this compound is the presence of a mobile hydrogen atom. In this connection, we may note the greater reactivity of the pyrrolidine derivative **19** compared with that of the pyridine derivative **15**. This finding suggests an important role for prototropism in phosphorylation, which is more probable for the phosphopyrrolidine **19** than for the aromatic phosphopyridine **15**.

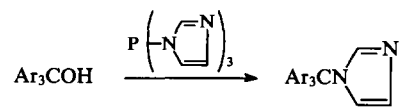
Comparison of compounds **20** and **21** revealed a relation which had already been discovered earlier for pyridines: the imine **21** is inferior in reactivity to the amide **20**. Nevertheless, comparison of the conditions in phosphorylation by these substances led to an unexpected observation — compound **21** does not require a catalyst in alcoholysis. Apparently, being one of the phosphorylated forms of an amidine, this compound exhibits a high reactivity and, together with an alcohol molecule, constitutes a catalytic complex for the phosphorylation reaction. Naturally, compound **19** is also a phosphorylated amidine but here the phosphorus atom is at the imine end of the amidine system, which lowers its basicity.



The interest in phosphorylated derivatives of heterocycles as phosphorylating agents for fine organic synthesis has become particularly marked nowadays in the study of phosphorazolides and related systems. Investigations on these lines began with the publication of the papers of Birkofer et al.[135] and Nifant'ev[136] and were vigorously continued in other studies[137–143] in which

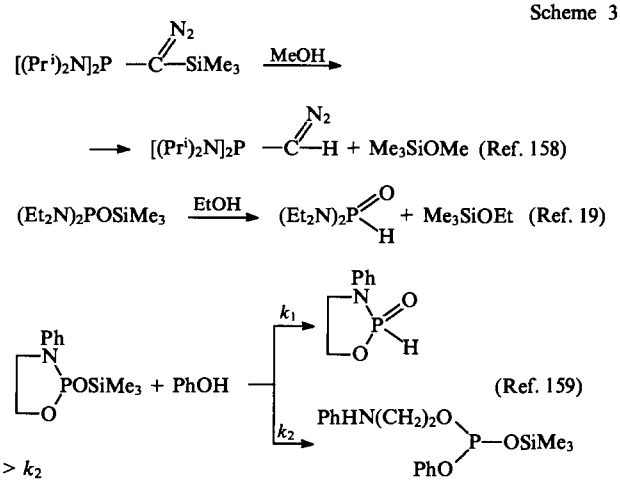
phosphorimidazolides were identified as the most reactive preparations. The tendency has arisen recently to expand this research and to treat the results systematically. In this connection, we may note a series of communications on the synthesis of various phosphorazolides and their phosphorylating capacity.[144-148]

It has been established that the reactivity of phosphorus(III) acid azolides decreased significantly in this case in the series diester phosphorazolidites > phosphorous diamide azolides > phosphinazolidites and, depending on the nature of the azole, in the series imidazolide > pyrazolide > triazolide > benzimidazolide.[120] A very marked influence of the solvent polarity on the phosphorylating capacity of the phosphorus(III) acid azolides was unexpected. It decreased sharply on passing from acetonitrile to chloroform and even more so on passing to dioxane and benzene.[120] Azoles are known to exist in nonpolar solvents in the form of linear oligomers or cyclic trimers.[149,150] With increase in solvent polarity, these self-associated species can decompose and the catalytic function of azoles comes to the fore, which accelerates the alcoholysis.



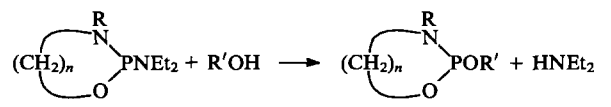
Continuing the consideration of the alcoholysis of heterocyclic phosphorus(III) acid amides and imides, we may point to the results of the phosphorylation of alcohols by phosphosydnone imine obtained in the following instance:[151,152]

This reaction has no special preparative advantages, but it is interesting because it is not accompanied by the accumulation of a nitrogenous base in the system, since the sydnone imine produced isomerises immediately to *N*-nitroso-1-phenylisopropylaminoacetonitrile. This product has optical properties differing strongly from those of phosphosydnone imine, so that it is easy to investigate the kinetics of its reactions by UV spectroscopy, including dilute solutions.



The first data have now been obtained also on the alcoholysis of the hydrazides,[153] hydroxyamides,[154] benzamidides,[155] and guanidides[156] of certian trivalent phosphorus acids. All these compounds exhibit an effective phosphorylating capacity, which intensifies with acid catalysts, but no characteristic features making them specially valuable have yet been noted.

The advantages of the phosphoramide phosphorylation method were indicated above: the mildness of the conditions and the absence of side reactions. This general rule has a few exceptions, which must be stated in the review. Thus it has been established that the phosphorylation of triarylcarbinols by phosphorous acid triimidazolide leads to triarylimidazolylmethanes and not to the expected product.[157]

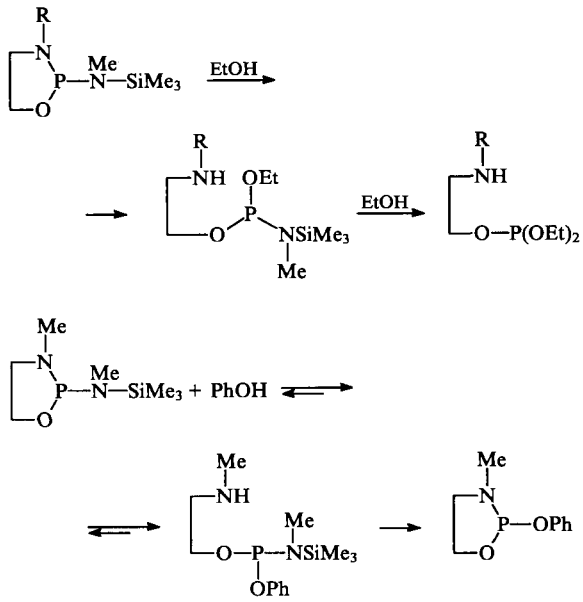


A deficiency of the phosphorus(III) acid amide method is also the unpredictability of the reactions of certain organoelement TPAA derivatives. Thus systems containing the C–Si[158] and O–Si[19,159] bonds can undergo cleavage at precisely these bonds on alcoholysis and phenolysis (Scheme 3)‡.

Scheme 3

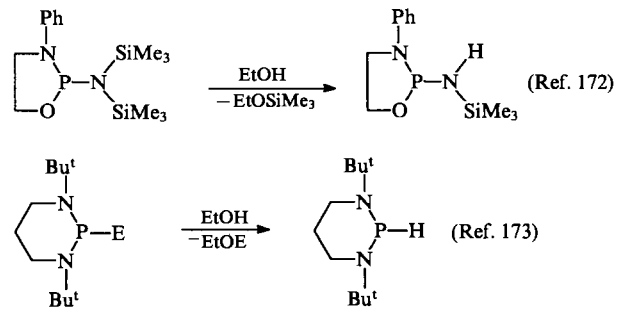
We shall consider the influence of structural factors on the mode of alcoholysis and phenolysis of cyclic systems, the molecules of which contain both exophosphoramide and endophosphoramide bonds. There are literature data on the interaction of alcohols and phenols, in equimolar amounts relative to the substrate, with 2-dialkylamino-1,3,2-oxazaphospholane[162-165] and [the corresponding] phosphorinane.[166-170] These reactions lead mainly to the dissociation of the exocyclic bond (Scheme 4).

Scheme 4



n = 2, 3; R,R′ = Alk, Ph

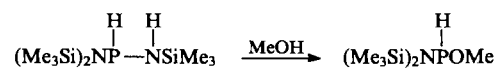
Oxazaphospholanes having a P–C exocyclic bond are much more reactive in the alcoholysis of the endocyclic P–N bond than the corresponding 2-alkoxy-derivatives, the introduction of an alkyl substituent in the 5-position in the oxazaphospholane ring resulting in a significant stability of the P–N bond.[171]



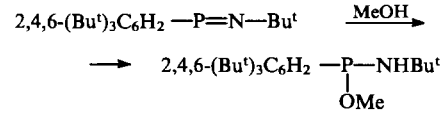
However, alcoholysis of oxazaphospholanes containing an exocyclic *N*-methyl-*N*-trimethylsilylamino-group begins with the rupture of the endocyclic P–N bond and only then of the exocyclic bond. In phenolysis, the ring is reformed in the second stage.[172]

‡ The acid catalyst (tetrazole) can, however, alter the mode of the reaction towards the dissociation of the P–N bond.[160,161]

When the molecules contain an exocyclic *N,N*-bistrimethylsilylamino-group[172] and trisubstituted P-silyl and P-germyl groups,[173] alcoholysis does not involve the cyclic skeleton of the molecules and begins with the dissociation of the N–Si and P–Si(Ge) exocyclic bonds (Scheme 5).



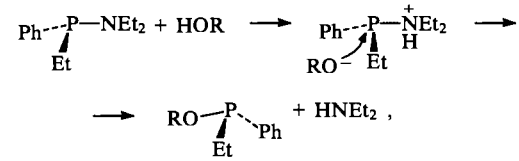
Scheme 5



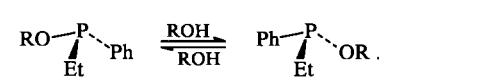
E = $SiEt_3$, $SiPh_3$, $GeEt_3$.

We may note the unusual nature of the alcoholysis of the P–N–Si acyclic systems. In the presence of two types of trimethylsilylamino-groups — secondary and tertiary — in the molecules of such TPAA, a secondary silylamino-group is the first to undergo alcoholysis (Scheme 6).

Scheme 6

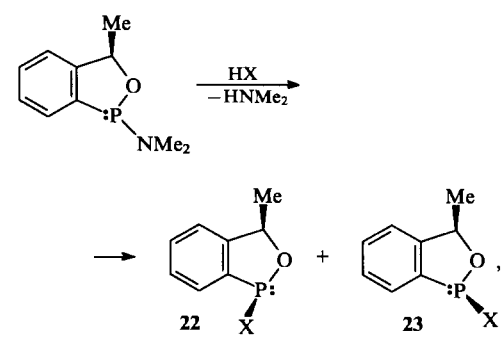


Finally, mention should be made of the possibility of the alcoholysis of the P=N π-bond in iminophosphine derivatives.[175,176]

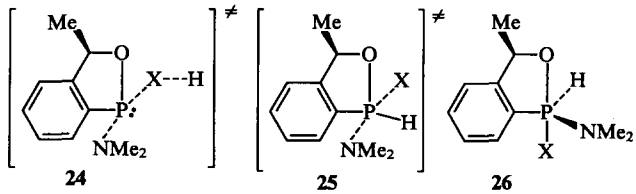


When an excess of the alcohol is used, there is a possibility of further alcoholysis, this time involving the P–N σ-bond.

The results of the study of the stereochemistry of substitution of the amino-group at the phosphorus(III) atom are difficult to interpret because it is essential to take into account the possibility of inversion at the phosphorus centre (especially at elevated phosphorylation temperatures) both in the initial TPAA and in the products of their reaction. Such inversion can occur readily under the influence of acid impurities[177,178] and other factors, for example owing to the presence of an excess of the alcohol (transesterification). Therefore the early studies, where the purity of the initial reactant was not rigorously monitored, must be treated with caution. This applies in the first place to the publications on the mechanisms of the reactions of optically active compounds, where the conclusions about their chemistry were reached solely on the basis of measurements of the angle of rotation of the reaction mixtures. As an example, we may point to a study[179] of the interaction of the optically active ethylphenylphosphinous diethylamide with methyl, ethyl, n-propyl, and isopropyl alcohols. A decrease in the angle of optical rotation was observed in these experiments. The above results were explained by two reactions. Firstly, by the substitution proper involving the inversion of the configuration at the phosphorus(III) atom:



and secondly, by the racemisation effected by the excess alcohol:

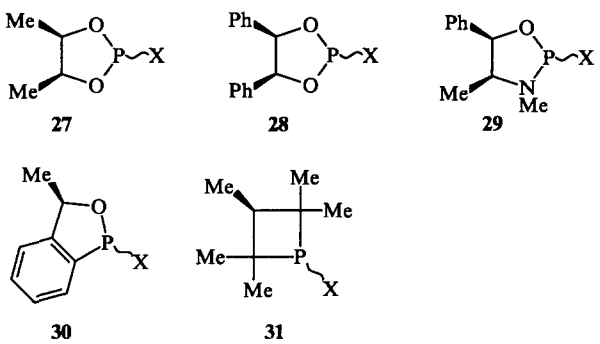


Under these conditions, retention of the configuration was observed in the reaction of *p*-cresol, which served as a basis for an explanation of the mechanism in terms of a four-membered transition state. In this connection, we emphasise that the authors[179] carried out the reaction with cresol for 1 h at 100 °C and were therefore unable to observe the primary inversion. Furthermore, the monitoring procedure they used enabled them to observe only the overall optical rotation of the mixture, while the influence of the initially inverted product might have been small owing to its insignificant amount.

More reliable results were obtained in the analysis of the stereochemical transformations of diastereoisomers by NMR spectroscopy. Thus, in the interaction of certain derivatives of phospholanes with phenol, Nielsen and Dahl[41,180] observed by ^1H NMR the initial inversion of the configuration of the phosphorus atom and the subsequent inversion in the reaction product. The latter led to the formation of a thermodynamically stable isomer (< 5 min). The data obtained in a study by ^1H and ^{31}P NMR of the nucleophilic substitution of a diastereoisomerically pure benzoxaphospholene, i.e.

where X = OMe, OBu^t, OPh, NMe_2, $N(CH_2)_5$, or NHPh, showed that the reaction with HX [X = OMe, OPh, $N(CH_2)_5$] at 25 °C in $CDCl_3$ proceeds with formation of two products, **22** and **23**, the product with the inverted configuration at the phosphorus atom being initially obtained preferentially. Subsequent reactions evidently lead to an equilibrium mixture of the diastereoisomers **22** and **23**. For X = OBu^t and NHPh, the rate of reaction is lower

than the rate of inversion and in this case an equilibrium mixture of compounds **22** and **23** was therefore immediately obtained. The authors believe that the $S_N2(P)$ type substitution mechanism at phosphorus(III) usually proposed (see, for example, Zavlin et al.[27]) is improbable because of the unfavourable diequatorial disposition of the phospholene ring in the transition states of two different types, **24** and **25**, and postulate the formation of a new type intermediate **26**.

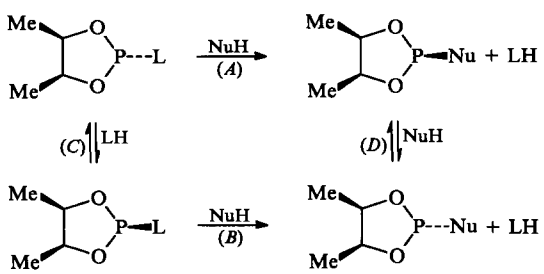


24 **25** **26**

Thus the stereochemical result of the reaction will depend on which pseudorotation (which is necessary to place the NMe_2 group in the axial position favourable for its elimination) in compound **26** has the lower energy barrier. In their analysis of possible pseudorotations, the authors conclude that the reaction proceeds with preferential inversion if the hydrogen is more apicophilic than NMe_2, which is known to be the case for phosphoranes of this kind.[181]

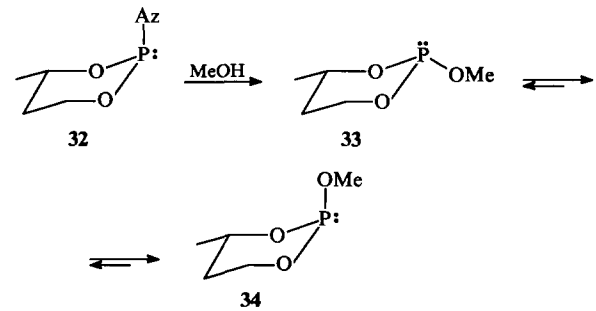
As a development of their research, Dahl and Nielsen investigated the stereochemistry of nucleophilic substitution in substrates **27–31** in their reactions with MeO^-, MeOH + NEt_3 (for compounds **27–31** with X = Cl), Et_2NH, PhOH, HCl, and MeOH (Scheme 7).[41]

Scheme 7



27 **28** **29**

30 **31**



X = Cl (a), NMe_2 (b), NEt_2 (c), OMe (d), OPh (e),  .

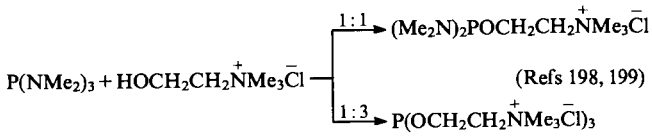
The majority of the compounds investigated were configurationally stable (with the exception of the compounds with X = Cl) at 25 °C only in a pure form and their isomerisation was readily accelerated by nucleophilic and acidic impurities (atmospheric moisture, alcohol, amines, acids, etc.). The scheme below reflects the different possibilities in the isomerisation of compounds **27–31**.

According to the authors, pure inversion is possible only when the substitution reactions (*A* and *B*) are much faster than the isomerisation reactions (*C* and *D*) (see also Horner and Jordan[179]). It was concluded that nucleophilic substitution in TPAA proceeds in most cases with complete inversion. We may note that this conclusion is to some extent arbitrary. Indeed, many cyclic compounds of trivalent phosphorus containing amino-groups are usually configurationally unstable and therefore the reactions of these substances are not stereoselective.

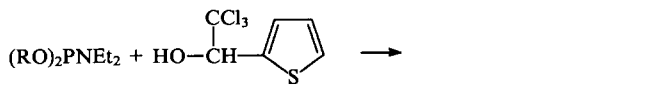
More clear-cut results were obtained in a study of the stereodynamics of the methanolysis of cycloasymmetric trivalent phosphorus acid (TPA) azolides **32**, which have been shown[145–148] to exist in the *trans*-configuration with the azolide substituent in the axial position.

32 **33** **34**

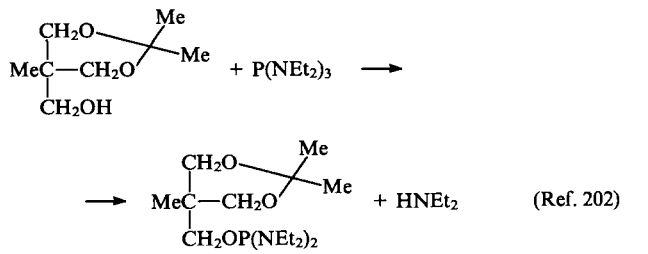
It has been demonstrated by ^{31}P NMR spectroscopy that, in contrast to TPA dialkylamides, alcoholysis takes place rapidly even at 20 °C (inversion of configuration) and a labile ester (isomer **33**) is formed and is then slowly converted into a stable ester—isomer **34**.



3. Trivalent phosphorus acid amides in fine organic synthesis



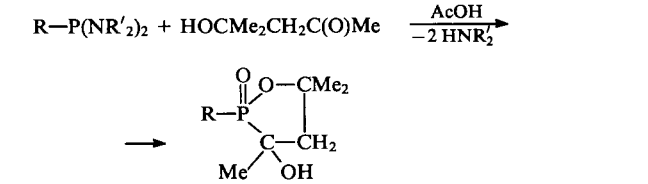
A considerable proportion of the publications on the chemistry of TPAA are devoted to problems of using these compounds in fine organic synthesis. This is due to their ready availability, high reactivity, convenience, and the mildness of the conditions under which they can be applied. The last fact permits specific phosphorylation of complex polyfunctional systems, avoiding at the same time isomerisations, dehydrations, and other unfavourable side reactions, which frequently occur in work involving phosphorochloridites and related reagents.

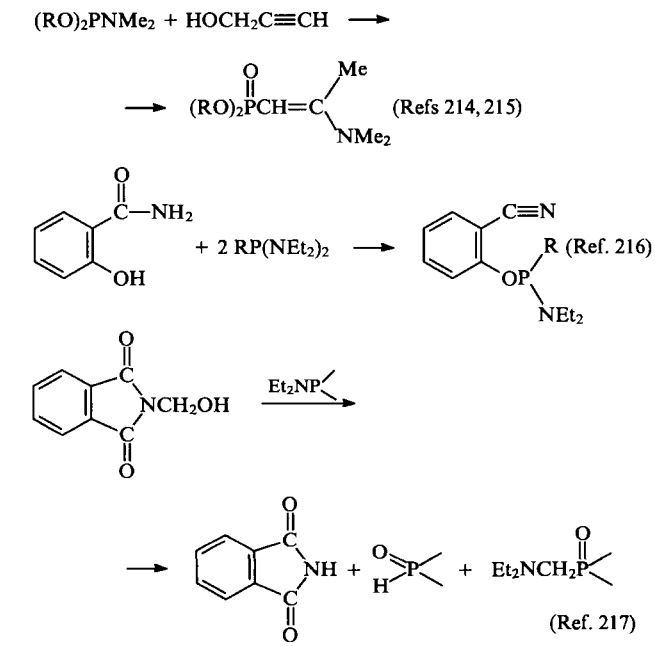


The principal synthetic results, arranged in terms of the types of hydroxy-compounds employed in phosphorylation will be examined below.

a. Phosphorylation of alkanols, phenols, and their functional derivatives

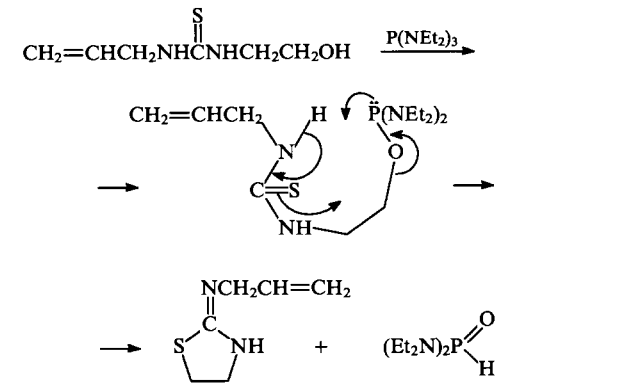
Phosphorylation of alkanols and phenols by TPAA is of a more general importance and is used to obtain the esters (amidoesters) of phosphorous, phosphonous, phosphinous, and hypophosphorous acids. This reaction was used initially to synthesise the simplest derivatives of compounds of the above classes and in this field has been recognised as not only convenient but also as preparatively useful[123–125] for purposes including the synthesis of sterically hindered phenol derivatives.[182,183] Subsequently the phosphoramide method came to be widely employed to obtain various functionalised systems, the molecules of which contain a trivalent phosphorus atom: phosphorylated aminoalcohols,[2,184–189] amidoalcohols,[190–197] cholines,[198,199] polyhalogenated alcohols,[200,201] partially acetalised triols,[167,168,183,184,202–211] etc. Certain examples are presented overleaf as an illustration.



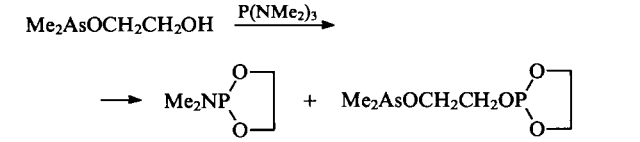


The phosphorylation of functionalised alcohols may be accompanied by additional reactions, which extend the possibilities of the classical synthesis and lead to simple procedures for the preparation of very interesting compounds (Scheme 8).[212,213-217]

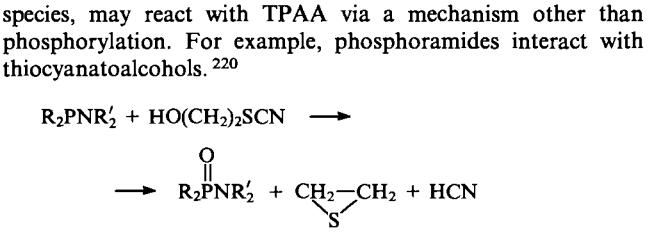
Scheme 8



R = Alk_2N, AlkO, Alk; R' = Alk (Ref. 213).



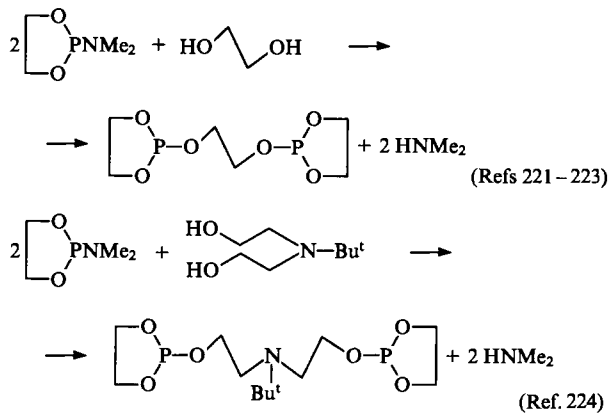
In a number of instances, phosphorylation leads to the creation of complex systems, which subsequently undergo the elimination of hydrophosphoryl compounds. In particular, it has been suggested that 2-allyliminothiazolidine be obtained in this way (Scheme 9).[218]



Scheme 9

The modes of the above reactions are treated quite clearly by the authors quoted. Nevertheless, some of the phenomena described in the literature have still not been adequately explained; these include, for example, the double phosphorylation of dimethylarsenylated ethylene glycol.[219]

Functionalised alcohols, capable of generating electrophilic species, may react with TPAA via a mechanism other than phosphorylation. For example, phosphoramides interact with thiocyanatoalcohols.[220]

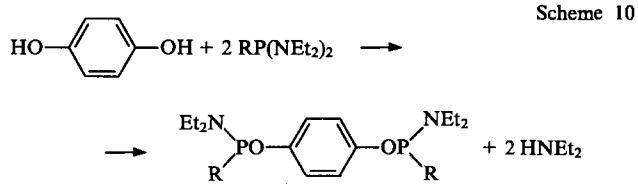


b. Phosphorylation of diols

Numerous publications have been devoted to the study of the reactions in the TPAA–diol system, which can be accounted for by the chemical diversity of the processes carried out and the importance of the products. The phosphorylation reaction is influenced by many factors: the nature of the reactants, their proportions, the reaction conditions, and also the characteristic features of the products. In many instances, this led to difficulties in the analysis of the results and then to erroneous conclusions. Subsequently these conclusions were revised.

It is possible to differentiate the following aspects of the phosphorylation of diols: (1) bisphosphorylation involving both hydroxy-groups of the diol and ending with the formation of a diphosphorous system; (2) monophosphorylation leading to phosphorylated hydroxy-compounds; (3) cyclophosphorylation and cyclooligophosphorylation. In addition, it is necessary to point out also the possibility of the combination of various aspects and also of polycondensations leading to polymeric esters. The last possibility will be examined separately.

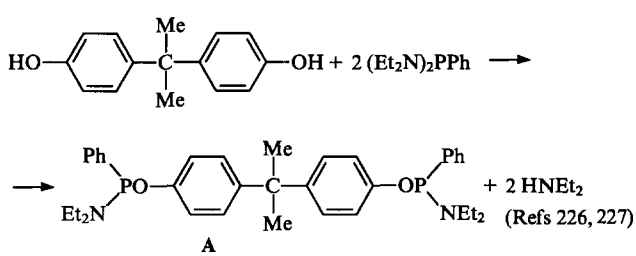
The bisphosphorylation of glycols and dihydric phenols has been widely investigated. A series of studies devoted to the use of trivalent phosphorus acid monoamides in reactions with glycols in molar proportions of 1 : 2 have been published. They result in the formation of diesters, for example:[221-224]



(Refs 221–223)

(Ref. 224)

We may note that the alternative method (the phosphorochloridite method) yields poor results owing to the interaction of the hydrogen chloride produced with the new reaction centre.

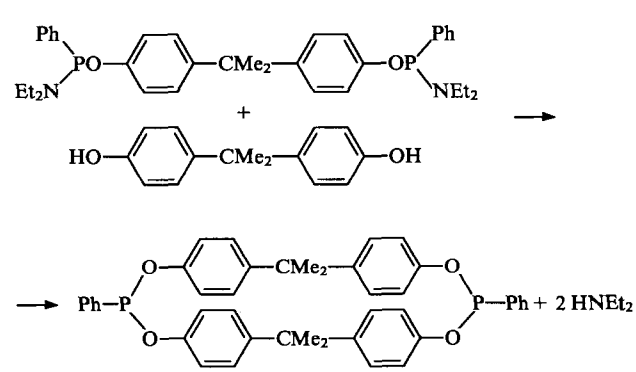


Many reactions with TPA diamides and triamides take place effectively (Scheme 10).[225–227]

Scheme 10

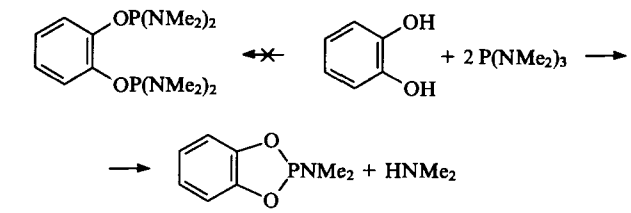
(Ref. 225)

R = NEt_2, OAlk



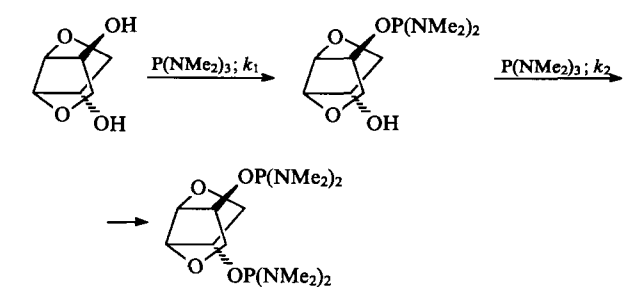
(Refs 226, 227)

A



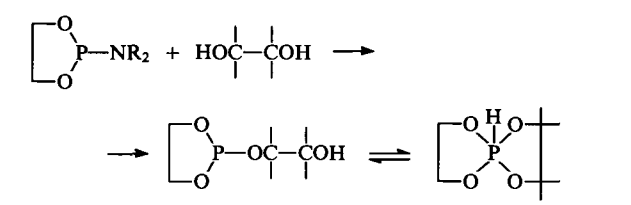
Compound A is interesting because, under the conditions discovered, it can react with an equimolar amount of 2,2-di-*p*-hydroxyphenylpropane (DIAN) and is converted into a phosphorus-containing cyclic system, which is the first representative of the new class of crown-ethers in the molecules of which arylene residues and trivalent phosphorus atoms alternate (Scheme 11).[226]

Scheme 11

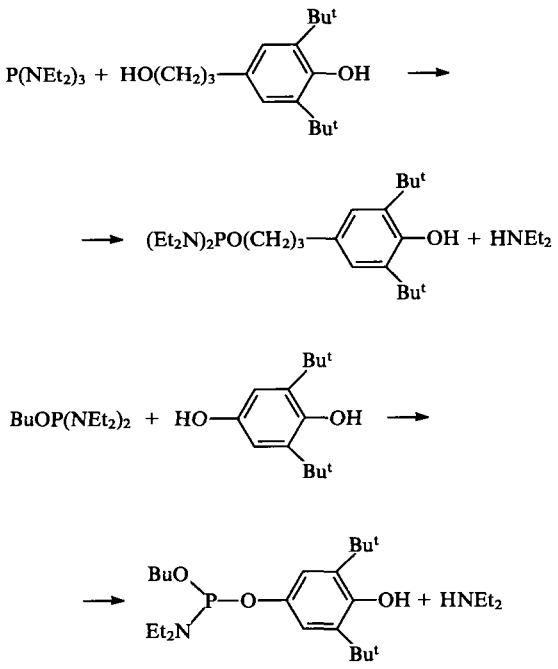


Cyclisation and not bicyclophosphorylation reactions are typical for experiments with diols in which the hydroxy-groups are close to one another in space. Half of the phosphoramide introduced into the reaction fails to react under these conditions. An example is provided by the phosphorylation of catechol and its derivatives by phosphorous acid hexaalkyltriamides (Scheme 12).[228–234]

Scheme 12



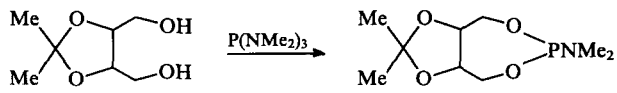
The interaction of phosphorous triamides with 1,4;3,6-dianhydromannitol merits special consideration. In this case, alcoholic hydroxyls in the initial compound are not quite so close in space as in catechol, so that phosphacyclisation is difficult.[235,236] On the other hand, the primary phosphorylation step leads to a novel situation: the free hydroxyl of the intermediate is apparently more reactive than the hydroxyl of the initial diol, the reactivity of which diminishes owing to the formation of intramolecular hydrogen bonds. The reactivity of the intermediate is manifested by the fact that in the interaction of even equimolar amounts of dianhydromannitol and phosphorous hexamethyltriamide results in the formation of mainly the bisphosphorylated product and residual unreacted dianhydromannitol remains.[237]



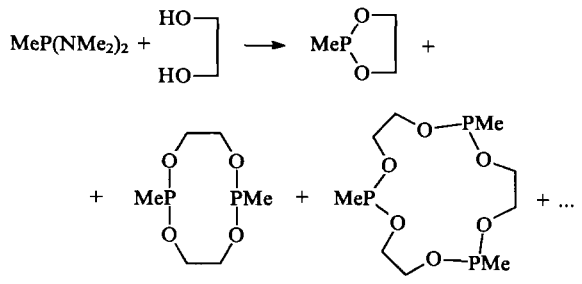
$k_2 \gg k_1$

Thus the geometrical characteristics of the initial diols may regulate significantly the nature of their phosphorylation.

The monophosphorylation of diols by an equimolecular amount of phosphorus(III) acid amides rarely affords satisfactory results. The group of reactions of cyclic TPAA with 1,2-diols has been investigated in greatest detail. The phosphoalcohols formed in this case as the primary product exhibited a tendency to undergo ring–chain tautomerism.

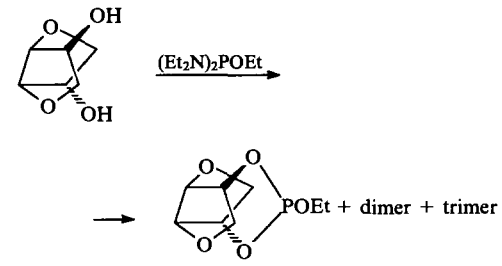


The position of the tautomeric equilibrium is determined by the structure of the compound, the solvent, and temperature. It is usually fully or largely displaced towards the formation of the form with pentacoordinate phosphorus—hydrospirophosphoranes. The history of this problem and the extent to which it has been investigated have been described in a series of reviews.[238–242] A different result was noted in the phosphorylation of diols the hydroxy-groups of which are of a different chemical nature: one of them is sterically exposed whilst the other is shielded. 4-(γ-Hydroxypropyl)-2,6-di-*tert*-butylphenol[243] and 2,6-di-*tert*-butylhydroquinone[210] may be included among these diols. In this case, phosphorous diamides and triamides interact regioselectively with an equimolecular amount of the diol.

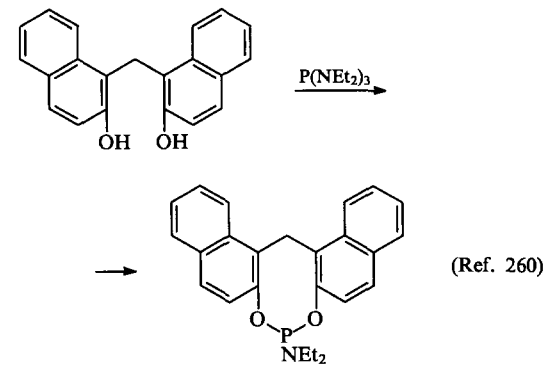


The phenyl phosphorodiamidites obtained are entirely stable. They can be distilled in a high vacuum and phosphorylate extraneous nucleophiles by virtue of their phosphoramide fragment.

The cyclophosphorylation and cyclooligophosphorylation of diols by TPAA has been comprehensively investigated. It has been shown that phosphorous diamides and tiramides effect the preparative phosphorous cyclisation of alkane-1,2 diols,[142,229,244-247] alkane-1,3-diols,[142,244,248,249] and alkane-1,4-diols[142,250-253] with formation of the corresponding 1,3,2-dioxaphosphacyclanes.

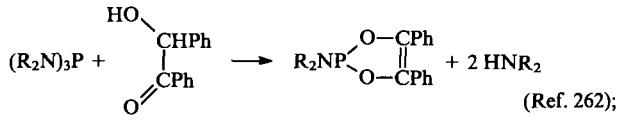


These phosphoramides cyclophosphorylate similarly also functional derivatives of diols,[254-257] for example, 2,3-isopropylidene-D-threitol.[257]

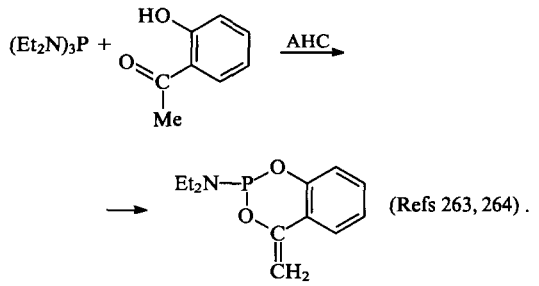


Many of the phosphacyclic compounds obtained in this way are used in the solution of stereochemical problems and in the synthesis of compounds of practical importance. It is very interesting that phosphorylation of alkane-1,2-diols and alkane-1,3-diols by phosphonous diamides leads to compositions comprising monocyclic and oligocyclic compounds which are in equilibrium, for example:[258]

It has recently been possible to extend the cyclophosphorylation reaction to 1,4;3,6-dianhydromannitol and to establish also the parallel formation of mono- and tri-cyclophosphorylated systems (this time phosphorous and not phosphonous).[236]

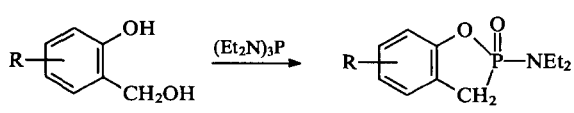


Normal cyclophosphorylation has been observed for catechols,[228-232] *o*-naphthalenediols,[259,260] and other dihydric phenols containing hydroxy-groups which are close in space.

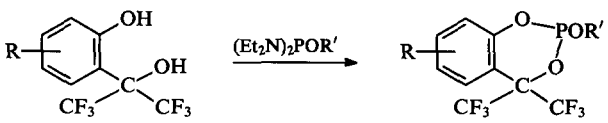


Aromatic heterocyclic *o*-diols—2,3-dihydroxypyridine[261] and 2,3-dihydroxyquinoxaline[259]—also form phosphacyclic compounds on reaction with TPAA. We may note, however, that the preparative conditions in these cyclisations are not identical. The latter diol is formed with considerable difficulty apparently owing to the great strength of its intermolecular hydrogen bonds.

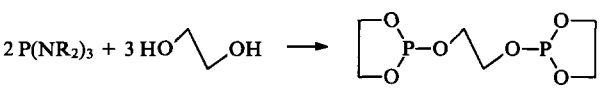
The ready cyclophosphorylation of hydroxyketones, which readily react in their enolic forms when the hydroxy-groups are close together in space, also merits attention:[262]



(Ref. 262);



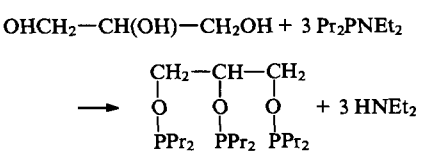
The last reaction is of interest because it leads to cyclisation only in the presence of amine hydrochlorides. Pure phosphoramides react with *o*-acetylphenol to form benzoxaphospholanes.[263,264]



A number of investigators have attempted to cyclophosphorylate saligenin or related *o*-hydroxymethylphenols with formation of benzophosphorinanes. These attempts were unsuccessful: benzoxaphospholanes were obtained instead of the expected compound.[265]

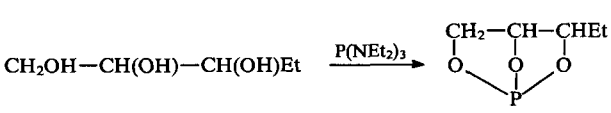
It was postulated that the benzyl cations, formed readily after the primary phosphorylation, play a crucial role in such reactions. Taking this into account, bistrifluoromethyl derivatives of saligenins were used in the cyclophosphorylation reaction, which led to the successful synthesis of previously unknown benzodioxaphosphorinanes.[266]

In conclusion of the subject of the cyclophosphorylation of diols, we may point to interesting instances of the combination of reactions leading ultimately to the formation of cyclic diphosphites. An appropriate reactant ratio is needed for this purpose. Such combination is particularly successful with 1,2-diols, for example ethylene glycol.[221,222]



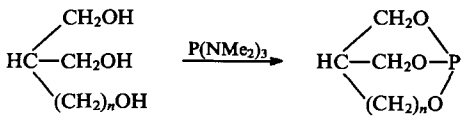
c. Phosphorylation of triols and higher oligools

TPAA were introduced into the range of popular phosphorylating agents during the period when the problem of the study of skeletal systems became of current interest in organic chemistry. It became necessary to develop specific procedures for the synthesis of phosphorus-containing skeletons. This was achieved in a series of leading scientific centres via the cyclophosphorylation of oligools by phosphorous and phosphonous amides. An extremely important feature is that, even in the first stages of the work involving the design and study of the properties of phospha-skeletal compounds, fundamentally important results were obtained, including the discovery of novel stereoelectronic interactions and other structural effects.



Studies on these lines are frequently experimentally complex and this is why there is still no well structured set of data. In view of this, we have arranged the published data in terms of a formal characteristic — the number of hydroxy-groups in the molecules of the phosphorylated oligools.

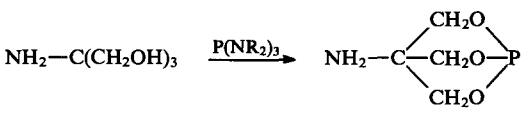
Phosphorylation of triols. The phosphorylation of glycerol with formation of open-chain triesters and phosphacyclic compounds has been described in the literature. Only one publication, reporting the interaction with dipropylphosphinous diethylamide, has been devoted to the triesters.[267]



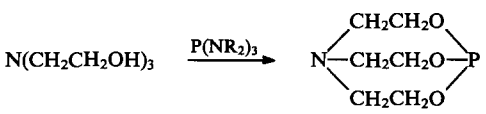
It was noted that the phosphoramide employed exhibits in this case a lower reactivity than in the phosphorylation of other alcohols.

It is noteworthy that glycerol is a poor coreactant in the bicyclophosphorylation reaction using trifunctional derivatives of phosphorous acids. The instability of the target product, having a strained central unit, adds to the difficulties in phosphorylation under these conditions.[268] On the other hand, terminally substituted glycerols, for example pentane-1,2,3-triol, are smoothly bicyclophosphorylated with formation of stable esters.[269]

It may be that in this case the molecules of bicyclophosphites interact stereoelectronically with participation of terminal substituents, which alters the parameters of the valence bonds and hence diminishes the angular strain. Furthermore, an effect of the Thorpe–Ingold type may exert some influence in this instance.

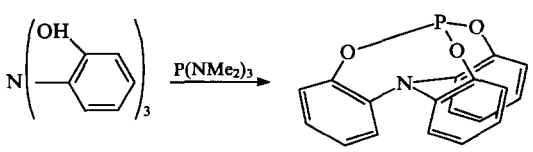


The related bicyclophosphites are obtained even more effectively on treating with phosphorous triamides linear triols having more widely separated hydroxyls: butane-1,2,4-triol,[270–273] pentane-1,2,5-triol,[274] and also related or branched systems — 1,1,1-tris(hydroxymethyl)methane[270] and 1,1,2-tris-(hydroxymethyl)ethane.[275]



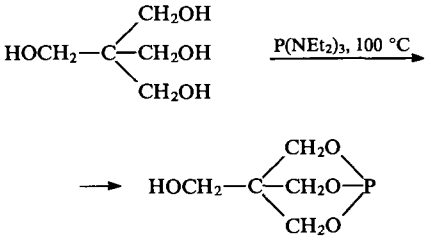
$n = 1, 2$

Stable skeletal bicyclophosphites, in the molecules of which 1,3,2-dioxaphospholane, 1,3,2-dioxaphosphorinane, and 1,3,2-dioxaphosphepane rings are condensed, are formed in all cases. Such skeletal systems have come to be widely used in fine organic synthesis and in coordination chemistry. They have attracted the attention also of physicochemical biologists[276] in connection with their ability to regulate membrane transport §.



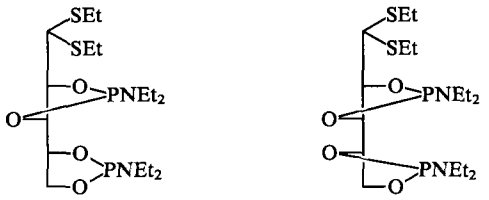
Phosphorous triamides can also interact with tris(hydroxymethyl)methylamine.[277]

A phosphorus-containing skeleton, the molecules of which contain two condensed six-membered rings and a free amino-group, is formed in this case. This aminoalkyl phosphite is a valuable ligand for the preparation of metal complex catalysts soluble in aqueous systems.[277] A formally, structurally similar, very labile system, which has been called phosphatrane, has been synthesised by the reaction of triethanolamine with phosphorous triamides.[278–282]



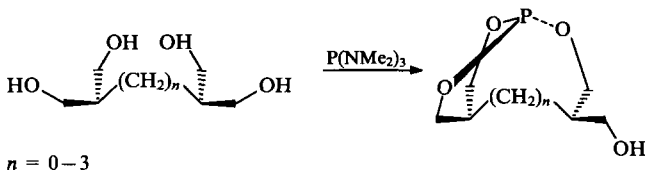
A skeletal amino-substituted phosphite, similar to that described above but containing *o*-phenylene groups and not ethylene groups as the main alkylene elements, has been synthesised by phosphorylating tris(*o*-hydroxyphenyl)amine with phosphorous hexamethyltriamide.[283]

This phosphite belongs to the class of rigid skeletal compounds of the 'cage' type. Its phosphorus and nitrogen atoms are not close to one another and do not therefore interact, as happens in phosphatrane. It is apparently of interest for the creation of supermolecular constructions.



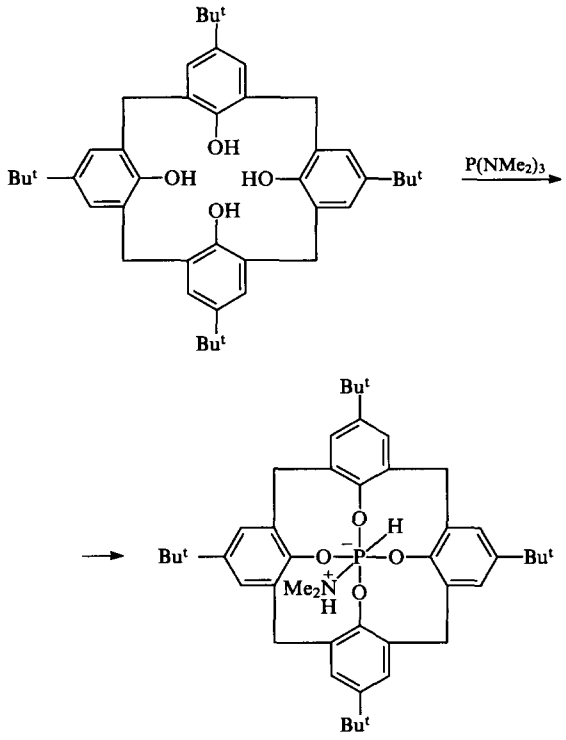
§ The synthesis of phosphaskeletal compounds is examined in greater detail in the section devoted to carbohydrate phosphites.

Phosphorylation of tetraols. All the publications dealing with 'tetraols' were concerned only with the problem of cyclophosphorylation. Pentaerythritol may be specified in the first place as a promising substrate for cyclophosphorylation. This symmetrical tetraol is readily available and various syntheses have been planned on its basis. Some of them have already been achieved. Thus it has been reported that, when pentaerythritol is heated with an equimolecular amount of phosphorous hexaethyltriamide, a symmetrical skeletal phosphite is formed—4-hydroxymethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane.[270]

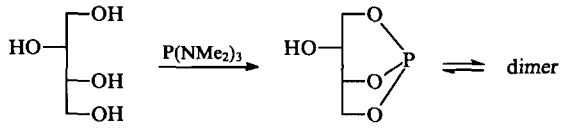


This compound is of great interest for subsequent reactions and also for use as a stabiliser of materials and as a ligand in the synthesis of metal complexes.

The 1,1-diethylthioacetals of aldopentoses—D-xylose and L-arabinose—are also bicyclophosphorylated with formation of compounds **35** and **36**.[284]

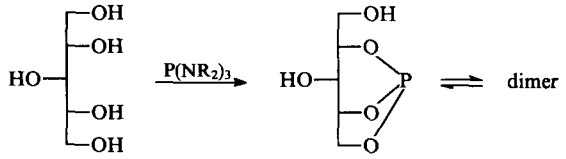


The group of α,α,ω,ω-tetrakis(hydroxymethyl)alkanes has been investigated in the reaction with an equimolecular amount of phosphorous hexamethyltriamide.[275]

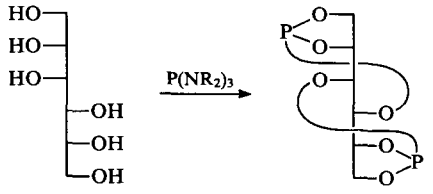


$n = 0-3$

The interaction of *p*-(*tert*-butyl)calix[4]arene with phosphorous hexamethyltriamide in equimolecular proportions is very interesting.[285] Triple phosphorylation of the calixarene occurs in this case and leads to the formation of a bicyclophosphite the phosphorus atom of which is very close to the phenolic hydroxyl which has not reacted. Owing to the spatial proximity of these groups, they readily react, which leads to the appearance of the phosphorane structure. The latter combines with a molecule of the dimethylamine produced. Naturally, the pathway described is only one of those possible in the reaction. A detailed study of this process can lead us to the discovery of new characteristics of the reactions of flattened skeletal phosphacyclic compounds.



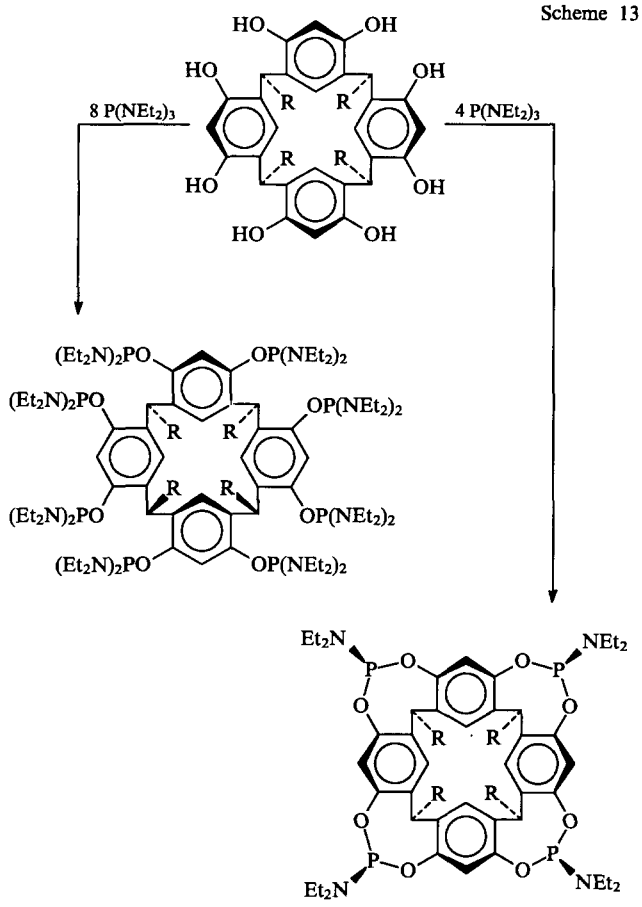
The phosphorylation of threitol, which is a conformationally labile tetraol, by TPAA is of a different kind. The interaction of equimolecular amounts of the reactants results in the initial formation of a mixture of products. Subsequently, it is converted into a 1,2,4-bicyclophosphite, which may dimerise reversibly.[286]



The entire information about these reactions has been obtained by ^{31}P NMR spectroscopy.[286]

Phosphorylation of higher polyols. The phosphorylation of higher polyols by TPAA leads to the formation of complex products[287-289] the structure of which has been reliably established only with the aid of NMR spectroscopy and X-ray diffraction.

Thus xylitol in contact with an equimolecular amount of phosphorous triamide behaves similarly to threitol.[286]

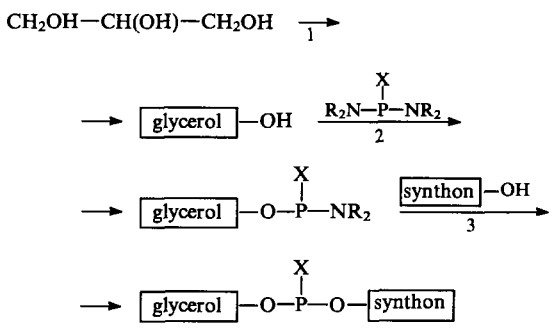


The reaction of mannitol with phosphorous triamide is more promising: in this case it was possible to obtain a bisbicyclophosphite—the product of the complete phosphorylation of the hexaol.[290]

We may note that a similar reaction with phosphorus trichloride affords much poorer results owing to the partial substitution of the hydroxyls by chlorine atoms. The structure and steric configuration of the compound obtained have been demonstrated by X-ray diffraction.[291]

Phosphorylation and cyclophosphorylation have been investigated also in the series of aromatic octaols in connection with the synthesis of ligands for the formation of supramolecular systems. Thus it has been shown[292,293] that octahydroxy[1$_4$]metacyclophane affords an octaamidophosphite on treatment with an eightfold molecular amount of phosphorous hexaethyltriamide, while treatment with a fourfold amount of this reagent gives rise to a tetracyclic derivative, which is the first reliably described representative of phosphorus-containing cavitands (Scheme 13).

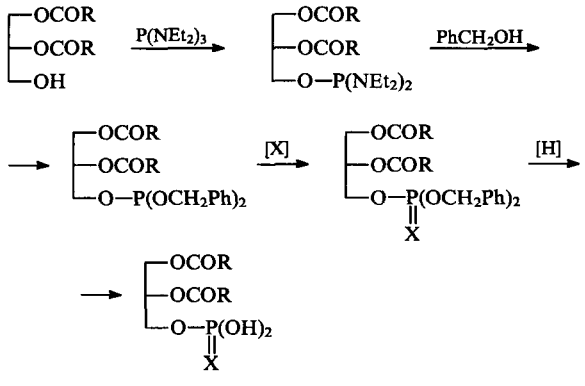
Scheme 13



4. Trivalent phosphorus acid amides in the chemistry of natural products

The development of the methods of organophosphorus chemistry has in many respects determined the progress in physicochemical biology. Thus, by virtue of the active employment of trivalent phosphorus reagents, especially TPAA, fundamentally important results have been obtained during the last 10–15 years in the synthesis of oligonucleotides, phosphorylated sugars, phospholipids, and other phosphorus-containing natural products as well as their analogues as regards the phosphorus-containing functional groups. This has been reflected in the publication of a series of reviews in which problems of the employment of phosphoramides in the design of specific classes of natural products have been discussed.[294–304] The publication of these reviews helped us in writing the present review, because it obviated the need for a difficult task and for the exhaustive quotation of a large set of communications, which are of the same type from the standpoint of organophosphorus chemistry, and thus made it possible to draw the reader's attention to the principles of phosphoramide synthesis and the current trends in its employment.

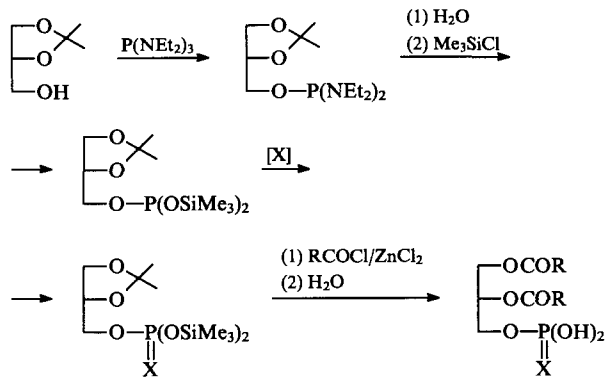
a. The synthesis of phospholipids



The commonest phospholipids in nature are glycerophosphates, especially phosphatidic acids and their various derivatives. These compounds perform exceptionally important biological functions and an enormous amount of attention has been devoted to their synthesis.[304–306]

We therefore begin the present section of the review with the consideration of the use of TPAA in the design of glycerophosphatides and their P-analogues. The strategy for these syntheses developed in recent years usually presupposes the carrying out of the following stages: (1) the synthesis of monohydroxy-derivatives of glycerol—either 1,2- or 1,3-acetals or 1,2- or 1,3-diacylates; (2) phosphorylation of glycerol derivatives via the alcoholysis of the phosphoramide linkage of a suitable TPAA; (3) oxidative and other necessary reactions leading to phosphatidic acids or other very simple phosphoglycerides, and construction of the complex phosphoglyceride by introducing into the glycerophosphite unit of an additional synthon as a result of the alcoholysis of the second phosphoramide linkage by a selected synthetic equivalent of this synthon.

This process is completed by oxidation reactions and the necessary reactions leading to the formation of the required complex glycerophospholipids.

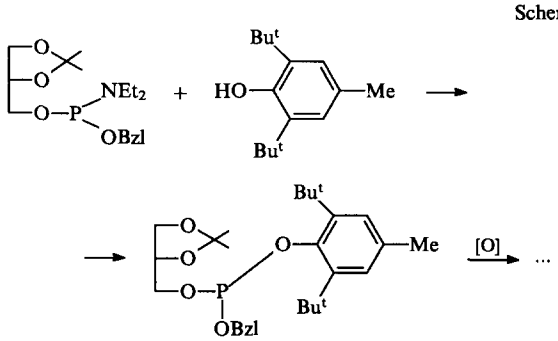


The general scheme presented above has now been embodied in numerous syntheses of various phospholipids and they have all been carried out on the basis of a narrow set of initial reagents and using convenient synthetic procedures.[304] We shall examine the syntheses of phosphatidic acids. These compounds can be obtained from 1,2- or 1,3-acylglycerols which are made to react with TPAA, this being followed by oxidation reactions and the removal of protecting groups, for example:[307,308]

X = O, S

The use of diacylglycerols in phosphorylation entails a risk, because the secondary amine produced can, generally speaking, add to the carbonyl group of acylates, which leads to their partial deacylation or isomerisation. Special studies were carried out which showed how it is possible to avoid these complications.[308,309] At the same time an analogous variant of the synthesis, based on the use of glycerol acetals instead of acylates, was proposed. Glycerol acetals are readily available compounds

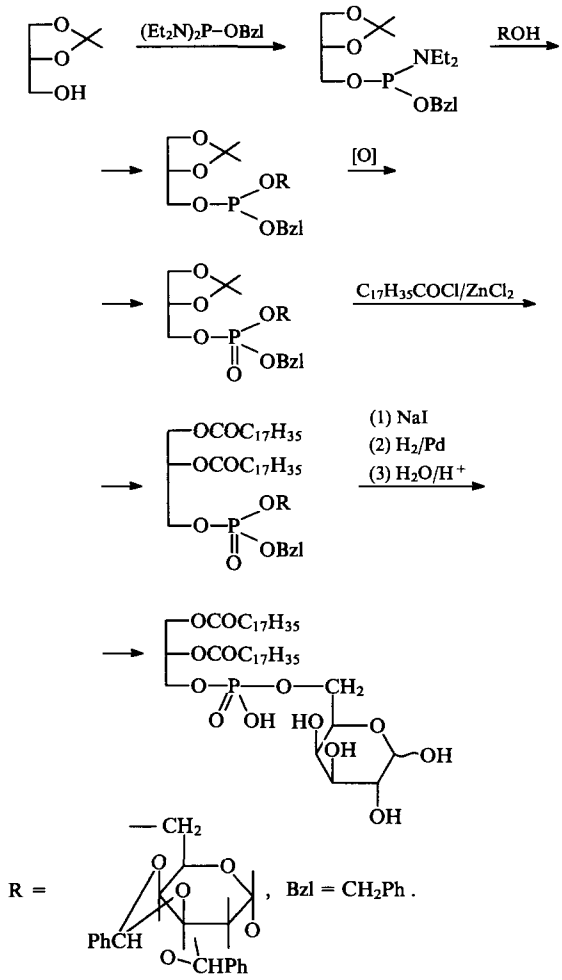
which are convenient to handle. They are readily phosphorylated by TPAA without side reactions, after which they are converted by hydrolysis into diols. These are subsequently acylated. Unfortunately, this procedure is preparatively difficult and requires a scrupulous selection of conditions.[187] Therefore a much simpler and effective process has developed—direct acylation of acetals.[310-313] Subsequently the general scheme for the synthesis of phosphatidic acids was supplemented also by other improvements.[304]



We emphasise that the proposed solution made not only phosphatidic acids but also their thio- and seleno-analogues really available. These analogues immediately began to be used successfully for the solution of important scientific problems, for example for the ^{31}P NMR study of phase transitions in lipid membranes.[314-315]

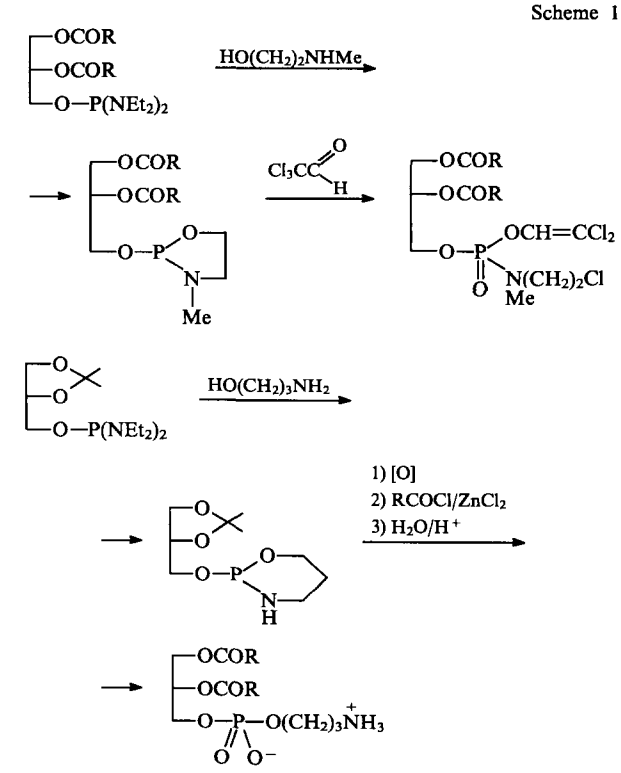
The use of the phosphoramidite synthesis is even more promising for the preparation of complex natural phosphatides and their analogues. For this purpose, glycerophosphoramidites are made to react[295,304] with aminoalcohols, glycerols, sugars, myoinositol, aminoacids, etc., which leads to the formation of the corresponding phosphatidic acid esters and amides¶. As an illustration, we present (above right) a scheme for the synthesis of 6'-(1,2-distearoylglycero-3-phospho)-D-galactose.[204,207]

Glycophospholipids containing D-glucose[185,207] and disaccharide (maltose)[316] residues were obtained in a similar way.



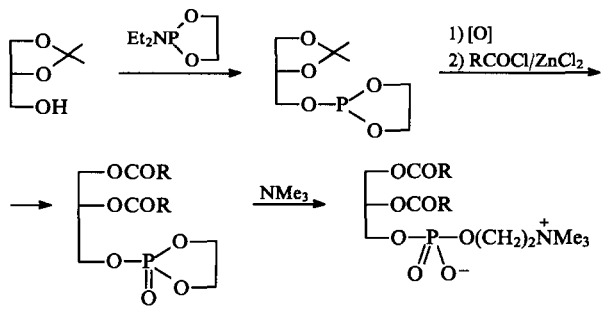
The method considered has been applied also to the synthesis of new constructions of fundamental importance, for example phosphatidyl derivatives of sterically hindered phenols (Scheme 14).[182,183] The preparations thus obtained are membranoaddressed bioantioxidants.

Scheme 14

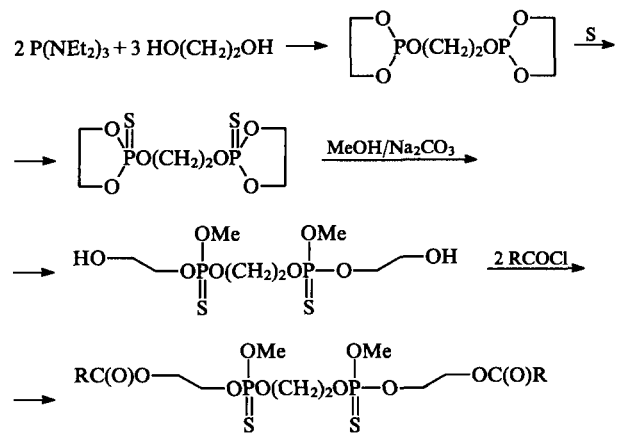


Reactions of glycerophosphorodiamidites with diols[188,206,317] and aminoalcohols[186,187] also merit attention. As in the phosphorylation of substituted glycerols by the amides of the

¶ In many cases an alternative approach may be useful. According to this procedure, the substituted glycerol incorporating sugar, aminoalcohol, etc. residues is phosphorylated by phosphoramidites.

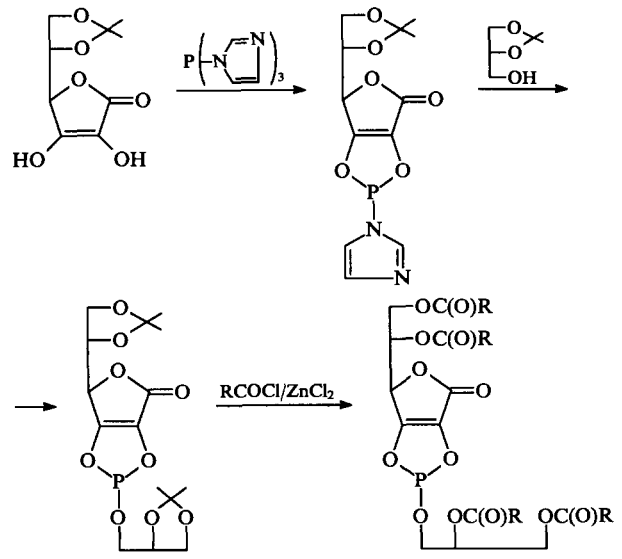


corresponding alkyl or alkylene phosphoramidites, various glycerophosphacyclanes are formed in such cases. There are good prospects for the use of phosphacyclanes for synthetic purposes (Scheme 15).



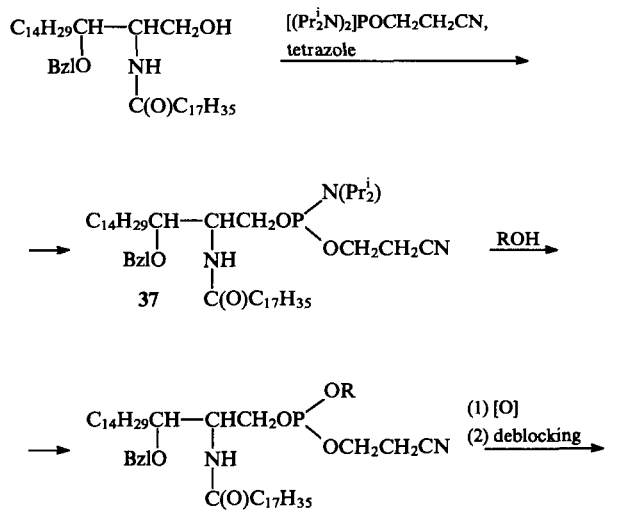
Scheme 15

During the study of such glycerophosphacyclic compounds, a promising reaction was discovered—alkylation of tertiary amines and other nucleophiles by alkylene cyclophosphites.[188, 206, 317–325] A simple method of synthesis of lecithins based on this reaction is presented below.

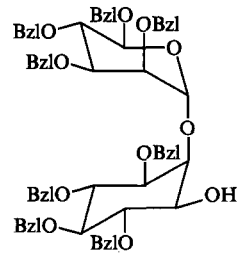


The successful development of glycerophosphoramidite syntheses stimulated research into the chemistry of diol phospholipids. A series of useful reactions leading both to the simplest diphosphites and to extremely complex substances which are difficult to obtain by other methods have been achieved.[326]

R = $C_{17}H_{35}$

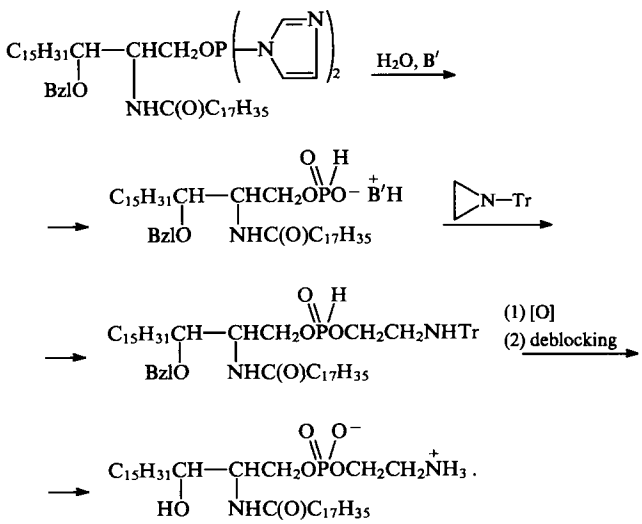


The synthesis of lipid systems from ascorbic acid is much more difficult.[327] For this purpose, 5,6-isopropylideneascorbic acid was cyclophosphorylated by phosphorazolidites, which act under mild conditions, to form an ascorbophospholene. The product was used subsequently as a phosphorylating agent in the reaction with 1,2-isopropylideneglycerol.



R = $C_{17}H_{35}$

Elegant studies have been carried out recently on the use of TPAA for the preparation of ceramidophosphoric systems. It was shown that the interaction of 3-benzoylceramide with β-cyanoethyl *N,N*-diisopropylphosphorodiamidite in the presence of tetrazole affords a phosphoramidite which can be converted by the methods mentioned above into extremely complex phosphate and phosphorothioate systems. As an illustration, we present the results of one of the latest studies[328] (Scheme 16).



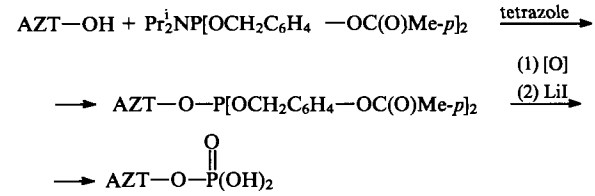
Scheme 16

ROH =

We may note that intermediate **37** and the corresponding phosphorodiamidite may be hydrolysed to form hydrophosphoryl compounds, which are phosphorous monoesters and diesters. These compounds are also promising for phospholipid syntheses: they have been introduced into a series of reactions, both those which have already proved useful in phospholipid practice[329, 330] and comparatively new ones, for example:[328]

Tr = CPh_3

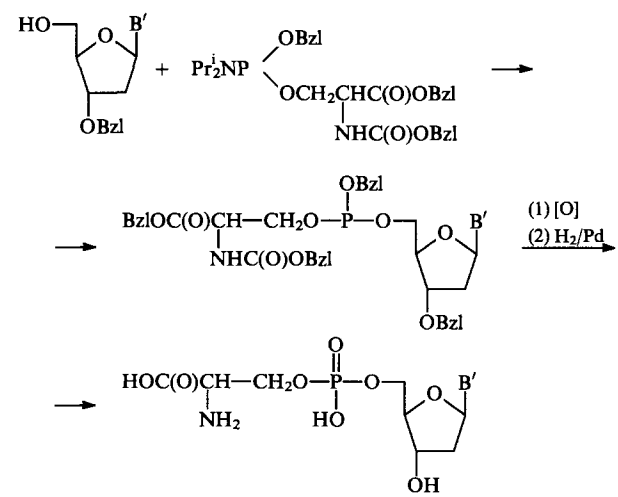
b. Phosphorylation of nucleosides and the formation of an internucleotide linkage



The methods of phosphate chemistry, intricately refined in many scientific centres, have been used for a long time for the phosphorylation of nucleosides, the formation of the internucleotide linkage, and the solution of other related problems. Nevertheless, owing to the low rates of phosphorylation, these methods do not meet the needs of modern research. Furthermore, the classical methods lead to poor results in the synthesis of thiophosphoryl and other nucleotide derivatives which are nonstandard in the phosphorus component. The employment of the highly reactive trivalent phosphorus derivatives and in the first place TPAA was seen as a method of overcoming the difficulties which have arisen.

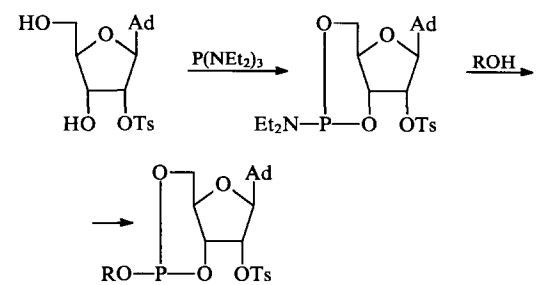
The possibility, in principle, of resorting to amides of phosphorous, phosphonous, and phosphinous acids in order to phosphorylate nucleotides was demonstrated at the end of the 1960s and the beginning of the 1970s.[331,332] Unfortunately, time was needed to become accustomed to the new reagents and they have only now, i.e. much later, been introduced into laboratory practice. TPAA are nowadays widely employed in different chemical, molecular biological, and gene engineering aspects of nucleotide syntheses. It must be emphasised that TPAA are used not only for the synthesis of oligonucleotides but also of a wide variety of their P-analogues, which have extended the possibilities of research involving biopolymers.

The use of TPAA in the chemistry of nucleic acids has been described in a series of interesting monographs and reviews,[300-302,333] and in the present review we shall consider only the key aspects of the problem.



We may note that especially reactive phosphorazolides, such as the triazolides,[111,334-338] tetrazolides,[103,104,334,339-341] imidazolides†,[140-143,334,342] or the 'usual' TPAA, are frequently employed for the phosphorylation of deoxyribo- and ribo-nucleotides in the presence of acid activators — usually tetrazole,[300-302] diisopropylammonium tetrazolide,[106-114] 4,5-dichloroimidazole,[100,102] and certain others. In most studies, the phosphorylation is combined with oxidation reactions and manipulations involving protecting groups. As a rule, in contrast to the acid chloride method,[343] in the phosphoramide method the phosphorylation of nucleosides hardly involves their nitrogen-containing heterocycles. However, this version of the reaction is nevertheless possible in certain situations, which has been specially noted in the literature.[99,344]

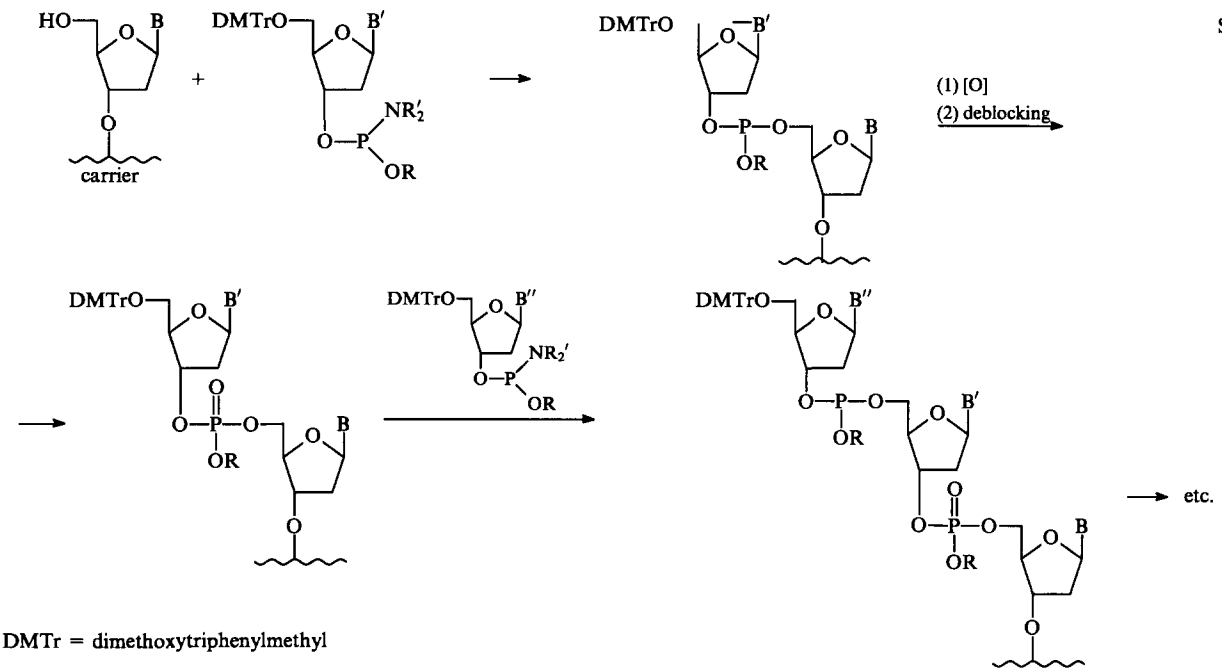
We shall consider the most fruitful procedures for the phosphorylation of nucleosides using TPAA. In many instances, this reaction has served as the basis of the synthesis of nucleotides of especially great importance, for example the synthesis of phosphorylated azidothymidine (AZT):[345,346]



It has been suggested that nucleotide-sugars, including derivatives of sialic acids, which are of interest in the fight against AIDS, can be synthesised using TPAA.[347] In addition, it has been possible to synthesise compounds the molecules of which include the so called 'reporter' groups, for example aminoxyl radicals which assist in the performance of detailed structural studies on the functions of nucleotide compositions.[348,349]

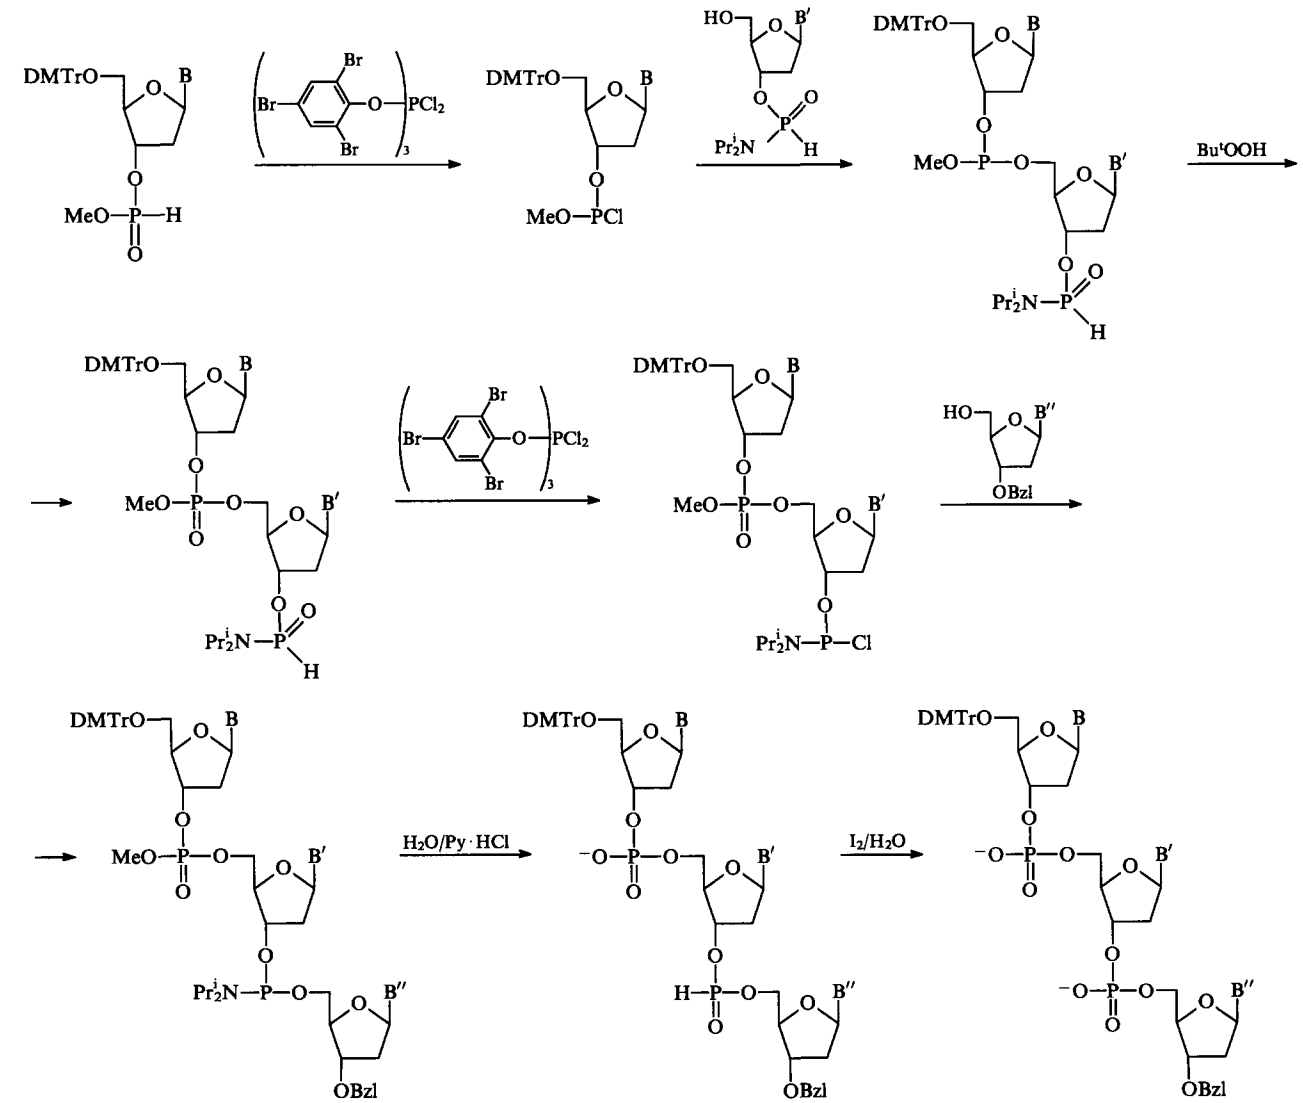
Phosphorylation by TPAA which contain residues comprising aminoacids or other biomolecules have also attracted the attention of investigators. In this case, the synthesis leads to the formation of the link component of nucleoproteins or other complex systems. As an illustration we present the synthesis of the phosphoserine link.[350]

In view of the great importance of adenosine (thymidine) monocyclophosphates, studies have been made on the synthesis of their phosphite and phosphonite analogues.[332,351-357]



The compounds obtained were used in Arbuzov alkylation, oxidation, and other reactions.

Apparently most publications have been devoted to the use of phosphoramides to form the internucleotide linkage and especially for the synthesis of oligonucleotides by this procedure. The relatively easy and rapid methods for the synthesis of a wide variety of higher oligonucleotides have nowadays revolutionised a number of aspects of molecular biology and gene engineering.[300-302,333] The most widely used scheme for the synthesis of oligodeoxyribonucleotides is presented overleaf in a general form (Scheme 17).



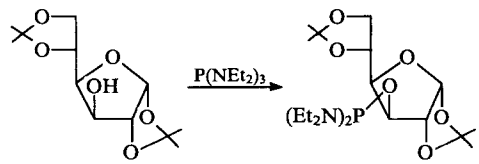
† The imidazolides are the most effective phosphorylating agents, but they are very sensitive to traces of moisture and are therefore unstable.

Scheme 17

DMTr = dimethoxytriphenylmethyl

Scheme 18

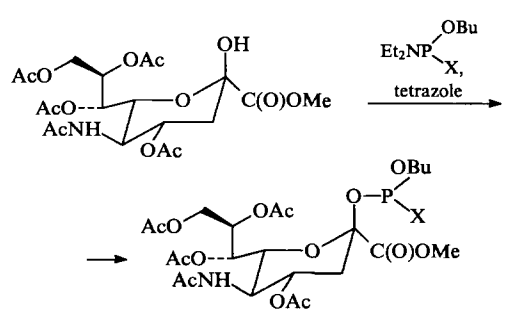
We may note that oligonucleotide condensations are most often carried out on solid carriers using automatic synthesisers which ensure a high process efficiency. It is sufficient to state that the typical phosphorylation step requires several minutes at 20 °C in these instruments. It is significant that nucleoside phosphoramidites, which are the principal reagents in the above condensations, have now become available as commercial preparations.[358, 359]



Oligoribonucleotides are also synthesised in accordance with a more complex programme.[104, 340, 359-361] It is very significant that, together with oligonucleotides, their phosphonate,[362-364] phosphoramidate,[106, 344, 365-367] phosphorothioate,[344, 365, 368-370] and phosphorodithioate[371-375] analogues can be obtained by the phosphoramidite method using the extensive procedures of the chemistry of trivalent phosphorus.

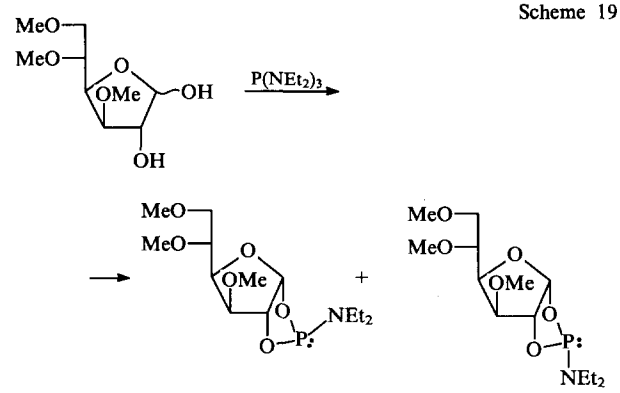
In molecular biology, the greatest interest attaches to solutions which make it possible to assemble from nucleoside phosphoramidites and diol oligomers [oligo(ethylene glycols) for example] complex constructions in which oligonucleotide and other chains are combined. A special review[302] published in 1993 was devoted to this current problem.

Finally, the phosphorylation of nucleosides by TPAA, supplemented by hydrolysis, sulfohydrolysis, or acidolysis, makes it possible to obtain primary[338, 376-383] and secondary[342, 367] nucleoside phosphites, phosphoramidites,[384] and phosphorothioites,[371] which are nowadays actively employed in a wide variety of hydrophosphoryl and thiophosphoryl syntheses. A new scheme for the synthesis of oligonucleotides with the aid of two different types of hydrophosphoryl compounds is presented (Scheme 18).[384]



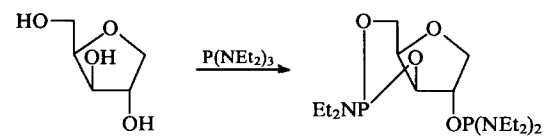
c. Phosphorylation of monosaccharides

Trivalent phosphorus acid esters and monosaccharides became the objects of independent systematic studies only after their synthesis began to be based on the phosphoramide method.[294, 298] TPAA of different nature readily phosphorylate monosaccharides the molecules of which contain a free alcoholic hydroxyl,[385, 390] for example, 1,2;5,6-diisopropylidene-D-glucofuranose.[386]



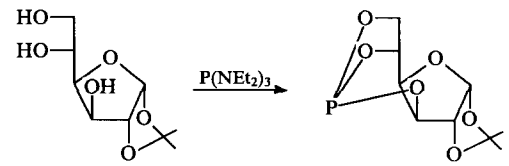
The products can be used subsequently as phosphorylating agents for various nucleophiles or can be introduced into a reaction with electrophiles (oxidants, alkyl halides, the simplest transition metal complexes, etc.).[185, 207, 391-393]

Monosaccharide derivatives are effectively phosphorylated also at the glycosidic hydroxyl,[394-396] whereupon the stereochemistry of the phosphorylated centre does not change during the reaction.[397] Such phosphorylation began to be extended to extremely complex systems in the most recent times. For example, β-sialyl phosphites and β-sialyl phosphoramidites have been obtained with the aid of TPAA.[347]

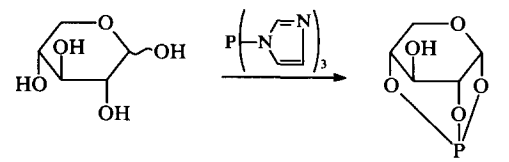


Treatment of monosaccharide derivatives containing two close hydroxyls can involve cyclophosphorylation. If one of the above hydroxyls is glycosidic, then stereochemical selection may take place (Scheme 19).[398]

Scheme 19



In this case, the selection concerns only the glycosidic and not the phosphoramide component of the system and therefore leads to the formation of two geometrical isomers the ratio of which may change on heating. The phosphorylation of triol systems takes place in different ways. Hydroxyls which are separated in space, as is the case in xylitan, are phosphorylated with formation of diphosphites.[392]



Such diphosphites began to be investigated as ligands for the preparation of chelate metal complex systems, which are likely to be used in enantioselective catalysis.[392, 393]

Monosaccharides—triols and tetraols with hydroxy-groups in close proximity—are phosphorylated particularly readily, being converted under these conditions into bicyclophosphites, for example:

(Ref. 399);

(Ref. 400).

As can be seen from the reaction presented, the latter case involves selective bicyclophosphorylation, the mode of which is determined by the steric characteristics of the sugar.

In the course of the development of the phosphoramide method for the bicyclophosphorylation of partly substituted and unsubstituted monosaccharides, a large group of skeletal systems was obtained. They proved to be interesting objects to study as regards stereochemistry, reactivity, and also practical use. The results of studies on the synthesis, steric organisation, and reactions of these new phosphaskeletal compounds have been recently summarised in a special review.[303]

d. Phosphorylation of other natural products

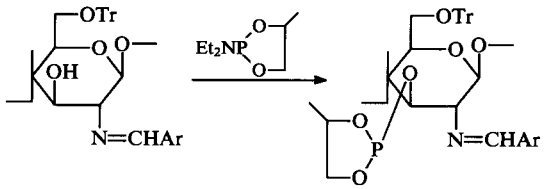
Aminoacids and peptides containing pentavalent phosphorus acid residues are widely investigated. Such studies involve the search for reactions based on new methods of organophosphorus chemistry.[401-403] The development of these investigations led to the study of the phosphorylation of carboxylic aminohydroxyacids by various TPAA, for example di(4-chlorobenzyl) *N,N*-diisopropylphosphoramidite[404] and benzyl bis(*N,N*-diisopropyl)phosphorodiamidite.[350,405] Subsequently the aminoacid phosphites obtained were introduced into oxidation reactions or were used as phosphorylating agents.

Steroid compounds have been relatively little studied in the phosphorylation reaction. It is noteworthy that studies were initiated recently on the phosphorylation of cholesterol and other steroids by various phosphorous amides.[95,406-409] Apparently there are good prospects for the synthesis from these derivatives of a wide variety of bioregulators, which can be addressed by means of the steroid component of the molecular system.

Simultaneously with steroids, α-tocopherol has been phosphorylated.[95,407,410,411] These studies are probably of interest for the development of research into bioantioxidants and other systems.

The specific phosphorylation of myoinositol[251-253,412-415] and its deoxy-derivatives[413,416] by phosphoramidite esters has clearly aroused interest recently. These studies were initiated mainly in connection with the development of effective methods of synthesis of complex phospholipids and the creation of cytostatic substances which are not targeted on DNA.[417]

TPAA have become the usual reagents for the phosphorylation of monosaccharides and other oligols in connection with the synthesis of the corresponding primary phosphites. The latter are successfully used nowadays in the synthesis of teichoic acids[418,419] and capsular polysaccharides.[420,421] Finally, TPAA have been used in the synthesis of a wide variety of biotin-containing phosphoramidites,[422-424] phosphoramidite derivatives of the alkaloid fagaronine,[425] and macrocyclic oligoester-oligodeoxynucleotide hybrid compounds in order to be able to 'recognise' DNA.[426] Unfortunately, the phosphorylation of alkaloids, a wide variety of plant phenols, terpenoids, and other polyfunctional natural products with the aid of TPAA has been scarcely investigated.



5. Trivalent phosphorus amides in the synthesis of phosphorus-containing polymers

TPAA have also begun to be used in macromolecular chemistry. The studies in this field can be divided into two aspects: (1) the introduction of phosphorus into hydroxylated polymers; (2) a polycondensation process with participation of diols and other oligools.

The first aspect has been investigated in greatest detail in relation to natural polymers. Thus it has been shown that anhydrous cellulose in a heterogeneous system is phosphorylated on heating to 80–120 °C by phosphorous hexaethyltriamide, various phosphoramidites, and also diethylphosphinous diethylamide.[427,428] In the reaction with the last reagent, it was possible to follow the degree of substitution and to achieve the degree of phosphorylation $\gamma = 180$. It is of interest that, in contrast to the initial cellulose, the phosphinite obtained is soluble in certain organic solvents.

The best phosphorylating agents proved to be the azolides of phosphorous and diphenylphosphinous acids, which modify cellulose at 20–50 °C with attainment of high degrees of phosphorylation.[429] The products obtained in the interaction with solutions of palladium chloride or bis(π-allylpalladium chloride) afford heterogeneous hydrogenation subcatalysts. Such systems exhibited a high catalytic activity in the hydrogenation of styrene under mild conditions.[429] A very important feature is that the above polymeric complexes are more effective than the complexes obtained using the chlorides of the corresponding trivalent phosphorus acids.[430]

The phosphorylation of chitosan derivatives soluble in organic solvents has been achieved very recently.[431]

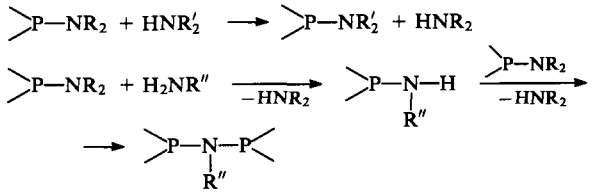
The above communication is the first on the phosphorylation of chitosan in general. Among other natural hydroxylated polymers, only lignin was phosphorylated by TPAA.[432] The properties of the esters obtained have not been studied in detail.

There have been indications also of the phosphorylation by TPAA of synthetic hydroxylated oligomeric and high-molecular-mass resins[433-435] and poly(allyl alcohol).[436] The products synthesised have been investigated as regards the formation of polymeric pesticides and in other promising technical applications.[437]

The second aspect of the use of TPAA in macromolecular chemistry includes studies on the phosphorylation of glycols[244] and dihydric phenols[438] by equimolecular amounts of phosphonous diamides and alkyl phosphorodiamidites. Unfortunately, this outwardly simple instance of polycondensation is supplemented by the simultaneous formation of monophosphorus-containing rings[244] and the corresponding macrocyclic systems,[438] as a result of which the molecular masses of the products are low. Presumably the use of the latest generation phosphoramides, for example phosphorus(III) acid azolides, makes it possible to carry out the polycondensation effectively at low temperatures, avoiding thereby the conversion of linear systems into cyclic systems.

$$n\,R{-}P(NEt_2)_2 + n\,HOR'OH \longrightarrow$$

$$\longrightarrow -(-R'{-}O{-}\underset{\displaystyle R}{\overset{\displaystyle |}{P}}{-}O{-})_n + 2n\,HNEt_2$$



Hexitols[288] as well as methyl glucoside[439] have been used in polycondensations with TPAA. For selected reactant ratios, under the conditions discovered, oligomers and high-molecular-mass phosphorus-containing polymers were obtained in such cases. They are of practical interest, for example as additives to lubricants and as stabilisers.[440]

Overall, the field under consideration has not yet been adequately developed in view of the complications noted above and the fact that the attention of phosphorylation specialists has been to a large extent diverted to the striking problems posed by molecular biology and gene engineering. However, the logic of the development of the chemistry of trivalent phosphorus and macromolecular chemistry leads us to execute the tasks associated with the second stage in the development of the problem. This also arises from the needs of related sciences, especially coordination chemistry. Indeed, despite all the attention devoted to macromolecular ligands and complexes based on them, the very promising polyphosphite, phosphoramidite, and phosphonite ligands have been neglected nowadays. The optimum procedures for the synthesis of such ligands may be based primarily on the achievements in the chemistry of TPAA.

III. Phosphorylation of amines

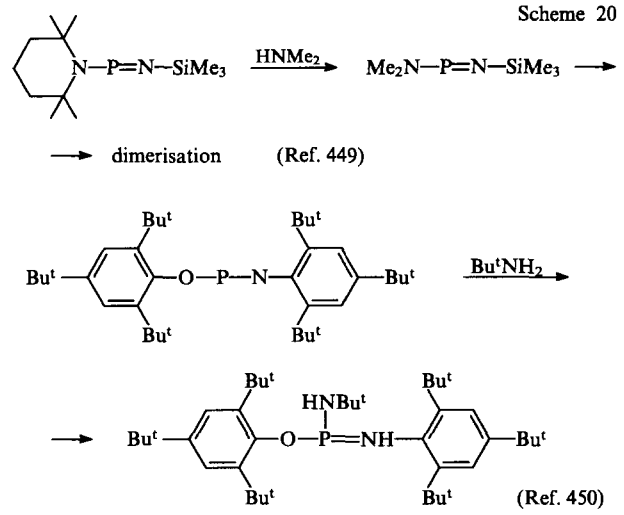
The alcoholysis, phenolysis, and aminolysis of TPAA are in principle related reactions. Furthermore they are comparable as regards their effectiveness and experimental conditions. However, preliminary analysis of these reactions indicates also differences between them. Firstly, in contrast to the alcoholysis and phenolysis, the aminolysis can include not only single but also

double phosphorylation steps when secondary and primary amines are used as substrates‡. Secondly, the structures of the intermediates in the reactions enumerated differ significantly. In the alcoholysis and phenolysis, the leaving and entering groups are based on different atoms (nitrogen and oxygen), whilst in the case of aminolysis they are based on the same atoms. This situation hinders the elucidation of the pathway followed in the migration of the hydrogen forming part of the composition of the intermediate, this being particularly difficult when several hydrogen atoms, occupying different positions in space, are attached to the nitrogen atom.

These factors have apparently contributed to the delay in research into the transamination of TPAA behind the study of the corresponding reactions with alcohols and phenols. Nevertheless, the transamination methods already employed made it possible to solve a series of interesting and promising problems, especially in the chemistry of complex phosphacyclic compounds and nitrogen-containing natural products.

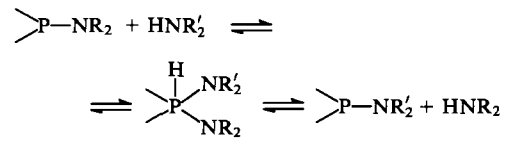
1. The history of the problem. Principal features of the reactions of trivalent phosphorus acid amides with amines

The first mentions of the possibility of the interaction of TPAA with amines leading to transamination date back to the end of the 1950s and the beginning of the 1960s.[135,441] Initial studies were on the simplest instances of transamination and were not associated with the solution of complex scientific problems. In the experiments, the low-boiling amine (usually diethylamine), which was one of the reaction products, was as a rule distilled away.[15,36,123,124,442–446] Approximately the same results were obtained in studies with the amides of phosphinous, phosphonous, and phosphorous acids.[447] The di- and tri-amides of these acids were used for complete and partial transamination. Mono- and polyfunctional amines of different chemical nature were selected as the substrates.



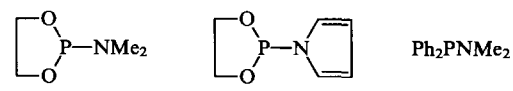
A high reactivity of the phosphoramide group was recorded in all the investigations. In this connection, we may note that even phosphorodifluoridous dimethylamide interacts with higher secondary amines via this group and not the phosphorofluoridite group.[448]

Studies on the interaction of primary and secondary amines with phosphenimidous compounds have been initiated recently. Various possibilities in the cleavage of the P–N σ- and π-bonds have been demonstrated in this connection: either substitution of a secondary amino-group[449] or the addition of an amine to the multiple bond (Scheme 20).[450] When an excess of the amine is used, more far reaching transamination processes can also occur.



‡ Generally speaking, triple steps are also possible when ammonia is used as a substrate, but such reactions have so far been very little investigated.[441]

Scheme 20



2. The chemistry of the transamination of trivalent phosphorus acid amides

On the basis of their own observations or merely on the grounds of general consideration, many investigators have expressed views concerning the dependence of the mechanism of the transamination of TPAA and of the rate of reaction on the structure of the reagent and the substrate. A mechanism involving addition of the phosphoramide to the amine with formation of a phosphorane and decomposition of the latter to the products detected has been proposed.[12,41,180,451,452]

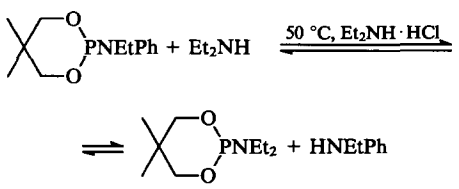
Mechanisms involving a four-centre transition state[23,24] and direct nucleophilic substitution at phosphorus have also been discussed. The second variant is most common in the usual reactions. It has been related recently to the experimental observation of acid catalysis—the acceleration of the phosphorylation reaction by the addition of amine hydrochlorides[15,22,23,36,189] and acids.[38]

Convincing arguments in support of the nucleophilic substitution mechanism were first put forward in a study[33] in which the influence of the basicity of the entering and leaving amines on the rate of reaction was estimated. The authors investigated the interaction of ethylene *N,N*-dimethylphosphoramidite **38** with amines having different basicities and observed an increase in the rate of phosphorylation with increase in the basicity of the reacting amine. Thus, on passing from morpholine (pK_a = 8.70) to pyrrolidine (pK_a = 11.27), the rate increases, while in attempted reactions with *N*-methylaniline (pK_a = 4.85) and pyrrole (pK_a = −0.27), dimethylamine (pK_a = 10.77)§ is not displaced. Accordingly pyrrolidine displaces pyrrole more readily in experiments with ethylene phosphoropyrrolidite **39** than dimethylamine in experiments with the amide **38**.

38 **39** **40**

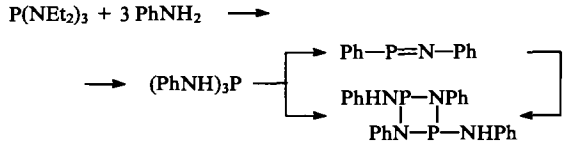
We may also point to the higher reactivity of the amide **38** than that of diphenylphosphinous dimethylamide **40**, which is consistent with the general principles of nucleophilic substitution at a trivalent phosphorus atom.[453] Unfortunately, the results of

§ The values of pK_a in water at 25 °C are quoted.



the transamination of the amide **38** were not obtained under equilibrium conditions, while those with the amide **39** were obtained under equilibrium conditions, so that strictly speaking their comparison is not valid. The difficulties in the interpretation of the results obtained with the pyrrolidite **39** have been noted also by other investigators.[31] We may note that the problem of the equilibrium nature of the transamination reaction has not been duly taken into account also in studies carried out in other laboratories (see, for example, Batyeva et al.[23]). Mosbo's study,[38] in which the transamination of the amino-derivatives of 1,3,2-dioxa- and 1,3,2-diaza-phosphorinanes was rigorously examined, is therefore especially important.

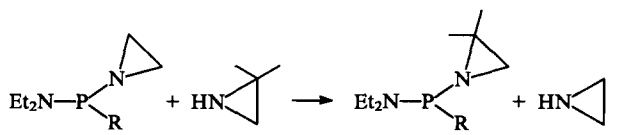
X = O, NMe; R = Et, $R_2 = (CH_2)_4$



It was shown in this series of reactions that equilibrium can be attained when aminolysis is carried out in both forward and reverse directions. The conclusion that the high basicity of the amine substrate is important for the substitution reaction was confirmed. The results of this investigation do not confirm the necessity for the intermediate conversion of the initial amide into the corresponding acid chloride with subsequent phosphorylation by the chloride of the amine (substrate).[22,23,454]

The acid chloride concept has also been rejected in another study[189] where acid-catalysed aminolysis was investigated at the kinetic level.

The occurrence of catalysis was clearly demonstrated in this investigation and the dependence of the rate of reaction on the basicity of the amine was confirmed, but the influence of the solvent polarity on the rate of phosphorylation was not observed. In addition, the ability of the substrate, taken in excess, to inhibit the phosphorylation reaction was established. Thus, the study of the transamination of TPAA at the kinetic level established certain characteristics of this process, which distinguish it from the corresponding alcoholysis reactions.

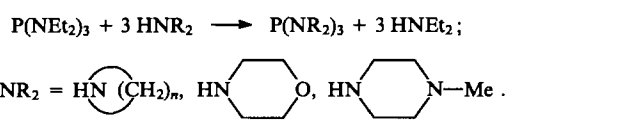


Comparison of the rates of phosphorylation and transamination of TPAA made it possible to make definite preparative recommendations. Thus it became clear that the best phosphorylating agents among the available phosphoramides are the anilides (*N*-alkylanilides).[127,189,209,447,455] We may note that the dialkylamides can react with aniline but only on heat treatment and with distillation of the dialkylamine evolved,[51,53] which shifts the equilibrium in the desired direction. The reaction considered is experimentally very complex and requires careful maintenance of constant phosphorylation conditions. Otherwise, elimination of self-phosphorylation reactions take place.[51,53,456-459]

The phosphorylation of dialkylamines by phosphorazolides merits attention.[145-148] The effectiveness of phosphorazolides increases in the sequence phosphinazolidite > phosphorodiamidous azolide > phosphorazolidite diester. The reverse reactions, i.e. the interaction of phosphorus acid dialkylamides with azoles, do not always take place. For example, they do not occur in the interaction of trivalent phosphorus acid diethylamides with imidazole.[145] The reason why this autocatalytic phosphorylation is impossible is the fact that the reaction involving the abstraction of a proton together with the imidazole residue by the intermediate is clearly preferred. We may note, however, that the problem of the chemical behaviour of phosphorus acid azolides, which are very unusual substances, has not yet been duly developed.

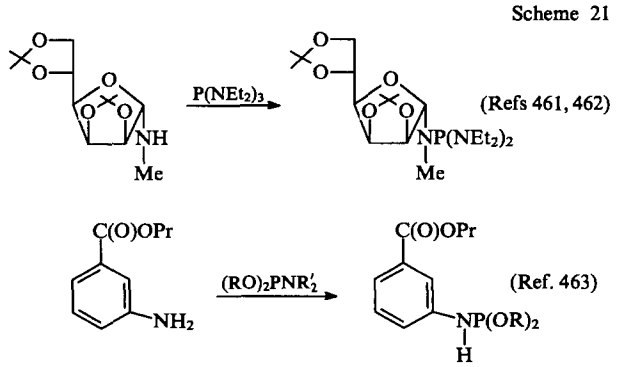
The rates of reactions of phosphorazolides under consideration depend definitely on the type of substituents at the phosphorus atom. Alkoxides ensure the maximum rates and alkyls the minimum rates,[145-148] which is also consistent with the concept of P-nucleophilic substitution. Nevertheless, a detailed description of the mechanism of the transamination of TPAA in the presence of acid catalysts is lacking in the literature. One may postulate that it is in principle analogous to the description of the alcoholysis of TPAA but differs by the migration of a proton between the linked nitrogen centres.

The problem of steric factors in the phosphorylation of TPAA has also been discussed in the literature, contradictory results being published. Thus the preferential phosphorylation of amines with less bulky substituents at the nitrogen atom has been reported.[38] On the other hand, the following reaction has been described:[445]



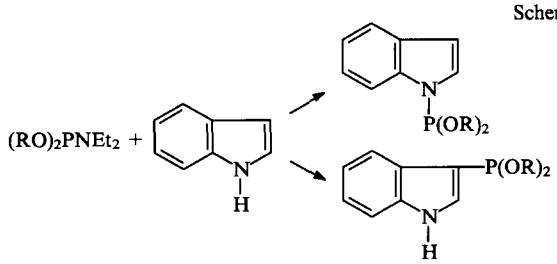
Thus our knowledge about the characteristic features of the transamination of TPAA requires further development.

3. The use of the transamination of trivalent phosphorus acid amides for the purposes of fine organic synthesis



a. Phosphorylation of higher and functionalised primary and secondary amines

A useful preparative method of synthesis of higher and other complex phosphoramides is the aminolysis of the simplest representatives of substances of this class. Thus phosphorous hexamethyl(ethyl)triamides, which are readily available commercial products, perform the function of key substances in the synthesis of various more complex triamides, for example:[123,124,460]



Complex asymmetric systems, including phosphorylated glucosylamines[461,462] and derivatives of *m*-aminobenzoic acid (Scheme 21),[463] can also be obtained in this way.

Scheme 21

Transamination may be supplemented by C-phosphorylation, as happened in experiments with indole (Scheme 22).[464] In the case of 3-mercaptoindole, phosphorylation can occur both at the nitrogen and at the sulfur depending on the conditions.[465]

Scheme 22

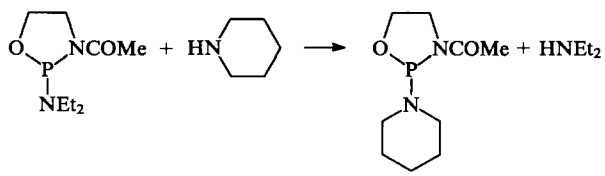
Higher primary α,ω-alkylenediamines are smoothly phosphorylated by *N,N*-dialkylphosphoramidites with formation of phosphorodiamidites which are difficult to obtain in other ways (Scheme 23).[447]

Scheme 23

$$2\,(RO)_2PNEt_2 + H_2N(CH_2)_6NH_2 \longrightarrow$$

$$\longrightarrow (RO)_2PNH(CH_2)_6NHP(OR)_2 + 2\,HNEt_2$$

For equimolecular reactants oligomeric or polymeric phosphoramidites may be formed.[442] This aspect has been investigated for cystamine.[444]

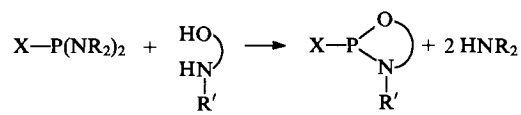


$$n\,RP(NEt_2)_2 + n\,H_2NCH_2CH_2SSCH_2CH_2NH_2 \longrightarrow$$

$$\longrightarrow \left[\begin{array}{c} \\ PHNCH_2CH_2SSCH_2CH_2NH \\ | \\ R \end{array}\right]_n$$

R = Alk, OAlk, Et_2N.

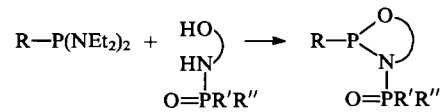
When phosphorous hexaethyltriamide is used, it is possible to obtain network and not linear polymers. All these compounds are of interest as long-acting radioprotectors [radiation protectives? Ed.].



The result of transamination using phosphoramides with partially functionalised amino-groups, which are usually inert, is very interesting.[191]

There are data on the reactions of phosphoramides, the structures of which incorporate a polymeric amine having a N–P bond, with a nucleoside phosphite oligomer. It has been established that the oligonucleotide unit can be conveniently removed from the support in many instances by treatment with an excess of an amine, for example tetrazole.[466,467]

b. Phosphorylation of aminoalcohols and *o*-aminophenols

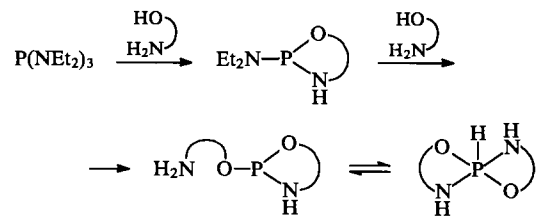


As mentioned above, the phosphorylation of tertiary aminoalcohols by treatment with TPAA leads to the formation of tertiary phosphoramidites and related compounds. The corresponding secondary aminoalcohols with functional groups in the 1,2- and 1,3-positions, including derivatives of 1,2-ethanolamine,[162,163,165,203,229,468–478] 1,3-propanolamine,[168,186,479–481] ephedrine,[473,482–486] prolinol,[484,487] etc. usually undergo phosphacyclisation on reacting with trivalent phosphorus acid diamides and triamides.

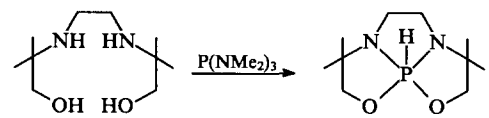
Aminomercaptans,[488] 1-alkylamino-1-deoxysugars,[489] and 3-imino-1-*N*-hydroxyethylpyrazoline[490] phosphacyclise in a similar manner.

Such reactions of aminoalcohols with TPAA are of extensive synthetic importance and are actively employed in the solution of many scientific and technical problems. We may point to the synthesis of phosphacyclic ligands for metal complex catalysis,[393,491,492] phospholipid systems (see the review by Nifant'ev and Predvoditelev[304]), and phosphacyclane derivatives of sugars.[303]

N-Phosphorylated aminoalcohols react similarly with TPAA.[194]



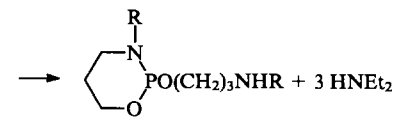
We may note that this scheme describes reactions for R = Alk or $NAlk_2$. When phosphorodiamidites are used, mono-*O*-phosphorylation turns out to be more probable.[194]



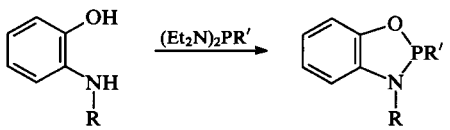
$$ROP(NEt_2)_2 + HO(CH_2)_3NHP(O)(OR')_2 \longrightarrow$$

$$\longrightarrow \begin{array}{c} NEt_2 \quad\quad O \\ | \quad\quad\quad \| \\ ROPO(CH_2)_3NHP(OR')_2 \end{array}$$

Many primary and certain secondary 1,2- and 1,3-aminoalcohols interact in a more complex manner with phosphorous triamides for a reactant molar ratio of 2 : 1; viz. 2-amino-1,3,2-oxazaphospholanes (phosphorinanes) are formed in the first stage of the synthesis and are then converted into phosphoramidites. The latter can be fully or partly converted into hydrospirophosphoranes (ring–chain tautomerism).[124,245,246,472,482,493–500]

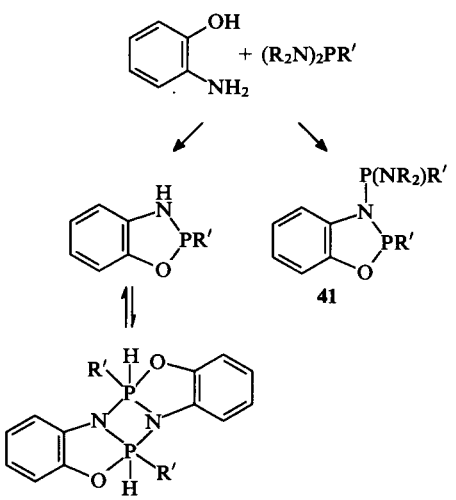


Similar, but this time tricyclic, hydrospirophosphoranes may be formed also in the phosphorylation of bisaminoethanols.[501]

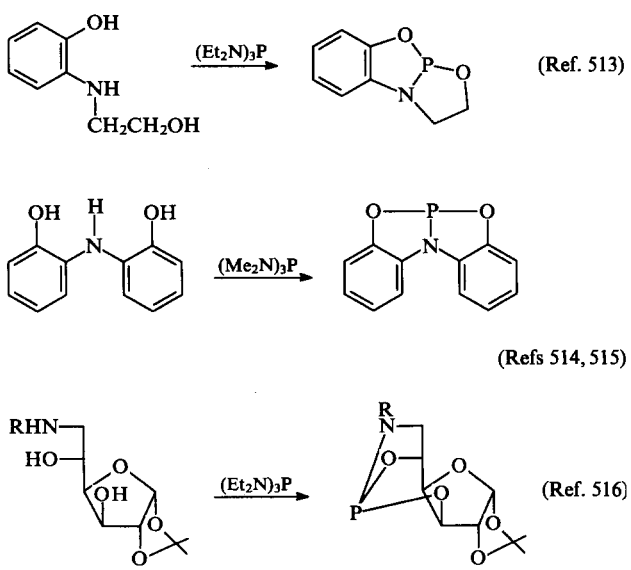


The ease of formation of the hydrospirophosphoranes is in many respects determined by the structure of the aminoalcohols. Vicinal, especially primary, aminoalcohols participate vigorously in this process. Secondary 1,3-aminoalcohols do not form spirosystems.[168]

$$P(NEt_2)_3 + 2\,HO(CH_2)_3NHR \longrightarrow$$



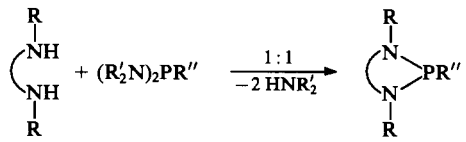
TPAA with two and three amino-groups effectively phosphorylate *o*-*N*-alkylaminophenols with formation of 4,5-benzo-1,3,2-oxazaphospholanes.[502,503]



o-Aminothiophenols[229,504–507] and derivatives of *N*-acylaminophenols[508] are cyclophosphorylated in a similar manner.

Depending on the phosphorylation conditions and the reactant ratio, *o*-aminophenol itself can be either converted, in its reactions with trivalent phosphorous diamides, into a benzoxazaphospholane, which is capable of dimerising, or it affords a diphosphorus product.[509–512]

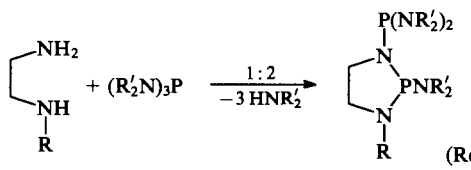
Aminophenols, namely *o*-(*N*-β-hydroxyethylamino)phenol[513] and di(*o*-hydroxyphenylene)amine[514,515] as well as 6-amino-6-deoxy-1,2-isopropylideneglucofuranose and 3-amino-3-deoxy-1,2-isopropylideneglucofuranose[516] are phosphorylated in an interesting manner. Rigid condensed systems are formed in such cases.



(Ref. 513)

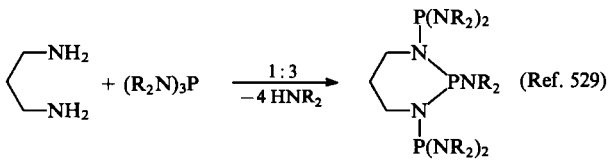
(Refs 514, 515)

(Ref. 516)



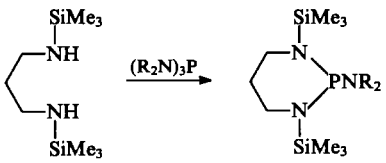
c. Phosphorylation of di, tri-, and tetra-amines

Alkylenediamines (1,2-alkylenediamine[517–519] and 1,3-alkylenediamine[520–522]), which include diprimary, primary-secondary, and disecondary representatives, are effectively phosphorylated by phosphorous and phosphonous diamides and triamides; in a few instances, the reaction has been achieved with 1,4-alkylenediamines.[523–527]

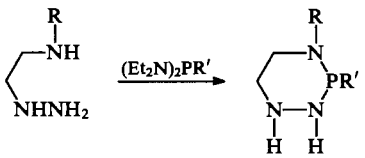


R = H, Alk.

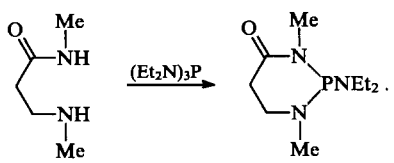
When two or three molar amounts of the phosphoramide relative to the diamide are used, it is possible to obtain diphosphaheterocycles[518,519,528] and triphosphaheterocycles.[529]



(Refs 518, 519, 528)

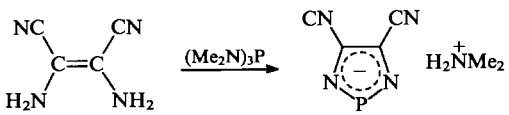


(Ref. 529)

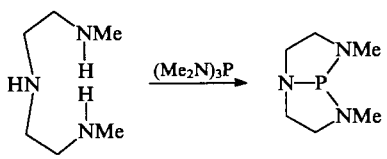


1,3-Disilylamines enter similarly into such reactions.[530]

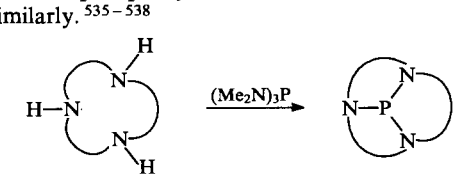
It is interesting that β-aminoethylhydrazines can undergo the same phosphacyclisations, affording triazaphosphorinanes.[18]



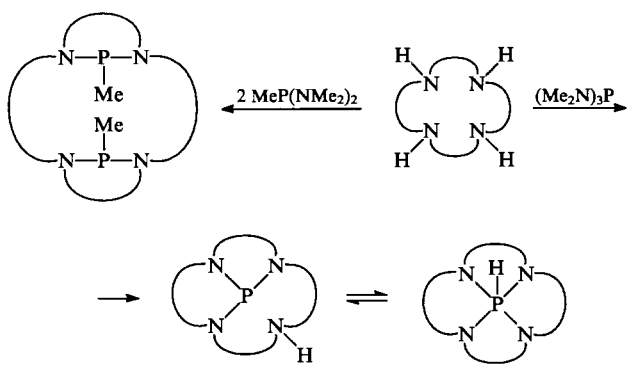
Certain aminoamides also enter into the phosphacyclisation reaction, for example:[531,532]



In the phosphacyclisation of diaminodicyanoethylene by phosphorous triamide, a stable anion may be formed—the isoelectronic 1,3,2-diazaphospholane (Scheme 24).[533]

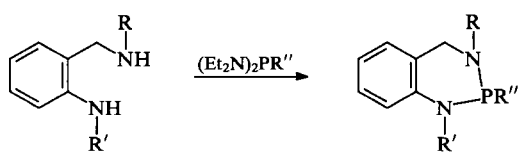


Scheme 24

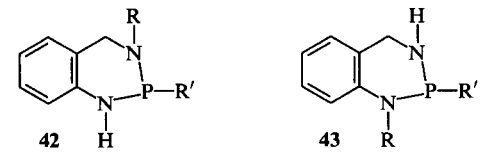


Mention must be made of the study of the phosphorylation of linear and alicyclic triamines and tetraamines, to which much attention has been devoted recently. It has been established that reaction of 2,5,8-triazanonane with an equimolar amount of phosphorous hexamethyltriamide affords a condensed bicyclic compound.[534]

The phosphorylation of trialkylenetriamines takes place similarly.[535-538]

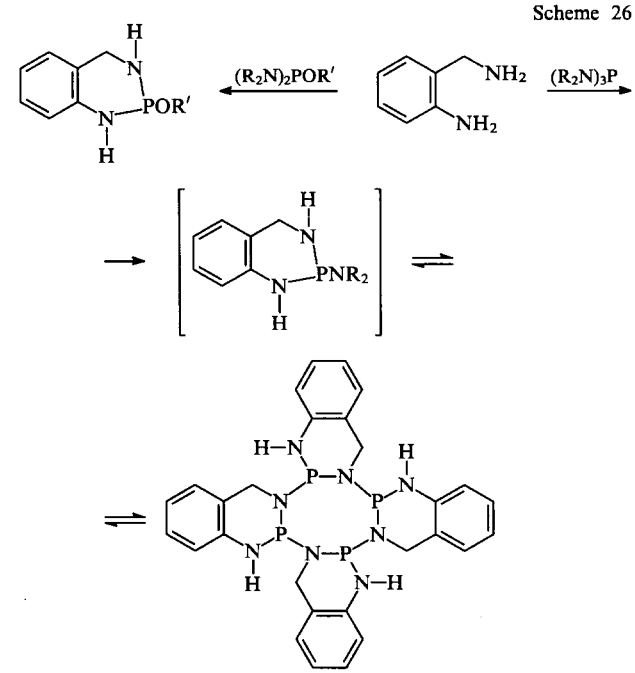


The phosphorylation of alkyenetetraamines has been studied even more extensively.[539-543]



An interesting case of prototropism, leading to a symmetrical hydrospirophosphorane, has been observed in this series of studies. The position of the equilibrium described depends on the nature of the solvent and of the alkylene group linking the nitrogen atoms into a single system.

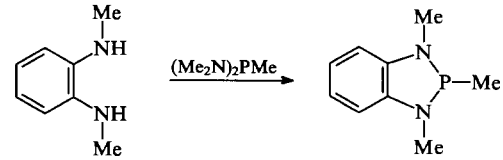
Aliphatic-aromatic diamines have been investigated even more vigorously in cyclophosphorylation by TPAA. Thus *N,N'*-dialkyl(aryl)-2-aminobenzylamines react with phosphorous diamides and triamides, forming readily and in high yields 1,3-disubstituted 4,5-benzo-1,3,2-diazaphosphorinanes.[544-547]



There are two types of 2-aminobenzylamines monosubstituted at the nitrogen atom. Each has been successfully phosphacyclised with formation of 4,5-benzo-1,3,2-diazaphosphorinanes of two classes—**42** and **43** (Scheme 25).[544-547]

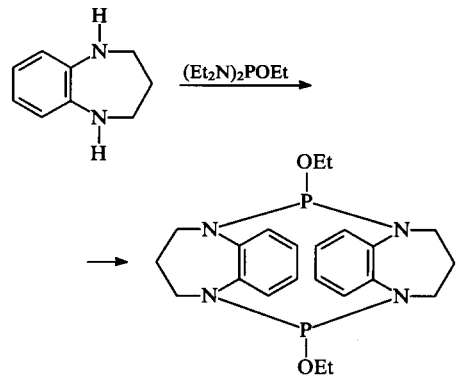
Scheme 25

Unsubstituted 2-aminobenzylamine also reacts with TPAA. Phosphorodiamidite esters give rise in this case to 2-alkoxy-4,5-benzo-1,3,2-diazaphosphorinanes, while phosphorous triamides afford 2-dialkylamino-4,5-benzo-1,3,2-diazaphosphorinanes, which immediately undergo cyclotetracondensation (Scheme 26).[548]



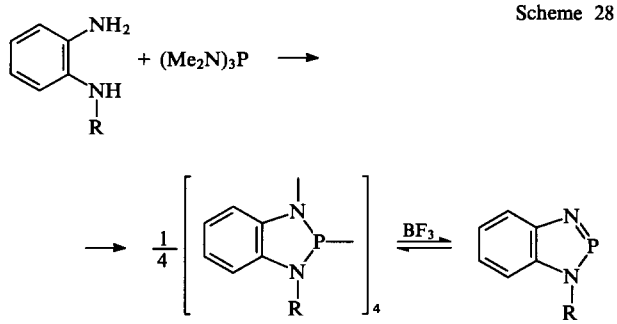
Scheme 26

The high efficiency (yield about 90%) and regiospecificity of the reaction [products containing only aminobenzyl nitrogen atoms in the tetraazaphosphacyanogen (tetraazatriphosphacyclooctane? Ed. of translation) ring] is striking. X-Ray diffraction data showed that a molecule of the product consists of a symmetrical crown in which the nitrogen atoms lie in a plane parallel to the plane of the phosphorus atoms. One can postulate that this and similar systems will be of considerable interest for the synthesis of new coordination systems.



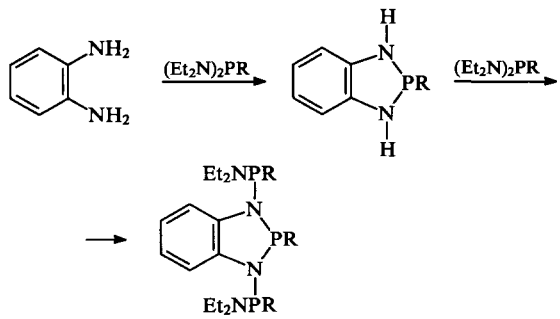
It is essential to note that as a rule all the phosphacyclisations examined above are more efficient than the corresponding reactions with phosphorous acid chlorides.

We shall now turn to the phosphorylation of aromatic diamines. Secondary *o*-diaminobenzenes interact readily with TPAA.[549]



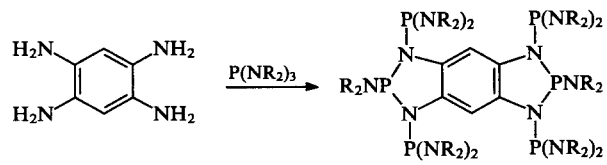
In the case of the cyclophosphorylation of *o*-phenylenediamine, in the molecules of which the nitrogen atoms are linked via a 1,3-propylene bridge, the process is more complex and leads to the formation of a diphosphorus system (Scheme 27).[550]

Scheme 27

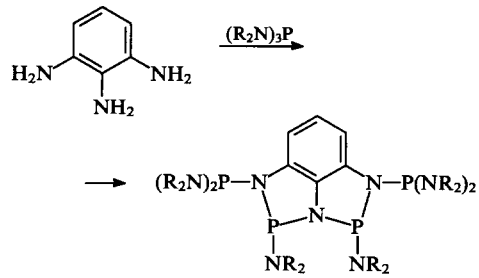


Primary-secondary diamines afford tetramers on reaction with phosphorous acid hexamethyltriamide (Scheme 28).[508,551-553]

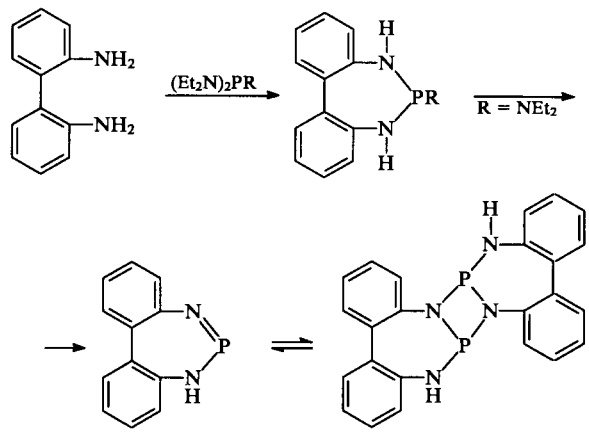
Scheme 28



On heating with boron trifluoride, this tetramer decomposes. The monomer has been detected in solution by ^{31}P NMR spectroscopy.



On phosphorylation with phosphorous diamides and triamides, unsubstituted *o*-phenylenediamine can give rise to the usual phosphacycles or the products of their additional phosphorylation at the nitrogen atom depending on the reaction conditions and the reactant ratio.[529,554-557]



The second phosphorylation pathway has also been achieved in a study with 1,2,4,5-tetraminobenzene.[558]

We may also note that 1,2,3-triaminobenzene affords a phosphacyclic system of a different chemical nature in an analogous situation.[558,559]

The interaction of a more complex aromatic amine — *o,o'*-diaminobiphenyl — with phosphorous diamides and triamides affords 4,5,6,7-dibenzo-1,3,2-diazaphosphorinanes.[560]

R = OAlk, NEt_2

When R = NEt_2, the primary product can undergo the elimination of the amine with formation of a derivative of dicoordinate phosphorus, which apparently dimerises as a result of the regular 1,2;1,2-cycloaddition.[560]

IV. Conclusion

It is seen from the data presented that TPAA have found extensive application for the phosphorylation of alcohols, phenols, and amines of a wide variety of chemical types. Virtually all the types of these proton-donating nucleophiles have already served as substrates in the synthesis of derivatives of phosphorous, phosphonous, and phosphinous acids. The success of the syntheses is apparently due to the experimental formulation of the reactions and primarily the use of optimum catalysts (activators) and solvating agents.

The discovery of a high reactivity in TPAA brought modern organophosphorus chemistry closer to other chemical disciplines and eliminated the barriers which have traditionally arisen between them. The most important result of such a mutual approach has been a radical alteration in strategy for the synthesis of natural products, including the most complex of these, namely nucleic acids and phospholipids. Furthermore, there has been a change in the principles governing the design of phosphorus-containing skeletal compounds and other complex phosphorus heterocycles. There has been a revival also in other interdisciplinary fields.

Nevertheless, the considerable chemical potential of TPAA has not yet been fully realised. It is sufficient to state that studies on the application of these reagents in macromolecular chemistry, both for the modification of polyfunctional polymers and the polycondensation of oligools and amines, have been dealt with only in outline. Nevertheless we may state that certain fundamental problems, the solution of which will apparently lead to useful recommendations, have been found in this field.

It has now been established that, apart from the nucleophiles already named, TPAA can readily phosphorylate also other compounds — various derivatives of acids, mercaptans, phosphines, transition metal hydrides, etc. They give rise to interesting results in reactions of other types as well. All this makes TPAA valuable reagents for fine organic synthesis.

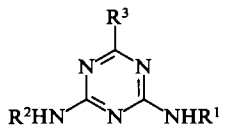
Immunochemical methods for the assay of herbicides of the 1,3,5-triazine group

S A Eremin, Zh V Samsonova, A M Egorov

Contents

I. Introduction	611
II. Principal components of the immunochemical assay methods	612
III. Solid-phase immunoenzyme assay using polyclonal antisera	614
IV. Solid-phase immunoenzyme assay using monoclonal antibodies	618
V. Quantitative determination of several herbicides in one sample	619
VI. Alternative immunoassay methods	620

Abstract. The review deals with studies published during the last 10 years on the development of immunochemical methods for the assay of herbicides of the 1,3,5-triazine group. Questions concerning the optimisation of methods for the immunoenzyme assay and their application in the determination of 1,3,5-triazines in various samples (water, soil, food products etc.) are discussed. The bibliography includes 75 references.



I. Introduction

The contamination of the environment as a result of man's economic activity has long become one of the contemporary global problems. An important aspect of this problem is the universal application of pesticides in agricultural practice. On the one hand, chemical protection of plants is the most radical method for combating pests, diseases, and weeds, but, on the other hand, nonrational application of pesticides can lead to their accumulation within objects in the environment and can induce the breakdown of relationships in ecosystems. For example, in the EEC member countries, norms has been established for the content of pesticides in drinking water: not more than 0.1 ng ml^{-1} for one pesticide and 0.5 ng ml^{-1} for all pesticides.[1] This is why it is important to have assay methods which permit a rapid and exact determination of residual amounts of pesticides in the soil, water, and food products. Ecological problems have in fact stimulated further development and improvement of the methods for the assay of physiologically active substances. The review deals with studies published during the last 10 years on immunochemical methods (ICM) for the assay of herbicides of the 1,3,5-triazine group within objects in the environment.

Herbicides of the 1,3,5-triazine group, used in agriculture to destroy weeds, comprise the largest group of herbicides in terms of the scale of their worldwide manufacture and consumption.[2]

Uspekhi Khimii **63** (7) 638 – 649 (1994); translated by A K Grzybowski

The main representatives of this group are presented in Table 1. Mainly simazine, atrazine, and prometryn are used in Russia.[3] The following limiting permissible concentrations (LPC) in water reservoirs for sanitary–domestic purposes have been adopted in our country: 0.5 mg $litre^{-1}$ for atrazine and 3.0 mg $litre^{-1}$ for prometryn; the presence of a residual amount of simazine is not allowed. Physicochemical assay methods (PCM), namely thin-layer chromatography (TLC), gas chromatography (GC) gas–liquid chromatography (GLC), and high performance liquid chromatography (HPLC), are employed traditionally for the assay of residual amounts of herbicides, including 1,3,5-triazines in air, water, soil, and food products.[4–7] These methods are irreplaceable in cases where it is necessary to identify rigorously the substance being sought, but they suffer from a number of significant disadvantages. These include their laborious nature, complex preparation of the specimen, long assay time, stringent requirements as regards the qualifications of the

Table 1. The structures of the herbicides of the 1,3,5-triazine group, their metabolites, and analogues.

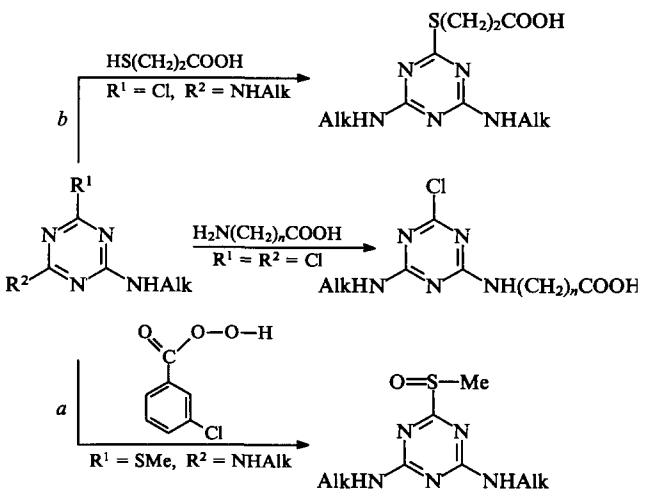
personnel, and the high cost of the equipment used. The technical equipment employed in physicochemical assay is being constantly improved, which increases its sensitivity and accuracy, but at the same time it also raises the cost of such equipment. It is therefore necessary to recognise that physicochemical assay methods are completely unsuitable for routine analyses and operational monitoring. The endeavour to create more effective methods for the analysis of air, soil, and food products for residual amounts of pesticides to reduce the cost of the determination has led to the development of immunochemical assay methods.

The possibility of employing immunochemical methods for the assay of pesticides in water, soil, and food products has been justified in detail in a number of reviews.[8-15] The advantages of immunochemical assay methods include specificity, sensitivity, accuracy, ease of application, high speed, the possibility of automation and use in routine analyses under field conditions, and easy preparation of the specimen (if it is required at all) which rules out the degradation of the test substance. Immunochemical methods are also characterised by a relatively low cost of the determination; for example, a single determination of the herbicide diflubenzuron by the immunoenzyme assay (IEA) method is 20 times cheaper than the determination by the HPLC method and 55 times cheaper than the determination by gas chromatography.[16] The disadvantages of the immunochemical assay methods include the following: the need for appropriate qualifications of the personnel and for the ability of antibodies to react with substances having related structures, which in many instances renders a rigorous qualitative determination of the test substance problematical. At the present time, immunochemical assay methods have been firmly introduced into analytical practice and are used in various branches of medicine, agriculture, and the microbiological and food industries and also for the monitoring of the environment.



II. Principal components of the immunochemical assay methods

The immunochemical assay methods are based on the specific binding of a particular compound to the corresponding antibodies. The complex form is detected by introducing a label (enzyme, fluorescence) into one of the initial components of the reaction system. If one of the components of the system is bound chemically (covalently) or by sorption to a solid carrier in order to separate a specific complex from the components of the reaction mixture, then the methods are referred to as heterogeneous. Otherwise, if there is no need to separate the components of the immunochemical reaction, the methods are called homogeneous.

Numerous studies devoted to the development and different aspects of the optimisation of immunochemical methods for the assay of herbicides of the 1,3,5-triazine group in objects within the environment and in food products have been published in recent years. The vast majority of the investigations are devoted to methods for the solid-phase immunoenzyme assay—ELISA (enzyme-linked immunosorbent assay). In order to carry out such an assay, it is necessary to have specific antibodies, a conjugate of the substance to be determined with a protein or an enzyme, as well as a solid phase on which one of the components of the immunochemical complex is adsorbed.

The principal components in any immunochemical assay method are specific antibodies—polyclonal and monoclonal. Like all pesticides, 1,3,5-triazines are haptens, i.e. they are incapable of inducing the production of antibodies when introduced into the organism and therefore, in order to obtain antibodies, they are conjugated with proteins. In the 1,3,5-triazine molecule there are no suitable reaction groups for binding to a high-molecular-mass carrier (a protein or an enzyme), so that investigators have to resort to the modification of the herbicide. The questions concerning the selection of the correct structure of the hapten in the synthesis of the pesticide immunogens for the successful production of antibodies have been described in detail.[16] We shall consider the procedures for the modification of 1,3,5-triazines. A carboxy-group is usually introduced into the *N*-alkyl side chain or in the 2-position in the trazine ring (see the Scheme below).

Scheme

2,4-Dichloro-1,3,5-triazines are conjugated to unbranched aminoacids with a terminal amino-group (the 2,4-dichloro-derivatives can be used immediately for conjugation).[17-19] 2-Methylthio-1,3,5-triazines are modified by oxidising them to the sulfoxides by 3-chloroperbenzoic acid (pathway *a*),[18,20-22] while 2-chloro-1,3,5-triazines are conjugated with 3-thiopropionic acid (pathway *b*). The reasons for using the latter modification method are as follows: the sulfur atom is most suitable for the simulation of a chlorine atom as it contains, like chlorine, two lone pairs; the resonance interaction between the sulfur atom and the triazine ring is limited; the atomic radii of sulfur and chlorine are similar; proteins do not add to sulfur just as they do not add to oxygen or nitrogen: the nucleophilicity of the thiolate anion facilitates the substitution of chlorine; finally, all the reagents can be synthesised.[17]

Table 2 presents the structures of the modified 1,3,5-triazines which were used, after conjugation with proteins, to obtain polyclonal antisera and monoclonal antibodies. The table shows that the polyclonal antisera and the monoclonal antibodies exhibit an appreciable percentage of cross-reaction with structurally similar herbicides. Furthermore, one may note the following features: an appreciable percentage of cross-reaction with atrazine is observed for antisera against a simazine derivative (hapten **2**); the antibodies obtained against atrazine derivatives (hapten **3**) exhibit an appreciable percentage of cross-reaction with propazine. The antibodies obtained to the conjugates of 1,3,5-triazines with 3-thiopropionic acid (haptens **9** and **10**) recognise also 2-methylthio-derivatives of herbicides (for example, ametryn and prometryn). In certain cases, the specificity of the antibodies obtained was unexpected.[18,19] Both homologous and heterologous haptens may be used for the synthesis of conjugates with an enzyme and a protein and also in analysis. We recall that, if a single hapten is used to obtain the immunogen and the conjugate and the method used to achieve its addition to the high-molecular-mass carrier is the same, then such a system is referred to as homologous. If, however, the haptens are different in the two cases the system is heterologous. The structure of the hapten used for conjugation to high-molecular-mass carriers can then exert an appreciable influence on the sensitivity of the assay. As will be seen below, heterologous systems are more sensitive than homologous ones.[17,23-26]

The conjugation of the modified carboxylated 1,3,5-triazine with the amino-groups of a protein or an enzyme to form a peptide linkage is carried out by the traditional methods used in protein

Table 2. The structures of the modified 1,3,5-triazines, the methods for the conjugation of derivatives with a carboxy-group, and the characteristics of the specificity of the monoclonal antibodies and polyclonal antisera obtained.

In most of the studies on the development of ELISA methods for 1,3,5-triazines, 96-well polystyrene trays are used. A number of investigators have also reported the employment of polystyrene test tubes,[30-37] spheres,[20-22] and magnetic particles.[29,38] The methods used to carry out the competitive enzyme-linked immunosorbent assay (formats) are also different (Fig. 1). Format I is usually employed for the screening of the antibodies obtained and is distinguished by a large number of stages. One of the modifications of format III involves preliminary adsorption of the antispecies antibodies or the protein A on the solid phase. It has been noted that an advantage of formats II and III over format I is a higher sensitivity and the fact that less time is required for the assay,[24-26,39] but they are more sensitive to the effect of the matrix and solvents.[24] The studies concerned with the comparative assessments of different forms of the ELISA method will be examined in greater detail below.

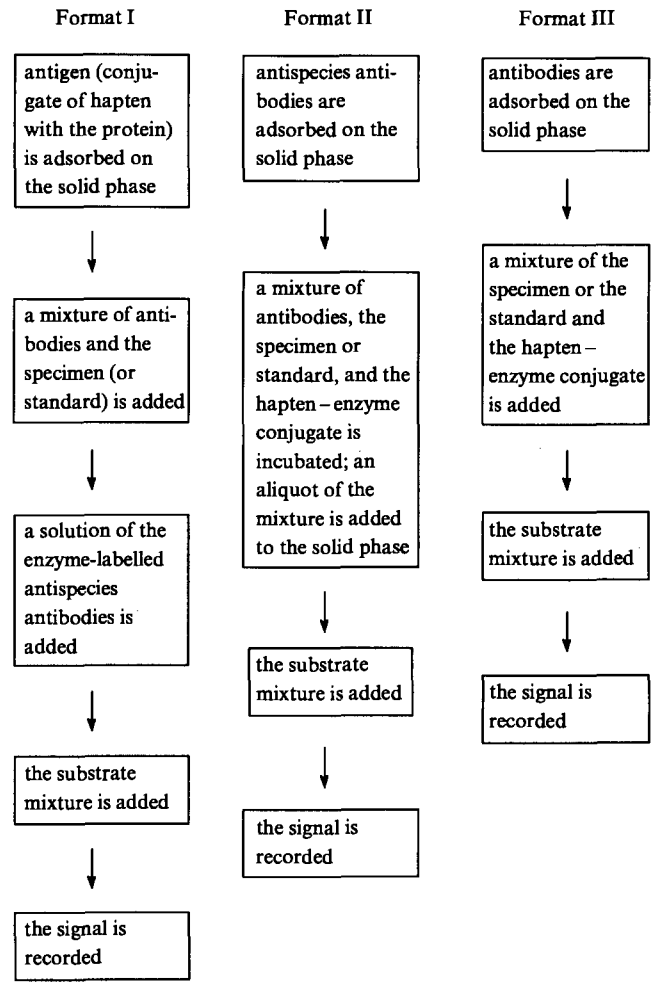

Figure 1. The ELISA formats used in the assay of haptens. After incubation, the unreacted components are washed off in each stage with a wash buffer containing clean Tween 20. Modification of format III: IIIa—antispecies antibodies are adsorbed on the solid phase in the first stage; IIIb—a protein A is adsorbed on the solid phase in the first stage.

A survey of published literature shows that 1,3,5-triazines are usually assayed by the ELISA method in water and soil although there have been reports also of other objects of study (Tables 3 and 4). Water is used for analysis without preliminary preparation, since its matrix does not as a rule affect the results of the assay. The data obtained by the ELISA and gas-chromatographic methods,[24,29,39-41] by the HPLC method,[26,30,36,37,42-44] and by gas chromatograph-linked mass spectrometry (GC/MS) [35] are satisfactorily correlated and the ELISA method does not afford any false negative results. A correlation of the results with HPLC data in the assay of liquid food products has been reported.[31] Herbicides from the soil, solid food products, and other objects are extracted with organic solvents or water. The results of such measurements are also satisfactorily correlated with physicochemical analytical data (Table 4).

III. Solid-phase immunoenzyme assay using polyclonal antisera

1. Determination of 1,3,5-triazines in objects within the environment

Among 1,3,5-triazines, most attention is devoted to atrazine, this being the most common herbicide of the given group used abroad, and its metabolites (Table 3). Assay methods developed on the basis of polyclonal antisera have been described in a series of publications.

[a] The formats used for the assay are specified.
[b] The detection limit is expressed in μg kg^{-1}.
[c] The detection limit is expressed in μmol litre^{-1}.

The first studies on the ELISA of atrazine were published in 1985.[20,45] The radioimmunoassay method was used to characterise the antiserum described in a patent.[45] The conjugate of the hapten with the methyl ester of tyrosine, which was suitable for the introduction of the ^{125}I label, was synthesised by the mixed anhydride method; the atrazine detection limit was 1 ng in the sample. An ELISA with a lower atrazine detection limit of 0.1 ng ml^{-1} was developed later.[28] In assay by format I of ELISA use was made of secondary antibodies conjugated with biotin which interacted with the streptavidin – horseradish peroxidase conjugate in the following stage.

Polystyrene trays and spheres were used in the development of a homologous ELISA for atrazine.[20,22] Purification of the polyclonal antiserum by immunoaffinity chromatography made it possible to lower the detection limit by a factor of 100. It was noted that, when spheres are used as the solid phase, the assay is less sensitive (Table 3). The characteristic features of this procedure are the different ratio between the volume of the specimen and the area of the solid phase, a possible increase in sensitivity with increase in the volume of the specimen only within a limited range (a large volume of the specimen is then required for the assay), a long assay time (5 h), and difficulties in mechanisation and automation. The same procedure has been used in the development of a homologous ELISA for terbutryn.[21] The terbutryn detection limit was improved by a factor of 250 using polystyrene spheres as the solid phase.[46] A similar range of measurable concentrations was obtained using ^{14}C-labelled terbutryn in radioimmunoassay.[46]

Wittmann and Hock[47] used different carbodiimides to synthesise the immunogen: 1,3-dicyclohexylcarbodiimide (DCC), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), and CMC as well as various hapten : protein and carbodiimide : hapten ratios. A number of the immunogens proved to be insoluble (especially when EDC was used). An immunogen having the hapten : protein = 4 : 1 composition was used for immunisation in the initial stage (hapten : protein = 200 : 1 and DCC : hapten = 1 : 2), but, since the titres of the antisera were low, an immunogen with the maximum number of attached molecules (hapten : protein = 35 : 1; reactant ratios — hapten : protein = 100 : 1, and DCC : hapten = 1 : 1) was employed for subsequent immunisation. Also synthesised were homologous conjugates with enzymes such as horseradish peroxidase (by the activated esters method) and alkaline phosphatase (using CMC). The hapten : enzyme and hapten : carbodiimide ratios were also varied in the synthesis. The conjugate with peroxidase exhibited a higher sensitivity of assay and was used for subsequent

optimisation. The method developed was applied to the analysis of water, soil, and algae.[43] In the last case, an ecosystem model with algae and organisms into which specific amounts of atrazine had been introduced was employed. The authors note that the method is fast and convenient, but appreciable cross-reactivity with propazine is one of its disadvantages. Three types of ELISA, based on various combinations of two antisera obtained against immunogens of different structure, and two enzyme conjugates, were subsequently assessed.[41] In the most sensitive assay, the cross-reactivity was 195% for propazine and 20% for simazine.

The use of magnetic particles as the solid phase in the development of ELISA for atrazine has been reported.[38] The degree of cross-reaction was 171% for ametryn, 132% for propazine, and 105% for prometryn. It was shown that the presence of various salts, metal ions, or a change in pH from 2 to 12 do not affect the results of the analysis of water specimens. The authors note the advantages of the assay developed: the assay time is 45 min and there are no problems with the coverage of the solid phase by antibodies (the antibodies are attached to magnetic particles via glutaraldehyde).

Investigators of the Shell Development Company obtained a highly specific antiserum to cyanazine which was used to develop the ELISA.[48,49] Cross-reaction was demonstrated only for cyanazine metabolites. The method was used to monitor water and soil and the analytical results were well correlated with gas-chromatographic data. The ELISA for cyanazine in water and soil on magnetic particles has been developed[29] by the method of Rubio et al.[38] A high specificity of the method for cyanazine and tolerance towards the matrix as well as sensitivity to changes in pH and different components of the medium (organic solvents, salts) were noted.

In Western countries, some firms already manufacture kits of immunochemical reagents for the assay of 1,3,5-triazines,[16] for example: Res-I-Mune™, Res-I-Quant™ ("Immunosystems"); Triazin-ELISA ('Riedel-de-Haen'); RaPID Assays® ('Ohmicron'); EnviroGard™, Triazine Test Kit ('Millipore'). Studies have been published where such kits have already been applied successfully. Bushway and coworkers developed an ELISA for atrazine in water,[30,36,37] soil,[30] liquid and solid food products,[31] and milk[32] using Res-I-Mune™, which incorporates polystyrene test tubes coated with polyclonal antibodies and all the necessary reagents. In one assay, it is possible to analyse eight specimens and the assay time is 15 min. The study of a large number of water, soil, food products, and milk specimens containing both natural and introduced herbicides demonstrated the high accuracy and satisfactory reproducibility of the results. In the analysis of food products, positive results were obtained for

two specimens. However, the HPLC method demonstrated the absence of herbicides from these samples. In the analysis of milk specimens, the authors noted that unduly low results are obtained for samples with a high fat content. They put forward a hypothesis according to which atrazine dissolves partly in the fat and becomes inaccessible to the antibodies. The authors divided milk into three groups in terms of its fat content: > 3.5%, 1.5%–3.5%, and < 0.5% and proposed that the milk specimens should be diluted to give a fat level of the order of 1%, although this lowers the detection limit. The cross-reactions of polyclonal antibodies have been investigated[32] and it has been observed that ametryn, propazine and simazine give rise to the highest percentage of cross reactions. In view of the simplicity and rapidity of the proposed method, the authors suggest that it be used also for assay under field conditions. It has shown that the assay is relatively insensitive to changes in pH, temperature, and the concentrations of calcium, sodium, and nitrate ions.[50]

An attempt to apply the Res-I-Mune™ kit to the assay of atrazine in the soil has been described.[33,34] It has been reported[33] that coextracted substances interfere with the determination. When extraction with water was used, atrazine was determined at concentrations of 0.5–5 ng ml^{-1}, while in the case where methanol was used as the solvent the concentration range was 5–20 ng ml^{-1}. Various solvents for extraction have been investigated (Table 4).[34] A water–methanol mixture and methanol were selected taking into account the ability of the solvents to extract the herbicide. However, the authors abandoned the use of methanol, since it affected the results of the assay at atrazine concentrations less than 50 ng ml^{-1}. The authors note that this assay is suitable for use in fields subjected to a known chemical treatment. The same kit has been used to analyse water specimens.[35]

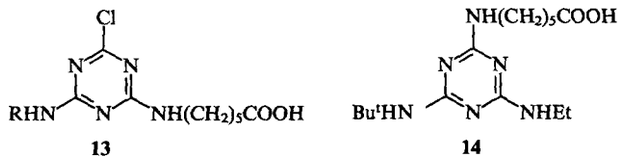
A commercial kit for the immunoenzyme assay of atrazine on Res-I-Quant™ 96-well trays has been described.[51] The authors tested two different methods and three solvents (Table 4) in the extraction of atrazine from the soil. The presence of organic solvents begins to affect the results of the assay at concentrations greater than 3.5%. It was shown that the best solvent as regards the percentage detection of the herbicide is acetonitrile.

The metabolites of 1,3,5-triazines have not been neglected either. A study has been devoted to the development of a homologous ELISA for deisopropyl- and de-ethyl-atrazine.[40] The calibration curves for both compounds virtually coincided. The method using a conjugate of the hapten to horseradish peroxidase proved to be more sensitive than the one employing a conjugate with alkaline phosphatase. The method developed for the assay of atrazine[43] and of its principal metabolite (de-ethyl-atrazine)[40] has been used to study the degradation of atrazine in the soil in the course of a year.[52] It was suggested that a simplified scheme be used for the extraction of the herbicide with water, which makes it possible to achieve its extraction from the soil at the level of 1/3–2/3 of the extraction with methanol. The ELISA for de-ethylatrazine has been used successfully in the analysis of water specimens.[44]

The application of ELISA for the determination of hydroxysimazine and hydroxyatrazine in various media (water, soil, and manure) and for the investigation of the degradation of atrazine by micro-organisms resistant to UV light has been demonstrated.[25] For use in the assay, haptens **2** ($n = 2$), **4**, and **5**, were conjugated to bovine serum albumin (BSA) and alkaline phosphatase by the activated esters method. The attempt to develop homologous and heterologous (conjugate based on hapten **5**) systems for hydroxysimazine was unsuccessful for all formats of ELISA. An unexpectedly high sensitivity was achieved using the enzyme conjugate based on hapten **2** ($n = 2$). The study of the antisera obtained by means of this system showed that three of the antisera recognise effectively hydroxysimazine and one recognises hydroxyatrazine. By using different modifications of format III, it was established that the direct coating of the tray with antibodies reduces the sensitivity by a factor of 2–5. The antiserum responding to both metabolites was selected to develop assay methods. It was shown that different salts and metal ions over a wide range of concentrations, pH (5–9), and matrices do not affect the results in the analysis of water specimens. It was suggested that this method be used to investigate ecosystems as regards their tolerance and ability to degrade xenobiotics.

Interesting data on two interlaboratory tests have been published.[53] For the first test, ten water specimens of different composition were sent to thirteen laboratories. Each laboratory analysed the specimens by the ELISA method, and the results were confirmed by GC/MS data. It was reported that only some laboratories were able to determine the correct amount of atrazine and none of the laboratories were able to determine correctly the total amount of 1,3,5-triazines. For the second test, six water specimens of different composition were analysed in twelve laboratories with the aid of the three ELISA procedures which were most successful in the first test. These results were also compared with gas chromatographic and GC/MS data and showed that among the three ELISA methods, one determines atrazine specifically, while the others determine the total amount of 1,3,5-triazines in the sample. Some useful comments were made: (1) it is necessary to certify immunochemical laboratories (the personnel working in these laboratories must be highly qualified); (2) it is necessary to describe the assay procedure in detail; (3) the working concen-tration range must be close to the middle of the calibration curve; (4) at least 6 standard solutions must be employed to plot the calibration curve; (5) if the matrix is unknown [?known (Ed. of Translation)], the substances analysed should be introduced into it; (6) four replicate measurements must be made for each specimen in order to avoid erroneous results.

2. The influence of the structure of the immunoreagents and of the format of the analysis on the sensitivity of the determination



It is seen from the foregoing that homologous systems are used as a rule in the development of ELISA. Hammock's group carried out a fundamental study designed to develop and optimise the ELISA methods for herbicides of the 1,3,5-triazine class and to determine the influence of the structure of the immunoreagents on the parameters of the analysis.[17,23] Two types of atrazine and simazine derivatives were synthesised and characterised: (a) haptens **9** and **10**; (b) haptens **2** and **3** with different lengths of the spacer, ranging from $n = 1$ to $n = 5$. Conjugates of haptens **2**, **3**, **9**, and **10** as well as dichlorosimazine and dichloroatrazine with BSA, conalbumin (CONA) and tyroglobulin (TG) were synthesised. Since problems concerning the solubility of the conjugates with TG and CONA arose, those with BSA were used as antigens in the analysis.

During the screening of the antibodies, the authors[17,23] noted the following features: the maximum binding was observed for all the antibodies in homologous systems, the majority of the antibodies exhibiting appreciable binding to at least one heterologous antigen. When immunogens based on atrazine were used, the sera were obtained with higher titres than in the case when simazine derivatives were used. For the former, high titres were observed in many instances when a heterologous antigen was applied, while in the latter this happened in only one case. Next, the assay was optimised for antisera with the highest titre in relation to a large number of heterologous systems using atrazine and simazine as inhibitors. It was shown that homologous systems are least sensitive. In a study of the conjugation site, of the length of the 'foot' (the length of the alkyl chain), and of the changes in the *N*-alkyl groups, it was observed that the sensitivity depends to the greatest extent on the conjugation site, although this rule has not always been observed. For example, the highest sensitivity of the antisera obtained against the protein conjugate of hapten **5** was attained using a protein conjugate of hapten **1** (in which the 'foot' was altogether absent).

In the study of the specificity of the antisera obtained, it was noted that homologous haptens induce the greatest inhibition. The authors note that the antisera can be divided into two groups: antisera obtained against protein conjugates of haptens **9** and **10**, which recognise not only atrazine but also other 2-methylthio-1,3,5-triazines, and antisera obtained against protein conjugates of haptens **2** and **3**, which effectively recognise the 2-chloro-compounds and hardly react with the 2-methylthio-derivatives. The loss of an alkyl group on substitution of a chlorine atom (methylthio-group) by a hydroxy-group led to an appreciable decrease of recognition by all the antisera.

The influence of the matrix and solvents in the sample has been examined[17,23] in the assay of water and soil specimens. It was observed that the most sensitive systems proved least resistant to the influence of the matrix and solvents in the extract. The authors note that, in the development of any assay method, it is necessary to find a compromise solution: between the most sensitive assay and the greatest tolerance to the influence of the matrix. The authors also emphasise that, in the presence of a set of well characterised antibodies and antigens of different structure, it becomes possible to determine quantitatively structurally similar substances in specimens of complex composition.

An attempt has been made[54] to follow the influence of the structure of the enzyme conjugate on the sensitivity of the assay. Conjugates with horseradish peroxidase were synthesised by the activated esters method. The haptens employed were compounds **13** with various side groups (ethyl, isopropyl, cyclopropyl, *tert*-butyl, cyclopentyl) and 2-*tert*-butylamine-4-(1-carboxypent-5-yl)amino-6-ethylamino-1,3,5-triazine **14**.

R = Et, Pr^i,  , Bu^t,  .

A distinct dependence of the sensitivity of the assay on the structure of the conjugates could not be found. For the antibodies obtained against the protein conjugate of hapten **3**,[47] the sensitivity decreased in the sequence (the substituents R are indicated) isopropyl > ethyl > cyclopropyl > *tert*-butyl > cyclopentyl when conjugates based on compound **13** were used. The same antibodies were scarcely bound to the conjugates obtained from compound **14**. For the antibodies to the protein conjugate of hapten **7**,[22] the greatest sensitivity was achieved when the enzyme conjugate of the hapten with an isopropyl side group was employed, while for the remaining conjugates scarcely any binding was observed.

As can be seen from the foregoing, the use of polyclonal antisera makes it possible to attain low detection limits for 1,3,5-triazines in various objects. However, the fact that the number of antisera obtained is limited and their quality (affinity, specificity) depends on the animal immunised precludes their standardisation. The last disadvantage can be avoided by using monoclonal antibodies for the assay.

IV. Solid-phase immunoenzyme assay using monoclonal antibodies

Monoclonal antibodies have found extensive application in the assay of 1,3,5-triazines. One of their advantages is the possibility of their standardisation and production in a virtually unlimited amount. Monoclonal antibodies to atrazine and its metabolite hydroxyatrazine have been described.[42] In the homologous ELISA, format I was used and the mixture of antibodies and the specimen was subjected to preliminary incubation before adding them to the tray.

Karu et al.[24] summarised the results of studies in three laboratories on the development of ELISA methods for 1,3,5-triazines using monoclonal antibodies. Three formats were investigated—I, II, and IIIa. They all exhibited approximately the same sensitivity (conjugates with hapten **3** were used), but the application of the enzyme conjugate of hapten **2** ($n = 2$) in format IIIa increased the sensitivity of the assay by a factor of 5. The study of the specificity of the antibodies obtained showed that monoclonal antibodies bind preferentially to 1,3,5-triazines containing an isopropyl group in the 4- or 6-position and a methylthio-group in the 2-position; *N*-dealkyl and hydroxy-derivatives hardly react with the antibodies. It was shown that the results of the assay of 75 water specimens by gas chromatography for atrazine and of 48 soil specimens by gas–liquid chromatography for simazine were satisfactorily correlated with ELISA results. The method was used to determine atrazine and simazine in sewage.

A whole series of studies have been carried out in which the monoclonal antibodies proposed by Karu et al. were used.[24] Lucas et al.[55] compared the advantages of two ELISA methods for simazine and atrazine using monoclonal antibodies[24] and polyclonal antisera.[17] One of the polyclonal antisera and the monoclonal antibodies were employed against the protein conjugate of hapten **9**, while another polyclonal antiserum was used against the protein conjugate of hapten **3**. Two ELISA formats were investigated (II and IIIa) using the conjugate of hapten **3** ($n = 2$) with alkaline phosphatase for the monoclonal antibodies and the conjugate of hapten **3** ($n = 3$) for polyclonal antisera. Comparison of the antibodies showed that the polyclonal antisera were more specific to atrazine than to simazine, while the monoclonal antibodies recognised both herbicides to approximately the same extent. The monoclonal antibodies showed a greater sensitivity, a weaker background, a more intense colour of the product of the enzymic reaction, and a greater resistance to the influence of the solvent on the matrix compared with the polyclonal antisera. They were therefore selected for the assay.

In the study of different assay formats, it was observed that the use of format IIIa increases the sensitivity by a factor of 10. However, format II proved to be more resistant to the influence of the matrix and gave rise to a weaker background. For example, the presence of methanol, acetonitrile, acetone up to 10%, and tetrahydrofuran up to 2.5% did not affect the results of the assay. Format II was selected for the analysis of water and soil specimens. The assay developed subsequently[55] was used successfully in the study of the leaching of simazine.[56] Soil specimens were collected from different depths after irrigation, the highest concentration of the herbicide being observed in the upper layers of the soil (0.2 m). The application of this assay method in the study of the content of atrazine and its metabolites in urine has been reported;[57] gas chromatography, mass spectrometry, and HPLC have been used to supplement and confirm the ELISA data in qualitative and quantitative determinations of the atrazine metabolites. It was shown that the main atrazine metabolites in the urine of people working with herbicides is atrazine mercaptourate. This metabolite was found at concentrations ten times greater than atrazine or its *N*-dealkyl derivatives. Atrazine mercaptourate was isolated from urine by affinity extraction using polyclonal antisera.[17,25] After monitoring for ten days the level of atrazine mercaptourate in the urine of people working with atrazine and who have received different doses of the herbicide through the skin or via the respiratory pathways, it was suggested that ELISA be used to determine atrazine mercaptourate as a biomarker of the dose received.

The influence of the ELISA format and of the structure of the enzyme conjugate on the sensitivity of the method has been analysed in detail;[39] the optimum variant was used to analyse water and soil specimens. Enzyme conjugates with horseradish peroxidase and alkaline phosphatase were synthesised for haptens **2** and **3** ($n = 2, 5$) by the activated esters method. Four formats were investigated — II, III, IIIa, and IIIb. Different

antigen : enzyme ratios were used in the synthesis of the enzyme conjugates. It was found that the sensitivity of the assay depends little on the antigen : enzyme ratio, although an increase in the amount of the hapten entailed a proportional increase in the optical density of the product of the enzymic reaction. Comparison of the enzyme conjugates showed that the use of haptens with the longest 'foot' ($n = 5$) for conjugates with horseradish peroxidase increases the sensitivity by a factor of 3–5 compared with haptens having a short 'foot' ($n = 2$). For conjugates with alkaline phosphatase, the opposite picture was obtained. In general, the conjugates with alkaline phosphatase proved inferior to the conjugates with horseradish peroxidase, since they required a smaller dilution and a longer time for the development of the colour of the product of the enzyme reaction. Ultimately the enzyme conjugate of hapten **3** with horseradish peroxidase proved to be best. The authors[39] note that this feature, found for different enzymes, is somewhat surprising and attribute it to the different molecular masses of the enzymes and hence to different dispositions of the hapten on their surfaces and to possible steric hindrance.

Comparison of different formats of the assay showed that format II was least sensitive and economical as regards the consumption of the reagent. Formats III, IIIa, and IIIb had approximately equal sensitivities but a longer time was required for format III to develop the colour of the same intensity as for formats IIIa and IIIb. In addition, the greatest scatter of the results from tray to tray was observed for this format. As regards formats IIIa and IIIb, the former was selected for the assay as being more economical. The greatest percentages of cross-reaction were observed for atrazine (100%), propazine (147%), ametryn (70%), and simazine (32%).

The preparation of monoclonal antibodies and an extremely simple semiquantitative method for the assay of atrazine on strips have been reported.[58] The duration of the assay is 20 min. The strips are coated in succession by antispecies antibodies, monoclonal antibodies, and casein. For the assay, an aliquot of the specimen assayed and the enzyme conjugate are mixed and placed on the strips for 5 min. After washing, the colour is developed. This method makes it possible to determine visually the content of atrazine in water at a concentration in excess of 0.5 ng ml^{-1}. Monoclonal antibodies have also been used in the development of ELISA. The employment of conjugates of haptens **2** and **3** with horseradish peroxidase involved hardly any differences in their calibration curves and the conjugate of hapten **3** was used for the assay.

After the use of atrazine had been prohibited in Germany, it began to be replaced universally by terbutylazine. This is the reason why a series of studies on the development of ELISA for this herbicide have appeared recently. Giersch and Hock[18] described the synthesis of homologous conjugates of terbutylazine with alkaline phosphatase involving the use of format III. Somewhat unexpected results were obtained. For antibodies synthesised against the conjugate of hapten **7**, the greatest cross-reactivity was shown by terbutryn and prometryn (the detection limits were 0.1 and 0.3 ng ml^{-1} respectively), while the antibodies to the protein conjugate **1** (Table 2) recognised aziprotryn most effectively (detection limit 1 ng ml^{-1}). The monoclonal antibodies obtained[18] were used in numerous investigations. It has been suggested[59] that dextran be employed as the high-molecular-mass carrier. When protein conjugates and the conjugate with dextran were used in format I, it was shown that the sensitivity of the determination is approximately the same in both cases. The advantages of the conjugates with dextran were noted: resistance to denaturation and resistance to high temperatures, different pH values, and salts.

The influence of the incubation time of the enzyme conjugate on the sensitivity of ELISA has been investigated. Monoclonal antibodies,[18,42] polyclonal antisera,[22,47] and format III were used. In order to obtain antibodies to the protein conjugates of haptens **3**, a homologous enzyme conjugate was employed, whilst for the remaining antibodies use was made of the conjugate of compound **14**. Conjugates with horseradish peroxidase were obtained by the activated esters method. The incubation time of the conjugate was varied from 1 min to 40 h. For the polyclonal antibodies, the variation in the position of the central point on the calibration curve was appreciable (by five orders of magnitude). The authors explained this by the presence in the polyclonal antiserum of antibody fractions with different affinities. It was noted that such a large range of measurable concentrations permits the analysis of an undiluted specimen over a wide range of concentrations solely by varying the incubation time of the enzyme conjugate. For monoclonal antibodies, the variation was much less (by about one order of magnitude). A decrease in the incubation time led to a decrease in the optical densities of the product of the enzymic reaction. It was observed that a decrease in the assay time did not diminish the cross-reactivity. For the optimised assay of atrazine based on the polyclonal antiserum, the detection limit was 2 ng $litre^{-1}$ (incubation time 1 min), whereas for monoclonal antibodies the detection limit in the assay for terbutylazine was 30 ng $litre^{-1}$ (incubation time 7 min).

Monoclonal antibodies to the protein conjugate of hapten **1** have been obtained.[19] ELISA for terbutylazine was optimised using various formats (I, modification of I by labelling monoclonal antibodies with biotin and subsequent interaction with the streptavidin–horseradish peroxidase conjugate, IIIa). A protein conjugate of hapten **2** was used in the assay involving format I, whereas for format IIIa use was made of the enzyme conjugate of hapten **2** with an isopropyl side group. It was shown that the sensitivity increased in the following series of formats: I, modified I, IIIa.

Thus the employment of monoclonal antibodies in the assay of 1,3,5-triazines make it possible as a rule to obtain a higher sensitivity of the assay compared with polyclonal antibodies. However, it is not possible to improve radically the specificity of the assay, since monoclonal antibodies also exhibit an appreciable cross-reaction with related 1,3,5-triazines. This may be associated with only slight differences between the structures of the herbicides of the given group, which as a rule involve only the alkyl substituent in the side chain.

V. Quantitative determination of several herbicides in one sample

Owing to the appreciable cross-reaction with structurally similar 1,3,5-triazines when the sample contains several related herbicides, it is impossible to determine quantitatively just one of them. We shall consider below the results of two studies in which ways of solving this problem have been proposed.

The application of a set of characterised monoclonal antibodies for the quantitative determination of atrazine, simazine, and cyanazine in a single specimen in the analysis of waste and wash liquids has been described.[26] Five monoclonal antibodies,[24] three formats [I (with preincubation of a mixture of a solution of antibodies and the specimen or standard), II, and IIIa], and various (homologous and heterologous) structures of the ELISA antigens were investigated. From the five antibodies proposed initially, three with different cross-reactivities in relation to atrazine, simazine, and cyanazine were selected. The highest sensitivity was observed for the heterologous systems. In terms of sensitivity, format II was best, while the sensitivity for format IIIa was slightly lower but the assay time was then shorter by 2 h. Initially all the antibodies were analysed by means of format I using the protein conjugates of haptens **3** and **9** with BSA, by means of format II using the enzyme conjugate of haptens **2** ($n = 2$) and **3** ($n = 2$), and by means of format IIIa using the enzyme conjugate of hapten **2** ($n = 2$). Three ELISA methods (with different antibodies) in format IIIa were used to analyse water specimens employing a conjugate of hapten **2** ($n = 2$). An approach to a quantitative determination of several herbicides was based on the assumption that the observed response and the

response measured in the immunoassay (i.e. in ELISA) of the antibodies binding to the antigens present in the sample represents an 'overall response' to all the reacting antigens. The observed response is represented by the equation

$$\text{ELISA response} = A(X_A) + B(X_B) + C(X_C) + \ldots + Z(X_Z),$$

where the ELISA response is the amount of substance assayed determined on the basis of the calibration curve for the antigen selected as the standard, A, B, C, and Z are the concentrations of different antigens, and X_A, X_B, X_C, and X_Z are the reactivity coefficients for these antigens.

In this case, the ELISA response was expressed in micromoles of atrazine, the reactivity coefficient for which was adopted as unity. The reactivity coefficients for other herbicides were determined from the slope of the plot of the linear dependence of the ELISA response on the antigen (simazine or cyanazine) concentration. In the analysis of specimens containing three herbicides, equations were derived for each ELISA:

$$\text{ELISA response 1} = A(X_{A1}) + B(X_{B1}) + C(X_{C1}),$$

$$\text{ELISA response 2} = A(X_{A2}) + B(X_{B2}) + C(X_{C2}),$$

$$\text{ELISA response 3} = A(X_{A3}) + B(X_{B3}) + C(X_{C3}),$$

where A, B, and C are the unknown concentrations of atrazine, simazine, and cyanazine and X_{Ai}, X_{Bi}, and X_{Ci} are respectively the reactivity coefficients of atrazine, simazine, and cyanazine when different antibodies are used ($i = 1-3$).

The amount of each herbicide in the sample was determined by solving three equations with three unknowns. Analysis of water specimens showed that atrazine and the total amount of herbicides are determined with a satisfactory accuracy and reproducibility, whereas the determination of simazine and cyanazine is less accurate.

The application of two antibodies with different specificities for the detection of a known pesticide in the sample has been reported.[61] A polyclonal antiserum (the cross-reactivities with respect to atrazine and terbutylazine were 100% and 4% respectively)[47] and monoclonal antibodies (the cross-reactivities for terbutylazine and atrazine were 100% and 25% respectively)[18] were used in the analysis of water specimens. In the assay of atrazine, the cross-reactivity in relation to terbutylazine (4%) was used to calculate the concentration equivalent of terbutylazine. Similar calculations were performed in the assay of terbutylazine. Next, the ratio of the smaller and higher concentration equivalents was determined for each herbicide. If the ratio was in the range 0.4–1, it was concluded that the herbicide was present in the sample. A satisfactory correlation of the results with gas-chromatographic data was obtained. Thus it was shown that the type of herbicide employed can be determined rapidly in the sample by the ELISA method.

VI. Alternative immunoassay methods

Apart from the spectrophotometric detection of the enzymic reaction product usually employed, it is possible to detect its fluorescence or luminescence.

Two versions of the immunoassay of atrazine and simazine with enhanced luminescence have been described.[62,63] In the former case, the peroxidase-labelled hapten competed with the substance assayed for the binding centres of polyclonal antibodies adsorbed on test-tubes. The test-tubes were then washed and the amount of peroxidase remaining with the antibodies was determined using the isoluminol reagent. When assay trays were used, the range of measurable concentrations was 0.01–1 ng ml^{-1}. The concentrations of the reagents were increased compared with the usual method in order to shorten the incubation time and make the assay suitable for field conditions.

Ulrich and Niessner[64] used a fluorogenic substrate for alkaline phosphatase in the development of an immunoassay for terbutylazine with fluorescence detection of the label. For a homologous assay on monoclonal antibodies,[18] the required incubation time of the substrate mixture was 20 h. Later is was possible to shorten the incubation time to 20 min by synthesising the enzyme conjugate by means of a modified method.[65] Glyme was used as the solvent for the synthesis of the enzyme conjugate, while, instead of the traditional *N*-hydroxysuccinimide, di(*N*-succinimidyl) carbonate was employed.[66]

The study of Seare et al.[67] was devoted to the application of fluorescence immunoassay (FIA) in the quantitative determination of 1,3,5-triazines. For this purpose, the hapten was conjugated with fluorophors (dansyl chloride or fluorescein).

Recently increasing attention has been devoted to versions of the immunochemical assay methods where the procedure is simplified to the maximum extent and which are most suitable for routine analyses under field conditions. The development of a semiquantitative method for the determination of atrazine on strips was described above.[58]

It has been suggested that immunobiosensors be used to assay atrazine in drinking water.[68] The immunobiosensor consists of a piezo-crystal with a vibration frequency of 10 MHz, which is coated in succession with a protein A and polyclonal antibodies. When the immunobiosensor is bound to atrazine, the mass of the crystal and hence the frequency of its vibrations changes, the effect being proportional to the content of the pesticide in water. After the removal of the antigen from the surface, such an immunobiosensor can be used for 8–9 measurements. The linear range of the measurable concentrations is 0.03–100 μg ml^{-1}.

The first description of flow-injection immunoassay for pesticide determination in water was published in 1991.[69] A polyclonal antiserum to atrazine[47] was immobilised on immunoaffine membranes. The 'stop-go' method was used when the reagents were passed through the membrane and a fluorimeter was employed to detect the product of the peroxidase oxidation of hydroxyphenylpropionic acid. The linear range of the calibration curve was 0.02–0.3 ng ml^{-1}. The reproducibility of the results was poorer than in the corresponding immunoenzyme assay method. This might have been due to the nature of the flow–injection reaction, the nonequilibrium reaction conditions, and the immobilisation method used.

The optic fibre immunosensor has been employed to assay atrazine in water.[70] The hapten was immobilised on the surface of the optic fibre via glutaraldehyde. The immunosensor was placed in a cell containing a mixture of the specimen to be analysed and monoclonal fluorescein-labelled antibodies[18] and the fluorescence was measured. In a later study,[71] it was possible to reduce the detection limit by a factor of 100 (0.01 nM atrazine concentration) by selecting the hapten for immobilisation.

An immunochromatographic method for the assay of atrazine in which ABICAP (antibody immunocolumn for analytical processes, Abion, Germany) immunochromatographic columns with a microheterogeneous medium, containing antispecies antibodies, are used, has been developed.[72] In the assay, the reagents are passed in succession through the column in the course of 10 min; the lower limit in the detection of atrazine is 0.1 ng ml^{-1}. Various detection methods (spectrophotometric, fluorescence, and chemiluminescence) are considered in the above communication.

The present authors are conducting studies designed to develop a polarisation fluorescence immunoassay (PFIA) for herbicides of the 1,3,5-triazine group and to investigate the influence of the structure of the labelled hapten on the sensitivity of the assay. The method is homogeneous, simple, and rapid. It is based on the competition between the antigen to be determined and the antigen with a fluorescence label for the limited number of binding centres of the antibody and on the measurment of the degree of polarisation of the reaction mixture. A PFIA has been developed[73] for simazine on the basis of a polyclonal antiserum with a lower detection limit of 5 ng ml^{-1}. The influence of the structure of the labelled antigen on the sensitivity of the assay has been studied.[74] It was shown that the assay employing

heterologous labelled antigen with the shortest chemical bridge is the most sensitive. The PFIA method is less sensitive than the ELISA method, but it is simpler and rapid.

One may conclude that immunochemical methods for the assay of herbicides of the 1,3,5-triazine group are used successfully in the analysis of various specimens. The results obtained by immunochemical and physicochemical analytical methods are as a rule satisfactorily correlated. The simpler and fast immunochemical methods will apparently also soon find extensive application in our country.

Abstract. Processes leading to the growth of intrinsic insulators (oxides, sulfides, and fluorides) on the surfaces of semiconductors of the III–V, II–VI, and IV–VI groups as well as their solid solutions are analysed with the aid of classical thermodynamics. Their phase compositions, found from the equilibrium phase diagram, are compared with the compositions found as a result of experimental studies of the semiconductor–insulator interface. It is shown that there is a relation between the characteristic features of the equilibrium phase diagram (in particular the segregation of a metal or nonmetal at the interface), the type of intrinsic lattice defects, and the electrophysical properties of the interface. The possible ways of creating an ideal compound semiconductor–insulator interface are considered. The bibliography includes 171 references.

I. Introduction

Oxidation is one of the first chemical reactions which humanity encountered at the dawn of history. With time, the number of known metals increased and the requirements which they had to meet became more stringent, but the problem remained in essence the same: how to protect finished articles from the destructive effect of the environment. Two main approaches were used. The first reduced to the search for a metal which would not be oxidised at all and it is not fortuitous that such metals have been called noble. The second involved the transformation of the enemy into a friend, i.e. the finding of an oxide which would serve as a protection. Aluminium oxide may serve as a successful example.

When it was proposed that the surface of silicon semiconductor devices be protected by silicon dioxide SiO_2, nothing new took place. However, when the first transistor based on a metal–oxide–semiconductor (MOS) system was created, the layer of oxide became an active component of the device itself and fundamentally new requirements, concerning primarily electrical parameters, were formulated for it. Almost all the electrical properties of the semiconductor–oxide interface are determined not by the bulk-phase characteristics of the oxides but by the extremely thin transition region, with a thickness of several nanometers, between the oxide and silicon, which contains a boundary phase with unusual composition and coordination of the silicon and oxygen atoms. Chemical engineering was therefore faced with the problem of regulating, with hitherto unheard of accuracy, the composition and structure of the interface formed on the surface of the conductor during oxidation.[1]

The problem of optimising the properties of the $Si–SiO_2$ interface was solved successfully and for the best MOS transistors the concentration of the electrically active defects on the interface does not nowadays exceed one defect per $10^4–10^6$ surface silicon atoms.† Nowadays the structure and properties of the $Si–SiO_2$ interface have been investigated in great detail, which is best indicated by the advances in silicon electronics. The relative simplicity of the technology, compactness, and the low power required by circuits based on MOS transistors made them irreplaceable in the manufacture of microprocessors and memory circuits, the wide scale employment of which determines in many respects the current progress in science and engineering.

The advance achieved in the development of silicon electronics permits one to hope that it will be repeated in the creation of devices based on binary semiconductors, particularly bearing in mind that the problems of regulating the bulk-phase properties have already been solved for most of them. This applies primarily to GaAs, in which the electron mobility is six times higher, its radiation stability is greater, and its working temperature range is wider (from −200 to 200 °C) compared with silicon. All this leads to most extensive prospects for the creation of ultrafast integrated circuits. The reason why these prospects have not been fully realised hitherto is mainly associated with the failure of the attempts, over a period of almost 30 years, to create a gallium arsenide–insulator interface the parameters of which would be close to those of the $Si–SiO_2$ interface.‡ In many respects this is

† We may note that a method for the modulation of the electrical conductivity in the surface layer of the material, which constitutes the basis of the operation of MOS transistors, was patented as early as 1926, but, owing to the lack of ability to regulate the properties of the surface, it could not be applied in practice for a long time.

‡ At the Jubilee XXth Conference on the Physics and Chemistry of Interfaces in Semiconductors (USA, 1992), it was noted that the reason for the failures is the complexity of the chemistry of the GaAs surface.[2]

associated with the much more complex chemical composition of the boundary phases. Thus the chemistry of interfaces has become a crucial problem in the creation of microelectronic devices based on compound semiconductors.

Valuable results of this kind have been obtained for III–V semiconductors using the methods of classical thermodynamics. With the aid of these methods, it has been possible to predict at the microlevel the phase composition of the interfaces, which is, generally speaking, unexpected for a macroapproach of this kind. There has been recently a certain renaissance of thermodynamic methods. Nowadays, when it is possible to determine experimentally with the aid of electronic and ionic spectroscopy the composition and structure of interfaces at the atomic level, it has been found that thermodynamic calculations make it possible to analyse extremely effectively such complex systems. Thus thermodynamic calculations have in fact successfully predicted the sequence in the formation of phases on interaction in metal–silicon structures.[3] Thermodynamic analysis of the oxidation of the test material in order to determine the phase composition of the intrinsic oxide on the semiconductor–oxide interface is of interest for MOS structures. One of the simplest procedures used successfully in such analysis involves the calculation of phase equilibrium diagrams for the semiconductor–oxygen system. This approach was in fact first used to analyse the oxidation of the surfaces of semiconductors of the III–V group by Schwartz[4] and members of the Institute of Inorganic Chemistry of the Siberian Division of the USSR Academy of Sciences[5] at the beginning of the 1980s; later it was extended to other semiconducting compounds.

It must be emphasised that at the present time the range of insulators which are potentially suitable for the creation of devices based on metal–insulator–semiconductor (MIS) systems has greatly expanded. These are not only oxides but also other intrinsic insulators, i.e. compounds during the formation of which the semiconductor atoms are incorporated in the composition of the growing layer of the insulator.[6] The interface between the semiconductor and such compounds has also been analysed successfully with the aid of the phase equilibrium diagram.

This review is devoted primarily to the analysis of the application of phase equilibrium diagrams in the description of the interaction of oxygen with binary semiconductors and solid solutions based on them. Attention is concentrated on the establishment of a relation between the chemistry of the interface and its electrophysical parameters since only the understanding of this relation will make it possible to create promising devices based on compound semiconductors.

II. Thermodynamic analysis of the compound semiconductor – intrinsic insulator interface

There is a definite relation between the advances in the silicon MOS technology and the relative simplicity of the chemical processes occurring in the oxidation of silicon.[1,7–9] Indeed, in terms of their chemical composition and structure, the SiO_2 layers on silicon resemble vitreous silicon dioxide (fused quartz), are characterised by a high degree of chemical uniformity, and correspond to the stoichiometric formula SiO_2 almost throughout the thickness of the layer. Only at the interface between the Si and SiO_2 phases, which have different crystal structures and chemical compositions, the surface regions of both materials are reconstructed, some of the surface chemical bonds are rehybridised, and new chemical groups (characteristic of the interface alone), in which silicon has the Si^{3+}, Si^{2+}, and Si^{+} oxidation states, are formed. The thickness of the transitional region, having the composition SiO_x ($x < 2$), does not exceed several nanometers. Although the SiO_2 layer, having a thickness of 1.5–3.0 nm, adjoining this transitional region does have the stoichiometric composition, it is nevertheless mechanically strained owing to the nonidentity of the lattice constants of silicon and SiO_2. The structure of two monolayers of silicon atoms adjoining the interface is disturbed on the side of the silicon support. It is assumed that the defects in the transitional SiO_x region actually determine many of the electrical parameters of the interface.§ Bearing in mind the deficiency of oxygen in the transition layer, one can assume that such intrinsic defects may be oxygen vacancies and the ruptured bonds involving silicon atoms (the so called trivalent silicon).

Overall, the picture of the $Si–SiO_2$ interface proved to be fairly complex and it was necessary to develop unique experimental methods in order to be able to characterise it fully.

Proceeding to the consideration of the chemistry of interfaces involving compound semiconductors, it must be emphasised that the problem of the formation of the $Si–SiO_2$ interface actually reduces merely to the correspondence between the crystal lattices of two single-phase stoichiometric materials, the problem being facilitated by the fact that one of them possesses fairly flexible interatomic bonds, the angle between which can vary within wide limits.

In the case of a binary semiconductor, the problem is immeasurably more complex: two elements are now oxidised, each of which can have several oxides and some of the oxides can be variable-composition phases. Furthermore, if the oxide of one of the elements is highly basic whilst that of the other is highly acidic, a salt is formed and the number of complex oxide phases, for example phosphates, can also be large. All this leads to a multiphase structure of the oxide layer, which is usually accompanied also by a spatial nonuniformity. Furthermore, under certain conditions, chemical interaction of the oxide phases not only with one another but also with the semiconductor support becomes possible. As will be shown below, by employing phase equilibrium diagrams, it is possible to predict the composition of the oxide layer and, what is especially important, of the compound semiconductor–intrinsic insulator interfaces.

The method of phase equilibrium diagrams is based on the analysis of the possible interactions in the test materials–oxygen system. For a two-component compound AB, the interaction of the phases in the A–B–O ternary system, represented by the Gibbs triangle, is considered. The specific form of the phase equilibrium diagrams for the III–V, II–VI, and IV–VI compounds considered in this review is presented in Fig. 1.

All the oxide phases in the A–B–O system are assumed to be pure individual compounds and only condensed phases under standard conditions are considered. The miscibility of the phases is neglected. The chemical reactions occurring between pure phases are therefore studied, so that the phase equilibrium diagram for the A–B–O system contains only straight lines connecting the phases pairwise. These lines represent the thermodynamic equilibrium states between the phases. The stability of the lines is estimated from the Gibbs free energies of the chemical reactions (ΔG) recorded at the point of intersection of the lines, the line connecting the products of the reactions with $\Delta G < 0$ being regarded as stable. The calculation of ΔG requires a knowledge of the standard molar Gibbs free energies of formation ΔG° of all the phases belonging to the A–B–O system. Since the free energies ΔG° are by no means known for all substances, a series of methods have been developed for the estimation of these quantities (see, for example, Barin et al.[14]).

The phase equilibrium diagram can be used, firstly, for the estimation of the phase composition of the oxide film formed on the surface of the test compound during reversible oxidation in dry oxygen. The number of phases and their spatial distribution in the bulk of the oxide film can be found by analysing the line connecting oxygen and the test material and by analysing the question of which phase regions are intersected by this line.

§ The properties of the interface, like those of the insulator itself, can be regulated with the aid of impurity atoms. A review has been devoted to this problem.[10]

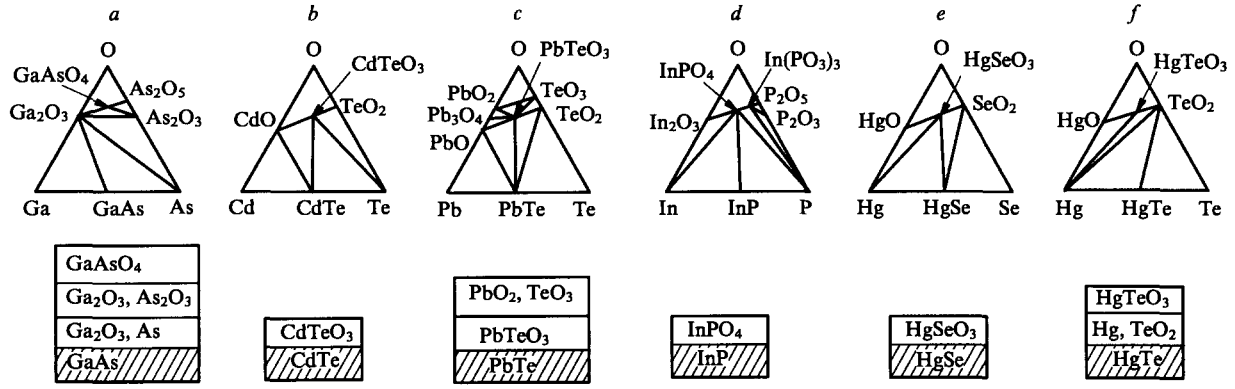

Figure 1. Phase equilibrium diagrams and phase composition profiles for the intrinsic oxides in various systems: (*a*) Ga–As–O;[4] (*b*) Cd–Te–O;[11] (*c*) Pb–Te–O;[12] (*d*) In–P–O;[4] (*e*) Hg–Se–O;[13] (*f*) Hg–Te–O.[11]

The chemical potential of oxygen is lowest at the semiconductor–oxide interface, increases monotonically along the thickness of the oxide film, and reaches a constant value in the gas phase. Consequently, movement along the line from the test compound, located at the base of the phase equilibrium triangle, to the apex of the diagram describes in succession the phase composition of the semiconductor–oxide interface and of the bulk-phase and surface components of the oxide film.

Another important practical application of phase equilibrium diagrams involves the possibility of predicting the chemical interaction of the oxide films formed with the support. It was noted above that the chemical potential of oxygen decreases monotonically from the oxide–gas phase interface to the support–oxide interface. The oxide film is formed until its thickness reaches a value for which the chemical potential of oxygen diminishes to a critical value which is insufficient for further growth of the oxide. If gaseous oxygen is removed (such a situation actually arises when the oxidised material is annealed *in vacuo* or under an inert gas atmosphere), then the oxide phases which are not linked by stable lines on the phase equilibrium diagram with the semiconductor may serve as the oxidant.

At the same time the method suffers from a fundamental limitation. The phase equilibrium diagram refers to a state of thermodynamic equilibrium and in no way describes the kinetics of the oxidation process. It provides a fundamental answer to the question of the possibility of the spontaneous occurrence of chemical reactions in the material–oxygen system investigated but does not indicate the time during which they take place. In practice, this means that the phase equilibrium diagram describes adequately the composition of the oxide film when the growth of the latter is sufficiently slow, so that its phase composition is determined by thermodynamic and not kinetic factors.

Additional complications in comparing data obtained by the method of phase equilibrium diagrams with experimental results may arise from the volatility of the oxide phases and their thermal decomposition or solubility, depending on the specific method used to oxidise the material.

A multiplicity of different versions of the structure of phase equilibrium diagrams is possible. For the binary semiconductors considered, six fundamentally different types of such diagrams are so far known. They are arranged in Fig. 1 in an order which reflects the transition from the preferential oxidation of the metal at the semiconductor–oxide interface in GaAs (Fig. 1*a*), through the synchronous oxidation of both components of the semiconductor with formation of a single complex oxide compound (Figs. 1*b*–1*e*), to the preferential oxidation of the nonmetal in HgTe (Fig. 1*f*).

We shall deal in greater detail with the diagram for GaAs bearing in mind that indium arsenide, indium and gallium antimonides,[4] as well as tin,[12] zinc,[13] and manganese[15] selenides and tellurides have qualitatively similar phase diagrams. When GaAs is oxidised, Ga_2O_3 and elemental arsenic are formed near the interface and the oxide consists of Ga_2O_3, As_2O_3, and $GaAsO_4$ (Fig. 1*a*). Thus, using the Ga–As–O phase equilibrium diagram it is possible to predict the formation of elemental arsenic at the GaAs–oxide interface as the phase corresponding to thermodynamic equilibrium. A similar conclusion concerning the preferential oxidation of the metal and the possible presence of the nonmetallic component in an elemental form at the semiconductor–oxide interface is also reached from the analysis of the analogous phase equilibrium diagrams for InAs, InSb, GaSb, SnTe, SnSe, ZnTe, ZnSe, MnTe, and MnSe. The phase equilibrium diagram for the Ga–As–O system also permits the technologically important conclusion that chemical reactions are possible between the semiconductor and the intrinsic oxide. Indeed, GaAs is linked on the phase equilibrium diagram by a stable line only with Ga_2O_3, i.e. the contacts between GaAs and arsenic oxides correspond to thermodynamic disequilibrium. If GaAs is linked by imaginary straight lines to As_2O_3, As_2O_5, or $GaAsO_4$, then the latter all intersect the stable Ga_2O_3–As line. This means that the oxidised arsenic is unstable in contact with GaAs and the chemical reactions occurring lead to the enrichment of the interface in elemental arsenic.

The phase equilibrium diagram for the Cd–Te–O system (Fig. 1*b*) has a fundamentally different structure. It contains the stable CdTe–$CdTeO_3$ line, which means that the oxidation of CdTe results in the formation of only one oxide compound — $CdTeO_3$. As for GaAs, the metal oxide is linked to the semiconductor by a stable line on the phase equilibrium diagram and the reaction between CdTe and TeO_2 can lead to the appearance of elemental tellurium in the region of the interface. Thus the CdTe–oxide interface is thermodynamically stable when the entire oxidised tellurium is in $CdTeO_3$.¶

PbTe undergoes yet another important change on the phase equilibrium diagram (Fig. 1*c*). Here the semiconductor is linked by stable lines to the first oxides of lead and tellurium and also to lead tellurite $PbTeO_3$. The PbTe–oxide interface is single-phase on either side and is thermodynamically stable relative to both PbO and TeO_2. Only when higher lead and tellurium oxides appear in the oxide film do reactions become possible in the semiconductor–oxide system, but in this case the components of the semiconductor should not be segregated at the interface in the elemental form.

The phase equilibrium diagram for the In–P–O system has a different structure (Fig. 1*d*). It contains the stable InP–$InPO_4$ line, but InP is not linked by stable lines with either phosphorus

¶ The possibility of formation of the compounds $CdTe_2O_5$ and $HgTe_2O_5$, the presence of which has been mentioned in a number of studies,[16–18] has not been taken into account in Fig. 1 for CdTe and HgTe.

oxides or with In_2O_3. The InP–interface formed under equilibrium conditions is also single-phase on either side. If the composition of the oxide layer differs from $InPO_4$, there is a possibility of the occurrence of chemical reactions between the support and the oxide layer, which probably results in the appearance of both indium and phosphorus in the elemental form in the region of the interface.

The phase equilibrium diagram for the Hg–Se–O system (Fig. 1*e*) is a mirror image of the analogous phase equilibrium diagram for Cd–Te–O. The HgSe–oxide interface is single-phase but is unstable relative to mercury oxide. Elemental mercury may appear at the HgSe–oxide interface as a result of chemical reactions between the support and HgO.

Similarly the phase equilibrium diagram for the Hg–Te–O system (Fig. 1*f*) is the mirror image of the corresponding diagram for the Ga–As–O system. In the region of the HgTe–oxide interface, the chalcogen is oxidised preferentially, while mercury remains in the elemental form. The HgTe–oxide interface is unstable, since the only stable line on the diagram is HgTe–TeO_2, linking HgTe to the oxide phases. It follows from the phase equilibrium diagrams that the reactions between the support and the oxide should lead to the enrichment of the HgTe–oxide interface in metallic mercury.

Thus, judging from the phase equilibrium diagrams for the III–V, II–VI, and IV–VI binary semiconductors, there is a possibility of different variants of the phase composition and thermodynamic stability on semiconductor–oxide interfaces.

No less interesting results have been obtained with the aid of phase equilibrium diagrams for semiconductor solid solutions. The first three-dimensional diagrams, consisting of tetrahedra, have been constructed for the $In_xGa_{1-x}As$ [19] and $Hg_{1-x}Cd_xTe$ [11,16] solid solutions. The methods used to construct such diagrams were supplemented by several important postulates compared with the methods used to construct the phase equilibrium diagrams for binary semiconductors.[11] Stable triangular planes in the three-dimensional diagram play the role of the stable lines in the two-dimensional diagram. Each apex of such a triangle must correspond to one of the phases of the test system, each side of the triangle represents a stable line of the phase equilibrium diagram, and at least one apex of the triangle is located on a face of the tetrahedron. All possible planes are considered and their stability is estimated from the calculated free energies ΔG.

As an example, Fig. 2 presents the phase equilibrium diagram for the Hg–Zn–Te–O system. We may note that, apart from the phase equilibrium diagrams for the Hg–Te–O and Zn–Te–O systems, the estimation of the form of the phase equilibrium diagrams for the Hg–Zn–O and Hg–Zn–Te systems was needed in order to construct the phase equilibrium diagram for the $Hg_{1-x}Zn_xTe$–O system. Such three-dimensional diagrams can be used to determine the phase composition of the solid solution–oxide interface. The phase composition profile is estimated from the points of intersection of the straight line connecting the solid solution to oxygen with the stable lines and planes of the phase equilibrium diagram. A definite compound corresponds to each such point. The phase composition profiles are presented for the diagrams considered. Such analysis can be carried out conveniently by considering the cross-section through the three-dimensional diagram along the plane connecting the binary compounds of the solid solution and oxygen.

The most interesting variants of such cross-sections are presented in Fig. 3. Analysis can be usefully begun with the thoroughly investigated Hg–Cd–Te–O system. In the oxidation of the $Hg_{1-x}Cd_xTe$ solid solutions, CdTe is initially oxidised (the $Hg_{1-x}Cd_xTe$–O straight line belongs to the stable HgTe–$CdTeO_3$–CdTe plane) (Fig. 3*a*). After the completion of the oxidation of CdTe (the $Hg_{1-x}Cd_xTe$–O straight line intersects the stable HgTe–$CdTeO_3$ line), the oxidation of HgTe begins with the preferential formation of the chalcogen in the initial stage, mercury being segregated in the elemental form at the interface.

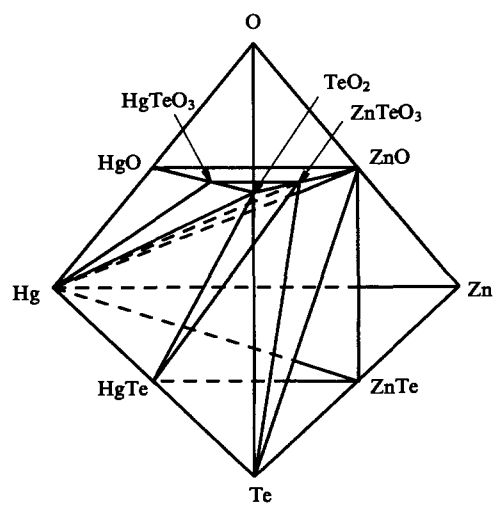

Figure 2. Phase equilibrium diagram for the Hg–Zn–Te–O system.[13]

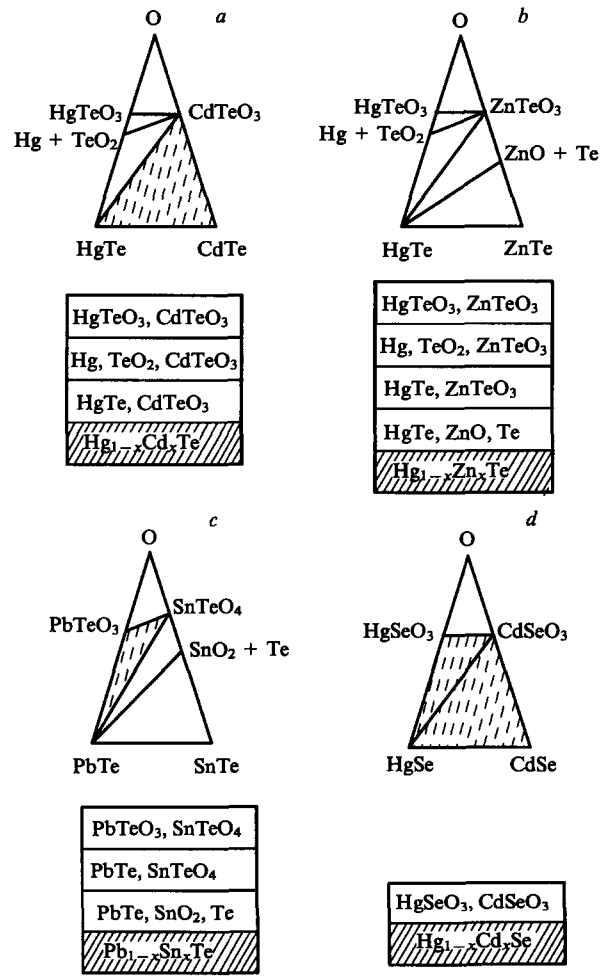

Figure 3. Sections through phase equilibrium diagrams for various systems:
(*a*) Hg–Cd–Te–O along the HgTe–O–CdTe plane;[11]
(*b*) Hg–Zn–Te–O along the HgTe–O–ZnTe plane;[13]
(*c*) Pb–Sn–Te–O along the PbTe–O–SnTe plane;.[12]
(*d*) Hg–Cd–Se–O along the HgSe–O–CdSe plane.[13]
The corresponding phase composition profiles for the intrinsic oxides are shown under the sections.

Thus the solid solution–oxide interface is multiphase and contains metallic mercury (Fig. 3*a*).

The opposite oxidation pattern is characteristic of the $Pb_{1-x}Sn_xTe$ solid solution (Fig. 3*c*). Here SnTe is oxidised first, giving rise to SnO_2 and elemental tellurium. Thus, in contrast to $Hg_{1-x}Cd_xTe$, the solid solution–oxide interface for $Pb_{1-x}Sn_xTe$ contains the elemental chalcogen.

An even more complex situation obtains for the $Hg_{1-x}Zn_xTe$ solid solution. Analysis of the HgTe–O–ZnTe section (Fig. 3*b*) shows that, in the oxidation of the $Hg_{1-x}Zn_xTe$ solid solution, ZnTe is the first to be oxidised with formation of ZnO and elemental tellurium [the $Hg_{1-x}Zn_xTe$–O line intersects the Hg–ZnO–Te plane (Fig. 2)]. Then tellurium is oxidised to zinc tellurite $ZnTeO_3$ (the $Hg_{1-x}Zn_xTe$–O line intersects the Hg–$ZnTeO_3$ line). Next, the oxidation of HgTe begins, tellurium being oxidised preferentially, and elemental mercury is evolved at the interface. Consequently the simultaneous presence of elemental tellurium and mercury in the region of the solid solution–oxide interface is characteristic of the $Hg_{1-x}Zn_xTe$ solid solution.

Analysis of the HgSe–O–CdSe section (Fig. 3*d*) shows that the $Hg_{1-x}Cd_xSe$ solid solution is unique. By virtue of the presence of the stable CdSe–$CdSeO_3$ and HgSe–$HgSeO_3$ lines on the phase equilibrium diagrams for the Cd–Se–O and Hg–Se–O systems, the corresponding HgSe–O–CdSe section represents a stable plane. The equilibrium oxidation of the $Hg_{1-x}Cd_xSe$ solid solution reduces to the oxidation of CdSe and HgSe to $CdSeO_3$ and $HgSeO_3$ respectively. Because of this, the solid solution–oxide interface should exhibit thermal stability. As regards other solid solutions considered above, the solid solution–oxide interface is multicomponent and thermodynamically unstable. In view of the absence of any stable planes in, for example, the HgTe–O–ZnTe section, the solid solution–oxide interface is multicomponent and potentially unstable. However, as will be shown below, this multicomponent property has a mutually compensating character (Hg^0 and Te^0) and paradoxically can actually improve the properties of the interface.

Similar phase equilibrium diagrams can also be constructed for even more complex systems. For example, the phase diagram for the $(PbSe)_{1-x}(SnTe)_x$ four-component solid solution has been published.[20] It was shown that in this system both chalcogens are present as a phase in thermodynamic equilibrium in the region of the solid solution–oxide interface.

The method of phase equilibrium diagrams can be employed also for the analysis of the processes occurring when a metal is deposited on the oxidised surface of a semiconductor.[21]

Fig. 4 presents as an example the phase equilibrium diagram for the Pb–Te–O–Al system. Analysis of sections through this diagram along the PbTe–O–Al plane makes it possible to estimate the phase composition of the PbTe–Al interface depending on the initial chemical state of the semiconductor surface. The composition of the PbTe surface is represented along the base of the PbTe–O–Al triangle by a point the movement of which, within the limits of the PbTe–$PbTeO_3$ segment, corresponds to the change in the state of the surface from that of a completely unoxidised semiconductor to a continuous oxide film. When aluminium is deposited on the unoxidised PbTe surface, chemical interaction takes place, which results in the formation of Al_2Te_3 and metallic lead (when the PbTe–Al straight line is drawn, it intersects the stable Al_2Te_3–Pb line). When aluminium is deposited on an oxidised PbTe surface, it initially interacts with the oxide, which results in the formation of Al_2O_3 and PbTe and then (depending on the thickness of the oxygen layer) it interacts with the semiconductor support or with the products of the first reaction. If the point on the PbTe–$PbTeO_3$ segment is connected with the apex of the PbTe–O–Al triangle, then the straight line is initially located in the PbTe–$PbTeO_3$–Al_2O_3 plane and then intersects the Pb–Al_2Te_3–Al_2O_3 plane. Thus, when aluminium is deposited on the oxidised PbTe surface, chemical interaction between the metal and the oxide is to be expected. This results in a decrease in the thickness of the oxide film and in the formation of

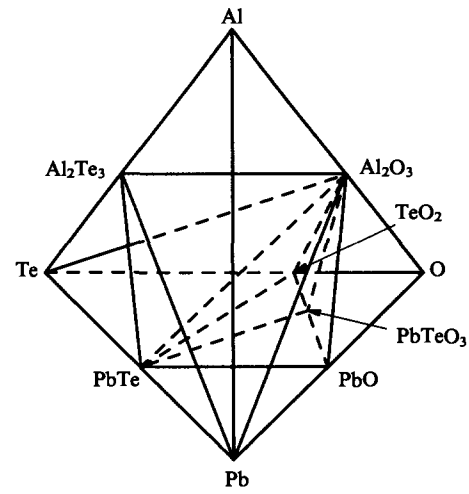

Figure 4. Phase equilibrium diagram for the Pb–Te–O–Al system.[21]

a boundary layer containing Al_2O_3, Al_2Te_3, and metallic lead and there is a possibility of the complete disappearance of the initial oxide.

It has been observed experimentally that different variants of the sulfidation † of the surfaces of semiconductors greatly improve their electrophysical properties. Phase equilibrium diagrams were constructed for certain semiconductor–sulfur systems (Fig. 5). None of them differ fundamentally from the phase equilibrium diagram for the Ga–As–O system, i.e. in this case the elemental nonmetal phase is formed at the semiconductor–sulfide interface. At the same time, the phase equilibrium diagram for the In–P–S system contains the stable InP–In_2S_3 line, while the phase equilibrium diagram for the Ga–As–S system contains the stable GaAs–GaS line, i.e. in each system there is a sulfide and the interface between the latter and the semiconductor is thermodynamically stable. An exchange reaction takes place in the Cd–Te–S and Hg–Te–S systems (Fig. 5*c*).

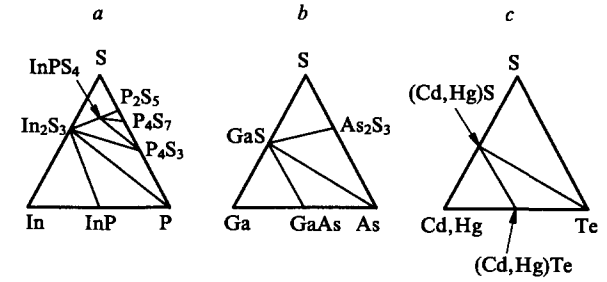

Figure 5. Phase equilibrium diagrams for different systems: (*a*) In–P–S;[22] (*b*) Ga–As–S;[23] (*c*) (Cd,Hg)–Te–S.[24]

Useful information about the composition and thermodynamic stability of the intrinsic insulator has been obtained with the aid of the phase equilibrium diagram for the $Hg_{1-x}Cd_xTe$–F system.[24] It was established that, as in the sulfidation of the III–V semiconductors, in the fluorination of CdTe at the CdTe–CdF_2 interface the elemental nonmetal is evolved and the CdTe–CdF_2 line is thermodynamically stable. On the other hand,

† The problem of the sulfidation of the surfaces of III–V semiconductors is one of the crucial problems in semiconductor materials science at the present time. We shall be concerned only with those aspects of the problem which are linked directly with the aim of this review.

on fluorination of HgTe the liberation of the components of the material in the elemental form should not be observed at all. Comparison of the sections through the Hg–Cd–Te–F diagram along the HgTe–F–CdTe plane, through the Hg–Cd–Te–S diagram along the HgTe–S–CdTe plane,[24] and through the Hg–Cd–Te–O diagram along the HgTe–O–CdTe plane (Fig. 3*a*) permits the conclusion that the principal feature of the $Hg_{1-x}Cd_xTe$–intrinsic insulator interface in the sulfidation and fluorination reactions is the absence of elemental mercury. On the other hand, the phase equilibrium diagram predicts the liberation of the elemental chalcogen in both cases. Its amount in the fluorination reaction should be significantly smaller, since the source of Te^0 is only CdTe, the content of which does not exceed 30% in the compositions of the $Hg_{1-x}Cd_xTe$ solid solution of the greatest practical importance.

It will be shown below whether the differences in the phase equilibrium diagrams presented above lead to different properties of the MIS materials based on these systems.

III. Experimental data on the oxidation of semiconducting compounds

Thin oxide films ($\leqslant 5$ μm) are used in semiconductor electronics, the thickness becoming continuously smaller with progress in the technology. For example, in modern MOS transistors the thickness of the oxide under the gate is ~25 nm. The composition of the semiconductor–oxide interface itself, whose thickness in most cases does not exceed several nanometers, is of greatest interest to investigators. This must be borne in mind in comparing the chemical compositions of the oxide films predicted by the phase equilibrium diagram and obtained experimentally.

Electronic and ionic spectroscopic methods, which make it possible to investigate the composition and structure of the surface and interfaces at the atomic level, are usually employed in the study of such oxide films.[25] In the first place these are methods, such as electronic Auger spectroscopy (EAS) combined with ionic etching, which make it possible to determine the distribution of the elements in the bulk of the structure. The particles of the specimen atomised by the primary ionic beam are analysed by secondary ion mass spectrometry (SIMS). The Rutherford back scattering (RBS) method has almost no disruptive effect, but is resolution as a function of depth is poorer.

Photoelectron spectroscopy (PES) affords the most valuable information about the chemical bonds linking the elements on the surface and the interface. Ultraviolet (UPES) and X-ray photoelectron spectroscopy (XPES) are distinguished by the energy range of the primary radiation beam.

Valuable information, particularly in the presence of Group V and VI nonmetals, has also been obtained with the aid of Raman spectroscopy and the voltammetric method.

For the purpose of analysis, it is convenient to divide the theoretical and experimental results into three groups depending on the oxidation conditions: 'natural' oxidation (at room temperature), thermal oxidation, and anodic electrochemical oxidation (photochemical oxidation and oxidation in an oxygen plasma are also usually included here). One should bear in mind that, for each of these oxidation procedures, there exist technological factors which lead to the deviation of the composition of the oxide films from the equilibrium composition — for example, thermal decomposition in thermal oxidation, different solubilities of the oxide phases in the electrolyte in anodic oxidation, etc. Only correct allowance for these factors makes it possible to achieve a correct comparison.

1. Gallium arsenide

The natural oxidation processes were initially investigated mainly on chemically etched surfaces, but the results obtained by different investigators proved to be extremely contradictory; this was associated primarily with the fact that etching can appreciably disturb the stoichiometry of the surface. In addition, oxidation is a component of the etching process which leads to the growth of insoluble oxide films of different composition depending on the composition of the etch. This has been demonstrated clearly for the InP surface.[26] According to data obtained by the XPES and RBS methods, the thickness of the grown oxide layer varied from 0.7 to 2.4 nm depending on the composition of the etch and the etching time, while the ratio of phosphorus and indium, normalised with respect to $InPO_4$, ranged from 0.2 to 1.5. Similar results have been obtained from GaAs[27] and $Hg_{1-x}Cd_xTe$.[18]

This is why the study of the oxidation of an atomically clean surface (ACS), usually obtained by cleaving the crystal in an ultrahigh vacuum or by ion bombardment, is of greatest interest. Electron spectroscopy makes it possible to observe the oxygen adsorption process at the monolayer level on such a surface. However, one should bear in mind that the thickness of the oxide, growing on the ACS of III–V and II–VI compounds, does not usually exceed 2–3 monolayers, i.e. it is too small to permit a description of these films by means of the thermodynamic parameters obtained for bulk phase specimens. Furthermore, the differences between the electronic and lattice subsystems of the atomic layers on the free surface and in the parallel layers in the bulk of the semiconductors are particularly strongly manifested precisely in the initial stages of the interaction of oxygen with the semiconductor.[28] These differences actually explain, for example, the finding that, when the ACS on silicon was oxidised for an oxide thickness of ~1 nm, unstable oxidation states of silicon were observed by the UPES method.[1]

Despite these limitations, it is possible to establish a definite relation between the phase equilibrium diagram and the oxidation of the ACS of semiconductors at room temperature. It has been established with the aid of electronic spectroscopy that the unexcited oxygen molecules interact with the surface of GaAs, InAs, and InP in three stages.[29–32] Adsorption takes place in the first stage but only on surface defects formed on cleavage or on cleaning the surface by ion bombardment. In the second stage, the oxygen molecule dissociates with formation of bridge bonds of the Ga–O–As type. The interaction accompanied by a chemical shift of the skeletal levels begins only in the third stage. For all three compounds, the atoms of both the metal and the nonmetal participate equally in the formation of bonds with oxygen, since the amplitude of the PE peaks due to oxidised indium (gallium) and arsenic (phosphorus) increases equally with increase in the surface coverage by oxygen in the range from 0.1 to 1.5 monolayers.[32,33] However, after brief annealing of InP in vacuo at 350 °C, the PE peaks for indium, phosphorus, and oxygen remain unchanged, whereas after annealing GaAs the peak for oxidised gallium increases and that for oxidised arsenic diminishes while the amplitude of the oxygen peak remains unchanged.

According to the phase equilibrium diagrams (Fig. 1), the oxide layer on InP consists of the compound $InPO_4$, which is stable on heating, while that on GaAs comprises a mixture of oxides,[34] the heating of which gives rise to the reaction

$$2GaAs + As_2O_3 = Ga_2O_3 + 4As. \quad (1)$$

On the other hand, on oxidation of the ACS on gallium arsenide by ionised oxygen, the chemical interaction is accelerated (peaks corresponding to Ga_2O_3 and As_2O_3 appear in the photoelectron spectrum) and a peak corresponding to elemental arsenic appears.[29] The appearance of elemental antimony has been observed in the oxidation of the ACS of gallium and indium antimonides.[35,36] The difference between even the initial stages of the oxidation of GaAs and InP is indicated by the analysis of the composition of thin ‡ layers obtained by the natural, chemical, and thermal oxidation of GaAs and InP specimens.[37,38] All the

‡ Thin layers are understood as layers whose thickness is comparable to the depth from which photoelectrons emerge (< 5 nm). Their composition, like that of the interface, can be analysed in depth without resorting to etching.

specimens were subjected to the same preliminary surface treatment and the composition was investigated by the XPES method with angular resolution, which makes it possible to vary the depth of the probed layer from 2 to 4 nm. Both elemental arsenic and gallium and arsenic suboxides were observed in all the oxide layers on GaAs under these conditions, whereas both elemental phosphorus and indium and phosphorus suboxides were absent from the oxidised InP surface and the entire oxidised phosphorus was present in the form of complex compounds.

Studies on the thermal oxidation of GaAs (see Wilmsen's review[39]) showed that elemental arsenic is present on the interface under different annealing conditions (dry and moist oxygen, O_2/As_2O_3 mixture) over a wide temperature range ($\leqslant 620$ °C). Only at higher temperatures does its concentration diminish and $GaAsO_4$ appears on the interface in addition to Ga_2O_3. The oxide layer at $T \leqslant 500$ °C consists largely of amorphous Ga_2O_3, which crystallises as β-Ga_2O_3 at higher temperatures; As_2O_3 is present in much smaller amounts. This is associated both with the consumption of As_2O_3 via reaction (1) and with its high volatility. The concentration of As_2O_3 in the bulk phase can be increased by growing the oxide in the vapour of As_2O_3 or the O_2/As_2O_3 mixture. The exact spatial disposition of arsenic remained unelucidated for a long time. It was assumed that it may accumulate in the form of a continuous film directly on the interface. However, the latest studies have shown that elemental arsenic is present throughout the bulk of the thermal oxide,[40] while analysis of the cross-sections through structures with the thermal oxide with the aid of transmission microscopy and microdiffraction confirmed that, for example after oxidation at 500 °C, the interface consists of an epitaxial layer of γ-Ga_2O_3 on GaAs, beween which are injected 5–10 nm precipitates of hexagonal arsenic with a density of $(2-5) \times 10^{11}$ cm^{-2}.[41] In addition, it was shown that arsenic may be formed not only in reaction (1) but also in the direct GaAs oxidation reaction

$$4GaAs + 3O_2 = 2Ga_2O_3 + 4As, \quad (2)$$

first put forward by Smirnova et al.[42]

One of the controversial questions is whether elemental arsenic is or is not formed at the interface in the low-temperature oxidation (electrochemical anodic, plasma, etc. oxidation). The majority of investigators believed that it appears at the interface only after the annealing of the grown oxides at $T > 250$ °C as a result of a secondary reaction. However, it was later shown[42] that As^0 could not be detected in the initial film as a consequence of the inadequate sensitivity of the Raman technique ($\sim 10^{15}$ atoms cm^{-2}). Thus, when solid-phase voltammetry having a sensitivity of $10^{11}-10^{12}$ atoms cm^{-2} was used, it was possible to detect elemental arsenic and antimony in the initial anodic oxide films (AOF) on GaAs, InAs, and InSb,[5,40,42] i.e. reaction (1) occurs also at room temperature under these conditions. Furthermore, it has been possible to carry out a layer-by-layer investigation using this method of not only the phase composition but also of the structure of the oxide layers and to establish its relation with the conditions governing the growth of the anodic oxide.[42]

Thus the anodic oxide film, approximately 100 nm thick, grown under galvanostatic conditions ($j \approx 5.0$ mA cm^{-2}) on the GaAs surface, has the following distribution of composition as a function of its thickness:[40]

Layer	Chemical composition
1	ε-Ga_2O_3, As_2O_3(cryst.), As_2O_3(amorph.), $GaAsO_4$(cryst.)
2	ε-Ga_2O_3, As_2O_3(amorph.), As_2O_3(cryst.), As_2O_5(cryst.), As_2O_4(cryst., traces)
3	α-Ga_2O_3, ε-Ga_2O_3, As_2O_3(amorph.), As_2O_5(cryst., traces)
4	α-Ga_2O_3, As_2O_3(amorph.), As_2O_5 (cryst., traces)
5	δ-Ga_2O_3, As_2O_3(cryst.), As(amorph.), As(cryst.)

Layer 5 adjoins the GaAs surface. Evidently, Ga_2O_3, As_2O_3, and As are formed at the interface, which agrees with the phase equilibrium diagram. On moving away from the interface, oxides appear in which arsenic has the highest oxidation state (As_2O_4, As_2O_5, $GaAsO_4$), and the nonequilibrium combinations of phases $As_2O_3 + As_2O_5$, and $Ga_2O_3 + As_2O_5$ are observed, which is most probably associated with kinetic factors. After a time or on heat treatment, this leads to the following solid-phase reactions:

$$As_2O_3 + As_2O_5 = 2As_2O_4, \quad (3)$$

$$Ga_2O_3 + As_2O_5 = 2GaAsO_4, \quad (4)$$

$$Ga_2O_3 + 2As_2O_4 = 2GaAsO_4 + As_2O_3. \quad (5)$$

Under these conditions, structural transformations also occur in the films—the amorphous forms of As and As_2O_3 crystallise and the less stable crystalline forms of Ga_2O_3 are converted into the more stable ones. The chemical state is in many respects determined by the conditions in the anodic oxidation.[40,43] Thus an increase in current density leads to additional oxidation of arsenic to the pentavalent state and to the appearance of As^0 at the interface in both amorphous and crystalline forms. Comparison of the spectra of the analytical signals due to the electrochemical transformations of the anodic oxide, the thermal oxide, and mixtures of reference compounds shows that none of these oxides are homogeneous, consisting of a mixture of phases of different structural modifications with a grain size greater than 5 nm.[40] This agrees well with the existing data showing that the oxides are initiated in isolated regions on exposure to an electron beam[44] and in the initial stages of the growth of the anodic oxide.[45]

The chemical composition of the oxide layer on GaAs, obtained by oxidation in an oxygen plasma,§ does not actually differ from the composition of the layer obtained on anodic oxidation and also represents a mixture of As_2O_3 and Ga_2O_3. Its composition is then influenced quantitatively by factors such as the rate of growth of the oxide, the degree of ionisation of the plasma, and the anodic current density. The concentration of arsenic in the plasma oxides is found to be higher than in the electrochemical oxides and can reach 4%–5% of the overall composition.[47] It is determined to a large extent by the dynamics of the growth of the oxide layer: the more intense the oxidation process, the smaller the amount of arsenic displaced to the interface. Its total amount at a high rate of growth (300 nm min^{-1}) is equivalent to a layer 4.2 nm thick, while at a low rate of oxidation it corresponds to 41 nm for an overall thickness of the layer of 160 nm.[48] One cannot rule out the possibility that the appearance of such a large amount of elemental arsenic is associated with the preferential oxidation of gallium as a consequence of the difference between the activation energies for the gallium and arsenic oxidation reactions in the plasma.[49]

2. Indium phosphide

XPES analysis of thin oxide films grown under an oxygen atmosphere at temperatures in the range 340–400 °C showed that they are a mixture of amorphous In_2O_3 and $InPO_4$ and that phosphorus is present as the phosphate and not P_2O_5 over the entire experimental temperature range (up to 650 °C), but, with increase in the oxidation time, i.e. for thicker films, elemental phosphorus appears at the interface.[39] With increase in the oxidation temperature from 350 to 550 °C, the amount of accumulated P^0 increases and then falls.[50] At ~ 650 °C, elemental phosphorus was not detected[39] and only $InPO_4$ was found at the interface, which is consistent with the phase equilibrium diagram. The appearance of P^0 is probably associated with the fact that at $T < 600$ °C the oxide grows as a result of the diffusion of indium and phosphorus to the oxide surface, the diffusion of phosphorus being appreciably slower than that of indium. The extent of the

§ The preparation of the oxides of compound semiconductors by plasma anodisation and their properties have been described in detail.[46]

diffusion of oxygen at these temperatures is low and the oxidation occurs on the surface, which in fact leads to the accumulation of unoxidised phosphorus at the interface. Furthermore, according to Mittova et al.,[51] unoxidised (or insufficiently oxidised) indium is formed in the bulk of the oxide during thermal oxidation at 575–675 °C. On the other hand, in general the excess indium present in the thermal oxide on InP, especially in the outer layer, is due to the evaporation of phosphorus from the surface.[52] Thus, in a certain temperature range, kinetic factors become dominant. Experiments on the oxidation of InP at oxygen pressures in the range from 1 to 500 atm confirmed that this is in fact so and that the appearance of P^0 is not associated with the reactions of types (1) and (2). At pressures of 150 atm and above, the interface consists of $InPO_4$, In_2O_3, and P_2O_5. Such a change in the composition of the interface can be explained by the increase in the rate of diffusion of oxygen, which in fact leads to the complete oxidation of the elements.[53] It is of interest to note that P^0 is not formed on oxidation of InP by oxygen in the presence of water vapour.[39]

A detailed comparison of the elemental compositions of the thermal, chemical, and anodic oxides of InP has been carried out with the aid of XPES using precision layer-by-layer chemical etching, which ruled out all the effects associated with the action of the ion beam.[50, 54–56] A sufficiently reliable identi-fication of different oxide phases was achieved by comparing the chemical shifts of the peaks for different levels of the skeleton, their intensities, and the spectra of the valence bands of the oxide films and reference compounds. If the thermal oxides represent a mixture of amorphous In_2O_3 and $InPO_4$ particles with the P^0 present at the interface, then they also include polyphosphates of the type $In(PO_3)_x$. The oxides grown in concentrated nitric acid under strong illumination are homogeneous throughout their thickness. Their average atomic composition corresponds to $In(PO_3)_{2.6}$ and is independent of the thickness of the oxide layer, time, and the temperature ($\leqslant 80$ °C) of the growth process. Anodic oxides have been grown in the familiar AGW electrolyte,[57] the pH of which was varied in the range from 2 to 12 by adding NH_4OH. They all consist of two layers, the outer layer being enriched in indium (P : In = 0.4) and representing apparently a hydrated mixture of $InPO_4$ and In_2O_3 or $In(OH)_3$. The inner layer, adjoining the interface, is enriched in phosphorus and has the average composition $In(PO_{3.2})_{3.9}$. This distribution remains unchanged for all anodic oxides with a thickness between 10 and 50 nm and is independent of both the pH of the electrolyte and the current density. The distributions of the elements in the anodic oxide and in the oxides grown in other electrolytes[58, 59] are quantitatively the same. This has been attributed to the growth mechanism specific for the anodic InP oxide, which cannot operate in, for example, GaAs, because the anodic oxide on GaAs is not a vitreous compound but a mixture of polycrystalline oxides.

Analysis of the photoelectron spectra of the valence band has shown that the inner part of the anodic oxide on the side of the interface consists of single-phase nonstoichiometric phosphate $In(PO_x)_y$ with x and y close to 3. Studies by the fast electron diffraction method showed that the oxides are amorphous. This agrees with the existence of vitreous $In(PO_3)_3$.[60] The study of the crystalline metaphosphate $In(PO_3)_3$ showed that the P–O–P bond angle in the PO_4 tetrahedron can vary within wide limits, like the O–Si–O angle in the SiO_2 structure, i.e. these structures are sufficiently flexible to ensure a good agreement between the phosphate and InP lattices, as happens in the Si–SiO_2 system. Annealing at temperatures up to 350 °C does not alter the chemical composition of the anodic oxide or of the interface with InP and, furthermore, according to data obtained by transmission electron microscopy, somewhat smoothes out the roughness of the interface at the atomic level. The change in the composition of the interface (the formation of a P^0 layer up to 0.5 nm thick) is observed only after annealing at 450 °C. The appearance of phosphorus can be explained, in conformity with the phase equilibrium diagram (Fig. 1*d*), by the fact that the InP–anodic oxide interface is nevertheless unstable and the reaction

$$4In(PO_3)_3 + 5InP = 8P + 9InPO_4, \quad (6)$$

takes place on it. One cannot rule out the possibility that, as a consequence of the presence of hydrates in the anodic oxide layer, additional reactions take place at high temperatures and result in the liberation of phosphorus.

An oxide consisting mainly of a polymeric polyphosphate phase has been obtained on indium phosphide by plasma oxidation.[61]

3. Semiconductor solid solutions

A few studies have shown that the oxidation reactions of solid solutions of III–V compounds can be regarded as a superposition of the oxidation reactions of the binary semiconductors. The appearance of a new As_zP_{1-z} phase in the oxidation of the $InAs_xP_{1-x}$ solid solution may be regarded as the most interesting result.[62]

It is noteworthy, in connection with the widescale use of $Hg_{1-x}Cd_xTe$ (x = 0.2, 0.3) and $Pb_{1-x}Sn_xTe$ (x = 0.2) in IR techniques, that mainly the solid solutions have been investigated, whereas the initial binary compounds HgTe and CdTe, as well as PbTe and SnTe, were considered only for a better understanding of the oxidation reactions of the solid solutions.

The study of the oxidation of the ACS of epitaxial $Pb_{1-x}Sn_xTe$ (x = 0, 0.2, and 1.0) showed that[63] SnTe is oxidised much more vigorously than PbTe. The rapid oxidation of tin is also characteristic of the solid solution and is accompanied by the enrichment of the surface in this element as a result of the sublimation of free tellurium. Vacuum annealing leads to the complete transition of tin to the oxidised state and hence to a decrease in the XPES peak associated with TeO_2. Bearing in mind the low temperature of the sublimation of elemental tellurium, the experimental data are seen to agree well with the phase equilibrium diagram (Fig. 3*c*).

The oxidation of the ACS of HgTe and $Hg_{0.7}Cd_{0.3}Te$ begins with the rupture of the Hg–Te bonds and the subsequent oxidation of tellurium but not mercury, the atoms of which leave the surface of this semiconductor, while both elements are oxidised in CdTe.[64] Comparison of the kinetics of the oxidation of all three materials showed that the solid solution is not oxidised as a simple mixture of two binary compounds. This can be explained by the fact that, on formation of the solid solution, a charge redistribution takes place between the mercury and cadmium ions and leads to the weakening of the Hg–Te bonds and to the strengthening of the Cd–Te bonds.[65]

Thermal oxidation has been investigated only for CdTe in view of the low thermal stability of mercury chalcogenides.[66] According to AES and XPES data, the thermal oxide, grown in both dry and moist oxygen at temperatures in the range 350–500 °C, consists of $CdTeO_3$ and no traces of enrichment of the interface in cadmium or tellurium were found. Furthermore, electron diffraction data show that epitaxial layers of cubic $CdTeO_3$ grow on CdTe at these temperatures. Complex cadmium and mercury oxide compounds are also present in the $Hg_{1-x}Cd_xTe$ oxides.[67]

Among all the variants of the oxidation reaction used to protect the $Hg_{1-x}Cd_xTe$ surface, anodic oxidation, carried out in 0.1 M KOH solution in 9 : 1 ethylene glycol–water mixture at a current density of 0.3 mA cm^{-2} under galvanostatic conditions, has unquestionably been most thoroughly investigated.[68] The composition and mechanisms of the growth of the anodic oxide have been studied by various methods. Fairly contradictory results have been obtained. At the present time, one can regard it as reliably established[69, 70] that the anodic oxide on $Hg_{1-x}Cd_xTe$ grows at the semiconductor–oxide interface as a result of the interaction of the atoms of the oxide with oxygen migrating to the interface via a vacancy mechanism. Oxygen vacancies migrate under the influence of the electric field in the direction towards the

outer boundary of the anodic oxide. At the oxide–electrolyte interface, the vacancies are filled with oxygen as a result of the electrochemical reaction. At this boundary, the oxide only dissolves in the electrolyte but does not grow.

Taking into account the available experimental data, the following model of the $Hg_{1-x}Cd_xTe$–anodic oxide interface has been proposed (Fig. 6*a*).[71,72] The $CdTeO_3$ layer is in direct contact with the semiconductor. The layer is formed because the binary components of the solid solution of CeTe and HgTe are oxidised separately — CdTe is oxidised preferentially, while HgTe remains partly unoxidised (private communication by Seelmann-Eggebert and H Richter — see Stahle et al.[73]). The anodic oxide grows into the semiconductor support, while the unoxidised HgTe remains in the layer adjoining the interface. The oxygen concentration is higher here, so that gradual further oxidation of HgTe takes place. In the bulk of the anodic oxide, all the components are fully oxidised and it is homogeneous as regards elemental composition. Comparison of the elemental composition determined experimentally by different methods with the composition calculated on the assumption that the entire oxidised semiconductor has been converted into a stoichiometric mixture of $HgTeO_3$ and $CdTeO_3$ has shown that more mercury than tellurium dissolves during the anodic oxidation. The anodic oxide has the following phase composition: 52% $HgTeO_3$, 30% TeO_2, and 18% $CdTeO_3$.[72] It is fully amorphous with the exception of the layer at the interface, where 2–5 nm crystalline particles are encountered. They have been identified as particles of unoxidised HgTe.

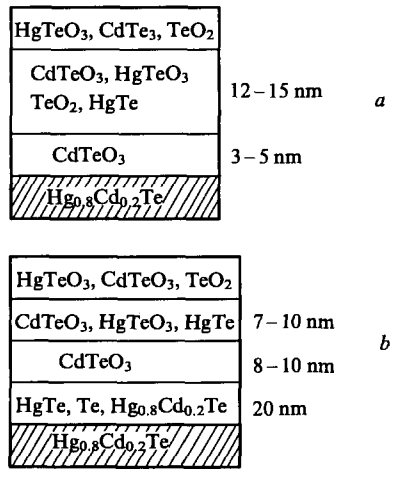

Figure 6. Phase composition profiles for the anodic oxide on $Hg_{0.8}Cd_{0.2}Te$: (*a*) after growth (before annealing; (*b*) after annealing at 220 °C.[72]

Annealing at relatively low temperatures (150 °C and above) leads to an appreciable redistribution of the elements at the interface, primarily to a decrease in the cadmium content in the semiconductor and an increase in its content of the oxide, the change in the composition involving HgTe being of the opposite kind.[71] This is unquestionably associated with the thermodynamic instability of the $Hg_{1-x}Cd_xTe$–oxide interface (Fig.3*a*). However, in the model illustrated in Fig. 6*a* the interface itself is thermodynamically stable, since $Hg_{1-x}Cd_xTe$ is in contact only with $CdTeO_3$, which is thermodynamically stable, and with HgTe and CdTe (continuous lines in Fig. 3a). It has therefore been suggested[72] that the $CdTeO_3$ layer in too porous and thin to prevent the interaction of TeO_2 with $Hg_{1-x}Cd_xTe$:

$$3TeO_2 + 10Hg_{0.8}Cd_{0.2}Te = 2CdTeO_3 + 8HgTe + 3Te. \quad (7)$$

This leads to some thickening of the $CdTeO_3$ layer and to the appearance of mercury telluride and tellurium in the semiconductor support (Fig. 6*b*). However, no account is taken of the possibility of the appearance of metallic mercury at the interface either directly during the period of oxidation or during subsequent heating as a consequence of a whole series of other thermodynamically feasible reactions, for example the interaction of $HgTeO_3$ with $Hg_{1-x}Cd_xTe$. However, in the presence of metallic mercury, it is impossible to account for the change in the electrical properties of the $Hg_{1-x}Cd_xTe$ surface layer (protected by the anodic oxide) during annealing.[71,74–76] According to RBS data, an appreciable increase in the mercury content after annealing at 200–250 °C is observed in the surface layer of the semiconductor approximately 20 nm thick.[76] The concentration of excess mercury under these conditions is up to 2×10^{21} cm^{-3}. Part of the mercury is actually segregated as HgTe, which alters the composition of the surface layer of the solid solution (according to optical absorption spectra, x diminishes to 0.125). The remainder accumulates in the form of mercury atoms in the interstices, which diffuse into the bulk of the semiconductor during annealing.

As in the case of GaAs and InP, the plasma oxide on $Hg_{1-x}Cd_xTe$ does not differ from the anodic oxide either as regards composition or the structure of the interface.[77] On the other hand, depending on the process conditions during photochemical oxidation, the compositions of both the oxide itself and of the interface, in particular their depletion or enrichment in mercury, can vary within wide limits. This is associated with the complexity of the oxide growth mechanisms.[78] Furthermore, it has been shown in relation to the photochemical oxide how greatly the composition of the interface for a compound semiconductor may depend on the preliminary treatment of the oxidised surface.[18]

An AES study of the anodic oxide on PbTe showed[79] that the distributions of the metal and the chalcogen in it agree fully with the distributions of cadmium and tellurium in the CdTe oxide.[67] This can be attributed to the fact that in both cases oxidation leads to the formation of the tellurite. RBS data indicate that the oxygen content in the bulk of the anodic oxide corresponds to lead in the Pb^{4+} oxidation state and not to Pb^{2+}, i.e. the appearance of the higher lead oxides — PbO_2 or $PbTeO_4$ — in the final stages of the oxidation reaction, predicted on the basis of the phase equilibrium diagram, has been confirmed experimentally for PbTe.

Comparison of the distributions of the elements at the oxide–semiconductor interface for the oxides on $Pb_{0.8}Sn_{0.2}Te$, obtained by the anodic,[80] plasma,[81] chemical,[82,83] and thermal[84] oxidation, yields interesting results. It shows that, although the compositions in the bulk of the oxides and especially in their outer layer differ appreciably, all the characteristics of the interface, which are already manifested on natural oxidation and, as stated above, are associated with the preferential oxidation of tin, are retained and actually intensify for all the oxidation methods. This concerns primarily the redistribution of tin and lead at the interface, which has been observed[85] in the oxidation of Pb–Sn alloys and which can be explained by topochemical substitution reactions typical for the initial stages of the oxidation of binary alloys of metals with different oxygen affinities.[86] However, also the appearance of elemental tellurium should be observed in the oxidation of tellurides (Fig. 3*c*).

Studies by Raman spectroscopy have made it possible to detect Te^0 on the naturally oxidised surface of only SnTe.[87] For $Pb_{0.8}Sn_{0.2}Te$, elemental tellurium can be detected only after thermal oxidation at $T \geqslant 250$ °C. For the anodic oxide on $Pb_{0.8}Sn_{0.2}Te$, elemental tellurium is also detected after annealing at this temperature. As in the case of As^0 in GaAs, its appearance here is associated primarily with the thermodynamically favourable secondary process

$$SnTe + TeO_2 = SnO_2 + 2Te. \quad (8)$$

At the same time, elemental tellurium could not be detected in the chemical oxide even on annealing. This is apparently associated with the characteristic features of the growth of the oxide film by this method.[83] The oxide always contains unoxidised PbTe, which

accumulates, in combination with SnO_2, at the interface, ensuring its thermodynamic stability.

Electrochemical anodisation has been used successfully to produce on the $Hg_{1-x}Cd_xTe$ surface other intrinsic insulators—sulfides[88] and fluorides.[89] The process is in both cases similar to anodic oxidation and is carried out respectively in Na_2S and KF + KOH solutions in ethylene glycol. During the growth of the anodic sulfide, HgS and TeS_2 are dissolved preferentially. The growing layer consists of 30% HgS and 70% CdS with some excess of tellurium in the form of hexagonal ~5 nm particles.[90] The $Hg_{1-x}Cd_xTe$–anodic sulfide interface is sharp and the change in composition is observed at appreciably higher annealing temperatures than for the anodic oxide (350 °C for annealing in air in the course of 15 days). The changes are mainly associated with the evaporation of mercury.[91]

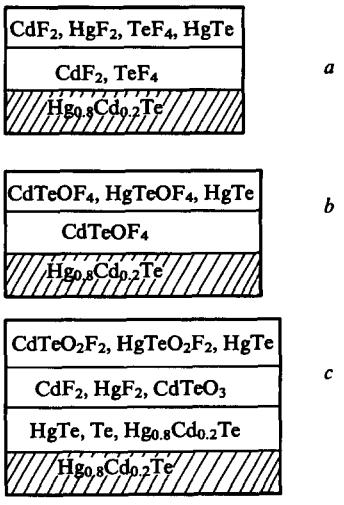

Figure 7. Phase composition profiles for the anodic fluoride on $Hg_{0.8}Cd_{0.2}Te$: (*a*) after growth; (*b*) after storage in air at room temperature; (*c*) after annealing at 220 °C.[92]

The study of the composition of the anodic fluoride on $Hg_{1-x}Cd_xTe$ showed,[92,93] that it consists mainly of 14% CdF_2, 21% HgF_2, 35% TeF_4, and 30% HgTe, i.e. the entire HgTe is not fluorinated. It is very significant that the interface is depleted in mercury fluoride and actually consists of only CdF_2 and TeF_4 (Fig. 7*a*). This should have promoted the thermal stability of the $Hg_{1-x}Cd_xTe$–anodic fluoride interface, but it has been found that the anodic fluoride is so sensitive to the presence of oxygen that oxide fluorides are formed even at room temperature (Fig. 7*b*). On heating, they react further with oxygen, which leads to the loss of fluorine:

$$2MTeOF_4 + O_2 = 2MTeO_2F_2 + 2F_2, \qquad (9)$$

where M = Hg or Cd. A reaction similar in many respects to that occurring in the annealing of the anodic oxide on $Hg_{1-x}Cd_xTe$ takes place at the interface, i.e.

$$3MTeO_2F_2 + 10Hg_{0.8}Cd_{0.2}Te = \\ = 3MF_2 + 2CdTeO_3 + 8HgTe + 3Te, \qquad (10)$$

which results in the formation of a multiphase interface similar to the $Hg_{1-x}Cd_xTe$–anodic oxide interface. It must be emphasised that the formation of metallic mercury is characteristic of only the $Hg_{1-x}Cd_xTe$–anodic oxide interface. As will be shown below, this is responsible for the fundamental differences between the electrophysical properties of these interfaces.

Owing to the instability of the anodic fluoride on $Hg_{1-x}Cd_xTe$ in the presence of not only oxygen but also water vapour, it is essential to provide additional protection to the anodic fluoride in practical applications, for example, by depositing ZnS.[94] Here it is necessary to take into account the possibility of chemical interaction between these compounds, leading to the appearance of ZnF_2, HgTe, and Te. When the anodic fluoride is sufficiently thick, its interaction does not affect the properties of the interface.

Similar chemical reactions, leading to partial reduction of the components of the anodic oxide on $Hg_{1-x}Cd_xTe$, occur also when ZnS[95] or metals (indium,[96] platinum, and gold[97]) are deposited on it. This must be taken into account in selecting the optimum thickness of the intrinsic insulator.

The knowledge of the possible chemical interactions in the semiconductor, the oxide, and the metal (Fig. 4) makes it possible to regulate specifically the properties of the metal–semiconductor interface with the aid of a thin intervening layer of oxide having a specified composition. Thus, by employing the chemical oxide, it has been possible to prevent the undesirable interaction of the metal with the semiconductor and to improve significantly the electrical and photoelectric properties of $M-Pb_{1-x}Sn_xTe$ (M = metal) barrier structures.[82]

IV. Electrophysical properties and chemistry of the compound semiconductor–intrinsic oxide interface

In the analysis of the requirements imposed on MOS (or MIS) structures by investigators developing electronic devices, the $Si-SiO_2$ system, which ideally satisfies all these requirements, may serve as a natural reference standard.[1]

The operation of MOS transistors is based on the possibility of inducing in the surface layer of the semiconductor an electric field which regulates the concentration of charge carriers up to the inversion of the type of conduction. The influence of the surface of the semiconductor is especially important in MOS transistors and other devices where the interface is an active region of the device (Schottky barriers, heterojunctions, superlattices). In practice, in order to optimise the parameters of any semiconductor device (dipolar transistor, photodiode, photoresistor), it is neces-sary to protect its surface by an insulator with fully defined characteristics.

Localised surface electronic states (SES),¶ the nature of which may be various, play the main role in all electronic phenomena on the surface and on the interface between the semiconductor and another material. In the first place, these are intrinsic SES arising due to the distortion of the periodic potential of the crystal lattice and the rupture of the chemical bonds involving surface atoms (the Tamm–Shockley levels). In addition, the appearance of SES may be caused by local surface imperfections of the type of structural defects, impurities, and their complexes.

The influence of the SES on the properties of the interface is determined by their charge state, disposition relative to the Fermi level (E_F) and distance from the interface.

A high SES concentration of the order of $10^{14}-10^{15}$ cm^{-2}, which is only a little less than the number of surface atoms, is observed on an atomically clean surface of silicon. The times of the electron exchange between the SES and the bulk phase are very short (less than 10^{-5} s) and such SES are called fast. Their high concentration leads to firm stabilisation of E_F (the so called 'pinning' of the Fermi level) on the surface near the centre of the forbidden gap E_g and it is almost impossible to regulate the properties of the surface with the aid of an external electric field.

During the thermal oxidation of the surface of silicon under optimum conditions, the SES concentration diminishes appreciably (to 10^9 cm^{-2}). This is probably associated with a certain degree of saturation of the ruptured bonds and a weakening of the

¶ The term 'surface electronic states' can be understood literally only for an atomically clean surface. For real interfaces, the SES are distributed in a finite three-dimensional layer.

Tamm factor in the perturbation of the periodic variation of the crystal lattice potential, which diminishes the degree of pinning of the Fermi level and makes it possible to modulate the bending of the bands at the $Si-SiO_2$ interface. However, the presence of structural defects in the oxide leads to the appearance of electron traps (the so called slow SES with a charge transfer time of $10^{-1}-10^{2}$ s).

A characteristic feature of the $Si-SiO_2$ interface is the presence of a built-in charge localised in a narrow (< 2 nm) region, the size and magnitude of which are most important characteristics. In fact it specifies the initial bending of the bands at the silicon surface and hence the conditions in the operation of the MOS transistor (depletion or enrichment). As regards the fast SES, their concentration should be minimal to ensure the maximum efficiency of the regulation of the surface conductivity. As already mentioned, for a high SES density (such as, for example, that at the ACS silicon), this effect is altogether absent. The SES charge transfer times, on which the frequency characteristics of the devices depend, are also important. The number of traps in the oxide should likewise be minimised, since their presence leads to instability of the parameters of the devices as a function of time.

In industrial manufacture, the decisive factor becomes not simply the development of processes ensuring the required parameters of the interface but also their technological suitability and, what is most important, their reproducibility. This requires a deeper understanding of the chemistry of the process in purely empirical developments. The initial advances in the creation of silicon MIS devices, which in the case of binary semiconductors proved useless, are associated with precisely such developments. This is confirmed by the fact that, as early as the 1970s, reports appeared concerning the development of MOS transistors based on GaAs and InP with parameters close to those of the silicon devices but in reality such devices had not been created at the time.

1. Gallium arsenide

Studies of the problem of the segregation of elemental arsenic at the GaAs–oxide interface must be regarded as fundamental. At the beginning of the 1980s, it began to be suspected that it is in fact the presence of As^0 at the interface that makes it unsuitable for the formation of GaAs-based MOS devices.[98] Analysis of the electrical parameters of the GaAs-based MIS structure showed that the concentration of surface electronic states and the position of E_F on the surface are independent of the method of preparation and even of the nature of the insulator (intrinsic oxides grown by means of the electrochemical, anodic, and plasma oxidation, SiO_2, Si_3N_4, $Si_xO_yN_z$, and Al_2O_3), although some dependence of the preliminary treatment of the GaAs surface was noted.[98,99] The density of the surface electronic states, fixing E_F in the vicinity of the middle of E_g, is so high that the bending of the semiconductor bands by the external electric field can be varied within limits insufficient for the attainment of the enrichment conditions or the inversion of surface conductivity.

Studies were carried out on the properties of the ACS of gallium arsenide and the changes in the latter when subjected to controlled influences. It has been established experimentally that there are no surface electronic states in the forbidden gaps of the absolutely clean GaAs and InP surfaces, so that, in contrast to silicon, there is no pinning of E_F on the surface in GaAs and its position is the same as in the bulk phase. However, when extraneous atoms are deposited onto the ACS in amounts appreciably less than a monolayer, the Fermi level in both *n*- and *p*-GaAs shifts approximately to the middle of E_g, where it is fixed and remains unchanged on further increase in the number of adsorbed atoms. Such behaviour of E_F is observed in the adsorption of both different metals and nonmetals, including oxygen.[100]

This made it possible to postulate that the pinning of E_F is caused by the surface electronic states associated with the intrinsic lattice defects and arising on adsorption of extraneous atoms. In the UDM (unified defect model),[101] it was initially assumed that such defects are gallium and arsenic vacancies. However, subsequently calculations and experiments on GaAs bulk phase specimens with different deviations from stoichiometry showed that antistructural defects of the type involving the transfer of arsenic to a Ga sublattice site (As_{Ga}) and conversely the transfer of gallium to an As sublattice site (Ga_{As}) are thermodynamically more favourable in GaAs. In particular, the EL2 trap, which determines many of the characteristic features of GaAs, represents either an isolated As_{Ga} defect or contains an interstitial arsenic atom on the {111} axis.[102] Whereas the appearance of an excess of As in the bulk phase of GaAs is related to the characteristics of its phase diagram,[103] in the oxidation reaction it is related to the GaAs–O structural diagram. Therefore in the approved version of the UDM model — the ADM (advanced defect model)[104] — the main cause of the pinning of E_F is believed to be the antistructural As_{Ga} defect which gives rise to two donor levels. The Fermi level is located between them and the position of E_F depends on the degree of compensation for As_{Ga} by the second defect Ga_{As}, which is an acceptor. An increase in the arsenic content on the surface shifts E_F to the conductivity band, whilst a decrease shifts it in the opposite direction.

One cannot claim that the ADM model fully explains the entire mechanism of the appearance of surface electronic states regulating the position of E_F on the interfaces with GaAs. It may be that effects associated with the presence of impurities, in the given instance adsorbed oxygen [the MIGS (metal induced gap states) model][105] and the disordering of the crystal lattice of the semiconductor in adsorption [the DIGS (defect induced gap states) model],[106] also make a definite contribution.

Convincing evidence that the pinning of E_F is in fact associated with the antistructural defects arising as a consequence of the liberation of arsenic on oxidation has been obtained in a study of thin (~5 nm) epitaxial GaAs layers.[107] The change in the position of E_F can be readily found from the change in the electrical conductivity of such layers on oxidation in air (after their removal from the growth chamber). It has been established that E_F for high-quality epitaxial *n*-GaAs layers, grown at 530 °C, varies nonmonotonically following an increase of exposure in air before becoming fixed. On the other hand, the position of the Fermi level for a similar layer grown at 300 °C does not change at all after exposure to air. Layers obtained at such a low temperature contain up to 5×10^{19} cm^{-3} As_{Ga} defects and their E_F is fixed from the beginning. High-temperature annealing of such layers is known to decrease the concentration of As_{Ga} by more than an order of magnitude. Indeed, the shift of E_F on oxidation for a similar specimen grown at a low temperature but then annealed at 530 °C occurred in the same way as for the usual specimens.

It has been established[108] that the position of E_F for layers grown at low temperatures with an excess of arsenic may be fixed not only by As_{Ga} point defects but also by As^0 precipitates segregated in the bulk of the material.† The position of E_F changes by more than 0.2 eV on passing from one pinning mechanism to another.

The changes in the electrophysical parameters of the GaAs-based MOS transistors may be caused not only by their thermodynamic instability, due to reaction (1), but also by the precipitation of As^0 on the interface described above.

The relation between the presence of As^0 and As_2O_3 on the GaAs surface and the fixation of the Fermi level has been confirmed by experiments involving the washing of the GaAs surface with water.[111] As_2O_3 is soluble in water, whereas As^0 dissolves in water only if the specimen has been illuminated with fairly intense light inducing photochemical reactions or if the water has been saturated with oxygen. In this case, As^0 is initially oxidised to As^{3+}, which then dissolves in water. Experiment shows that the intensity of the photoluminescence, which depends on the degree of fixation of E_F, increases appreciably only when

† The so called internal Schottky barrier model,[109] which permits a new approach to the problem of semi-insulating semiconductors.[110]

the GaAs specimens have been washed in a stream of water saturated with O_2 or under illumination. This leads to the washing away of both As_2O_3 and As^0. However, after storage for several minutes in air, especially at an elevated temperature, the photoluminescence intensity falls to the previous level, which is associated with the reoxidation of the GaAs surface. The new stage involving washing with water again increases the brightness of the luminescence and this cycle can be repeated several times.

Treatment of the GaAs surface with a $Na_2S.9H_2O$ solution also leads to an appreciable increase in the effectiveness of the photoluminescence.[112,113] A series of methods have been developed for the treatment of the GaAs surface with sulfides, which greatly diminishes the rate of surface recombination. After such treatment, the oxides are removed from the GaAs surface and an ideal crystal lattice is created on the latter, in the first layer of which the sulfur atoms substitute all the arsenic atoms and form thermodynamically stable bonds with gallium atoms (Fig. 8).

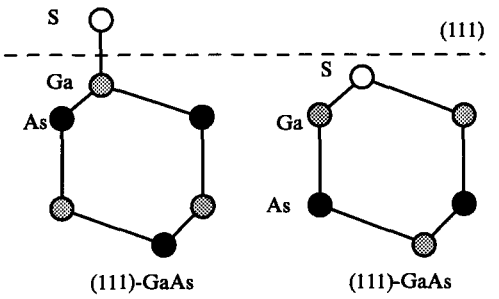

Figure 8. Distribution of sulfur atoms on the (111) surface of GaAs passivated with sulfur.[2,149]

The importance of the complete removal of arsenic is indicated by the comparison of the efficiencies of the treatment of the GaAs surface with Na_2S and $(NH_4)_2S$ solutions.[114] Experiments with a layer of arsenic especially sputtered on showed that, in contrast to Na_2S, the $(NH_4)_2S$ solution effectively dissolves arsenic. Sulfidation with this solution actually leads to a more than twofold decrease in the density of surface traps and hence to a decrease in the rate of surface recombination. However, since the heats of formation of sulfides are lower than those of the corresponding oxides, a GaAs surface treated with sulfide solutions is unstable on storage in air and in the course of several days the initial properties of the surface are restored.

All the experiments involving the study of the stability of the GaAs surface freed from As by different methods have shown that the reason for the subsequent appearance of arsenic is reoxidation. Therefore all the technological processes for the creation of an insulator–GaAs interface must be devised in such a way that the oxidation of the GaAs surface is ruled out.

In the plasmochemical etching methods, it is technologically easy to combine in a single cycle the cleaning of the GaAs surface and the deposition of insulators. An example is provided by the etching of the surface in a hydrogen HF plasma with subsequent deposition of Ga_2O_3,[115] which is thermodynamically stable in relation to GaAs. The protecting layer is generated by evaporating gallium in an oxygen plasma. In order to rule out the reoxidation of GaAs under these conditions, the GaAs specimens are additionally etched in a nitrogen plasma, which creates a thin layer of arsenic nitride saturating the free arsenic bonds. The interfaces thus obtained have a low density of surface electronic states and the E_F level is not fixed. Under these conditions, degradation of the parameters was not observed even after storage of the specimens for several months in air.

It has been established[116] that treatment of the GaAs surface in a CF_4 plasma before depositing Si_3N_4 leads to the effective removal of As^0 and As_2O_3 and also to the formation of a passivating layer made up of Ga_2O_3 and GaF_3. Such a passivating coating greatly improves the characteristics of high-power GaAs-based transistors and prolongs their working life. The stability of the interface can be achieved also by the direct deposition of GaF_3 if the GaAs surface has been subjected to a preliminary treatment in $(NH_4)_2S$ solution.[117]

Another method for producing an ideal interface involves not the removal of the oxides from the GaAs surface but their reduction. This can be carried out by depositing a thin layer of silicon on the GaAs surface. For a correctly selected thickness of the layer (~0.8 nm) and of the temperature of the subsequent annealing, it is possible to reduce the oxides on GaAs completely and a layer of SiO_2 with a specified thickness can be deposited on the structure thus obtained.[118]

It is noteworthy that the understanding of the chemistry of all processes leading to the oxidation of the GaAs surface has actually made it possible in recent years to take definite steps towards the creation of GaAs-based MIS devices.

2. Indium phosphide

It follows from the phase equilibrium diagram that the chemistry of the InP–intrinsic oxide interface is qualitatively different. It is of interest to elucidate how this is reflected in the electrophysical properties of MOS structures.

When oxygen is adsorbed, E_F on the InP surface is also fixed but not in the middle of E_g, as in GaAs, but closer to the bottom of the conductivity band (as a result of an intrinsic lattice defect different from that in GaAs).[101] In combination with the fact that the density of surface electronic states on the interface involving InP is an order of magnitude lower than in GaAs, this makes it possible to achieve different versions of InP-based MOS transistors.[99] Slow surface electronic states and traps, which lead to a prolonged drift of the characteristics, are always present on the interfaces obtained between InP and intrinsic oxides as well as other insulators.

The effects associated with the instability of the characteristics can be eliminated by employing thin (< 30 nm) oxide layers[119] consisting only of the phosphate $In(PO_3)_3$, in which the width of the forbidden gap is fairly considerable ($E_g \simeq 7$ eV). Under these conditions, the edge of the conduction band E_c in the oxide is higher by 2.3 eV than in InP, which ensures an adequate potential barrier preventing the injection of electrons from InP into the oxide.[56] In the case of thick oxide films, the outer layer of which consists partly of In_2O_3 having an appreciably lower E_g (~ 3.5 eV), the difference $E_c(In_2O_3) - E_c(InP)$ is apparently also small. This leads to the possibility of the tunnelling of electrons from InP through $In(PO_3)_3$ and into In_2O_3.[120] This factor is apparently the cause of the marked frequency dispersion and the hysteresis characteristics of the MOS capacitors prepared on the basis of thick oxides. Having etched away the outer layer of the anodic oxide leaving only the layer consisting of $In(PO_3)_3$, it is possible to eliminate the deficiencies noted above. Furthermore, this operation greatly diminishes the hygroscopicity of the specimens. Thus, whereas after the storage of unetched specimens for several hours in air an appreciable increase in the thickness of the initial anodic oxide (up to 40%) is observed, for the anodic oxide with an etched outer layer such a change is much slower (up to 30% in one month). Furthermore, annealing of an anodic oxide of this kind at 250 °C in nitrogen for 30 min stabilises its properties. Having sputtered a layer of Al_2O_3 onto it with a thickness of 100 nm, it was possible to obtain, on the basis of a semi-insulating InP substrate, a transistor with significantly more stable characteristics.[56]

Having selected the plasma oxidation conditions in such a way that the contents of In_2O_3 and P_2O_5 are reduced to a minimum, it is possible to obtain an interface with nearly theoretical electrical parameters.[61]

Under optimal conditions, the interface between InP and an intrinsic oxide is sufficiently ideal. During its formation, it is important to eliminate (bearing in mind the low thermal and

radiation stabilities of the InP surface) the possibility of both a general structural disordering[106, 121] and of the appearance of intrinsic lattice defects. For example, the phosphorus vacancies arising during the annealing of an absolutely clean (100) surface of InP in vacuo lead to an appreciable alteration of its properties and, in the view of a number of investigators, are responsible for the pinning of E_F.[122] One cannot also exclude the possibile formation on the InP surface of other types of intrinsic defects which may exist in the bulk of InP in the presence of an excess of one of the components.[123–125] This has been clearly demonstrated by Hu et al.,[127] who obtained the oxide by plasma oxidation under the conditions which excite electron cyclotron resonance. This process is closer to thermal than to anodic oxidation, although it does occur at room temperature. Indeed, after the formation in the plasma of an oxide film 9 nm thick, an appreciable amount of elemental phosphorus appears at the InP – intrinsic oxide interface according to XPES data. It was possible to eliminate this effect by placing a screen between the source of plasma and the InP surface, which greatly reduced the rate of growth of the oxide film (by a factor greater than 2) but eliminated the direct bombardment of the InP surface by high-energy ions. A layer of SiO_2 having a thickness of 70 nm was grown by the same method on the oxide 3 nm thick obtained in this way. The structures with the oxide grown in shielded plasma have a very low density of fast and slow surface electronic states.

3. Semiconductor solid solutions

Fairly satisfactory properties of the interface were obtained already in the first experiments on the formation of CdTe-based MOS structures. The phase equilibrium diagram for this compound also predicts equilibrium oxidation with formation of only one compound (Fig. 1*b*). Anodic,[128] thermal, chemical, and plasma[129] oxidation reactions were tested, but the best parameters of the interface and of the insulator itself were obtained for the thermal oxide. The properties of the MOS structures depend in many respects on the initial treatment of the semiconductor surface. It is not fortuitous that the best parameters were obtained after the preliminary annealing of CdTe under an atmosphere of hydrogen, which restores the stoichiometry of the CdTe surface disturbed by chemical polishing.

Despite the complexity of the chemical reactions occurring in the oxidation of $Hg_{1-x}Cd_xTe$, only $CdTeO_3$ is present at its interface with the anodic oxide (Fig. 6*a*). This is precisely why the interface before annealing has a very low density of the fast and slow surface electronic states, which is actually comparable to the density at the $Si-SiO_2$ interface.[24, 72] It has been shown[24] that the (100) surface of $Hg_{1-x}Cd_xTe$ can be brought into virtually ideal conformity with the (011) surface of $CdTeO_3$, which has the perovskite crystal lattice. This minimises the number of ruptured bonds at the interface. The interfaces between $Hg_{1-x}Cd_xTe$ and the anodic sulfide[88] and fluoride[89] also have a low density of the fast and slow surface electronic states. In the former case, this is associated with the fact that the interface actually represents a heterojunction formed by II–VI solid solutions, while the reason for the latter is that the cadmium oxide fluoride (Fig. 7*b*), the parameters of which are close to those of $CdTeO_3$, is always actually present at the $Hg_{1-x}Cd_xTe$–fluoride interface.

A high built-in charge, which always has a positive sign, is characteristic of the $Hg_{1-x}Cd_xTe$–anodic oxide interface. It has been suggested that the positive sign is due to positively charged oxygen vacancies.[72] This agrees well with the mechanism of ion transport during the growth of the anodic oxide and also with data for the cathodoluminescence of the anodic oxide on $Hg_{1-x}Cd_xTe$.[130] The latter data show that the radiative recombination centres are associated with the deficiency of oxygen in TeO_2 or in more complex compounds based on it. A significant disadvantage of the anodic oxide on $Hg_{1-x}Cd_xTe$ is its low thermal stability. Heating of *n*-type specimens at relatively low temperatures leads to an increase in the built-in charge, while heating of the *p*-type specimens results in the inversion of the type of conductivity, the thickness of the *n*-type layer produced reaching 40 μm depending on the temperature and duration of the annealing.[74–76] The mercury accumulated at the interface during anodic oxidation diffuses during annealing to the bulk of the crystal and is annihilated on recombining with mercury vacancies. This accounts for the inversion of the type of conductivity. The reactions occurring at the interface during annealing may serve as an additional source of mercury.

The $Hg_{1-x}Cd_xTe$ surface acquires *n*-type conductivity during natural, anodic, and plasma oxidations. On the other hand, the conductivity of the surfaces of PbSe, $Pb_{1-x}Sn_xSe$,[131] and $Pb_{1-x}Sn_xTe$ [132] is always of the *p*-type. Comparison of the phase equilibrium diagrams for $Hg_{1-x}Cd_xTe$ and lead and tin chalcogenides suggested[133] that the preferential oxidation of the chalcogen in the former case and of the metal in the latter is in fact responsible for the opposite type of surface conductivity in these materials. The presence of free chalcogen or metal atoms at the interface, appearing as a consequence of such oxidation, can exert a decisive influence on the entire assembly of defects in the oxide responsible for the built-in charge. This is indicated by data on the cathodoluminescence of the anodic oxides on $Hg_{1-x}Cd_xTe$ [130] and $Pb_{1-x}Sn_xTe$,[134] demonstrating the different nature of the radiative recombination centres. Furthermore, differences are manifested also in the mechanisms of mass transfer during the growth of anodic oxides on the surfaces of both materials.[69, 135] As a consequence of the excess of one of the components on the interface, as in the case of As in GaAs, the concentration of the intrinsic lattice defects increases. Different point defects, whose electrical behaviour and influence on the diffusion processes in the semiconductor have not yet been finally established, may occur in mercury and lead chalcogenides.[136–138] However, one may expect that their contributions to the properties of the interface will be different.

The same phenomena have been observed in the study of the $Hg_{1-x}Zn_xTe$–anodic oxide interface, where both the metal and the chalcogen are liberated according to the phase equilibrium diagram (Fig. 3*b*). The differences between the properties of the $Hg_{1-x}Zn_xTe$–anodic oxide and $Hg_{1-x}Cd_xTe$–anodic oxide interfaces can be accounted for by the competing influence of the elemental tellurium appearing in the region of the interface.[133] Firstly, the magnitude of the built-in charge in the $Hg_{1-x}Zn_xTe$-based MOS structures is smaller than in the analogous $Hg_{1-x}Cd_xTe$-based structures.[139–141] Secondly, the layer with *n*-type conductivity on $Hg_{1-x}Zn_xTe$ arises at higher annealing temperatures and its thickness is smaller by a factor of 2 than that of the anodic oxide on $Hg_{1-x}Cd_xTe$ obtained under similar conditions. This indicates a small amount of mercury liberated at the $Hg_{1-x}Zn_xTe$–anodic oxide interface. Similar changes are also observed during annealing for the $Hg_{1-x}Mn_xTe$–anodic oxide system.[75, 142] Since the zinc and manganese contents in the solid solutions investigated are low compared with the mercury contents, the liberation of tellurium is insignificant compared with mercury and there is a correspondingly small compensating effect.

The changes in the properties of the $Hg_{1-x}Cd_xTe$–anodic sulfide (or fluoride) interface are greater than the changes in the properties of the $Hg_{1-x}Cd_xTe$–anodic oxide interface. According to the phase equilibrium diagrams, mercury should not be liberated at all at the interface in such systems. Indeed, the sign of the built-in charge for the anodic sulfide is reversed,[88] while that for the fluoride, although remaining positive, is an order of magnitude smaller compared with the anodic oxide and its magnitude is to a large extent regulated by the conditions in the electrochemical process.[89] Finally, on heating both the sulfide and fluoride on $Hg_{1-x}Cd_xTe$, an *n*-type layer does not arise,[75, 142] which indicates the absence of the liberation of mercury at the $Hg_{1-x}Cd_xTe$–intrinsic insulator interface.

V. Current trends in the development of insulators for metal – insulator – semiconductor devices and protection of the surfaces of compound semiconductors

1. Gallium arsenide

In the development of a technology for the formation of GaAs-based insulators, it was necessary to exclude the possibility of the fortuitous oxidation of the semiconductor surface, for example on contact with the atmosphere between individual operations, and of a side oxidation reaction as a consequence of some kind of secondary process. New intrinsic defects of the As_{Ga} antistructural defect type must not arise under these conditions and structural disordering of the interface must not occur, i.e. it is essential to exclude all factors inducing the appearance of surface electronic states.

A theoretically ideal semiconductor–insulator interface can be obtained by growing epitaxial layers of a single crystal insulator on the semiconductor. Such insulators may be the alkaline earth metal fluorides CaF_2 and SrF_2. On evaporation in an ultrahigh vacuum, these materials sublime without dissociating, which makes it possible to obtain stoichiometric single crystal layers with the aid of molecular beam epitaxy. MIS structures based on the GaAs–SrF_2 and GaAs–CaF_2 systems have been investigated.[144,145] The differences between the types of chemical bonds as well as the lattice constants and thermal expansion coefficients of these fluorides and III–V semiconductors are responsible for the high density of surface electronic states at the interface, although it can in fact be diminished by rapid annealing. Best results have been obtained with the aid of the epitaxy of cubic gallium sulfide.[146,147] Bearing in mind that the discrepancy between the lattice constants of the two compounds is small and that the sulfur in gallium sulfide is satisfactorily compatible with the GaAs lattice (Fig. 8), it is possible to obtain an ideal interface with parameters indicating that there are good prospects for the practical employment of such structures.

An ideal interface can also be obtained by employing semiconductors of the same III–V group in which the width of the forbidden gap is large (quasi-insulators). The lattice constants of these semiconductors and GaAs should agree. A satisfactory interface with a low density of surface electronic states and a high stability has been obtained for the GaAs–$Al_xGa_{1-x}As$ structure,[148] but the gap between the bands of the insulator and the semiconductor is then too narrow (only 0.4 eV) to prevent the transfer of electrons from the semiconductor to the insulator. A larger gap between the bands exists in another couple, namely GaAs–ZnSe.[2]

Two-layer structures, in which the first layer, without adequate chemical stability primarily towards atmospheric oxygen, forms an interface with the required electrical parameters, while the second performs protecting functions, are promising.[2] According to the authors,[2] interfaces with GaAs having nearly ideal parameters are ensured by a monolayer of antimony, which gives rise to an ordered structure of the (110) surface of GaAs in which there are no ruptured bonds. The principal problem under these conditions is the creation of a second layer: it must be formed without disturbing the properties of the GaAs–Sb interface. This is achieved by sputtering on CaF_2. At any rate the GaAs surface passivated by sulfur remains stable after the deposition of CaF_2 even on annealing at temperatures up to 410 °C.[149]

Amorphous or crystalline germanium or silicon layers can also be employed as an intervening layer. The GaAs–Si–SiO_2, GaAs–Si–Si_3N_4, and GaAs–Si–AlN structures have been vigorously investigated recently.[150] The best results were obtained for GaAs–Si–Si_3N_4 when a layer of silicon was grown in the presence of atomic hydrogen. The parameters of such MIS structures approach those of the Si–SiO_2 system. This permits the hope that, by employing precisely this technology, it will be finally possible to create GaAs-based MIS devices.

2. Indium phosphide

The parameters of the InP–oxide interface are significantly higher than those of the GaAs–oxide interface. It is believed[150] that further improvement of the characteristics may be achieved only by employing a technology which excludes any kind of oxidation. Therefore many of the methods described above are used also for InP. These include epitaxy of the alkaline earth metal fluorides CaF_2[151] and $Ba_{1-x}Sr_xF_2$[152] and of the quasi-insulators $In_xAl_{1-x}As$.[144] Interesting results have been obtained for InP (as for GaAs) on deposition of an antimony monolayer.[122] However, it is still too early to speak of InP-based devices.

More promising results have been obtained on deposition of phosphorus[153] or boron[154] nitrides. However, it is then necessary to carry out the process under mild conditions which rule out a disturbance of the stoichiometry of the InP surface.

At the same time, the form of the phase equilibrium diagram for the InP–O system suggests that, in order to improve the parameters of InP-based MIS devices, there is no need at all to avoid oxidation but it is necessary to optimise the process in such a way that a thermodynamically stable phosphate phase is grown on the InP surface. This view is supported by the continuing development of different methods for the creation of oxide films — by anodic,[56] plasma,[61,155] photochemical,[156] and thermal[51] oxidation and by the thermal evaporation of P_2O_5.[157]

3. Semiconductor solid solutions

Intrinsic insulators are used quite widely for the passivation of the surfaces of devices based on $Hg_{1-x}Cd_xTe$ as a layer forming an interface with the semiconductor. The anodic oxide combined with thermally sputtered ZnS is used in photoresistors,[158,159] whilst the anodic sulfide in the same combination is employed in photodiodes.[6,160] Their main disadvantage is their low thermal stability. Some improvement is afforded by the replacement of the anodic oxide by the anodic fluoride.[6]

It is believed that a radical improvement of the properties of the $Hg_{1-x}Cd_xTe$–intrinsic insulator interface and of the thermal stability will be achieved by employing as the quasi-insulator wide-band semiconductors of the same group — CdTe and $Cd_{1-x}Zn_xTe$[159–162] and of $Cd_{1-x}Mn_xTe$ for $Hg_{1-x}Mn_xTe$.[163] These materials have a much higher E_g compared with the protected semiconductor, which makes the use of quasi-insulators in this case much more effective than for III–V semiconductors. The satisfactory correspondence of the crystal lattices makes it possible to obtain, using different epitaxial methods, an almost ideal interface between such semiconductors and $Hg_{1-x}Cd_xTe$.

The electrochemical methods for the generation of CdTe[164,165] on the $Hg_{1-x}Cd_xTe$ surface are also of interest. A single crystal interface cannot be obtained with their aid owing to the low process temperature, but it is possible to combine in one technological operation the precision chemical cleaning of the $Hg_{1-x}Cd_xTe$ surface and the deposition of CdTe. Interesting results have been obtained on electrochemical reconstruction of the $Hg_{1-x}Cd_xTe$ surface layer on ZnTe on which a layer of ZnS was subsequently deposited by means of gas-phase epitaxy.[166]

In conclusion one should note that the possibilities of generating on $Hg_{1-x}Cd_xTe$ a high-quality interface with the aid of classical insulators such as Al_2O_3,[167] SiO_2,[168] and their combinations[169] cannot be regarded as fully exhausted. Thus the best parameters of the interface for the $Hg_{1-x}Zn_xTe$ solid solution have in fact been obtained with the aid of SiO_2.[140] Incidentally, despite the disadvantages mentioned above, even oxidation has found an application in the creation of lasers based on $Al_xGa_{1-x}As$–GaAs quantum-well heterostructures[170,171] by virtue of the excellent optical characteristics of the oxides.

* * *

Comparison of the entire set of experimental data obtained in studies of compound semiconductor–intrinsic insulator interfaces with the corresponding phase equilibrium diagrams has shown that in many instances there is a direct relation between the characteristics of the phase diagrams such as segregation of the metal or the nonmetal and the intrinsic lattice defects arising under these conditions, on the one hand, and the electrophysical parameters of the interface, on the other.

All this demonstrates that the ideas underlying the models of intrinsic defects[101,104] for the III–V compounds are fully applicable also to the analysis of the interfaces involving the II–VI and IV–VI semiconductors.

II.	Addition reactions	641
III.	Elimination reactions	649
IV.	Substitution reactions	649
V.	Oxidation reactions	654
VI.	Other reactions	655
VII.	The practical use of trichloroethylene and its derivatives	656

Abstract. The literature data on the chemistry of trichloroethylene are surveyed. Reactions involving the addition of inorganic and organic reagents to trichloroethylene are examined and cycloaddition reactions with participation of trichloroethylene are classified. A systematic account is given of the reactions of trichloroethylene with various nucleophiles occurring with the substitution of 1 – 3 chlorine atoms by nucleophilic residues. The elimination and oxidation reactions of trichloro-ethylene as well as aspects of the practical application of its derivatives are considered. The analysis demonstrates the extensive possibilities for the synthesis of polyfunctional organic compounds of various classes from trichloroethylene. The bibliography includes 310 references.

I. Introduction

Trichloroethylene (TCE) is nowadays one of the main products of organochlorine synthesis, the annual production of which is more than 1 million tonnes.[1] Its practical applications are exceptionally extensive and are being continually expanded. It is one of the most important technical solvents and is used in various branches of industry and for domestic purposes. It is employed as an inhalation agent for narcosis and anaesthesia in medicine. Industrial methods of synthesis from trichloroethylene of a number of important products, including chloroacetic acid, pentachloroethane, and dichloroacetyl chloride, have been developed.

The synthetic possibilities of TCE as a polyfunctional compound containing three chlorine atoms and a carbon – carbon double bond are very great. It enters into chemical reactions of various types (substitution, elimination, addition, oxidation, etc.), which makes it a valuable and in certain cases an irreplaceable intermediate in organic synthesis.

Received 10 May 1994
Uspekhi Khimii **63** (8) 673 – 692 (1994); translated by A K Grzybowski

The publication of a large number of studies on TCE chemistry, which have revealed various new aspects of its synthetic and practical use, required a systematic survey. The very first data on TCE chemistry were briefly described in two communications.[2,3] The state of research in TCE chemistry towards the beginning of the 1980s was given in greater detail in a monograph.[4] Extensive information about the reactions of TCE, published during the last 10 – 15 years, have still not been surveyed and analysed critically. Only reactions involving the addition to TCE of compounds containing N – Cl bonds and the thiylation of TCE have been considered in recently published reviews.[5-7]

Experimental data on the chemical reactions of TCE collected and dealt with systematically in the present review include communications and patent data up to 1993.

II. Addition reactions

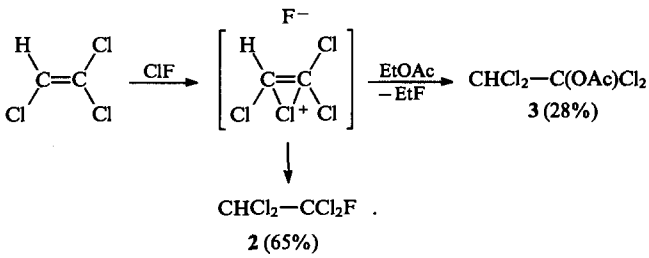
Addition to TCE has been used to synthesise a wide variety of polyfunctional organochlorine compounds. This reaction of TCE is one to have been most thoroughly investigated.

1. Halogenation

Initial studies of the reaction of halogens (chlorine, bromine, and fluorine) with TCE showed that it leads mainly to the formation of the corresponding adducts — 1,2,2-trichloro-1,2-dihaloethanes.[2-4] Iodine does not react with TCE; positive results were not obtained even when the reaction was initiated by γ-radiation.[8]

Pentachloroethane **1** can be synthesised by the addition of chlorine to TCE in both gas and liquid phases.[9] The chlorination of TCE in the dark proceeds only slightly, but the rate of reaction increases sharply in the presence of ethylene.[10] When TCE is chlorinated with a solution of chlorine in carbon tetrachloride (under illumination from an incandescent filament lamp), pentachloroethane is formed in a quantitative yield.[11] The role of radical addition increases significantly in the presence of complex-forming solvents (benzene, carbon disulfide).

The interaction of TCE with chlorine in liquid hydrogen fluoride proceeds by an electrophilic mechanism via the formation of ion pairs and leads to compound **1** and the coupled chlorofluorination products — 1,1,2,2-tetrachloro-1-fluoroethane. The overall yield of pentachloroethane and tetachlorofluoroethane relative to the TCE which has reacted is 82% and their ratio is 85 : 15.[12]



Under pressure and in the presence of free radical initiators, chlorination of TCE is more far reaching, leading ultimately to the formation of CCl_4 and C_2Cl_6.[13]

Other chlorinating agents have no advantages over chlorine. Thus the chlorination of TCE with a solution of trichloroamine in methylene chloride (molar ratio NCl_3 : TCE = 0.04 : 0.09) in the presence of small amounts of added benzoyl peroxide (BP) affords pentachloroethane in 41% yield.[14] In the interaction of perchloryl fluoride with TCE in the presence of aluminium halides, addition of two halogen atoms from the aluminium halide is observed. When $AlCl_3$ is used, pentachloroethane is produced.[15] The oxychlorination reaction of TCE in the presence of hydrogen chloride, oxygen, and the Deacon catalyst involves additive chlorination with formation of compound **1**, which is subsequently dehydrochlorinated to tetrachloroethylene.[16] When epoxyethane or epoxycyclohexane reacts with TCE and liquid chlorine, coupled chlorination of TCE accompanied by telomerisation is observed.[17]

Bromine adds readily to TCE both in the presence and absence of catalysts, affording a 1,2-adduct — 1,2-dibromo-1,1,2-trichloroethane.[2,18]

The interaction of TCE with fluorine proceeds less selectively than with chlorine and bromine, a mixture of chlorofluoroalkanes being formed; the main product is 1,1,2-trichloro-1,2-difluoroethane.[2] The formation of side products is appreciably reduced when the reaction is carried out at 70–85 °C.[19,20] Data on the gas-phase fluorination of TCE in the presence of chromium catalysts have been published.[21,22]

The reactions of TCE with mixed halogens have been investigated for the reaction with chlorine monofluoride, which added readily to TCE.[23] It is suggested that, owing to the appreciable polarity of the Cl–F bond and the high electrophilicity of the chlorine atom in the ClF molecule, the addition is electrophilic. In order to establish the mechanism of this reaction, the chlorofluorination was carried out in the presence of an external nucleophile (ethyl acetate).[24] The reaction gave a mixture of products **2** and **3**, the formation of which may be represented by the following scheme:

The results demonstrate that the mode of addition of both the internal (F^-) and the external (EtOAc) nucleophiles to TCE is virtually the same.

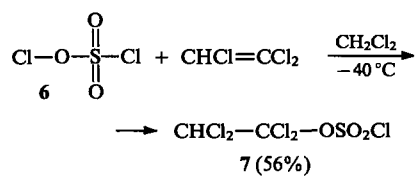
The reaction of TCE with the SbF_5–HF–Cl_2 system has been investigated[25] and it has been shown that this system is a source of stoichiometric equivalents of chlorine monofluoride. The reaction afforded the coupled halofluorination product $CHCl_2CCl_2F$ in a quantitative yield. When the SbF_5–HF–Br_2 system was used, the product was 2-bromo-1,1,2-trichloro-1-fluoroethane.

2. Hydrohalogenation

On reaction with excess gaseous dry hydrogen chloride in the presence of small amounts of $FeCl_3$ at room temperature, TCE gives 1,1,1,2-tetrachloroethane **4** in 49% yield. When $FeCl_3$ is replaced by $AlCl_3$ (5%–10%), the yield of the adduct **4** increases to 86%–88% (reaction temperature 30–40 °C). At a higher temperature (50 °C and above), the yield of compound **4** falls and the formation of 1,1,2,2-tetrachloroethane, 1,1,2,4,4- and 1,1,2,3,4-pentachlorobutadienes, and hexachlorobenzene is observed.[2] A method has been proposed recently for the synthesis of tetrachloroethane **4** by hydrochlorination of TCE in the presence of $FeCl_3$ or $AlBr_3$ at a pressure exceeding 500 kPa and at a temperature in the range 10–160 °C. Thus, when gaseous HCl was introduced into a mixture of 2 moles of TCE and 1% of $FeCl_3$ (relative to the weight of TCE) up to a pressure of 3.46 MPa and the mixture was heated for 3 h at 70–80 °C, the target product was obtained in 96.4% yield.[26]

Hydrogen bromide adds to TCE only in the presence of catalysts. Ionic addition (small amounts of added $FeCl_3$ and $AlCl_3$) follows the Markovnikov rule and leads to the formation of 1-bromo-1,1,2-trichloroethane (80%). In the presence of peroxides, anti-Markovnikov addition of hydrogen bromide to TCE occurs (the Kharasch 'peroxide effect') with the exclusive formation of 2-bromo-1,1,2-trichloroethane (yield 91%).[27]

The interaction of hydrogen fluoride with TCE under the influence of various catalysts has been described in the patent literature.[28–36] These reactions proceed in a complex manner and lead to a mixture of chlorofluoro-compounds, among which derivatives containing 3–4 fluorine atoms predominate. Thus, when a gaseous stream of TCE and HF (1 : 3.5) is passed over γ-Al_2O_3 on a metallic support at 230 °C, mainly 2-chloro-1,1,1-trifluoroethane **5** is formed (yield 91.5%).[28] Reaction of TCE with hydrogen fluoride proceeds similarly in the presence of chromium(III) halides on activated charcoal.[29] When HF is brought into contact with TCE over a chromium catalyst [1%–10% chromium(III) oxide] deposited on β- and/or α-AlF_3 and treated with 1,2-dichloro-1,1,2,2-tetrafluoroethane, 1,1,1-trifluoroethane is formed at 350 °C in 95% yield.[30] When the 6% CrO_3 + 3% $TiCl_3/Al_2O_3$ catalyst treated beforehand with hydrogen fluoride is used, the products of the reaction of TCE with HF at 500 °C are compound **5** (50%) and 1,1,1,2-tetrafluoroethane (20%).[31] According to other data,[32,33] the halides TaF_5, NbF_5, $MoCl_5$, and $TiCl_4$ are also catalysts of the reaction of HF with halogenated alkenes, including TCE.



The reaction of TCE with anhydrous HF under pressure in an autoclave takes place at 115–130 °C. In the presence of fluorination catalysts (arsenic and antimony compounds to which transition metal derivatives have been added[34–36]), the yield of the main reaction product — 2-chloro-1,1,1-trifluoroethane **5** — reaches 87%–92%.

Methods for the synthesis of monofluoro- and difluoro-derivatives from TCE have been proposed in recently published patents.[37,38] It has been shown[37] that, in the presence of an aluminium oxide–magnesium oxide catalyst (Al_2O_3 : MgO = 3 : 1) subjected to a preliminary treatment with HF, the main products of the interaction of TCE with HF were 1,1,2-trichloro-1-fluoroethane (53%) and 1,2-dichloro-1,1-difluoroethane (41.5%). The formation of compound **5** was observed in this process, but its yield did not exceed 1.1%. 1,1,2-Trichloro-1-fluoroethane — the product of the Markovnikov addition of hydrogen fluoride to TCE — was obtained in 80% yield in the presence of WF_6 at 50–150 °C and at a pressure of 137 kPa.[38]

Hydrogen iodide does not add to TCE. After prolonged illumination of a mixture of TCE with hydrogen iodide, only partial reduction of TCE to 1,1,2-trichloroethane was observed.[2]

3. Addition of certain other reagents

Chlorine chlorosulfonate **6**, which has become available recently, readily undergoes Markovnikov addition to TCE to form 1,1,2,2-tetrachloroethyl chlorosulfonate **7**.[39,40]

Chlorine and fluorine fluorosulfonates react similarly with TCE, affording respectively 1,1,2,2-tetrachloroethyl fluorosulfonate (yield 80.7%) and 1,1,2-trichloro-2-fluoroethyl fluorosulfonate (yield 70%).[41,42] After brief heating of a mixture of TCE and sulfur dichloride (2:1) in the presence of Bu_3PO_4 at 110 °C, 1,1,2,2-tetrachloroethanesulfenyl chloride is formed.[43] Under radical conditions this reaction gives a similar product only after prolonged irradiation of the mixture, in the presence of small amounts of added phosphorus trichloride, by light from a mercury lamp.[44]

UV irradiation of equimolar amounts of thiocyanogen chloride and TCE in acetic acid gave two α-chloro-β-thiocyanato-derivatives with preferential formation of the anti-Markovnikov isomer: $CHCl_2C(SCN)Cl_2$ (yield 52%) and $CHCl(SCN)CCl_3$ (yield 6%).[45] It is noteworthy that TCE does not react with thiocyanogen chloride heterolytically.[46]

In the presence of SbF_3, the reaction of trifluoromethyl hypochlorite with TCE gives a high yield of 1,1,2,2-tetrachlorotrifluoromethoxyethane.[47]

4. Addition reactions leading to the formation of new C–C bonds

Reactions involving the condensation of various organic compounds with TCE have opened a pathway to the synthesis of compounds with dichloro- and trichloro-vinyl groups which are difficult to synthesise. Such reactions proceed both in the presence of radical initiators and under the influence of the Friedel–Crafts catalysts.

a. Radical condensation

The chlorovinylation of saturated hydrocarbons with the aid of TCE, which proceeds on treatment with organic peroxides, was first achieved by Schmerling[48] in 1949. He later investigated the condensation of TCE with alkenes,[49–51] alicyclic compounds,[52] and benzene derivatives.[53] The products of these reactions — compounds with β,β-dichlorovinyl groups — have found applications in the synthesis of alkenynes,[49] chlorinated alkenylbenzenes,[50] and cycloalkenes containing a triple bond in a side chain.[52]

A series of patents have been devoted to the development of methods of synthesis of the practically important 1,1-dichloro-4-methylpenta-1,3-diene, which is based on the condensation of TCE with isobutene (or a *tert*-butyl halide).[54–58]

This reaction can be achieved both in the liquid and gas phases (125–550 °C) in the presence of 0.05–5 mol% of radical initiators. However, it is noteworthy that a high yield of the target product is attained only when a twofold to threefold excess of TCE is employed. On the other hand, in the presence of an excess of isobutene, preferential formation of 2,5-dimethylhexa-1,5-diene is observed.

The photochemical addition of bromotrichloromethane to TCE leads to the formation of a complex mixture of products, among which the following have been found: $CHClBr-CBrCl_2$ (2%), $CCl_3-CHCl-CBrCl_2$ (< 1%), CCl_3-CCl_3 (30%), $CBrCl=CHCl$ + $CHBr=CCl_2$ (26.5%), $CCl_3-CCl=CHCl$ (0.9%), $CCl_3-CH=CCl_2$ (29.1%), and $CHCl_2-CBrCl_2$ (11.9%).[59] The kinetics and mechanism of this reaction have been investigated.[60]

The interaction of TCE with hexane in the presence of *tert*-butyl peroxide (TBP) has been studied in detail.[61] It has been established that the reactivities of the hydrogen atoms of the first, second and third carbon atoms in hexane are respectively 0.04, 1.68, and 1.0. The chlorovinylation of hexane occurred mainly in the 2-position and to a lesser extent in the 3-position. The formation of the main products of this reaction can be represented schematically as follows:

$$ROOR \longrightarrow 2\,RO^{\cdot}$$

$$RO^{\cdot} + C_6H_{14} \longrightarrow ROH + {}^{\cdot}C_6H_{13}$$

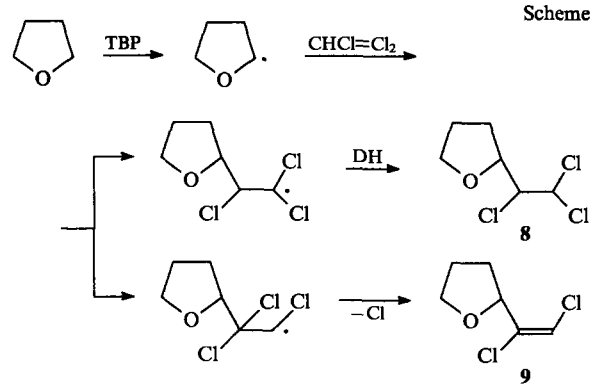
$${}^{\cdot}C_6H_{13} + CHCl{=}CCl_2 \longrightarrow C_6H_{13}{-}CHCl{-}{}^{\cdot}CCl_2$$

$$C_6H_{13}{-}CHCl{-}{}^{\cdot}CCl_2 + C_6H_{14} \longrightarrow$$

$$\longrightarrow C_6H_{13}{-}CH{=}CCl_2 + HCl + {}^{\cdot}C_6H_{13}$$

R = Bu^t; ${}^{\cdot}C_6H_{13}$ = $MeC^{\cdot}HBu^n$ or $EtC^{\cdot}HPr^n$.

When hexane is treated with a mixture of TCE and carbon tetrachloride, the main reaction product is 2-chlorohexane and dichlorovinyl derivatives are not then formed.



The high-temperature condensation of TCE with naphthalene at 535 °C leads to a complex mixture of isomeric products — *cis*-RCCl=CHCl, *trans*-RCCl=CHCl, $RCH=CCl_2$, *cis*-R'CCl=CHCl, *trans*-R'CCl=CHCl, and $R'CH=CCl_2$ (R = β-$C_{10}H_7$, R' = α-$C_{10}H_7$).[62] The isomer $RCH=CCl_2$ predominates, but it could only be isolated in 10.6% yield in a pure form, which undoubtedly lowers the preparative value of this reaction.

Reaction of TCE with 1- and 2-methylnaphthalenes proceeds via the side chain to form a mixture of the corresponding dichloropropenylnaphthalenes.[63] Under these conditions, the main products contained the α,α-dichloropropenyl fragment (yield ~90%), which makes this reaction preparatively promising.

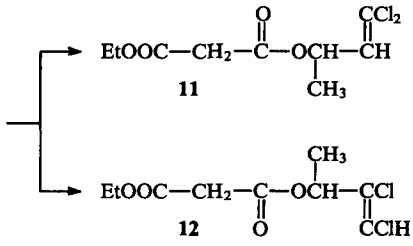
The addition to TCE of *m*-carbaboran-9-yl radicals, formed on photolysis of bis(*m*-carbaboran-9-yl)mercury, has been achieved recently.[64] The radical-adduct obtained is stabilised by elimination of a chlorine atom, affording 9-(2,2-dichlorovinyl)-*m*-carbaborane in 50% yield; 9-chloro-*m*-carbaborane (8%) and *m*-carbaborane (10%) were also isolated.

In the presence of TBP, tetrahydrofuran reacts with TCE to form 1,2,2-trichloro-1-(tetrahydro-2-furyl)ethane **8** (main product), 1,2-dichloro-1-(tetrahydro-2-furyl)-ethylene **9**, and 1,2-dichlorohex-1-en-3-one.[65] The presence of 1,2-dichlorohex-1-en-3-one among the reaction products confirms that hydro-2-furyl radicals arising on treatment with the peroxide are consumed in both addition and isomerisation reactions. The formation of the first two products is presented in Scheme 1.

Scheme 1

DH = hydrogen donor.

It has been shown that the phenyl radicals obtained on decomposition of 2-phenylazopropan-2-ol add to the less-substituted carbon atom of TCE. The $PhCHCl-{}^{\cdot}CCl_2$ radicals are formed and stabilised in this case by hydrogen atom abstraction, and not by chlorine atom loss, affording trichlorophenylethane in 48% yield. The interaction of TCE with 1-cyclohexenyl radicals, formed on decomposition of 1-(1-azacyclohexenyl)cyclohexanol, gives a product with a similar group in the side chain — cyclo-$C_6H_9CHClCHCl_2$ (23%).[66]



Syntheses based on the reaction of TCE with alcohols, acids, ethers, and amines have opened a pathway to the preparation of a whole series of polyfunctional compounds which were previously difficult to obtain. Thus the reaction of TCE with methanol (525–540 °C), initiated by CCl_4 and $CHCl_3$ in a quartz flow reactor, leads to $CCl_2=CHCH_2OH$ in 22% yield.[67] A method has been developed for the synthesis of chlorinated alcohols of the type $CHCl_2CCl_2CRR'OH$ and $CCl_2=CClCRR'OH$ on the basis of the reaction of alcohols RR'CHOH (where R and R' = Alk or H) with TCE in the presence of organic peroxides.[68,69]

2-Alkyl-3,4-4-trichlorobutyric acids have been synthesised in preparative yields from TCE and carboxylic acids, having an α-hydrogen atom, in the presence of peroxide initiators at 40–200 °C.[70]

Esters react with TCE under similar conditions, mainly the α-carbon atom of the alcohol component of the ester molecule participating under these conditions in the formation of a new carbon–carbon bond in the adducts.[71,72] The reaction of diethyl malonate **10** with TCE proceeds via two pathways with formation of compounds **11** and **12**.

$$CH_2(COOEt)_2 + CHCl=CCl_2 \longrightarrow$$

10

11 **12**

Dichlorovinyl-substituted amines $C_7H_{15}CH(CH=CCl_2)NH_2$ and *cyclo*-$C_6H_{10}(CH=CCl_2)NH_2$ have been obtained by the reaction of TCE with the corresponding amines in the presence of TBP.[73]

b. Heterolytic addition

The synthesis of the practically important nonachloro-pentene is based on the reaction of hexachloropropene with TCE on heating in the presence of catalysts [$AlCl_3$ and metallic aluminium in proportions of (2–6):1].[74]

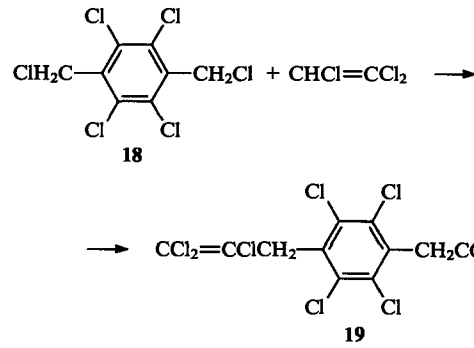
Aromatic compounds interact with TCE to form condensation products. However, one should note that the reactions of benzene and ethylbenzene with TCE are accompanied by appreciable tar formation and are of no practical value.[75,76] Benzene derivatives **13**, containing between 2 and 4 substituents, react with TCE, affording substituted α,β-dichloro-styrenes **14** in preparative yields.[77]

$$R_nC_6H_{6-n} + CHCl=CCl_2 \xrightarrow{AlCl_3} R_nC_6H_{5-n}CCl=CHCl$$

13 **14**

R = Alk, Hal, Alk_{Hal}; n = 2–4.

Polychlorotoluenes **15** react with TCE to form the chlorinated propenylbenzenes **16** and **17**.[78,79]



$$RCl + CHCl=CCl_2 \longrightarrow RCCl=CCl_2 + HCl$$

15 **16, 17**

R = $C_6Cl_5CH_2$ (**16**), $C_6Cl_5CCl_2$ (**17**).

It is noteworthy that, apart from compound **17**, *cis*- and *trans*-$C_6Cl_5-CCl=CCl-CCl_3$, $C_6Cl_5\overline{C=CCl(CCl_2)_2}CCl_2$ and *trans*-$C_6Cl_5-CCl=CClCCl_2CHClCCl_3$ are also formed in the reaction of TCE with perchlorotoluene.

2,3,5,6-Tetrachloro-1,4-bis(2,3,3-trichloroprop-2-enyl)-benzene **19** is a product of the interaction of 2,3,5,6-tetrachloro-1,4-bis(chloromethyl)benzene **18** with TCE. Its formation may be represented by the following scheme:[80]

18 **19**

Substituted chlorodiphenylethylenes (p-$ROC_6H_4)_2C=CHCl$ (R = H, Me) are obtained by the reaction of PhOR with TCE in the presence of trifluoromethanesulfonic acid.[81]

In the presence of sulfuric acid, trichloroethylene and formaldehyde condense, (the Prins reaction), with formation of α-chloro-β-hydroxypropionic acid **20**, which is dehydrated under the reaction conditions, giving α-chloroacrylic acid **21**. In the presence of alcohol, the reaction product is methyl α-chloro-acrylate **22**.[82]

$$CH_2O + CHCl=CCl_2 \xrightarrow{80\%\ H_2SO_4} HOCH_2-CHCl-COOH \longrightarrow$$

20

$$\xrightarrow{H^+,\ T} CH_2=CCl-COOH$$

21

$$\xrightarrow{H^+/EtOH} CH_2=CCl-COOEt$$

22

The condensation of TCE with bis(chloromethyl)ether in methylene chloride or carbon disulfide in the presence of aluminium chloride proceeds readily. The reaction product is bis-(2,3,3,3-tetrachloropropyl) ether **23** (yield 87.5%).[83,84] The ether **23** can be obtained using 1,3,5-trioxane instead of bis(chloromethyl) ether, which is a powerful lachrymator. When dry hydrogen chloride was passed through a mixture of TCE, 1,3,5-trioxane, and aluminium chloride, the yield of the ether **23** was 92%.

$$+ CHCl=CCl_2 \xrightarrow{HCl,\ AlCl_3} (CCl_3CHClCH_2)_2O$$

23

On treatment with zinc, perfluoroalkyl iodides and TCE condense with formation of β,β-dichlorovinylperfluoroalkanes $R_FCH=CCl_2$, which are the starting compounds in the synthesis of valuable perfluoroalkanoic acids.[85]

5. Addition reactions leading to the formation of a carbon–heteroatom bond

a. Radical thiylation

The reaction of aromatic thiols **24** with TCE in the presence of benzoyl peroxide (BP) leads to aryl β,β-dichlorovinyl sulfides **25**.[86–89]

$$XC_6H_4SH + CHCl=CCl_2 \xrightarrow[-HCl]{BP} XC_6H_4S-CH=CCl_2$$

24 **25**

X = 4-MeO, 4-Me, 3-Me, H, 4-Cl, 4-NO_2.

Diaryl disulfides are side products in this reaction, while in the interaction of TCE with *p*-nitrothiophenol oxidation products of β,β-dichlorovinyl *p*-nitrophenyl sulfide—the corresponding sulfone and sulfoxide—were detected.

Thiylation of TCE by aliphatic thiols, which leads also in this case to the formation of the corresponding β,β-dichlorovinyl sulfides, can be more conveniently carried out with irradiation by UV light and heating of the reaction mixture (the TCE : thiol ratio varies from 3 : 1 to 4 : 1).[88,89] The free-radical chlorovinylation of diaryl disulfides **26** by TCE leads to the formation of a complex mixture of products.[90,91]

$$ArSSAr + CHCl{=}CCl_2 \xrightarrow{h\nu} ArS{-}CH{=}CCl_2 + ArS{-}CCl{=}CHCl + ArS{-}CCl{=}CCl_2 + ArS{-}CHCl{-}CCl_3 + CCl_2{=}CH{-}CCl_2{-}CHCl_2$$

26 **25** **27** **28** **29** **30**

Ar = *p*-MeC_6H_4, Ph, *p*-ClC_6H_4.

Earlier studies on the free-radical thiylation of TCE and other polychloroalkenes and diaryl sulfides have been surveyed by Voronkov et al.[7]

b. Synthesis of compounds with C–N and C=N bonds

Voronkov and coworkers[92,93] investigated the addition of compounds containing a N–Hal bond to TCE and demonstrated its extensive synthetic possibilities. Thus, the reaction of *N,N*-dichloroarenesulfonamides **31** with TCE leads to pentachloroethane and (trichloroethylidene)arenesulfonamides **32**.[92,93]

$$RNCl_2 + CHCl{=}CCl_2 \longrightarrow RN{=}CHCCl_3 + CHCl_2{-}CCl_3$$

31a–c **32a–c** **1**

R = $PhSO_2$ (**a**), *p*-$MeC_6H_4SO_2$ (**b**), *p*-$ClC_6H_4SO_2$ (**c**).

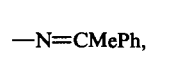
The reactions of TCE with *N,N*-dibromobenzenesulfonamide,[94] *N,N*-dibromourethane,[95] and *N,N*-dichloroethylphosphoramide[96] proceed similarly. They afforded respectively *N*-(2-bromo-2,2-dichloroethylidene)benzenesulfonamide, *N*-(2-bromo-2,2-dichloroethyl)ethoxycarbonylimine, and 1,1,1-trichloro-2,2-bis(diethylphosphoramido)ethane. The interaction of *N,N*-dichlorourethane with TCE leads to chloral *N*-ethoxycarbonylimine.[97] When water is introduced into the reaction mixture, chloral reacts with it and the urethane formed as a side product, giving 2,2,2-trichloro-1,1-bis(*N*-ethoxycarbonylamino)ethane (50%) and 2,2,2-trichloro-1-(*N*-ethoxycarbonylamino)-1-hydroxyethane (20%).[98] The free-radical mechanism of the reactions involving the addition of *N,N*-dichlorobenzenesulfonamide and *N,N*-dichlorourethane to TCE was subsequently confirmed.[99]

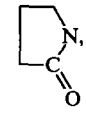
It has been shown[100] that the reactions of *N,N*-dichloroacetamide **33a** and *N,N*-dichlorobenzamide **33b** with TCE under an inert atmosphere give reaction products of the corresponding chloral acylimines **34a** and **34b**—1,1-diacetamido-2,2,2-trichloroethane **35a**, 1,1-dibenz-amido-2,2,2-trichloroethane **35b**, *N*-(2,2,2-trichloro-1-hydroxy-ethyl)acetamide **36a**, *N*-(2,2,2-trichloro-1-hydroxyethyl)benzamide **36b**, and pentachloroethane:

$$RCONCl_2 + CHCl{=}CCl_2 \longrightarrow RCON{=}CHCCl_3 + CHCl_2{-}CCl_3$$

33a,b **34a,b** **1**

$RCONH_2$ | H_2O



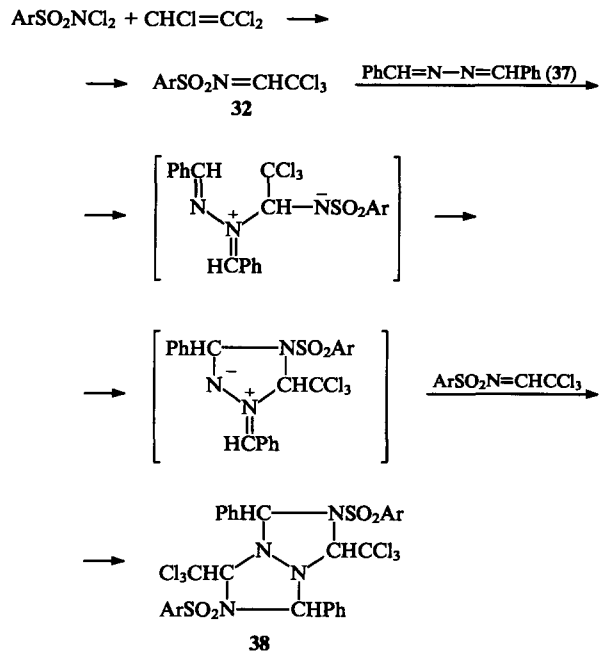


$(RCONH)_2CHCCl_3$ **35a,b** $RCONHCH(OH)CCl_3$ **36a,b**

R = Me (**a**), Ph (**b**).

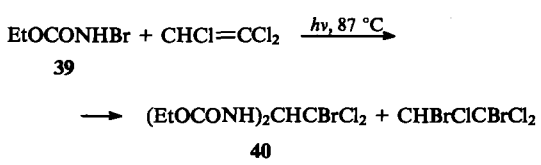
The high electrophilicity of the acylimines obtained from trichloroethylidenearenesulfonamides and TCE made it possible to introduce them into reactions with nucleophiles, without preliminary isolation, and to develop ways of obtaining different polyfunctional compounds having the general formula

$CCl_3CHR'(NHSO_2R)$ (Refs 101–104)



R = Ph, 4-MeC_6H_4;

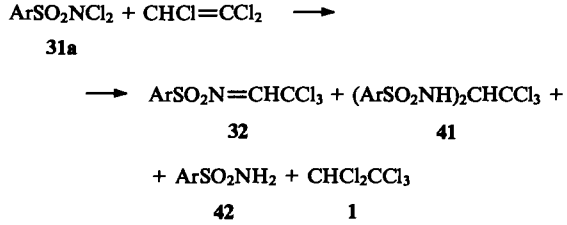
R′ = OH, OMe, OEt, OPh, $PhSO_2NH$, 4-$MeC_6H_4SO_2NH$, PhC(O)NH, MeC(O)NH, OBu^n, OCH_2CH_2Cl, O—N=CMePh,  , O—N=CMeBu^t, MeCOO, SCH_2COOH,  , PhNH,  , PhNHNH, PhNHC(O)NH, MeNH, Bu^tNH.



The reaction of *N*-(2,2,2-trichloroethylidene)arenesulfonamides, obtained from *N,N*-dichloroarenesulfonamides and TCE, with bifunctional nucleophiles such as mercaptoethanol and monoethanolamine proceeds via the mercapto- and hydroxy-groups respectively, giving the corresponding adducts—*N*-[2,2,2-trichloro-1-(2-hydroxyethylthio)ethyl]- and *N*-[1-(2-aminoethoxy)-2,2,2-trichloroethyl]-arenesulfonamides; in reactions with ethylene glycol, the products of both mono- and bis-*o*-amidoalkylation of the latter were obtained: *N*-[2,2,2-trichloro-1-(2-hydroxyethoxy)ethyl]arenesulfonamides and 1,2-(1-arenesulfonamido-2,2,2-trichloroethoxy)ethanes. The products of the reactions of *N*-(2,2,2-trichloroethylidene)arenesulfonamides with mercaptoethanol—*N*-[2,2,2-trichloro-1-(2-hydroxyethylthio)ethyl]arenesulfonamides—give rise to 3-arenesulfonyl-2-trichloromethyl-1,3-thiazolidines on successive treatment with thionyl chloride and then alkali.[105]

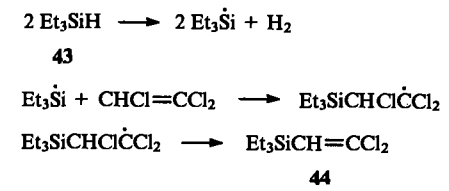
In the reactions of chloral arenesulfonylimines **32** with benzylideneazine **37**, the latter behaves as a 1,3-dipolar reagent, which combines with 2 moles of the imine to form 1,3,5,7-tetraazabicyclo[3.3.0]octanes **38**.[106]

It has been shown recently[107] that the product of the interaction of *N*-bromourethane **39** with TCE is 2-bromo-2,2-dichloro-1,1-di(ethoxycarbonylamino)ethane **40**. The reaction mechanism includes a series of processes—disproportionation of *N*-bromourethane to *N,N*-dibromourethane and urethane, the reaction of *N,N*-dibromourethane with TCE to form *N*-(2-boromo-2,2-dichloroethylidene)ethoxycarbonylamine, and the addition of urethane to the latter—which lead to the final product **40**.

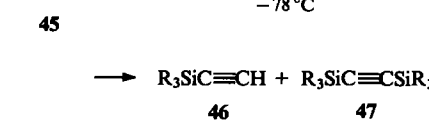


Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4.

The reactions of *N*-haloamides with TCE have been considered in greater detail in two reviews,[5,6] covering studies up to and including 1987.

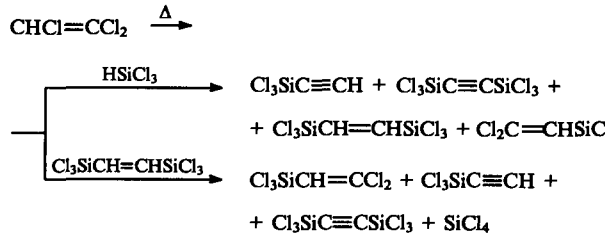


The ionic addition of *N*-haloamides to unsaturated compounds, including TCE, has been studied inadequately compared with the radical addition. It is known only that the interaction of *N*,*N*-dichloroarenesulfonamide **31a** with TCE in the presence of Lewis acids gives a complex mixture of compounds **1**, **32**, **41**, and **42**.[108,109]



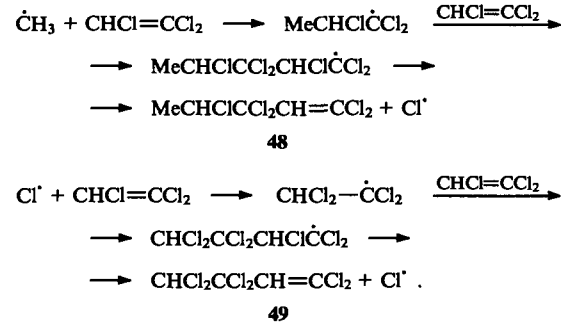
The reaction of TCE with the amide **31a** on heating and subsequent addition of acetamide to the reaction mixture leads to $PhSO_2NHCH(NHCOMe)CCl_3$. When acetoxime was used instead of acetamide, the product $PhSO_2NHCH.(ON=CMe_2)CCl_3$ was obtained.[108] It has been shown that *N*-(2,2,2-trichloro-ethylidene)arenesulfonamides can be used, without isolating them from the reaction mixture, as arenesulfonamidoalkylating agents. The *C*-alkylation of thiophene[110] and aromatic compounds[111] has been achieved with their aid.

c. Synthesis of compounds with a C–Si bond



The dichlorovinylation of triethylsilane **43** has been carried out with the use of TCE (the reaction is initiated by γ-radiation). The formation of dichlorovinyltriethylsilane **44** can be represented as a free-radical addition–elimination mechanism.[112]

The interaction of trialkylchlorosilanes **45** with TCE in the presence of lithium gives the trialkylethynylsilanes **46** in 44%–54% yield. The side products of this reaction are bis(trialkylsilyl)alkynes **47**.[113]



The gas-phase thermal reactions of TCE with trichlorosilane[114] and 1,2-bis(trichlorosilyl)ethylene[115] are more complicated.

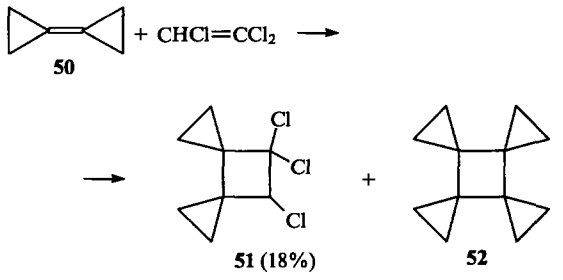
Other organosilicon compounds with ethynyl groups—diorganoethynylchlorosilanes and diorganoethynylalkoxysilanes—have been obtained by the reaction of TCE with diorganodichlorosilanes and diorganoalkoxychlorosilanes respectively in $PO(NMe_2)_3$ in the presence of zinc dust.[116]

6. Dimerisation of trichloroethylene

On treatment with various initiators, TCE can dimerise to form $C_4H_2Cl_6$ or products of its dehydrochlorination having the composition C_4HCl_5.[117–121] Despite the fact that numerous studies were devoted to these processes, in particular the reactions occurring in the presence of free-radical initiators, the available information about the structure of the dimer formed remained contradictory for a long time.[117] It has been shown recently that the products of the reaction of acetyl peroxide with TCE are 1,1,3,3,4-pentachloropent-1-ene **48** and 1,1,3,3,4,4-hexachlorobut-1-ene **49** (in yields of 0.6 and 4.0 mole per mole of the peroxide respectively). The formation of these substances can be explained in terms of the following scheme:[122]

Hexachlorobutene **49** is a readily available and extremely valuable organic intermediate. The synthetic possibilities of compound **49** and of its derivatives have been reflected in a large series of studies by the authors of the present review.[123–133]

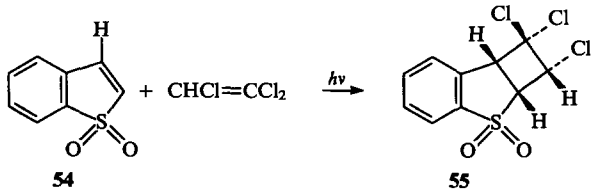
The dimerisation of TCE under the influence of fluorosulfonic acid proceeds differently: two hexachlorobutenes containing the CCl_3, $CHCl=CClCHClCCl_3$, and $CCl_3CH=CClCHCl_2$ groups are formed in an overall yield of 37%.[134] At high temperatures (460–530 °C) trichloroethylene dehydrodimerises, giving principally hexachlorobutadiene (30%) and hexachlorobenzene (24%).[135,136]



The results of early studies of the interaction of TCE with aluminium chloride are contradictory.[137–139] Detailed investigation of this reaction showed that 2*H*-pentachlorobuta-1,3-diene predominates among the three isomers of C_4HCl_5 formed.[140]

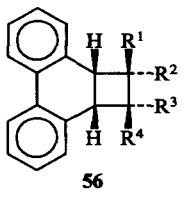
7. Cycloaddition reactions

Cycloaddition reactions with participation of TCE opened a synthetic pathway to chlorine-containing cyclic compounds which were previously difficult to obtain. Methods for cyclobutane ring construction have been most thoroughly developed in this series.



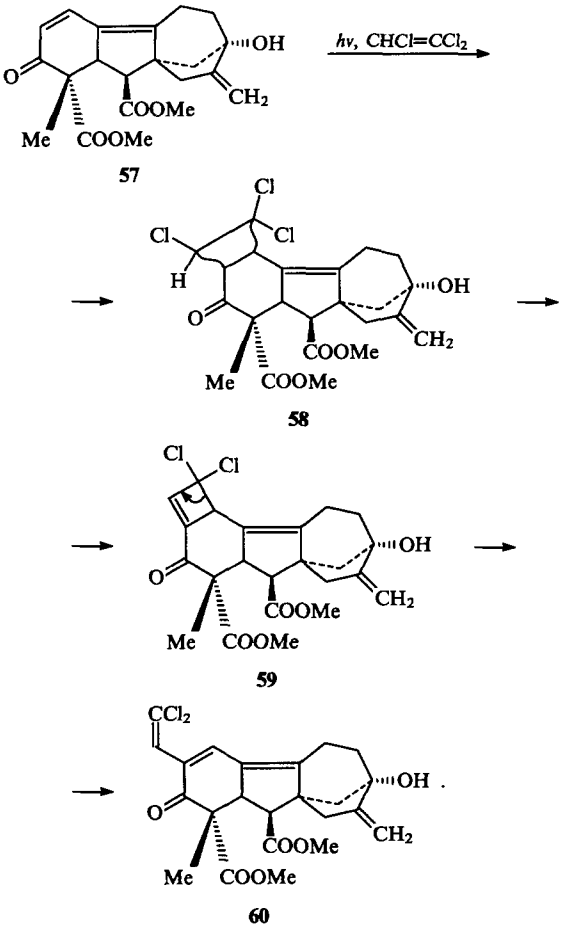
a. [2+2]-cycloaddition reactions

When a mixture of bicyclopropylidene **50** and TCE was heated (at 180 °C) for 96 h, 7,7,8-trichlorodispiro[2.0.2.2]octane **51** and the cyclopropylidene cyclic dimer **52** were obtained.[141,142]



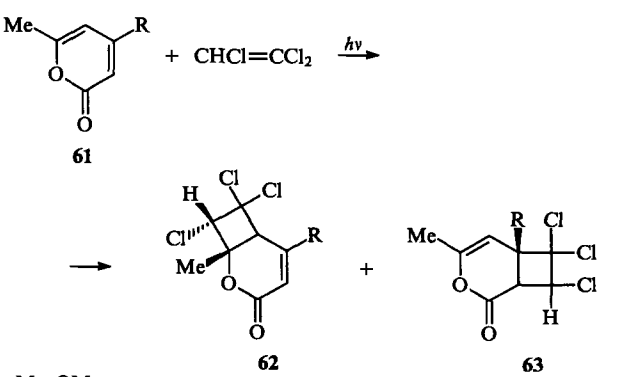
The cycloaddition reaction of dehydrobenzene, generated in situ from benzenediazonium-2-carboxylate, with TCE gives 1,1,2-trichlorobenzocyclobutene **53** in 18% yield. The use of dehydrobenzene, generated in 1,2-dichloroethane and containing a 15-fold excess of TCE, increased the yield of the target trichloro-derivative **53** to 42%, but it was contaminated by 2% of biphenyl.[143]

On irradiation of a mixture of benzo[*b*]thiophene 1,1-dioxide **54** and TCE with light at a wavelength of 300 nm and above, the adduct **55** was obtained in 52% yield.[144]



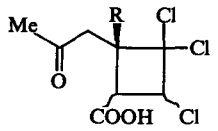
The photochemical reaction between phenanthrene and TCE leads to two cyclic adducts—the *anti*- and *syn*-isomers of 1,1,2-trichloro-1,2,2a,10b-tetrahydrocyclobuta[*e*]phenanthrene **56**—in an overall yield of 55%. Each adduct has *cis*-stereochemistry at the 2a- and 10b-positions and the *anti*-isomer ($R^1 = R^2 = R^4 = Cl$, $R^3 = H$) and the *syn*-isomer ($R^1 = R^2 = R^3 = Cl$, $R^4 = H$) were isolated in 48% and 7% yields respectively.[145]

1,4,5,8-Tetraazaphenanthrene also undergoes the cycloaddition reaction. When its mixture with TCE was irradiated with UV light, a cyclic adduct was obtained in 32% yield.[146]



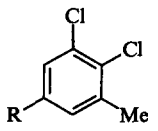
Photolysis of the dimethyl ester of 3-dehydrogibberellenic acid **57** in the presence of an excess of TCE in methylene chloride leads to two dimers (50%) and the photoadduct **58**.[147] Apparently owing to the presence of a chlorine atom in the β-position relative to the CO group, the latter is unstable and, after elimination of HCl and isomerisation of the highly strained cyclobutene derivative **59**, is converted into the stable final product **60** in 43% yield in accordance with the following scheme:

It is noteworthy that the photocycloaddition of the dienone **57** to TCE is distinguished by a high stereospecificity and leads to only one adduct.



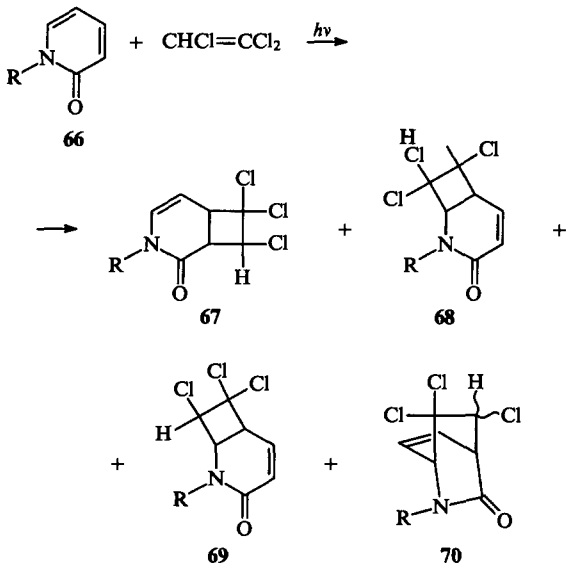
The photochemical syntheses of a series of new heterocyclic systems from 2-pyrones and 2-pyridones have been achieved. These reactions proceed in the presence of various sensitisers.

2-Pyrones **61** afford two types of cyclic adducts—**62** and **63**.[148]



R = Me, OMe.

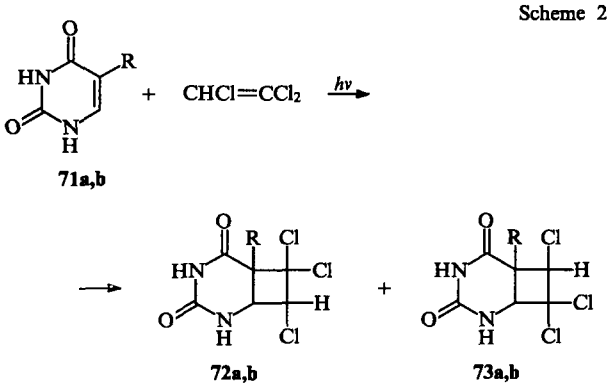
Hydrolysis of the cyclic adducts formed as a result of TCE addition to the C(3)=C(4) double bond of 2-pyrones yielded compounds **64** and **65**.



64

65

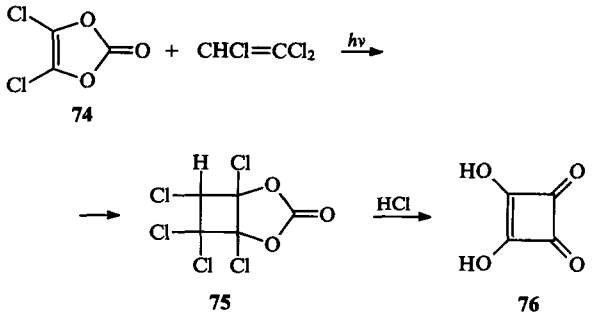
The reactions of 2-pyridones **66** with TCE gave a complex mixture of cyclic adducts **67**–**70**, among which the 5,6-adducts **68** and **69** predominate.[149]



7,7,8-Trichloro-2-R-2-azabicyclo[2.2.2]oct-5-en-3-one **70**, formed as a result of the Diels–Alder reaction, is a [4+2]-adduct.

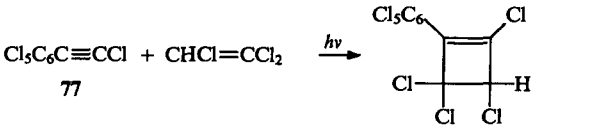
66 **67** **68** **69** **70**

The photochemical reactions of TCE with thymine **71a** and 5-fluorouracil **71b** opened a pathway to the synthesis of the corresponding cyclobutapyrimidinediones **72** and **73** (Scheme 2).[150]



Scheme 2

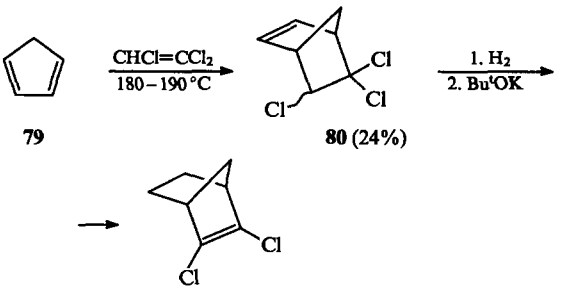
71a,b **72a,b** **73a,b**



R = Me (a); R = F (b).

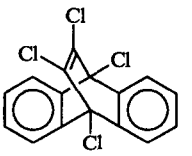
Quadratic acid **76**, which is of practical value, has been synthesised by the reaction of TCE with dichlorovinyl carbonate **74** and subsequent hydrolysis of the cyclic adduct — 1,2-carbonyldioxy-1,2,3,3,4-pentachlorocyclobutane **75**.[151]

74 **75** **76**



TCE has been used to achieve the direct synthesis of cyclobutene derivatives in the reaction of perchlorophenylacetylene **77** with TCE. When a mixture of the alkyne **77** with TCE, present in large excess in a sealed Pyrex tube, was irradiated with UV light, 3*H*-nonachloro-1-phenylcyclobutene **78** was obtained.[152]

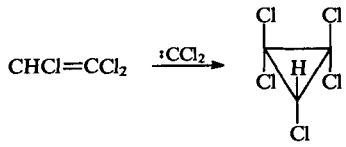
77 **78** (58%)



b. The Diels–Alder reaction

The [4+2]-cycloaddition reaction of TCE has been investigated only for certain cyclic dienes. Thus cyclopenta-1,3-diene **79** reacts with TCE to form 5,5,6-trichloronorbornene **80**.[153] Successive hydrogenation of the adduct **80** and dehydrochlorination of the saturated compound obtained yielded 2,3-dichloro-2-norbornene **81**.[154,155]

79 **80** (24%) **81** (17%)



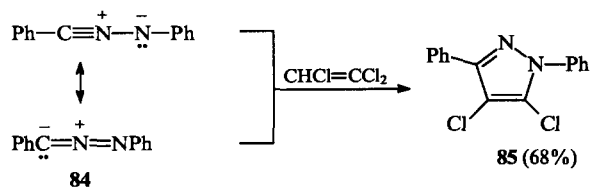
When 9,10-dichloroanthracene is treated with TCE (autoclave, 230 °C, 48 h), a mixture of Diels–Alder adducts is formed, the main one being 1,4,7,8-tetrachlorodibenzobicyclo[2.2.2]octatriene **82**.[156]

82 (10%)

c. Cyclopropane formation reactions

The formation of cyclopropane rings by reaction with dihalocarbenes is known to be one of the best methods for this purpose. Since both TCE and dihalocarbenes have pronounced electrophilic properties, it might have been expected that reaction between them would proceed with difficulty. Indeed pentachlorocyclopropane **83** has been obtained only after prolonged refluxing (~$2^1/_2$–5 days) of a mixture of TCE and sodium trichloroacetate in 1,2-dimethoxyethane.[157]

83 (22.4%)



By varying the conditions in the cyclopropane formation reaction, it was later possible to raise the yield of the adduct **83** to 45%.[158,159] By generating dichlorocarbene from organomercury compounds, it is possible to carry out the cyclopropane formation reaction at room temperature. Thus, cyclopropane **83** has been obtained in 22% yield by the reaction of bromodichloromethyl-(cyclohexyl)mercury with TCE.[160]

The simpler method for the generation of $:CCl_2$ from sodium trichloroacetate in the presence of phase transfer catalysts makes it possible to carry out the cyclopropane formation reaction in an aqueous medium, but the adduct **83** is formed in a low yield (~9%).[161]

Methods for the synthesis of halocyclopropenes and halocyclopropanes,[158,162] which were previously scarce, and a convenient method for the synthesis of 7,7-difluorocyclopropabenzene[163] and other compounds have been developed which involve the use of pentachlorocyclopropane **83**.

e. Other cycloaddition reactions

It has been found[164] that, on interaction with TCE, diphenylnitrile imine **84** behaves as a 1,3-dipolar reagent. This reaction is completed by the formation of 4,5-dichloro-1,3-diphenylpyrazole **85** and is an example of the [3+2]-cycloaddition reaction.

84

85 (68%)

III. Elimination reactions

Among elimination reactions, the dehydrochlorination of TCE and to a lesser extent its dechlorination have been investigated in the greatest detail. The elimination of a hydrogen chloride molecule from TCE proceeds on treatment with alkalies and leads to the formation of dichloroethyne **86**, which is an extremely explosive product.[165] When the dehydrochlorination of TCE is carried out in diethyl ether, dichloroethyne is isolated in the form of the stable complex $ClC{\equiv}CCl \cdot Et_2O$ **87**. Various modifications of this method have been described.[166-169]

Under laboratory conditions, small amounts of compound **86** can be obtained by treating a TCE–ether mixture with lithium hexamethyldisilazide in hexane, but this procedure requires the use of an expensive base and careful drying of the reactants.[170]

87

Two improved methods for the synthesis of dichloroethyne have been proposed recently. One of them is based on the phase transfer catalytic method. Makosza and coworkers[171] showed earlier that, in the presence of ammonium catalysts, TCE gives rise to the trichlorovinyl anion, which decomposes above 40 °C to form dichloroethyne.[172] Treatment of a mixture of TCE and ether with a 50% aqueous solution of NaOH in the presence of triethylbenzylammonium chloride (TEBA) at 70 °C led to the formation of complex **87** in a high yield.

Another rapid method for the synthesis of pure dichloroethyne, also in a high yield, is based on the reaction of TCE with potassium hydride in tetrahydrofuran (THF) in the presence of catalytic amounts of methanol.[173] When TCE is exposed to laser radiation, the dehydrochlorination reaction predominates and dechlorination is a side process.[174-179] When low pressures are employed, the yield of dichloroethyne **86** diminishes, whereas that of chloroethyne **88** increases. On exposure to an electric discharge at a reduced pressure, TCE gives rise to chloroethyne **88**.[180-182]

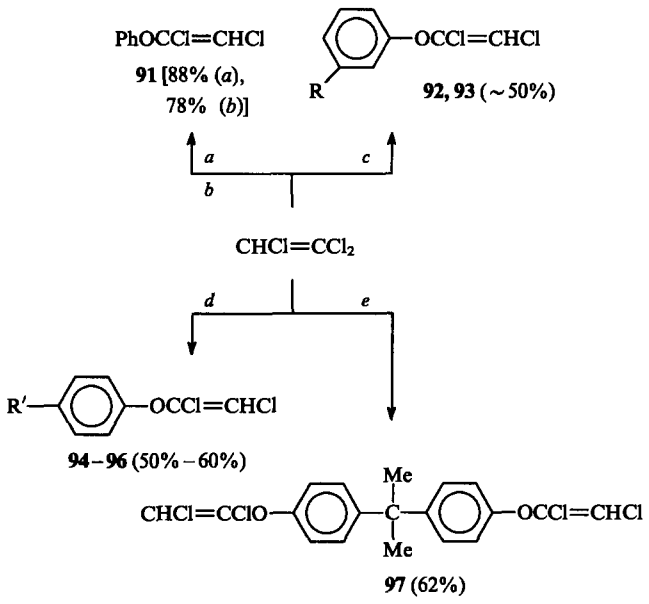
The reaction of TCE with naphthalenesodium in pentane or THF leads to the complete dechlorination of TCE with formation of ethyne and ethene (overall yield 97%).[183]

IV. Substitution reactions

1. Interaction of trichloroethylene with nucleophiles

Nucleophilic substitution at a vinyl carbon atom is known to be difficult. In some studies, one can encounter the claim even nowadays that TCE does not enter into nucleophilic substitution reactions. Indeed, under the usual conditions, TCE is not hydrolysed by aqueous solutions of alkalies, which makes it possible to employ them for the purification of TCE. However, under certain conditions TCE does react with nucleophiles of different nature, which can be accounted for by the presence in its molecule of the C=C electrophilic bond. The synthesis of a wide variety of products has been achieved by using nucleophilic substitution reactions of TCE.

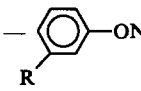
The reactions of nucleophiles with chloroethenes can proceed via at least two pathways: (1) via the addition–elimination mechanism;[184] (2) via the elimination–addition mechanism.[185] TCE apparently reacts with nucleophiles via the second mechanism. Dichloroethyne is formed initially and the nucleophile then adds to it. The nucleophilic addition stage proceeds stereoselectively and constitutes an anti-process, which leads in most cases to final products with the (*E*)-configuration.



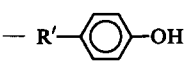
a. Interaction with O-nucleophiles

The reaction of O-nucleophiles with TCE was first investigated in its reaction with sodium ethoxide: the product was 1,2-dichlorovinyl ethyl ether **89**.[2]

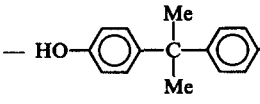
The interaction of sodium alkoxides with TCE has been studied recently in very great detail in connection with the use of alkyl dichlorovinyl ethers **90** for the synthesis of various derivatives of alkoxyalkynes.[186] It was found that alkoxides of primary and secondary alcohols react with TCE on refluxing to form the ethers **90** in moderate yields (34%–54%).

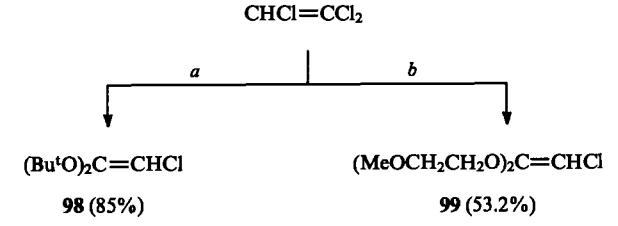


According to a patent,[187] ether **89** is obtained by treating TCE with an alcoholic solution of alkali and is used subsequently in the synthesis of 2-bromo-2-chloro-1,1,1-trifluoroethane. The reactions of sodium phenoxide and its derivatives with TCE proceed readily in aprotic solvents.[188-190] It has been shown recently that TCE interacts with various phenols also under phase-transfer catalytic conditions in the presence of Makosza's catalysts.[191] The products of these reactions are the 1,2-dichlorovinyl ethers **91–97** having the (*E*)-configuration. The simplest and most convenient method for the synthesis of the ethers is under the conditions of phase-transfer catalysis.



When two chlorine atoms in the TCE molecule are replaced by nucleophilic residues, chloroketene acetals are formed. It was found that potassium *tert*-butoxide interacts extremely vigorously with TCE, affording the acetal **98**,[186] whereas the acetal **99**—the product of the reaction of sodium β-methoxyethoxide and TCE—takes place under fairly severe conditions.[192]





a — PhOH; Na + MeOH, DMFA;[188]

b — PhONa; DMSO;[189]

c —  (R = NO_2, Me); DMFA;[190]

d —  (R' = Me, Et, NO_2); H_2O, NaOH, $C_6H_5CH_2\overset{+}{N}(Pr^n)_3Cl^-$;[191]

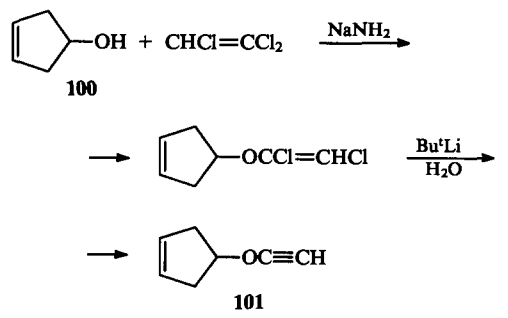
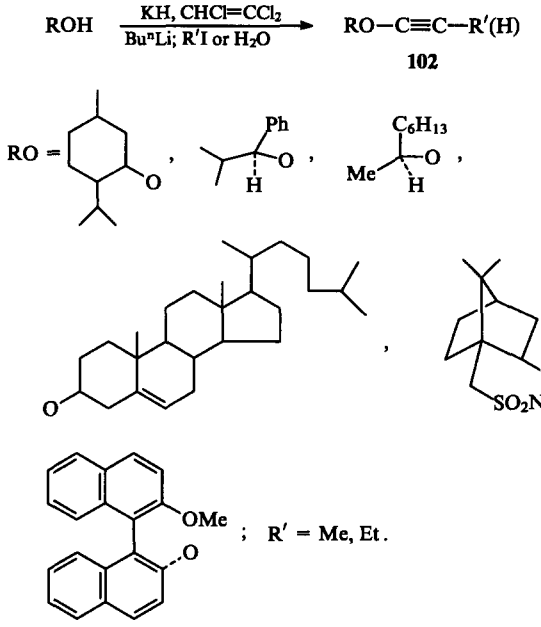
a — Bu^tOK, THF, −60 °C;[186]



b — $MeOCH_2CH_2ONa$, xylene, 100–130 °C.[192]

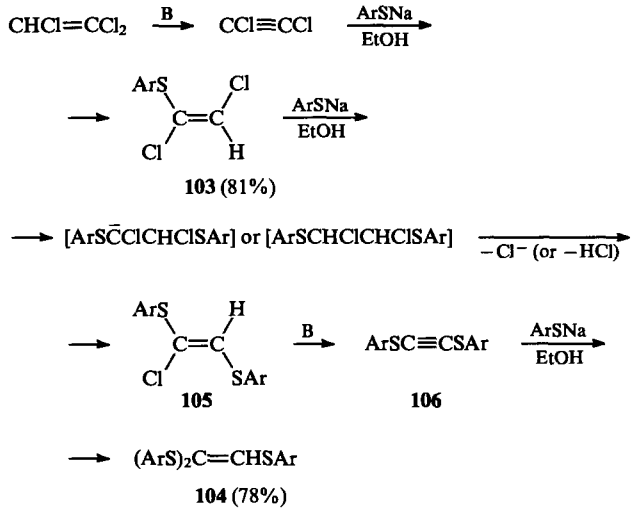
The product of the interaction of TCE with tetrahydrofurfuryl alcohol and sodium under a nitrogen atmosphere is the orthoester



which indicates the possibility of the addition of a molecule of the nucleophile to the intermediate chloroketene.[193]

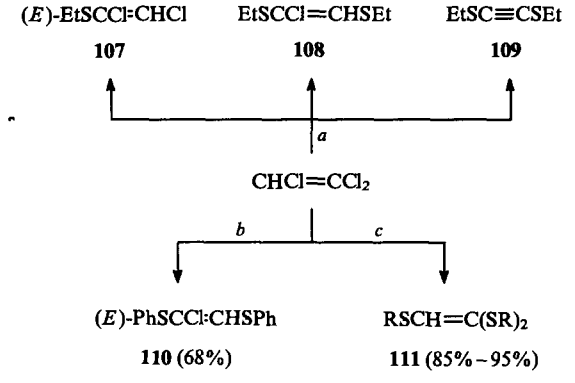
Convenient methods for the synthesis of acetylenic esters from TCE have been proposed recently.[194,195] The possibility of the synthesis of the alkyne **101** has been demonstrated in the reaction of cyclopentenol **100** with TCE.[194]

A simple and general method of synthesis of acetylenic ethers **102** has been developed on the basis of secondary alcohols and TCE.[195]



; R' = Me, Et.

A new and effective two-stage synthesis of propargyl ethers $ROCH_2C{\equiv}CH$ [R = cyclohexyl, (−)-menthyl, (−)-bornyl, or 1-adamantyl] has been achieved by isomerising 1-propynyl ethers $ROC{\equiv}CMe$, obtained from the corresponding secondary alcohols and TCE, on treatment with potassium 3-aminopropylamide.[196] According to a patent,[197] TCE and other alkenyl polyhalides are used in the esterification of resin acids and their derivatives.

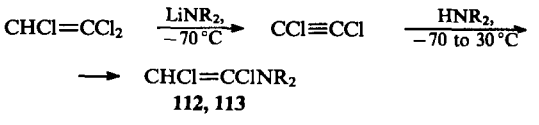


b. Interaction with S-nucleophiles

When TCE interacts with S-nucleophiles, products containing one or several thiolate residues are formed depending on the reaction conditions. A detailed study has been made of the reaction of sodium *p*-methylthiophenoxide with TCE, which proceeds only in the presence of sodium ethoxide.[198] For a 1 : 1 reactant ratio and after brief heating of the mixture, the main reaction product is 1,2-dichloro-1-(*p*-tolylthio)ethylene **103**. In the presence of a four-fold excess of the thiolate and after prolonged heating of the reactant mixture, 1,1,2-tris(*p*-tolylthio)ethylene **104** was obtained. By varying the reaction conditions, it was also possible to isolate the intermediates in this reaction: 1-chloro-1,2-di(*p*-tolylthio)-ethylene **105** and di(*p*-tolylthio)ethylene **106**. The results show that the reaction of TCE with sodium toluene *p*-thiolate proceeds via elimination–addition and addition–elimination mechanisms:

B = base, Ar = *p*-MeC_6H_4.

The reaction of other thiolates with TCE in aprotic solvents also leads to the initial formation of (*E*)-1,2-dichlorovinylation products, for example compound **107**, which can be involved in further reactions, giving compounds with two and three thiolate groups, for example, compounds **108–111**.

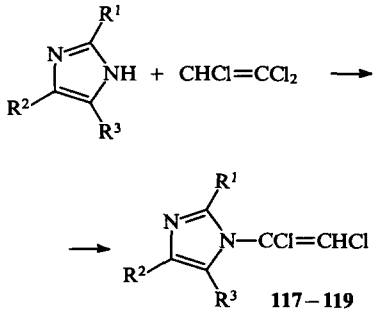


a — EtSNa, DMF;[188]
b — PhSNa, PhSNa : TCE = 3 : 1, DMF;[199]
c — Pr^{i}SNa or MeSNa, DMF.[199]

c. Interaction with N-nucleophiles

TCE reacts with amines only in the presence of strong bases, which shows that the reaction proceeds via the elimination–addition mechanism. The 1,2-dichlorovinylation of certain amines has been achieved with TCE, and convenient methods have also been developed for the formation of chloroketene aminals, diaminoalkynes, and glycine and its derivatives.

The dichlorovinylation of aliphatic amines has been investigated in relation to dimethyl- and diethyl-amines. 1,2-Dichloro-1-(*N*,*N*-dialkylamino)ethylenes **112** and **113** have been obtained by treating TCE initially with lithium dialkylamide in ether and then with the amine.[200]

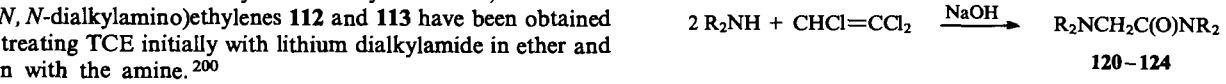


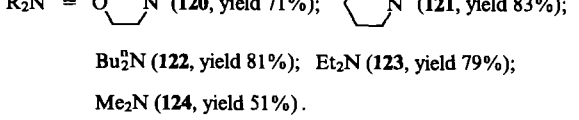
R = Me (**112**, yield 75%); R = Et (**113**, yield 85%).

On heating (60–70 °C) with an excess of dimethyl- and diethyl-amine, the enamines **112** and **113** are converted into the corresponding chloroketene aminals $CHCl=C(NR_2)_2$ [R = Me (compound **114**), R = Et (compound **115**)].[200] The mono- and di-substituted products **112–115** have found applications in the synthesis of diaminoalkynes of the type $R_2N-C\equiv C-NR_2$,[200,201] which are important synthons.[202]

The direct synthesis of these compounds has been developed only for bis(dimethylamino)ethyne **116**, which is obtained via the reaction[203]

The interaction of TCE with heterocyclic amines has been more widely investigated. Thus treatment of TCE with a mixture of potassium hydride and imidazole in THF in the presence of catalytic amounts of methanol leads to the formation of *N*-(1,2-dichlorovinyl)imidazole in 80% yield.[173] Another method has been proposed[204] for the alkenylation of imidazole and its derivatives, which involves treatment of the reaction mixture with an aqueous solution of NaOH in the presence of dimethyl sulfoxide (DMSO). The reaction proceeds stereoselectively with formation of the corresponding (*E*)-derivatives of imidazole **117–119** in 60%–62% yield.

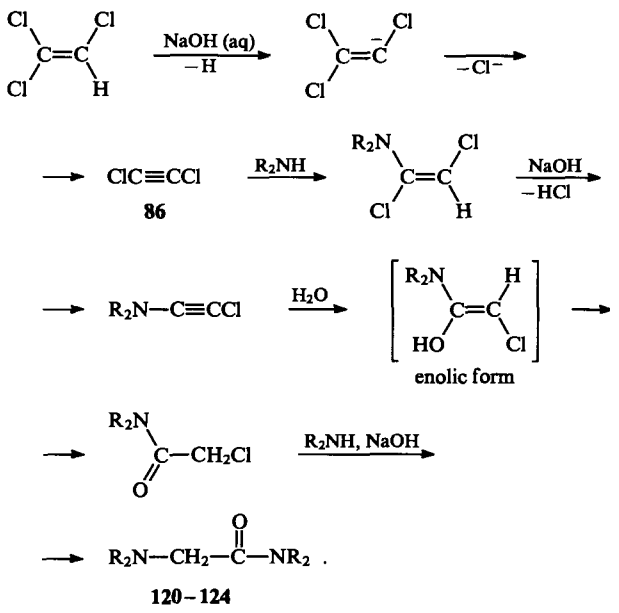




$R^1 = R^2 = R^3 = H$ (**117**); R^1 = Ph, $R^2 = R^3 = H$ (**118**);
$R^1 = H$, $R^2 = R^3$ = Ph (**119**).

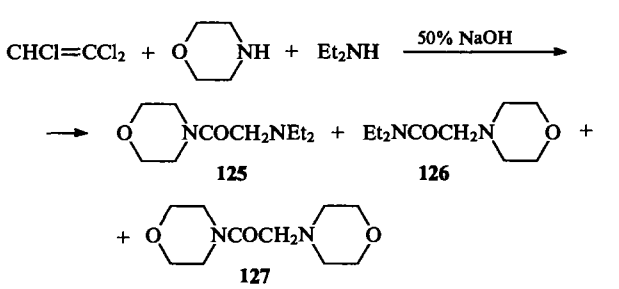
N-[(*E*)-1,2-dichlorovinyl]benzimidazole is formed in 60% yield from benzimidazole and TCE under similar conditions.

The interaction of carbazole and its derivatives with TCE under phase-transfer catalytic conditions has been investigated recently.[205] On treatment with aqueous NaOH and catalytic amounts of triethylbenzylammonium chloride, this reaction proceeds stereoselectively via the intermediate formation of dichloroacetylene **86**, affording high yields (~80%) of 9-[(*E*)-1,2-dichlorovinyl]carbazole derivatives.



A new general method of synthesis of symmetrically substituted, *N*,*N*,*N*′,*N*′-tetraalkylglycine amides **120–124** has been developed based on the reaction of TCE with more nucleophilic secondary amines under phase-transfer catalytic conditions.[172,206]

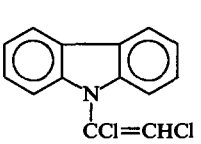
The less nucleophilic aromatic amines do not react with TCE under these conditions.



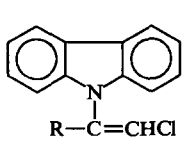
It has been suggested that the reaction takes place via the intermediate trichlorovinyl anion,[171] which is converted into the alkyne **86** and the latter reacts with the amine in accordance with the mechanism

120–124

In order to confirm the postulated mechanism, an attempt was made to isolate the intermediates, but R_2NCOCH_2Cl was isolated only in the reaction of TCE with morpholine.

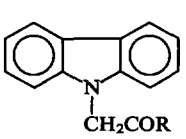


The reactions of TCE with a mixture of two unequally nucleophilic amines in the presence of phase-transfer catalysts is of definite synthetic interest. Thus, when a mixture of morpholine and diethylamine was used, the glycine amide derivatives **125–127** were obtained, the main product being compound **125**.[207]



125 **126**

127



Treatment of TCE with carbazole and a secondary aliphatic amine leads to the formation of the products **128–130**, the yields of which depend on the nature of the aliphatic amine and the ratios of all the reactants.[208]

128

129

130

R = Et_2N, Pr_2N, , .

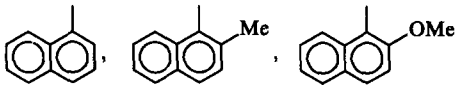
The synthesis of glycine, **131**, based on the reaction of TCE with an aqueous ammonia solution is important.[209,210] The reaction takes place in an autoclave on treatment with various alkaline catalysts, among which the most effective is $NaHCO_3$. Under optimum conditions (14% aqueous ammonia, pressure 294 kPa, temperature 180 °C, 4 h), the yield of glycine is 71.6%.

It has been suggested that the reaction proceeds via the initial formation of aminoacetonitrile **132** in accordance with the mechanism

$$2NH_3 + CHCl{=}CCl_2 \longrightarrow \underset{\mathbf{132}}{NH_2CH_2CN} \xrightarrow{H_2O} NH_2CH_2COOH\,.$$

131

Indeed, when anhydrous ammonia and lower temperatures (70–80 °C) are used, the main reaction product is the nitrile **132** (yield 70%).[211]



d. Reactions with C-nucleophiles

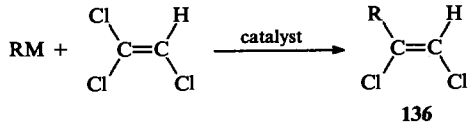
Study of the reactions of TCE with C-nucleophiles is of undoubted interest because the problem of new C–C bond formation is extremely pressing.

The reaction of TCE with organomagnesium compounds leads to the formation of a complex mixture of substances.[189] Grignard reagents are known to be fairly strong bases and moderate nucleophiles, so that the occurrence of competing elimination and substitution reactions is possible. In the presence of catalysts, TCE reacts with Grignard reagents more selectively and the nature of the catalyst influences the mode of the reaction more significantly. Thus aromatic Grignard reagents and TCE afford diarylalkynes **133** and biaryls **134** (by reduction of the Grignard reagent) on treatment with cobalt(II) or nickel(II) salts.[212]

$$ArMgBr + CHCl{=}CCl_2 \xrightarrow{CoCl_2\ (or\ NiCl_2)} \underset{\mathbf{133}}{Ar{-}C{\equiv}C{-}Ar} + \underset{\mathbf{134}}{Ar{-}Ar} + ArH$$

Ar = Ph, *p*-MeC_6H_4, 1,3,5-$Me_3C_6H_2$,

The yields of the alkynes **133** depend on the structure of the reagent employed. For example, in the reaction of TCE with 1,3,5-$Me_3C_6H_2MgBr$ the yield of the corresponding alkyne is 48%, whereas when phenylmagnesium bromide was used the target product was obtained in a yield of only 5%.

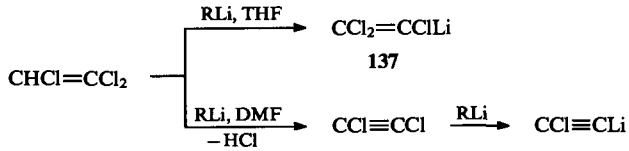


The interaction of TCE with organomagnesium compounds proceeds differently in the presence of phosphinepalladium-(nickel) catalysts. A simple method of synthesis of substituted 1,1-dichloroalkenes **135** has been developed which employs the reaction of a Grignard reagent with TCE catalysed by tetrakis-(triphenylphosphine)palladium (or nickel).[213] It has been suggested that the reaction proceeds via the initial formation of intermediates involving the oxidative addition of the catalyst in a monosubstituted position in TCE. The intermediate then reacts with the Grignard reagent and is converted into the corresponding alkene after reductive elimination.

$$RMgCl + CHCl{=}CCl_2 \xrightarrow[or\ Ni(PPh_3)_4]{Pd(PPh_3)_4} \underset{\mathbf{135}}{RCH{=}CCl_2}$$

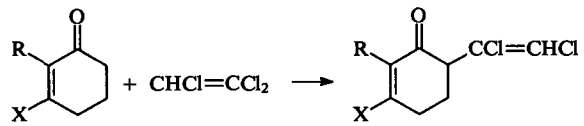
R = n-C_8H_{17} (65%–75%), n-C_6H_{13} (60%–72%), Bu^i (55%), Pr^i (52%), cyclo-C_6H_{11} (81%).

The reaction proceeds under mild conditions (room temperature, solvent—mixture of ether with benzene), but we may note that phenylmagnesium bromide gives a mixture of three products in 40% yield under these conditions.



The regio- and stereo-selective monoalkylation and monoarylation of TCE by Grignard reagents or organozinc reagents was achieved for the first time in the presence of the phosphinepalladium catalyst $\{PdCl_2[Ph_2P(CH_2)_4PPh_2]\}$.[214] In this case, the reaction involves the CCl_2 group of TCE and is completed by the formation of monosubstituted (*Z*)-1,2-dichloroethylenes **136** in good or high yields.

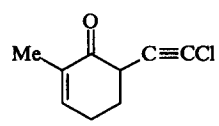
136



R = Ph, 4-ClC_6H_4,  M = MgBr or ZnCl.

When TCE was treated with organolithium compounds, metallation products of both TCE (trichlorovinyllithium **137**)[215] and dichloroethyne (chloroethynyllithium **138**) were obtained.[189]

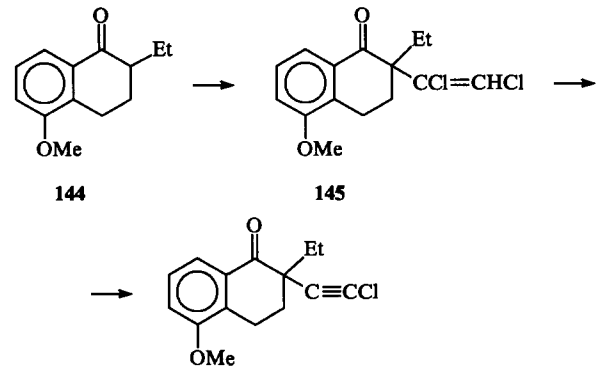
The carboxylation of vinyllithium **137** leads to the formation of trichloroacrylic acid in 81% yield.[179]



It has been shown in a number of studies[216–218] that TCE is an effective agent for the alkenylation of tertiary conjugated enolates. Although the latter are in fact ambident nucleophiles, only their tertiary carbon atoms are subjected to electrophilic attack. Thus lithium enolates, obtained from the substituted cyclohexenones **139** and **140** (lithium dialkylamide, THF, −78 °C), react with TCE under mild conditions, giving the 1,2-dichlorovinylation products—the dichlorovinyl ketones **141** and **142**.[216]

139, 140 **141, 142**

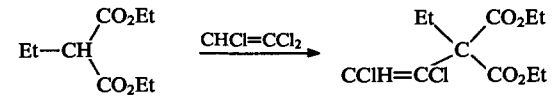
X = OEt, R = H (**139, 141**); X = H, R = Me (**140, 142**).



When the enolate **140** is used, the chloroalkyne **143** is formed as well.

143

It has been shown with the aid of X-ray diffraction that the ketone **142** has the (*E*)-configuration.

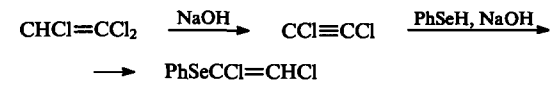


Two products are formed in the reaction of the lithium enolate of the substituted tetralinone **144** with TCE: the dichloroalkyne **145** and the chloroalkyne **146**. The complete conversion of compound **144** into the chloroalkyne derivative **146** (yield 44%) is achieved by repeated treatment of the mixture of products with lithium dialkylamide (THF, −78 to 20 °C).

144 **145**

146

Diethyl ethylmalonate **147** condenses with TCE under more severe conditions (NaH, THF, HMPA, refluxing), forming compound **148**.



147 **148**

The dichlorovinylation of ethyl 2-acetylpropionate proceeds similarly. The reactions with participation of deuteriated TCE have shown that the dichlorovinylation of the tertiary enolates investigated takes place by the elimination–addition mechanism via dichloroethyne as an intermediate.[217] The condensation of enolates with TCE can be formally regarded as a reaction involving substitution of a chlorine atom in the dichloromethylene group of TCE. The attempt to extend this reaction to other types of enolates was unsuccessful.[218]

e. Reactions with other nucleophiles

It has been shown[219,220] that selenophenol reacts with TCE in concentrated NaOH solution to form 1,2-dichlorovinyl phenyl selenide **149** in a high yield. The reaction is catalysed by ammonium salts and leads to the (*Z*)-isomer for an equimolar ratio of the catalyst and the selenol. In the presence of a tenfold excess of the selenol, a mixture of the (*Z*)- and (*E*)-isomers is formed. It has been suggested that the interaction of the selenol with TCE takes place by the elimination–addition mechanism and subsequent isomerisation of the (*Z*)-selenide, formed initially, to the thermodynamically more stable (*E*)-isomer.

(*Z*, *E*)-**149**

Diethyl ether is used to bind the dichloroethyne formed *in situ*. The nucleophilic substitution of chlorine in TCE by the PhSe-ion in ethanol and DMF also leads to a mixture of the (*Z*)- and (*E*)-selenides, but the product yields are appreciably lower than in a two-phase system.

The interaction of TCE with diphenyl and dimethyl diselenides **150** in the presence of tributylbenzylammonium chloride as the phase-transfer catalyst proceeds, on the whole, similarly to the reaction with the selenol. However, under these conditions, an appreciable amount of trichlorovinyl selenides **151** and 1,2-dichloro-1,2-bis(organoseleno)ethylenes **152** is formed together with the expected (*Z*)-1,2-dichlorovinyl selenides and the products of their isomerisation [the (*E*)-isomers].[221]

$$CHCl{=}CCl_2 + RSeSeR \xrightarrow{(10\%-15\%)\ NaOH\ -\ Et_2O}$$

150

$$\longrightarrow RSeCCl{=}CClSeR + RSeCCl{=}CCl_2 + Z(E)\text{-}RSeCCl{=}CHCl$$

152 **151**

R = Ph, Me.

The data obtained can be accounted for by the formation, in the course of the reaction, of selenolate ions RSe^- by heterolytic cleavage of the selenides in an alkaline medium, the ions adding to the $CCl{\equiv}CCl$ generated in situ from TCE.

TCE is phosphonylated by the sodium salts of dialkyl phosphites. Depending on the structure of the phosphites employed and the reaction conditions, the esters of tri- and/or tetra-phosphonic acids are produced.[222]

f. Hydrolysis

When TCE vapour is passed through concentrated sulfuric acid heated to 180 °C, a technically valuable product is formed — monochloroacetic acid **153**.[1] In order to increase the yield of the acid **153** and to reduce the process temperature, it is recommended that the hydrolysis be carried out at a reduced temperature.[1,223]

A method has been proposed for the synthesis of monochloroacetyl chloride through hydrolysis of TCE in the liquid phase in the presence of partly suspended iron(II) chloride with continuous passage of hydrogen chloride under pressure. The acid **153** is in this case a side product of the reaction.[224,225] Alkaline hydrolysis of TCE (steel reactor, sodium methoxide, 60–65 °C) leads to the formation of methyl monochloroacetate.[226]

2. Interaction with electrophiles

The reactions examined above confirm that TCE has pronounced electrophilic properties. One can therefore postulate that its interaction with electrophiles is difficult and is possible only with electrophiles stronger than TCE itself.

According to patent data,[227,228] TCE reacts with nitric acid. Thus, when TCE is refluxed with 30%–80% aqueous HNO_3 and also on slow addition of 90%–100% HNO_3 to TCE at 65–75 °C, trichloronitroethylene is formed in a preparative yield. However, together with the nitration of TCE, the molecules of the latter are degraded, which results in the formation of dichlorodinitromethane.

Trichloroethylenesulfonyl chloride has been obtained in high yield by the reaction of TCE with chlorosulfonic acid.[229] The reaction is carried out at the boiling point of TCE (87 °C), the hydrogen chloride formed being removed by passing dry nitrogen through the reaction mixture.

V. Oxidation reactions

1. The effect of oxygen

The oxidation of TCE by oxygen, the study of which was begun as early as 1911,[220] is nowadays being investigated in fair detail commercially. Its main products are dichloroacetyl chloride **154** and trichloroepoxyethane **155**, the yields of which depend to a considerable extent on the oxidation reaction conditions.

The studies on the oxidation of TCE published up to 1970 have been examined in a monograph.[4] The oxidation of TCE under the influence of ionising radiation has been described in a recent monograph.[231]

The patents, published during the last 10–15 years and devoted to this problem, are concerned primarily with improvement of the synthesis of compound **154**.[232–241] It has been shown[233] that the photochemical oxidation of TCE at 70–80 °C in the presence of catalytic amounts of a chloride in DMF makes it possible to obtain compound **154** in 90% yield with ~90% conversion of TCE. Compound **154** has been obtained in a high yield also by oxidising TCE in the presence of azobisisobutyronitrile (AIBN) or benzoyl peroxide and trialkylamines,[234] pyridines,[235,236] quinoline, and isoquinoline.[237] The rate of oxidation increases appreciably when TCE containing small amounts of added compound **154** is irradiated by short-wavelength light.[238] The target product **154** was obtained with 99.47% purity and 99.9% conversion by varying the power of the UV irradiation.[239]

There are data showing that haloalkenes are oxidised on heating under pressure without a catalyst.[240] In industry, dichloroacetal chloride is obtained by the continuous oxidation of TCE with air or an oxygen–air mixture at 170 °C under a pressure of 491 kPa in the presence of benzoyl peroxide and amide catalysts.[241]

Trichloroepoxyethane **155** — the second main product formed on oxidation of TCE — is extremely reactive and is used in the synthesis of a wide variety of substances. It is obtained by McKinney's method[242] involving the autoxidation of TCE in methanol in the presence of RCOOOH under irradiation with light from an Hg lamp[243] or as a result of radiation-chemical oxidation.[244]

Study of the low-temperature photoinitiated oxidation of TCE showed that selectivity in epoxide formation increases after the addition of aromatic ketones and on irradiation with light at $\lambda = 300$ nm for low (15%–20%) conversions of TCE. An increase in the yield of the epoxide is also promoted by carrying out the process at low temperatures.[245] The radiation-chemical method of synthesis of the epoxide **155** is promising because in this case the oxidation reaction proceeds at low temperatures.[246]

The characteristic features of the oxidation of haloalkenes, including TCE, have been examined in communications[247–250] and monographs.[231,251–253]

Results of kinetic studies on the oxidation of TCE in both liquid and gas phases indicate a radical-chain oxidation mechanism. However, the mechanism of the oxidation of TCE has not hitherto been fully elucidated.

Certain quantitative characteristics of the liquid-phase AIBN-initiated oxidation of TCE have been established recently.[254,255] It has been shown that, in the presence of the above initiator, TCE is oxidised via a radical-chain mechanism, compounds with long chains ($n \gg 10$) without degenerate branching being obtained. The epoxide **155** and dichloroacetyl chloride **154** are formed simultaneously, their ratio remaining constant at ~3, i.e. the selectivity with respect to the epoxide is ~75%–80%.

Taking into account the literature data on the oxidation kinetics of alkenes[252,253] and haloalkenes,[250,251] Kucher et al.[255] proposed on the basis of the results obtained a mechanism for TCE oxidation in which, together with the radical pathway, a molecular pathway leading to the formation of the epoxide **155** is described. In the gas-phase oxidation of TCE, the main reaction product is also dichloroacetyl chloride.[256] Various modifications of the gas-phase oxidation reactions of TCE have been examined.[257]

Interesting data have been obtained for the joint oxidation of certain organic compounds with TCE. It was concluded[258] that the co-oxidation of cyclohexane with TCE, which gives rise to very reactive peroxyl radicals, can serve as an effective method for the regulation of both the rate and selectivity of the oxidation of cyclohexane to alcohol, a ketone, and adipic acid. The co-oxidation of cyclohexane with TCE at 75 °C has been investigated[259] and it has been shown that cyclohexanol and cyclohexanone are formed simultaneously in the chain termination reaction. It was established that, when the TCE concentration is varied from zero to 50 vol.% in a mixture with cyclohexane, the cyclohexanol : cyclohexanone ratio can be varied in the range from 1.75 to 3.3.

It has been established[260] that the presence of two chlorine atoms in the terminal $-CCl_2OO^{\cdot}$ fragment of the peroxyl radicals

leads to an appreciable increase in their electrophilicity and reactivity in the dehydrogenation of organic compounds. It has been shown that the reactivity of secondary C–H bonds in n-alkanes is independent of the length of the carbon skeleton of the molecule.

The co-oxidation of TCE with aromatic alkyl compounds [261] and oxygen-containing aliphatic compounds [262] has been recently investigated and it has also been shown that the reactions involved in hydrocarbon processing, which proceed via a radical mechanism, can be facilitated by their co-oxidation with TCE, which generates highly reactive peroxyl radicals.

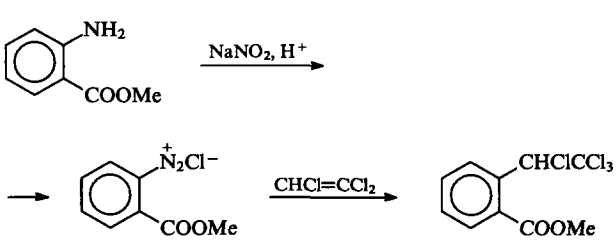
The main product of the reaction of TCE with PCl_3 in the presence of oxygen is acetyl chloride **154** (yield 45%), while the phosphorus-containing compounds **156** and **157**, formed as a result of the rupture of the C = C bond of TCE, were found among the side products. [263]

$$CHCl{=}CCl_2 \xrightarrow{PCl_3 + O_2} CHCl_2COCl\ (\mathbf{154}) + Cl_2P(O)CHCl_2\ (\mathbf{156}) + Cl_2P(O)OCHCl_2\ (\mathbf{157})$$

2. The effect of ozone

On treatment with ozone, TCE undergoes oxidative cleavage. The main products of this reaction are phosgene, hydrogen chloride, and carbon oxides. [247,264,265] The kinetics of the ozonisation reaction in various media have been investigated. [266,267] Peroxyformic acid has been detected among the products of the gas-phase reaction of ozone with TCE. [268]

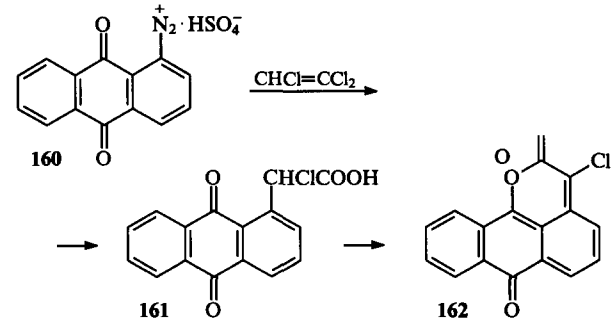
3. The effect of peroxide reagents



The main products of the reaction of TCE with peracetic acid are dichloroacetic acid and pentachloroethane. The optimum conditions for this reaction have been investigated and possible pathways leading to the formation of the main and side products have been proposed. [269]

The interaction of TCE with benzoyl peroxide leads to the formation of trichloroepoxyethane **155**, which readily isomerises to $CHCl_2COCl$ in the presence of catalysts (for example, Et_4NBr). [270]

VI. Other reactions



1. Reaction with diazonium compounds

The diazonium derivative of methyl anthranilate **158** reacts with TCE to form methyl *o*-(α,β,β,β-tetrachloroethyl)benzoate **159**. [271]

158 **159**

The reaction of anthraquinonediazonium sulfate **160** with TCE in acetic acid leads to the highly reactive 3-chloro-2*H*,7*H*-dibenzo[*de*,*h*]chromene-2,7-dione **162**, possibly as a result of cyclisation and dehydration of the anthraquinone-1-chloroacetic acid **161** formed initially. [272]

160 **161** **162**

2. The Bott reaction

Bott [273–275] showed that compounds of the adamantane and norbornane series, which form stable carbonium ions in sulfuric acid, react with TCE, affording substituted chloroacetic acids **163**.

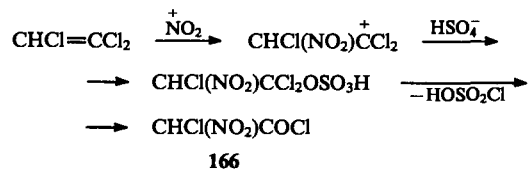
$$R^+ + CHCl{=}CCl_2 \xrightarrow{H_2SO_4} RCHCl{-}\overset{+}{C}(Cl)Cl \xrightarrow{\text{solvolysis}} RCHClCOOH\ (\mathbf{163})$$

The syntheses of numerous adamantylchloroacetic acids in preparative yields have been achieved in this way. When the acids formed contain a hydrogen atom at the bridgehead carbon atom of the bridged system, new carbonium ions arise, which results in the appearance of dibasic adamantane-1,3-bis(chloroacetic) acids among the reaction products.

The reaction of norbornene with TCE leads to 2-*exo*-norbornylchloroacetic acid in 66% yield. [273] Numerous substituted benzyl alcohols and their ethers **164**, which give rise to stable benzyl cations in sulfuric acid at temperatures above 80 °C, react with TCE, affording derivatives of α-chlorohydrocinnamic acids **165** in 30%–85% yield. [274,275]

$$RC_6H_4CH_2OR'\ (\mathbf{164}) + CHCl{=}CCl_2 \xrightarrow{H_2SO_4,\ 85-95\ ^\circ C} RC_6H_4CH_2CHClCOOH\ (\mathbf{165})$$

R = *p*-O_2N, *m*-O_2N, *p*-HOOC, *m*-HOOC, *p*-$MeSO_2$, *p*-$PhSO_2$, *p*-Bz; R′ = H or Ac.



The substituted 1,1,2-trichloroalkenes $RC_6H_4CH_2CCl{=}CCl_2$ are side products in this reaction.

The Bott reaction has undergone further development recently. Thus the interaction of hydroxyadamantanes with TCE in concentrated H_2SO_4 leads to a mixture of the corresponding diadamantylchloroacetic and diadamantanebis(chloroacetic) acids. [276] A method has been proposed for the synthesis of various derivatives of diamantane-4,9-bis(chloroacetic) acid. [277]

We may note, however, that, in the interaction of diamantane-3-spiro-3′-diazirine with TCE under the conditions of the Bott reaction, the corresponding acids are formed in only trace amounts, while the principal products are diamantane, diamantanone, 3-chlorodiamantane, and 1-chlorodiamantane. [278]

3. Reaction with nitric acid and its oxides

The interaction of nitric acid and its oxides with TCE proceeds in a complex manner. The main product of the reaction of TCE with the $HNO_3 + H_2SO_4$ nitrating mixture is the chloride of chloronitroacetic acid **166**, obtained in 80%–85% yield. [279] The acid chloride **166** is apparently formed as a result of the initial addition of the nitronium cation to the double bond of TCE and the subsequent reactions of the carbonium ion. [280]

166

Dichloroacetyl chloride, pentachloroethane, and nitryl chloride were found among the side products of this reaction. The influence of the composition and amount of the nitrating mixture on the nitration process has been investigated.[281]

The interaction of TCE with nitrogen monoxide involves nitration, nitrosation, oxidative degradation, and chlorination reactions, which lead to the formation of 1,1,1,2-tetrachloro-2-nitroethane **167**, dichloroacetic acid **168**, pentachloroethane **1**, 1,1,3,3,4-pentachloro-4-nitrobut-1-ene, and also carbon dioxide and monoxide. The same set of products has been obtained also in the reaction of N_2O_3 with TCE.

In the dark and at a temperature above 100 °C, nitrosyl chloride behaves only as a chlorinating agent. In the reaction of TCE with nitrosyl chloride in sunlight at room temperature, pentachloroethane **1**, 1,1,1,2-tetrachloro-2-nitrosoethane, the nitroalkane **167**, the acid **168**, and a pentachloronitrobutene, whose structure has not been established, were obtained. Consequently, under conditions promoting the formation of free radicals, nitrosyl chloride exhibits nitrosating, nitrating, and oxidising activities.[283]

VII. The practical use of trichloroethylene and its derivatives

By virtue of its high reactivity, incombustibility, and inappreciable toxicity, TCE is an excellent solvent and is used widely in the national economy.[1] In addition, it is used in medicine as a powerful narcotic.[284,285] According to patent data,[286,287] the addition of TCE improves the properties of insecticidal preparations. One of the ways of eliminating hexachloroethane from hexachlorobutadiene is based on the fractional distillation of the mixture in the presence of TCE.[288] The use of this compound as a solvent in the pentafluorobenzylation of organic acids appreciably increases the yield of benzyl esters.[289] In the synthesis of *m*-chloroperbenzoic acid, TCE has also been recognised as the best inert solvent.[290] A new reaction involving the thermal heterocyclisation of arylchlorosilanes in the gas phase, which proceeds in the presence of TCE (and certain other halo-derivatives), has been discovered.[291] Thus the pyrolysis of dichlorodiphenylsilane in a mixture with TCE (1 : 1 ratio) leads to 9,9-dichloro-9-silafluorene (yield 35%).[292,293]

The chemical properties and in particular the poly-functionality of TCE have led to extensive possibilities for its employment in organic synthesis (see the present review) and in chemical engineering[294] as a most valuable intermediate. Industrial methods of synthesis of monochloroacetic acid, which is an intermediate in the synthesis of dyes and pesticidal and medicinal preparations, have been developed on the basis of TCE.[295] The chloride of dichloroacetic acid, formed in the oxidation of TCE, is the main intermediate in the synthesis of the antibiotic levomycetin.[295]

Further examples of the practical use of other TCE derivatives have now been discovered. Thus it has been suggested that 1,2-dibromo-1,1,2-trichloroethane be used as an anaesthetic.[18] The product of the interaction of TCE with HF—1,1,1,2-tetra-fluoroethane—is a potential blood substitute.[31] According to patent data,[296,297] the steroids synthesised with participation of TCE, containing the chloroethynyl group in the C(17) position, possess a broad spectrum of physiological activity. Other TCE derivatives are physiologically active as well, such as—chlorine-containing amines,[73] 2-bromo-2-chloro-1,1,1-trifluoro-ethane,[298] and substituted vinylthioacetamidooxacephalo-sporins.[299]

Many of the compounds obtained with participation of TCE have been proposed as pesticides. Derivatives of urea[190,300,301] and chlorine-containing aromatic compounds[77] exhibit a herbicidal activity. 4-(Diphenylacryloyl)morpholines are used as fungicides[302] and 4-chlorobenzyl 2,2-dichlorovinyl sulfide is a nematocide.[303] Insecticidal activity has been discovered in chloronorbornenes. Trichloronitroethylene,[228] bis(dichlorovinyl) sulfide,[304,305] bis(dichlorovinyl) disulfide,[306] and 1,1-dichloro-4-methylpenta-1,3-diene, which is a product of the condensation of TCE with isobutene (it is used in the synthesis of pyrethroids[56–58]), have a broad spectrum of activity.

Fireproofing agents[307] and flame extinguishers[308] as well as regulators of molecular mass in the manufacture of silicone rubbers and oils[116] have been found among TCE derivatives. The polylactones obtained from TCE and paraformaldehyde are used in the manufacture of insulating materials and detergents.[309]

* * *

The claim that TCE is a relatively unreactive compound can still be encountered in the literature. For example, in a recently published monograph[310] it is noted that TCE does not enter into nucleophilic substitution reactions. However, our analysis demonstrated the extensive synthetic possibilities of TCE, including their use in processes involving the formal nucleophilic substitution of chlorine atoms. Convenient methods of synthesis of polyfunctional compounds of different classes have been developed on the basis of TCE, substances with useful properties, which were previously difficult to obtain, have been synthesised, and new nontrivial features of certain chemical processes have been discovered.

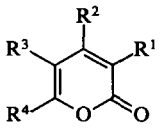
Organoelement derivatives of 2-pyrone and their applications in organic synthesis

V N Kalinin, O S Shilova



Contents

I. Introduction
II. The synthesis and properties of organoelement σ-derivatives of 2-pyrone
III. η^4-Iron tricarbonyl complexes of 2-pyrones

Abstract. The methods of synthesis and properties of organometallic (Li, Cu) and organoelement (Si, N, S) σ-derivatives and η^4-iron tricarbonyl complexes of 2-pyrone are considered. The Diels-Alder reactions of the organoelement derivatives of 2-pyrone with dienophiles take place stereoselectively and under mild conditions, which opens new pathways to the specific synthesis of polyfunctional cyclohexenes and cyclohexadienes. The bibliography includes 40 references.

I. Introduction

2-Pyrone systems **1** [1] form part of the composition of steroid,[2-4] nor- and dinor-diterpenoid[5-9] and many monocyclic[10] natural products with a broad spectrum of physiological activity.

1

Thus steroid bufadienolides exhibit cardiotonic and antineoblastic[3] properties while certain nor- and dinor-diterpenoid of 2-pyrones are insecticides[9] and cytotoxic agents.[5-7]

The use of 2-pyrones as dienes in Diels-Alder reactions with acetylenic[11,12] or olefinic dienophiles[13] gives rise to extensive possibilities for the stereoselective synthesis of cyclohexene and cyclohexadiene derivatives. Derivatives of 2-pyrone and the methods of their synthesis are therefore of great interest for organic chemists engaged in synthesis.

The chemistry of 2-pyrones has been reviewed,[1,14] but organoelement derivatives of 2-pyrones have been little studied. Two types of organoelement derivatives of 2-pyrones are known: Li, Cu, Si, N, S compounds with a σ-bond between the element and the carbon atom of the pyrone ring and η^4-iron tricarbonyl complexes of 2-pyrones.

The present review is an attempt at a systematic treatment of the available literature data on organoelement compounds of 2-pyrones, the methods of their synthesis, their reactivities, and the prospects for their use in organic synthesis.

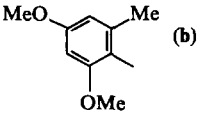
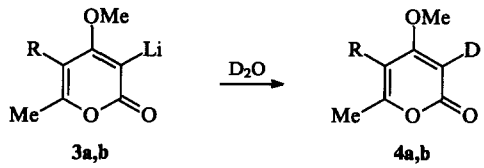
II. The synthesis and properties of organoelement σ-derivatives of 2-pyrone

The synthesis of organolithium derivatives of 2-pyrone is associated with certain difficulties since the pyrone ring is extremely sensitive to nucleophiles. The nucleophile attacks the carbonyl carbon atom of 2-pyrone,[15-19] which leads to the opening of the pyrone ring and its recyclisation to a ring of a nonpyrone type, for example a benzene ring (Scheme 1).[16]



Scheme 1

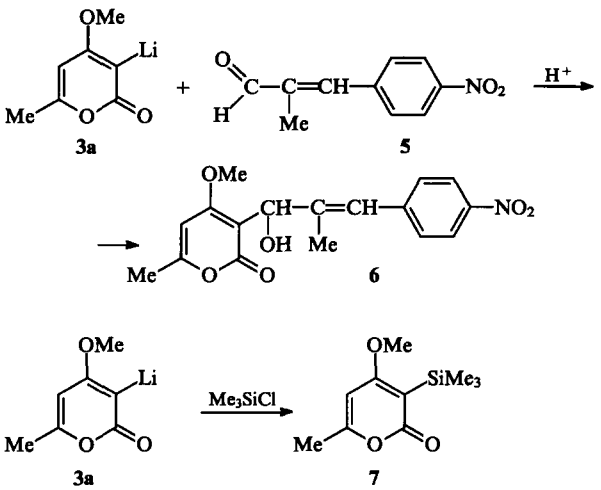
However, it has been found that lithium can be substituted in the 3-position of 4-methoxy-2-pyrones **2** under mild conditions on treatment with lithium diisopropylamide (LDA) with formation of organolithium derivatives **3**.[17]



2a,b **3a,b**

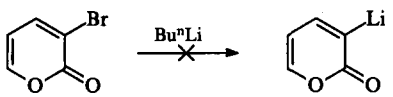
R = H (**a**),  (**b**)

The authors suggest that the simultaneous presence of 4-methoxy- and 2-oxo-groups in compounds **2** can influence both the mode of the lithium substitution reaction and the stability of the carbanion formed.



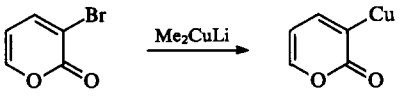
The lithio-derivative **3a** has also been obtained in 70% yield from compound **2a** by treatment with n-butyllithium.[18]

Lithium-substituted pyrones **3a, b** interact with heavy water to form the 3-deuterio-derivatives **4a, b**.[17]



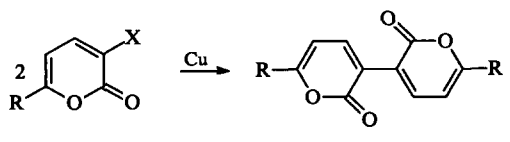
3a,b **4a,b**

The lithio-derivative **3a** interacts with 2-methyl-3-(4-nitrophenyl)-prop-2-enal **5**, affording the secondary alcohol **6**,[18] and also with chlorotrimethylsilane to form 4-methoxy-6-methyl-3-trimethylsilylpyrone **7**.[17] 4-Methoxy-6-phenyl-2-pyrone can also be lithium-substituted in the 3-position but the yield of products obtained from it has not been stated.[17]

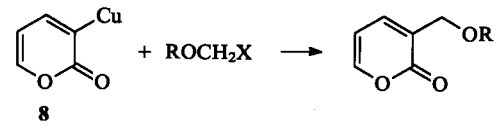


3a **5** **6** **3a** **7**

The attempt to obtain 3-lithio-2-pyrone without other substituents in the pyrone ring, by treating 3-bromo-2-pyrone with n-butyllithium, was unsuccessful.[19]

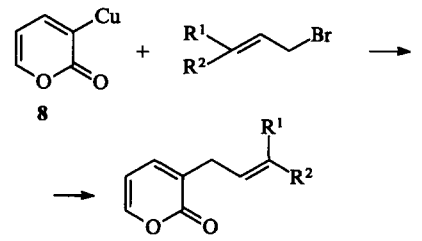


In 1985 Posner et al.[19] obtained for the first time 3-cuprio-pyrone **8** by the reaction of 3-bromopyrone with lithium dimethylcuprate.



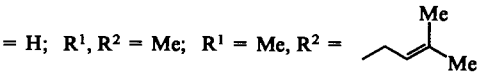
8

Previously Sokolovskaya and Moldovanova[20] synthesised a series of bispyrones by the Ullmann reaction, which proceeds via the intermediate formation of organocopper compounds.[21]

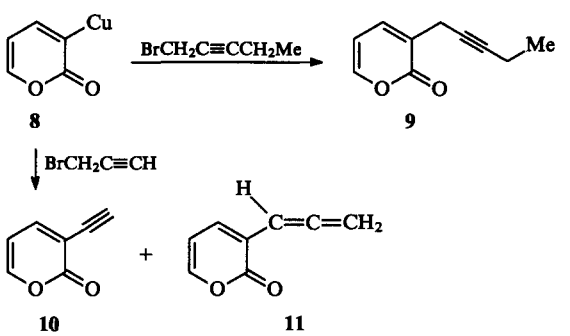


R = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 2-$C_{10}H_7$; X = Br, I.

3-Cuprio-2-pyrone **8** reacts under mild conditions with chlorobenzyl and bromomethyl ethers[19] and with allyl bromides.[19,22]

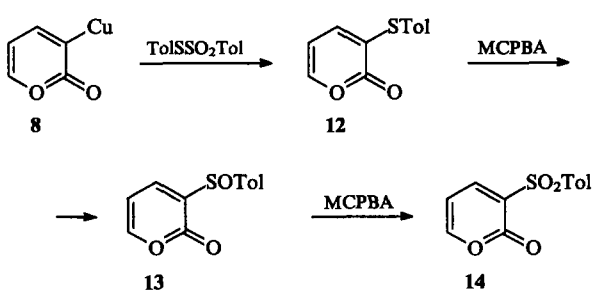


8



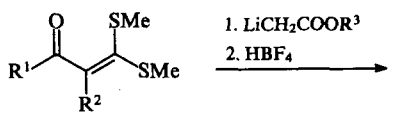
R = Me, X = Br; R = $PhCH_2$, X = Cl.

8

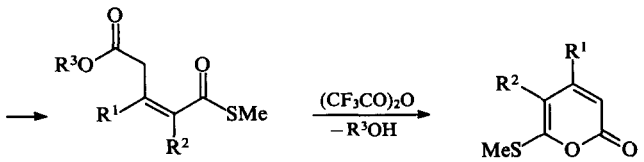


3-Cuprio-2-pyrone reacts with 1-bromopent-2-yne to form 3-(pent-2-yn-1-yl)pyrone **9** while its reaction with propargyl bromide affords a mixture of 3-propargylpyrone **10** and 3-allenylpyrone **11** in proportions of 3:1, but it does not react with alkyl, benzyl, and benzoyl halides and is thus an appreciably less nucleophilic agent than the majority of the organocopper compounds described previously.[19]

8 **9** **10** **11**



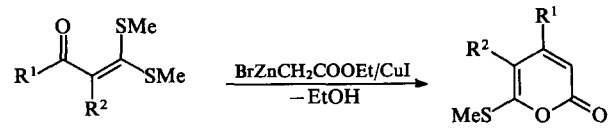
3-Cuprio-2-pyrone **8** reacts with $TolSSO_2Tol$ (Tol = 4-MeC_6H_4) to form 3-tolylthiopyrone **12**, which can be oxidised with *m*-chloroperbenzoic acid (MCPBA) to 3-tolylsulfinylpyrone **13** and 3-tolylsulfonylpyrone **14** respectively.[19]



8 **12** **13** **14**

Another method of synthesis of organosulfur derivatives of pyrone involves the cyclisation of the thioesters of unsaturated dicarboxylic acids.[23-25]

Dieter and Fishpaugh[24] observed that α-oxoketene dimethyl thioacetals **15** react with *tert*-butyl or isopropyl lithioacetates to form the monothioesters of pent-2-ene-1,5-dioic acids **16**, which cyclise to substituted 6-methylthiopyrones **17** on treatment with trifluoroacetic anhydride.



15

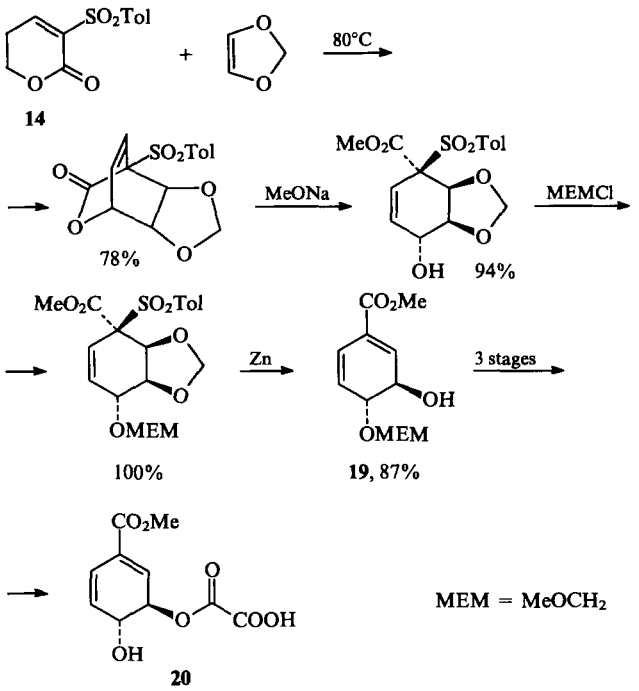
R^3 = Bu^t, Pr^i.

Bromozinc acetates in the presence of univalent copper may be used instead of lithioacetates.[23]

R^1 = Me, Ph, Tol, α-$C_{10}H_7$,  ;
R^2 = H, Me

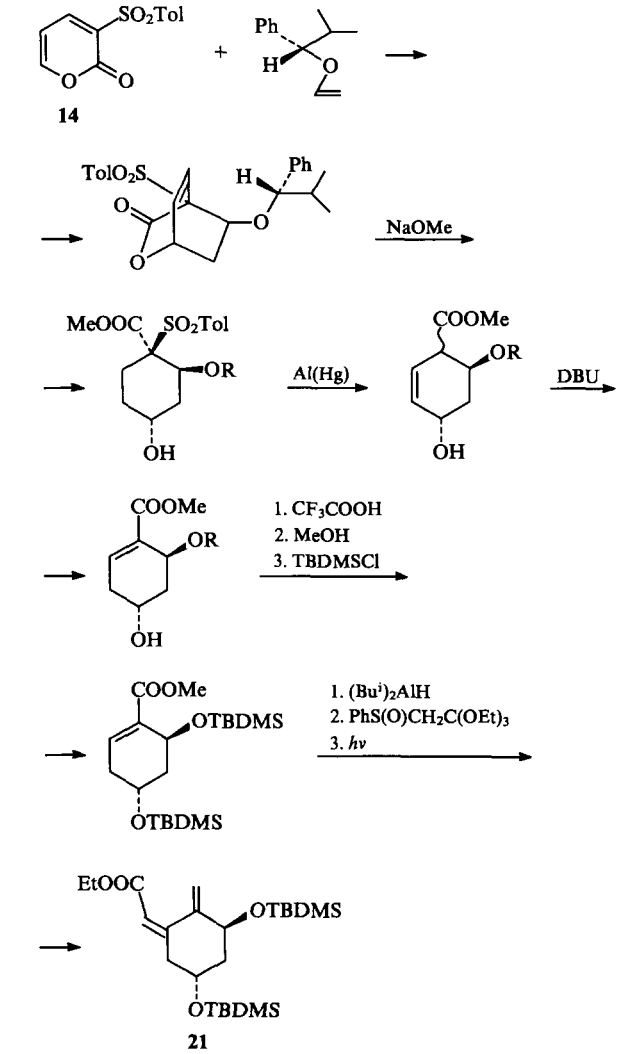
A review by Posner is devoted to the reactivity of organosulfur derivatives of 2-pyrones.[26] The introduction of the electron-donating 4-tolylthio- and electron-accepting toluene-4-sulfinyl and toluene-4-sulfonyl substituents alters sharply the reactivity of 2-pyrones towards dienes. Thus, whereas 2-pyrones without organosulfur groups react with dienes at 100–200 °C, 3-(4-tolylthio)-2-pyrone **12** interacts with electron-deficient dienes (for example, with nitroethylene and acrolein) even at 85–90 °C. Mild reaction conditions make it possible to isolate the intermediate bicyclic lactones **18**, which lose CO_2 at high temperature.[27] The reactions of tolylthiopyrone **12** with nitroethylene, acrolein, 2-methylpropenal, and but-3-en-2-one take place stereoselectively (the ratio of *endo*- and *exo*-isomers is 98:2).[27]



12 18

R^1 = H, Me; R^2 = NO_2, CHO, COMe

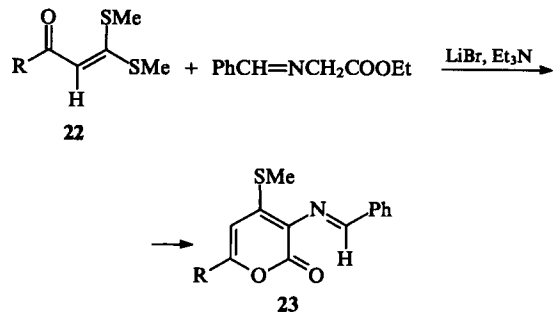
Stereoselectivity is much lower in the reactions of compound **12** with acrylonitrile, methylacrylate, methylmethacrylate, and benzyl acrylate, but the *endo*-isomer is still the main product of the reaction.[27]



The introduction of electron-accepting sulfinyl and especially sulfonyl substituents into the pyrone ring greatly facilitates the reaction of the pyrone with electron-donating alkenes such as vinyl ethers and dioxoles.[28] As in the case of 3-(4-tolylthio)-2-pyrone **12**, in the reactions of 3-(toluene-4-sulfonyl)-2-pyrone **14** with dienes it is possible to isolate bicyclic intermediates. These reactions also proceed stereoselectively, which fact has been used successfully in the synthesis of the cyclic compounds **19**. The scheme constitutes a convenient method of synthesis of the cyclic compound **19**, which is a precursor of chorismic acid **20**.[26] Chorismic acid is in its turn a key intermediate in the shikimate biosynthetic pathway which bacteria and lower plants use to convert carbohydrates into aromatic compounds.[29,30]

The toluenesulfonylpyrone **14** has also been used in the synthesis of the A ring of hydroxyvitamin D_3 **21**.[26]

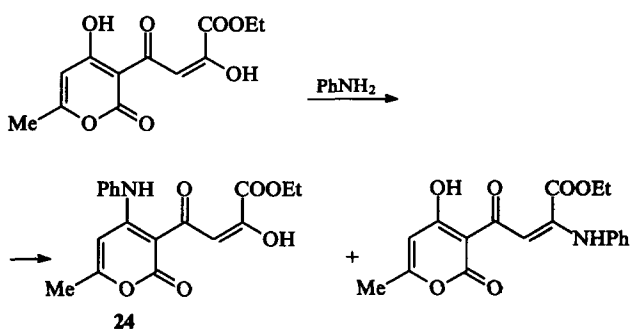
20



MEM = $MeOCH_2$

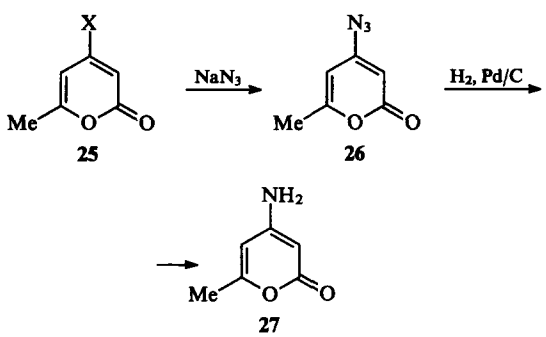
21

TBDMS = Bu^tSoMe_2;
DBU = 1,5-diazabicyclo[5.4.0]undec-5-ene.



The reaction of the bis(methyl thioacetal) **22** with benzylideneaminoacetate leading to pyrones containing thio- and imino-substituents (compound **23**) is interesting.[31]

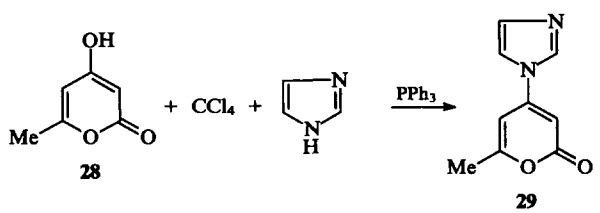
22 **23**



R = Alk, Ar

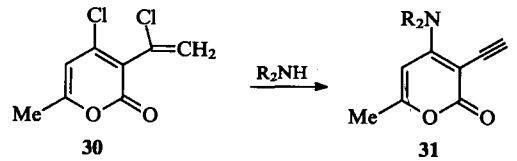
Ammonia and amines are known to open the pyrone ring with formation of acyclic products, which then recyclise to benzene derivatives or pyridones.[32,33] However, phenylaminopyrone **24** was obtained in the reaction of substituted 4-hydroxypyrone with aniline.[34]

24



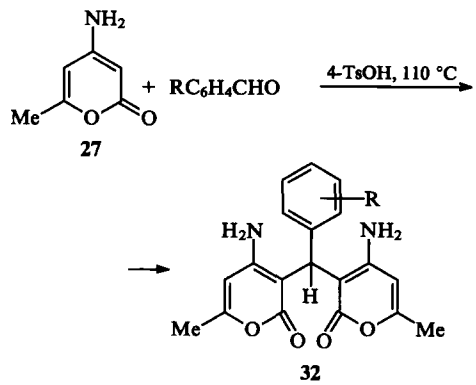
The pyrone **27**, containing a primary amino-group, was synthesised by the exchange of the halogen in 4-halo-6-methylpyrones **25** for the azido-group and the subsequent reduction of the 4-azidopyrone **26** with hydrogen over a palladium catalyst.[35]

25 **26** **27**



X = Cl, Br

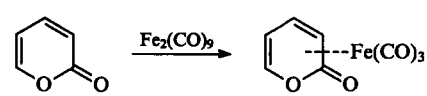
When an attempt was made to obtain 4-chloro-6-methylpyrone by substituting the OH group in the pyrone **28** for chlorine on refluxing with CCl_4, imidazole, and triphenylphosphine, only 4-(1-imidazolyl)-6-methylpyrone **29** was isolated.[35]



28 **29**

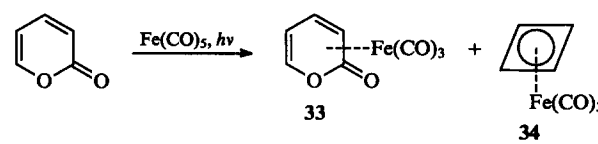
There are literature data showing that the reaction of 4-chloro-3-(1-chlorovinyl)-6-methylpyrone **30** with secondary alkylamines leads to 4-dialkylamino-3-ethynyl-6-methylpyrones **31**.[36]

30 **31**



In the presence of toluene-4-sulfonic acid, 4-amino-6-methyl-2-pyrone **27** reacts with aldehydes at the 3-position in the pyrone ring to form bis(4-aminopyron-3-yl)methanes **32**.[34]

27 **32**

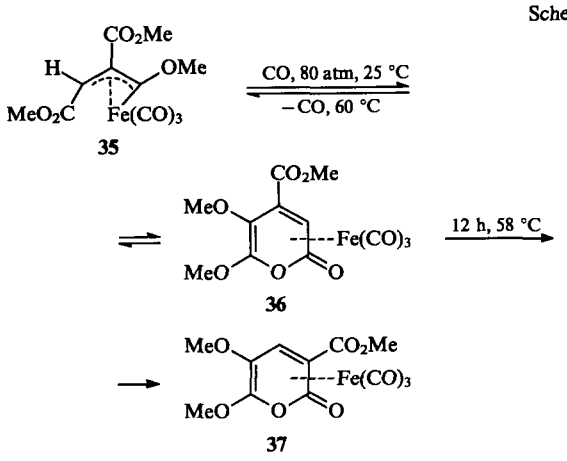


III. η^4-Iron tricarbonyl complexes of 2-pyrones

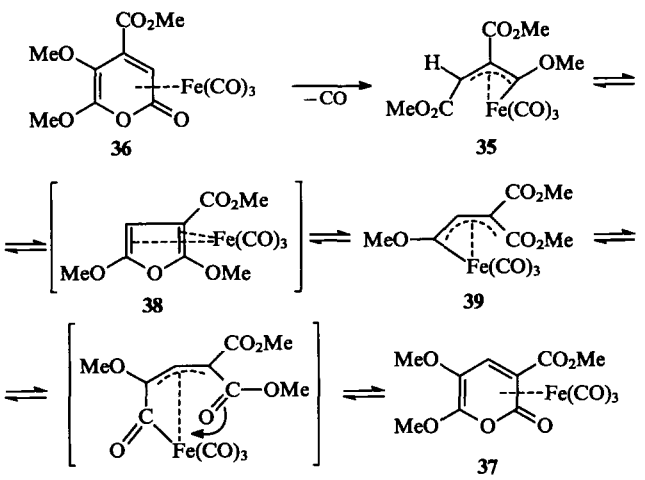
The diene system of the pyrone ring can form complexes with transition metal atoms. Thus the first organometallic derivative of 2-pyrone—the η^4-diene complex **33**—was obtained in 1967 by heating 2-pyrone and diiron nonacarbonyl in heptane.[37]

33

Irradiation of the pyrone and iron pentacarbonyl with UV light leads to the formation of a mixture of complex **33** and cyclobutadieneiron tricarbonyl **34**. (The overall yield of the products **33** and **34** is 10%–15%.)



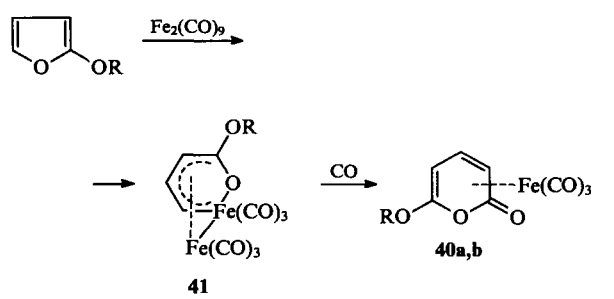
33 **34**



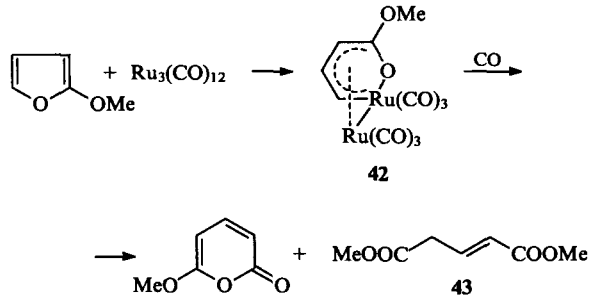
The authors confirmed the structure of the pyroneiron tricarbonyl complex by IR and ^1H NMR spectroscopic data. The product **33** is the only η^4-diene complex of pyrone obtained by the interaction of the latter with a metal carbonyl. In the remaining cases, the η^4-pyrone ligands were formed as a result of the cocyclisation of ligands having a simpler structure in the coordination sphere of the transition metal.

Mitsudo et al.[38] described the synthesis of the η^4-pyrone ligand by carbonylating the σ,π-allyliron tricarbonyl derivative **35** under pressure (Scheme 2). On heating in dichloroethene, the η^4-pyrone complex **36** is converted into the isomeric product **37** in 21% yield. The structures of compounds **36** and **37** were established by X-ray diffraction. On heating to 60 °C, complex **36** is decarbonylated and reconverted into the initial σ,π-allyl derivative **35**.

Scheme 2

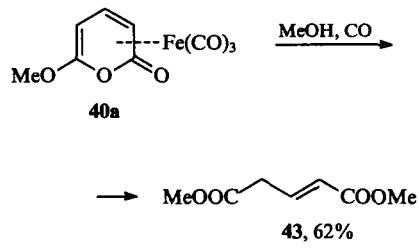


Scheme 3

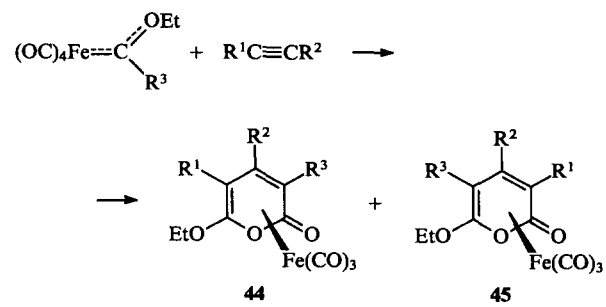


Bearing in mind that on heating under CO pressure complex **36** does not isomerise to complex **37** Mitsudo et al.[38] proposed the mechanism of the rearrangement presented in Scheme 3. In the initial stage, the η^4-pyrone complex **36** is decarbonylated to the σ,π-allyl derivative **35**, which rearranges to the σ,π-allyl derivative **39** via the intermediate formation of the fairly unstable 2,5-dimethoxyfuran complex **38**. The derivative **39** is probably carbonylated and is then converted into complex **37**. If account is taken of the fact that complex **37** is formed on carbonylation of compound **35** under pressure, then the authors' hypothesis that compound **39** is carbonylated in solution in the absence of pressure appears doubtful, but is nevertheless probable since the rearrangement product **37** is obtained in a low yield.

Mitsudo et al.[38] mention the formation of the 6-methoxypyroneiron tricarbonyl complex in the reaction of 2-methoxyfuran and diiron nonacarbonyl, which evidently proceeds via the insertion of CO in the furan ring.

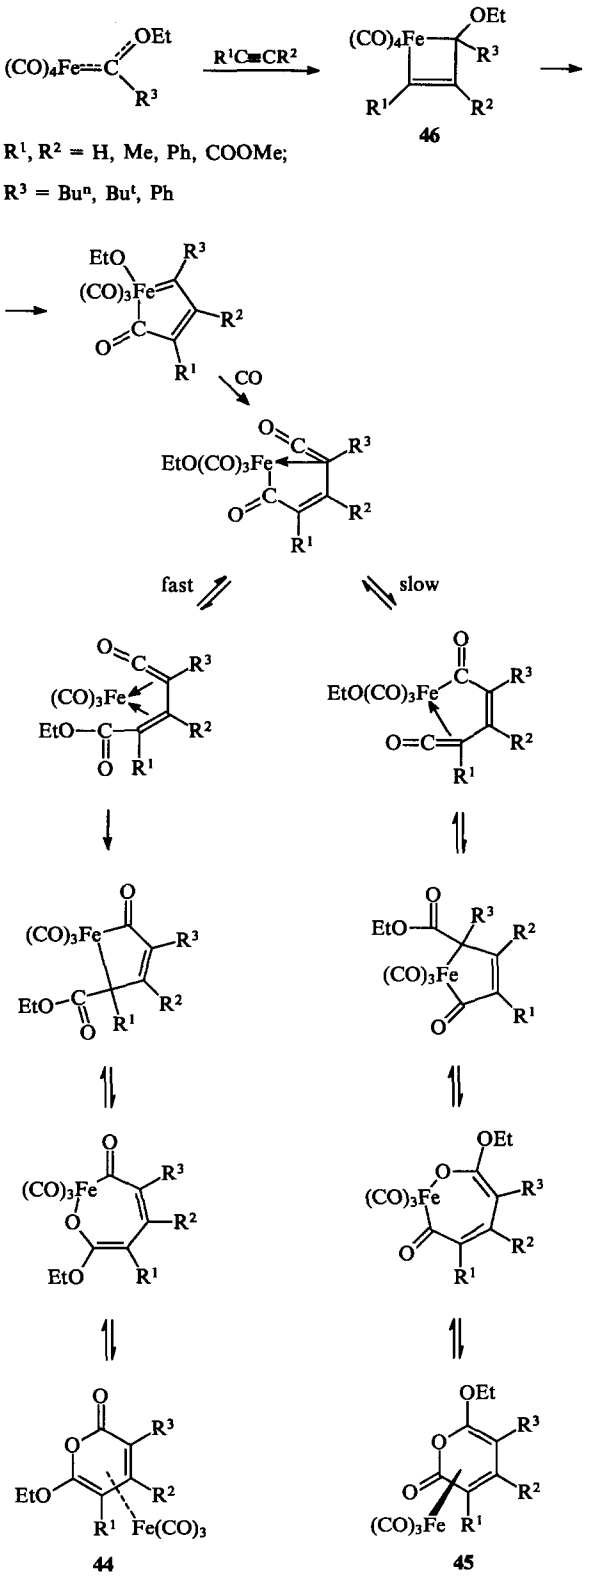


R = Me (**a**), Bu^t (**b**).



In a later study, Mitsudo et al.[39] showed that 2-alkoxyfurans interact with diiron nonacarbonyl to form η^4-(6-alkoxypyrone)iron tricarbonyl complexes **40**. It is postulated that complexes **41**, containing a metallacycle and an iron-iron bond, are formed initially. Their carbonylation leads to compounds **40**. In contrast to diiron nonacarbonyl, triruthenium dodecacarbonyl reacts with 2-methoxyfuran at 120 °C, affording only the ruthenacyclic compound **42**. Under more severe conditions (150 °C) and under CO pressure, appreciable amounts of 6-methoxypyrone and dimethyl glutaconate **43** were obtained together with compound **42**.[39]

The mechanism of the formation of compound **43** is not entirely clear, but the authors[39] suggest that it is obtained by the reaction of 6-methoxypyrone with the methanol formed as a result of the decomposition of 2-methoxyfuran. In order to confirm their hypothesis, the authors carried out the reaction of the pyroneiron tricarbonyl derivative **40a** with methanol under CO pressure and obtained dimethyl glutaconate **43**.[39]



The η^4-pyroneiron tricarbonyl complexes **44** and **45** were obtained by the reaction of the carbene complexes of iron with acetylenes under CO pressure.[40] The pyrone ligand is formed in this case from the carbene ligand, two CO molecules, and an acetylene molecule. η^4-Pyrone complexes were isolated in high yields, the isomer **44** predominating. The authors proposed the following scheme for the formation of the pyrone complexes (Scheme 4), although they believe that the reaction mechanism has not been established exactly. However, rapid chromatography of the reaction mixture on silica gel led to the isolation of the product **46**, to which a metallacyclobutene structure may be assigned on the basis of ^{13}C NMR spectroscopic data. The product **46** is unstable and decomposes readily with formation of the pyroneiron tricarbonyl complex **44** and other compounds.[40]

R^1, R^2 = H, Me, Ph, COOMe; R^3 = Bu^n, Bu^t, Ph

Scheme 4

The reactions involving the formation of the η^4-pyrone ligand from the allyl fragment and a CO molecule[38] and also from an acetylene molecule and the carbene and carbonyl ligands in the coordination sphere of the iron atom[40] have no analogies in the organic chemistry of 2-pyrones. Presumably the use of transition metals will significantly expand the scope of the synthesis of 2-pyrones and their derivatives.

The review has been prepared with the support of a European grant INTAS-93-1588 ISF MA8000 and a grant from the Russian Fundamental Research Fund No.93-03-4403.

V. Conclusion	681

Abstract. The characteristic features of radical polymerisation in homogeneous and heterogeneous systems are considered from the standpoint of the kinetic nonuniformity of the elementary reactions. The kinetic nonuniformity is due to the variation of the properties of the reaction system during the process and to the appearance of kinetically nonequivalent zones for certain critical conversions. The kinetic nonuniformity in heterogeneous systems is examined in relation to emulsion polymerisation and polymerisation in the presence of a solid dispersed phase. It is shown that the specific formation in the reaction systems of kinetically nonuniform zones makes it possible to control effectively the polymerisation process and the properties of the polymers formed. The bibliography includes 143 references.

I. Introduction

The theory of radical polymerisation was created over several decades and was largely formulated in its classical version towards the end of the 1950s. Its principal postulates have been reflected in a series of monographs (see, for example, Refs 1 – 4). Many kinetic features predicted by the theory have been confirmed experimentally. However, at the same time results have accumulated which do not fit fully within the framework of the classical theory. The theory was supplemented by the concept of the gel effect and by studies of the influence of the cage effect and of diffusional control on the characteristic features of polymerisation at high conversions of the monomer into polymer.[3,4]

Analysis of the kinetics of radical polymerisation was based on the idea that the polymerisation system is homogeneous and on the use of approaches and concepts typical for liquid-phase reactions. Even in studies carried out during recent years,[5–7] the kinetics have been analysed without taking into account the possible kinetic nonequivalence of individual zones in the polymerisation system, although the concept of macromolecular effects in polymerisation had in fact been introduced.

During the last decade significant changes have taken place in our ideas about chemical processes in polymer systems. The essential features of these changes have been described in the monograph by Emanuel' and Buchachenko[8] and somewhat later in that of Denisov.[9] It has been shown that a chemical reaction in a solid polymer phase differs appreciably from that in the liquid phase. There is a possibility that the relative rates of various competing reactions and the criteria governing the diffusion and kinetic regimes may differ significantly and the rate-limiting stages and the physical significance of the kinetic constants may change. Together with changes in the energy state of the molecules and the kinetic nonequivalence (nonuniformity) arising on this basis, other causes of nonequivalence appear in such systems — the differences in the conformational state of the species, in the structure of their environment, in their disposition in space, and in the mobility of molecules or their fragments. Such kinetically nonequivalent states lead to an arbitrary distribution of species among assemblies differing in kinetic parameters. As a result, the reaction system may be characterised by a certain set of rate constants, activation energies, and pre-exponential factors in the Arrhenius equation. The kinetics of the reactions in such a system are polychromatic and sensitive to the structural-physical properties of the polymer.

The question arises of the stage in which the above features of chemical reactions in polymer systems should be used in the analysis of the kinetics of radical polymerisation. Can one assume the kinetic nonuniformity of the system and to what extent can it affect the molecular characteristics, structure, and hence the properties of the polymer formed? The answers to these questions are not unambiguous if one takes into account the presence in the polymerisation system, together with the polymer formed, of one or several monomers, which can eliminate or weaken the effect of the kinetic nonuniformity, and the permanent dynamic behaviour of the system as a consequence of the chemical conversion of the monomer into the polymer.

In the present review, an attempt is made to consider the possibilities of the appearance and manifestation of the kinetic nonequivalence of individual zones in homogeneous (in the initial system) and heterogeneous radical polymerisation.

II. Polymerisation in homogeneous systems

The view that the theory of radical polymerisation is complete, expressed in the 1960s, proved to be unjustified. This has been demonstrated by numerous publications which appeared in 1970 – 1980 and which were devoted to the analysis and improvement of the theory of radical polymerisation. Nevertheless, despite

the significant progress in the development of ideas concerning the kinetics and mechanism of radical polymerisation, it has still not been possible to create a quantitative theory which could describe the diverse polymerisation systems for different conversions of the monomers from a single standpoint. The main reason for this is apparently the difficulty of taking into account and describing the changes in the physical properties of the reaction system during polymerisation.

We shall analyse briefly the most interesting, from our standpoint, studies concerning the characteristic features of the kinetics of polymerisation in homogeneous systems which have appeared during the last two decades.

In 1982, Soh and Sundberg[10] introduced the concept of four stages of radical polymerisation in homogeneous systems. The first, ideal polymerisation stage fully obeys the classical equations of radical polymerisation. The second stage is characterised by autoacceleration due to the change in the rate constants for elementary reactions, primarily the chain termination reaction. In the third stage, autoacceleration ceases whilst a high overall rate of polymerisation is maintained and the molecular mass of the polymer formed is reduced. In the last (fourth) stage, the rate of polymerisation diminishes (or the polymerisation comes to a stop). It has been found that, as the polymer is formed in the reaction mixture, the kinetic parameters of virtually all the processes (initiation and chain termination, propagation, and transfer reactions) change.

For a long time, the efforts of many investigators were directed to the search for equations describing the kinetic changes in advanced stages of polymerisation and the models explaining these changes. It is possible to distinguish two types of approach to the explanation of the characteristic features of polymerisation for high conversions of the monomer into the polymer: (a) kinetic; (b) structural (the free volume concept).

The kinetic approaches or models reduced to the establishment of the dependences of the rate constants for elementary reactions on the viscosity of the polymerisation system.[3,4,6,9,11-13] In the structural models, an attempt was made to take into account the changes in the physical properties of the reaction medium on attainment of the critical concentrations and dimensions of the macromolecules. Under these conditions, there is mutual interpenetration and overlap of the macromolecular coils with formation of a stable network of entanglements.[10,14-17]

For polymerisation systems characterised by the segregation of a polymer phase during the reaction, the explanation of the kinetic deviations was associated both with the possibility of occlusion of the growing radicals of the polymers and with the appearance of a two-phase model of the propagation of polymerisation.[3]

The kinetic constants for radical polymerisation obtained by various experimental methods have been analysed.[18,19] It has been proposed that one should distinguish not four stages, as in the study of Soh and Sandberg,[10] but three stages of polymerisation depending on the degree of conversion and the type of reaction systems. The first stage represents the low conversion regime (the dilute solution regime), in which nonoverlapping macromolecular coils are formed (entanglements do not arise in this system). The low conversion regime continues until the onset of an increase in the rate. The high conversion regime begins from the instant when the chain propagation becomes diffusion-controlled and the effectiveness of initiation falls sharply. There is a transitional regime between the above two regimes, during which the reaction mechanism changes. Buback et al.[19] emphasised that it is fairly difficult to establish the boundaries of the above regimes. They depend on the type of polymerisation system, the nature of the monomer, and the rate of initiation and these are difficult to determine by measuring some characteristic of the system. In the same study, attention was drawn to the significant discrepancies between the experimental data obtained in the determination of the kinetic parameters and the rate constants for the elementary reactions in radical polymerisation.

The existence of a transitional regime and the associated change in the radical polymerisation mechanism are usually explained by a transition from the chemical control of the polymerisation kinetics to physical control. Chemical control should be understood as the activation barrier to the reaction and physical control as the predominance of diffusional limitations over activation limitations.[8,19] Analysis of the simple equation

$$\frac{1}{k} = \frac{1}{k_{\text{chem}}} + \frac{1}{k_{\text{diff}}}$$

shows that the rate of reaction is controlled by one mechanism, since we have either $k_{\text{chem}} \gg k_{\text{diff}}$, or $k_{\text{diff}} \gg k_{\text{chem}}$, where k_{chem} and k_{diff} are respectively the activation and diffusional components of the reaction rate constants k. On passing from one regime to another, the rate-determining stage changes for at least one of such elementary reactions. One may assume[19] that $k_{\text{t chem}} \gg k_{\text{t diff}}$ for all the regimes, $k_{\text{p}} \approx k_{\text{p chem}}$ for the low conversions regime and the intermediate regime, and $k_{\text{p}} \approx k_{\text{p diff}}$ for the high conversions regime, where k_{t} is the chain termination rate constant and k_{p} the chain propagation rate constant.

The kinetics of radical polymerisation and the changes in the constants for the elementary reactions have been analysed in numerous investigations[6,7,11,13] from the standpoint of the influence of diffusional limitations. At the same time, with increased conversion a change has been observed in the distribution of the concentrations of the system components in the polymerisation of methyl methacrylate[20,21] and in the polymerisation and copolymerisation of divinyl derivatives.[22]

This finding already indicates directly the nonuniformity of the distribution of the components in the system and hence the appearance of kinetically nonuniform zones. The appearance and growth of the nonuniformity of the distribution of the concentrations of the components (the monomer and initiator) with increase in conversion has also been mentioned.[23,24]

Deviations from the principal rules in radical polymerisation have been noted. Thus two groups of investigators observed independently a change in the composition of the copolymers formed in radical copolymerisation as a function of the change in the rate of initiation of the polymerisation.[25-29] The authors attribute this effect to the influence of the copolymer formed and also to the change in the relative concentrations of the comonomers in the chain propagation reaction zone as a consequence of the selective sorption of the comonomers by the macromolecular coils formed. This is one of the manifestations of the macromolecular effects in radical polymerisation noted by Semchikov et al.[5]

We believe that the above features of the kinetics and mechanism of radical polymerisation and copolymerisation should be considered from a single standpoint, i.e. should be related to the characteristics of the macromolecules formed during the reaction, the nonuniformity of the reaction medium produced, and the dynamics of its variation with conversion and hence with the kinetic nonequivalence of the zones.

The theory of radical polymerisation was formulated before the appearance of ideas concerning the characteristic features of the reactions in polymers and polychromatic reaction kinetics.[8,9] According to these ideas, any polymer system is a 'motley mosaic' of regions with different packing densities of the macromolecules, sometimes differing in the alternation of the amorphous and crystalline sections, molecular mobility, and average size and mobility of the holes through which molecules or species diffuse during chemical reactions. The cause of polychromatic kinetics or kinetic nonuniformity is the 'rigid cage' of the polymer, which is responsible for the hindrance to the diffusion of species and which leads to the levelling of the reactivities of the reactants. The 'cage effect' has been related mainly to unimolecular radical formation reactions. However, it has been shown recently[30] that it influences also slow bimolecular reactions. It is important to note that the principal postulate of the theory of radical polymerisation, which

is that the reactivity of the monomers and radicals is determined by their structure and is independent of their molecular mass, does not hold for reactions in polymer systems.

The results of studies of the influence of solvents on the rate of polymerisation of water-soluble monomers and on the rate constants for the elementary chain propagation and termination reactions merit special attention in this sense.[31-34] It has been shown that the change in the density of the polymer coil and the conformational transitions of the coil–globule type can lead to the appearance of steric hindrance to the interaction of the macroradicals and the monomer. The possibility of such transitions naturally depends on the rigidity of the macrochain.

Thus one should bear in mind the possibility, for certain critical conversions in the formation of the polymer phase during polymerisation, of both the appearance of concentration nonuniformities (the nonuniformity of the distribution of the components in the system) and of a change in the conformational state of the macromolecules and hence in the reactivity of the growing chains. These two factors may lead to the kinetic nonequivalence (nonuniformity) of the zones in the system.

The possibility of the appearance of kinetic nonuniformity has been confirmed in Khokhlov's study,[35] in which the fluctuations in local density in the macromolecular system have been attributed to specific entropy effects arising on formation of the macromolecular system. The local concentration gradients of the units lead to entropy losses, which can affect the free energy of the chain propagation reaction.

The above analysis suggests a new approach to the characteristics of radical polymerisation, taking into account the possibility of the appearance during the monomer–polymer transformation of kinetically nonequivalent (nonuniform) zones associated with the nonuniformity of the system as regards both concentration and composition. This approach presupposes initially homogeneous uniform kinetics in the polymerisation system up to a critical conversion. Such critical conversion should depend on the nature of the polymer, the rigidity of the polymer formed, the polymerisation temperature, and the compatibility in the monomer–polymer system. At this instant, the polymerisation system can be represented as an assembly of kinetically nonequivalent dynamically varying zones where the polymerisation process is propagated.

We shall understand kinetic nonuniformity (KN) as the manifestation of the variability of the kinetic constants and parameters of the polymerisation process in time and space (in the microzones of the reaction system). Under these conditions, KN may not be observed experimentally owing to the difficulty of finding the zones and determining their kinetic parameters, but it must influence the structure and molecular characteristics of the polymer formed. As a consequence of the dynamic nature of the system, the experimental kinetic parameters are average quantities characterising the kinetic behaviour in different microregions.

The proposed concept is supported by experimental data on the nonuniform distribution of the components in the polymerisation process.[23,24] The specification of three regimes in the polymerisation process proposed by Buback et al.[19] can also be accounted for from the standpoint of KN.

In the low conversion regime, the polymerisation system is virtually homogeneous. The formation of the polymer phase and the appearance of concentration nonuniformities, initially as a result of the fluctuations in density and in the concentrations of the reactants and subsequently owing to the change in the polymerisation conditions and the type of system, begin in this regime. The process involving the appearance of concentration nonuniformities gradually reaches a critical stage and the system passes to the intermediate regime. The change in the characteristics of the kinetically nonuniform zones continues and the number of denser zones, formed by the polymer molecules, increases. In the high conversion regimes, a polymerisation system nonuniform in space is fully formed.

The change in the mechanism of chain termination from bimolecular to linear can be fully accounted for within the framework of the KN concept.[12,23,24]

On the basis of the foregoing, it is possible to formulate the principal factors responsible for the appearance of KN in radical polymerisation processes.

1. The formation and accumulation of the polymer and the appearance of fluctuations in the density of macromolecules in the reaction system.

2. The change in the distribution of the concentrations of the components of the polymerisation system (monomer, initiator, regulator, etc.) under the influence of the macromolecular nonuniformities which have arisen.

3. The possible phase separation during polymerisation.

4. The change in the thermodynamic conditions and rate constants for the elementary reactions of the polymerisation process.

It is possible to put forward the following classification of polymerisation systems in terms of the type of the kinetic and structural nonuniformities arising in them.

1. Polymerisation systems in which the polymer formed is compatible with its monomer. For these systems, the appearance of KN is latent in character and depends on the properties of the monomer–polymer system (for example, on the glass point) and the reaction conditions (temperature, rate of initiation, etc.). Such systems are formed in the polymerisation of styrene and methacrylic and acrylic monomers.

2. Polymerisation systems in which the polymer formed is insoluble or its solubility in its own monomer is limited (or in the reaction medium when solvents or precipitants are used). Starting from a certain degree of conversion of the monomer, microheterogeneities begin to be produed in such systems. The polymer or macromolecular aggregates segregated to form a zone comprising grains of the polymer phase in which the rate constants for the elementary reactions and the concentrations of the reactants can differ from their values in another zone. The quantitative ratio of these zones varies with the degree of conversion of the monomer in favour of the polymer zone, which is reflected in the dynamics of the heterogeneity and the kinetics and mechanism of the reaction. The systems used in the polymerisation of vinyl chloride and fluorinated monomers and many copolymer systems may serve as examples. The characteristic features of the polymerisation in such systems have been described.[36,37]

3. Systems in which monomers with several polymerisable groups are polymerised. With increase in the degree of conversion of the monomer in such systems, the structure formation process in the reaction medium intensifies, which leads to the appearance of microheterogeneity and KN. The characteristic features of the polymerisation of such systems have been noted by Berlin and Korolev.[38,39]

4. Emulsion polymerisation systems in which the heterogeneity and hence the possibility of the appearance of KN are specified by the polymerisation conditions. The characteristic features of the polymerisation in such systems have been described in a series of monographs and reviews[4,40-42]. For such systems, it is of interest to analyse the role of KN in the establishment of the properties of the polymerisation products formed.

5. Heterogeneous systems in which polymerisation proceeds in the presence of the surface of a solid phase. Such systems have been vigorously investigated.[4,43,44] They are of interest as model systems for the investigation of polymerisation in adsorption layers of the monomer and also in the formation of filled polymers (polymerisation filling). Systems of this kind are of interest from the standpoint of the specific generation of KN in order to create complex preplanned heterogeneous structures of different kinds.

In proposing the above classification of polymerisation systems, we take into account the fact that KN is a consequence of the concentration or phase nonuniformity. However, the change

in the mechanisms of elementary reactions is not always manifested in the study of the polymerisation macrokinetics as a consequence of the possible compensation effects.

For the first two groups of polymerisation systems, the characteristics of the accumulation of the kinetic and spatial nonuniformities were examined above. We may note that hitherto no attempts have been made to apply the phenomenological models of polychromatic kinetics to homogeneous polymerisation processes, although they might yield interesting results.

For the third group of systems, interesting generalisations concerning the characteristic features of the kinetics of the polymerisation process are available in the literature.[38,39]

A multiphase structure and the presence of an interface already in the initial state are combined in systems of the fourth and fifth groups. On the one hand, this complicates the study of such systems and, on the other hand, there is a possibility that microheterogeneities may arise in these systems, with parameters which can be predicted beforehand. Taking this factor into account and also the fact that there has been no systematic analysis of such systems from the standpoint of KN, in the subsequent sections we shall concentrate on the consideration of precisely such systems and we shall attempt to establish the specific factors characteristic of these systems alone and also to determine the possibility of using them to regulate the kinetics of the processes and the properties of the products.

III. Kinetic nonuniformity in emulsion polymerisation processes

The factors responsible for KN which were examined above are manifested with certain characteristic features in emulsion polymerisation (EP). The very nature of the emulsion creates preconditions for the appearance of additional factors in KN. The first precondition is due to the distribution of the reactants between two phases: the continuous phase (usually water) and the discrete phase, while the second precondition is due to the physical and chemical natures of the phases.

Attention should be drawn to the ambiguity of the very concept of 'discrete phase' in the study of the characteristics of emulsion polymerisation. According to the familiar ideas of Harkins,[45] Yurzhenko and Kolechkova,[46] and Smith and Twart,[47] in the initial stages the reaction system consists of several types of particles: drops of the monomer, micelles of the emulsifier containing the solubilised monomer, and polymer-monomer particles (PMP) formed as a result of the entrainment of free radicals by the micelles and the polymerisation of the solubilised monomer. The nucleation centres are emulsifier micelles into which the monomer diffuses from the drops.

There are also other ideas[48,49] concerning the nucleation of particles according to which PMP are formed via a homogeneous mechanism, namely as a result of the polymerisation of the part of the monomer which is dissolved in water, the precipitation of the oligomeric radicals from the aqueous phase after they have attained a certain size, and agglomeration to primary particles which undergo further limited coagulation. The particles arising in this way are stabilised by the emulsifier molecules and sorb the monomer from the drops, after which they are converted into the PMP.

There is a possibility also of a third variant of the nucleation — the creation with the aid of special emulsifying systems or with the aid of special procedures of microemulsions the particles of which are the nucleation centres.[50-52]

Evidently the conditions for the occurrence of the elementary reactions may differ significantly in the PMP formed via different mechanisms. The situation is complicated because certain elementary steps in the course of the entire polymerisation process can develop not only in the PMP or in the aqueous phase but also at the interface. The above reaction zones are kinetically nonequivalent.

Thus additional factors in the KN in emulsion polymerisation processes are the nucleation of the PMP and the characteristic features of the elementary steps occurring in particles of different type and in other reaction zones. We shall analyse the causes of the appearance of KN from the standpoint of the above factors concentrating attention particularly on the KN arising in the PMP already formed, since precisely this form of KN determines to a large extent the molecular characteristics of the polymer, the dispersity of the latex formed, and the morphology of the latex particles.

1. Nucleation of the particles

The latexes formed as a result of emulsion polymerisation are as a rule polydisperse systems. The diameter of the PMP and the nature of their size distribution usually change during the process. It is known from the theory of emulsion polymerisation that the kinetics of polymerisation in a separate particle are influenced to a large extent by the particle size, which is associated with the dependence of the monomer concentration in the PMP on its radius.[53]

Another group of factors is associated with the differences between the kinetic parameters of polymerisation in particles of different size. In particular, the rate of capture of the free radicals generated in the aqueous phase when water-soluble initiators are used depends on the radius or surface area of the PMP. It has been shown[54] that, in the seeded emulsion polymerisation of styrene, initiated by potassium persulfate, the rate constant for the incorporation of the free radicals in the PMP at similar initiator concentrations increases by a factor greater than 10 with increase in the radius of the seeding particles from 40 to 100 nm. A consequence of this is the nonidentity of the chain termination conditions in PMP differing in size. Furthermore, the different volumes of the particles presuppose different contents of the radicals in the PMP,[55] which is also reflected in the characteristics of the chain termination. A fundamental feature is that, in the presence of a single free radical in the PMP, the incorporation of the next radical induces chain termination. If the particle attains a size sufficiently large to accommodate two radicals, the possibility of a bimolecular termination of the macroradicals with all its consequences (dependence of k_t on the microviscosity in the PMP and the appearance of the gel effect) arises.

One should also note that the total number of the PMP, i.e. the number of reaction sites and hence the concentration of the free radicals, varies as a function of the mechanism and kinetics of the nucleation in the polymerisation system.

In discussing the mechanisms of the nucleation of the PMP, we may note that one common feature is characteristic of each of them — the particles are not formed instantaneously but during a definite time interval. This can be explained by the fact that the rate of generation of free radicals is as a rule insufficiently high to convert simultaneously all the potential nucleation centres into the PMP. Indeed, in emulsion systems the rates of initiation do not usually exceed $10^{-9}-10^{-7}$ mol litre^{-1} s^{-1} or $10^{14}-10^{16}$ free radicals formed in 1 s in 1 litre of the reaction volume, whereas the total number of reaction sites (micelles or microemulsion particles) reaches $10^{20}-10^{21}$ litre^{-1}. In homogeneous nucleation, the particles are formed over a definite period and their nucleation ceases only after the disappearance of the free emulsifier.

The presence on the kinetic curves for the accumulation of the polymer in emulsion systems of a section involving an acceleration of the process (usually up to a 5%–10% conversion) before the curve attains the stationary stage has in fact been explained by the nucleation of particles over a period of time.[4] In certain systems, the stationary section on the curve is altogether absent, which has been accounted for by the continuous nucleation of the particles throughout the process. An example of such a process is provided by the emulsion polymerisation of styrene in a microemulsion generated with the aid of the sodium dodecyl sulfate–1-pentanol emulsifying system.[50]

The long duration of the nucleation process leads to different growth times of various particles. This results in the polydispersity of the latex formed and the KN of the emulsion polymerisation as a consequence of the differences between the rates of polymerisation of particles of different size.

There are also other causes responsible for the polydispersity of the latex formed. Such phenomena are as a rule associated with the use of surfactants which are relatively readily soluble not only in water but also in the monomer phase. For example, in the potassium persulfate-initiated emulsion polymerisation of styrene in the presence of hydroxyethylated tridecyl alcohol,[56] in the first stage the PMP are initiated in the micelles of the emulsifier dissolved in water. After this, polymerisation takes place in the presence of a constant number of particles at a constant rate of up to 30%–40% conversion. As the monomer is consumed, the emulsifier dissolved in the monomer phase is liberated and a secondary nucleation of the particles, leading to a bimodal size distribution of the latter, takes place. Similar results have been obtained when the emulsion polymerisation of styrene was carried out using a block copolymer [poly(ethylene oxide)–poly(propylene oxide)] as the emulsifier.[57]

Periodic nucleation of the particles is characteristic of continuous and semicontinuous emulsion polymerisation processes. The latter version presupposes a continuous supply of the components, for example of the monomer, and periodic removal of the reaction product. Cyclic oscillations in the number of particles in the continuous processes have been explained by the periodic variation of the concentration of the free emulsifier in the reactor,[42] which has been confirmed experimentally by measuring the surface tension of the latex formed in the polymerisation of styrene in the presence of sodium alkanesulfonate and potassium persulfate.[58] For an average residence time in the reactor of 40 min, the surface tension varied in the range 30–50 mJ m^{-2}, which corresponded to a transition from the complete adsorption saturation of the PMP to unsaturation. Such effects are associated with the fact that the rate of formation of the interface in the continuous emulsion polymerisation of nonpolar monomers is usually higher that the rate of supply of the emulsifier to the reactor. As a result, at certain stages of the polymerisation the formation of PMP ceases and the process proceeds in particles already formed, whereupon the rate of increase in the overall surface area of the particles diminishes. Fresh portions of the emulsifier supplied after saturation of the surfaces of the growing particles induce a new nucleation of the PMP and a decrease in the degree of adsorption saturation of the interface, the cycle being repeated.

Oscillations in the surface tension of latexes and in the number of particles formed occur also in the semicontinuous emulsion polymerisation of acrylic esters (ethyl and butyl acrylates) in the presence of the ammonium persulfate–sodium metabisulfite initiating system.[59] However, the explanation of the appearance of oscillations is different and the authors[59] attribute them to characteristic features of the emulsion polymerisation of polar monomers partially soluble in water. The oscillations in the surface tension indicate a periodic variation of the system between two states. The first state is characterised by the presence in the reaction system of an excess of the free emulsifier. In the second state, the emulsifier is almost fully adsorbed on the surface of the particles and its content in the aqueous phase is below the critical concentration for micelle formation (CCM). These oscillations are associated with the variation of the overall surface area of the particles. At a certain stage of the process, the surface of the particles adsorbs the entire micellar emulsifier. The further increase in the surface area as a result of the growth of the particles and the formation of new PMP via a homogeneous mechanism render the surface adsorption unsaturated, which lowers the stability of the system towards aggregation and leads to the flocculation of the particles. As a result of this process, the overall surface area of the particles diminishes, the emulsifier is liberated, and conditions suitable for nucleation of new particles arise, which leads to the repetition of the cycle. Thus both the number and size of the particles vary periodically during the process.

There is yet another cause responsible for the expansion of the size distribution of the particles and in certain cases for the appearance of a polymodal distribution. It is associated with the possibility of the nucleation of the PMP via several simultaneous mechanisms.

Evidently the micellar nucleation mechanism can operate only in the presence of emulsifier micelles in the aqueous phase. The nature of the initiator employed is less significant than the concentration of the emulsifier. However, one should note that the use of oil-insoluble initiators increases the probability of polymerisation in monomer drops. The formation of the polymer in two different reaction zones leads to a bimodal molecular mass distribution (MMD) of the polymer formed,[60,61] which is a consequence of the KN in such systems.

Homogeneous nucleation is more probable for the emulsion polymerisation of monomers which are relatively readily soluble in water, such as vinyl acetate or lower acrylic acid esters. In carrying it out, use of water-soluble initiators of the type of persulfates is preferable, although in the presence of enough emulsifier the homogeneous nucleation of PMP is possible also when compounds of the type of azobisisobutyronitrile (AIBN), which are only partly soluble in water, are used.[62,63] The PMP are formed exclusively via a homogeneous mechanism in the polymerisation of nonpolar monomers sparingly soluble in water (for example, styrene) in systems without an emulsifier or in the presence of a surfactant at concentrations below the CCM. In other cases, it is fairly difficult to distinguish the homogeneous mechanism from the micellar one.[64–66]

Certain ideas concerning the mechanism of nucleation or the contributions of the micellar and homogeneous mechanisms to the formation of PMP can be derived from the kinetic dependence of the rate of emulsion polymerisation on the emulsifier concentration. Presumably the absence of such a dependence, which is characteristic of the polymerisation of monomers comparatively readily soluble in water,[67] can be explained by the homogeneous nucleation of the particles. One may assume that, when the reaction order with respect to the emulsifier is close to 0.6 (the value corresponding to the Smith–Ewart theory[47]), the PMP are formed via the micellar mechanism. Intermediate reaction orders between 0 and 0.6 suggest the occurrence of nucleation via two mechanisms simultaneously.[67] However, the conclusions concerning the nature of the nucleation based on kinetic data require additional confirmation, since it has been shown[64,65] that this kind of reaction order can be explained also by homogeneous nucleation.

There are data concerning the emulsion copolymerisation of monomers differing greatly in their solubility in water,[68] which may be treated from the standpoint of the micellar or homogeneous nucleation of particles or of the variation of the relative contributions of these mechanisms depending on the reaction conditions. It has been shown[68] that the effective constants for the copolymerisation of vinyl acetate (VA) and n-butyl acrylate (BA) depend on the method of preparation of the reaction system. When the system is carefully freed of dissolved atmospheric oxygen, the copolymerisation constants have values characteristic of the copolymerisation of these monomers under homogeneous conditions ($r_{VA} = 0.074$ and $r_{BA} = 4.89$).[69] The copolymerisation takes place either in microdrops or in micelles containing the solubilised monomers. If the copolymerisation is carried out in a system containing oxygen solubilised by the emulsifier micelles, then the copolymerisation constants assume different values ($r_{VA} = 0.67$ and $r_{BA} = 0.91$). The values obtained can hardly be explained by a change in the reactivities of the monomers. It is most likely that vinyl acetate and n-butyl acrylate copolymerise in conformity with their true relative reactivities and the observed anomalies are due to a change in the relative concentrations of the monomers in the reaction zone. On this assumption the ratio VA : BA = 7.60, derived from the composition of the copolymer

at low conversions, is approximately consistent with the ratio of the solubilities of the monomers in water. The latter results suggest that the copolymer is formed as a result of the copolymerisation of the monomer dissolved in water, i.e. the nucleation proceeds via the homogeneous mechanism. The example presented demonstrates that, even in the emulsion polymerisation of the same monomers, the nucleation mechanism may vary as a function of specific conditions.

Other combinations of nucleation mechanisms are also possible. For example, when the polymerisation is carried out in microemulsions, it is by no means always possible to achieve the process exclusively in microdrops and the PMP may be partly formed via other mechanisms (micellar or homogeneous). In discussing the microemulsion mechanism of the nucleation of PMP, it has become usual nowadays to distinguish two types of microemulsions: miniemulsions (particle diameter greater than 50 nm) and microemulsions proper (particle diameter 10–50 nm). In contrast to the first type, emulsions of the second type constitute a thermodynamically stable system, which is usually formed when high concentrations of special emulsifying systems based on ionogenic surfactants and higher aliphatic alcohols or hydrocarbons are used.[50] Miniemulsions are formed in the presence of traditional surfactants under the conditions of intense hydrodynamic forces[42] or when the emulsifying systems mentioned above are used but at relatively low concentrations.[70] Miniemulsions can also be produced in systems where the emulsifier is first dissolved in the monomer phase[71] or is obtained in situ at the interface.[72,73]

As a consequence of the low rate of formation of the PMP, KN arises for any of these variants of the preparation of microemulsions or miniemulsions. The low rate of nucleation when the process is initiated by water-soluble initiators is due to the low rate of transfer of radicals from the aqueous phase as a consequence of the appearance at the interface of ionogenic surfactant–aliphatic long-chain alcohol complexes in the form of liquid-crystal formations.[50,70]

For the reasons stated, nucleation during emulsion polymerisation continues in some cases throughout the polymerisation process.[50] For this reason, not all the particles of the microemulsion are converted into the PMP. An appreciable fraction of the particles serve merely as a source of the monomer, which is transported into the reactive PMP (containing the free radical). This results in a wide size distribution of the particles despite the narrow distribution in the initial microemulsion. Similar effects arise also in miniemulsion polymerisation.[74]

There are data indicating the possibility of the simultaneous nucleation of PMP in miniemulsions or microemulsions via two mechanisms. For example, such effects have been observed in the emulsion polymerisation of methyl methacrylate (MMA) in miniemulsions obtained using the stabilised sodium lauryl sulfate–hexadecane system.[75] The simultaneous formation of particles in microdrops and via the micellar mechanism leads to the formation of latexes with a wide size distribution of the particles. When the miniemulsions are produced in the presence of ionogenic surfactants, it is also impossible to avoid fully the micellar nucleation as a consequence of the vigorous hydrodynamic action, which is indicated by the formation of latexes with a bimodal size distribution of the particles.[76,77]

The particles formed via different mechanisms are kinetically nonuniform not merely because of the differences between their sizes. Firstly, the monomer concentrations in such particles are different. For example, the monomer : polymer ratio in the PMP formed via the homogeneous mechanism is lower than in the particles obtained from micelles.[78] Secondly, the rate of incorporation of the radicals in the PMP and hence also many other kinetic parameters also depend on the method of nucleation. If under the conditions of the microemulsion nucleation mechanism a proportion of the particles are formed homogeneously, there is no doubt that the PMP obtained from the microemulsion are characterised by a significantly lower rate of capture of the radicals.

Thus nucleation is a powerful factor influencing the emulsion polymerisation kinetics. By regulating the rate and mechanism of the nucleation process, it is possible to carry out the polymerisation under kinetically uniform or extremely nonuniform conditions and to regulate thereby the characteristics of the products formed. Evidently, the occurrence of emulsion polymerisation under uniform conditions requires the maximum reduction of the nucleation period and the process must be carried out via a single mechanism. There are a number of ways of regulating these parameters.

It has been shown[79] that, by altering the emulsifier and initiator concentrations or the rate or initiation, it is possible to influence effectively the polydispersity of the latex formed, i.e. the particle nucleation time can be changed. The decrease in the emulsifier concentration and the increase in the rate of initiation as a result of the increase in the initiator content in the reaction system or in temperature ensure the formation of latexes with particles which are most uniform as regards size (Figs 1, 2).

An effective procedure for accelerating the PMP nucleation involves the use of active chain-transfer agents.[80] The low-molecular-mass radical formed when the chain is transferred to

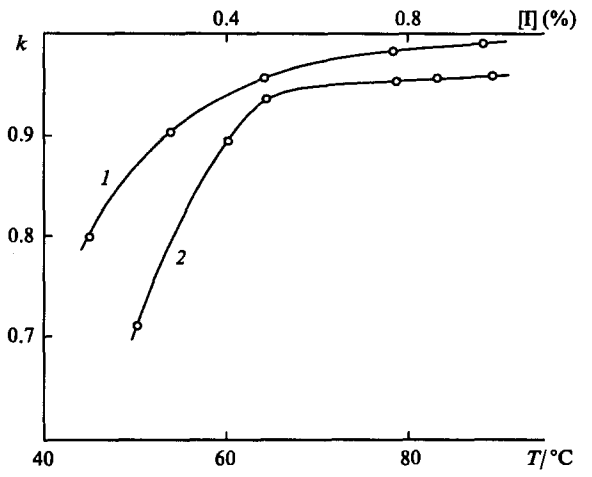

Figure 1. Dependence of the coefficient of the monodispersity of PMMA latex particles on the initiator (ammonium persulfate) concentration (curve *1*) and on temperature (curve *2*); emulsifier concentration — 0.1% relative to the mass of the monomer; T = 80 °C (curve *1*).

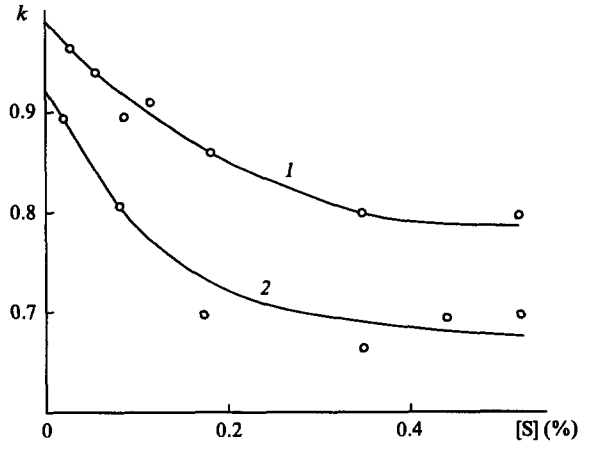

Figure 2. Dependence of the coefficient of the monodispersity of PMMA (curve *1*) and PMA (curve *2*) latex particles on the emulsifier (sodium dodecyl sulfate) concentration; T = 80 °C; initiator concentration — 0.5% of the mass of the monomer.

the molecular mass regulator can leave the PMP. As a result of such processes, each primary radical initiates a large number of PMP, which significantly shortens the nucleation stage.

Morrison et al.[65] established that the rate of nucleation varies in the emulsion polymerisation of styrene in the presence of indifferent electrolytes (NaCl) or inert solvents (ethylbenzene). In the former case, the nucleation period is shortened and in the latter lengthened, which is reflected in the polydispersity of the latex formed.

The possibility of regulating the process by inhibiting (with oxygen) the nucleation of the PMP in the micellar phase was examined above in the discussion of the copolymerisation of vinyl acetate and n-butyl acrylate. It was shown that the transition from the micellar to the homogeneous mechanism of the formation of particles makes it possible, in principle, to vary the effective copolymerisation constants and to obtain copolymers with a more homogeneous composition.[68]

The approach based on the use of inhibitors capable of excluding selectively a particular nucleation mechanism has been developed recently in the studies by Barton and coworkers.[62,63,81] By carrying out the emulsion polymerisation of styrene or methyl methacrylate in the presence of a water-soluble inhibitor (potassium nitrososulfonate) and an oil-soluble initiator (benzoyl peroxide), Barton and Juranicova[81] succeeded in fully excluding the possibility of homogeneous nucleation. On the other hand, in the emulsion polymerisation of the same monomers in the presence of an oil-soluble inhibitor (4-stearoyloxy-2,2,6,6-tetramethylpiperidine 1-oxide) and a water-soluble initiator or an initiator partially soluble in water (AIBN)[62,63] nucleation proceeded only via the homogeneous mechanism. It is of interest to note that in both cases the polymerisation occurred without an induction period.

Oganesyan et al.[82] proposed a simpler method for the regulation of the nucleation of particles. It consists in altering the water/monomer phase ratio (φ) and the particle radius (r). The rate of adsorption (z) of the radical growing in water is described by the equation[82]

$$z = 4\pi\bar{r}DN,$$

where $\bar{r}$ is the reduced radius of the monomer drops and of the growing radical ($\bar{r} = r$), D is the sum of their diffusion coefficients, and N is the number of particles defined by the formula

$$N = \frac{3}{4\pi r^3(1+\varphi)}.$$

The rate of growth of a single radical in water (w_p) is

$$w_p = k_p[M]_w,$$

where k_p is the chain propagation rate constant and $[M]_w$ the monomer concentration in water. The ratio of the rate of adsorption of the radical to the rate of its growth, i.e.

$$\theta = \frac{z}{w_p} = \frac{3D}{k_p[M]_w r^2(1+\varphi)},$$

determines the probability of the formation of particles in the aqueous phase or of the capture of radicals by the monomer drops.

Evidently, when $\theta \gg 1$, the growing radicals pass from the aqueous phase to the monomer drops already in the early stages and for $\theta \ll 1$ polymerisation develops in the aqueous phase. Calculation shows that chain propagation in the aqueous phase is possible for the emulsion polymerisation of styrene when $r \gg 10^{-4}$ cm. In the remaining cases, the growing radicals are adsorbed by the surfaces of the monomer drops having failed to recombine rapidly enough in the aqueous phase regardless of the value of φ. For vinyl acetate, the probability of the growth of the radical in water increases greatly for $r > 10^{-5}$ cm. For $r < 10^{-5}$ cm, the polymerisation of both styrene and vinyl acetate occurs in the monomer drops whatever the phase ratio.

2. Kinetic nonuniformity and elementary reactions in emulsion polymerisation

a. Initiation

The problem of the initiation of emulsion polymerisation has a direct bearing on the mechanism of the nucleation of PMP because the type of initiator determines to a large extent the region of the emulsion system where the particles are formed. Until recently, the accepted procedure was to distinguish two types of initiating systems: water-soluble and oil-soluble. However, it is now possible to differentiate also a third type — initiators with distinct surface-active properties.[67,83–85] Such initiators are located in the region of the interface.

The above classification is in a certain sense arbitrary, since many initiators are able to dissolve in both phases, and organic hydroperoxides, which possess some surface activity, can also be concentrated in the region of the emulsifier adsorption layers. The distribution of the initiator between different zones of the reaction system leads to the appearance of several types of nucleation centres, which renders the process kinetically nonuniform.

When the emulsion polymerisation of styrene in the presence of AIBN is considered as an example, it is possible to note three possible radical-formation zones: monomer drops, emulsifier micelles, and the aqueous phase (bearing in mind some solubility of AIBN in water).[86] The presence of several nucleation zones leads to the appearance of a polymer nonuniform with respect to molecular characteristics (bimodal molecular mass distribution). However, the nonuniformity diminishes during the polymerisation process, since following the appearance of a large number of PMP the contribution of the processes occurring in the monomer drops becomes insignificant.[86]

Another type of KN may be due to the difference between the kinetic parameters of the radical formation reaction in different reaction zones. Such effects are most marked when hydroperoxides are used as initiators of emulsion polymerisation.[87,88] Table 1 shows that the kinetics of the decomposition of isopropylphenyl hydroperoxide vary appreciably as a function of the reaction conditions. The most significant changes then occur when an interface appears in the system (in the isopropylbenzene–water emulsion). Even more marked differences between the kinetic parameters of the decomposition of the initiators as a function of the zones in which they are located in the latex system are observed for peroxides which are copolymers of vinyl monomers with the methacrylic acid ester of α-hydroxyethyl-*tert*-butyl peroxide.[83] The decomposition constants for the peroxy-groups located in the surface zone of the particles are 2–3 orders of magnitude higher than those for the same functional groups located in the bulk of the latex particles.

When water-soluble initiators such as potassium or ammonium persulfate are employed, it is usual to assume that at temperatures in the range 50–70 °C they generate free radicals at an almost constant rate, because only a small proportion of the initiator decomposes during polymerisation at moderate temperatures and its concentration changes little from its initial value. The persulfates are almost insoluble in organic media, so that free radicals are generated only in the aqueous phase. The second step in the initiation reaction — the interaction of the primary radical

Table 1. Kinetic parameters of the thermal decomposition of isopropylphenyl hydroperoxide at 95 °C.

Decomposition medium	k_d^a/min^{-1}	E_a/kcal mol^{-1}	Refs
Isopropylbenzene	5.0×10^{-4}	23.6	87
Water	3.3×10^{-4}	–	88
Isopropylbenzene–water emulsion (2:3) stabilised by potassium palmitate	1.1×10^{-3}	18.0	88

[a] k_d = thermal decomposition rate constant.

with a monomer molecule—also occurs in the aqueous phase according to the existing ideas for the commonest systems in which anionic surfactants are used as emulsifiers.[89] The above considerations should seemingly indicate the kinetic uniformity of the process involving initiation by persulfates. However, the results of studies by Okubo and Mori[90] and Georgescu et al.[91] suggest that the conditions governing the decomposition of the initiator into free radicals may vary during polymerisation. These hypotheses are based on the mechanism, discovered by the authors, by which the rate of decomposition of the persulfate is influenced by the emulsifier in the free state, in the micellar state, and in the state where it is adsorbed on the surface of the particles.

According to Okubo's data,[90] the mechanism of the decomposition of persulfates in the presence of an emulsifier, for example sodium dodecyl sulfate (SDS), can be represented as follows:

$$S_2O_8^{2-} \longrightarrow 2\,SO_4^{\cdot-},$$

$$SO_4^{\cdot-} + CH_3CH_2(CH_2)_{10}OSO_3^- \longrightarrow HSO_4^- + CH_3\dot{C}H(CH_2)_{10}OSO_3^-,$$

$$CH_3\dot{C}H(CH_2)_{10}OSO_3^- + S_2O_8^{2-} \longrightarrow SO_4^{\cdot-} + SO_4^{2-} + [X].$$

The activating effect of the emulsifier consists in inducing the decomposition of persulfates by the surfactant radicals. If the emulsifier is present in the form of micelles or in the adsorbed state on the surface of the PMP, then the interaction of the radical-anions with the hydrocarbon fragments of the surfactant is inhibited by electrostatic and steric hindrance. Furthermore, exchange reactions of the type

$$^{\cdot}SDS_{free} + SDS_{mic} \rightleftharpoons {}^{\cdot}SDS_{mic} + SDS_{free},$$

$$^{\cdot}SDS_{free} + SDS_{adsorb} \rightleftharpoons {}^{\cdot}SDS_{adsorb} + SDS_{free},$$

lower the concentration of the $^{\cdot}SDS$ radicals in a free state.

Thus, with increase in the surface area of the particles during polymerisation, the free emulsifier and its radicals are removed from the aqueous phase, which diminishes the rate of decomposition. Indeed the increase in the surface tension of the latex during emulsion polymerisation described above indicates the disappearance of the free emulsifier, while the presence of latex particles, for example those of poly(vinyl chloride),[91] diminishes the rate of decomposition of the persulfate approximately by a factor of 4 compared with the rate of decomposition at a surfactant concentration in the aqueous phase close to the CCM.

The effects examined should alter appreciably the rate of initiation of the emulsion polymerisation especially in those stages where the formation of the PMP has been completed (the micellar emulsifier has been exhausted). If the process proceeds in the presence of a constant number of PMP, then the rate of emulsion polymerisation also changes little because the stationary concentration of free radicals in the system is constant (the second case of the Smith–Ewart theory, $n = 0.5$).[47] However, as a consequence of the change in the overall surface area of the particles and in the rate of initiation, a varying frequency of the entry of free radicals into the particles alters the molecular characteristics of the polymer formed.

The increase in microviscosity in the PMP with increase in conversion after the disappearance of monomer drops should also change the initiation conditions. It is known from the theory of radical polymerisation[3] that, at advanced conversions of the monomer, the initiator decomposition rate constant and the initiation efficiency diminish. Clearly this phenomenon can occur only for compounds which are almost insoluble in water. For water-soluble initiators, the above effect is of no importance, since free radicals are generated outside the PMP.

Thus the KN in the emulsion polymerisation initiation reaction is determined primarily by colloidal-chemical causes: the presence of an interface, the change in the overall area of the interface and its adsorption saturation, and the existence of the emulsifier in several states (free, micellar, and adsorbed).

b. Chain propagation and termination reactions

When the KN in the chain propagation and termination reactions is considered, three aspects must be discussed:

1. the nonuniformities arising in connection with the possible occurrence of these reactions in the PMP produced and in the aqueous phase.

2. The nonuniform distribution of the concentrations of the monomer and of the growing radicals in the bulk of the PMP.

3. The variation during polymerisation of the chain propagation and termination rate constants.

In discussing the homogeneous PMP nucleation processes, we drew attention to the fact that the chain propagation reaction develops partially in the aqueous phase up to the instant of the capture of an oligomeric radical by the particle. The nature of this reaction depends on the nature of the monomer employed. Depending on the solubility of the monomer in water, from several to several tens of monomer units can add to the primary free radical before the oligomeric radical enters the PMP and its growth continues under other conditions. This means that the chain propagation reaction in emulsion polymerisation is kinetically extremely nonuniform. It occurs initially at very low monomer concentrations (10^{-3}–10^{-1} M) in the aqueous phase and then continues at a concentration of 5–7 M in the PMP. Despite this two-stage mechanism of the chain propagation (in water and in the PMP), the molecular characteristics of the polymer formed are largely determined by the processes in the PMP, because, for 10^3–10^4 additions of the monomer to the free radical in the particle, there are not more than several tens of chain propagation steps in water.

The latter claim is valid only provided that the growing radicals have insufficient time to undergo bimolecular termination in the aqueous phase before being trapped by the PMP. It has been shown[92,93] that the probability of chain termination exists and is most marked in the emulsion polymerisation of monomers sparingly soluble in water, characterised by low chain propagation rate constants (such as styrene), and also at high initiator concentrations, i.e. under the conditions of a low rate of chain propagation and a high rate of generation of free radicals in the aqueous phase. The bimolecular chain termination in water leads to an appreciable nonuniformity of the polymer with respect to molecular mass. This is indicated by experimental data which confirm the presence in the polymer of a low-molecular-mass fraction ($M_n = 10^3$) together with the high-molecular-mass fraction ($M_n = 10^5$–10^6).[94–96] The formation of two polymer fractions can be explained not only by the different monomer concentrations in water and in the PMP but also by different chain termination rate constants (k_t) in different media. Whereas in the PMP, where the polymer concentration is usually 40% to 50%, termination takes place in a highly viscous medium with $k_t = 10^3$–10^5 litre mol^{-1} s^{-1},[89] in the aqueous phase this reaction has been shown recently to be characterised by the constant $k_t = 10^9$ litre mol^{-1} s^{-1}.[64]

The rate constants for the elementary reactions change appreciably in the third stage of emulsion polymerisation, where the process proceeds with formation of PMP in the absence of monomer drops. Under these conditions, the microviscosity in the PMP rises rapidly, as a result of which the chain propagation reaction becomes diffusion-controlled at a certain degree of conversion. As regards chain termination, this reaction is the same as in the stationary stage of emulsion polymerisation, where the polymer content in the PMP reaches high values. The increase in conversion in the third stage leads to a further lowering of k_t, which induces the gel effect. It is noteworthy that the gel effect manifested in emulsion systems is fairly unusual. It is known that in emulsion polymerisation the gel effect usually arises for conversions in excess of 40%–50%, whereas in homogeneous systems this phenomenon occurs for lower conversions of the monomer. Furthermore, the explicit appearance of the gel effect (increase in the rate of polymerisation) is not always observed in emulsion polymerisation, because the increase in the average

number of radicals in the PMP, responsible for the increase in the rate of polymerisation, can occur only when the particle reaches a certain size (usually more than 100 nm). If the latter condition is not fulfilled, then the gel effect is absent even in the polymerisation of methyl methacrylate.[67]

The chain propagation reactions in emulsion systems differ significantly from those in homogeneous systems. If methyl methacrylate is polymerised in an oil at 50–60 °C, then the reaction ceases for a conversion of 84%–85%, because the reaction system approaches the vitreous state,[97] whereupon the chain propagation rate constant tends to zero, as shown by Marten and Hamielec.[98] In the emulsion polymerisation of methyl methacrylate at similar temperatures, it is possible to attain a conversion of 97% and above[97] and the constant k_p remains fairly high (of the order of 10^1 litre mol^{-1} s^{-1}) even for such conversions of the monomer.

The differences between the homogeneous and emulsion systems can be explained by two causes.

Firstly, the data presented by Marten and Hamielec[98] were obtained without taking into account the appreciable change in initiation efficiency at high conversions. It has been shown[99] that for azo-compounds the initiation efficiency decreases from 10^{-4} at 80% conversion to 10^{-6} at 82%–83% conversion. The latter factor shows that the data of Marten and Hamielec[98] are incorrect. The constants k_p listed in Table 2 are more reliable, because they were calculated from direct measurements of the concentration of active centres by EPR. The decrease in initiation efficiency can then be disregarded, since free radicals are generated in the aqueous phase, the viscosity of which remains virtually constant during polymerisation.

Secondly, the rate constants for the diffusion-controlled chain propagation reaction under homogeneous conditions and in emulsion polymerisation may indeed differ owing to the different conditions governing the transport of the monomer molecules to the active centres. During polymerisation in an oil, the average distance between the free radicals is ~100 nm. In an emulsion system for a PMP diameter of ~50 nm, the pathway which the monomer molecule must traverse before encountering a free radical is approximately four times shorter,[97] which suggests a higher value of k_p for the same diffusion coefficient.

The characteristic features of the chain propagation reaction at high monomer conversions examined above make it possible to formulate the principal conditions governing the formation of latexes with a minimal content of the residual monomer.

1. The use of water-soluble initiators. This rules out a decrease in the initiator decomposition rate constant and in initiation efficiency with increase in the microviscosity in the PMP.

2. The increase in the reaction temperature above the glass point of the polymer formed.

3. The introduction of solvents which reduce the glass point of the reaction system.

4. The increase in the monomer concentration in the PMP. This is needed particularly for monomers which are readily soluble in water (methyl acrylate, vinyl acetate, acrylonitrile). A change in the distribution of the monomer between the aqueous phase and the particles can be achieved by reducing the surface tension at the PMP–water interface and by selecting conditions ensuring the formation of a latex with particles having a minimal size. The last recommendation follows Morton's equation,[53] which relates the equilibrium monomer concentration in the PMP to a series of physicochemical parameters of the system.

In considering the polymerisation process developing in the PMP, one should note that the particles formed, like the reaction system as a whole, are nonuniform. In the discussion of the initiation reactions, it was shown that the surface of the particle and its bulk phase are kinetically nonequivalent. For the chain propagation and termination steps, these factors are less important. The polymerisation of monomers with surface-active properties is an exception. Their location in the adsorption layer influences significantly the kinetic parameters.[100] In other cases, it is possible to restrict the treatment to the consideration of the inhomogeneities associated with the nonuniform distribution of the reactants in the bulk of the PMP.

According to the ideas of Williams and coworkers[101,102] concerning the monomer concentration gradient in PMP, the polymerisation process develops mainly in the shell of the particles as a consequence of the higher monomer concentration in the surface layers. For the majority of simple systems, the concept of a thermodynamically improbable monomer concentration gradient has not received reliable experimental confirmation, although in certain cases an equilibrium monomer concentration may in fact not be established throughout the bulk of the PMP by virtue of kinetic causes (for example, the rate of diffusion of the monomer into the reaction zone may be lower than the rate of its polymerisation). Such a situation arises in the polymerisation of polar monomers characterised by high constants k_p[67] or when the monomer is supplied to the reactor at a rate lower than the rate at which it reacts.[78] Under these conditions, the monomer, having insufficient time to penetrate into the core of the particle, polymerises in its shell. For example, Kao et al.[103] showed that, in seeded emulsion polymerisation of styrene with a low rate of supply of the monomer, the thickness of the shell does not exceed 16% of the particle radius.

Another cause which explains the formation of particles of the core–shell type in the PMP during emulsion polymerisation without resorting to the concept of the monomer concentration gradient is associated with the nature of the initiator generated in the decomposition of the radical-anions, for example $SO_4^{\cdot-}$ formed on decomposition of persulfates. The electrical charge arising at one end of the growing macromolecule maintains it in the surface zone of the PMP, which restricts or altogether prevents the translational mobility of the macromolecule. Similar effects occur when surface-active initiators are used. Simple calculation shows that the statistical average size of the polymer coil with a degree of polymerisation of 10^4 should not exceed 10^2 Å even in a dilute solution. It has been shown[95] that, in the emulsifier-free, seeded potassium persulfate-initiated emulsion polymerisation of styrene, the polymerisation reaction proceeds in a shell ~100 Å thick on seed particles 2000 Å and more in diameter.

It is noteworthy that, in order to account for the possibility of the formation of PMP of the core–shell type, the concept of the fixation of one end of the growing macroradical is not always adequate. It is well known,[104,105] that by no means all

Table 2. Kinetic parameters of the emulsion polymerisation of methyl methacrylate initiated by $K_2S_2O_8$ at 50 °C.[97]

macromolecules have terminal SO_4^- groups formed as a consequence of the reaction

$$SO_4^- + HOH \longrightarrow HSO_4^- + HO^\cdot ,$$

and the subsequent initiation of the polymerisation by hydroxyl radicals. One cannot rule out the hydrolysis of the SO_4^- end groups, which also leads to the appearance of electrically neutral terminal fragments. The SO_4^- groups may be partly 'buried' in the bulk of the PMP.

Chern and coworkers[106] proposed the concept of a nonuniform distribution of free radicals in the bulk of PMP regardless of the type of end groups. The authors calculated the radical distribution function along the particle radius assuming that the movement of the radical is random and is caused by the chain propagation, i.e. polymerisation. The movement of the growing radical stops as a result of chain termination or after the radical is completely surrounded by segments of the inactive polymer. Modelling of such movement by the Monte Carlo method showed that the distribution function is exponential and that it assumes the highest values for the surface layers of PMP, tending to zero for regions close to the centre of the particle.

The nonuniformities arising in the formation of PMP can be used in the formation of polymer dispersions with particles having a complex morphology and in securing specified properties of the polymeric product. A typical case is that of the synthesis of ABS copolymers by the seeded copolymerisation of styrene and acrylonitrile on polybutadiene particles. This type of technology, ensuring the formation of particles of the core–shell type, is widely used for the synthesis of different polymeric materials.[67, 107, 108] It actually makes it possible to obtain materials with opposite properties from the same monomeric raw material: plates with rubber inclusions which are distinguished by a high impact strength; elastomers reinforced by particles of rigid-chain polymers; latexes with a low minimum film-formation temperature due to the formation of a soft shell on hard particles. Studies have been carried out recently on the synthesis of latexes with particles containing inclusions of mineral pigments or fillers[109, 110] and dispersions of particles with microcavities.[111, 112]

The required properties of latexes or of the polymeric materials based on them are attained when particles with a specified morphology are obtained. The creation of the required core–spherical shell structure involves serious difficulties in many cases. The first problem — the carrying out of the process on seed particles — is solved relatively easily. It is sufficient to create conditions which exclude the formation of new particles. This is attained by carrying out the seeded emulsion polymerisation in the absence of the free emulsifier, the presence in the system of seed particles reducing sharply the probability of forming new PMP via the homogeneous mechanism.[113]

It is more difficult to guarantee the formation of a polymer solely on the surface of the seed particles. Under the conditions of equilibrium swelling of the particles in the monomer, polymerisation can occur also in the bulk of the PMP with formation of a new polymer in the form of inclusions in the seed particles. Such a process can be fully excluded, provided that the monomer and the polymer formed are thermodynamically incompatible with the polymer of the seed. In this case, seeded emulsion polymerisation on mineral microparticles is ideal. However, even when the conditions listed above are fulfilled, the correct core–shell structure is not always attained. Sometimes the polymer is formed on the seed particles in the form of excrescences[114] or has the raspberry fruit shape.[115]

The causes responsible for a particular morphology can be elucidated on the basis of thermodynamic and kinetic analysis of the processes occurring in the formation of heterogeneous particles. A complete analysis of the thermodynamics of the formation of particles with a complex structure has been carried out by Sundberg and coworkers[116, 117] in terms of the free surface energy (G) of the three-phase system (polymer 1, polymer 2, and water):

$$G = \sum \gamma_{ij} A_{ij} ,$$

where γ_{ij} is the interfacial tension between phases i and j and A_{ij} is the area of the interface between phases i and j. In such analysis, each morphology of the particle should be associated with its own free energy. For example, the free energies for particles with two extreme structures of the core–shell type can be represented by the following equations:

$$G = \gamma_{12} 4\pi r_1^2 + \gamma_{2w} 4\pi r_2^2 , \quad (1)$$

polymer 2 is polymerised in the form of a shell with a radius r_2 on seed particles of polymer 1 with a radius r_1);

$$G = \gamma_{12} 4\pi r_2^2 + \gamma_{1w} 4\pi r_1^2 , \quad (2)$$

(polymer 2 is polymerised in the bulk of the seed particles and forms a core with a radius r_2 surrounded by a shell of polymer 1 with a radius r_1).

In the above equations, γ_{12} is the interfacial tension between polymers 1 and 2 and γ_{1w} and γ_{2w} are the interfacial tensions at the polymer 1–water and polymer 2–water boundaries respectively.

Using similar equations, Sundberg and coworkers[116, 117] demonstrated the possibility of predicting the morphology of the particles. Naturally, the most probable morphology is that which has the minimum free energy. Indeed it has been demonstrated in practice[107, 108] that, when polymer 2 is more polar and hydrophilic than polymer 1, then it forms a shell on cores comprising the seed particles. If polymer 2 is hydrophobic while polymer 1 has hydrophilic properties, then the formation of the opposite morphology is more probable.

The interfacial tension may be influenced with the aid of surfactants. The usual low-molecular-mass surfactants are known to diminish effectively the polymer–water interfacial tension. Therefore the use of surfactants, especially for the preparation of particles with a hydrophobic shell, is an essential procedure. It has been shown[118] that the use of more effective surfactants in the formation of particles in which the core consists of poly(methyl methacrylate) while the shell consists of polystyrene promotes the attainment of the required morphology. The interfacial tension at the polymer 1–polymer 2 interface can be regulated by forming during the synthesis graft copolymers on the interface, which play the role of surfactants capable of stabilising emulsions of the oil in oil type. As an example, one may quote yet again the synthesis of the ABS copolymers during which a certain amount of a graft copolymer is produced as a result of the grafting of styrene and acrylonitrile to polybutadiene macromolecules.

Yet another thermodynamic factor is the compatibility of the polymers. It would seem that the ideal case is that of complete incompatibility of the seed polymer and the polymer formed in the second stage. However, it is then difficult to count on the formation of a continuous shell. The heterogeneous particles formed can have a mushroom or raspberry shape. A limited compatibility of the polymers is therefore desirable. It is achieved, for example, by the partial grafting of the shell polymer to the core polymer already mentioned. The problem of the incompatibility of the polymer arises only at a certain stage of the process after a certain degree of conversion of the monomer, because in the initial state the PMP is as a rule homogeneous (the monomer is a solvent for the seed polymer).

In order to predict the morphology of the particles, it is necessary to take into account kinetic as well as thermodynamic factors. We shall consider certain kinetic factors which determine the possibility of achieving the polymerisation process in the shell of the particle. These factors are associated either with the localisation of the active centres in the surface zone of the PMP or

with the creation of conditions preventing the penetration of the monomer and of the polymer formed in the second stage into the bulk of the seed particle and promoting the appearance of new interfaces: polymer 1–polymer 2 and polymer 2–water. As an example, we shall consider the most complex thermodynamically unfavourable case — the creation of a hydrophobic shell on hydrophilic seed particles.

As shown above, the localisation of the active centres in the PMP shell is promoted by the use of initiators generating radical-ions on thermal decomposition, which fix one end of the growing macroradical in the surface zone of the particle. In the polymerisation of styrene on poly(methyl methacrylate) (PMMA) seed particles in the presence of potassium persulfate, it is not possible to obtain a continuous polystyrene (PS) shell, but an appreciable proportion of the polystyrene domains are on the surface of the PMMA particles.[118] A similar picture is observed in the polymerisation of styrene on poly(vinyl acetate) particles, but, in contrast to the first case, only under the conditions of a slow supply of the monomer to the reaction system.[113] If AIBN is used to initiate the seeded emulsion polymerisation of styrene in the presence of PMMA particles, then a completely inverted structure arises (the polystyrene is present in the form of a core within the bulk of the PMMA seed particle).[118]

The use of initiators linked by covalent bonds to the surface of the seed particles is an effective method for the preparation of core–shell particles. Such a possibility has been demonstrated[67] in the polymerisation of n-butyl acrylate on seed particles comprising the styrene–methacrylic acid ester of α-hydroxyethyl-*tert*-butyl peroxide (MEP) copolymer. The formation of a continuous poly(butyl acrylate) shell is indicated by the low minimum latex film formation temperature (the film was obtained even at 0 °C). It is noteworthy that in this case the MEP units ensure not only the initiation of the process but also the grafting of n-butyl acrylate, which assists in the formation of a regular structure.

Particles with a regular core–shell morphology are formed when purely kinetic approaches are used. These are based on introducing the monomer into the seed latex at a rate equal to or lower than the rate of its polymerisation. The polymerisation of styrene on seed particles comprising hydrophilic polymers [poly-acrylates, poly(vinyl acetate)] under the conditions of a reduced rate of supply of the monomer to the reactor ('monomer starvation') ensures the formation of surface polystyrene domains and in certain cases of a continuous shell.[113, 118, 119]

Another procedure, which also hinders the diffusion of the monomer into the bulk of the seed particles, involves the use of cross-linked polymers as the seed.[118] If the cross-linking agents are also used in the seeded emulsion polymerisation stage, then a continuous shell of the hydrophobic polystyrene on the particles of the cross-linked poly(butyl acrylate) is formed even when an oil-soluble initiator is employed.[119] When seeded emulsion polymerisation is carried out at a reduced temperature, the rate of diffusion of the monomer is also lowered, which makes it possible to obtain sometimes a regular core–shell morphology without resorting to the 'monomer starvation' procedures.[120]

The procedures described above for the regulation of the morphology of heterogeneous particles are listed in Table 3. Analysis of the data presented makes it possible to differentiate the following factors governing the structure of the particles formed: the degree of compatibility of the polymers in the core and in the shell; the existence of a chemical bond between the polymers (grafting) or the formation of interpenetrating networks (the use of cross-linked agents); the relation between the hydrophilic and

Table 3. The influence of the conditions in seeded emulsion polymerisation on the morphology of the heterogeneous particles.

Seed	Monomer	Initiator	Surfactant	Method for emulsion polymerisation	Morphology of particles	Ref.
PMMA	Styrene	$K_2S_2O_8$	P-8	Single introduction of all components	Incomplete inversion. PS domains within and on the surface of particles	118
PMMA	Styrene	AIBN	P-8	Ditto	Complete inversion	118
PMMA	Styrene	AIBN	P-40	"	Incomplete inversion. PS domains within and on the surface	118
Styrene–MEP copolymer	n-Butyl acrylate	MEP units	E-30	"	Core — copolymer, shell — poly(butyl acrylate)	67
PMMA cross-inked by AM	Styrene	AIBN	P-80	Semicontinuous emulsion polymerisation ('monomer starvation')	PS domains on the surface of PMMA	118
Poly(vinyl acetate)	Styrene (monomer : seed = 0.3–0.35)	$K_2S_2O_8$	–	Ditto	PS domains on the surface of poly-(vinyl acetate)	113
Poly(butyl acrylate) cross-linked by AM (1%)	Styrene + divinyl-benzene (0.5%)	AIBN	–	"	Core–shell (PS shell)	119
Poly(vinyl acetate)	Styrene (monomer : seed = 0.7	$K_2S_2O_8$	–	"	Core–shell (PS shell)	113
Polystyrene	Methyl methacrylate	–	–	Once only introduction of components	Core–shell (PMMA shell)	120
Polystyrene	Methyl methacrylate	–	–	Ditto	Core–shell (PS domains in the core)	120

Note. The following notation has been adopted: AM = allyl methacrylate; P-8 = hydroxyethylated nonylphenol (8 hydroxyethylene units); P-40 = hydroxyethylated nonylphenol (40 hydroxyethylated units); E-30 = sodium alkanesulfonate (alkane = $C_{15}H_{31}$).

hydrophobic properties of the polymers of the core and the shell; the nature of the surfactant; the type of initiator; the method used in carrying out the seeded emulsion polymerisation (by introducing the monomer into the seed latex in one go or by carrying out the process under the conditions of 'monomer starvation'); the process temperature; the seed polymer : monomer ratio.

Thus emulsion polymerisation is kinetically an extremely nonuniform process. It is characterised by the same elements of KN which obtain in radical polymerisation under homogeneous conditions, namely the change in the elementary reaction rate constants at high conversions. However, this type of KN in emulsion polymerisation is manifested in a fairly unusual manner (the gel effect arises at higher conversions and under certain conditions is absent even in the polymerisation of methyl methacrylate). When the emulsion polymerisation is initiated by water-soluble compounds, viscous effects do not influence the initiation reaction.

The fundamental difference between emulsion polymerisation and other radical systems, even heterogeneous ones, is associated with the characteristics of the nucleation of the PMP. The polydispersity of the particles, the different mechanisms of their nucleation, and the possibility of the nucleation of the particles via several mechanisms simultaneously lead to a new type of KN which is not characteristic of other types of radical polymerisation. The KN of this type introduces additional elements which are responsible for the nonuniformity of the molecular characteristics of the polymers formed. On the one hand, the KN in emulsion systems induces appreciable nonuniformities in the properties of the polymerisation product (polydispersity of the latex, a broad molecular mass distribution, nonuniformity of the composition of the copolymers) and, on the other, can be used to establish and regulate the properties of new polymeric materials. The most interesting approaches, which can be employed in emulsion systems, involve the formation of particles of the core–shell type having a heterogeneous structure.

In conclusion of this section of the review, we may note that analysis of the causes responsible for the KN in emulsion polymerisation permits a specific selection of the process conditions ensuring the minimum (or maximum) manifestation of KN or its complete elimination. Emulsion polymerisation on radicals, separated in space on individual PMP, may serve as an example. The polymers formed under these conditions are almost monodisperse.[121]

IV. Kinetic nonuniformity in polymerisation processes in the presence of a dispersed solid phase

Systems with a dispersed solid phase have been introduced into research practice comparatively recently. The results have been surveyed in a number of reviews.[43,44,122,123] As in emulsion polymerisation, the heterogeneity of the system is specified by the initial polymerisation conditions (degree of dispersion of the solid phase and its permeability to the monomer, the nature of the monomer and other system components, etc.).

One of the principal problems is that of the state of the monomer and initiator molecules and of the growing radicals in different zones of the polymerisation system and of their role in the polymerisation kinetics in the creation of the structure of the macromolecules formed.

If dispersed inorganic materials incompatible with and impermeable to the monomer, initiator, etc. are used as the initial solid phase, we can differentiate three zones in which the elementary polymerisation reactions take place (Fig. 3): I—zone located in the immediate vicinity of the surface of the solid phase where the monomer (or the initiator) can be bound chemically or physically to the solid surface; II—transitional zone; III—the bulk phase (of the monomer or its solution) zone.

Near the surface zone, the components of the polymerisation system (the monomer, the initiator, etc.) can have reactivities

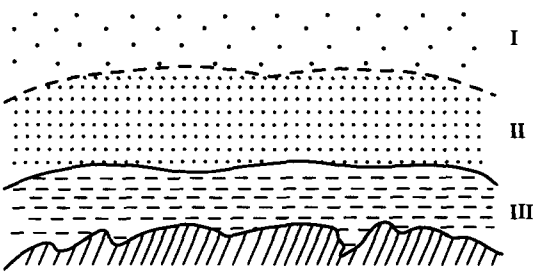

Figure 3. Schematic illustration of the establishment of the concentration nonuniformity in heterogeneous polymerisation in the presence of a dispersed solid phase: (I) bulk phase (monomer vapour or solution); (II) transitional layer; (III) layer of monomer physically adsorbed or chemisorbed on the surface or in the immediate vicinity of the surface of the dispersed phase.

different from those of the same components in the bulk of the liquid phase, which is the cause of the KN.

If the solid phase (for example, the polymer phase dispersed in the polymerisation system) is permeable to the polymerising monomer, then the reaction zone may arise there during polymerisation and may spread directly in the polymer phase.[124–128]

It has been shown[122,123] how significant is the adsorption and molecular transport of the monomers (or other components) on the surface in determining the characteristics of heterogeneous polymerisation. In the model proposed for the reaction zone, the monomers are divided into systems with strong and weak bonding depending on the adsorption mechanism and the adsorption bonding forces. Examples of such systems are presented in Table 4.

A mobile nonlocalised adsorption, which is reversible close to room temperature, is characteristic of systems weakly bound to the surface. The surface diffusion coefficients in these systems are fairly high (10^{-4}–10^{-5} cm^2 s^{-1}). For systems with strong bonding, the distribution of the monomer on the surface is of a localised type and the adsorption is irreversible and activated.

In systems with strong bonding to the surface, the surface of the dispersed solid phase is modified by the chemical interaction and is fully covered by a molecular monomer (or initiator) layer. Thus dispersed inorganic fillers with surface (anchoring) monomer groups or initiating peroxy-groups of the type of macromonomers or macroinitiators can be obtained by the interaction of the hydroxy-groups of aerosil with alkoxy- or halo-groups of organosilicon compounds containing polymerisable (vinyl) bonds or initiating groups.[43,44,130–132]

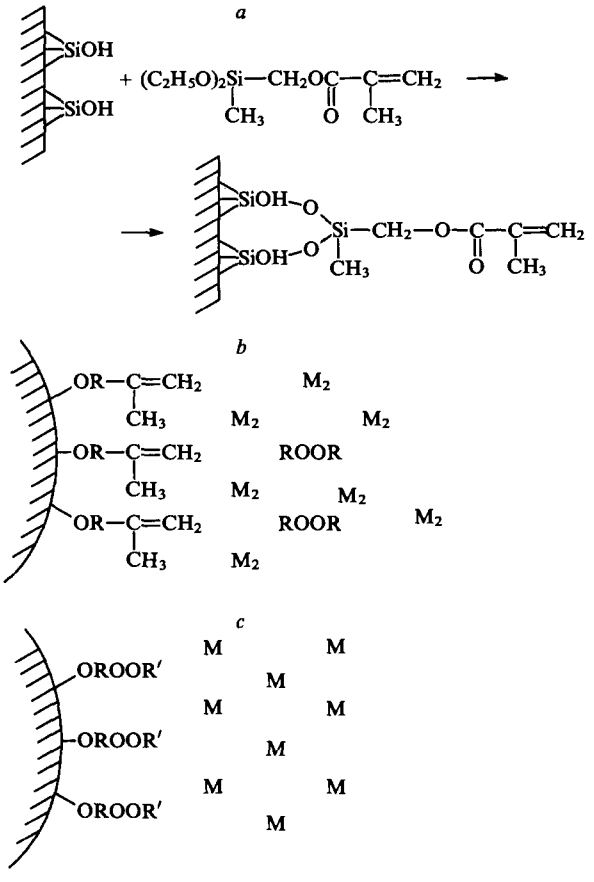
In polymerisation systems with such components, we encounter an artificial nonuniform distribution of the concentrations of the initiator or the comonomer established beforehand in the polymerisation system (Fig. 4). Naturally, in such systems the KN underlies the very structure of the distribution of the initial components of the recipe and makes it possible to some extent to predict beforehand or to establish the microheterogeneity of the polymer systems or compositions formed and to obtain polymer-inorganic compositions or block copolymers with a satisfactory enforced compatibility of the solid phase with the polymer phase produced during polymerisation. Such compatibility is achieved by the chemical grafting of the polymer to the solid phase.[44,133–135]

The study of the kinetics of polymerisation in the heterogeneous systems considered is far from complete and there is virtually no theory of heterogeneous radical polymerisation. The characteristics of the elementary reactions constitute a key to the understanding of the experimentally observed kinetic features. Therefore, in analysing the KN of such systems, we shall concentrate on the characteristics of their occurrence in some of the most thoroughly investigated systems.

Table 4. The mechanisms of the adsorption of vinyl monomers in certain systems.[129]

Monomer	Adsorbent	Characteristics of sorption mechanism	Characteristics of adsorption bonding force
Alkenes and dienes	SiO_2	Formation of weak π-complexes between C=C bonds (or a system of C=C bonds) and surface OH groups	$\Delta\nu(OH) \approx 100-120$ cm^{-1}
Carbonyl-containing compounds (VA, MMA, MA, OMA)	SiO_2	Formation of hydrogen bonds between carbonyl and silanol groups. At low coverages, the oxygen of the methoxy-group may participate in the adsorption interaction	$\Delta\nu(OH) \approx 300$ cm^{-1} $\Delta H_\alpha \approx 49-53$ kJ mol^{-1}
Carbonyl-containing compounds (VA, MMA, MA, OMA)	MgO Al_2O_3	Chemisorption as a result of strong coordination of C=O group to the surface	$\Delta\nu(C=O) = 170$ cm^{-1}
Unsaturated carboxylic acids	SiO_2	Possibility of the interaction of the carboxy-group with two OH surface groups	$\Delta\nu(OH) = 350$ cm^{-1}
Unsaturated carboxylic acids	Aminated aerosil	Ionisation of acids in the presence of adsorbed water	
Nitrogen-containing vinyl monomers (4-VP, 2-VP, *N*-VPD, etc.)	SiO_2	Acid–base interaction with surface OH groups	$\Delta\nu(OH) \approx 700-950$ cm^{-1} $\Delta H_\alpha = 140$ kJ mol^{-1}
4-VP	Carboxylated aerosil	Formation of ionic bonds in the presence of adsorbed water	
Styrene	SiO_2	Formation of weak π-complexes with surface OH groups. Resolution of the rotational structure in IR spectra	$\Delta\nu(OH) = 120$ cm^{-1}

Note. The following notation has been adopted: OMA = octyl methacrylate, VP = vinylpyridine, *N*-VPD = *N*-vinylpyrolidinone.



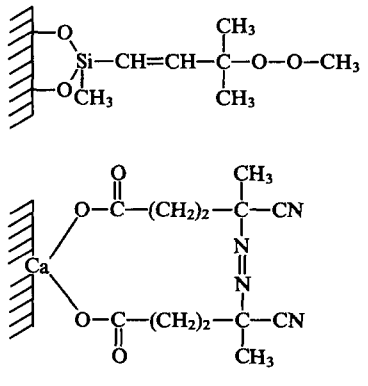


Figure 4. Schematic illustration of the formation of anchoring compounds on the aerosil surface (*a*) and illustration of the concentration nonuniformity in the distribution of the comonomer (*b*) and the initiator (*c*) in a heterogeneous polymerisation system.

1. Initiation of heterogeneous radical polymerisation in the presence of a dispersed solid phase

Such a reaction can be achieved in several ways.

1. By means of the functional group of the initiator fixed on the solid surface (as a result of a chemical reaction with the surface groups of the solid phase).[130–132, 136, 137]

Such initiating systems may be assigned to the class of macroinitiators.

2. By means of initiators deposited on the solid surface as a result of preliminary physical adsorption from solution.

3. By means of an initiator introduced into the monomer phase.

4. By means of radiation initiation or photoinitiation.

The choice of the type of initiation of heterogeneous polymerisation is frequently determined by the endeavour to obtain the maximum amount of the polymer grafted to the solid surface.

For the first two versions, we may note the nonuniformity of the distribution of the initiator and hence the localisation of the initiation reaction in the zone adjoining directly the surface, which by itself leads to KN. It has been shown in a number of studies[23, 131, 136–138] that, together with this feature, the localisation of the initiator in the surface zone can alter significantly the

Table 5. The constants k_p and k_t for the polymerisation reactions of vinyl acetate and methyl methacrylate on the surface (monolayer coverage) and in the liquid phase (in bulk) at 50 °C.

Parameter	Vinyl acetate			Methyl methacrylate		
	on the surface		in the liquid phase	on the surface		in the liquid phase
	AS/400	MAS		AS/400	AS/200	
k_p/litre mol^{-1} s^{-1}	34	160	1500–2600	22	15.4	350–410
$10^{19} k_p$/cm^3 molecule^{-1} s^{-1}	1.4	2.7	25–43	0.39	0.26	5.8–6.8
k_t/litre mol^{-1} s^{-1}	–	5.4×10^3	2.5×10^7	–	–	2×10^7
$10^{19} k_t$/cm^3 molecule^{-1} s^{-1}	–	0.9	4.2×10^3	–	–	3.3×10^3

Note. The following notation has been adopted: AS/400, AS/200 = aerosil; MAS = methylated aerosil.

kinetics of radical formation. We noted the acceleration of the decomposition of hydroperoxides in heterogeneous systems (Table 1) in the analysis of the characteristic features of emulsion polymerisation. Similar data have been obtained[138] for the decomposition of cumenyl hydroperoxide on the surfaces of particles of titanium compounds.

The kinetics of the decomposition of initiators (derivatives of azonitriles and peroxides) fixed by covalent bonds on the surface of copper or aerosil have been studied in greatest detail.[131,136,137,139] The initiators fixed on the surface decompose much faster (with the exception of 4-azobis-4-cyanopentanoic acid[129,136]) and the activation energy for the decomposition reaction is lower than for the decomposition in the liquid phase under similar conditions. However, as for emulsion systems,[83] a decrease in the effectiveness of initiation is observed. Such a decrease depends on the way in which the initiator is fixed on the solid surface (via one or both ends of the initiator) and can differ by an order of magnitude.

A mechanism which explains these results has been proposed. Its essential feature reduces to the orientation effect on the surface as a function of the method of fixation of the initiator and to the increase in the role of the cage effect in connection with the hindrance to the separation of the radical pair by diffusion and hence a greater probability of a radical acceptor mechanism of the liberation of the initiating radicals.

When an initiator introduced into the monomer phase of the system is used, the initiation reaction differs little from that in homogeneous systems if a distribution of the initiator concentration does not occur under the influence of the solid surface.

The radiation initiation and photoinitiation in heterogeneous systems have been analysed in detail.[122,123,129] One may note the coupled influence of the nature of the dispersed solid phase and of the polymerising monomer on the initiation reactions and on the appearance of nonuniform zones in the system and hence on the KN.

2. Chain propagation reactions

The elementary chain propagation and chain termination reactions in radical polymerisation in the presence of dispersed solids have been surveyed by Bruk and Pavlov,[122,123] and also by Krul'.[124] The experimental polymerisation rate constants in a number of heterogeneous systems have shown that the reactivity of the monomers in the region of the surface of the solid is significantly lower (by 1–2 orders of magnitude) than in the liquid phase.[123,129] We obtained similar data for monomers grafted to the aerosil surface.[140] The possible energetic nonuniformity of the surface relative to the adsorbed or bound monomer and the lateral interactions in the absorption layer must be regarded as the main causes of this behaviour.

The elucidation of the role of diffusional inhibition is important for the determination of the causes of the decrease in the reactivity of the monomers in the region of the surface. The possibility of diffusional inhibition is indicated by the dependence of k_p on the degree of surface coverage by the monomer. However, it has been shown[141] that an appreciable influence of diffusional retardation on k_p in polymerisation on the surface can be assumed only for systems characterised, together with a low surface mobility of the monomers, by a low equilibrium monomer vapour pressure. This is possible only for certain systems with strong bonding of the monomer to the surface and provided that the polymerisation is carried out from the gas phase at low monomer partial pressures. Certain kinetic parameters of the polymerisation of vinyl acetate and methyl methacrylate adsorbed on a surface and in the liquid phase, taken from a monograph,[123] are presented in Table 5.

Evidently, the chain propagation rate constants expressed in comparable units are at least an order of magnitude lower on the surface than in polymerisation in the liquid phase. This difference is greater in systems with strong bonding of the monomer to the surface. One may assume that an increase in the volume of the monomer molecules (an increase in the length of the substituent) can lower k_p and enhance the stereocontrol on the surface in the chain propagation steps.

In the adsorption layer, the monomer copolymerisation constants may change significantly.[123] These changes are most marked for monomers differing in the strength of their adsorption to the surface. Table 6 presents the copolymerisation constants for certain monomers taken from the monograph of Bruk and Pavlov.[123]

Table 6. Copolymerisation constants in the liquid phase and on the surface of aerosil.[123]

VA/4-VP	MMA/4-VP	VA/VPD
Liquid phase		
0/30	0.57/0.79	0.20/3.3
AS surface, 70 °C		
0.14/0.11	0.50/0.50	0.27/3.0
AS surface, 20 °C		
0.25/3.5	0.45/0.15	0.65/1.3

3. Kinetic chain termination processes

One of the principal features of the polymerisation in heterogeneous systems in the presence of dispersed solids is the inhibition of the quadratic chain termination processes in the interaction of the growing radicals. This can be caused by the decreased capacity for diffusion and by the possibility of the insulation of the growing radicals in space. The quantitative data presented in Table 5 and obtained in the determination of the quadratic termination constants for the growing radicals in the region of the surface in the polymerisation of vinyl acetate are 3–4 orders of magnitude lower than in the liquid phase. The low values of k_t give rise to long average lifetimes of the kinetic chains. The low translational mobility and the long average lifetimes of the kinetic chains enhance the role of alternative chain termination mechanisms, for example the linear mechanism.

The mechanism of the linear termination is usually related [123] to the immobilisation of the growing macroradical at a certain propagation stage without the chemical destruction of the growing radical. The loss of the reactivity of the radicals in the propagation reaction is observed when they attain certain chain lengths or as a result of a conformational transition with localisation of the active centre within the globule or as a result of the immobilisation or enclosure in a structural trap — a micropore. This is promoted by an increase in the rate of termination with increase in the content of micropores in the solid phase.

The immobilisation effect is manifested to a lesser extent for macroradicals characterised by a high reactivity (for example, in the case of vinyl acetate). The probability of chain transfer to the monomer as a variant of the linear termination mechanism may increase for such systems.

In any polymerisation system, there is a possibility of the simultaneous retention of conditions for the quadratic and linear termination of the growing chains. Mixed termination, expressed by an initiation reaction order between 0.5 and 1.0, frequently obtains in practice.

It is of interest to note the results obtained in the study of the dependence of the fraction of the immobilised radical α on the average distance between the initial active centres r and on the nature of the polymerising monomer.[129] For high values of r, the fraction α is close to 1 (Table 7). With decrease in r, the fraction α diminishes monotonically as a consequence of the interaction of the growing macroradicals. Quadratic termination begins to compete with the linear termination at a radical concentration of $(1.5-2) \times 10^{14}$ m^{-2}, which can be adopted as the onset of the effective overlap of the coils on the surface.

Table 7. The influence of the nature of the monomer, the average distance between the growing chains r, and the polymerisation temperature on the capacity of the growing macroradicals for immobilisation on the surface of aerosil modified by methacrylic acid (monomer temperature in the feeding device 0 °C).

Monomer	Fraction of immobilised chains		
	r = 30 nm, T = −78 °C	r = 114 nm, T = 25 °C	r = 7 nm, T = 25 °C
Methyl methacrylate	1	0.98 [a]	0.40
Methacrylic acid	1	0.44	0.41
α-Methylstyrene	0.5 [b]	0.60	0.22
Acrylonitrile	0.27	0.36	0.20
Methyl acrylate	0.22	0.39	0.14
Vinyl acetate	0.30	0.23	–
Styrene	0.18	0.33	0.16

[a] Temperature of liquid monomer in the feeding device: 25 °C.
[b] Temperature of liquid monomer in the feeding device: −23 °C.

4. Characteristic features of the chain propagation and termination in the polymerisation of monomers sorbed in polymer matrices

The polymerisation of monomers sorbed in polymer matrices is one of the variants of heterogeneous polymerisation in which the reaction zone [apart from the monomer (liquid) phase] can spread through the polymer phase. It has now been established [128, 129] that the characteristic dimensions of the microheterogeneity arising in the polymer matrix are comparable with the dimensions of the individual macromolecules formed. This justifies the consideration of the polymerisation processes in polymer matrices as typically heterogeneous reactions with segregation of a polymer microphase.

The study of the polymerisation of methyl methacrylate sorbed in polypropylene and PTFE matrices [129] led to the conclusion that the initial radicals are converted quantitatively into the PMMA chain propagation radicals and that the reaction ceases at a constant concentration of the growing radicals and of the sorbed monomer. With increase in the monomer vapour pressure in the gas phase, polymerisation is renewed at the previous rate. It has been found by a special method and with the aid of deuteriated methyl methacrylate that the equilibrium in the chain propagation reaction is established after the attainment of a definite length of the macroradical. Detailed analysis of the experimental data permitted the conclusion that the 'self-entombment' or immobilisation of the growing radicals is associated not with the diffusional hindrance of the monomer transport and the decrease in the mobility of the macroradical but with the decrease in the true reactivity of the growing macroradicals after they attain a certain chain length.[129] The restriction of the reactivity of the macroradical concerns only the chain propagation reaction and does not extend to the chain transfer reaction. These kinetic effects are a consequence of the thermodynamic conditions and are characteristic of both polymer matrices and of disperse inorganic systems.

V. Conclusion

The theoretical ideas and experimental data examined permit the claim that, in the determination of kinetic parameters, especially at advanced stages of the polymerisation reaction, it is essential to take into account the KN and the factors which determine it. In many cases the KN may be regarded as an effective instrument for controlling the polymerisation process and the characteristics and operating properties of the polymer formed. The latter may be confidently considered to apply to emulsion polymerisation and polymerisation in the presence of a dispersed solid phase. This is associated with the fact that the elements of the KN in heterogeneous polymerisation systems can be generated comparatively readily even before the onset of polymerisation (a specified distribution of the components in different kinetically nonequivalent reaction zones and their predicted reactivity in these zones).

In homogeneous systems, the KN is not always manifested explicitly, which hinders the use of the structural-kinetic approach in calculations for specific technological polymerisation processes. Nevertheless, in terms of the structural-kinetic aspect, the problems considered lead to definite prospects for the development of approaches which will make it possible to describe from a single standpoint the set of complex phenomena accompanying the polymerisation process. The creation of such an approach is complicated by the fact that the radical polymerisation process is characterised by a large set of interdependent parameters, the variation of which it is at present fairly difficult to predict.

One may assume that the most fruitful route to the solution of the problem involves a further development of ideas about the reactivity of molecules. Speaking of the latter, we draw attention yet again to the complexity of this concept for polymer systems and to the need to take into account not only the purely chemical factors (the electronic state of the molecules and radicals and the steric factors due to the presence of various substituents in the molecules) but also physical (diffusion) factors.

In conclusion we may note a further two considerations.

Firstly, in the development of kinetic mechanisms for radical polymerisation, it is necessary to take into account the possibility of a change as a function of conversion in not only the initiation, propagation, and termination reaction rate constants but also in the rate constants for other possible elementary reactions, for example the chain transfer rate constants. A simple approach has been proposed [142] to the calculation of the constants for chain transfer to the monomer as a function of the degree of conversion of the monomer into the polymer and it has been shown that, for example in the polymerisation of methyl methacrylate, a change in conversion from 80% to 90% lowers the rate constants for chain transfer to the monomer by a factor of approximately 3.

Secondly, in estimating the decrease in k_t with conversion only the change in the translational and segmental mobility of the macroradicals has been taken into account hitherto. Nevertheless,

there exists yet another form of motion of the macroradical—due to the polymerisation chain propagation. Buback et al.[143] noted a significant contribution of the latter type of motion to the overall decrease in k_t with conversion, having demonstrated the actual dependence of k_t on k_p at advanced stages of the polymerisation process.

We hope that the proposed approach to the generalisation of the ideas about the KN in radical polymerisation processes and about the polymerisation mechanism at different conversions will stimulate further studies in this field.

Modification of chemical additives to elastomeric compositions

A A Mukhutdinov, B S Grishin

Contents

I. Introduction 685
II. Physical modification of chemical additives 686
III. Physicochemical modification of chemical additives 689
IV. Conclusion 693

Abstract. The physicochemical principles of the modification of crystalline chemical additives to elastomeric compositions are examined. A classification of various types of modifications based on scientific principles is given. The modifications are subdivided into physical and physicochemical depending on the configuration of the molecules in the crystals, the defectiveness and dispersity of the crystalline particles, the melting points of the crystals, and the presence of nucleophilic and electrophilic centres in the molecules of the components of binary and complex eutectic mixtures. The effectiveness of the modification of the chemical additives is determined by the manifestation in binary systems of these components in elastomeric compositions of physical and chemical synergism due to the occurrence of the relevant processes in such systems. A relation has been discovered between the physical and chemical phenomena accompanying the modification of the chemical additives in binary and complex eutectic mixtures, their influence on the properties of the elastomeric composition is examined, the ecological problems associated with the processing of such materials are discussed, and the relation between the structure and properties of the molecules of the additives is analysed using quantum-chemical calculations. The bibliography includes 92 references.

I. Introduction

Chemical additives to elastomeric compositions, i. e. the components of sulfur-based vulcanising systems and antiageing agents, constitute molecular crystals (zinc oxide and liquid accelerators are an exception) whose structures are formed via intermolecular forces in accordance with the close packing principle.[1] In the processing of elastomeric compositions, it is essential that the crystalline chemical additives should be well dispersed and dissolved in the elastomer and that they should manifest at a certain instant a high chemical reactivity as moderators of prevulcanisation and as accelerators of the vulcanisation of elastomeric compositions and as antiageing and antifatigue agents in rubbers.

In the existing methods for the preparation of elastomeric compositions, the main criterion of the uniform distribution of crystalline chemical additives in the elastomer is their solubility. According to Gardiner[2] and Ikeda et al.,[3] the limiting solubilities of crystalline accelerators and sulfur in elastomers depend greatly on temperature. However, not the limiting but current solubilities of the components in the elastomers are more important. It has been established[4] that the times required for the dissolution of sulfur, di(2-benzothiazolyl) disulfide (DBTD), and *N*,*N*′-diphenylguanidine (DPG) with a 0.2 mm particle size in butadiene rubber at 130 °C are respectively 2.8, 11.4, and 4.6 min. Similar times are characteristic also of other chemical additives.

Crystalline accelerators and sulfur are introduced into elastomeric compositions at a temperature below 112 °C and the mixing time is 2.5 min. Under such conditions, a proportion of the additives introduced into the elastomer remains in the form of small crystalline particles, which behave as centres for the formation of defects in rubbers.[5]

Another important index of the effectiveness of chemical additives in elastomeric compositions is the extent to which they manifest their functional properties. In order to attain the maximum effectiveness of the chemical additives, compounds of different classes have been synthesised.[6] It was found that the effective manifestation of the properties of chemical additives cannot be achieved by using traditional methods for their introduction into elastomeric compositions. The use of chemical additives in the form of dustlike powders and readily fragmented grains leads to the impairment of the environment in the processing of elastomeric compositions[7–13] and polymers.

Various methods for the modification of chemical additives are used to improve their effectiveness. Some of them are listed below.

1. The preparation of dispersions of powdered components in mineral oils in the form of pastes of different consistencies.[14,15] The use of such pastes facilitates the dispersion of the components in elastomeric compositions as a result of their preliminary wetting by the oil and prevents the formation of a dust during mixing.[16] However, the preparation and application of viscous pastes is associated with technological difficulties.

2. The mixing of the powdered components with polymeric binders, including encapsulation in microcapsules made from high-molecular-mass amino-compounds,[17–19] which melt during the vulcanisation of the elastomeric compositions, and also in capsules made from a polymer based on cellulose acetate.[20] However, the preparation of such microcapsules is difficult.

3. The use of binary and complex synergistic chemical additive systems (for example accelerators of the sulfur-based vulcanisation of elastomers[21] and antioxidants[22]). The synergistic effect, manifested by such systems in elastomeric compositions and rubber, has a both physical and chemical nature.[23] The chemical interaction of the components of synergistic systems takes place in the highly viscous elastomer under diffusional conditions, which lowers the probability of encounters of the molecules and prevents the complete manifestation of the synergistic effect.

4. The preparation on the basis of binary and complex chemical additive systems of simple eutectic mixtures, substitutional solid solutions, molecular complexes, and new chemical compounds,[21,24-26] which can form strong and readily diffusable granules at the temperature corresponding to eutectic fusion. The molecules retain their individuality in the eutectic mixtures and substitutional solid solutions, whilst in the molecular complexes there is a redistribution of electron density.[27]

In contrast to synergistic systems of chemical additives, introduced into the polymer compositions in the form of individual powders, in the eutectic mixtures and molecular complexes the components interact in the kinetic region in both the crystalline and fused states, which promotes the most complete manifestation of the synergistic effect.

Depending on the extent of the processes in the binary and complex chemical additive systems promoting an increase in their effectiveness in elastomeric compositions, physical and physicochemical modification procedures are distinguished.[28]

II. Physical modification of chemical additives

The physical modification of chemical additives is based on the increase in the defectiveness and dispersity of the crystals and the increase in the melting points of the components in the binary and complex eutectic systems and substitutional solid solutions.[28] All these factors tend to increase their effectiveness in elastomeric compositions.

The aim of the physical modification of chemical additives is the most complete manifestation of the synergism of their functional properties, which promotes a more complete and rapid (compared with the use of individual solvents) vulcanisation reaction of elastomeric compositions, an increase in the duration of the induction period for the process, and a decrease of reversion in the vulcanisation process. This ensures the formation of rubbers with effective physicomechanical parameters.

Physical synergism is manifested when the accelerators in the binary systems form only simple eutectic mixtures or substitutional solid solutions. These binary systems include CBS (*N*-cyclohexylbenzothiazole-2-sulfenamide)–OBS (morpholinobenzothiazole-2-sulfenamide), TMTD (tetramethylthiuram disulfide)–TMTM (tetramethylthiuram monosulfide), CBS–DBTD, TMTD–TETD (tetraethylthiuram disulfide), TMTD–DPG, TBTD–MBT (2-mercaptobenzothiazole), etc. The synergism of the properties of these systems of accelerators in elastomeric composition is due to the following causes.

The increase in the defectiveness and dispersity of the crystalline particles in the eutectic mixtures, which leads to an increase in the surface free energy and hence in the chemical reactivity of the accelerator, and the latter increases the rate of vulcanisation of elastomeric compositions.

The increase in the solubility of one accelerator in the elastomeric composition in the presence of another accelerator.

The sharp decrease in the melting points of the accelerators in the eutectic mixtures, which promotes their dispersion and improves their distribution in the elastomeric compositions and hence ensures a more complete vulcanisation with formation of a uniformly distributed and less defective three-dimensional network in rubbers.

The possibility and the effectiveness of the physical modification of chemical additives is determined primarily by the following characteristics of the components of binary and complex mixtures: the structure of the molecules in the crystals, the defectiveness of the crystals in eutectic mixtures, the dispersity of the crystalline particles, and the melting points of the components.

1. The conformation of the molecules in crystals of chemical additives

Analysis of the results of X-ray diffraction studies on the components of sulfur-based vulcanising systems[21] indicates different configurations of their molecules (with the exception of MBT and DBTD).

Even activated molecules are known[29] to react with one another only when they are oriented relative to one another in a specific manner. The configuration of the molecules in organic crystals is determined in its turn by the spatial disposition of the bonded atoms making up the molecule.[30] Thus the thiocarbamic acid residue in dithiocarbamate and thiuram accelerators has a planar structure.[31-33] The same configuration is characteristic also of stearic acid[34] and the benzothiazolyl group in MBT and DBTD.[35] On the other hand, the benzothiazolyl group in CBS–OBS has the chair configuration.[36,37]

Simple eutectic mixtures in binary systems of accelerators are formed when the molecules have significantly different configurations and are characterised by approximately the same nucleophilicity or electrophilicity (for example, the TMTD–TETD and CBS–DBTD systems). If the molecules of the components have similar configurations, as in the DBTD–MBT system, a substitutional solid solution is formed. When the energy of the interaction of unlike molecules is appreciable, i. e. when they contain nucleophilic and electrophilic centres and have a favourable orientation, molecular complexes (π- and *n*-complexes) may be formed in the eutectic mixtures. Then the composition of one of the phases will correspond fairly closely to an integral molar ratio of the components within certain temperature limits.[38]

The addition of zinc oxide to binary mixtures of accelerators may promote a change in the conformation of the molecules as a result of their adsorption.[39,40] This alters the ratio of the components in the eutectic mixtures or the substitutional solid solution and hence increases or lowers the eutectic melting point (T_{eu}) and the enthalpy of fusion (ΔH_m), which has been confirmed by studies on binary and ternary mixtures of the components of sulfur-based vulcanising systems by differential scanning calorimetry (Table 1).[28]

Table 1. Variation of the properties of the eutectic mixtures as a function of composition.

Binary or ternary mixture	Mass ratio of components	T_{eu}/ °C	ΔH_m/kJ mol^{-1}
MBT–TMTD	0.5:0.5	103	18.40
MBT–ZnO–TMTD	0.5:2.0:0.5	102	24.07
DBTD–TMTB	0.5:0.5	106	29.47
DBTD–ZnO–TMTD	0.5:2.0:0.5	112	27.08
CBS–TMTD	0.7:0.3	76	24.47
CBS–ZnO–TMTD	0.7:2.0:0.3	84	26.75

2. Defectiveness of crystals of chemical additives in eutectic mixtures

Crystal defects include dislocations and point, volume, and surface defects.[41] In organic crystals, dislocations are crystal lattice defects which disturb the regular disposition of molecular planes. Point defects comprise vacancies and interstitial impurity molecules introduced by substitution and volume effects comprise pores, cracks, and inclusions of other phases. Surface defects are defects in the packing of the crystals and in their surface relief.

The state corresponding to an ideally regular crystal is the most stable.[42] Such a crystal has the minimum entropy and free energy. Structural defects diminish the stability of the crystal because they lead to an increase in entropy and free energy.

Substances with more defective crystals exhibit a higher chemical reactivity. A mixture of defective crystals is characterised by a higher reactivity than a mixture of crystals with an ideal structure.

Surface, volume, and point defects, the number of which may be increased by the physical modification of the components leading to the formation of simple eutectic mixtures and substitutional solid solutions, promote an increase in the effectiveness of crystalline chemical additives in elastomeric compositions.

Table 2 presents the principal characteristics of binary mixtures of crystalline components of sulfur-based vulcanising systems obtained by the method of thermal analysis.[25,28] Evidently the formation of equilibrium eutectic systems is accompanied by a significant decrease in the enthalpy of fusion and an increase in the activity coefficients of the components, which is due to the increase in the defectiveness and dispersity of the crystals.

The increase in the defectiveness of the crystals (up to 42%) during the formation of simple eutectic systems, substitutional solid solutions, and molecular complexes (Table 3) has been confirmed quantitatively by the results of investigations by NMR (analysis of broad lines) and differential scanning calorimetric methods.[25]

According to Zalkin,[43,44] the increase in the defectiveness of the crystals in eutectic mixtures of the components of sulfur-based vulcanising systems is caused by the following factors. In the solid eutectic mixtures, the surfaces of two crystals 'trap one another' via intermolecular forces, which leads to the elastic deformation of the crystal lattices in the boundary regions. The surface of the crystal with a higher melting point is then the 'active substrate' and tends to distort the surface of the low-melting crystals in conformity with its surface relief. As a result, the excess free energy is concentrated in the contact zone together with the increased number of surface and volume defects, such free energy being the cause of the increased chemical reactivity of the components of the eutectic mixture.

In the solid solutions, the substitution of one molecule in the crystal lattice of the first component by a larger molecule of the second component leads to loosening of the packing and to the appearance of strains and distortions in neighbouring molecules, the number of which may reach 400 and more.[1] When a larger molecule is substituted by a smaller one, contraction takes place, whereupon the number of molecules subjected to strain and distortions does not exceed 350. Accordingly, the increase in the activity coefficient of DBTD in the DBTD–MBT substitutional solid solution (Table 3) is due to the fact that, when one DBTD molecule in the DBTD unit cell is substituted by two MBT molecules (the volume of two MBT molecules is greater than the volume of the DBTD molecule by the volume of two hydrogen atoms), the structure is loosened, which is accompanied by an increase in the free energy of DBTD and hence also in its activity coefficient. On the other hand, the replacement of two MBT molecules by one smaller DBTD molecule leads to contraction of the unit cell of MBT and to some decrease in the free energy and in the activity coefficient of MBT.[28] The introduction of such eutectic mixtures and substitutional solid solutions into elastomeric compositions makes it possible to increase the rate of vulcanisation whilst retaining the duration of the prevulcanisation period at the level of control specimens. The rubbers thus obtained have a higher tensile strength, a greater wear resistance on repeated deformations, and a greater resistance to thermal ageing.

Table 3. Defectiveness of the crystals of binary mixtures of accelerators.

Binary mixture	Degree of defectiveness of crystals			Increase in degree of defectiveness of crystals in eutectic mixture compared with additive value (%)
	A	M	E	
MBT–TMTD	0.365	0.44	0.51	39.72
DBTD–TMTD	0.305	0.36	0.42	37.70
CBS–TMTD	0.370	0.42	0.46	24.32
OBS–TMTD	0.360	0.38	0.38	5.55
MBT–DBTD	0.365	0.48	0.52	42.46
DBTD–ZDMDTC	–	0.46	0.48	–

Remarks. The following notation has been adopted: A—additive mixture, M—mechanical mixture, E—eutectic mixture..

3. The dispersity of crystalline particles of chemical additives

An increase in the dispersity of a crystal is known to diminish its stability owing to the increase in the surface free energy. As a result of this, more highly dispersed crystals exhibit a higher chemical reactivity. For this reason, the properties of elastomeric compositions depend to a large extent on the dispersity of the particles of the powdered chemical additives; the smaller the particle size the more effectively are they dispersed in the elastomeric compositions and the greater their functional effectiveness.[16,45,46]

The distribution of the powdered accelerators, sulfur, and antiageing agents in elastomeric compositions occurs most effectively at the level of crystalline particles, which cannot ensure

Table 2. Certain thermodynamic characteristics of the components of the binary systems for the sulfur-based vulcanisation of elastomers.

Binary mixture	Molar ratio of components	T_{eu}/ °C	T_{per}/ °C	Enthalpy of fusion/kJ mol^{-1}			Activity coefficients of components[a]		Type of mixture formed
				ΔH_{ad}	ΔH_{mix}	ΔH_{eq}	1	2	
Sulfur–MBT	0.49:0.51	104	–	18.70	17.00	15.20	1.816	1.686	Simple eutectic
Sulfur–OBS	0.30:0.70	77	–	20.00	18.00	12.60	2.070	1.750	" "

the same concentration gradients of these components throughout the bulk of the elastomer because in the vicinity of the particles themselves an increase in the concentration of dissolved molecules is maintained.[4,28] This is indicated also by the structure of the particles of certain powdered components established on the basis of crystal-chemical data (Table 4).

If it is assumed that the particles of crystalline components are approximately spherical,[47] it is possible to calculate the number of unit cells in them and, knowing the number of molecules in each cell,[21] it is possible to determine the total number of molecules in each spherical particle. It is seen from the data presented in Table 4 that the particles of the powdered components contain an enormous number of molecules and their uniform distribution in the particles solely as a result of dissolution is hardly possible despite the fairly high solubility of sulfur and of the accelerators in elastomers at the mixing temperatures.[3,4] Under these conditions, a uniform distribution of the chemical additives in the bulk of the elastomeric composition can be attained by increasing their dispersibility in the fused state.

By analogy with the diffusion of gases in liquids,[48] the following equation is used for the mathematical description of the distribution and diffusion of chemical additives in an elastomer:[28]

$$\frac{dc}{dt} = D\frac{d^2c}{dx^2},$$

where dc/dt is the rate of accumulation of the molecules of the component in a unit elementary volume, D the diffusion coefficient of the molecules of the component in the elastomer, and d^2c/dx^2 the derivative of the concentration gradient characterising the distribution of the component in the elastomer.

Evidently the rate of increase in the concentration of the component is dissolved in the elastomer depends on the rate of distribution of its molecules, and the more effectively the component is dispersed in the bulk of the elastomer in the form of small fused particles, the faster the equalisation of the concentration gradient of its molecules throughout the bulk of the elastomer.

The dispersion of powdered and fused components during the mixing of chemical additives and the diffusion of the dissolved molecules of the component accompanied by the equalisation of the concentration throughout the entire bulk of the substance are illustrated schematically in Fig. 1.

It follows from the foregoing that, in order to improve the distribution of chemical additives in elastomeric compositions, it is necessary to fuse them at the very beginning of the mixing process. The fusion of the particles after their dispersion in the crystalline state does not promote an improvement in the dissolution of the components because, in conformity with thermodynamic ideas, under identical conditions a solid and its melt dissolve in the same way.[49] On the other hand, the component fused initially is dispersed in the elastomeric composition much more effectively than the same component in the powdered state and it executes its functional task more effectively, for example as an accelerator,[50] a vulcanising agent, an antiageing agent, etc. Nevertheless, the melting points of the majority of the widely used chemical additives, except for CBS, OBS, and stearic acid (StA), are higher than the temperatures corresponding to their introduction into elastomeric compositions. The dispersion of such chemical additives in elastomeric compositions is improved in the presence of zinc stearate, which is capable of forming reversed micelles in the nonpolar elastomer; these solubilise the accelerators and sulfur in the polar core.[51] The low critical concentration for micelle formation (2×10^{-3} M) confirms the possibility of accumulating sufficient zinc stearate for the formation of micelles in elastomeric compositions as a result of the reaction of stearic acid with ZnO at the very beginning of the mixing process.[53]

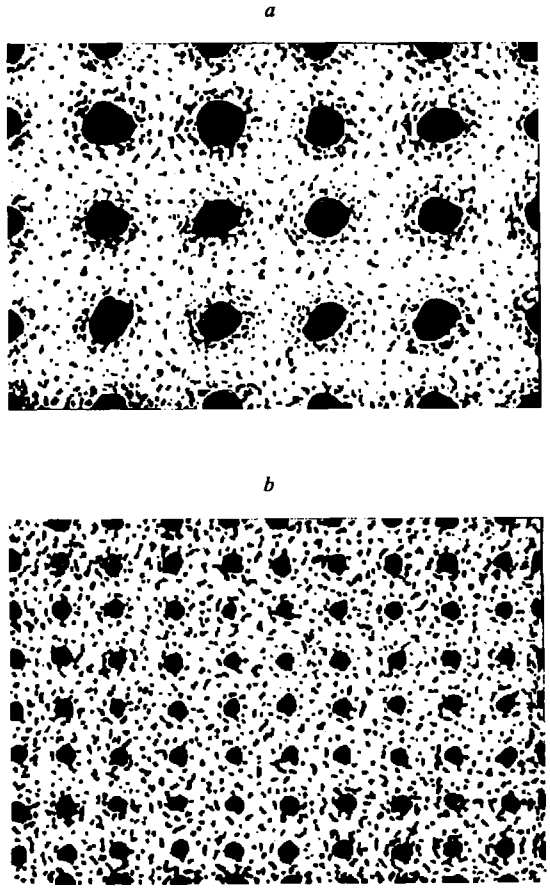

Figure 1. Schematic illustration of the dispersion and dissolution of powdered (*a*) and fused (*b*) components in the elastomer during the mixing process.

When the components of sulfur-based vulcanising systems are used in the form of readily fusible eutectic mixtures, the dispersity of the particles can influence the properties of the elastomeric compositions and rubbers if the mixing temperature is lower than the temperature of eutectic fusion or the equilibrium temperature on the liquidus of the phase diagram, determined by the ratio of the concentrations of the initial accelerators in the binary eutectic system. If the temperature of the preparation of the elastomeric composition is above the liquidus line, the eutectic mixture is dispersed in the elastomeric composition in the fused state and the dispersity of the particles of the components constituting the eutectic mixtures does not affect the properties of the elastomeric compositions and rubbers.

The formation of eutectic mixtures is known[49] to be accompanied by an increase in the dispersity of the crystalline particles of the constituent components, which increases their chemical reactivity as a consequence of the increase in the surface free energy. Hence it follows that, when the eutectic mixtures are introduced into elastomeric compositions at temperatures below the temperature of eutectic diffusion, the accelerators are more highly dispersed and are more chemically reactive than in the initial state. This applies also to the case where the temperature of the preparation of the elastomeric composition is below the liquidus line of one of the components. The crystalline particles of the accelerator in equilibrium with the melt are more highly dispersed than the particles of the initial accelerator.

In those cases where the accelerators and sulfur are adsorbed in the form of eutectic mixtures on zinc oxide, the dispersity of the particles of these components undergoes an additional increase as a consequence of the retardation of the crystallisation of the adsorbed components and the formation of a large number of nuclei.[54]

4. The melting points of crystals of chemical additives

In simple eutectic systems, the eutectic temperature (T_{eu}) is lower and closer to the centre of the phase diagram the smaller the difference between the melting points (T_m) of the components. The greater the difference between the melting points T_m of the components of eutectic mixtures the greater the displacement of T_{eu} towards the low-melting component. This type of variation of T_{eu} as a function of the T_m of the constituent components makes it possible to attain the maximum synergistic effect by varying the proportions of the accelerators with different T_m within wide limits (by virtue of the better dispersion and distribution of the accelerators in the elastomeric compositions in the fused form and the increase in the defectiveness and dispersity of the crsytalline particles). This promotes an increase in the free surface energy and hence in the chemical reactivity of the components.

Furthermore, the properties of the binary eutectics are influenced by the polymorphic transformations of the crystals of the chemical additives[34,56,57] occurring following an increase in temperature and promoting a change in the miscibility of the components in the solid state.

* * *

Thus the effectiveness of the physical modification of chemical additives in binary and complex eutectic mixtures and substitutional solid solutions is determined by the differences between the configurations of the molecules and the melting points of the components as a result of the increase in the defectiveness and dispersity of the crystalline particles. The physical modification not only improves the distribution of the components in elastomeric compositions and increases their chemical reactivity but also facilitates the formation of strong (0.35–0.4 MPa) and readily fusible granules of the eutectic melts of the chemical additives without the introduction of binders.[28] This is one promising way of solving the environmental problems in the processing of elastomeric compositions and polymers.

III. Physicochemical modification of chemical additives

An increase in the chemical reactivity of the components of binary eutectic mixtures, exhibiting nucleophilic and electrophilic properties relative to one another, leads to the formation of molecular π- and n-complexes or new more active accelerators exhibiting a high thiophilicity in relation to free sulfur and hence increasing the rate of vulcanisation of the elastomeric compositions and reducing the activation energy for the process. The physical and chemical transformations occurring under these conditions can be regarded as the physicochemical modification of the chemical additives.[28]

The synergistic effect in the binary systems on formation of molecular complexes and new accelerators may intensify also as a result of the retardation of the migration of the molecules of the complexes to the surfaces of the elastomeric compositions as a consequence of the increase in molar volume and the more complete functional utilisation of the system of accelerators.

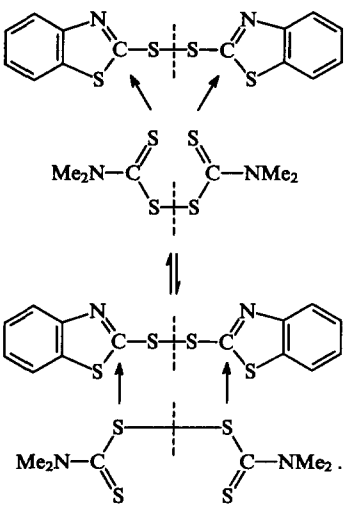
The combination of physical and chemical synergism is characteristic of binary systems such as OBS–TMTD, DBTD–TMTD, CBS–TMTD, OBS–DTDM (*N,N'*-dithiodimorpholine), CBS–ZDMDTC (zinc dimethyldithiocarbamate), CBS–MBT, etc., whose components form molecular complexes and new compounds—more active accelerators of the sulfur-based vulcanisation of the elastomers than the initial compounds.[28,58,59]

Thus the presence in the crystals of the components of active centres capable of interacting with one another is very important in the physicochemical modification of chemical additives.

1. The active centres in the molecules of chemical additives

The molecular diagrams of components of sulfur-based vulcanising systems have been obtained[60–63] by quantum-chemical methods. Analysis of the results of the quantum-chemical calculations and of the molecular diagrams presented in a number of studies[59–62,64–66] makes it possible to arrange the components of the sulfur-based vulcanising systems in the following series in terms of the increase in their nucleophilicity:

$$ZnO < ZnX_2 < S_8 < DTDM < OBS < CBS \leqslant DBTD \leqslant MBT < DPG < TMTD.$$



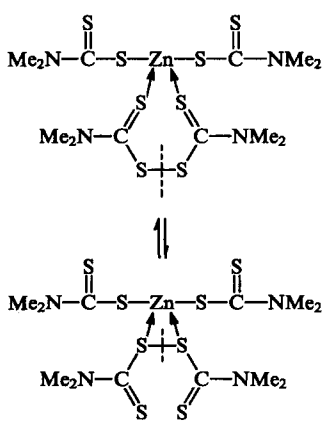
Zinc oxide, zinc mercaptide, zinc dialkyldithiocarbamates, sulfur, and DTDM exhibit electrophilic properties in relation to CBS, DBTD, MBT, DPG, and TMTD. In binary systems containing the zinc salts of mercaptobenzothiazole or dialkyldithiocarbamic acid, on the one hand, and thiazole, sulfenamide, or thiuram accelerators, on the other, the latter behave as ligands coordinated to the zinc atom and bound to it both as a result of the partial shift of the n electrons of the nitrogen or sulfur atoms to the unoccupied p orbitals of the zinc atom[67] and also as a result of the formation of a π-bond when the occupied d orbitals of zinc overlap with the antibonding π^* orbital of the ligand.[68] The involvement of the zinc atom in the formation of a π-bond has been confirmed by the fact that the transfer of one of its d electrons to a higher energy level requires an energy of only 15.5×10^{-19} J cm^{-1}.[69]

2. The formation of molecular complexes

Together with the eutectic point, a peritectic point appears on the phase diagrams of binary systems of accelerators exhibiting donor–acceptor properties relative to one another, which confirms the formation of a molecular complex in the mixture.[55] This shows that the charge transfer from the donor to the acceptor molecule in a mixture of crystalline substances is facilitated on eutectic fusion. Consequently the formation of π- and n-complexes is preceded by an increase in the chemical reactivity of the components in the eutectic mixtures. The light hypsochromic shift characteristic of the UV spectra of dilute solutions of such binary systems indicates the preferential formation of n-complexes in the latter.[63]

The nature of the molecular complexes formed and the factors promoting the mutual activation of their components can be discovered by comparing the crystal-chemical properties of the initial components and the binary systems.

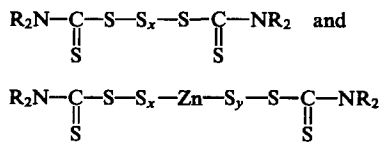
In the TMTD–DBTD binary system, the nucleophilic centres are the sulfur atoms of TMTD, while the electrophilic centres are the carbon atoms of the benzothiazolyl fragments of DBTD.[62] The TMTD molecule can be represented by several structures,[70] which form the following *n*-complexes:



The enhancement of the accelerating function of such complexes can be explained by the weakening of the disulfide linkage in the latter and by the more ready addition of free sulfur to the complex.

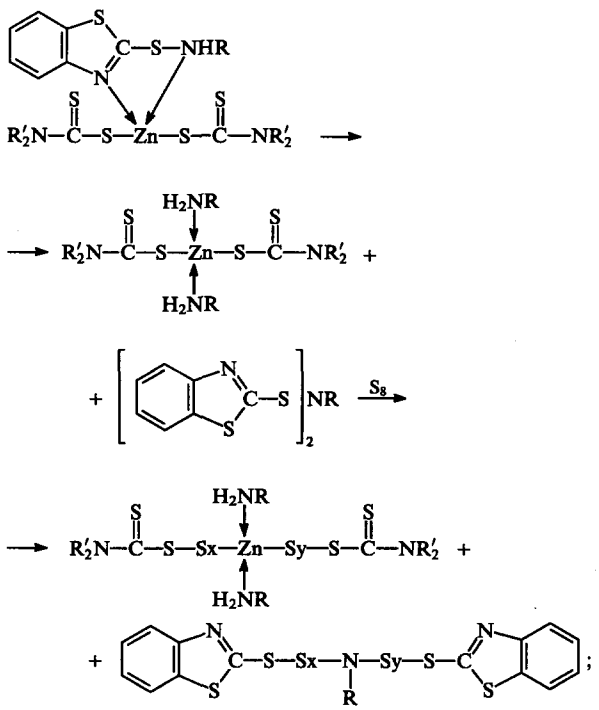
The interaction of the accelerators in the TMTD–CBS and TMTD–OBS binary systems is accompanied by the formation of similar complexes with the sole difference that the electrophilic centres in the CBS and OBS molecules are the carbon atoms involved in the double bond of the benzothiazolyl fragment, the carbon atoms in the cyclohexyl group,[65] and the nitrogen atom in the morpholine fragment.[71]

The synergistic effect of the accelerators in the *n*-complexes is caused by, firstly, their more effective functional employment as a consequence of the better dispersion of the eutectic mixture in the fused form and, secondly, by the facilitation of the interaction of the complexes with S_8. Such interaction leads to the formation of tetramethylthiuram polysulfide, polythiobissulfenamide, and dibenzothiazolyl polysulfide,[72] as well as the hydroammonium polysulfides $[H_3NR]^+S_x^-$ and $[H_2NR']^+S_x^-$ (R = cyclohexyl, R′ = morpholinyl), which ensure a high rate of vulcanisation of elastomeric compositions.[71]



In binary systems where one of the accelerators is zinc dialkyldithiocarbamate or zinc mercaptide, the electrophilic zinc atom plays a significant role in the formation of molecular complexes.

Scheme 1



The structure of the ZDMDTC–TMTD complex is presented in Scheme 1.[73]

Complexes of this type prevent premature vulcanisation[70] and also ensure a higher rate of vulcanisation compared with the accelerators taken separately, owing to the weakening in the latter of the Zn–S and S–S bonds and facilitation of the interaction with S_8 leading to the formation of polysulfide compounds.[74]

The formation of a *n*-complex, an amine complex, and a number of other compounds in the ZDMDTC–CBS system can be represented as follows:[73]

R = cyclo-C_6H_{11}; R′ = Me.
